Tibet Autonomy Region of China is host to a number of populations that are different in their language, culture and ethnic identity. However, rare genetic studies based on STR markers on Tibetans and Sherpas have been reported in literature till date. In the present study, we genotyped 15 forensic autosomal STRs from 225 unrelated Tibetan individuals and 181 Sherpas from Zhang-mu Town of Shigatse Prefecture. Genetic studies of Tibetans and Sherpas were performed using Cervus 3.0, Arlequin (version3.5) software package, Structure (version 2.3.4) software, R statistical software version 3.0.3 and Distruct version 1.1. The results suggested that Tibetans and Sherpas are most similar to the East Asians, and the least similar to Africans. Our results suggested that Tibetans and Sherpas shared very similar membership with other East Asian populations, especially revealing a common genetic makeup. **Key Words:** Tibetans; Sherpas; STRs; Genetic origin   **Acknowledgments** We are grateful to all of the individuals in this study who made this work possible. .

Genetic diversity and natural selection footprints of the glycine amidinotransferase gene in various human populations. *A. Khan[1,2], L. Tian[1], C. Zhang[1], K. Yuan[1], S. Xu[1].* 1) Biochemistry, Abdul Wali Khan Unversity Mardan, Mardan, KPK, Pakistan; 2) CAS-MPG Partner Institute of Computational Biology, Shanghai Institute of Biological Sciences, Shanghai China.

The glycine amidinotransferase gene (GATM) plays a vital role in energy metabolism in muscle tissues and is associated with multiple clinically important phenotypes. However, the genetic diversity of the GATM gene remains poorly understood within and between human populations. Here we analyzed the 1,000 Genomes Project data through population genetics approaches and observed significant genetic diversity across the GATM gene among various continental human populations. We observed considerable variations in GATM allele frequencies and haplotype composition among different populations. Substantial genetic differences were observed between East Asian and European populations (FST = 0.56). In addition, the frequency of a distinct major GATM haplotype in these groups was congruent with population-wide diversity at this locus. Furthermore, we identified GATM as the top differentiated gene compared to the other statin drug response-associated genes. Composite multiple analyses identified signatures of positive selection at the GATM locus, which was estimated to have occurred around 850 generations ago in European populations. As GATM catalyzes the key step of creatine biosynthesis involved in energy metabolism, we speculate that the European prehistorical demographic transition from hunter-gatherer to farming cultures was the driving force of selection that fulfilled creatine-based metabolic requirement of the populations.

Baboon *Alu* elements gone wild. *M.K. Konkel, V.E. Jordan, C.J. Steely, T.O. Beckstrom, J.A. Walker, E. Bennett, B. Clement, A. Robichaux, M.A. Batzer for the Baboon Genome and Analysis Consortium.* Department of Biological Sciences, Louisiana State University, Baton Rouge, LA.

The habitat of baboons (genus *Papio*) ranges across sub-Saharan Africa and the southern Arabian Peninsula. Baboons, which radiated ~2-3 million years ago, have a complex speciation history with evidence for introgressive hybridization. A consensus of six distinct baboon species has recently emerged: olive, yellow, Guinea, hamadryas, chacma, and kinda. However, the evolutionary relationships among baboons continue to be controversial, likely in part due to the presence of stable hybrid zones where baboons meet in the wild and produce fertile offspring. The divergence of baboon-macaque occurred at a comparable time to the human-chimpanzee-gorilla divergence, allowing for direct comparisons of mobile element evolution and amplification. Our analyses of the *Papio anubis* (olive baboon) [papAnu2] draft genome assembly support a rapid expansion of *Alu* elements, suggesting a roughly 6-fold increase in the *Alu* insertion rate compared to the human lineage. To investigate the population and phylogenetic relationships within genus *Papio,* we analyzed a panel of 80 diverse baboons (encompassing all six baboon species) using 497 informative polymorphic *Alu* insertions. To reduce ascertainment bias we selected candidate insertion loci from both the baboon reference genome assembly and from high-throughput sequencing data of a diversity panel that contained individuals of six species within *Papio*. Our analyses reveal a high degree of *Alu* insertion polymorphism across different baboon species and unexpectedly high homoplasy rate, in agreement with extensive incomplete lineage sorting, recent speciation, and/or ongoing introgressive hybridization. Depending on marker selection, our data reflect previously reported evolutionary discrepancies. Analysis of older *Alu* insertion data supports a Northern (olive, Guinea, and hamadryas) and Southern (yellow, chacma, and kinda baboon) species divergence . Inclusion of all the polymorphic *Alu* loci suggests a more complicated history, in agreement with continuous introgression. Our Structure analyses clearly distinguish the six baboon species. Furthermore, yellow baboons from the Southwest primate center show varying degrees of admixture with olive baboons. Two distinct population clusters each are supported within kinda and yellow baboons. In summary, our analyses support the complex relationships among baboons, and provide evidence for rapid mobile element expansion possibly linked to inter-species hybridization.

1075W

Leveraging large-scale clinical biobanks to study recent human evolution. *C. Simonti[1], W. Bush[2], J.A. Capra[1,3], eMERGE Consortium.* 1) Vanderbilt Genetics Institute, Vanderbilt University, Nashville, TN; 2) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH; 3) Department of Biological Sciences, Vanderbilt University, Nashville, TN.

We introduce a high-throughput approach for characterizing the function of variation arising in recent human history and use it to demonstrate that introgressed Neanderthal alleles and targets of recent positive selection influence diverse biological systems, including psychiatric, skeletal, and immunological traits. Thousands of variants throughout the human genome have been identified in studies of positive selection, archaic admixture, and other evolutionary events that have shaped human populations. However, the functions of the vast majority of these variants are unknown. Historically, determining the phenotypic effects of such variants relied on indirect evidence, such as the function of nearby genes, or low-throughput methods for functional characterization, such as enhancer reporter assays. To overcome this limitation, we mined the electronic health records (EHRs) of ~28,000 genotyped individuals from seven hospitals across the US to identify cases and controls for ~1,500 clinical phenotypes. To illustrate the use of this resource in evolutionary studies, we identified phenotypic associations for two classes of variants important in recent human history: those present in the human genome due to admixture with Neanderthals, and variants appearing on the human lineage that have risen to near fixation since divergence with chimp (hominin-derived). We discovered and replicated associations of introgressed Neanderthal alleles with neurological, psychiatric, immune, skin, and reproductive phenotypes. Among the hominin-derived variants, we found several that influence risk for skeletal disorders, including bone fracture. Using functional genomics data from ENCODE/Roadmap Epigenomics and gene expression data from GTEx, we demonstrate that many of these variants influence the regulation of nearby genes relevant to the associated phenotypes. Our results establish that recent hominin-derived variants and archaic admixture influence risk for diverse, evolutionarily-relevant phenotypes in modern humans, and demonstrate the utility of EHR data linked to genotypes to inform evolutionary analyses.

Tibetans are well adapted to the hypoxic environments at high altitude, yet the molecular mechanism of this adaptation remains elusive. We reported comprehensive genetic and functional analyses of EPAS1, a gene encoding hypoxia inducible factor 2α (HIF-2α) with the strongest signal of selection in previous genome-wide scans of Tibetans. We proved that the Tibetan-enriched EPAS1 variants down-regulate expression in human umbilical endothelial cells and placentas. Heterozygous EPAS1 knockout mice display blunted physiological responses to chronic hypoxia, mirroring the situation in Tibetans. Furthermore, we found that the Tibetan version of EPAS1 not only accounts for the relatively low hemoglobin level as a polycythemia protectant, but also enables low pulmonary vasoconstriction response in Tibetans. We demonstrated that the down-regulation of EPAS1 serves as the molecular basis of Tibetans' adaption to high-altitude hypoxia.

Selection and functional consequence of Neanderthal introgression. *N. Telis[1], K. Harris[2], J.K. Pritchard[2,3,4].* 1) Biomedical Informatics, Stanford, CA; 2) Genetics, Stanford, CA; 3) Biology, Stanford, CA; 4) Howard Hughes Medical Institute.

There has been a long history of interest in the extent of, and selective consequences of, human interbreeding with other hominins. Existing knowledge of Neanderthal introgressed variants across the genome has revealed several deserts, as well as a general depletion in the vicinity of genes, with weak association with testes expression. Introgression has been linked with risk for multiple diseases, and therefore it seems prudent to understand broader trends in functional consequences of introgression. Moreover, characterizing sources of strong pressures against presumably deleterious Neanderthal introgression can shed light into broader functional trends of modern selection. By examining distributions of introgression across regulatory elements, we identify genome-wide depression of introgression in promoters and enhancers. This genome-wide depletion increases in extremity with increasing allele frequencies. Alongside this broader depletion of Neanderthal introgression in regulatory regions, we confirm independent depletion signals in brain, embryonic stem cell, and muscle tissues. Regulatory variants with likely severe effects (due to binding site alteration) also appear depleted, with variants affecting lymph node as a notable exception. Based our our analysis, we present a model linking regulatory consequence with fitness and distribution of existing Neanderthal variations.

Determinants of mutation rates in germline and soma. *C. Chen[1], H. Qi[3], Y. Shen[3], J.K. Pickrell[1,2,4], M. Przeworski[1,3,4].* 1) Department of Biological Sciences, Columbia University, New York, NY; 2) New York Genome Center, New York, NY; 3) Departments of Systems Biology and Biomedical Informatics, Columbia University Medical Center, New York, NY; 4) Co-supervised this project.

Understanding the determinants of fine-scale mutation rates is of crucial importance for many efforts in human and evolutionary genetics. Recent studies of somatic mutations in tumors and of germline mutations in pedigrees have led to the identification of a number of factors that influence mutation rates, including CpG methylation, expression levels, replication timing and GC content. Interestingly, some of these effects appear to differ between somatic and germline tissues. Notably, while mutation rates have been reported to decrease with expression levels in tumors, no such effect has been detected in the germline, leading to speculation that error or repair processes may differ among tissues. It is hard to know whether these apparent discrepancies are real, however, as different approaches were taken to analyze the data in different studies, with distinct sets of variables included as covariates and varying window sizes as the unit of analysis. To enable a cleaner comparison, we considered a model in which the mutation rate in a gene is predicted by GC content, expression levels, replication timing and two histone repressive markers. We applied this model to a large set of germline mutations identified in exomes from recently published studies on developmental disorders, and to exonic somatic mutations in four types of tumors from the Cancer Genome Atlas. Our analysis indicates that germline and soma share most determinants of mutations, but with some differences. Most intriguingly, the degree of strand asymmetry and germline mutation rate increase with expression in ovaries and testes, whereas the degree of strand asymmetry and somatic mutation rates have opposite dependencies on expression levels in somatic tissues matched to the tumor type. We speculate that the source of this difference between germline and soma is the occurrence of domain-associated repair (DAR) in somatic cells. .

Admixture inference of African Americans and Latinos in the United States through time. *M.L. Spear[1], D.G. Torgerson[2], R.D. Hernandez[1,3,4].* 1) Department of Bioengineering and Therapeutic Sciences, University of California, San Francisco, San Francisco, CA; 2) Department of Medicine, University of California, San Francisco, San Francisco, CA; 3) California Institute for Quantitative Biosciences (QB3), University of California, San Francisco, San Francisco, CA; 4) Institute for Human Genetics, University of California, San Francisco, CA.

The study of admixed populations has provided important insights into medical genetics and population history. The genomes of admixed individuals are mosaics of segments originating from different ancestral populations. At the genome-wide level, the proportion of one's genome deriving from each ancestral population is referred to as "global ancestry proportions". However, modern statistical methods enable inference of the ancestry at individual SNPs within a genome, "local ancestry", which allow us to reconstruct the mosaic pattern of ancestry tracts across an individual's genome. Local ancestry inference is critical for the analysis of admixed genomes and has been widely studied in the fields of medical genetics and human demographic history. Local ancestry tracts can be used to infer migration histories but the question remains how these histories have shaped ancestry proportions over time, particularly in the United States, a "melting pot" country that has faced changing societal norms over the past century. It has yet to be determined how the length distribution of ancestry tracts in admixed individuals has changed over decades as well as how the variation in ancestry proportions across chromosomes and individuals may differ. Thus, we estimated local ancestry for 4,600 Latinos and 2,100 African Americans from the Genetic Epidemiology Research on Adult Health and Aging (GERA) dataset using RFMix. With these local ancestry tracts, we used TRACTS to compare the observed length of the ancestry tracts to predictions of different demographic models of migration scenarios. Individuals were grouped by 5-year birth year categories, and comparisons were made between the demographic models generated from each birth year category. Overall, the local ancestry tracts of African Americans and Latinos from the United States have provided insights into the change in complexity of their genetic structure throughout the 20th century. .

Genomic and transcriptomic diversity in Xinjiang's Uyghurs. *L. Tian[1,2], C. Zhang[1,2], Y. Yuan[1], X. Wang[1,2], D. Lu[1,2], M. Shi[1,2], Y. Lu[1], K. Yuan[1,2], H. Lou[1], Q. Feng[1,2], R. Fu[1,2], X. Zhang[1,3], A. Khan[1], Y. Yang[4], Y. Guan[5], S. Xu[1,2,3,6].* 1) Chinese Academy of Sciences (CAS) Key Laboratory of Computational Biology, Max Planck Independent Research Group on Population Genomics, CAS-MPG Partner Institute for Computational Biology (PICB), Shanghai Institutes for Biological Sciences, CAS, Shanghai; 2) University of Chinese Academy of Sciences, Beijing 100049, China; 3) School of Life Science and Technology, ShanghaiTech University, Shanghai 200031, China; 4) State Key Laboratory of Genetic Engineering and Ministry of Education (MOE) Key Laboratory of Contemporary Anthropology, School of Life Sciences, Fudan University, Shanghai 200433, China; 5) Department of Biochemistry and Molecular Biology, Preclinical Medicine College, Xinjiang Medical University, Urumqi 830011, P. R China; 6) Collaborative Innovation Center of Genetics and Development, Shanghai 200438, China.

Whole-genome sequencing simultaneously DNA (30–60×) and mRNA in blood of Uyghurs and Han Chinese allows us, for the first time to our knowledge, to systematically investigate genomic and transcriptomic diversity in a Eurasian admixed population. We observed substantial splicing variation in Uyghurs and alternative splicing explains a substantial proportion of gene expression diversity. We identified a considerably large number of eQTLs and sQTLs, and differentiated contribution of the different ancestries to the gene expression patterns or levels. We argue that analyzying admixed populations facilitates to our understanding of the nature of genetic variants that affect gene expression and provide insights into elucidating the causes of phenotypic variation.

Assessing the value of population specific reference genomes by the '1000 Swedes project'. *A. Ameur[1], R. Karlsson[2], H. Che[1], I. Bunikis[1], P. Olason[1], I. Höijer[1], S. Häggqvist[1], I. Jonasson[1], P. Magnusson[2], U. Gyllensten[1]. 1) SciLifeLab, Uppsala University, Uppsala, Sweden; 2) Swedish Twin Registry, Karolinska Institutet, Sweden.*

We are undertaking the largest human whole-genome sequencing (WGS) project in Sweden to date; the generation of a reference database that reflects the genetic structure of the population. 1000 individuals were included in the study, selected to cover the genetic variation within Sweden based on results from PCA analysis of available SNP array data. All of these 1000 individuals have been subjected to short-read WGS using Illumina technology at 30X coverage. Two of these individuals were also chosen for long-read single molecule real-time (SMRT) sequencing on the PacBio RSII platform, generating ~50X coverage of the human genome with sequence reads of >10kb length on average.   A principal aim of this project is to establish a reference database of genetic variants in the Swedish population for use in disease association studies and as a look-up resource for the evaluation genetic variants identified in sequencing of patients. This database will be the first of its kind in Sweden and is needed both for GWAS-based disease association studies and for evaluating the clinical relevance of genetic alterations detected during clinical diagnostic analyses. It will also provide a unique dataset for research on the structure of genetic variation within Sweden, as well as for international collaborative projects.   Within this project we also investigate the benefits of creating novel reference genome sequences for the Swedish population. From the PacBio data, we have *de novo* assembled draft reference genomes using the FALCON software. This resulted in more than 2.8Gb of sequence data, distributed on ~7000 contigs, for each of the two individuals investigated. Our *de novo* assemblies showed very high similarity to the available human genome reference and 98.6% of the bases in our contigs could be mapped to GRCh38. Using the software Sniffles, we detected a substantial number of large insertions (~4000), deletions (~3700), inversions (~900) and duplications (~1300) with respect to the GRCh38 reference. Interestingly, we also found several mega bases of novel sequence data in our local PacBio genome assemblies, i.e. sequences not present in GRCh38. We are now using the Illumina data to validate these findings and to estimate the prevalence of the complex rearrangements in the Swedish population.

1082T

Large protein-coding polymorphisms in the human genome. *S. Cantsilieris[1], J. Huddleston[1,2], M.J.P. Chaisson[1], L. Harshman[1], K. Munson[1], M. Scofield-Sorensen[1], E.E. Eichler[1,2]. 1) Genome Sciences, University of Washington School of Medicine, Seattle, WA; 2) Howard Hughes Medical Institute, Seattle, WA, USA.*

Massively parallel sequencing of whole genomes and exomes has provided remarkable insight into the spectrum of both rare and common genetic variation that underlies protein-coding DNA. Here, we focus on regions of the genome that are inaccessible to short-read whole-genome shotgun sequencing with a specific focus on protein-coding sequence variation. Leveraging long sequence reads generated by single molecule, real-time (SMRT) sequencing of human genomes, in combination with methods to detect indels and structural variants up to 30 kbp, we identified >30 structural variant calls >1 kbp that intersect protein-coding genes. Selecting the largest and most complex events, we sequenced and assembled large-insert clones (>250 fosmid/BAC) from eight diverse humans in order to understand the extent of human variation and haplotypic differences among genes and gene families. For example, our investigation of 11 mucin gene family members identifies individual haplotypes where protein-coding sequences differs by tens of kilobases due to expansions of protein-encoding higher-order repeat structures. The expansions maintain frame and suggest that different human haplotypes produce protein molecules that can differ by as much as 5000 amino acids or 550 kilodaltons. Additionally, we observe similar hyperexpanded protein-coding sequence genes associated with immune response, lipoprotein levels and epidermal barriers (hornerin, filaggrin, and repetin). Using this approach, we also generated a 220 kbp alternate haplotype of the amylase gene cluster, a group of genes embedded within a series of tandem duplications thought to be important for human adaptation to starch-rich diets. Sequence analysis reveals signatures of positive selection and interlocus gene conversion during human and primate evolution. Comparison with the human reference assembly shows that many of these regions are enriched for "black tag" annotations or contain sequences that are missing or incompletely assembled within the human reference genome. Our analysis has characterized a striking level of protein-coding polymorphism achieved by large-scale expansion of tandem repeats within coding exons that include a subset of human genes associated with environmental interaction and host defence. These high-quality alternate reference haplotypes provide insight not only into the mutability and complex patterns of human genetic coding variation but also a starting point for association with human disease.

1083F

Identifying adaptive variants and tracing their ancestral origins in Tibetan highlanders by whole-genome deep sequencing. *L. Deng[1,2], C. Zhang[1,2], H. Lou[1], K. Yuan[1,2], D. Lu[1,2], X. Wang[1,2,3], Y. Lu[1], R. Fu[1,2], Y. Wang[1,2], X. Yang[1,2], Y. Hu[4], Q. Ding[4], Y. Zhou[1,2], Q. Feng[1,2], Z. Wu[1,2,3], X. Zhang[1,2,3], L. Tian[1,2], Y. Yang[1,2], S. Li[4], L. Jin[4], Y. Current knowledge of the genetic basis of Tibetans' adaptation to altitude is largely based on genotyping known variants or sequencing single candidate genes. Here, we report the first whole-genome deep sequencing (30–60×) study of 38 Tibetan highlanders living at seven different altitudes above 2,500 meters and 39 lowland Han Chinese. We identify 11.57 million variants with 2.22 million novel to known human variation. We build a list of putative adaptive genetic variants (AGVs) including 48 missense and 7 loss-of-function variants which affect 29 genes related to hypoxia adaptation. The majority of the AGVs are significantly correlated with altitude. Notably, we observe two highly differentiated genomic regions which show their elevated archaic ancestry and typical anatomically modern human origin, respectively. In both genomic regions, the sequences harboring AGVs in Tibetan highlanders trace their most recent common ancestor (MRCA) back to the time predating the Last Glacial Maximum. Our results indicated a much more complicated mechanism of human adaptation to altitude than previously thought, with key adaptions to the extreme environment contributed by pre-LGM populations.Current knowledge of the genetic basis of Tibetans' adaptation to altitude is largely based on genotyping known variants or sequencing single candidate genes. Whole-genome sequencing in French Canadians from Quebec. *C. Low-Kam[1], D. Rhainds[1], K.S. Lo[1], S. Provost[1], I. Mongrain[1], A. Dubois[1], S. Perreault[2], J.F. Robinson[3], R.A. Hegele[3,4], M.-P. Dubé[1,5], J.-C. Tardif[1,5], G. Lettre[1,5].* 1) Montreal Heart Institute, Montréal, Québec, Canada; 2) Faculté de Pharmacie, Université de Montréal, Montréal, Québec, Canada; 3) Robarts Research Institute, Schulich School of Medicine and Dentistry, Western University, London, Ontario, Canada; 4) Department of Biochemistry, Schulich School of Medicine and Dentistry, Western University, London, Ontario, Canada; 5) Faculté de Médecine, Université de Montréal, Montréal, Québec, Canada.

We present the first large-scale low-pass whole-genome sequencing (WGS) effort of the French-Canadian population. These genomes were collected as part of a larger project that focuses on the relationship between the functionalities of high-density lipoproteins (HDL) and coronary artery disease in French Canadians. Our work builds on previous studies that targeted specific subpopulations to discover population-specific genetic variation, in particular rare and low-frequency coding DNA variants. We sequenced at ~5.6x coverage the whole-genome of 1,970 French Canadians recruited by the Montreal Heart Institute Biobank and identified 29 million bi-allelic variants (51% novel), including 19 million variants with a minor allele frequency (MAF) <0.5%. Genotypes from the WGS data are highly concordant with genotypes obtained independently by exome array on the same individuals (99.8%), even when restricting this analysis to rare variants (MAF <0.5%, 99.9%) or only heterozygous sites (98.9%). Likely detrimental DNA sequence variants are enriched at the rarer end of the allele frequency spectrum, consistent with purifying selection. For instance, whereas 17% of synonymous SNVs are common, 4% of nonsense and 11% of frameshift indel variants have a MAF >5% . To validate the utility of our dataset to discover genetic associations, we showed that despite its modest sample size, we can effectively replicate associations with myocardial infarction risk and blood lipid levels. For instance, 51 of the 69 (binomial P=9x10^{-5}) SNPs previously shown to be associated with HDL cholesterol levels have an effect in the right direction, and eleven of these are nominally significant (P<0.05). To explore the value of our WGS dataset beyond association analysis, we built a French-Canadian-specific imputation reference panel and showed that it slightly outperforms the 1000 Genomes Project reference haplotypes for rare variants in independent French-Canadian samples (mean r^2 of 0.76 *vs.* 0.71). Although most of the participants were recruited in the Montreal area, we used information on their ancestry to illustrate how this WGS dataset reflects the population structure in the Province of Quebec. This collection of results shows that low-pass WGS is a promising resource to analyze the genetics of human diseases in the founder French-Canadian population.

Detection of small indels in 133 rhesus macaques (*Macaca mulatta*) by whole genome sequencing. *M. Raveendran[1], R. Alan Harris[1], L. Cox[2], G. Fan[3], B. Ferguson[4], J. Horvath[5,6,7], S. Kanthaswamy[8,9], H. Michael Kubisch[10], D. Liu[11], M. Platt[12,13], D.G. Smith[8], B. Sun[11], E.J. Vallender[10,14], R.W. Wiseman[15], D.M. Muzny[1], R.A. Gibbs[1], J. Rogers[1].* 1) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 2) Southwest National Primate Research Center, San Antonio, TX; 3) Univ. of California, Los Angeles; 4) Oregon National Primate Research Center; 5) North Carolina Museum of Natural Sciences; 6) North Carolina Central University; 7) Dept. of Evolutionary Anthropology, Duke University; 8) California National Primate Research Center; 9) Arizona State University; 10) Tulane National Primate Research Center; 11) Anhui University, Anhui, China; 12) Dept. of Neurobiology, Duke University; 13) Univ. of Pennsylvania; 14) New England National Primate Research Center; 15) Wisconsin National Primate Research Center.

Among closely related species (e.g. humans and chimpanzees) small insertion-deletion differences (indels) account for more genetic divergence than single base substitutions. Indels are also known to explain a number of damaging mutations associated with human disease. Rhesus macaques (*Macaca mulatta*) are one of the most commonly used nonhuman primates in biomedical research, and genetic variation among rhesus can be useful in studying and understanding human diseases. However, little is known about the frequency or functional consequences of small indel polymorphisms among rhesus macaques. Here we describe the identification of small indels (1 to 60 bases in length) in a sample of 133 rhesus macaques (124 Indian-origin and 9 Chinese-origin). Using GATK software to call indels from whole genome sequence data (average coverage 26.7x), and excluding variant calls that do not pass quality control filters or are likely the result of errors in the reference genome, we identified 7,926,645 indels across the 133 animals. This includes 3,026,673 insertions, 3,951,905 deletions and 948,067 more complex sequence alterations with ambiguous mechanism. Out of these 7.92 million indels, 1.68 million are found only in Chinese rhesus and 2.94 million are Indian-origin specific. Across the full dataset, we observed 2.6 indels per 1kb of the rhesus genome. 48.25% of bases affected are due to insertions and 51.75% are due to deletions. Most of the indels (74.5%) are 1 to 4 basepair in length. The average number of indels per animal is 1,249,646, which is higher than observations for individual human personal genomes. To determine potential effects on gene function or protein sequence, we analyzed all rhesus indels using the Ensembl Variant Effect Predictor (VEP) tool and identified stop codons altered (365), coding sequence frameshift indels (7,664), inframe insertions (1,563), inframe deletions (2,165) and splice region indels (4,317). In order to identify possible disease models, we queried the DisGeNET database (http://www.disgenet.org) with genes containing frameshift indels. This identified several genes associated with specific human diseases, including muscular dystrophy (DMD), microcephaly (MCPH1), cleft palate X-linked (TBX22) and Tangier disease (ABCA1).

Mutation load is compensated by allele specific expression per individual and across populations. *I. Alves[1], H. Edgington[1], V. Bruat[2], J-C. Grenier[2], M-J. Favé[2], P. Awadalla[1,2,3].* 1) Ontario Institute for Cancer Research, OICR, Toronto, Ontario, Canada; 2) Sainte-Justine University Hospital Research Centre, Department of Pediatrics, University of Montreal, Quebec, Canada; 3) Department of Molecular Genetics, University of Toronto, Ontario, Canada.

Recently, several studies have shown that individual genomes and populations harbor varying numbers of putatively deleterious mutations, most of which are present at low-frequencies in the population. For example, the mutation load appears to vary depending on the size of the population, being particularly more pronounced in very small or founding populations. However, inferred mutation load from genome sequence data does not integrate information with respect to transcriptional or translational variation, including relationship to phenotypes. By combining whole-blood transcriptomic and genome-wide SNP-chip data from ~ 650 individuals with European and French-Canadian ancestry from the CARTaGENE Project, we measured individual allele specific expression (ASE) across all heterozygous SNP positions and incorporated ASE proportions across individuals to understand whether those variants showed a derived-, ancestral- or no biased expression profile at the population level. We then summarized the population derived allele frequencies, using the site-frequency spectrum (SFS), by independently conditioning on variants falling into the three expression profiles. We found that sites with derived-biased expression across the population show enrichment for derived alleles near fixation, but no bias towards functionally relevant alleles was found. On the other hand, sites showing an average allele expression bias towards the ancestral allele are enriched for rare derived alleles and carry an increased proportion of constrained, putatively damaging and missense alleles when compared to those variants with no bias in expression levels. Finally, when the burden carried by a particular derived allele is weighted according to its transcript abundance, the distribution of the mutation load per individual is inferred to be slightly smaller, but still significant, than one retrieved without accounting for ASE. Overall, our results suggest that allele specific expression tends to compensate for inferred genomic mutation load by reducing the expression of potentially damaging alleles at the level of the individual transcriptome, thereby possibly reducing the overall cost of deleterious mutations on individual' fitness. .

The NHGRI Sample Repository: A collection of cell lines and DNA for human genetic research. *A.M. Resch, F. Rahimov, M. Berkowitz, L. Brown.* Coriell Institute for Medical Research, Camden, NJ.

Knowledge of the spectrum of genetic variation across diverse human populations is important for reconstructing human evolutionary history and understanding the genetic basis of disease. Established in 2006, the NHGRI Sample Repository maintains and distributes a collection of well-characterized cell line and DNA samples to support studies of the human genome, including genetic variation in human populations. The NHGRI Repository hosts over 3,700 unique cell cultures and DNA samples collected for the International HapMap and 1000 Genomes Projects. Whole blood samples were collected from anonymized and de-identified donors and were contributed with consent to broad data release for use in future studies, including genotyping and sequencing, gene expression and proteomic studies, and all other types of genetic variation research. The samples include no identifying or phenotypic information. The HapMap and 1000 Genomes collections include samples from 27 distinct populations spanning 5 continents, making it one of the most comprehensive and unique resources of its kind. The 1000 Genomes Project is one of the few large-scale open access genomic datasets with companion cell lines and DNA. By providing the research community with a standard set of biomaterials of known provenance, invesitgators and clincians around the world can compare and contrast results. These standardized resources are critical elements in the efforts to take full advantage of the Human Genome Project for understanding the genetic origin of disease. Cell line and DNA samples from these collections are available to researchers around the globe and may be used by academic, non-profit and commercial entities. The full catalog of samples from the HapMap and 1000 Genomes collections can be accessed at https://catalog.coriell.org/1/NHGRI.

The origin of Tibetans remains one of the most contentious puzzles in history, anthropology and genetics. Analyses of deep sequenced genomes (30–60×) of 38 Tibetan highlanders and 39 Han Chinese lowlanders together with available archaic and modern human data allows us, for the first time, to comprehensively characterize the ancestral makeup of Tibetans and uncover their origins. Tibetans arise from a mixture of multiple ancestral gene pools but much more complicated and ancient than previously suspected. They share the largest proportion of genetic ancestry with modern human populations from East Asia, and to a lesser extent with those from Central Asia, Siberia, South Asia, western Eurasia and Oceania. Moreover, non-modern human sequences, possible inherited from Neanderthal, Denisovan and other unknown ancient people, comprise ~6% of the Tibetan gene pool and elevated in some genomic regions. In particular, highly differentiated sequences harbored in the highlanders' genomes were likely inherited from multiple non-modern human ancestral origins, and maintained in high frequency by natural selection.

1089F

Modeling human population separation history using physically phased genomes. *S. Song[1], E. Sliwerska[2], S. Emery[2], J. Kidd[1,2].* 1) Department of Computational Medicine and Bioinformatics, University of Michigan, Ann Arbor, MI; 2) Department of Human Genetics, University of Michigan, Ann Arbor, MI.

Phased haplotype sequences are a key component in many population genetic analyses since variation in haplotypes reflects the action of recombination, selection, and changes in population size. Haplotypes are typically estimated from unphased sequence or genotyping data using statistical models applied to large reference panels. To assess the importance of correct haplotype phase on population history inference, we performed fosmid pool sequencing and resolved phased haplotypes of five individuals from diverse African populations (including Yoruba, Esan, Gambia, Massai and Mende). We physically phased 98% of heterozygous SNPs into haplotype-resolved blocks, obtaining a block N50 of 1 Mbp. We combined these data with additional phased genomes from San, Mbuti, Gujarati and CEPH European populations and analyzed population size and separation history using the Pairwise Sequentially Markovian Coalescent (PSMC) and Multiple Sequentially Markovian Coalescent (MSMC) models. We find that statistically phased haplotypes yield an earlier split-time estimation compared with experimentally phased haplotypes. To better interpret patterns of cross-population coalescence, we implemented an approximate Bayesian computation (ABC) approach to estimate population split times and migration rates by fitting the distribution of coalscence times inferred between two haplotypes, one from each population, to a standard Isolation-with-Migration model. We inferred that the separation between hunter-gather populations and other populations happened around 120,000 to 140,000 years ago with gene flow continuing until 30,000 to 40,000 years ago; separation between west-African and out of African populations happened around 70,000 to 80,000 years ago, while the separation between Massai and out of African populations happened around 50,000 years ago.

1090W

Fine-mapping the favored mutation in an ongoing positive selective sweep. *A. Akbari[1], A. Iranmehr[1], S. Mirarab[1], V. Bafna[2].* 1) Electrical & Computer Engineering, University of California San Diego, La Jolla, CA; 2) Computer Science & Engineering, University of California San Diego, La Jolla, CA.

Motivation. Methods for detecting genomic regions under selective constraints are heavily studied and have been successful in identifying many ongoing selective sweeps. However, detecting the favored mutation itself remains an important but difficult problem. Here, we present a statistic for Selecting Alleles Favored in Evolution (SAFE). **Method.** SAFE combines scores derived from an extended version of Multivariate Ewen's Distribution on the number of distinct haplotypes in the sub-population of carriers of a mutation (Conditional Coalescent Tree) and the distribution of the Haplotype Allele Frequency (HAF) score. The HAF score, assigned to individual haplotypes in a sample, has previously been shown to successfully separate carriers of the favored allele from non-carriers in ongoing selective sweeps. **Result.** We tested SAFE on both simulated and real data including both hard and soft sweep (standing variation) as well as different demographic models, with very promising results. As an example, we ranked ~300 SNPs (50Kbp region) in each of 1,000 samples from populations simulated under selection with moderate selection coefficient (s=0.01), and standard population genetic parameters (effective population size Ne=10k, mutation rate u=2.5e-8, and recombination rate r=1.25e-8). The median of predicted rank of the favored mutation was 2. The favored mutation was ranked 1 in 46% of samples, and in the top 5% (respectively, 10%) in 94% (respectively, 99%) of samples. We also applied SAFE to Phase 3 of 1000 Genome Project data in regions where the selective sweep is well characterized, and the favored mutation is known with high confidence. Table 1 shows the excellent performance of our method on well-known selective sweeps. SAFE thus provides a sharper tool for studying evolutionary process at work, and complements methods based on functional analysis of variants in the region.

Table 1. Preliminary Result of detecting favored mutations of well-known selective sweeps.						
Genes	Population	Favored SNP	Frequency	Rank	Total # SNPs	Percentile (%)

1091T

Genomic identification of recent positive selection in populations from Andean highlands and Southern Chile. *R. Verdugo[1], P. Contreras[1], A. Blanco[1], A. Moreno-Estrada[2,4], K. Sandoval[2,4], C. Eng[5], S. Huntsman[5], E. Burchard[5,6], C. Gignoux[2,3], C. Bustamante[2,3], E. Llop[1], M. Moraga[1].* 1) Programa de Genetica Humana ICBM, Universidad de Chile, Santiago, RM, Chile; 2) Center for Computational, Evolutionary and Human Genomics, Stanford University; 3) Department of Genetics, Stanford University, Stanford, California; 4) Centro de Investigación y Estudios Avanzados, Instituto Politécnico Nacional, Mexico; 5) Department of Medicine, University of California, San Francisco, California; 6) Department of Bioengineering and Therapeutic Sciences, University of California, San Francisco, California.

Human migrations into South America reached the southern area of the continent by at least 14,800 BP. Therefore, populations inhabiting different regions in the continent may have developed local adaptations to their environment, adding to the genetic variation among indigenous populations. We evaluated genomic evidence of microevolutionary processes in three Amerindian populations from the Andes highlands in Peru (77 individuals from Puno) and Southern Chile (13 Pehuenche and 9 Huilliche) by genotyping with the Axiom LAT1 platform. We found sizable levels of genetic divergence between these populations. The Fixation Index Fst between the Highlands and Southern Chile was 0.046 and between Pehuenche and Huilliche was 0.025. To identify recent selective sweeps (less than 30,000 BP), we calculated iHS and XP-EHH scores in 7600~ windows (200 kb). We found that windows with the highest scores in these tests (p-value <0.05) are enriched in genes related with biological processes as Vitamin D metabolism in Andean individuals, and MHC class II protein complex in Southern Chile. Among these high scored windows, we highlight a region on chromosome 6 (51.8-52.6 Mb) that showed strong evidence of selection in all the three groups analyzed, as previously reported in other Amerindian populations. This region harbors genes associated with regulation of inflammatory responses and calcium homeostasis, among others. These results suggest that selective pressures on these biological mechanisms may have been present during the recent history of Native South American populations and represent a potential source of genetic variation in admixed individuals from South America.

1092F

Demography-aware method for inferring strength of selection on polygenic traits. *C. Antelope, R. Nielsen.* University of California Berkeley, Berkeley, CA.

Detecting selection acting on a polygenic trait is challenging because no single locus affecting the trait may alone show strong evidence of selection. However, the signal from multiple loci affecting the trait can be combined to provide strong signals of selection. We develop a maximum likelihood method for estimating the selection differential of a quantitative trait. The method combines the marginal likelihood functions for selection coefficients across multiple individual loci, using a classic quantitative genetics result from Lande and Arnold. The method assumes the availability of effect size estimates and their variances from GWAS studies, but does not assume complete ascertainment of causal loci. This facilitates formal testing of the hypothesis of selection acting on human polygenic traits in a specific population using a likelihood ratio test, and it provides maximum likelihood estimates of the trait-level selection differential. The method can also be used to predict the average change in the phenotypic value per generation due to selection. We validate the method using simulations and apply it to human GWAS data from Europeans to test previously proposed hypotheses regarding selection acting on height and Type II Diabetes. The method looks at selection in a single population, which complements previously published methods that take advantage of population differentiation to detect polygenic selection.

1093W

Painting by evolutionary history: Inference of local ancestry in admixed genomes. *A. Berens, J. Lachance.* School of Biology, Georgia Institute of Technology, Atlanta, GA.

Local ancestry inference is important for understanding demographic history and predicting hereditary disease risks in admixed populations, which are increasingly becoming the norm as human migration around the world accelerates. Current local ancestry painting methods require reference sequences from ancestral (or at least closely related proxy) populations. Unfortunately, some populations, including Native Americans, are underrepresented in the publically available global population-level genomic datasets due to deficient sampling or absence in modern genomes because of recent admixture. Additionally, current ancestry inference methods overlook potentially relevant information about the historical relationships between these ancestral populations. We propose a new hierarchical, reference-free chromosome painting method to infer individual local ancestries. From whole genome sequence data of admixed individuals, we estimate ancestry proportions on a chromosomal scale. These proportions are used to weight the contribution of individual alleles to ancestral population haplotype frequencies. Using a Hidden Markov Model, we estimate ancestry of each individual at the most informative sites between each population. Local ancestry is painted based on a weighted majority vote from multiple overlapping sliding windows that have been traversed in both the forward (5' to 3') and backward (5' to 3') directions. Our approach provides highly accurate (>90%) local ancestry predictions for simulated genomic data and produces summed local ancestry estimates that successfully recapture global ancestry proportions inferred by ADMXITURE (R^2 = 0.99) using real data from the 1000 Genomes Project. Future applications include iteratively increasing the number of ancestral populations by splitting a single population into two daughter populations and repainting local haplotypes to include these new ancestral populations. This hierarchical approach of painting chromosomes captures evolutionary relationships between ancestral populations.

1094T

The African Genome Resource. *T. Carstensen[1,2], D. Gurdasani[1,2], M.O. Pollard[1,2], C. Pomilla[1], AGR Investigators[1,2,3,4,5].* 1) Global Health and Populations, Wellcome Trust Sanger Institute, Hinxton, Cambridgeshire, United Kingdom; 2) University of Cambridge, Cambridge, Cambridgeshire, United Kingdom; 3) Stonybrook University, New York, United States of America; 4) MRC Uganda, Entebbe, Wakiso District, Uganda; 5) University of KwaZulu-Natal, KwaZulu-Natal, South Africa.

Despite large scale sequencing efforts such as 1000G, DNA and RNA sequence data collected from the African continent and made readily available to researchers is still limited. Capturing representative genetic diversity is important to provide a framework for medical genetics in Africa, as well as a resource for imputation and fine-mapping. In addition to facilitating GWAS, resources are needed to interpret associations in African populations, given that many of these arise from population specific variation. Existing resources examining the transcriptomic landscape in African populations, specifically focusing on genetic variants associated with gene expression are inadequate. The African Genome Resource here presented encompasses approximately 3000 whole genome sequences, 600 transcriptomes and an infrastructure for computation and capacity development in the form of a new informatics centre in Uganda. The three elements of the AGR are as follows: The African Diversity Reference Panel (ADRP). Whole genome DNAseq data at 4x-8x depth from approximately 3,000 Africans of 14 distinct ethnicities, which is the largest and most diverse set of haplotypes for the continent comprising more than 90 million SNPs of which many (more than 20 million) are novel and unique to the continent. This large count of unique SNPs highlights the importance for the development of reference panels, SNP arrays and RNA sequencing resources specific to the continent. The African Transcriptomics Resource. RNAseq data from 6 different populations is the first large-scale resource to examine eQTLs within Africa, as well as diversity of splicing isoforms, and will help to identify novel transcripts, and exons across the genome. Such a resource will be invaluable for the interpretation of findings from large-scale GWAS being conducted in Africa, supporting initiatives such as the H3A consortium. The Uganda Medical Informatics Centre (UMIC). A computational facility in Entebbe enabling local storage and handling of data from across the continent and supporting long term capacity building. Together, these three tangible resources will enable substantial advances in medical genetics in Africa. The large number of private variants across the continent and within individual populations highlights the future need to further sequence indigenous populations across the continent.

1095F

Fine-scale population structure in France: Loire River as genetic barrier.

C. Dina[1,2], J. Giemza[1], M. Karakachoff[1,2], F. Simonet[1,2], K. Rouault[3], E. Charpentier[1,2], S. Lecointe[1,2], P. Lindenbaum[1], J. Violleau[1,2], H. Le Marec[1,2], C. Férec[3], S. Chatel[1,2], S. Hercberg[4], P. Galan[4], J-J. Schott[1,2], E. Génin[3], R. Redon[1,2]. 1) Thorax Inst, INSERM-CNRS, Nantes, France; 2) CHU Nantes, Nantes University; 3) Inserm UMR 1078, CHRU Brest, University Bretagne Occidentale, EFS, Brest France; 4) Université Paris 13, Equipe de Recherche en Epidémiologie Nutritionnelle, Centre de Recherche en Epidémiologie et Statistiques, Inserm (U1153), Inra (U1125), Cnam, COMUE Sorbonne Paris Cité, F-93017, Bobigny, France.

Background The genetic structure of human populations varies throughout the world, being influenced by migration, admixture, natural selection and genetic drift. Human population structure has first been investigated at broad scales, between and within continents. Currently researchers focus on finer scales, examining genetic structure within countries. Characterising such genetic variation is of interest as it provides insight into demographic history and informs research on disease association studies, especially on rare variants. We here explored the genetic structure of a population living on the French territory (hereafter called French population) both on the whole territory and then on Western part where interesting stratification was identified.   Methods and Results We genotyped genome-wide ; 2276 individuals with known department of origin from French Population (SU.VI.MAX study) using Illumina Chip; 456 individuals (PREGO study) from Western France Atlantic Coast, from *Finistère* to *Vendée*, with at least three of their grandparents born within a 15 kilometres distance using Axiom CEU Chip. With EEMS software we visualised areas with low effective migration rates - the migration barriers, which match with geographical features, with particularly strong barrier on the lower course of Loire in Western France. We then focused on the PREGO study and Principal Components analysis revealed that individuals from the same departments form clusters. In both datasets we observed a high correlation between geographical position and components (p-value < 2e-16). Many independent methods support the hypothesis that Loire River is a genetic barrier. The two groups of individuals, from north or south of Loire, are well differentiated along PC1 axis. ADMIXTURE estimated different ancestry proportions for the two groups. The first split of hierarchical clustering returned by fineSTRUCTURE, and the one based on normalized counts of identity-by-descent segments is between north and south of Loire.   Conclusion   We here report genetic stratification at the level of continental French territory. The migration pattern is following the geographical structure. A specific pattern is noticed around the Loire River. We confirm both evidence for isolation by distance and existence of a genetic barrier, the Loire River. The discovered fine-scale population structure may have consequences in association analyses, especially for rare variants which tend to be geographically clustered. .

1096W

Genomic diversity and affinities in major population groups of Punjab, India: An analysis of microsatellite loci.

M. Kaur[1], B. Doza[2]. 1) Viral Research and Diagnostic Laboratory, Government Medical College, Amritsar, Punjab, India; 2) AMU Murshidabad Centre, Jangipur Barrage, Murshidabad, West Bengal, India.

The present study is motivated by the fact that negligible study is available regarding genetic structure of Punjabi population. In purview of this the present study was conducted to find out the genetic similarity and phylogenetic position of five endogamous population groups, namely Jat Sikh, Mazhbi Sikh, Brahmin, Ramdasia and Muslim from the Northwest districts of Punjabi population, with respect to admixture of other Indian and international populations in the past history. A total of 1246 subjects, including 252 Jat Sikh, 255 Mazhbi Sikh, 248 Brahmin, 251 Ramdasia and 240 Muslim samples were analyzed for six autosomal microsatellite markers (THO1, TPOX, CSF1PO, vWA, D7S820 and FGA). Statistical analyses were performed to interpret allele frequencies, heterozygosities, gene diversity, analysis of molecular variance (AMOVA), phylogenetic analysis (neighbor joining (NJ) method) and multidimensional scaling (MDS). The average heterozygosity for each locus in each population as a whole was substantial. Significant deviations from HWE were observed in almost all the populations and all the loci. In the entire analyses the Brahmin and the Mazhbi Sikh formed same cluster, while Jat Sikh and Ramdasia were placed close to their cluster, whereas, Muslim population group maintained the genetic distance from all the other population groups. Jat Sikh, Mazhbi Sikh, Brahmin and Ramdasia groups formed a clear and distinct separate cluster when compared with other Indian populations. The present study has also examined the affinities of Northwest Punjabi population with international populations, and some elements of central Asia, Middle East, Caucasoid and European populations were evident among the present studied groups. In conclusion**,** overall, a low level of genetic differentiation was observed in the studied population groups, especially, Jat Sikh, Mazhbi Sikh, Brahmin and Ramdasia indicating that genetic drift might have been small or negligible in shaping the genetic structure of the Northwest Punjabi populations.

1097T

The genetic structure of the world's first farmers. *I. Lazaridis[1,2], D. Nadel[3], G. Rollefson[4], D.C. Merrett[5], N. Rohland[1], S. Mallick[1,2,6], D. Fernandes[7,8], M. Novak[7,9], B. We report the first genome-wide DNA from the ancient Near East, including some of the world's first farmers, their hunter-gatherer predecessors, and their successors. The early farmers of the Levant and of Western Iran were highly differentiated and each descended from local hunter-gatherers. All ancient Near Eastern populations derived part of their ancestry from a 'Basal Eurasian' lineage that had less Neanderthal ancestry than other non-Africans. Over time, Near Eastern farmers admixed with each other and with the hunter-gatherers of Europe to transform West Eurasia from a region of high genetic differentiation into one of relative homogeneity by the Bronze Age. We find that many populations outside West Eurasia also trace part of their ancestry to some of the same sources as West Eurasians: East Africans to the Levant, East Asians to north Eurasia, and South Asians to populations related to the ancient peoples of both Iran and the Eurasian steppe.

1098F

The paternal demographic history of African-derived Brazilian *quilombo* **populations inferred by high density SNPs array.** *R. Mingroni-Netto[1], L. Kimura[1], K. Nunes[1], L.I. Macedo-Souza[1], J. Rocha[2], D. Meyer[1].* 1) Dept. of Genetics and Evolutionary Biology, University of São Paulo, São Paulo , Brazil; 2) Dept. of Biology, Sciences Faculty, University of Porto, Portugal.

Quilombo remnants are relics of communities founded by runaway or abandoned slaves, but often with subsequent extensive and complex admixture patterns with European and Native Americans. In the present study we combine genetic studies and anthropological surveys in order to obtain a portrait of *quilombo* population structure and history, a region that gathers the largest number of *quilombo* remnants in São Paulo State. Samples from 289 individuals from *quilombo* remnants were genotyped using a set of 17 microsatellites (AmpFlSTR-Yfiler). A subset of 82 samples was also genotyped using SNPs array (Axiom-Affymetrix). We estimated haplotype and haplogroup frequencies; haplotype diversity and sharing; and pairwise genetic distances through F_{ST} and R_{ST} indexes.We identified 95 Y chromosome haplotypes, classified into 15 haplogroups. The most common were: R1b (European, 34.2%), E1b1a (African, 32.3%), J1 (European, 6.9%) and Q (Native American, 6.2%). Genetic differentiation among communities was high (F_{ST}=0.0983; R_{ST}=0.0768), and haplotype sharing was extensive. Available data (genetic, genealogical and oral survey) allows us to detect five main founder haplotypes, which explain a total of 27.7% of the Y chromosome lineages in *quilombos*. Our results showed a high European patrilinear genetic contribution among the founders of *quilombos*, high amounts of gene flow and a recent common origin of these populations. Predominant haplotypes and genealogical data indicate a pattern of origin of *quilombos* from few male individuals. As such, our study reinforces the importance of a dual approach, including both anthropological and genetic data. .

1099W

Genetic architecture of five endogamous groups from Punjab, Northwest India – A study based on autosomal markers. *G. Singh[1,2], I. Talwar[1], K. Matharoo[2], A.J.S. Bhanwer[2].* 1) Department of Anthropology, Panjab University, Chandigarh, India; 2) Department of Human Genetics, Guru Nanak Dev University, Amritsar, India.

India represents a pool of culturally and genetically diverse populations. The region of Punjab (India) has an extreme importance in understanding the population diversity of India as it acted as a passage to the foreign invaders from Eurasia and Central Asia. The present study was designed to explore the genetic diversities and affinities among the five major endogamous groups using autosomal markers. A total of 1021 unrelated samples belonging to Banias, Brahmins, Jat Sikhs, Khatris and Scheduled Castes were genotyped for four Ins/Del (*ACE, APO, PLAT, D1*) and six restriction fragment length polymorphisms [*ESR (PvuII), LPL (PvuII) T2 (MspI*) and three *DRD2* (Taq1A, Taq1B, Taq1D)]. All the loci were found to be polymorphic among the studied populations. The average heterozygosity among the studied populations is fairly substantial ranging from 0.3816 in Banias to 0.4311 in Scheduled Castes. The genetic differentiation among studied populations ranged from 0.0418-0.0022 for the *PLAT* and Taq1A loci, respectively, with an average value being 0.0136. Phylogenetic analysis revealed that Banias and Khatris are genetically closest to each other. The Jat Sikhs are genetically close to Brahmins and are distant from the Banias. The Jat Sikhs, Banias, Brahmins and Khatris are genetically very distant from the Scheduled Castes. Overall, a uniform allele frequency distribution pattern and low level of genetic differentiation was observed in the studied population groups indicating that genetic drift might have been small or negligible in shaping the genetic structure of North-West Indian Populations. **Keywords**: *Alu* Insertion/Deletion, North-West India, Genetic diversity, endogamous group, SNP.

Genetic structure in the Sherpa and neighboring Nepalese populations. *A.M. Cole[1], S. Cox[2], C. Jeong[3], N. Petousi[4], D. Aryal[5], Y. Droma[6], M. Hanaoka[6], M. Ota[7], N. Kobayashi[7], P. Gasparini[8,9], H. Montgomery[2], P. Robbins[4], A. Di Rienzo[3], G.L. Cavalleri[1].* 1) Department of Molecular and Cellular Therapeutics, Royal College of Surgeons in Irelnad, Dublin 2, Ireland; 2) Institute for Human Health and Performance, University College London; 3) Department of Human Genetics, University of Chicago; 4) Department of Physiology, Anatomy and Genetics, University of Oxford; 5) Paropakar maternity and Women's hospital, Thapathali , Kathmandu, Nepal; 6) First Department of Medicine, Shinshu University School of Medicine, Matsumoto, Japan; 7) Department of Legal Medicine, Shinshu University School of Medicine, Matsumoto, Japan; 8) University of Triests, Italy; 9) Division of Experimental Genetics, Sidra, Doha, Qatar.

Introduction: Nepal, located on the southern slope of the Himalayan arc, has an intricate demographic history. Today Nepal is an ethnically diverse country with 125 recognised ethnic groups, including the Sherpa, whom migrated from Tibet 400-600 years ago. **Aim and Methods:** We set out to describe the fine-scale population structure across the eastern region of Nepal using dense genotype data. We sampled five indigenous Nepalese ethnic groups, and the Nepalese Sherpa from eight villages in the Khumbu region of Nepal. We complemented this dataset with dense genotype data representing a variety of different populations resident across the greater Himalayan region including Tibet, China, India, Pakistan, Kazakhstan, Uzbekistan, Tajikistan and Kirghizstan, establishing a cohort of 1117 individuals. Using this dataset, we performed analysis of principal components, admixture, F4 ratio estimation, D-statistic and homozygosity. **Results and Conclusion:** We identified clear substructure across populations resident in the Himalayan arc. The genetic structure broadly mirrors the geographical features of the region. Ethnic subgroups within Nepal show distinct genetic structure. We detected differential proportions of ancestry from northern Himalayan populations across Nepalese subgroups, with the Nepalese Rai, Magar and Tamang carrying the greatest proportions of Tibetan ancestry. The Sherpa appear as a remarkably isolated population, with little gene flow from surrounding Nepalese populations. We confirmed the presence of an ancestral component that appears specific to high altitude populations of the Himalayas and is enriched in the Nepalese Sherpa, with particularly high proportions identified in individuals from a specific Sherpa village in the Khumbu valley of eastern Nepal.

Contributions of LINE-1 retrotransposon ORF0 to genomic output in the primates. *A.M. Denli, M. Pena, A. Saghatelian, F.H. Gage.* Laboratory of Genetics, The Salk Institute for Biological Studies, La Jolla, CA.

What are the molecular underpinnings of diversity and evolution? The answer to this question has important implications for human health and biology: variations in disease predisposition, response to pathogens and drug therapies play roles in lifespan and quality of life. A comprehensive molecular understanding of diversity and evolution requires the availability of population-level genomic sequences, well-annotated transcriptomes and proteomes, as well as experimental models for functional genomics. This talk will summarize our recent efforts in the latter two. Transposable elements (TEs) are mobile genetic elements that can alter their chromosomal locations in the host genomes and occupy nearly 45% of the human genome. It has been estimated that ~2,000 common TE polymorphisms exist in human populations. LINE-1s, as the sole autonomously active retrotransposons in humans, are a major class of TEs that diversify our genomes. We have recently shown that primate LINE-1 5'UTR contains a primate-specific open reading frame (ORF) in the antisense orientation that we named ORF0. This ORF is present in more than 3,000 loci across human and chimpanzee genomes and forms fusion proteins with proximal exons, leading to insertion-specific novel contributions to the proteome. ORF0 expression is elevated in pluripotent stem cells as well as a subset of cancers. Our most recent analyses suggest that transcribed ORF0 polymorphic loci exist in human genomes and, in addition to the direct proteomic contributions, ORF0 also influences gene expression. The influence of TEs on the host cells will be discussed.

Conserved microRNA targeting of dosage-sensitive genes on mammalian X and avian Z chromosomes. *S. Naqvi[1,2], D.W. Bellott[1], D.C. Page[1,2,3].* 1) Whitehead Institute, Cambridge, MA; 2) Department of Biology, Massachusetts Institute of Technology, Cambridge MA; 3) Howard Hughes Medical Institute, Whitehead Institute, Cambridge MA.

The mammalian X and Y chromosomes arose from a pair of autosomes. Genes originally present on these autosomes evolved independently along a multistep path characterized by Y gene loss and the subsequent acquisition of X chromosome inactivation (XCI) in females. We assessed repression by microRNAs (miRNAs) to identify dosage constraints that led to three stable evolutionary fates along the pathway. X-linked genes at the beginning (with a surviving Y homolog) and end (with no Y homolog and subject to XCI) of the pathway have been under greater pressure to maintain miRNA targeting than evolutionary intermediates (with no Y homolog but escaping XCI). Such pressure has also acted upon avian Z-linked genes with surviving homologs on the female-specific W chromosome. We conclude that in addition to sex chromosome-wide mechanisms, purifying selection maintained ancestral X- or Z-linked gene dosage though retention of miRNA targeting. We propose that a combination of upward and downward constraints on ancestral dosage determined the evolutionary fates of sex-linked genes..

1103T

Key differences and similarities between human and mouse genes that escape X inactivation. *A. Slavney[1,2], A. Keinan[2], A. Clark[1,2].* 1) Molecular Biology and Genetics, Cornell University, Ithaca, NY; 2) Biological Statistics and Computational Biology, Cornell University, Ithaca, NY.

In eutherian mammals, X chromosome inactivation (XCI) silences transcription from one ChrX homolog in each female cell to equalize ChrX gene dosage between XX females and XY males. However, some genes are never fully inactivated, and are termed XCI escapers. XCI escape introduces variation in gene expression level between females and males, making these genes intriguing candidates for involvement in the many complex diseases that show substantial sex biases. Approximately 15% (n~200) and 7% (n=38) of human and mouse ChrX genes escape XCI, respectively. Analysis of the differences between human and mouse XCI escapers may elucidate the evolutionary drivers of XCI escape, and by extension the role of XCI escapers in normal and disordered phenotypes. Toward this end, we compared XCI status for orthologous human and mouse ChrX genes, and examined functional annotations and patterns of evolutionary conservation for XCI escapers in each species. Using a consensus XCI data set generated from 5 previous studies, we observed strikingly poor conservation of XCI status between human and mouse ChrX orthologs. In particular, only 13 orthologs escape XCI in both species. Additionally, several genes escaping XCI in one species have translocated to the autosomes in the other, consistent with the common hypothesis that dosage-sensitive genes are prone to escaping XCI. When we compared PANTHER gene ontology annotations of human and mouse XCI escapers, we observed high overlap in top biological process hits. However, the proportions of genes in the same functional categories differ greatly between species. In particular, human XCI escapers show a higher proportion of genes with metabolic functions than mouse XCI escapers. Lastly, we compared the distributions of exonic phyloP scores between XCI escapers and X-inactivated genes within each species to assess how conserved these gene groups are across vertebrates. In agreement with previous studies, we observed that human XCI escapers show a greater degree of sequence conservation than X-inactivated genes. While XCI escapers are also more conserved than X-inactivated genes in mouse, the difference is much less dramatic than in humans. Taken together, these results suggest that certain biological functions and strong evolutionary conservation are common features of XCI escapers in mammals, despite the fact that the XCI status of individual genes is highly lineage-specific.

Improvements in genotype imputation by using a population specific reference panel in Africa. *J. Chen[1], M. Sun[2], T. Carstensen[1], A. Morris[2], F. Pirie[3], A. Motala[3], M. Sandhu[1], M. McCarthy[2], I. Barroso[1], E. Wheeler[1], A. Mahajan[2].* 1) Wellcome Trust Sanger Institute, Cambridge, Cambridge, United Kingdom; 2) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 3) University of KwaZulu-Natal, Nelson R Mandela School of Medicine, Durban, South Africa.

Genome-wide association study (GWAS) has proven to be a powerful tool to detect disease/trait associated variants. An important step to boost power in GWAS is genotype imputation where untyped variants are inferred from the genotype data and known haplotypes in a reference panel. As discovery efforts in non-European ancestry populations increase, it has become popular to supplement existing imputation panels with population specific reference panels. In our study, we conducted a GWAS of type 2 diabetes (T2D) in African subjects of Zulu descent (1,602 cases/976 controls), and compared the imputation quality of two different imputation schemes. In scheme 1, we utilized the 1,000 genomes phase 3 reference panel (Panel 1) with uniformly distributed 1Mb chunks. Panel 1 was merged with 2,298 African samples with sequence data from the African Genome Variation Project (AGV) and the Uganda 2,000 Genomes Project (UG2G) into 1000Gp3+AGV+UG2G panel (Panel 2). In scheme 2, we used panel 2 with chunks containing 200 more variants in both the genotyped data and panel 2, avoiding large gaps and shorter than 5Mb. The imputation quality was evaluated in three aspects: number of variants imputed, imputation accuracy and imputation information score. Imputation accuracy was assessed using 97 Zulu samples with both genotype and sequence data. The sequence data was treated as the truth set and four metrics (genotype concordance, non-reference sensitivity, non-reference genotype concordance and precision) were applied to evaluate the similarity between the genotype data and the sequence data. As expected, 20,262,808 bi-allelic variants were imputed in scheme 2 only because of the additional African specific variants present in panel 2. When comparing variants common to both schemes, variants imputed in scheme 2 were more accurate (more similar to the sequence data) than those imputed in scheme 1 for all chromosomes and all minor allele frequency bins (common, low frequency and rare). We also observed an improvement in the imputation quality from the chunking strategy utilized in scheme 2, evident when considering Chromosome X, for which panel 2 is the same as panel 1. Overall, in our data, panel 2 both increased the number of imputed variants and improved the imputation accuracy and information score.

Inferring local demographic history and the age of mutations from haplotype cluster graphs. *G. Gliner[1], D.C. Aguiar[2], B.E. Engelhardt[2,3].* 1) Department of Operations Research and Financial Engineering , Princeton University, Princeton, NJ; 2) Department of Computer Science , Princeton University, Princeton, NJ; 3) Center for Statistics and Machine Learning , Princeton University, Princeton, NJ.

The age of a genomic mutation, as well as its frequency within a population, provides information about selective forces acting on a genomic locus, including susceptibility to disease, population structure, and demographic history. With the ability to rapidly sequence, genotype, and impute vast catalogues of genetic variation, developing novel data-driven statistical methods to estimate the age of a genetic mutation is possible. Here we present a statistical framework to estimate the age of genomic mutations across multiple individuals leveraging information contained in the haplotype cluster graph, a genetic model for haplotype sequences. Rather than relying singularly on population based statistics such as allele frequencies or attempting to reconstruct full ancestral recombination graphs, our approach explicitly models recombination and mutation deduced from the haplotype clusterings; this approach provides a much finer resolution of shared ancestry than methods that rely on genotypes or conservative linkage disequilibrium thresholding (e.g. 4-gamete test) in haplotypes. From the haplotype cluster graph, we generate marginal trees describing the ancestry of the extant subsample inheriting the mutation across unrecombined regions that, in turn, provide estimates for the shared physical and genetic distances and the number of mutations on each branch of the marginal tree following a coalescent statistical model to estimate the age of the locus. The novelty of our model originates from the ability to compute variant age estimates across multiple individuals and the synthesis with a robust statistical haplotype cluster graph model to estimate accumulation of ancestral mutations along ancestral branches and shared genetic and physical distances. We simulate whole-genome data with empirically estimated recombination patterns and compare results on inferring the age of mutations from a number of related methods showing both greater flexibility in application and more accurate estimates of age. Further, we apply our method to estimating mutational age in the 1000 Genomes Project data and show patterns of enrichment for specific functional categories..

1106T

Identification and characterization of common haplotypes found in a database of one million human genomes. *H. Guturu[1], K. Noto[1], J. Byrnes[1], S. Song[1], P. Carbonetto[1], R.E. Curtis[2], E. Elyashiv[1], J.M. Granka[1], E. Han[1], E.L. Hong[1], A.R. Kermany[1], N.M. Myres[2], K.A. Rand[1], Y. Wang[1], C.A. Ball[1], K.G. Chahine[2].* 1) Ancestry.com DNA, LLC, San Francisco, CA; 2) Ancestry.com DNA, LLC, Lehi, UT.

Introduction: A common DNA-based method to detect relatives and ancestors ("cousins") is to identify and match shared portions of chromosomes (haplotype blocks) between an individual and their potential relatives. Identifying and matching the shared haplotype blocks is challenging due to the non-uniform halving of genetic information that takes place during the meiosis events of each generation. As the number of generations increases, the average size of matching haplotype blocks shrink, due to successive chromosomal recombination. Additionally, genetic drift, flow and selection establish population structure that skews the distribution of frequency and size of some haplotype blocks. We aim to characterize haplotype blocks based on their frequency profiles and link haplotypes to ancestral communities ("genetic ethnicities") and more recent admixed communities. **Methods:** Using a novel haplotype block matching algorithm, we identify haplotype blocks that occur frequently in a database of over one million samples genotyped by Ancestry.com DNA, LLC. We review the frequency profiles of each haplotype, and associate them with metadata inferred from global and local estimated admixture ("genetic ethnicity") as well as aggregated family history data from public family trees associated with some of the genotypes. **Results:** Common SNP windows have been characterized as identifying signatures of the gamut from ethnicities to more recent admixed communities resulting from migration. Further, we show that these signals of ethnic populations and communities can be used to improve the accuracy of identifying distant "cousin" matches by correcting for matches that are predominately generated due to more ancient signals of ancestry. **Conclusion:** By linking common haplotype blocks to ancestral groups of varying age of origin, we can improve the accuracy of ancestor identification for the desired task – ancient haplotype blocks for ethnicity admixture detection to more recent haplotype blocks that reflect recent cousins. Additionally, our characterization of haplotype blocks by ancestral groups reveals interesting candidates for further study and interpretation of their functional implications in various ethnic and community groups.

Maps of effective migration as a summary of human genetic diversity. *B. Peter, D. Petkova, M. Stephens, J. Novembre.* University of Chicago, Chicago, IL.

A dominant pattern of genetic diversity in humans is that geographically proximal populations are generally more genetically similar to one another; however, there are exceptions to this rule. Persistent geographical features such as mountains, oceans, or deserts, have allowed excess genetic differences to accumulate in some regions more than others. Conversely, historical migrations and population movements have led to cases where exceptional levels of similarity persist across large geographic distances. To provide more insight into how genetic differentiation is distributed geographically in humans, we examine the fine-scale genetic structure of humans. We produce maps that represent the spatial structure of human genetic diversity using a recently developed, spatially explicit method (EEMS, Estimation of Effective Migration Surfaces). We apply EEMS on global, continental, and sub-continental scales, analyzing genetic data from 8,740 individuals from 469 geographically localized populations, obtained from 24 different source studies. In addition to the major, well-known barriers such as the Sahara, Himalayas and Mediterranean, we detect barriers that correlate with historic language group boundaries (boundaries of Slavic and Bantu speakers with their neighbors), mountain ranges (Zagros, Caucasus, Ural) and marine features (English Channel, Adriatic Sea, Wallace line). We also identify regions showing high connectivity despite having geographic separation (Britain and Scandanavia, Iceland and Denmark, among the Lesser Sunda Islands). Simultaneously, we find that levels of diversity vary more smoothly, decreasing gradually with distance from Africa. Overall, our results suggest that diversity patterns are consistent and primarily shaped by the signature of the Out-of-Africa expansion, but that migration rates are strongly influenced by geography and local events.

1108W

Thousands of adaptive polymorphisms in human proteins and their prevalence in disease. *L. Scheinfeldt, R. Patel, T. Lanham, S. Kumar.* Temple University, Philadelphia, PA.

Hundreds of thousands of polymorphic missense mutations have been discovered in the human genome. However, fewer than 100 of these polymorphisms are known to carry signatures of positive selection. If true, this would make the incidence of adaptation through protein sequence changes to be an extremely rare phenomenon. Through an evolutionary time-series analysis, which uses between-species differences to generate neutral expectations and discover candidate adaptive polymorphisms (*caps*) based on the discordance between neutral expectations and observed allele frequencies, we have discovered more than 18,000 missense *caps*. Using available genome-wide association data, we have validated >6,000 *caps* to be involved in phenotypic traits, which are further validated by their disease-association (>5,000 *caps*). Therefore, we have identified 100-times more *bona fide caps* (*bf-caps*) than known previously. Missense *cap*-containing proteins are over-represented in several biological processes (e.g. sensory perception, immunity, and metabolism), and disease associated *caps* are enriched for several auto-immune diseases (including lupus, multiple sclerosis, rheumatoid arthritis, and asthma). Our new multidimensional approach integrates inter-species, intra-species, and phenotypic information in one framework to discover adaptations that have shaped human phenotypic variability and the disease landscape.

Dynamics of chromatin accessibility and transcription factor binding in human and chimpanzee pluripotent stem cells. *I. Gallego Romero[1,2], S. Gopalakrishnan[3], Y. Gilad[4].* 1) School of Biological Sciences, Nanyang Technological University, Singapore, Singapore; 2) Lee Kong Chian School of Medicine, Nanyang Technological University, Singapore, Singapore; 3) Natural History Museum of Denmark, University of Copenhagen, Copenhagen, Denmark; 4) Department of Human Genetics, University of Chicago, Chicago, IL, USA.

Many human-specific traits have long been hypothesised to be driven by gene regulatory differences between ourselves and our close evolutionary relatives. To test this hypothesis, we have generated maps of genome-wide chromatin accessibility using ATAC-seq in induced pluripotent stem cell (iPSC) lines derived from 6 humans and 7 chimpanzees (Pan troglodytes, our closest living relative), and quantified patterns of transcription factor (TF) binding activity in nearly 240 million putative sites across 1,229 different TFs. As expected, we find that sharing of chromatin accessibility patterns between the two species is strongest near orthologous transcription start sites (orthoTSS, r^2 = 0.949), and decreases with distance from orthoTSS. Combining these results with RNA-sequencing data from the same cell lines we find that significant inter-species differences in chromatin accessibility near orthoTSS occur more often than expected ($p < 10^{-5}$) at differentially expressed genes. Similarly, when we focus on transcription factor binding patterns in the two species, we find that TF binding sites most likely to be bound in both species are preferentially located close to orthoTSS and tend to have high position weight matrix (PWM) scores ($p < 2.2*10^{-16}$). Intriguingly, some of the transcription factors with the most divergent inter-species binding patterns have been implicated in early developmental processes, suggesting that the differences we observe at the pluripotent stage might underlie other interspecies cellular-level, and potentially even organismal-level, differences between humans and chimpanzees. Taken together, our results suggest that changes in chromatin accessibility and transcription factor activity are a likely gene regulatory mechanism through which human-specific traits can arise.

1110F

Deep sequencing of the human MHC region reveals long structural variation of ancient origins. *A.Q. Fu[1,2,3], E.Y. Kim[4], Y.I. Li[2], M. Stephens[1,5], S. Wolinsky[4].* 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) Department of Genetics, Stanford University, Stanford, CA; 3) Department of Statistical Science, University of Idaho, Moscow, ID; 4) Division of Infectious Diseases, Department of Medicine, Northwestern University Feinberg School of Medicine, Chicago, IL; 5) Department of Statistics, University of Chicago, Chicago, IL.

The major histocompatibility complex (MHC) region in humans plays a central role in immunity and exhibits high genetic diversity, which makes it difficult to study, or even to sequence this region. Here we used a combination of targeted sequence capture and high-coverage pyrosequencing (Roche 454) to characterize genetic variation in 63 people. We captured 73% of this region of 4.75 Mb (chr6:28.70-33.45 Mb; hg19), and achieved good coverage (55X on average) across the region. Unexpectedly, de novo assembly of the sequencing reads (median 450 bp) revealed that, in addition to HLA genes, 30 people carried extra DNA segments (median 2 kb) that are more similar to the MHC of the great apes (chimp, gorilla, or orangutan) than to the eight standard major human MHC reference haplotypes. Most (76%) of the ape-like segments share the highest levels of sequence identity with gorilla HLA-A (Gogo-A). We confirmed the presence of these gorilla-like segments (GLSs) also in the DNA of individuals from the 1000 Genomes Project. The GLSs are present in 20 of our samples, and tend to co-occur with several human HLA-A alleles that are closely-related in phylogeny (A*30:01, A*31:01, A*32:01, A*33:01/02/03, and A*68:02; p<1e-3), indicating close proximity of the GLSs to HLA-A in the sequence. Interestingly, the GLSs harbor a previously characterized pseudogene HLA-BEL, the first two exons of which are highly similar to a functional allele (Gogo-A*05:01) in gorilla. Although HLA-BEL has been reported to be untranscribed in humans, we validated its transcription through cDNA sequencing in all three individuals carrying this pseudogene. We also found HLA-BEL-like reads in the RNA-seq data of at least 6 (2%) blood samples from the Genotype-Tissue Expression (GTEx) cohort, thus validating its expression in a more general population. Additionally, we found an unknown gene-like sequence that is <70% similar to pseudogene HLA-W, 10 kb downstream of HLA-A. We named this sequence HLA-WLK, but did not find evidence for its transcription. These ape-like segments suggest additional complexity in the evolutionary history of the MHC region. Whereas ancestral, functional copies of the GLSs likely existed before the human-gorilla split, it is difficult to determine when these additional segments arose near HLA-A. However, transcription of HLA-BEL suggests that its promoter has not yet eroded through genetic drift, while HLA-WLK may have been pseudogenized further in the past.

Repeated expansion of human amylase genes create multiple independent CNV series. *N.A.A. Shwan[1], S. Louzada[2], F. Yang[2], J.A.L. Armour[1].* 1) School of Life Sciences, University of Nottingham, Nottingham , United Kingdom; 2) Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, Cambridge,United Kingdom.

The human amylase gene family is highly copy number variable, and the salivary (*AMY1*) and pancreatic (*AMY2A* and *AMY2B*) amylase genes encode the starch-digesting enzyme expressed in the salivary gland and pancreas, respectively. High *AMY1* copy number (CN) has been shown to be correlated with adaptation to human dietary starch intake, and low *AMY1* CN reported to be a predisposition factor to obesity. These findings have not been replicated independently, and reliable measurement methods and accurate structural characterisation of the region are important to address such findings. Here we show independent allelic series of amylase CN variants (CNV) in sub-Saharan Africans using high-resolution measurement methods and segregation analysis in trios. To confirm the haplotype compositions we used fibre-FISH (Fluorescence *in situ* hybridization), which unveiled some structural complexity difficult to observe using conventional methods. Our work showed rearrangements including multiple expansion of a unit containing one copy each of *AMY1*, *AMY2A* and *AMY2B*. Overall, our data demonstrated at least five independent rearrangements of pancreatic amylase genes, in which the region has undergone homologous and non-homologous rearrangements to create new haplotypes, some of which contain five copies each of the *AMY2A* and *AMY2B* genes. The structural features shared by fundamentally distinct lineages strongly suggest that the common ancestral state for the human amylase cluster contained more than one, and probably three, copies of *AMY1*. These additional rearrangements we have discovered in the pancreatic amylase genes suggest that the pancreatic amylase genes should be taken into account when evaluating the adaptive significance of variation in this gene cluster. Furthermore, our results suggest that the CNV typing procedures we have developed constitute an accurate, reliable and high throughput method for measuring amylase CN in a large set of samples.

1112T

Association of toll-like receptor-3 gene polymorphism in patients with dengue as compared to controls: A case-control study. *A. Singh, A. Jain.* King George's Medical University, Lucknow, Select a Country.

Background: Toll-like receptors (TLR) are expressed by immune cells engaged in signalling cascades that culminates in inflammatory and immune defence response. Therefore, we aimed to assess the association of rs3775291, rs3775290, rs3775296 in cases with Dengue as compared to controls in Indian population. **Material and methods:** It was a hospital based case-control study, 98 Dengue cases and 98 age and sex matched controls were recruited. Cases included were laboratory conformed cases of dengue virus (DV) infection, confirmed by Either NS-1 antigen positivity or DV-RNA positivity or Demonstrating antibody in sera. Children with no past and present viral infection history were included as control. We determined TLR3 genotypes by polymerase chain reaction and followed by sequencing using chain termination method (PCR-sequencing) using ABI 3130 genetic analyser. **Results:** In the present study, **i**ncreased risk was observed in rs3775291 polymorphism in cases as compare to control (TT genotype OR=5.74, 95 %CI =1.47-2.42, p = 0.0001) (CT+TT genotype OR=2.1, 95 %CI =1.28-3.80, p = 0.0001). Significantly higher risk was found in individuals carrying (CT+TT) genotype of rs3775296 polymorphism among cases and controls (OR=1.94, 95 %CI =1.13-3.31, p = 0.0001). No significant difference was observed in rs3775290 polymorphism of TLR gene. **Conclusion:** TLR3 gene polymorphism might confer host genetic susceptibility to Dengue in Indian population.   .

The African Genome Resource Project: Patrilineal and matrilineal inheritance through the Y chromosome and the mitochondrial genome. *F. Abascal, D. Gurdasani, T. Carstensen, M. Pollard, C. Pomilla, M. Sandhu on behalf of AGR investigators.* Human Genetics, Wellcome Trust Sanger Institute, Hinxton, Cambridge, United Kingdom.

Background The Y chromosome and the mitochondrial genome are inherited from the paternal and maternal lines, respectively. The lack of recombination in the mitochondrial genome and in large part of the Y chromosome leads to evolution almost in isolation from the autosomal genome. As a result, the Y chromosome and the mitochondrial genome offer a unique perspective on human demographic processes. Y chromosome (Y-) and mitochondrial (mt-) haplogroups can be very informative about human origins, migrations and admixture, as well as about potential sex biases during these processes. Further characterisation of the diversity of Y- and mt-haplogroups within Africa is essential to understand human history. Here, we present the mitochondrial and Y chromosome diversity among ~5000 individuals from the African Genome Resource panel. **Methods** We predicted the mt- and Y-haplogroups for 4,990 individuals and 2,399 males, respectively, representing diverse ethno-linguistic groups from Ethiopia, Uganda, South Africa, Egypt, and 5 African populations sequenced within the 1000 Genomes project. Mitochondrial and Y haplogroups were predicted with Haplogrep and YFitter, respectively. We called the mitochondrial genome and the Y chromosome for each sample and reconstructed their phylogenetic relationships with FastML. **Results** We found evidence for Eurasian admixture among several populations across sub-Saharan populations. Eurasian mt haplogroups appeared in 23% of the Ethiopians and 0.8% of the Ugandans. No Eurasian mt haplogroups were detected for the Zulu and Nama. We identified 13% Ethiopians, 0.5% Ugandan, and 43% Nama/Khoe-Sans with Eurasian Y haplogroups. Eurasian admixture is prevalent in Ethiopia but it is not distributed homogenously. Whereas the Gumuz show no Eurasian haplogroups, the Amhara show the highest frequencies. Within the Nama/Khoe-San there is not a single Eurasian mitochondrial haplogroup but up to 43% of Eurasian Y haplogroups, revealing a strong sex bias (p=1e-12). Consistent with previous reports, the oldest haplogroups are found in highest frequencies within the Khoe-Sans. **Conclusions** We present the largest panel of mt and Y chromosome sequences across Africa, including highly diverse Khoe-San populations from South-Africa. Our findings suggest substantial variation in Y chromosome and mt haplogroups across Africa, and provide evidence for extensive Eurasian admixture among several populations across Africa.

Whole-genome sequence analyses provide new insights into the demographic history and local adaptation of African populations. *S. Fan[1], D.E. Kelly[1], M.H. Beltrame[1], M.E.B. Hansen[1], S. Mallick[2,3,4], T. Nyambo[5], S. Omar[6], D. Meskel[7], G. Belay[7], A. Froment[8], N. Patterson[3], D. Reich[2,3,4], S.A. Tishkoff[1,9].* 1) Department of Genetics, University of Pennsylvania, Philadelphia, PA 19104, USA; 2) Department of Genetics, Harvard Medical School, Boston, MA 02115, USA; 3) Broad Institute of Harvard and MIT, Cambridge, MA 02142, USA; 4) Howard Hughes Medical Institute, Harvard Medical School, Boston, MA 02115, USA; 5) Department of Biochemistry, Muhimbili University of Health and Allied Sciences, Dares Salaam, Tanzania; 6) Kenya Medical Research Institute, Center for Biotechnology Research and Development, Nairobi, Kenya; 7) Department of Biology, Addis Ababa University, Addis Ababa, Ethiopia; 8) UMR 208, IRD-MNHN, Musée de l'Homme, Paris, France; 9) Department of Biology, University of Pennsylvania, Philadelphia, PA 19104, USA.

Africa is the origin of modern humans within the past 200,000 years. There are more than 2,000 ethnolinguistic groups in Africa, which encompass around one-third of the world's languages. To infer the complex demographic history of African populations and adaptation to diverse environments, we sequenced the genomes of 94 individuals from 44 indigenous African populations using high coverage Illumina sequencing technology. Phylogenetic analysis confirms that the San lineage is basal to all other modern human population lineages. The location of other African populations in the phylogenetic tree correlates with geographical location, with the exception of the Central Africa rainforest hunter-gatherer (RHG) populations, who group with Southern African populations. We characterize ancient African population structure by inferring the effective population size and divergence time between populations. A common population bottleneck for all African populations was observed at ~200 thousand years ago (kya), corresponding with paleobiological evidence for modern human origins. Since then, the San and RHG populations have maintained the largest effective population size compared to other populations prior to 10 kya. Using MSMC analysis, we infer that the San population split from the RHG and the East African Khoesan-speaking Hadza and Sandawe hunter-gatherers within the past 66-82 kya, suggesting these populations could have originated from a historically more widespread population of hunter-gatherers. By contrast, the San diverged from all non-Khoesan speaking populations ~100-120 kya The divergence times of Niger-Kordofanian, Nilo-Saharan and Afroasiatic speaking populations were within the past ~22 to 41 kya. In the RHG populations, the oldest divergence was found between Eastern and Western RHG at ~36-51 kya; the time of divergence of the western RHG populations was inferred to be ~12-18 kya. Based on the ADMIXTURE analysis, Niger-Kordofanian and RHG populations were pooled for analyses of natural selection. We observed signatures of positive selection at genes involve in muscle development, bone synthesis, reproduction, immune function, energy metabolism, cell signaling, and neural development. This work is supported by NIH grants 1R01DK104339-01, 1R01GM113657-01, and DP1 ES022577-04 to SAT. The sequencing was funded by the Simons Foundation (SFARI 280376) and the U.S. National Science Foundation (BCS-1032255) grants to DR.

Investigating the evolution of human metabolic traits using primate iPSCs. *S.C. Makohon-Moore[1], G.A. Wray[1,2,3].* 1) Biology Department, Duke University, Durham, NC; 2) Evolutionary Anthropology Department, Duke University, Durham, NC; 3) Center for Genomic and Computation Biology, Duke University, Durham, NC.

Humans differ from our closest living relatives in a variety of important metabolic traits including disease susceptibilities. Understanding the evolutionary basis and molecular underpinnings of these uniquely human traits has previously been hampered by the limited ability to perform experiments on and access to samples from non-human primates. The development of induced pluripotent stem cell (iPSC) lines allows us to control genetic background, design rigorous experimental manipulations and remove environmental variability. iPSCs can be differentiated into a variety of cell types allowing for the characterization of specific cellular traits and responses to environmental stimuli. We are using iPSCs to identify genetic, epigenetic and environmental effects on the evolution of physiology during human origins. In particular, we are focusing on adipocytes, the key component cell of fat, which allows for the identification of differences in molecular, cellular and metabolic traits. Changes in these traits were likely necessary during human evolutionary origins as shifts in metabolic function were of particular importance. These questions would remain impossible to answer using any other existing approach. Using adipocytes differentiated from human and chimpanzee iPSCs along with multi-omic approaches we can infer how specific metabolic pathways have changed throughout evolution. Our results demonstrate that stem cells provide valuable insights into key metabolic traits that distinguish humans from our closest relatives and may be important for human specific disease susceptibilities.

1116F

The evolutionary history of human-specific gene duplications. *P. Moorjani[1,2], B. Handsaker[2,3,4], F. Polleux[5], S. McCarroll[2,3,4], M. Przeworski[1,6].* 1) Department of Biological Sciences, Columbia University, New York, NY; 2) Program in Medical and Population Genetics, Broad Institute, Cambridge, MA; 3) Department of Genetics, Harvard Medical School, Boston, MA; 4) Stanley Center for Psychiatric Research, Broad Institute, Cambridge, MA; 5) Department of Neuroscience, Zuckerman Mind Brain Behavior Institute and Kavli Institute for Brain Science, Columbia University, New York, NY; 6) Department of Systems Biology, Columbia University, New York, NY.

While gene duplications are known to have led to evolutionary novelty in many species, the functional consequences of duplications that arose on the human lineage are unknown. Intriguingly, human-specific duplications (i.e., duplicates present in humans but not in other primates) appear to be enriched for genes expressed in the developing brain. A subset (notably *SRGAP2*, *ARHGAP11B*) has been shown to have important functions in spine maturation and neocortex expansion and may contribute to the risk of neuropsychiatric diseases. Motivated by these observations, we decided to use the high quality primate genomes now available, to systematically characterize the repertoire of human-specific duplications, and to learn about when and under what selective pressures the duplicates arose. As a first step, we inferred the genomic location and copy number of the ancestral and duplicated gene copies from high coverage, whole genome sequences for ~280 humans sampled across the world, two archaic humans (Denisova and Neanderthal), and samples of great apes (chimpanzees, gorillas and orangutans). After identifying a set of duplications that arose in humans after separation from chimpanzees and gorillas and that are fixed in our relatively large sample of humans, we applied an Approximate Bayesian Computation method to estimate the timing of each gene duplication event. Importantly, our dating method accounts for paralogous gene conversion between the gene copies, leading to significantly older dates than had previously been reported, in particular for *SRGAP2* that had been previously dated as coincident with the transition from *Australopithecus* to *Homo* and the beginning of the neocortex expansion. Together, these analyses allow us to gain a comprehensive picture of the chronology and evolution of human-specific duplications.

1117W

A critical review and reassessment of archaic admixture inference. *S. Gopalan, E. Atkinson, B.M. Henn.* Ecology and Evolution, Stony Brook University, Stony Brook, NY.

   The controversial question of whether humans and archaic hominins interbred over the past 100,000 years has been a focus of population geneticists and paleoanthropologists alike for decades and which could not, until recently, be definitively answered. The earliest studies of archaic hominin ancient DNA were of mitochondrial (mt) sequence, and these largely concluded that such interbreeding did not occur. However, theoretical work which involved extensive modeling and simulations of demographic scenarios were more mixed; some supported the conclusions drawn from the genetic data while others contended that even relatively high rates of interbreeding could not be ruled out from mtDNA evidence alone. Recent advances in DNA sequencing and ancient DNA technology in the last 10 years have allowed geneticists to test the archaic introgression hypothesis more thoroughly by using multilocus genetic data from both archaic hominins and *Homo sapiens*. The sequencing of the Neandertal genome led to the conclusion that introgression into anatomically modern humans did occur, and that modern 'Out of Africa' human genomes contain a small percentage of this archaic DNA (1%-4%). Further ancient DNA studies, including the sequencing of the Denisovan genome, have continued to support the occurrence of archaic admixture, which is now the consensus among geneticists. However, there continue to be inconsistencies in the results between studies, and the methods used to obtain them are often opaque to even specialized audiences. In this research, we critically review the statistical methods used to infer archaic admixture in modern humans, the timing of admixture, and estimates of species divergence. Additionally, we reanalyze estimates of archaic introgression after controlling for reference genome bias and differential coverage, and testing for contamination using monophyletic loci.

1118T

The phenomes, genomes, and microbiomes of thirteen indigenous populations from the Himalaya. *A. Jha[1,2], Y. Gautam[1], D. Bhandari[3], S. Tandukar[3], J. Sherchand[3,4], C. Bustamante[1,2,5].* 1) Stanford Center for Computational, Evolutionary, and Human Genomics (CEHG), Stanford University, Stanford, CA; 2) Department of Genetics, Stanford University, Stanford, CA; 3) Publich Health Research Laboratory, Institute of Medicine, Tribhuvan University Teaching Hospital, Kathmandu, Nepal; 4) Department of Microbiology, Institute of Medicine, Tribhuvan University Teaching Hospital, Kathmandu, Nepal; 5) Department of Biomedical Data Science, Stanford University, Stanford, CA.

   Understanding human histories and identifying functional variants in the human genome that influence human adaptation and heritable traits are some of the central goals in human genetics. More recently, studies have indicated that human microbiomes may have influenced human evolution and they continue to affect human health. Despite the progress in characterizing genetic and microbial diversity and their functions in humans, those in many human populations remain to be cataloged. The Himalaya, which extends 2,337 miles from Myanmar to Afghanistan, is geographically, culturally, and ethno-linguistically diverse. Despite being home to five hundred ethnic populations, relatively little is known about the genomic and microbial diversity in this region. We have, for the first time, collected human DNA samples along with phenotypic measurements of 13 traits (including height, weight, BP, heart rate, skin pigmentation, and bitter tastes), dietary information, and household characteristics from ~500 individuals across thirteen Himalayan ethnic groups, many of which are underrepresented even in anthropological literatures. We have also, for the first time, extracted microbial DNA from stool, saliva, dental crevice, and tongue from a subset of individuals across four populations (N > 10 for each tissue), including recently settled nomads, primitive (slash and burn) agriculturalists, and commercial agriculture. Here, using our preliminary data, we present a comprehensive characterization of the genomic, microbial, and phenotypic variation in diverse Himalayan populations and discuss the potential approaches using which we intend to understand their population histories, investigate the genetic basis of local adaptations, identify genetic variants that influence morphological variations. Comparison of microbial diversity across these populations may show shifts in microbial populations in the mouth and gut, which may reveal key insights into diet-mediated adaptations in our species.

1119F

Non-allelic gene conversion is ten times faster than the rate of point mutations in humans. *X. Lan[1,3], A. Harpak[2], J.K. Pritchard[1,2,3].* 1) Department of Genetics, Stanford University, Stanford, CA; 2) Department of Biology, Stanford University, Stanford, CA; 3) Howard Hughes Medical Institute, Stanford University, Stanford, CA.

Gene conversion is the unidirectional transfer of genetic sequence from a "donor" region to an "acceptor". In one of its modes, non-allelic gene conversion (NAGC, also known as interlocus gene conversion), the donor and the acceptor are homologous sequences on the same chromosome. Despite the implication of NAGC as the cause of various genetic diseases, and its role in the concerted evolution of many human gene families, the rates and contributing factors of NAGC are not well-characterized. Recent gene duplications are of focal interest in studying NAGC as NAGC is contingent on high sequence similarity between donor and acceptor. Notably, NAGC events are expected to distort the genealogy of a gene family at an affected region. Here, we develop a machine learning tools to survey duplicate gene families across primates in search of such local genealogy distortions, and identify converted regions in 44% of duplicate gene families surveyed. In addition, we estimate the parameters governing NAGC in humans. We estimate a tenfold higher rate of NAGC than point mutations in humans, with a median NAGC tract length of 525bp. Finally, we quantify the effects of genomic features which determine NAGC rates, including GC content, methylation levels and homology between donor and acceptor sequences. This work improves our understanding of the mechanisms behind NAGC and of the role NAGC plays in shaping sequence evolution in humans.

1120W

Impacts of Neandertal-introgressed sequences on the landscape of human gene expression. *R.C. McCoy[1], J. Wakefield[2,3], J.M. Akey[1].* 1) Department of Genome Sciences, University of Washington, Seattle, WA; 2) Department of Statistics, University of Washington, Seattle, WA; 3) Department of Biostatistics, University of Washington, Seattle, WA.

Approximately 2% of the genome of each non-African modern human traces ancestry to Neandertals. Recent studies suggest that Neandertal-inherited haplotypes contribute to variation in modern human traits, yet the mechanistic bases by which these phenotypes manifest remain poorly characterized. To this end, we leveraged RNA-seq data from GTEx (214 individuals and 52 tissues) to systematically quantify the regulatory impacts of introgression revealed by patterns of allele specific expression (ASE). We developed a Bayesian generalized mixed model approach to combine information across individuals and tissues and quantify allelic effects at single nucleotide polymorphisms (SNPs) that tag Neandertal-introgressed haplotypes. A total of 5055 tag SNPs were identified in 2034 genes and compared to 581,124 non-introgressed control SNPs in 26,437 genes. At a false discovery rate of 10%, 1236 introgressed SNPs (24.5%) exhibited significant ASE, as compared to 161,590 non-introgressed SNPs (27.8%). Stratifying by allele frequency to account for power differences, the proportion of introgressed SNPs exhibiting ASE and the distribution of allelic effects were comparable to non-introgressed SNPs. Several introgressed variants previously associated with human phenotypes showed evidence of ASE, suggesting regulatory mechanisms driving these associations. Notable examples include rs3765107 and linked SNP rs1385374 (r^2 = 1.0) in *SLC15A4*, which have a robust association with systemic lupus erythematosus risk and show strong down-regulation of the Neandertal allele. Patterns of ASE varied across tissues [χ^2(df=51) = 281.3, $P < 10^{-10}$], potentially reflecting differences in the rates of regulatory divergence. Driving this signal, we observed significant down-regulation of Neandertal alleles in brain tissues compared to non-brain tissues (β = -0.0168, $P < 10^{-10}$). One representative gene with significant down-regulation of the Neandertal allele is *NTRK2*, which encodes a neurotrophic tyrosine receptor kinase that regulates neuron survival and differentiation as well as synapse formation. Testis-expressed SNPs exhibited a similar pattern of down-regulation (β = -0.0145, $P = 0.0010$), which is particularly intriguing given that genes with high expression in the testes are significantly depleted of Neandertal ancestry. Together, our analyses reveal measurable impacts of Neandertal introgression on human gene expression that contribute to variation in modern human phenotypes.

1121T

Complex ancient genetic structure and cultural transitions in southern African populations. *F. Montinaro[1], G. Busby[2], M. Gonzalez-Santos[1], O. Oosthuizen[3], E. Ooosthuizen[3], P. Anagnostou[4], G. Destro-Bisol[4], V.L. Pascali[5], C. Capelli[1].* 1) Zoology, University of Oxford, Oxford, United Kingdom; 2) Wellcome Trust Centre for Human Genetics, Oxford, OX3 7BN, UK; 3) School of Medicine, University of Namibia, Windhoek, Namibia; 4) Dipartimento di Biologia Ambientale, Universit` a "La Sapienza", Rome, Italy; 5) Istituto Italiano di Antropologia 00185, Rome, Italy.

The characterization of the structure of southern Africa populations has been the subject of numerous genetic, medical, linguistic, archaeological and anthropological investigations. Current diversity in the subcontinent is the result of complex episodes of genetic admixture and cultural contact between the early inhabitants and the migrants that have arrived in the region over the last 2,000 years, with some of the variation present in the past being now lost as the result of cultural and demographic assimilation by surrounding populations. Here we analyze 1,856 individuals from 91 populations, comprising novel and available genotype data to characterize the genetic ancestry profiles of southern African populations. Combining local ancestry and allele frequency analyses we identify a tripartite, ancient, Khoesan-related genetic structure, which correlates with geography, but not with linguistic affiliation or subsistence strategy. The fine mapping of these components in southern African populations reveals admixture dynamics and episodes of cultural reversion involving several Khoesan groups and highlights different mixtures of ancestral components in Bantu speakers and Coloured individuals.

1122F

Evolutionary and functional plasticity of the nucleophilic elbow promotes novel activities in alpha/beta hydrolases. *J.J. O'Byrne[1], S-J. Reilly[2], M. Fares[3], M.C. Hunt[4], S.E.H. Alexson[2].* 1) Department of Clinical Genetics, Our Lady's Childrens Hospital Crumlin, Dublin 12, Ireland; 2) Karolinska Institutet, Department of Laboratory Medicine, Division of Clinical Chemistry, C1-74, Karolinska University Hospital at Huddinge, SE-141 86 Stockholm, Sweden; 3) Department of Genetics, Smurfit Institute of Genetics, Trinity College Dublin, Dublin 2, Ireland; 4) School of Biological Sciences, Dublin Institute of Technology, Dublin 8, Ireland.

Enzymes are proteins that exhibit an astonishing diversity of functions, being a paradigm for the evolution of biological novelties. Many such enzymes emerged as a result of largely diversified gene families generated by gene duplication. Since organisms are well adapted to their environment, the mechanism that underlies the origin of novel, likely un-adapted, functions is not fully understood. In this study we explore the evolution of a small, highly conserved gene family belonging to the alpha/beta hydrolase superfamily of acyl-CoA thioesterases/acyltransferases expressed from bacteria to man. This gene family has evolved a number of different functions on a wide variety of substrates, including catalyzing the hydrolysis of acyl-CoAs to free fatty acids and CoASH (acyl-CoA thioesterases) and the conjugation (or amidation) of fatty acids or bile acids to taurine or glycine (acyl-CoA:amino acid *N*-acyltransferases). Phylogenetic, evolutionary and syntheny analyses of members of acyl-CoA thioesterases/acyltransferases, including acyl-CoA thioesterase 1 (*ACOT1*), bile acid-CoA:amino acid *N*-acyltransferase (*BAAT*) and acyl-CoA:amino acid *N*-acyltransferase (*ACNAT*), supports the hypothesis that these genes originated via duplication of a common ancestral gene, which was followed by the specialization of gene copies in the catalyses of distinct substrate-specific reactions. Structural and evolutionary analyses identified a common protein structure known as the nucleophilic elbow, which contains the active site nucleophilic residue, as the source of the enzymatic functional promiscuity. Our results point to the nucleophilic elbow as an ancestral reservoir of multiple coexisting functions, each of which became fixed after gene duplication in some gene copies, leading to the partition of ancestral functions. All members of this gene family have evolved subtle differences in the strand helix motif of their active sites that allows for the various activities and in part also substrate specificities to occur. The molecular engineering of the strand helix motif results in the redesign of these enzymatic functions. In summary this study neatly demonstrates "genomic enzymology", an expansive strategy for understanding the structural basis for functional plasticity and catalysis as well as the design principles nature employs to develop/evolve/redesign existing enzymes into new catalysts for new or even unnatural reactions.

1123W

Estimating the timing of adaptation for a beneficial allele. *J. Smith[1], M. Stephens[2,3], G. Coop[4,5], J. Novembre[2,1].* 1) Ecology and Evolution, University of Chicago, Chicago, IL; 2) Department of Human Genetics, University of Chicago, Chicago, IL; 3) Department of Statistics, University of Chicago, Chicago, IL; 4) Center for Population Biology, University of California-Davis, Davis, CA; 5) Department of Evolution and Ecology, University of California-Davis, Davis, CA.

A beneficial mutation carries linked information about its history which can shed light on the ecological context and putative cause for its increase in frequency. In particular, its age relies on the pattern of decay that mutation and recombination impose on its linked background. We provide a method to exploit this pattern and infer the time to the common ancestor of a positively selected allele following a rapid increase in frequency. We do so using a hidden Markov model which accounts for the accumulation of derived mutations on the ancestral background, its length distribution, and the surrounding haplotype diversity to infer the time to the common ancestor. Using simulations, we demonstrate how the inclusion of information from both mutation and recombination events increases estimate accuracy. We also show the behavior of estimation in cases where data do not conform to model assumptions, and provide some diagnostic routines for improving inference. Using the 1000 Genomes Project panel, we leverage population specific patterns to provide a global perspective on the timing of adaptation for several variants which show evidence of recent selection and functional relevance to diet, skin pigmentation, and morphology in humans. .

1124T

Whole-genome screen for disease-associated variants with extreme local allele frequency differences. *A. Sulovari[1,2], J. Hudziak[3], D. Li[1,4,5].* 1) Department of Microbiology and Molecular Genetics, University of Vermont, Burlington, VT 05405, USA; 2) Cell, Molecular and Biomedical Sciences Graduate Program, University of Vermont, Burlington, VT 05405, USA; 3) Vermont Center for Children, Youth, and Families, Department of Psychiatry, University of Vermont, Burlington, VT 05405, USA; 4) Department of Computer Science, University of Vermont, Burlington, VT 05405, USA; 5) Neuroscience, Behavior, and Health Initiative, University of Vermont, Burlington, VT 05405, USA.

Variants with extreme allele frequency difference (EAFD) between two populations of the same continent may underlie human health disparities. To identify novel disease-associated EAFD loci, we systematically surveyed 81 million genomic variants from 2,504 unrelated individuals of 26 world populations (phase III of the 1000 Genomes Project). We mapped the identified EAFD variants to genes, and tested for enrichment of gene pathways, diseases and traits in each of five continental populations. Our results revealed known disease or trait-associated EAFD genes, such as *LCT* (lactose tolerance) and *SLC24A5* (skin pigmentation). More importantly, we identified novel EAFD genes, such as *GRM5* (synaptic plasticity), *TRIM40* (gastrointestinal inflammation), and *MICU1* (mitochondrial calcium uptake). We found several complex diseases influenced by EAFD, including alcohol consumption (adjusted $P = 0.0002$) and attention-deficit/hyperactivity disorder ($P = 0.003$). Our findings strongly support that variants with EAFD among populations contribute to genetic susceptibility of many complex human diseases.

1125F

Genome-wide detection of directional selection in Chileans, an admixed population. *L. Vicuña[1,2], F.I. Martinez[2], F. Crespo[1,2], S. Eyheramendy[1].* 1) Department of Statistics, Facultad de Matemáticas, Pontificia Universidad Católica de Chile, Av. Vicuña Mackenna 4860, Macul, Santiago 6904411, Chile; 2) Interdisciplinary Center for Intercultural and Indigenous Studies, Anthropology Program, Institute of Sociology, Pontificia Universidad Católica de Chile, Av. Vicuña Mackenna 4860, Macul, Santiago 6904411, Chile.

   The advent of genomics has brought along a radical transformation in the study of natural selection in humans, changing from a single-gene hypothesis-driven paradigm to a new paradigm that is exempted from a priori assumptions regarding candidate genes for selection. Most of the research so far has focused in native populations that have been geographically isolated for thousands of years, e.g. African, Inuit and Andean populations, and therefore exhibit clear genetic differentiation. There are, however, few studies reporting directional selection in recently admixed populations, where natural selection is more difficult to detect, and most of them have been done in African Americans and Latino populations from North America. The Chilean population represents an interesting model for population genetics studies. This population from South America is the result of an admixing process that started in the 16th century with the arrival of male Spanish conquistadores to the Chilean territory who mixed with Native American women, a process that continued with several minor migratory events (mainly from Europe) at later times. In this study, we aimed at detecting footprints of positive selection in the Chilean genome, represented by a cohort of 195 individuals, using a panel of 633744 autosomal SNPs. With this purpose, we used a slightly modified version of the Composite of Multiple Signals (CMS, described by *Grossman et al 2010*), a composite of 5 test statistics that account for three parameters of population genetics: the presence of long-range haplotypes (iHS, ΔiHH and XP-EHH tests), population differentiation (F_{ST} test) and the presence of high-frequency derived alleles (ΔDAF test). Through a rigorous analysis that included simulated genetic and demographic data, we found novel selected variants associated with genes responsible for important physiological and pathophysiological processes such as lipid metabolism, immunity and pathogen resistance. Hereby, we incorporated a novel demographic model for the peopling and admixture in the Chilean territory, which closely reflects real genetic data and historical records. The results of this study contribute to understanding the genetic basis underlying adaptation and disease, shed light into human demographic history and have implications in anthropology and medicine. .

1126W

Diversity across the pseudoautosomal boundary varies across human populations. *D. Cotter[1], T. Webster[1], M. Wilson Sayres[1,2].* 1) School of Life Sciences, Arizona State University, Tempe, AZ, USA; 2) Center for Evolution and Medicine, The Biodesign Institute, Arizona State University, Tempe, AZ, USA.

   Unlike the autosomes, recombination on the sex chromosomes is limited to the pseudoautosomal regions (PARs) at each end of the chromosome. PAR1 spans approximately 2.7 Mb from the tip of the proximal arm of each sex chromosome, and a pseudoautosomal boundary between the PAR1 and non-PAR region is thought to have evolved from a Y-specific inversion that suppressed recombination across the boundary. In addition to the two PARs, there is also a human-specific X-transposed region (XTR) that was duplicated from the X to the Y chromosome. Genetic diversity is expected to be higher in recombining than nonrecombining regions for many reasons, including that recombination reduces the effects of linked selection, allowing neutral variation to accumulate. We previously showed that diversity decreases linearly across the previously defined pseudoautosomal boundary (rather than drop suddenly at the boundary), suggesting that the pseudoautosomal boundary may not be strict as previously thought. In this study, we analyzed data from 1271 genetic females to explore the extent to which the pseudoautosomal boundary varies among human populations (broadly, African, European, South Asian, East Asian, and the Americas). We find that, in all populations, genetic diversity is significantly higher in the PAR1 and XTR than in the non-PAR regions, and that diversity decreases linearly from the PAR1 to finally reach a non-PAR value well past the pseudoautosomal boundary in all populations. However, we also find that location at which diversity changes from reflecting the higher PAR1 diversity to the lower non-PAR diversity varies by as much as 500 kb among populations. The lack of genetic evidence for a strict pseudoautosomal boundary and the variability in patterns of diversity across the pseudoautosomal boundary suggest that the boundary itself may vary across populations, or that population-specific demographic histories have shaped diversity spanning the pseudoautosomal boundary.

1127T

The Genome Diversity in Africa Project: A deep catalogue of genetic diversity across Africa. *D. Gurdasani[1,2], J.P. Martinez[1], M.O. Pollard[1,2], T. Carstensen[1,2], C. Pomilla[1,2], GDAP Investigators[1,2].* 1) Wellcome Trust Sanger Institute, Cambridge, Cambridgeshire, United Kingdom; 2) Department of Medicine, University of Cambridge, Cambridge.

Background While recent efforts have greatly extended our understanding of genetic diversity in Africa, current sequence panels are limited in their capture of African genetic variation. Deeper sequencing with sampling of diverse indigenous populations is needed to capture diverse haplotypes across Africa. The Genome Diversity in Africa Project (GDAP) aims to characterise diversity from representative populations across all of Africa, including from several indigenous hunter-gatherer populations across the region. This would provide an important global resource to understand human genetic diversity and provide insight into population history and migrations across Africa in recent times. The project has completed sequencing of 575 samples across 23 populations in Africa, including populations from the Gambia, Ghana, Morocco, South Africa, Sudan, Chad, Kenya, South Africa, Uganda, Egypt and Ethiopia. Here, we present preliminary results from the project on 133 samples from 5 ethno-linguistic groups groups from Morocco, Ghana (Ashanti), Nigeria (Igbo), Kenya (Kalenjin) and South Africa (Zulu) sequenced on the Hiseq X platform (30x). **Methods** Reads were mapped to the GRCh38 reference. Following quality control, variant sites were called using HaplotypeCaller v3.5 for each sample to generate gVCFs. GenotypeGVCFs was run across all samples for joint calling. VCFs were filtered using VQSR calibrated on DP, QD, FS, SOR, ReadPosRankSum and MQRankSum annotations. A tranche sensitivity threshold of 99.5% was applied for filtering of SNPs and 99% for indels. Only sites called in >90% of individuals were included. **Results** We identified 25.1M SNPs and 2.9M indels among 133 individuals in the GDAP pilot phase, with 25% and 47% of SNPs and indels being novel (not in dbSNP141), respectively. A large proportion of variants per population were private, varying from 12-18%, being greatest among the Kalenjin and Zulu. We found the highest level of heterozygosity and genetic variation among the Zulu, consistent with reported Khoe-San admixture in this group. **Conclusions** We present the pilot phase of the Genome Diversity in Africa Project, identifying a high level of diversity across 5 populations from Africa. Inclusion of indigenous population groups, such as the Hadza, Twa Pygmies, and Ju/'hoansi in the next phase will materially advance the understanding of genetic diversity across African populations, and provide an invaluable resource to researchers worldwide.

1128F

Sequence diversity of *AZFc* genes on the human Y chromosome. *M.T. Oetjens[1], J.M. Kidd[1,2].* 1) Department of Human Genetics, University of Michigan Medical School, Ann Arbor, MI, 48109, USA; 2) Department of Computational Medicine and Bioinformatics, University of Michigan Medical School, Ann Arbor, MI, 48109, USA.

The AZFc region of the human Y-chromosome contains five multi-copy gene families arranged in long stretches of repetitive DNA termed amplicons. Amplicons introduce a susceptibility for amplification or deletion of the interstitial sequence through non-allelic homologous recombination. The AZFc gene families: *DAZ*, *RBMY*, *BPY2*, *PRY*, and *CDY* have critical roles in spermatogenesis, as large AZFc deletions associate with idiopathic male infertility. Recent studies have captured widespread structural diversity of Y-linked amplicons across global reference populations. Yet with respect to selection, the significance of structural diversity in Y-chromosomes is unclear. In contrast, nucleotide level variation of the Y-linked single-copy genes exhibit a strong bias against protein coding variation, suggesting strong purifying selection on the human Y-chromosome. However, little is known about AZFc nucleotide diversity and whether or not purifying selection of the AZFc has contributed to the low nucleotide diversity found across human Y-chromosomes remains an open question. To address this question, we called AZFc gene nucleotide variation in nine 1000 Genomes samples representing three haplogroup clades: E, O, and R. Here, we extracted reads within the boundaries of AZFc genes and psuedogenes with high identity and remapped them to intervals of a single copy where nucleotide variation between members was low and alignment quality was high. We filtered regions that exhibited extreme sequence depth, interspersed repeats identified by RepeatMasker, and indels identified in our alignment. Our callset includes 51,089 intronic, 2,852 non-synonymous, and 826 synonymous unique sites within the AZFc. To confirm the sensitivity of our analysis, we performed a sequence alignment of members within families of AZFc genes to identify single-family variants (SFVs) in the hg19 reference genome (haplogroup-R). Of 153 SFVs identified in hg19, only one was not seen and 40 are found to be polymorphic across our sample set. Expanding our results to non-reference SFVs, we in total call 223 intronic, 5 synonymous, and 2 non-synonymous polymorphic SFVs in the AZFc. We are currently applying this method to a globally diverse population of Y-chromosomes representing all major haplogroups and utilizing long-read sequencing technology to phase psuedogenes from fully functional genes to infer purifying selection of the AZFc region.

1129W

Searching for multiple sources of archaic introgression in African-American genomes. *S. Vattathil, J.M. Akey.* Genome Sciences, University of Washington, Seattle, WA.

When modern humans migrated out of Africa, they encountered sister hominin populations that had spread into Europe and Asia several thousand years prior. The presence of Neanderthal and Denisovan DNA segments within the genomes of contemporary humans of non-African descent is proof that ancient modern humans interbred with members of these closely-related but genetically distinct populations. Observations of introgressed fragments have now been collected from hundreds of individuals of diverse ancestry. These catalogs provide the basis to test models of the timing, location, and extent of the ancient interactions, and therefore refine our understanding of the prehistoric migration patterns of the human population. In addition, some of the introgressed alleles show strong evidence of selection, and therefore reveal variation important to human adaptation and evolution. Analogous interbreeding is reasoned to have occurred in Africa between ancient modern humans and local hominin populations, and we postulated that introgressed sequences persist in the genomes of contemporary individuals of African ancestry. We examined whole-genome sequence data from 61 African-American genomes for evidence of archaic introgression using the S* framework. Previous introgression studies using S* employed a 2-step approach, first identifying putative introgressed sequences using S* scores and then filtering this initial set based on similarity to the Neanderthal or Denisovan genome to derive a set of high-confidence introgressed sequences. Using this approach, we identify Neanderthal introgressed sequences in the European-derived chromosomes at a rate consistent with previous results, and effectively no Neanderthal introgression in African-derived chromosomes. Since using DNA sequence similarity is not an option for filtering for archaic African sequences (because no sequenceable archaic African DNA has been recovered), we explored other sequence characteristics such as divergence and haplotype length to define criteria for identifying likely introgressed sequences. In contrast to studies of Eurasians, the choice of reference population when using S* to study African chromosomes is not straightforward. We assessed the impact of using different reference populations.

Whole-genome reference panel of Tohoku Medical Megabank Organization (ToMMo) and allele frequency of pathological variants in the Japanese population. *Y. Yamaguchi-Kabata, Y. Kawai, K. Kojima, T. Mimori, F. Katsuoka, K. Kinoshita, S. Kure, Y. Suzuki, N. Fuse, H. Kawame, M. Nagasaki, J. Yasuda, M. Yamamoto.* Tohoku Medical Megabank Organization, Tohoku Univ, Sendai, Japan.

Tohoku University Tohoku Medical Megabank Organization (ToMMo) have sequenced whole genomes of 1,070 cohort participants, and constructed the whole-genome reference panel (1KJPN) as a catalogue of genomic variants for foundation for genomic medicine in the Japanese population. We opened a website "integrative Japanese Genome Variation Database (iJGVD; http://ijgvd.megabank.tohoku.ac.jp/)", and publicly released allele frequency data of SNVs obtained from the 1070 individuals. We are annotating variants of 1KJPN with biological and medical information to identify variants having possible biological or pathological effects. By using a database of known pathological variants (the Human Gene Mutation Database, HGMD), we identified 4,368 HGMD variants (including 1,002 disease-causing variants) in 1KJPN. On the other hand, based on gene-based annotation, we identified loss-of-function variants including more than 3000 stop-gained SNVs. Among these stop-gained SNVs in 1KJPN, only a small proportion (4.5%) were annotated as known pathological variants, and biological effects are unknown for most of stop-gained variants. Individual variant load was calculated for disease-causing variants and stop-gained variants. The estimates were very similar with those in East Asian populations (Japanese in Tokyo, Han Chinese in Beijing, and Southern Han Chinese) in the 1000 Genomes Project (1KGP), therefore we did not find any signature of strong bottleneck in history of the Japanese population. However, incidence rates for inherited diseases vary among populations and it is known that incidence rates of inherited metabolic disorders were lower in the Japanese population compared to those of European ancestry. We compare allele frequencies of the pathological variants in 1KJPN with those in other population. In comparison to each of 14 populations of 1KGP, 2,638 HGMD variants showed significantly different allele frequency (P value<10⁻⁵; Fisher's exact test) in comparison to at least one population of the 1KGP. These differences in variant frquency between populations may partially explain the difference in the disease prevalence. .

1131F

Genetic diversity and founder effects in the Sea Island Gullah African Americans. *K.D. Zimmerman[1], S.P. Sajuthi[1], W. Chen[2], J. Divers[1], J.K. Fernandes[3], G.S. Gilkeson[3], K.J. Hunt[3], D.L. Kamen[3], U. Nayak[2], W.T. Garvey[4], M.M. Sale[2], C.D. Langefeld[1], P.S. Ramos[3].* 1) Department of Biostatistical Sciences and Center for Public Health Genomics, Wake Forest University, Winston-Salem, NC; 2) Department of Public Health Sciences and Center for Public Health Genomics, University of Virginia, Charlottesville, VA; 3) Department of Medicine, Medical University of South Carolina, Charleston, SC; 4) Department of Nutrition Sciences and Birmingham VA Medical Center, University of Alabama, Birmingham, AL.

The Gullah form a unique population of African ancestry in the U.S., with lower European admixture (less than 11% on average) and higher ancestral homogeneity from the Sierra Leone area in Far-West Africa supported by historical evidence. Given their relative genetic and environmental homogeneity and ties to Sierra Leone, it is often questioned if the Gullah have reduced genetic diversity and increased frequencies of some disorders as the result of founder events and population bottlenecks. The goal of this study was to compare the genetic diversity of the Gullah and Sierra Leone populations in order to elucidate whether population bottlenecks and genetic isolation can account for the current genetic structure of the Gullah population. We used genotype data on 277 healthy Gullahs and 400 Sierra Leoneans (SL) to compute, for each population, the mean heterozygosity (HET) per SNP and inbreeding co-efficient (F) per individual based on expected and observed heterozygous calls, with $F = (HET_{exp} - HET_{obs})/(HET_{exp})$. After pruning SNPs in high LD ($r2 > 0.5$) with PLINK, the remaining 395K shared SNPs between populations were used to calculate the HET and F. A standard two-tailed t test was used to calculate the significance of the difference in HET and F between populations. To explore the amount of genetic variation within the Gullah and Sierra Leone (SL) populations, we first measured the mean heterozygosity. We observed a lower level of heterozygosity among Gullah individuals (HET=0.3326) compared with SL (HET=0.3336). This difference was statistically significant (P=0.036) even after pruning SNPs that were in high LD. This lower diversity in the Gullah compared with SL is paralleled with a higher inbreeding coefficient (F=-0.0018 in Gullah vs. F=-0.0045 in SL), which was very close to statistically significant (P=0.057). Collectively, these results suggest that the SL population is more outbred and genetically diverse than Gullah, and provide the first evidence supporting founder events in Gullah African Americans. Further analyses are underway to elucidate if the Gullah carry other evidence for founder effects. Understanding the genetic diversity of the Gullah contributes to a better understanding of the natural history and disease risks in this population and it helps inform future medical genetics research in African Americans.

1132W

The whole genome sequences and experimentally phased haplotypes of 182 personal genomes. *Q. Mao[1], S. Ciotlos[1], R.Y. Zhang[1], M.P. Ball[2,3], R. Chin[1], P. Carnevali[1], N. Barua[1], S. Nguyen[1], T. Clegg[2,4], A. Connelly[2,4], W. Vandewege[2,4], A.W. Zaranek[2,4], P.W. Estep[2], G.M. Church[2], R. Drmanac[1,5], B.A. Peters[1,5].* 1) Complete Genomics, Inc., 2071 Stierlin Ct., Mountain View, CA 94043; 2) Harvard Personal Genome Project, Harvard Medical School, NRB 238, 77 Avenue Louis Pasteur, Boston, MA 02115; 3) PersonalGenomes.org, 423 Brookline Avenue, #323, Boston, MA 02215; 4) Curoverse Inc, 212 Elm St, 3rd Floor, Somerville, MA 02144; 5) BGI-Shenzhen, Shenzhen 518083, China.

Background Since the completion of the Human Genome Project in 2003 it has been estimated that over 200,000 individual whole human genomes have been sequenced; a stunning accomplishment in such a short period of time. However, most of these were sequenced without experimental haplotype data and as such are missing an important aspect of genome biology. In addition, much of the genomic data generated is not available to the public and lacks phenotypic information. **Findings** As part of the Personal Genome Project (PGP), 182 participants' blood samples were collected and processed with Complete Genomics' Long Fragment Read (LFR) technology. Here we report the results for the experimental whole genome haplotyping and sequencing of these samples to an average read coverage depth of 100X. This level of coverage is approximately 3 fold higher than the read coverage applied to most whole human genome assemblies and was done to ensure the highest quality results. Currently 114 genomes from this data set are freely available through the PGP and *GigaScience* and are associated with rich phenotypic data. All 182 participants' genomes will be made freely available in the near future. 10 genomes were sequenced at least two times using independently made LFR barcoded libraries for reproducibility analyses. Additionally, 7 genomes were also sequenced using Complete Genomics' standard non-barcoded library process. **Conclusions** These genomes represent a unique source of haplotype and phenotype data for the scientific community, an order of magnitude larger than existing sets of experimentally phased genomes. In total, the dataset represents over 200 million phased variants in contigs with an average N50 of greater than 500kb. In addition, we report over 2 million high quality rare variants not previously identified in dbSNP or Phase 3 1000 Genomes Project (1KG) data. The data presented here should help expand our understanding of the human genome evolution and functioning.

1133T

High-coverage sequencing of the Human Genome Diversity Project (HGDP-CEPH) Panel. *S. McCarthy[1], A. Anders Bergström[1], Y. Xue[1], Q. Ayub[1], S. Mallick[2,3,4], M. Sandhu[1], D. Reich[2,3,4], R. Durbin[1], C. Tyler-Smith[1].* 1) Wellcome Trust Sanger Institute, Cambridge, United Kingdom; 2) Department of Genetics, Harvard Medical School, Boston, MA; 3) Broad Institute of Harvard and MIT, Cambridge, MA; 4) Howard Hughes Medical Institute, Boston, MA.

We discuss the completion of high coverage (>30x), whole-genome sequencing of all 952 core individuals in the Human Genome Diversity Panel (HGDP-CEPH), with the results being made available as an open access population data resource. This widely used panel contains samples from 52 populations spanning Africa, the Middle East, Europe, Asia, Oceania and the Americas, and previous genotype data from these samples have been an important reference resource for human genetic diversity. As seen in the 1000 Genomes Project, having fully open access data, unencumbered by managed access restrictions and other hurdles, is an invaluable driver for democratized data analysis and methods development Building on previous sequencing efforts by the Simons Genome Diversity Project, we have completed sequencing of the panel and are making the data available via the ENA and the 1000 Genomes Project data management successor, the International Genome Sample Resource (IGSR) (www.internationalgenome.org). All data has moved to the new GRCh38 reference and we present preliminary results on the call set derived from this data. We have GATK HaplotypeCaller and fermikit primary calls, are making mpileup and freebayes calls, and will present an integrated call set that has been computationally phased, together with initial population genetic analyses. A small number of samples are being experimentally phased using 10X Genomics technology which will allow evaluation of phasing accuracy, and also unbiased use of haplotype-based analyses such as MSMC.

1134F

Interleukins 4 and 13 gene polymorphism increases asthma risk: A meta analysis including 14,527 cases and 17,696 controls. *P. Dixit, S. Awasthi.* King George`s Medical University, Lucknow, India.

Background: Studies on the association of cytokines in asthma pathogenesis have yielded conflicting results. Therefore, we aimed to assess the association in north Indian children with asthma and include an updated meta-analysis. **Methods:** Odds ratios (ORs) with corresponding 95% confidence intervals (CIs) were computed to calculate the association. **Data Sources:** Pub Med (till July 2015) **Results:** Of total sixty nine case-control studies were included in this meta-analysis. Included were 14,527 cases and 17,696 controls. Significant association of IL13 -1112C/T and IL 4 C589T gene polymorphism was observed (OR = 1.12, 95% CI 1.01–1.25, P = 0.03) (OR=1.43, 95%CI= 1.13-1.81, P= 0.003) in a dominant genetic model. Significant association was observed in IL13 -1112C/T OR = 1.39, 95% CI 1.10–1.74, P=0.00) and IL 4 C589T (OR= 1.95, 95%CI=1.52-2.52, P= 0.00) polymorphism among Caucasians. Moreover, significant association of IL 4 C589T was also observed in African –American (OR= 1.61, 95%CI=1.17-2.22, P=0.00) population. **Conclusion:** IL 4-C589T and IL13 -1112C/T increases the risk of asthma development. .

1135W

Polymorphisms associated with European skin pigmentation in Oceanic populations. *I. Naka[1], N. Nishida[2], R. Kimura[3], K. Yamaguchi[4], T. Furusawa[5], T. Yamauchi[6], K. Natsuhara[7], T. Ishida[1], T. Inaoka[8], Y. Matsumura[9], R. Ohtsuka[10], J. Ohashi[1].* 1) Biological Sciences, The university of Tokyo, Tokyo, Tokyo, Japan; 2) Research Center for Hepatitis and Immunology, International Medical Center of Japan Konodai Hospital, Ichikawa, Japan; 3) Faculty of Medicine, University of the Ryukyus, Nakagami, Okinawa, Japan; 4) School of Natural Sciences and Psychology Liverpool John Moores University, U.K; 5) Graduate School of Asian and African Area Studies, Kyoto University, Kyoto, Japan; 6) Health Sciences, Hokkaido University School of Medicine, Sapporo, Hokkaido, Japan; 7) The Japanese Red Cross Akita College of Nursing, Akita, Akita, Japan; 8) Human Ecology, Faculty of Agriculture, Saga University, Saga, Saga, Japan; 9) Faculty of Health and Nutrition, Bunkyo University, Chigasaki, Kanagawa, Japan; 10) Japan Wildlife Research Center, Sumida, Tokyo, Japan.

The Oceania is geographically classified into three areas: Melanesia, Micronesia and Polynesia. Although Oceanic people are genetically close to Asians, their skin color is darker than Asians. In Oceania, people living in Melanesian have the darkest skin color, which is comparable to that of people living in Sub-Saharan Africa. To understand the genetic basis of skin pigmentation in Oceanic people, we investigated eight SNPs previously reported to be associated with self-reported tanning ability in European ancestry using Digitag2 and TaqMan assay in five Oceanic populations. The genotype data of YRI (African), CEU (European ancestry), JPT (East Asian), and CHB (East Asian) populations were obtained from the HapMap database. All the alleles associated with tanning ability were ancestral ones. The Fst analysis showed that some SNPs were highly differentiated between Melanesian and HapMap-YRI populations. We further calculated the tanning ability associated allele count and the tanning ability score ($\Sigma \beta_i x_{ij}$) for each individual. The number of allele counts was the highest in YRI and the lowest in CEU. Of particular interest, the mean of the tanning ability score is lower (i.e., lighter skin color) in Tongan (Polynesian) and Rawaki (Micronesia) populations than in HapMap-JPT and CHB (East Asian) populations. The present results suggest that the genetic variation that produces darker skin color of Oceanians is different from that of Asians.

1136T

Fine-scale identity-by-descent and birth records in Finland provide insights into recent population history. *A.R. Martin[1,2], S. Kirminen[3], A.S. Havulinna[4], A. Sarin[3], A. Palotie[1,2,3], V. Salomaa[4], S. Ripatti[3], M. Pirinen[3], M.J. Daly[1,2].* 1) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA, USA; 2) Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, MA, USA; 3) Institute for Molecular Medicine Finland (FIMM), University of Helsinki, Helsinki, Finland; 4) National Institute for Health and Welfare (THL), Helsinki, Finland.

Finland provides unique opportunities to investigate both population and medical genomics because of its adoption of unprecedented uniformity in national electronic health records, concerted coordination of research centers across the country, detailed historical records, as well as recent population bottlenecks that drove specific disease alleles to high frequency. We investigate recent population history (up to ~50 generations ago), particularly relevant to rare, disease-conferring alleles, using identity-by-descent (IBD) haplotype sharing in >10,000 Finns. We compare IBD sharing in Finland to nearby Scandinavian countries with considerably different population histories, including >8,000 Swedes and >30,000 Danes. We find drastically more sharing on average in Finns, including many long tracts. By leveraging fine-scale birth record data, we find a non-linear decay of pairwise IBD sharing with increasing distance across Finland. This arises from pockets of excess IBD sharing; e.g. pairs of individuals from northeast Finland share on average several-fold more of their genome IBD than pairs from southwest regions containing the major cities of Turku and Helsinki. We demonstrate inference of recent migration patterns from IBD sharing patterns. For example, high IBD sharing in northeast Finland radiates from north to south rather than to the west, indicating that migration is restricted near the Russian border. We also investigate recent effective population size changes across regions of Finland and find evidence supporting the distinction between early and late settlement areas. However, our results indicate a more continuous flow of migration than previously posited, with a minimum N_e occurring ~12 generations ago in the northernmost Lapland region and moving further back in time to the south, with a bottleneck detectable in the early settlement area ~40 generations ago. Lastly, we leverage IBD sharing for genetic disease mapping and show that rare, functional haplotypes show more significant association via IBD mapping than single variants with linear mixed effect models.

1137F

Partitioning heritability and polygenic risk scores by hominid ancestry using genome-wide association summary statistics. *G. Athanasiadis, M.H. Schierup, B.J. Vilhjálmsson.* Bioinformatics Research Centre, Aarhus University, Aarhus, Denmark.

  Researchers have previously attempted to describe the phenotypic legacy of Neanderthals to non-African anatomically modern humans using raw genomic data and a collection of relevant phenotypes. Here, we provide further insights into the Neanderthal contribution to the genetic architecture of 47 complex traits. We do so by calculating the proportion of heritability due to Neanderthal introgressed SNPs and the relative importance of those SNPs in polygenic risk scores. We also estimate the phenotypic impact of the Neanderthal introgressed SNPs, contrasting the predicting human phenotype with the predicted Neanderthal phenotype using LDpred polygenic risk scores. We base our analyses on summary statistics from large-scale publically available GWASs. We introduce a new statistic – conceptually similar to LD score – that uses the 1000 Genomes as reference panel to detect summary statistic inflation due to residual population structure. Using this statistic we can flag potentially biased heritability estimates and polygenic risk scores. Moreover, we account for the estimated summary statistic inflation due to residual population structure, arriving at more accurate results. The use of publically available GWAS summary statistics in our analysis allows for a more accurate assessment of the Neanderthal phenotypic legacy because SNP effects had been better estimated (i.e. the error of the effect is smaller.

1138W

Meiotic recombination is an important driver of sequence evolution at hotspots. *I. Tiemann-Boege[1], B. Arbeithuber[1], A. Heissl[1], A.J. Betancourt[2].* 1) Johannes Kepler University, Linz, Austria; 2) Vetmeduni Vienna, Vienna, Austria.

  Meiotic recombination, a key biological process during germ cell production, is clustered in recombination hotspots that undergo rapid sequence degeneration, as shown repeatedly by population data analysis. The exact mechanisms driving this sequence evolution are still not well known. By sequencing a large number of single recombinants obtained from human sperm, we have shown that recombination is mutagenic and crossovers are enriched for *de novo* CG to TA transitions, especially at methylated CpG sites, which could be the predominant mutational pattern in processes involving single stranded DNA. Another mechanism driving the sequence evolution at hotspots is biased gene conversion. Our large data set also provided new evidence that the transmission of GC-alleles is favored during crossing-over and showed that GC biased gene conversion (gBGC) is a strong driver of hotspot sequence evolution opposing mutation. We have also examined the evolution of short tandem repeats (STR) at hotspots by analyzing the transmission of polymorphic STRs and their effect on recombination. We observed that a long polymorphic tract of polyAs (A9/A19) located at the center of the hotspot can shift the hotspot center and reduce the overall crossover frequency. In addition, the transmission of STRs do not follow the Mendelian rules of segregation (50:50), but longer repeats are transmitted more frequently than shorter ones, and our data show for the first time with experimental evidence an insertion-biased gene conversion (iBGC) in a STR (A6/A7) within a hotspot. The molecular mechanisms inducing the observed patterns are not clear yet; however, the recurrent repair of double-strand breaks (DSB), required for the initiation of recombination, seems to play an important role.

1139T

Studies of canine breed development on the island of Sardinia recapitulate genomic features of human population isolates. *D.L. Dreger[1], B.W. Davis[1], R. Cocco[2], S. Sechi[2], A. di Cerbo[3], H.G. Parker[1], M. Polli[4], P. Crepaldi[4], E.A. Ostrander[1].* 1) National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 2) Dipartimento di Medicina Veterinaria, Sezione Clinica Medica, University di Sassari, Italy; 3) School of Specialization in Clinical Biochemistry, G. d'Annunzio University, Italy; 4) Dipartimento di Medicina Veterinaria, Universita di Milano, Italy.

The island of Sardinia has long been a focus for studies of human genetic disorders and complex traits due to the unique ancestral background of its inhabitants and the maintenance of population isolation due to restrictive geography as well as cultural and linguistic separation. Like most human population isolates, the inhabitants share decreased genomic diversity, increased linkage disequilibrium, and increased inbreeding coefficients. Canines have been the constant companions of humans since the earliest days of their domestication, with breeds often arising through human-driven selection of characteristics to meet an ideal standard of appearance and function. However, in certain regions, dogs and humans have been exposed to the same natural and human-driven forces of environment, migration, cultural development, industrial growth, population expansion, and geography. We therefore hypothesized that the events that result in isolated canine populations or breeds, would be mirrored in human populations from the same region. Sardinia is home to an endemic dog population, the Fonni's Dog, with documentation dating to the 19th century establishing the dogs as fierce protectors and guardians. The Fonni's Dog, however, has not been subjected to the intensive system of artificial selection of a typical dog breed, but rather has developed along side the human populations of Sardinia, influenced primarily by geographic isolation and unregulated selection based only on its adaption to the environment and aptitude for its owner-desired behaviors. Through analysis of whole-genome sequence and ~170K genome-wide single nucleotide variants, we have produced a genomic illustration of the Fonni's Dog in the context of 27 additional Mediterranean dog breeds. Patterns of homozygosity, relatedness, and private variation confirm within-breed similarity, while population structure and phylogenetic analyses provide spatial identity of Fonni's Dog to other Mediterranean breeds. Investigation of admixture and fixation indices reveal intriguing insights into the Fonni's Dog's involvement in breed development throughout the Mediterranean. We describe how characteristics of population isolates are reflected in dog breeds that have undergone artificial selection, and have been mirrored in the Fonni's Dog through traditional isolating factors that affect human populations. Lastly, we show that the genetic history of Fonni's Dog parallels demographic events in local human populations.

1140F

Patterns of germline mutation from exome sequencing of 8,000 parent-offspring trios. *J. Kaplanis[1,2], M. Hurles[1] on behalf of the DDD Study.* 1) Wellcome Trust Sanger Institute, Hinxton UK; 2) University of Cambridge, Cambridge UK.

Germline mutation is the fundamental root of evolution and disease causing variants. The characteristics of these mutations, and their flanking sequences, can reveal information about the source and timing of these events and improve our understanding of the mutational process We identified ~17,000 high confidence mutations in ~8,000 exome sequenced trios from the Deciphering Developmental Disorders (DDD) Study which consists of families with children with severe developmental disorders. De novo mutations (DNMs) are a major cause of developmental disorders. We phased these de novo mutations on to their parental haplotypes and built a statistical model to identify post-zygotic mutations. We found that ~3% of the de novo mutations arose post-zygotically in the child. We then explored parental effects with respect to differences in mutational rates and spectra. We found that the number of DNMs increases with both paternal and maternal age, with the paternal effect being considerably stronger. In general, the number of DNMs per child follows the expected Poisson distribution, however, I will also describe our investigation of outliers for potential germline mutator phenotypes within the DDD cohort. In summary, these analyses can help us build a better understanding of germline mutation which has important implications in genetic disease.

1141W

Comprehensive context-specific estimation of tandem repeat mutation rates and variant densities. *A. Tan, H.M. Kang.* University of Michigan, Ann Arbor, MI.

It is known that ~50% of all indels are found in the 2% low complexity regions of genome where most Indels are variable number of tandem repeats (VNTRs). Because VNTRs are highly affected by polymerase slippage dependent on sequence context, it has been challenging to precisely measure their mutation rates. Comprehensive measurement of indel mutation rates or variant density in a context-specific manner expands our understanding of mutational mechanisms and allows us to distinguish between germline tandem repeat variants and PCR or alignment induced variants. We produced a comprehensive catalog of context-specific tandem-repeats using a novel computational algorithm. Our method estimates the boundaries of repetitive regions of each VNTR by the left-right alignment of alleles to systematically classify sequence context of exact and inexact tandem repeats. Thus, we can estimate context-specific mutation rates or variant densities by comparing genome-wide count of specific repeat contexts with the observed number of (de-novo or population-based) variants and its allele frequency spectrum. We applied our method to characterize context-specific VNTR densities for NA12878 and other deeply sequenced genomes. We observed that poly-A stretches show the largest context-specific variant densities. Interestingly, the density of 2-bp A deletion in poly-A context is observed to be one third of 1-bp deletion in the same context, suggesting a higher likelihood of multi-nucleotide slippages. For most repeat-contexts, when the repeat tract length is 15bp or greater, there were >100-fold enrichment of variant density compared to non-repetitive regions. For moderate repeat lengths often ignored in tandem repeat studies (e.g. 5-10bp) we observed a significant >10-fold enrichment in variant densities across all repeat contexts, which was only 3-4-fold lower compared to 15bp repeats. We also observed striking under-representation of VNTRs in standard callsets like Genome-In-the-Bottle, reducing its utility as a measure for Indel sensitivity analysis. We find that filters exacerbate the inconsistencies between different callsets. For example, VNTRs in poly-A contexts are different between variant callers due to poly-A filtering, while poly-AAC VNTRs are more consistent between callers. Our approach provides another step towards understanding the complexities of calling the spectrum of indels. .

Pleiotropic noncoding regulatory elements are under purifying natural selection. *D. Radke[1,2,3], D. Balick[2,3], J. Sul[4], S. Akle[2,5], M. Maurano[6], R. Green[2,3], J. Stamatoyannopoulos[7], S. Sunyaev[2,3].* 1) Program in Genetics and Genomics, Harvard Medical School, Boston, MA; 2) Division of Genetics, Brigham and Women's Hospital, Boston, MA; 3) Broad Institute of Harvard and MIT, Cambridge, MA; 4) Department of Psychiatry and Biobehavioral Sciences, University of California, Los Angeles, CA; 5) Department of Organismic and Evolutionary Biology, Harvard University, Cambridge MA; 6) Institute for Systems Genetics, New York University, New York City, NY; 7) Department of Genome Sciences, University of Washington, Seattle, WA.

   Assessing the role of natural selection on genetic variation in noncoding regulatory regions has been difficult up to the present, because most work has only utilized SNP variation, which has hampered functional interpretation because of the lack of clear loss-of-function (LoF) SNPs in noncoding loci. Genomic deletions, either partial or complete, provide a powerful LoF model in noncoding regions due to a deletion event removing the nucleotide component space altogether. To gain high-resolution deletion allele frequency information for population genetic analysis, we performed deletion discovery and genotyping from high-coverage WGS data within a cohort of >750 unrelated individuals, identifying ~15K unique deletions. Using regulatory annotations from primary tissues and cell-types characterized as part of the Roadmap Epigenomics Project, and accounting for covariates based on genomic regional context, we find a statistically shift in the allele frequency spectrum (AFS) towards reduced frequency of deletions overlapping noncoding regulatory loci versus deletions occurring in nonfunctional loci, indicating the action of purifying selection on regulatory elements. Since the functional outputs from the regulatory annotation data are derived from multiple distinct human tissues and cell-types of wide-ranging organismal function, yet share overlapping genomic coordinates, the overall functional epigenetic information present within a locus can serve as a proxy for the pleiotropy of the locus. We hypothesize that regulatory loci exhibiting highly-pleiotropic effects (i.e., loci with regulation across many diverse tissues) should be under stronger purifying selective pressure than cell-specific or nonfunctional loci. Analyzing the pleiotropy at each locus for each of the genotyped noncoding deletions, we find a very statistically significant shift in the AFS towards deletions being rarer which overlap highly-pleiotropic regulatory loci. We find that either the average pleiotropy or the maximum pleiotropy along the length of a deletion is sufficient to explain shifts in the AFS. We interpret these results as evidence of the action of purifying selection on regulatory elements, the strength of which is determined by the amount of pleiotropy. These findings open up the noncoding genome to more rigorous functional interpretation for use in medical or experimental studies.

1144W

CYP2D6 **allele frequencies in the Asian population.** *W. Chan[1], P.Y. Cheung[1], M.S. Li[1], S.K. Sundaram[1], B. Tomlinson[2], C.H. Tzang[1].* 1) Prenetics, Limited , Hong Kong; 2) The Chinese University of Hong Kong, Hong Kong.

   Background: Cytochrome P450 CYP2D6 plays a crucial role in drug metabolism. CYP2D6 is known to be highly polymorphic with enzymatic activity ranging from complete deficiency to ultra-rapid. The genetic variation of CYP2D6 has been associated with variability in drug responses. The frequency of CYP2D6 genetic polymorphisms varies significantly between different ethnic groups. While the frequencies of CYP2D6 alleles are generally known in Asian populations, data on frequencies of the copy number variations (CNV) in CYP2D6 and complex haplotype backgrounds in which they occur are less well studied in these populations. The objective of this study is to determine and report the observed CYP2D6 allele, genotype and derived phenotype frequencies in the Asian populations in the East and Southeast region. **Methods:** Genotyping was performed using Prenetics Limited (Prenetics) iGenes Pharmacogenomics Test (PGx) at Prenetics' ISO15189:2012 accredited laboratory using TaqMan genotyping, CNV, as well as digital PCR technology (Life Technologies, USA). CYP2D6 phenotypes of study subjects were then stratified into Ultra-rapid Metabolizers (UMs), Extensive Metabolizers (EMs), Intermediate Metabolizers (IMs) and Poor Metabolizers (PMs) based on predicted activity scores predicted from the genotypes. **Results:** Out of the 800 genotyped individuals, 735 (92%) were self-identified as Asians, 56 (7%) were Caucasians and 9 (1%) were mixed race. Among the Asian group, the prevalence rates of CYP2D6 alleles were as follows: CYP2D6*1 (23.5%), CYP2D6*2 (10.5%), CYP2D6*4 (0.5%), CYP2D6*5 (3.3%), CYP2D6*6 (0.2%), CYP2D6*10 (21.9%), CYP2D6*10-*36 Tandem Repeats (31.2%), CYP2D6*14A (0.4%), CYP2D6*14B (1.6%), CYP2D6*36 (4.1%), and CYP2D6*41 (2.7%). Duplicated CYP2D6 alleles were observed in 74 individuals (10.1%). The observed phenotype frequency of CYP2D6 UM, EM, IM and PM were 3.3%, 49.9%, 46.4%, and 0.4%, respectively. **Conclusions:** The present study provides a comprehensive analysis on different CYP2D6 alleles in an Asian population which is the largest study in terms of the number of individuals genotyped and the number of CYP2D6 alleles analyzed in this population. Our results contribute to the overall knowledge of pharmacogenomics specifically in the Asian population and may help the implementation of precision medicine in East and Southeast Asia.

Temporary pulses of accelerated mutagenesis in human and great ape population history. *K. Harris[1], J.K. Pritchard[1,2].* 1) Genetics, Stanford University, Palo Alto, CA; 2) Howard Hughes Medical Institute.

Like any complex physiological trait, the germline mutation rate has the potential to evolve as the result of selection and genetic drift. Understanding the dynamics of mutation rate evolution is technically challenging but fundamentally important to evolutionary biology. Present-day mutation rates can be estimated by counting de novo changes that distinguish parents from children, but ancestral mutation rates must be estimated via more uncertain phylogenetic methods. Here, we introduce a novel method for inferring recent mutation rate evolution from population genetic data, specifically by comparing the site frequency spectra of different mutation classes to determine whether the rates of any mutation classes have accelerated. We find several mutation spectrum changes that appear to have fixed early in primate history, for example, an A→T transversion rate increase in the human/chimp common ancestor. More surprisingly, we find several "mutation pulses" where a mutational process with a unique signature appears to have acted for a short time before subsiding. Such a pulse appears to have affected Europeans approximately 10,000 years ago, producing excess transitions in the context TCC→TTC.

1146F

Analysis of global ancestry, ethno-linguistics, and migration correlates ancestry with linguistic data. *J.L. Baker, D. Shriner, C.N. Rotimi.* Center for Research on Genomics and Global Health, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD.

Genetic studies have established a sub-Saharan African origin for anatomically modern humans with subsequent migrations out of Africa. Characterizing the genetic variation and relationships among global populations stemming from these events is challenging due to gene flow and admixture. Analysis of ancestry effectively removes the effects of recent instances of these confounding factors, revealing history in the distant past. Using the largest multi-locus data set for a study of genetic variation known to date, we investigated the genetic differentiation of early modern humans during global peopling, the extent of human admixture and migration events, and the relationships among ancestries and language groups. We compiled publicly available genome-wide genotype data on autosomal single nucleotide polymorphisms. The data set includes 5,966 individuals from 282 global samples genotyped at ~19K SNPs. Thirty of the world's 141 primary language families, accounting for 97.8% of people, are represented in this data set. The best evidence from these data supports 21 ancestries that delineate genetic structure of the global human population during the Upper Paleolithic, 17 of which are present in Africa. Independent of self-identified ethno-linguistic labels, we found that the vast majority (97.4%) of present-day individuals in this global dataset have mixed ancestry with evidence of multiple ancestries in 96.7% of samples and 100% of continents. We find evidence for migration events between Eastern and Northern Africa and between Omotic ancestry and the node leading to Northern European, Arabian, Northern African, Southern European, and Western Asian ancestries. We found a moderate to strong positive correlation between ancestries and language families or branches, such that ancestry data support or refute several proposed linguistic relationships and the linguistic data point to possible resolutions of heterogeneity in the ancestry data. Thus, ancestry data yield insight into a deeper past than linguistic data can, while linguistic data provide clarity to ancestry data. Finally, these data do not provide genetic support for the existence of distinct human racial groups. These data will be a public resource that can be used to describe genetic variation observed at multiple levels, from worldwide to continental to population to individual.

1147W

Y-chromosomal composition of mediaeval and contemporary populations in Norway and adjacent Scandinavian countries: Y-STR haplotypes and the rare Y-haplogroup Q. *B. Berger[1], S. Willuweit[2], H. Niederstätter[1], P. Kralj[1], L. Roewer[2], W. Parson[1,3].* 1) Institute of Legal Medicine, Medical University of Innsbruck, Innsbruck, Austria; 2) Department of Forensic Genetics, Institute of Legal Medicine and Forensic Sciences, Charité-Universitätsmedizin, Berlin, 13353, Germany; 3) Forensic Science Program, The Pennsylvania State University, PA, USA.

   In the framework of the project "Immigration and mobility in mediaeval and post-mediaeval Norway" molecular genetic analyses were performed on 97 pre-modern human remains including genetic sexing and Y-chromosomal DNA typing. All samples were subjected to molecular genetic analyses of the sex using "Genderplex" consisting of two different regions of the amelogenin gene, SRY and four X-STR loci. From 90% of the extracted remains (n=87) sex assignment was possible. Of these, 49 (56.3%) brought a genetically male result. All of these DNA extracts were subjected to Y-STR analysis using Yfiler Plus PCR Amplification Kit (Thermo Fisher Scientific) and/or PowerPlex Y23 System (Promega). At least partial Y-STR profiles were obtained from all samples. A detailed comparison between mediaeval/post-mediaeval and contemporary Y-chromosomes was performed by searching the obtained haplotypes (HTs) in the Y Chromosome Haplotype Reference Database (YHRD: https://yhrd.org) comprising 154,329 haplotypes from 991 populations in 129 countries at the time of query (Release 50). YHRD searches of the pre-modern haplotypes yielded full matches plus neighbor-matches differing at only one allele from the query HT. Matches are presented with geographical and ancestry information of the contemporary HTs. For samples without direct YHRD-matches, this information is provided through their neighbor HTs. AMOVA was performed using the YHRD online tool on pairwise R_{ST} values to create the corresponding MDS plots. The pre-modern HTs were grouped according to medieval and post-medieval origin and compared to contemporary populations from Scandinavian (Norwegian, Swedish and Danish), Northwest European, and Northeast European populations. Both pre-modern populations showed small genetic distances to contemporary Scandinavians and larger distances to Northeast Europeans with Northwest European populations in between. As expected, an initial assessment of the Y-chromosomal haplogroups (HGs) showed that most of the samples were attributable to the main European HGs I1, R1a and R1b. However, one of the HTs seemed to be associated with HG-Q which is rare in Europe and hitherto little evaluated in this region. Network analysis was applied for detecting similar HTs in contemporary samples from Norway and adjacent Northern European countries stored in the YHRD. The outcomes of this survey should initiate a detailed SNP based HG-assessment of HG-Q candidate samples.

Detecting polygenic adaptation using GWAS data. *C. Bhérer[1], J.K. Pickrell[1,2].* 1) New York Genome Center, New York, NY, USA; 2) Department of Biological Sciences, Columbia University, New York, NY, USA.

   Natural selection on a polygenic phenotype may drive local adaptation via small shifts in allele frequencies at many loci. To test for this mode of adaptation in humans, we introduce a hierarchical model for detecting selection on a phenotype from changes in allele frequency at loci identified by genome-wide association studies (GWAS). Our method uses the normal approximation to genetic drift to jointly model neutrality and selection in a three-population tree, and a MCMC to estimate the strength of selection. Simulations show that our three-population test has increased power to detect selection compared to a related sign test. We test for polygenic adaptation in contemporary human populations using GWAS data for over 40 traits (Pickrell et al. 2016), and genomic data from Bray et al. 2010, Lazaridis et al. 2014 and The 1000 Genomes Project. We confirm selection for increased height in northern European populations (and decreased height in southern European populations), and find suggestive evidence in populations from other continents. Intriguingly, we also find evidence for selection on unibrow in some European and African populations. Our study shows how to leverage results from GWAS studies to gain insights into the evolutionary history of alleles that contribute to current phenotypic variation, notably disease risk.

1149F

Evidence for detailed historical European population structure from large-scale, diverse genetic polymorphism data. *P. Carbonetto[1], J. Byrnes[1], J.M. Granka[1], Y. Wang[1], K. Noto[1], E. Han[1], A.R. Kermany[1], K.A. Rand[1], E. Elyashiv[1], H. Guturu[1], N.M. Myres[2], E.L. Hong[1], R.E. Curtis[2], K.G. Chahine[2], C.A. Ball[1].* 1) Ancestry.com DNA, LLC, San Francisco, CA; 2) Ancestry.com DNA, LLC, Lehi, UT.

Despite the recent surge of interest in ancient genomes, we show that there is still much to be elucidated about human demography from contemporary genomes. Here, we demonstrate the use of genealogical data to generate demographic insights from analysis of a large-scale, heterogeneous genetic data set. Specifically, we show that an unsupervised ADMIXTURE analysis of genotypes from 131,293 primarily US-born individuals, followed by a simple statistical analysis of the 3 million pedigree records linked to these genotype samples, yields novel insights into European genetic diversity. In contrast to principal component analysis (PCA), which is the most widely used approach to investigating European genetic diversity, we use ADMIXTURE to infer genetically differentiated source populations reflecting more distant historical time periods. Unsurprisingly, among European-origin individuals, admixture is pervasive. Despite this, our ADMIXTURE analysis with $K = 12$ ancestral populations identifies 5 stable, genetically differentiated groups within Europe (with putative historical counterparts in parentheses): Ashkenazi Jewish, Irish (Celts), Eastern Europeans (Slavs), Scandinavians (Nordics) and Iberians, featuring Basques and Sardinians. The genealogical data also allow us to provide a detailed portrait of the genetic composition of contemporary peoples across North America (e.g., Iberians in Cuba), and other parts of the world. This work suggests the potential for drawing more detailed connections between present-day and ancient genetic variation by leveraging large, heterogeneous genetic data sets.

1150W

Extremely rare variants reveal sequence context and genomic features that shape the germline mutation rate in humans. *J. Carlson[1], J. Li[1,2], S. Zöllner[3,4], The BRIDGES Consortium.* 1) Department of Computational Medicine and Bioinformatics, University of Michigan, Ann Arbor, MI; 2) Department of Human Genetics, University of Michigan, Ann Arbor, MI; 3) Department of Biostatistics, University of Michigan, Ann Arbor, MI; 4) Department of Psychiatry, University of Michigan, Ann Arbor, MI.

Mutation is a fundamental biological process that drives evolution and the incidence of heritable disease. The human germline mutation rate is known to correlate with various features of the genomic landscape, but the exact effect of these predictors is unknown. Existing approaches are insufficient to study the variation in mutation rate across the genome in an unbiased, high-resolution manner: comparative genomics methods are confounded by selection and biased gene conversion, whereas *de novo* mutation events ascertained by pedigree sequencing are too sparse to characterize mutation rate heterogeneity in great detail. Here, we present a novel approach to comprehensively assess predictors of mutability. We collect a dataset of over 36 million high quality singleton variants from 3765 whole-genome sequences. These extremely rare variants arose very recently in the population, and are thus largely unaffected by confounding evolutionary factors. Using these singletons, we develop statistical models to predict the effect of genomic context and adjacent nucleotides on the mutation rate at a single-base resolution. We find strong evidence for heterogeneity in the mutation rates of short sequence motifs, with up to a 60-fold difference between the mutation rates of non-CpG 7-mer motifs within a single mutation class. These sequence-specific mutation rates vary by an additional order of magnitude when we account for local genomic and epigenomic features, such as replication timing and chromatin organization, suggesting that the genomic landscape is important in modulating the efficiency of DNA damage and repair mechanisms. We apply this knowledge to develop a model that predicts the distribution of true *de novo* mutations with greater accuracy than competing models trained using common polymorphisms and/or ignoring the influence of genomic features. Adapting this strategy to model singleton density in genomic windows, we are able to explain over 97% of variance in the genome-wide distribution of recent mutations. This detailed atlas of germline mutation rates can be applied to many important topics in the field, ranging from population genetics inference to clinical sequencing.

1151T

Using whole-genome sequencing to shed insight on the complex pre-history of Sardinia. *C. Chiang[1], J. Marcus[2], C. Sidore[3], M. Zoledziewska[3], M. Steri[3], H. Al-asadi[2], S. Sanna[3], G. Abecasis[4], D. Schlessinger[5], F. Cucca[3], J. Novembre[2].* 1) Psychiatry, UCLA, Los Angeles, CA; 2) Human Genetics, University of Chicago, Chicago, IL; 3) Istituto di Ricerca Genetica e Biomedica, CNR, Cagliari, Italy; 4) Center for Statistical Genetics, University of Michigan, Ann Arbor, MI; 5) Laboratory of Genetics, NIA, NIH, Baltimore, MD.

Genetic studies of complex traits using individuals from the island of Sardinia have been fruitful for decades. Understanding the population history of Sardinia may provide insights to how risk alleles arise in Sardinia and the expected degree of sharing with mainland populations. Current models for the peopling of Europe consider extant Europeans as having varying ancestral contributions from Paleolithic hunter-gatherers, Neolithic farmers, and Steppe pastoralists. In these analyses, extant Sardinians are inferred with the largest amount of Neolithic farmer ancestry among Europeans. However, previous studies of uniparental markers have highlighted the high frequency of the Y-chromosome haplotype I2a1a1 in Sardinia, which has been associated with Paleolithic ancestry in Europe. Here we aim to elucidate finer details of the population history of Sardinia. We study >3,500 whole-genome sequenced individuals across Sardinia together with reference European datasets and recently published ancient humans. We confirm that compared to mainland Europeans, Sardinians exhibit the greatest amount of shared drift with Neolithic farmers. Within the island of Sardinia, there is a demarcation of individuals from the Lanusei Valley in the geographically isolated province of Ogliastra and individuals from other provinces. In unsupervised analyses, a Sardinian-specific ancestry component correlates with shared drift parameters with both the Neolithic farmers and Paleolithic hunter-gatherers, and is consistent with supervised estimates of ancestry proportions in which the Ogliastra individuals have higher Neolithic farmer and Paleolithic hunter-gatherer ancestries, while individuals from the rest of the island show an infusion of the pastoralist ancestry. Finally, we find that the Sardinian people exhibit increased sharing of alleles with the Neolithic farmers on the X chromosome compared to the autosome (P < 1x10^{-4}), suggesting a sex-biased demographic history in Sardinia. Together, our results indicate that in addition to the strong Neolithic farmer component of ancestry, isolated regions of Sardinia also harbors significant ancestry components from Paleolithic Europe and that the Neolithic transition in Sardinia may have involved sex-biased demographic change. These results help provide more insight into the history of Sardinians and the frequency distribution of variants they carry.

1152F

Mutation load and health outcomes are modulated by allele specific expression and the environment. *H. Edgington[1], M.J. Fave[1,3], I. Alves[1], J.C. Grenier[3], V. Bruat[3], P. Awadalla[1,2,3].* 1) Ontario Institute for Cancer Research Informatics and Biocomputing 661 University Ave. Suite 510 Toronto, Ontario M5G 0A3 Canada; 2) University of Toronto Department of Molecular Genetics 1 King's College Circle Toronto, Ontario M5S 1A8 Canada; 3) Centre Hospitalier Universitaire Sainte-Justine 3175 Chemin de la Côte-Sainte-Catherine Montréal, QC H3T 1C4 Canada.

While mutation load is often inferred by counting the number of mutations in an individual genome or population, it does not incorporate expression or translation information, or impact on phenotypes or fitness. For example, allele-specific expression (ASE), the imbalanced expression of alleles at a particular locus, is a phenomenon that is frequent and pervasive. Not only are patterns of ASE heritable, they have important consequences for biological processes and functions. In this study we used genomic, transcriptomic and endophenotypic data captured from a population cohort of over 40000 individuals in Quebec to infer the impact of mutation, allele specific expression and regional variability including environmental exposures on phenotypic data and clinical outcomes. Allelic proportions from RNAseq data were combined with genotype data from approximately 1000 individuals to characterize the intersection of ASE, individual phenotype, and population exposures, genome-wide. Tests of associations between ASE summary statistics such as expression-weighted mutation load and three groups of phenotypes, demographic and lifestyle traits, health and disease related traits, and medication use, revealed significant associations between ASE and several phenotypes including bowel disease and arterial stiffness. Using coinertia analyses, we identified variants showing the strongest covariance between allelic expression patterns and phenotypic variation. Genes showing consistent bias towards the ancestral alleles were enriched for biological processes critical to cell function and replication, such as metabolic and localization processes and immune pathways. Furthermore, we found that the unique demographic history of the French-Canadian population has impacted ASE patterns in this cohort. French-Canadians are descendants of a founder population that has expanded by a series of sequential founder events following colonization of Quebec. We compared ASE between three subpopulations and found that individuals at the forefront of expansion exhibit increased ASE as well as reduced heterozygosity. We conclude from these results that patterns of ASE at a genomic scale are correlated with important measures of individual health, and describe novel associations between expression profiles at specific variants and health outcomes. Additionally, we found that like genetic variation, expression profiles vary among populations that have experienced rapid demographic change.

1153W

Genomic insights into the population structure and history of the Irish Travellers. *E.H. Gilbert[1], S. Carmi[2], S. Ennis[3], J.F. Wilson[4,5], G.L. Cavalleri[1].* 1) Molecular and Cellular Therapeutics , Royal College of Surgeons in Ireland, Dublin, Leinster, Ireland; 2) Braun School of Public Health, The Faculty of Medicine, The Hebrew University of Jeruslam, Jerusalem, Israel; 3) School of Medicine and Medical Science, University College Dublin, Dublin, Ireland; 4) Centre for Global Health Research, Usher Institute for Population Health Sciences and Informatics, University of Edinburgh, Teviot Place, Edinburgh, Scotland; 5) MRC Human Genetics Unit, Institute of Genetics and Molecular Medicine, University of Edinburgh, Western General Hospital, Crewe Road, Edinburgh, Scotland.

  Aims: The Irish Travellers are a population with a history of nomadism. Consanguineous unions are common, and as a population they are socially and genetically isolated from the surrounding, "settled" Irish population. A previous low-resolution genetic analysis suggested a common Irish origin between the settled and the Traveller populations. What is not known, however, is the extent of population structure within the Irish Traveller population, the time of divergence from the general Irish population, and the extent of autozygosity. **Methods**: We recruited Irish Travellers from across Ireland and the UK. To be included a participant had to have had at least three grandparents with a surname associated with the Irish Travellers. DNA was extracted from saliva samples, and genotypes were generated using the Illumina OmniExpress SNP genotyping platform. With this data, we investigated population structure using fineStructure, quantified the levels of autozygosity with PLINK, and estimated a time of divergence using a method based on Identity by Descent (IBD) segment identification. **Results**: We merged, cleaned, and analysed data from 42 Irish Travellers, 2232 settled Irish, 2039 British, 143 Roma Gypsies, and 931 individuals from 57 world-wide populations. We confirm an Irish origin for the Irish Travellers, demonstrate evidence for population substructure within the population, confirm high levels of autozygosity consistent with a consanguineous population, and for the first time provide estimates for a date of divergence between the Irish Travellers and settled Irish. **Conclusion**: Our findings have implications for disease mapping within Ireland, as well as on the social history of the Irish Traveller population.

1154T

A compendium of worldwide surveys of population-specific F_{ST} for forensic Y-STR markers. *T.O. Hall[1], B.S Weir[2].* 1) Institute of Public Health Genetics, University of Washington, Seattle, WA; 2) Department of Biostatistics, University of Washington, Seattle, WA.

  Y-STR markers are particularly useful forensically for identifying the male contributor to a male-female DNA mixture. A population genetic approach to estimation of the match probability is dependent on an appropriate estimate of θ, which is calculated empirically as F_{ST}. This estimate depends on the choice of F_{ST} estimator, the markers included and how they are combined. This paper looks at the characteristics of estimates obtained using a population-specific F_{ST} estimator in three datasets: Y-Chromosome Haplotype Reference Database (YHRD), Human Genome Diversity Project (HGDP), and data published by Xu et al in 2014. Individuals with missing data were excluded. To emphasize that a population-specific estimate of θ can only be calculated relative to a total, our estimator is written as one minus the heterozygosity within population i at locus l, divided by the average heterozygosity between all populations in the total sample: $\beta_{il}=1-(H_{il}/H_{Bl})$. $H_{il} = 1-sum(p^2_{Ail})$ where p_{Ail} is the sample allele frequence of allele A at locus l in population i. Average heterozygosity between populations is $H_{Bl}= sum(H_{ijl})/(r(1-r))$, where $i \neq j$ and r is the number of populations. Conventional F_{ST} is the average of the β_{il}'s, here denoted as β_{Wl}, and can be calculated as: $\beta_{Wl}=1-(H_{Wl}/H_{Bl})$, where $H_{Wl} = sum(H_{il})/r$. Because markers on the Y-chromosome are assumed to be linked, multi-marker haplotypes are considered a single locus. β_{il}'s were calculated using the above equations for the population in each of the three datasets for l = haplotype combinations of Y-STR loci, where n=23 (YHRD), n=19 (HGDP) and n = 16 (Xu et al.) and k = 1, 2, …, 13. β_{Wl}'s's were calculated for each haplotype within regional ethnicity. Median worldwide β_{il}'s ranged from -0.01 to 0.26. Because Y-STRs are linked, we hypothesized that there would also be substantial dependency between pairs of single-locus β_{il}'s. However, we observed low to moderated correlation for all three datasets. There appears to be a weak relationship between β_{il} correlation and LD. As the number of loci included in a haplotype increased, mean β_{W} decreased, and the range of β_{W} values became smaller. The rate of decrease in mean β_{W} is not linear and related to correlation among single-locus β_{il}'s.

1155F

SMC²: Using particle filters to infer historic population sizes and migration rates from whole genomes and multiple samples. *D. Henderson, J. Zhu, G. Lunter.* Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom.

The sequentially Markovian coalescent model is widely used to infer historic population sizes from whole-genome sequence data from a few individuals. The complexity of the state space, a sequence of genealogies, severely limits the number of samples involved in the analysis and necessitates simplifications, such as discretization of time. Previous methods, such as MSMC, are able to consider samples from multiple populations enabling inference of a measure similar to migration rate. However, in MSMC the ability to consider multiple samples comes with a cost of reduced resolution in the distant past. We propose a simulation-based approach which allows for the explicit inference of migration rates and population sizes in the distant past. Our method, sequential Monte Carlo inference of the sequentially Markovian coalescent model (SMC²), simulates sequences of genealogies and weighs these according to their likelihood given the genotypes of the individuals in the sample. The weighted sample of sequential genealogies is used to update our parameter estimates for the recombination rate, historic population sizes, and historic migration rates. SMC² is able to accurately infer either bi-directional or uni-directional migration between two populations along with the effective population sizes. Due to its high resolution inference of the distant past, SMC² is an attractive method for investigating ancient populations and gene flow. As such, we have incorporated ancient samples into our analyses for comparing Neanderthal, Denisovan, and modern human population histories. We have developed a flexible tool for demographic inference from whole-genome sequences of a few individuals. The use of simulation-based techniques allows us to fit complex demographic models, and in particular enables nonparametric inference of migration rates.

1156W

Evolutionary history of Tibetans inferred from whole-genome sequencing. *H. Hu[1], N. Petousi[2], G. Glusman[3], Y. Yu[1], R. Bohlender[4], T. Tashi[5], J.M. Downie[6], J.C. Roach[3], A.M. Cole[7], F.R. Lorenzo[5], A.R. Rogers[4], M.E. Brunkow[3], G. Cavalleri[7], L. Hood[3], A.M. Alpatty[8], J.T. Prchal[5,6], L.B. Jorde[6], P.A. Robbins[9], T.S. Simonsons[10], C.D. Huff[1].* 1) Epidemiology, UT MD Anderson Cancer Center, Houston, TX; 2) Nuffield Department of Medicine, University of Oxford, Oxford, OX3 7BN, UK; 3) Institute for Systems Biology, 401 Terry Avenue North, Seattle, WA; 4) Department of Anthropology, University of Utah, Salt Lake City, UT; 5) Department of Medicine, University of Utah School of Medicine and George E. Wahlin Veterans Administration Medical Center, Salt Lake City, UT; 6) Department of Human Genetics, University of Utah, Salt Lake City, UT; 7) Molecular and Cellular Therapeutics, Royal College of Surgeons in Ireland, Dublin 2, Ireland; 8) Skaggs School of Pharmacy and Pharmaceutical Science, UC San Diego, CA; 9) Department of Physiology, Anatomy and Genetics, University of Oxford, Oxford, OX1 3PT, UK; 10) Department of Medicine, Division of Physiology, University of California San Diego, La Jolla, CA.

The indigenous people of the Tibetan Plateau have been the subject of much recent interest because of their unique genetic adaptations to high altitude. Here we report the first analysis of whole-genome sequences from Tibetans. A total of 27 Tibetan genomes were sequenced, allowing us to infer a detailed history of demography and natural selection of this population. We demonstrate that Tibetans and Han Chinese likely first diverged in the middle Paleolithic period between 44 and 58 thousand years ago, but with substantial gene flow until between 3 and 11 thousand years ago; both populations have undergone large expansions since they diverged. Using a recently developed statistical approach to detect archaic admixture, we show that the Han and Tibetan genomes each contain about 0.4% admixture from ancient Denisovans. The Composite of Multiple Signals (CMS) test identified *EPAS1* and *EGLN1* as the top two positive selection candidates genome-wide, consistent with previous reports. Both genes encode components of the hypoxia-inducible factor (HIF) pathway. The CMS test identified additional high-altitude adaptation candidates, including *PTGIS*, *VDR*, and *KCTD12*. Our haplotype analysis found that the advantageous Tibetan *EPAS1* haplotype contained a large number of variants shared with the Denisovan genome, consistent with previous reports, but with an ancient gene tree divergence between the Tibetan and Denisovan *EPAS1* haplotypes of about one million years ago. With the exception of *EPAS1*, we observed no evidence of positive selection on Denisovan-like haplotypes, strongly suggesting that adaptive introgression from a Denisovan-like ancestor was a unique occurrence in the evolutionary history of Tibetans.

1157T

Parallels between processes of genetic and linguistic admixture in Cape Verde. *E.M. Jewett[1], P. Verdu[2], T.J. Pemberton[3], N.A. Rosenberg[4], M. Baptista[5].* 1) EECS and Statistics, UC, Berkeley, Berkeley, CA; 2) CNRS/MNHN, Paris Diderot/Sorbonne Paris Cite, Paris, France; 3) Biochemistry and Medical Genetics, University of Manitoba, Winnipeg, MB; 4) Biology, Stanford University, Stanford, CA; 5) Linguistics and Afroamerican and African studies, University of Michigan, Ann Arbor, MI.

The Cape Verdean archipelago, located near the western coast of Africa, provides one of the earliest examples of admixture between European and African populations, resulting in a population that is highly diverse in both genetic and linguistic ancestry. Because present-day genetic and linguistic variation in Cape Verde arose from the same well-documented migration and admixture events beginning in the late 1400s, Cape Verde provides an important resource for studying similarities and differences between processes of linguistic and genetic transmission during admixture. We investigated patterns of genetic and linguistic diversity among 44 unrelated Cape Verdean individuals, sampling genotypes at ~2.5 million genome-wide SNPs and sampling the spontaneous speech of individuals in Cape Verdean Creole. We found evidence for the vertical transmission of speech patterns in Cape Verde, finding that variation in parental birthplaces was predictive of variation in the speech patterns of study participants. We also found that individual levels of African genetic ancestry in Cape Verde were significantly positively correlated with the number of words of putative African origin used by each individual. This finding suggests that similar processes of transmission, diffusion, and isolation have led to similar patterns of genetic and linguistic variation despite non-vertical transmission and potentially strong influences from sociocultural factors on individual speech patterns. Although the vertical transmission of speech patterns can partly account for the observed correlation between genetic and linguistic ancestry, we also found evidence for the influence of cultural practices on linguistic transmission, finding that maternal birthplaces were more predictive of speech patterns in offspring than paternal birthplaces, a result that is consistent with patterns of marriage and remarriage in Cape Verde. Our study provides an improved understanding of the processes that have shaped diversity in the present-day Cape Verdean population and the degree to which linguistic and genetic changes occur in parallel.

1158F

How molten is the pot? Analyzing self-reported and genetic ancestry of individuals and reproducing couples in the USA. *K.E. Kaseniit, S. Nazareth, C. Lo, K. Wong, J.D. Goldberg, E.A. Evans, I.S. Haque.* Counsyl, Inc., South San Francisco, CA.

Purpose: The 2010 US Census showed that 15% of US marriages occur between spouses of different ethnicities, a more than double increase over the previous two decades (Pew Research Center). Further, although prior studies in personal genetics have noted that self-reported ethnicity (SRE) is not fully concordant with genetic ancestry (GA), current medical genetics guidelines are based around SRE. We sought to characterize the increasing diversity of the US population and its impact on medical practice by exploring both the discordance between SRE and GA and current inter- and intra-ethnic mating patterns. **Methods:** Deidentified data was drawn from >100,000 individuals receiving carrier screening; all individuals self-reported ethnicity, including options for unknown and for mixed ethnicity. To evaluate discordance between SRE and GA, we adapt an existing ancestry analysis method [1] for use with sparse (<5000 reads/sample) off-target sequencing reads and analyze data from >60,000 individuals tested by next-generation sequencing. To evaluate mating patterns, we analyze the paired self-reports from 37,719 couples in which both members of the couple were tested. **Results:** We demonstrate the ability to robustly recover GA coefficients from extremely sparse sequencing data. We find that over one-sixth of the samples with unknown SRE have a true GA that would have prompted additional screening under existing medical guidelines. Further, over 4% of all patients have at least 25% GA from a different population than their self-reported ethnicity, suggesting at least one ancestrally different grandparent. We find that 39.7% of couples were of mixed ethnicity with significant divergence in behavior between males and females. Women who identify as as East Asian, Southeast Asian and Mixed/Other Caucasian are more likely to partner with men outside of their self-reported ethnic group than are men of the same groups. Men who identify as Ashkenazi Jewish, African American or European (Northern or Southern) are more likely to partner with women outside of their self-reported ethnic group than are women from those groups. **Conclusions:** SRE is not fully reliable in the clinical setting and a large fraction of couples cross ethnic boundaries, suggesting that existing medical standards that rely on single-ethnicity self-reports are likely to become untenable in the near future. Fine-scale genetic diversity of Japanese population. *Y. Kawai, K. Misawa, T. Mimori, K. Kojima, F. Katsuoka, M. Yamamoto, J. Yasuda, M. Nagasaki.* Tohoku Medical Megabank Organization, Tohoku University, Sendai, Japan.

Japanese population is isolated from other east Asian populations due to its geological location. It is thought that the modern Japanese people are admixture of two ancestral populations; migrants in Jomon period (16 000–3000 year before present; YBP) and migrants in Yayoi period (3000–1700 YBP). However, despite current large census population size (approximately 127 million), demographic history after spread into the Japanese Archipelago is still not well understood. Thus, the study of detailed genetic structure within the population is important not only in human genetic studies but also from a biomedical point of view. We investigated the genetic history of the modern Japanese population using the genome-wide data of the cohort study of Tohoku Medical Megabank Organization. The whole genome sequencing and SNP genotyping data obtained from cohort participants some of whom all four grandparents originated from the same area were used for population structure and demographic inferences. The haplotype-based fine scale genetic structure is consistent with geographic variation. The analysis of cross coalescent rate using the whole-genome sequence data suggests that the genetic differentiation within Honshu island has begun after the last migration event in Yayoi period.

Characterization of local adaptation in Africa from whole genome sequence data. *D.E. Kelly[1,2], S.H. Fan[1], M.H. Beltrame[1], M.E.B. Hansen[1], S. Mallick[3,4,5], T. Nyambo[6], S. Omar[7], D. Meskel[8], G. Belay[9], A. Froment[10], N. Patterson[4], D. Reich[3,4,5], S.A. Tishkoff[1,2,10].* 1) Genetics, University of Pennsylvania, Philadelphia, PA 19104, USA; 2) Genomics and Computational Biology Graduate Group, University of Pennsylvania, Philadelphia, PA 19104, USA; 3) Department of Genetics, Harvard Medical School, Boston, MA, 02115, USA; 4) Broad Institute of Harvard and MIT, Cambridge, MA, 02142, USA; 5) Howard Hughes Medical Institute, Harvard Medical School, Boston, MA, 02115, USA; 6) Department of Biochemistry, Muhimbili University of Health and Allied Sciences, Dares Salaam, Tanzania; 7) Kenya Medical Research Institute, Center for Biotechnology Research and Development, Nairobi, Kenya; 8) Department of Biology, Addis Ababa University, Addis Ababa, Ethiopia; 9) UMR 208, IRD-MNHN, Musée de l'Homme, Paris, France; 10) Department of Biology, University of Pennsylvania, Philadelphia, PA 19104.

Humans have lived in Africa for much of their evolutionary history, and the diversity of climates, diets, and pathogens across the African continent have imposed unique selective pressures. Different ethnic groups in Africa have undergone local adaptation in response to these pressures, selecting for genes and biological pathways in a population- or region-specific manner. A powerful method for detecting local adaptation is the population branch statistics (PBS), which partition measures of population differentiation along the branches of a given evolutionary tree. We applied this approach to whole genome sequencing data from 52 individuals representing 22 ethnic groups from across Africa, pooled into 6 ancestries based on *ADMIXTURE* analyses. Using pairwise F_{ST} measures between ancestral groups and a fixed tree topology, branch lengths which best explain the observed patterns of population differentiation were inferred at all variable loci. A sliding-window approach was used to identify localized regions of enriched PBS values, indicating putative selection on genes related to taste perception in the San and Rainforest Hunter Gatherers, keratinization in the San and Nilo-Saharan/Cushitic groups, and immunity in Bantu-speaking populations. This work is supported by NIH grants 1R01DK104339-01, 1R01GM113657-01, and Pioneer Award DP1 ES022577-04 to SAT. The sequencing was funded by the Simons Foundation (SFARI 280376) and the U.S. National Science Foundation (BCS-1032255) grants to DR.

A temporal perspective on the interplay of demography and selection on deleterious variation in humans. *E. Koch[1], J. Novembre[1,2].* 1) Department of Ecology and Evolution, University of Chicago, Chicago, IL; 2) Department of Human Genetics, University of Chicago, Chicago, IL.

   Population genetic theory has long stressed the importance of population size in determining the abundance of mutations with small effects on fitness in populations. The effects of population size become complex when population sizes have been changing as part of a dynamic, non-equilibrium demographic history. Several recent papers in human population genetics have focused on this interplay of demographic history and deleterious variation. Here we investigate how deleterious variation responds to population size change by providing a temporal view and mechanistic explanation of changes in the site frequency spectrum. We focus on demographic events thought to have occurred during human history, specifically contrasting a history representative of an Out-of-Africa population experiencing a bottleneck and growth versus a relatively stable population history representative of an African population. We then analyze exome sequence data from the Exome Aggregation Consotrium (ExAC), including 33,370 and 5,203 individuals in empirical ancestry clusters of African and non-Finnish European individuals, respectively. Our theoretical results emphasize how even simple summaries of the site frequency spectrum can have potentially complex responses to demographic change. This problem grows as higher moments of the frequency spectrum are considered, and we use the proportion of segregating sites predicted to be deleterious as an example. Our results help explain the difficulty of inferring slight differences in the distribution of deleterious variation using next generation sequence data. These findings have implications for comparisons of deleterious variation between populations that are based only on summary statistics of the site frequency spectrum, indicating such comparisons can be ambiguous about differences in the efficacy of selection.

Personal ancestry inference at the finest scale reveals more sub-structure in the UK. *D. Lawson, G. Weyenburg.* Integrative Epidemiology Unit, University of Bristol, Bristol, UK, United Kingdom.

   Chromosome Painting has revealed genetic differences within the UK at a very fine scale [1], with structured genetic variation within a single county in some cases (such as Cornwall & South Wales). However, in that work, it was not possible to genetically distinguish much of England, which appeared as a single homogeneous group. Here, we describe an extension to the Fine-STRUCTURE [2] clustering that can further distinguish ancestry even within England; for example, identifying regions such as Norfolk, the Midlands and the South as genetically distinct. The approach works by using the known county locations to craft genetic features to use in unsupervised clustering. Specifically, we group individuals by their geographic sampling location into reference donor populations. This forms an ancestry profile - which can be viewed as a careful choice of feature vector - that still allows unsupervised genetic clustering for all individuals. Further, we describe how this approach allows individuals to be described as an admixture of the inferred geographical clusters. This allows ancestral information to be recovered for individuals who are not purely represented by a single geographical location. This also allows us to characterise the genetic relationship between the inferred clusters, several of which represent drift that is most strongly represented by a particular geographical region (including Cornwall, Wales, Scotland and the North of England) and others of which represent characteristic admixture proportions between these ancestral drifted populations. Beyond improving resolution, this approach facilitates personal genomics because individuals can be represented in terms of the fixed reference panel. We demonstrate the utility of the approach by describing the ancestry of the UK10K participants in terms of the new, high resolution POBI clusters. Previously, a similar analysis [3] without geographical information inferred little population structure in the UK from these samples, but now we have a rich representation of their population structure, including an assessment of admixture from outside the UK. This highlights the value in high quality fine-scale geographic sampling, which could now facilitate this level of ancestry identification for many other countries. 1163T

Exploring detailed demographic histories using stairway plot 2. *X. Liu.* Human Genetics Center, UTHealth School of Public Health, Houston, TX.

Inferring human demographic history using genetic information can shed light on important prehistoric evolutionary events such as population bottleneck, expansion, migration, and admixture, among others. Recently we developed a model-flexible method called stairway plot (Liu and Fu, Nature Genetics, 2015), which infers detailed population size changes over time using SNP frequency spectra (SFS). This method can be applied to low-coverage sequence data, pooled sequence data or RAD-seq data from non-model organisms with hundreds of individuals. We have extended this method to be applicable to folded SFS, therefore will not be biased by incorrected inferred ancestral alleles. We also used an ensemble approach to control model overfitting. Using extensive simulation we showed that the accuracy of stairway plot with folded SFS is similar to that with correct unfolded SFS. We also compared our improved method (aka stairway plot 2) to the state of the art method for inferring demographic history, multiple sequentially Markovian coalescent (MSMC) (Schiffels and Durbin, Nature Genetics, 2014), and showed that our method outperforms the MSMC for inferring recent population size changes. We applied our method to whole genome sequence data of some human and non-human primate populations and showed their detailed demographic histories.

1164F

Testing directional selection on polygenic traits using ancient DNA. *J. Marcus, J. Novembre.* Department of Human Genetics, University of Chicago, Chicago, IL.

Understanding the evolutionary basis of trait variation requires the ability to distinguish between models where a trait has recently undergone directional selection as opposed to stabilizing selection or simply neutral evolution. Methods to distinguish amongst such models are still poorly developed, especially for highly polygenic traits. Recent progress in understanding the polygenic basis of trait variation, using genomewide association studies (GWAS), and the increasing availability of ancient DNA (aDNA) samples provide new opportunities. Here, we develop and compare several possible inferential procedures that intersect putative quantitative trait loci discovered via GWAS with aDNA data to test whether a phenotype has experienced directional selection on the basis of allele frequency change. We consider key challenges for methods development in this area, specifically, uncertainty in effect sizes and allele frequencies. We compare Bayesian procedures that take these uncertainties into account with approaches that use simple heuristic test statistics. We show that for several methods power exists even with small aDNA sample sizes when the signature of selection is distributed across many loci, and we apply these approaches to investigate signatures of selection on a panel of quantitative traits in humans (e.g. height, BMI, autoimmune disease risk) using published GWAS and aDNA data. While aDNA studies in some species are rapidly scaling upwards in sample size, even small samples will be helpful for shedding light on the evolution of polygenic traits.

The area of southeastern Europe known as the Balkans has always been a crossroads between Europe and Asia: a conduit for people, culture and language. Beginning around 6,500 BCE, the Balkans was the first place in Europe to become transformed by farming, brought by a new wave of migrants from Anatolia. From this staging point, farming and people spread to all corners of Europe. However, the dynamics of the interaction between farmers and indigenous European hunter-gatherers in the first place that they encountered each other remains poorly understood because of the near complete absence of genetic data from prehistoric specimens from this region.   We generated new genome-wide ancient DNA data from 65 farmers from the Balkans and adjacent regions dating as far back as 6,400 BCE. We document how the dynamics of admixture between the regions first farmers and its indigenous hunter-gatherers was complex, with evidence of local admixture from hunter-gatherers related to those from Scandinavia and Eastern Europe. The population admixture was patchy across both space and time, varying in magnitude between 0% and 30% for different early Balkan farming populations. The hunter-gatherer admixture in the early farmers of the Balkans is not closely related to the hunter-gatherer admixture that is predominant in present-day Europeans. This suggests that the waves of farmers that contributed most of the migrants to northern and western Europe were not ones that mixed substantially with local Balkan hunter-gatherers.   We also analyze the data to generate new insights about natural selection. The first farmers of the Balkans were in the initial stages of adaptation to environments that were dramatically different from those that their ancestors had encountered. We show that many of the adaptations related to diet and immunity that later become common in Europe were already present in early Balkan farmer populations, but not at high frequency. Thus, the adaptation of the first European farmers to their local environment was driven to a substantial extent by pre-existing variantion.

1166T

Detecting mutagenic recombination using genome-wide divergence data. *T.N. Phung, C.D. Huber, K.E. Lohmueller.* Bioinformatics IDP, University of California, Los Angeles, Los Angeles, CA.

Mutation is the ultimate source of genetic variation that is acted on by evolutionary processes and gives rise to disease. Currently, the reasons why the mutation rate varies across the genome are not well understood. One possibility is that recombination could be mutagenic and as such, variation in the recombination rate contributes to variation in the mutation rate. A positive correlation between human-chimp neutral divergence and recombination rate has lent support to this hypothesis. However, this correlation could also be driven by the effects of natural selection. To date, the degree to which recombination is mutagenic in the human genome remains unknown. To address this question, here we develop a likelihood-based framework to test the extent to which natural selection and/or the coupling between recombination and mutation contributes to the variation in human-chimp divergence. Our method is built upon the idea that natural selection primarily affects divergence in regions of low recombination while mutagenic recombination affects regions of high recombination. We model the effects of natural selection on linked neutral divergence following Hudson and Kaplan 1995. We also estimate the degree of coupling between mutation and recombination. Application of this method to human-chimp divergence reveals that a model including background selection and mutation-recombination coupling fits the data substantially better than a model only including background selection (P-value < 0.01). Further, we use various filters to evaluate the role of biased gene conversion in generating these patterns. We will discuss implications of our results for understanding genetic variation across the human genome. Our inference framework can be applied to study mutation rate variation in non-model species where direct sequencing of family trios is not feasible.

With a population size more than 10 million, the Uyghur people residing in Xinjiang are believed to be descendants of the most ancient of Turkish tribes with mixed Caucasian and East Asian ancestries. However, their genetic origins, population structure and admixture history remain poorly understood and debatable. Here we systematically assessed genetic diversity and individual ancestry composition of the Xinjiang's Uyghurs (XJU) by genotyping ~1,000 Uyghur individuals, roughly proportional to population size of 13 geographical regions, with high-density single nucleotide polymorphism arrays. We observed a southwest-northeast differentiation within the XJU, which is different from the expected north-south differentiation as separated by Tianshan Mountain. In the context of comparative analyses of 2,477 individuals representing 206 worldwide populations, four major ancestries were identified in XJU without very much variation among individuals, i.e., East Asia, Siberia, West Eurasia, and South Asia. However, XJU showed an overall unique genetic make-up and divergent history from surrounding neighbors including the other modern Turkic speaking populations. The results suggest a long history of population admixture and isolation. Facilitated by new methods including one developed in this study, our analyses shed exciting new light on genetic origins and admixture history of Uyghurs.

The Singapore Integrative Omics Cohort (IOMICs) establishes population reference measurement across multiple omics technologies in 364 samples from three major population groups (Chinese, Malay and Indian) in Southeast Asia. Using resources of(i) more than 2.5 millions single nucleotide polymorphisms (SNPs) that cover whole genome, exon regions, and pharmacogenomic variants, 198 HLA typing alleles across eight HLA loci, (ii) 21,649 transcript variants, (iii) 297 lipid species, (iv) 274 circulating miRNAs and (v) 296 non-omic variables that were related to clinical, lifestyle and diet of each participant. About half of the Malays and a third of the Indians have also been deeply whole-genome sequenced. Omics data on the other hand potentially provides information on homogeneity of a population. For intra-omics analysis, we conducted population structure analyses with principal component analysis for intra-omics analysis and identified inter-ethnic variation using ANOVA for non-genetic data and Wright's Fst index for genetic data. From the population structure analyses, our study observed genetic information distinctly determined the membership of the population as compared to other omics information. Based on intra-omics analyses, we observed Chinese population in Singapore is biologically more homogenous whereas the Singapore Indians are biologically more heterogenous. The high-throughput omic datasets allows careful characterization of intra- and inter-omic correlation within and across all three populations, providing valuable insights towards bridging the functional relevance of existing genetic findings.

1169T

Robust and scalable inference of population history from hundreds of unphased whole-genomes. *J. Terhorst[1], J.A. Kamm[1,2], Y.S. Song[1,2,3,4].* 1) Department of Statistics, University of California, Berkeley, CA 94720, USA; 2) Computer Science Division, University of California, Berkeley, CA 94720, USA; 3) Department of Integrative Biology, University of California, Berkeley, CA 94720, USA; 4) Departments of Biology and Mathematics, University of Pennsylvania, PA 19104, USA.

The genomes of present-day individuals contain a wealth of information about their ancestors, and there has been a surge of interest in utilizing this information to learn about the history of humans and many other organisms. It has been demonstrated recently that inference methods based on genealogical processes with recombination can reveal past population history in unprecedented detail. However, these methods scale poorly with the sample size, which limits resolution in the recent past (within the last 1000 generations), and they require phased genomes, which contain switch errors that can catastrophically distort the inferred history.   In response to these challenges, we have developed SMC++, a new statistical tool capable of analyzing orders of magnitude larger samples than existing methods while requiring only unphased genomes as input (its results are independent of phasing). SMC++ also requires far less memory and computation time than these methods, and can analyze genome-scale data on a laptop computer. We have implemented SMC++ as an open-source software package which features an easy-to-use graphical user interface.   We apply SMC++ to analyze sequence data from over a thousand genomes in eight human populations in Africa and Eurasia, hundreds of genomes from a Drosophila population in Africa, and tens of genomes from zebra finch and long-tailed finch populations in Australia. Our results suggest that, despite the wide range of biological differences between these species (e.g., in the generation time, mutation rate, and recombination rate), their long-term effective population size changes in the last 200,000 years follow a remarkably similar pattern, with major growth, decline and bottleneck events lining up in time very closely.

1170F

Mutation rate estimation from population data. *X. Tian[1], B.L. Browning[2], S.R. Browning[1].* 1) Department of Biostatistics, University of Washington, Seattle, WA; 2) Division of Medical Genetics, Department of Medicine, University of Washington, Seattle, WA.

The two primary methods for mutation rate estimation have been counting de novo mutations in parent-offspring trios and comparing sequence data between species. With trio analysis it is difficult to control for genotype error and resolution is limited because each trio provides information from only two meioses. Inter-species comparison is difficult to calibrate and can be affected by selection. Genome-wide mutation rate estimates from inter-species comparisons have been twice as high as those from family-based studies [1]. A new class of methods for mutation rate estimation is based on segments of identity by descent (IBD) between pairs of individuals. The length of an IBD segment provides information on the number of meioses linking the two haplotypes through their common ancestor, and differences in the haplotype sequences provide information on the total number of mutations from those meioses. Recently, Palamara et al. proposed an IBD-based method for estimating mutation rates from perfectly phased data, such as that obtained from parent-offspring trios [2]. Whereas ordinary trio-based analysis uses only meioses within trios, Palamara et al.'s approach uses meioses from IBD between pairs of trio offspring, and is thus more powerful than counting de novo mutations. We develop IBD-based mutation rate estimation further by using multi-individual IBD rather than pairwise IBD. Multi-individual IBD provides more information that can be used to address haplotype phase uncertainty and genotype error. Our method is applicable to sequence data with or without close relatives. As a first stage, we have implemented our method for perfectly phased data. Analysis of simulated data indicates that our method is unbiased and has high precision when using actual or inferred IBD segments, actual or inferred effective population size, and genotypes with or without genotype error. With simulated genome-wide data having a mutation rate of 1.25×10^{-8}, a constant population size of 10,000 and a sample size of 400 diploid individuals, our method has standard errors of approximately 0.01×10^{-8} for the mutation rate estimate. 1171W

Background selection in the human genome explains F_{ST} better than recombination rate alone. *R. Torres[1,3], R.D. Hernandez[2,3].* 1) Biomedical Sciences Graduate Program; 2) Department of Bioengineering and Therapeutic Sciences; 3) UCSF, San Francisco, CA.

The consequences of linked selection in the human genome have been well characterized and studied. As a proxy for understanding the consequences of linked selection, much previous work has focused on the correlation of genetic diversity and differentiation with recombination rate, since the effects of linked selection are expected to be stronger in regions of low recombination. Using this proxy, decreased genetic diversity and divergence and increased population differentiation in regions of the genome under low recombination have been observed. However, recombination rate alone is not sufficient to describe the total effects of linked selection since the density of functional elements and magnitude of natural selection along the genome are also of considerable importance. In order to better measure the total effect of linked selection on population differentiation in humans, we utilize phase 3 of the 1000 Genomes Project and measure F_{ST} as a function of background selection, which takes into account the density and magnitude of natural selection along the genome in addition to recombination rates. When modeling the effects of both background selection and recombination rate on F_{ST} using multiple linear regression, we observe that the effect of recombination rate on F_{ST} is no longer significant. We also observe substantial differences in estimates of F_{ST} between the strongest and weakest background selection regions of the human genome. We find that F_{ST} estimates at putatively neutral sites vary by as much as a factor of 2 when comparing populations from different continents. By comparison, when binning the genome by recombination rate alone, F_{ST} varies by less than 10%. Our results demonstrate the marked consequences of linked selection for generating accurate estimates of population differentiation in humans and may have implications for other measures of population structure utilizing genome-wide data.

1172T

Inference of evolutionary relationships among human populations based on the estimates of effective population size. *A. Urnikytė, A. Molytė, E. Pranckevičienė, V. Kučinskas.* Department of Human and Medical Genetics, Faculty of Medicine, Vilnius University, Santariskiu St. 2, LT-08661 Vilnius, Lithuania.

The effective population size (*Ne*) quantifies the rate at which genetic diversity is eroded by genetic drift, a fundamental process of evolutionary change, as well as provides an insight into the demographic history and dynamics of modern human populations. The main interest of this study was to estimate the effective population size of the Lithuanian population and to elucidate the evolutionary relationships on a global scale. The data set consisted of the Lithuanian and HGDP-CEPH population samples. SNP genotyping of 294 Lithuanian population samples was performed with Illumina 770K HumanOmniExpress-12v1.0 array. The effective population size of the Lithuanian population was estimated using a new R package NeON based on linkage disequilibrium (LD) patterns. The estimates of *Ne* for the populations contained in the CEPH panel were obtained from M. Mezzavilla and S. Ghirrotto, 2015 (University of Trieste, Italy) estimated with the NeON R package. We also estimated the time of divergence between the Lithuanian and HGDP-CEPH (with a sample size > 20 individuals) populations with the NeON R package as well as. The pairwise Weir and Cockherman *Fst* between pairs of populations was estimated using the software 4P (Benazzo A et al., 2014). To visualize the evolutionary relationships among studied populations an unrooted UPGMA was calculated from the divergence time matrix using *phangorn* R package. The estimated *Ne* for Lithuanian population is 5404, confidence interval (CI) [4910; 5643]. The Ne estimates and the matrix of interpopulation *Fst* values of 23 populations studied are summarized in a neighbor-joining (NJ) phylogenetic tree. The tree provides a clear picture that recent separations of populations are related with geographical area. The separations happened more recently between Europe, Middle East and Central South Asia populations. We observe three major groups: Africans, East Asians and Europeans. The largest divergence times are observed between Africans and non-African populations. From the divergence analysis we can observe the recent separations between studied populations and reconstructed past dynamics of Ne and split times. This study is part of the LITGEN project, which was approved by the Vilnius Regional Research Ethics Committee No. 158200-05-329-79, date: 2011-05-03.

1173F

Assembling an ancestry reference panel of diverse Asian populations through genotype imputation. *C. Wang, S. Chothani.* Computational and Systems Biology, Genome Institute of Singapore, Singapore, Singapore.

Knowledge of ancestry background of the sample is important for many genetic studies, such as to control for population structure in association studies. Estimating individual ancestry often requires a reference dataset of diverse populations genotyped at a large number of markers overlapping with the study sample. In this study, we aimed to construct a publicly available Asian reference panel by combining genome-wide SNP data of 43 Asian populations from five studies. Based on 154,865 shared SNPs, we found a striking similarity between genes and geography in Asia through principal components analysis and projection Procrustes analysis, enabling us to construct a geographic reference ancestry map. We then expanded the data to ~5.5 million SNPs by genotype imputation. We evaluated imputation accuracy across diverse Asian populations, and the impact of imputation error on the estimation of ancestry and the Fst statistic based on three populations in Singapore: Chinese, Malay and Indian. We showed that imputation error tends to reduce population differentiation, as indicated by smaller Fst values based on imputed genotypes. Such impact can be greatly mitigated by filtering low-quality imputed SNPs. In contrast, ancestry estimates derived from the LASER software are more robust to imputation error than the estimation of Fst. Therefore, our Asian ancestry panel integrated through imputation will be a useful resource for ancestry estimation and other population genetic analyses on Asian populations.

1174W

Chromosome painting for arbitrary sample collections. *G. Weyenberg, D. Lawson.* Integrative Epidemiology Unit, University of Bristol, Bristol, United Kingdom.

Haplotype-based methods have been demonstrated to be capable of detecting fine scale structure within human populations—to the point of distinguishing genetic variation at the sub-county level in the South West of England [1]. However, the aforementioned method implements an all-against-all analysis of sampled individuals, which is not suited to all applications, including personal genomics where samples are obtained individually or in small batches. Here, we describe an extension of the FineSTRUCTURE [2] method to allow for painting of individual samples against a panel of pre-calculated reference haplotype clusters, making the method computationally feasible for on-demand analysis of individuals. The choice of the reference panel also allows the user to tailor the analysis to emphasise targeted features of the data. For example, in the context of a personal ancestry imputation, panels may be constructed to focus on global-, continental-, or national-scale genetic features, and the low computational cost of painting an individual against a pre-computed panel makes sample-level exploratory analysis feasible. Another application of the panel-based painting is to use high-quality reference data to impute unknown geographical labels to samples where such information is either unavailable, or was collected at an undesirable resolution. To demonstrate the latter application, we analysed several populations with suspected Northern-European ancestry—including the Hapmap CEU and ASW populations, and the UK10K dataset—with respect to panels of Europeans and the high-resolution People of the British Isles (POBI) samples. These individuals are characterised in terms of an admixture of inferred clusters in the reference populations. Whilst many individuals were best described as an complex admixture that likely occurred over many generations, many others had a clear signal of geographically distinct ancestry. 1175T

Inference of local pedigrees using Markov Chain Monte Carlo. *A. Ko, R. Nielsen.* University of California, Berkeley, Berkeley, CA.

As genomic datasets used for GWAS and other genetic analyses become larger, the fraction of individuals who have at least one relative in the sample increases. Family relationships are typically either ignored, by removing related individuals, or is modeled using pairwise relatedness matrices. However, the pedigree structure in itself can provide valuable information and can help increase mapping power and provide improved estimates of heritability. Despite the importance of pedigree inference, existing methods are limited to inferring only close relationships or analyzing a small number of individuals or loci. We present the first full Markov chain Monte Carlo (MCMC) for estimating pedigrees in large samples of otherwise seemingly unrelated individuals. The method supports complex pedigree structures such as polygamous families, multi-generational families, and pedigrees in which many of the member individuals are missing. Computational speed is greatly enhanced by the use of a composite likelihood function which approximates the full likelihood. Using simulations, we show that the new method leads to improved estimates of relatedness and improved mapping power in GWAS studies.

1176F

Large-scale whole genome sequencing of the Estonian population reveals novel loss-of-function variants and new insights into the population history. *M. Metspalu[1], G. Hudjashov[1,2], M. Mitt[3], L. Pagani[1,4], L. Saag[1], M. Kals[3], K. Pärn[3], L. Milani[3], D. Lawson[5], T. Esko[3], A. Metspalu[3], R. Mägi[3].* 1) Estonian Biocentre, Tartu, Estonia; 2) Statistics and Bioinformatics Group, Institute of Fundamental Sciences, Massey University, Palmerston North, New Zealand; 3) Estonian Genome Center, University of Tartu, Tartu, Estonia; 4) Department of Biological Anthropology, University of Cambridge, Cambridge, United Kingdom; 5) Integrative Epidemiology Unit, School of Social and Community Medicine, 7 University of Bristol, Bristol BS8 2BN, UK.

Altogether 2244 whole genomes of geographically diverse individuals from Estonia were sequenced to a median depth of 30x using Illumina HiSeq with TruSeq PCR-free library preparation method. We found 19M SNVs and 6.6M indel variants with allele count larger than two and of which 8.4M were novel. Within this study we have analysed both loss-of-function variants revealed as well as the population structure of Estonia. We found a total of 14,531 autosomal loss-of-function (LOF) SNVs and indels in 6,991 genes. Out of these genes, 3.3% contained homozygous or compound heterozygotes LOF variants with minor allele frequency less than 2%. By combining the data of complete gene knockouts of individuals with their disease history and variety of available endophenotypes (proteomics, NMR, biochemistry) will help us to study the function of these genes and will lead to better understanding the phenotypic consequences of the variation within these genes. To study the fine-scale genetic structure of the Estonian population, we concentrate on a subset of the genomes (N=436), which comprehensively cover rural Estonia to minimize the mixing effect of historical urbanization. We further combine these genomes with a pan Eurasian panel of high coverage genomes from hundreds of populations. Using haplotype and allele frequency based methods we show that the genetic structure within Estonia is largely in line with the division of *inland* vs. *maritime* Estonia what has been proposed based on archaeological findings. Furthermore, we identify and quantify the relative contributions of the three major genetic domains of the European gene pool in Estonians and estimate split times from linguistically and geographically adjacent populations. We use Finestructure and inter-population doubleton distribution to reveal patterns of genetic sharing between Estonians and other European populations and infer population history in a series of population splits and admixture events in pre-historic and historic times.

1177W

Fine-scale population structure in southern Africa reflects ecoegeographic boundaries. *C.P. Uren[1], M. Kim[2], A.R. Martin[3,4], D. Bobo[2], C.R. Gignoux[5], P.D. van Helden[1], M. Möller[1], E.G. Hoal[1], B.M. Henn[2].* 1) SA MRC Centre for TB Research, DST/NRF Centre of Excellence for Biomedical Tuberculosis Research, Division of Molecular Biology and Human Genetics, Faculty of Medicine and Health Sciences, Stellenbosch University, Cape Town; 2) Department of Ecology and Evolution, Stony Brook University, Stony Brook, NY; 3) Analytic and Translational Genetics Unit, Department of Medicine, Massachusetts General Hospital, Boston, MA; 4) Program in Medical and Population Genetics, Broad Institute of Harvard and MIT, Cambridge, MA; 5) Department of Genetics, Stanford University, Stanford, CA.

Recent genetic studies have established that the KhoeSan populations of southern Africa are distinct from all other African populations and have remained largely isolated during human prehistory until about 2,000 years ago. Dozens of different KhoeSan groups exist, belonging to three different language families, but very little is known about population history within southern Africa. We examine new genome-wide polymorphism data and whole mitochondrial genomes for more than one hundred South Africans from the ≠Khomani San and Nama populations of the Northern Cape, analyzed in conjunction with 19 additional southern African populations. Our analyses reveal fine-scale population structure in and around the Kalahari Desert. Surprisingly, this structure does not always correspond to linguistic or subsistence categories as previously suggested, but rather reflects the role of geographic barriers and the ecology of the greater Kalahari Basin. Regardless of subsistence strategy, the indigenous Khoe-speaking Nama pastoralists and the N|u-speaking ≠Khomani (formerly hunter-gatherers) share recent ancestry with other Khoe-speaking forager populations that form a rim around the Kalahari Desert. We reconstruct earlier migration patterns and estimate that the southern Kalahari populations were among the last to experience gene flow from Bantu-speakers, approximately 14 generations ago. We conclude that local adoption of pastoralism, at least by the Nama, appears to have been primarily a cultural process with limited impact from eastern African genetic diffusion.

1178T

Local ancestry patterns inferred from one million genomes recapitulate fine-scale population history. *Y. Wang[1], K. Noto[1], J. Byrnes[1], R.E. Curtis[2], E. Han[1], E. Eyal[1], G. Harendra[1], P. Carbonetto[1], A.R Kermany[1], J.M. Granka[1], K.A. Rand[1], N.M. Natalie[2], E.L. Hong[1], C.A. Ball[1], K.G. Chahine[2].* 1) Ancestry.com DNA, LLC, San Francisco, CA; 2) Ancestry.com DNA, LLC, Lehi, UT.

In a country of immigrants, population structure is shaped by a long, ongoing history of immigration, followed by subsequent admixture and migration. All these events have left their footprints in the genomic landscape of current residents and make it possible for geneticists to reconstruct population history from genomic data. However, deciphering the signature of these forces requires accurate inference of genomic tracts that one individual inherits from ancestors of different origins. Previously, several methods have been developed for inferring local ancestry with varying levels of success. Unfortunately, none of these methods can be feasibly applied to a data set of one million genomes. Recently, our team presented *Polly*, a novel algorithm for estimating genome-wide ancestry proportions in admixed samples. *Polly*, built on a modified version of the BEAGLE haplotype model, relies on this model to achieve two things: First, to account for phasing uncertainly, and second, to provide a measure of distance between a query haplotype and a reference haplotype. Using haplotype models learned from hundreds of thousands of haplotypes and subsequently annotated with over eight thousand single-origin reference individuals, *Polly* performs ultra-fast inference of both global and local ancestry. In this study, we evaluate *Polly*'s accuracy in predicting local ancestry using simulated admixed samples with known genomic composition. We assess the assignment accuracy, the switching pattern and the tract length distribution. Using cross-validation experiment, we confirm that *Polly* makes highly accurate local ancestry estimates even at the subcontinental level. We further use *Polly* to analyze one million genomes from the United States and discover distinct local ancestry patterns among different ethnic groups and communities, especially among African Americans and Latino Americans. We map local ancestry estimates to individuals' geographic locations. Our results illustrate clear population structure arising from immigration routes, assortative mating and isolation by distance. We also find evidence that supports large-scale domestic migration events, as exemplified by the Great Migration of African Americans following the abolition of slavery. Finally, we attempt to date known historical events from ancestry tract length distributions. Overall, our analysis demonstrates the power of combining local ancestry analysis with big data in studying fine-scale population history.

1179F

Identifying type 1 diabetes risk variants in a low prevalence population.
S.S. Rich[1,2], S. Onengut-Gumuscu[1,2], W-M. Chen[1,2], E. Farber[1], J. Bonnie[1], P. Concannon[3,4], Type 1 Diabetes Genetics Consortium (T1DGC). 1) Center for Public Health Genomics, University of Virginia, Charlottesville, VA; 2) Department of Public Health Sciences, University of Virginia, Charlottesville, Virginia, USA; 3) Department of Pathology, Immunology and Laboratory Medicine, University of Florida, Gainesville, FL; 4) Genetics Institute, University of Florida, Gainesville,.

Type 1 diabetes (T1D) is one of a family of disorders characterized by dysregulation of glucose homeostasis. In T1D, an autoimmune process of unknown origin results in the destruction of the insulin-secreting pancreatic β cells and a life-long dependence on exogenously-administered insulin for survival. The reported incidence of T1D varies from 0.1 to 40.9 per 100,000 individuals, with the highest incidence rates in European ancestry populations and the lowest rates in Asian and African ancestry populations. To date, studies of the genetics of T1D have focused almost exclusively on European ancestry populations with ascertainment of large numbers of individual cases or multiple case families. GWAS and subsequent fine-mapping efforts, carried out by the T1DGC, identified more than 40 loci with significant evidence of association with T1D risk. Here, we extend these studies to subjects of African ancestry. We determine which of the T1D-associated SNPs in risk loci identified in European ancestry populations influence risk in African ancestry individuals, fine-map known T1D risk regions using linkage disequilibrium (LD) patterns in African ancestry samples, and identify new T1D risk loci. We densely genotyped 1036 T1D case and 3220 control samples of African ancestry using a custom genotyping panel (ImmunoChip), consisting of ~200K SNPs in 186 loci associated with autoimmunity (T1D and 11 other immune-mediated diseases). A total of 14 of the previously reported T1D risk loci exhibited evidence of association ($P < 1 \times 10^{-4}$) in the African ancestry T1D collection, and 4 other loci had nominal evidence of association ($1 \times 10^{-4} < P < 1 \times 10^{-3}$). We identified 2 novel regions (1q25.1, $P = 4.98 \times 10^{-7}$, OR=1.32, 95% CI=1.19–1.48, and 16q23.3, $P = 4.02 \times 10^{-7}$ OR=1.34, 95% CI=1.19–1.50) associated with T1D. The LD pattern differences between African and European ancestry samples have allowed us to refine associations in T1D risk loci, reducing the number of credible SNPs by 50% in many loci. The biological influence and detailed functional role of each risk variant will need to be further elucidated in future functional studies.

1180W

Emerging pattern of possible genetic and lifestyle risk factors associated with diabetic retinopathy: An Indian cohort study.
A. Bhanwer[1], R. Sikka[1], V. Vig[2]. 1) Human Genetics, Guru Nanak Dev University, Amritsar, Punjab, India; 2) Dr. Sohan Singh Eye Hospital, Amritsar Punjab, India.

Diabetic Retinopathy (DR) is a complex polygenic complication of T2D in which both genetic and environmental factors play cumulative role for the disease development and progression. The previous candidate gene studies mainly focused on *VEGF, RAGE, eNOS, TCF7L2*; *TNFα*; *ALR* and *ACE* polymorphisms. The major limitation of these studies was combining of heterogeneous phenotype in DR cases and smaller sample size. Therefore, the present study is designed to investigate the various lifestyle risk factors responsible for the predisposition/progression of DR and to undertake comprehensive analysis of 30 SNPs predisposing to DR in a large cohort from North-West India (Punjab). A total of 414 DR cases and 434 gender and ethnicity matched above the age of 50 years healthy controls were screened with the help of Sequenom MassARRAY technology. The clinical and anthropological data analysis revealed that the mean values of Waist, Hip circumference, Waist-Hip Ratio and Waist-Height Ratio were higher among cases which represented role of central obesity towards DR. History of hypertension [p<0.001; OR=13.64 (9.15=20.34)], male gender [p=0.003; OR=1.86 (1.22-2.81)], BMI [p<0.001; OR=1.31 (1.17-1.46)] and increasing age were the main risk factor for the DR. Single locus analysis revealed that *TCF7L2* rs12255372 and rs11196205 were significantly associated with DR (p<0.05). Haplotype analysis revealed that *TCF7L2* (rs12255372-rs11196205-rs6585205) C-T-T and C-T-G haplotype provided risk however, G-G-T and G-G-G haplotypes provided protection towards DR. Strong linkage disequilibrium was observed for *TLR-4*, *TCF7L2* and *AKR1B1* among controls. The present study provides some insights for the various lifestyle and genetic risk factors in the studied population. .

1181T

HLA-DPB1 and type 1 diabetes in Han Chinese. *Y. Lee[1,3,4], C. Huang[2], W. Ting[2,6], F. Lo[5], C. Lin[1], T. Chang[1], H. Yang[1], W. Lin[1].* 1) Dept Pediatrics & Med Res, MacKay Memorial Hosp, New Taipei City, Taiwan; 2) Dept Pediatrics, MacKay Children's Hospital; 3) Dept Pediatrics, Taipei Medical University; 4) Institute of Biomedical Sciences, MacKay Medical College; 5) Dept Pediatrics, Chang-Gung Memorial Hospital, Taoyuan, Taiwan; 6) Dept Nursing, MacKay Medicine, Nursing and Management College.

Type 1 diabetes (T1D) is an autoimmune disease characterized by T cell-mediated destruction of pancreatic β cells and the presence of autoantibodies against several β cell autoantigens. Both genetic susceptibility and environmental factors contribute to the pathogenesis.Because the destruction of insulin-producing β cells in type 1 diabetes is likely to involve the activity of CD4+ T lymphocytes and because T-lymphocyte activating is dependent on recognition of MHC class II molecules. We reported association between DPB1 gene and type 1 diabetes in Han Chinese living in Taiwan.**Patients**The subjects were 404 T1D patients (181 boys and 223 girls) aged 8.0 (SD 4.1) years. Patients had a HbA1c level of ≥6.5%, a fasting plasma glucose level ≥ 7 mmol/l (126 mg/dl) at least 2 times, or a random glucose level ≥11.1 mmol/l (200 mg/dl) with diabetic symptoms, and at least one of autoantibodies to islet cell antigens, glutamic acid decarboxylasee (GAD) and Islet antigen-2 (IA-2).**Controls**The 381 control subjects consisted of 135 males and 246 females. They included hospital personnel and individuals who underwent routine health examinations or minor surgery. None had a history of autoimmune disease.All patients and controls were Han Chinese in Taiwan. Our institutional review board approved this study and all subjects or their guardians gave informed consent.**Genotyping of the DPB1 gene**We used sequencing-based typing to genotype the DPB1 gene.**Statistical analysis**Statistical difference in genotype, allele, and carrier distributions between patients and controls were assessed by the chi-square test. Odds ratios (OR) and 95% confidence intervals were also calculated.The Bonferroni correction, Pc = 1 –(1-P)n, was used for multiple comparisons where Pc is the corrected P value, P the uncorrected value, and n the number of comparisons. In this study, n is 13 for each allele, or carrier. A Pc value of less than 0.05 was considered statistically significant.**Results**The DPB1*05:01 allele was the most frequent in patients (30.2%) and controls (46.7%). It was also significantly less frequent in patients than in controls, OR (95%CI)=0.49 (0.40-0.61), Pc = 2.16E-10. The DPB1*04:01 allele was the second most frequent in patients (25.9%) and in controls (6.7%) and conferred susceptibility of T1D, OR= 4.86 (3.59-6.59), Pc = 2.22E-23.**Conclusion**DPB1 was associated with T1D in Han Chinese in Taiwan. DPB1*04:01conferred susceptibility to T1D while *05:01 rendered protection against T1D.

1182F

Childhood predictors of adult fatty liver - The Cardiovascular Risk in Young Finns Study. *A. Ahola-Olli[1], M. Oikonen[1], N. Pitkänen[1], E. Suomela[1], J. Virtanen[2], R. Parkkola[2], E. Fatty liver without excessive alcohol consumption is the most common form of chronic liver disease in obese and diabetic people living in the Western countries. Since there is no cure for advanced fatty liver, the prevention of this disease is vital. The main modifiable risk factors assocaited with fatty liver include obesity, hyperlipidemia and type 2 diabetes. These risk factors tend to track from childhood to adulthood and therefore their early prevention is important. The current study aims to identify childhood risk factors that are associated with fatty liver later in adulthood. The study includes 3,596 Finnish children at baseline who have been followed for over 30 years. The subjects were randomly chosen from national population registers from cities of Tampere, Turku, Helsinki, Oulu, Kuopio and Turku in addition to their rural surroundings. The study began in 1980 and the latest follow-up study was organized in 2011. This follow-up included liver ultrasound examination along with extensive laboratory measures. Genes previously associated with liver fat accumulation include *PNPLA3* and *TM6SF2*. Variants from these genes (rs738409 and rs58542926) predict the development of fatty liver (OR (95 %CI) 1.63 (1.29-2.07); 1.57 (1.08-2.30), respectively) after adjusting for age, sex, body-mass index, insulin concentration, and birth weight. When the genetic variants from *PNPLA3* and *TM6SF2* were added to prediction model containing standard clinical risk factors the net reclassification and integrated discrimination index were significantly improved. Our results demonstrate that prediction of adulthood fatty liver can be significantly improved after taking genetic factors in account. This kind of genetic risk stratification can be used to target treatments to high risk individuals. This could reduce the number of subjects needed to treat in order to prevent one clinical end point.

1183W

Thrifty functional characteristics of the major variant in *CREBRF* associated with body mass index in Samoans. *C.T. Su[1], R.L. Minster[1], N.L. Hawley[2], E.E. Kershaw[3], R. Deka[4], D.E. Weeks[1,5], S.T. McGarvey[6,7], Z. Urban[1]. 1)* Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 2) Department of Epidemiology (Chronic Disease), Yale University School of Public Health, New Haven, CT; 3) Department of Medicine, Division of Endocrinology, University of Pittsburgh, Pittsburgh, PA; 4) Department of Environmental Health, University of Cincinnati College of Medicine, Cincinnati, OH; 5) Department of Biostatistics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 6) International Health Institute, Department of Epidemiology, Brown University School of Public Health, Providence, RI; 7) Department of Anthropology, Brown University, Providence, RI.

Pacific islanders, and among them Samoans, have the highest rates of obesity worldwide. Our genome-wide association study of body mass index in Samoans and subsequent targeted sequencing, fine mapping and selection studies, identified a nonsynonymous coding variant (rs373863828, c.1370G>A, p.Arg457Gln) in *CREBRF* as the most significantly associated and likely causative variant. To evaluate the functional consequences of this variant, we performed overexpression, knockdown, adipocyte differentiation, neutral lipid accumulation and metabolic profiling studies using a mouse 3T3-L1 pre-adipocyte cell model. Overexpression of *CREBRF* significantly induced adipocyte differentiation, lipid accumulation, glycolysis, oxidative phosphorylation, and protected cells from starvation-induced death. Knockdown of *CREBRF* produced the opposite effect for each of these variables. Overexpression of the p.Arg457Gln variant *CREBRF* increased lipid accumulation more than wild type, but decreased both glycolysis and oxidative phosphorylation. However, it protected against starvation-induced cell death the same as the wild type *CREBRF*. Thus, p.Arg457Gln variant could cause obesity-related cellular phenotypes by promoting the accumulation of neutral lipids while using less energy than wild type *CREBRF*. Prioritization of nutritional energy storage over energy use by p.Arg457Gln *CREBRF* supports a "thrifty variant" hypothesis for obesity and suggests that this variant could be selected for in populations subject to nutritional insecurity, as archeological and historical evidence indicates Samoans may have been.

1184T

Identification of interactions in the *MADD-PTPRN-RAB3* complex with type 2 diabetes in multiple populations. *G. Chen[1], T. Cai[2], F. Tekola-Ayele[1], A. Doumatey[1], J. Zhou[1], A. Adeyemo[1], A. Notkins[2], C. Rotimi[1]. 1)* NHGRI/NIH, National Institutes of Health, Bethesda, MD; 2) NIDCR/NIH, National Institutes of Health, Bethesda, MD.

The missing heritability for complex traits including type 2 diabetes (T2D) remains a major unresolved challenge; It has been hypothesized that gene-gene interactions may explain some of this missing heritability. Genes encoding proteins in insulin pathway of islet beta cells are known to be associated with T2D. We investigated gene-gene interactions among *MADD, PTPRN/PTPRN2*, and *RAB3A/RAB3C*, three genes that encode proteins known to form a complex that has a molecular link with insulin-containing dense core secretory vesicles (DCVs). Using the model based multifactor dimensionality reduction (MB-MDR) method , we identified statistically significant gene–gene interactions among these genes with respect to T2D status in eight independent studies, including exome SNP array analyses in three studies [i.e., the Africa America Diabetes Mellitus (AADM, n = 2,189, p value 3.1×10^{-5}), Howard University Family Study (HUFS, n = 1,841, p value 4.7×10^{-5}), Chinese American Diabetes Mellitus (CADM, n = 1,908, p value 5.7×10^{-6})]. The other studies were GWAS SNP array analyses in five additional studies [i.e., the Atherosclerosis Risk in Communities study (ARIC, n = 3,137, p value 3.9×10^{-8}) , Cleveland Family Study (CFS, n = 653, p value 6.2×10^{-8}), HUFS (n = 1,976, p value 4.0×10^{-9}), Jackson Heart study (JHS, n = 2,187, p value 4.7×10^{-8}), and Multi Ethnic Study of Atherosclerosis (MESA, n = 1,611, p value 1.9×10^{-5})]. Notably, single gene analyses did not find any significant association between these genes and T2D in any of these studies. These interactions are consistent with previous studies that showed a molecular link between the MADD, PTPRN/PTPRN2, and RAB3A/RAB3C complex and insulin-containing DCVs. *PTPRN/PTPRN2* is a specific linker for tethering *MADD-RAB3A/RAB3C* complex (in *MADD* domain) to DCV. MADD is implicated in the GDP/GTP exchange of RAB3A/RAB3C to provide energy to move cargo to membrane and release insulin. In summary, gene–gene interactions between *MADD, PTPRN/PTPRN2*, and *RAB3A/RAB3C* were identified in association with T2D across eight independent multi-ethnic studies that included a total of 15,502 participants. The underlying biological mechanism is likely to involve how the complex of *MADD, PTPRN/PTPRN2*, and *RAB3A/RAB3C* is linked to DCVs thereby influencing the process of insulin release.

1185F

An exome-wide association study for type 2 diabetes-attributed end-stage kidney disease in African Americans. *M. Guan[1,2], J.M. Keaton[2], L. Dimitrov[2], P. Mudgal[2], P.J. Hicks[2], J.G. Wilson[3], B.I. Freedman[4], D.W. Bowden[2,5,6], M.C.Y. Ng[2,5].* 1) Integrative Physiology and Pharmacology Program, Wake Forest School of Medicine, Winston-Salem, NC, USA; 2) Center for Human Genomics and Personalized Medicine Research, Wake Forest School of Medicine, Winston-Salem, NC, USA; 3) Department of Physiology and Biophysics, University of Mississippi Medical Center, Jackson, MS, USA; 4) Department of Internal Medicine, Wake Forest School of Medicine, Winston-Salem, NC, USA; 5) Center for Diabetes Research, Wake Forest School of Medicine, Winston-Salem, NC, USA; 6) Department of Biochemistry, Wake Forest School of Medicine, Winston-Salem, NC, USA.

African Americans (AAs) are at higher risk for developing end-stage kidney disease (ESKD) compared to European Americans. Genome-wide association studies (GWAS) have identified variants associated with diabetic and non-diabetic kidney disease. However, common SNPs identified in GWAS are largely non-coding variants, have modest effects, and cumulatively explain only a small proportion of disease variance. Therefore, we evaluated the contribution of coding variants in type 2 diabetic (T2D) patients on dialysis or with high risk for T2D-ESKD (eGFR<30 ml/min/1.73 m^2). Exome-sequencing data in 1,391 AA subjects including 456 T2D-ESKD cases and 935 non-diabetic, non-nephropathy controls from the T2D-GENES Consortium were examined. Single-variant association was performed for an additive effect with a mixed logistic regression model that corrects for sample structure and hidden relatedness using the analysis package GMMAT. A total of 618 nominal associations ($P<0.01$) from exome-sequencing were replicated in 2,041 T2D-ESKD cases and 1,140 non-diabetic, non-nephropathy controls genotyped on a custom array. Discrimination analysis in 667 T2D cases lacking nephropathy was performed to exclude T2D-associated SNPs. Meta-analysis of 4,572 discovery and replication samples revealed five modest associations ($P<1E-4$) with T2D-ESKD at *DLGAP5* (rs10144326), *PRX* (rs268671), *APOL1* (rs73885319), *RAD51AP2* (rs834514) and *RREB1* (rs41302867). Removal of *APOL1* renal-risk genotype carriers identified an additional association at *IGSF22* (rs61886892) and confirmed association in *RREB1* (rs41302867). Coding variants at *PRX* (rs268671, V882A, $P=2.54E-5$, OR=1.33), *APOL1* (rs73885319, S338G, $P=1.21E-5$, OR=1.32), and *RAD51AP2* (rs834514, G1037D, $P=3.95E-5$, OR=1.32) are predicted to disrupt protein function. These findings may partially explain the genetic predisposition to T2D-ESKD in AAs. Future directions include replication in additional AA populations and evaluation of the contribution of T2D-ESKD associated genetic variants to the susceptibility of non-diabetic ESKD. Functional studies are also warranted to illustrate the potential mechanisms underlying the effect of these newly identified genetic associations.

1186W

Exome sequencing of >20,000 Finnish individuals identifies rare variants influencing cardiovascular and metabolic phenotypes. *A.E. Locke[1,2], K.M. Steinberg[1], S. Service[3], H. Abel[1], V. Ramensky[3], M. Pirinen[4], L. Stell[5], C. Chiang[3], H.M. Stringham[2], A.U. Jackson[2], P. Yajnik[2], D. Ray[2], D.E. Larson[1], D.C. Koboldt[1], L.J. Scott[2], R.S. Fulton[1], J. Nelson[1], T.J. Nicholas[1], N.O. Stitziel[1], I.M. Hall[1], C. Sabatti[5,6], S. Ripatti[4,7,8], V. Salomaa[9], A. Palotie[4,7,10], M. Laakso[11], M. Boehnke[2], R.K. Wilson[1], N. Freimer[3].* 1) McDonnell Genome Institute, Washington University School of Medicine, Saint Louis, MO; 2) Department of Biostatistics and Center for Statistical Genetics, University of Michigan, Ann Arbor, MI; 3) Center for Neurobehavioral Genetics, Semel Institute for Neuroscience and Human Behavior, University of California Los Angeles, Los Angeles, CA; 4) Institute for Molecular Medicine Finland (FIMM), University of Helsinki, Helsinki, Finland; 5) Department of Biomedical Data Science, Stanford University, Stanford, CA; 6) Department of Statistics, Stanford University, Stanford, CA; 7) Department of Public Health, Hjelt Institute, University of Helsinki, Helsinki, Finland; 8) Wellcome Trust Sanger Institute, Hinxton, Cambridge, UK; 9) National Institute for Health and Welfare, Helsinki, Finland; 10) Broad Institute of MIT and Harvard, Cambridge, MA; 11) Institute of Clinical Medicine, Internal Medicine, University of Eastern Finland, Kuopio, Finland.

Low frequency, deleterious variants are enriched in the Finnish population due to recent bottlenecks, increasing power to detect genetic associations for complex traits. We sequenced the exomes of 20,029 individuals from two large population-based longitudinal studies of metabolic and cardiovascular disease in Finland: METSIM and FINRISK. We identified >1.5M SNPs and >138,000 short indels, of which nearly 90% have MAF<1%; 44,126 are loss-of-function, and 420,940 are protein-altering. PolyPhen2 predicts 168,969 of these non-synonymous SNPs to be damaging to the resulting protein, and 54,933 are predicted to be damaging by five different prediction algorithms used in Purcell et al. (Nature 2014). In addition to this robust genetic dataset, we have data for 255 quantitative measures of cardiovascular and metabolic health, covering lifestyle factors, anthropometrics and obesity, blood pressure, kidney function, inflammation, glycemic traits, and >200 measures from proton NMR. The population history of Finland, the breadth of phenotypes, and the large scale of this exome sequencing study allow us a unique opportunity to identify rare coding variation influencing cardiovascular and metabolic traits. We tested each phenotype for genetic associations using EMMAX and EMMAX-SKAT-O. Using an exome-wide significance level of $5x10^{-7}$, we identified 248 associations at 79 variants with MAF<1% in 112 unique phenotypes. Sixty associations, at 13 variants, remain significant after Bonferroni correction based on an assumption of 255 independent traits ($1.9x10^{-9}$). We continue to work with multivariate approaches to account for the correlation between phenotypes. Among the associated rare variants are two missense variants in *GLDC* (MAFs=.0098 and .0025) and a premature stop codon in *ALDH1L1* (MAF=.0026) associated with glycine levels, a frameshift variant (MAF=.0015) in *SLC16A10* associated with increased tyrosine levels, a splice variant in *ADIPOQ* (MAF=.0026) associated with decreased adiponectin, a splice donor variant in *CETP* associated with increased serum ApoA1, and a premature stop variant and splice variant (MAFs=.0001) in *PKD1* both associated with increased serum creatinine levels. We also identified a splice donor variant in *APOC3*; missense variants in *LIPC*, *LIPG, and CD300LG;* frameshift variants in *LDLR* and *ANGPTL4*; and a premature stop variant in *c19orf80* associated with altered levels of multiple lipoprotein particles, primarily subclasses of LDL and HDL.

   Insulin resistance (IR) and impaired insulin secretion contribute to type 2 diabetes and cardiovascular disease. Both are associated with changes in the circulating metabolome, but causal directions have been difficult to disentangle. We combined untargeted plasma metabolomics by liquid chromatography/mass spectrometry in three non-diabetic cohorts with Mendelian Randomization (MR) analysis to obtain new insights into early metabolic alterations in IR and impaired insulin secretion. In up to 910 elderly men we found associations of 52 metabolites with hyperinsulinemic-euglycemic clamp-measured IR and/or β-cell responsiveness (disposition index). These implicated bile acid, glycerophospholipid and caffeine metabolism for IR and fatty acid biosynthesis for impaired insulin secretion. In MR analysis including two additional cohorts (n = 3,342) followed by replication in three independent studies profiled on different metabolomics platforms (n = 7,824 / 8,961 / 8,330), we discovered and replicated causal effects of IR on lower levels of palmitoleic acid and oleic acid, as well as on higher levels of tyrosine. In summary, in one of the largest studies combining "gold standard" measures for insulin responsiveness with non-targeted metabolomics, we found distinct metabolic profiles related to IR or impaired insulin secretion. We hypothesize that the causal effects on monounsaturated fatty acid levels explain parts of the raised cardiovascular disease risk in IR that is independent of diabetes development.

   Glycated hemoglobin (HbA1c;%) is produced by non-enzymatic glycation of hemoglobin by glucose, and widely used as a long-term biomarker of glycemic status. We previously identified a genome-wide significant signal for HbA1c in 1,721 Singapore Malays without diabetes from the Singapore Malay Eye Study (SiMES) ($P = 3.89\times10^{-22}$) on chromosome 17q21.31. The lead SNP rs12603404 (MAF = 3%) was an intronic variant in *C17orf53*, and the minor allele was associated with lower HbA1c by 0.33%. However, this association was not replicated in other populations where allele frequencies were similar. To test the hypothesis that this represents an ancestry-specific association, we extended our study to an independent set of 1,003 Singapore Malays and 1,206 Singapore Chinese with both genome-wide array and whole exome sequences. We replicated the association at this locus with meta-analysis combined P-value of 2.15×10^{-34} in 2,724 Malays (lead variant chr17: 4227290; intronic on *ATXN7L3*). No association was observed in Chinese. We further tested the exome sequence data for association with HbA1c in Malays, and the lead variant was a 27bp deletion chr17:42335410 on *SLC4A1* (MAF = 1.5%; $P = 9.33\times10^{-11}$). This deletion was not observed in Chinese. Conditional analysis on the 27bp del eliminated the association at both rs12603404 and chr17: 4227290. Adjustment for fasting glucose did not attenuate the association with HbA1c. We then combined GWAS array and exomes to create a Malay-specific reference panel, and imputed the 27bp del into SiMES. The strongest association with HbA1c in SiMES was observed at the well-imputed 27bp del (imputation $R^2 = 0.94$; $P = 1.38\times10^{-32}$). We confirmed a population-specific association between a 27bp deletion at *SLC4A1* and HbA1c in Malays (meta-analysis beta = -0.53%; $P = 1.38\times10^{-39}$). This deletion results in the deletion of nine amino acids from *SLC4A1*, and is the cause of Southeast Asian ovalocytosis, an asymptomatic hereditary red blood cell condition (OMIM #166900), suggesting that this association is mediated via a non-glycemic pathway. The presence of this variant may have implications for the diagnosis of diabetes using HbA1c in this population.

Aggregate effects of type 2 diabetes genetic loci on diabetic retinopathy in a multi-ethnic Asian population. *C.Y. Cheng[1,2,3], Y.H. Chong[2], Y.C. Tham[1], A. Gan[1], S.P. Tan[1], G. Tan[1,2], J.J. Wang[4], P. Mitchell[4], T.Y. Wong[1,2,3], The Singapore Epidemiology of Eye Diseases Study.* 1) Singapore Eye Research Institute, Singapore National Eye Centre, Singapore; 2) Duke-NUS Medical School, Singapore; 3) Department of Ophthalmology, Yong Loo Lin School of Medicine, National University of Singapore, Singapore; 4) Centre for Vision Research, Department of Ophthalmology and Westmead Millennium Institute, University of Sydney, Sydney, Australia.

   Purpose: Genetic association studies to date have not identified any widely reproducible risk loci for diabetic retinopathy (DR). We hypothesized that individuals having more diabetes genetic risk alleles had a higher risk of developing DR. We aimed to evaluate the aggregate effects of multiple type 2 diabetes-associated genetic variants on DR.   Research Design and Methods: A total of 1528 diabetic participants (480 Malays, 750 Indians and 298 Chinese) were recruited from the Singapore Epidemiology of Eye Diseases Study, of which 547 (35.8%) were diagnosed to have DR. Participants underwent a comprehensive ocular examination, including dilated fundus photography. Retinal photos were graded using the modified Airlie House classification system to assess the presence and severity of DR following a standardized protocol. We identified 76 previously discovered type 2 diabetes-associated single nucleotide polymorphisms (SNPs) and constructed multi-locus genetic risk scores (GRSs) for each individual by summing the number of risk alleles for each SNP weighted by the respective effect estimates on DR. Two GRSs were generated: an overall GRS that includes all 76 discovered type 2 diabetes-associated SNPs, and an Asian-specific GRS that includes a subset of 55 SNPs which were previously found to be associated with type 2 diabetes in East and/ or South Asian ancestry populations. Associations between the GRSs with DR were determined using linear and logistic regression analyses. Discriminating ability of the GRSs was determined by the area under the receiver operating characteristic curve (AUC).   Results: Participants in the top tertile of the overall GRS were 2.56 times (95% CI: 1.92–3.40, P = 1.5 x 10[-10]) likely to have DR compared to participants in the bottom tertile. Participants in the top tertile of the Asian-specific GRS were 2.00 times (95% CI: 1.51–2.65, P = 1.3 x 10[-6]) likely to have DR compared to participants in the bottom tertile. Both GRSs were associated with higher DR severity levels (P < 0.001). We did not observe any inter-ethnic differences. Addition of the GRSs to traditional risk factors improved the AUC modestly (AUC difference = 0.02–0.03, P < 0.05). Conclusions: GRSs constructed from type 2 diabetes-associated SNPs were significantly associated with greater risks of DR. Our findings may provide new insights to further our understanding of the genetic pathogenesis of DR.

1190T

Relative contribution of type 1 and type 2 genetic risk loci to latent autoimmune diabetes in adults. *D.L. Cousminer[1,2], R. Mishra[1], A. Chesi[1], M.I. Hawa[3], J.P. Bradfield[1], K.M. Hodge[1], V.C. Guy[1], H. Hakonarson[1], D. Mauricio[4], N. Schloot[5], K.B. Yderstræde[6], B.F. Voight[2], S. Schwartz[7], R.D. Leslie[3], B.O. Boehm[8,9], S.F.A. Grant[1,2].* 1) Children's Hospital of Philadelphia, Philadelphia, PA; 2) University of Pennsylvania, Philadelphia, PA; 3) Queen Mary University of London, London, UK; 4) Hospital Universitari Germans Trias i Pujol, Spain; 5) German Diabetes Center, Düsseldorf, Germany; 6) Odense University Hospital, Odense, Denmark; 7) Main Line Health System, Wynnewood, PA; 8) University of Ulm , Ulm, Germany; 9) Nanyang Technological University, Singapore.

   Latent autoimmune diabetes in adults (LADA) exhibits features of both type 1 (T1D) and type 2 diabetes (T2D), and its genetic etiology remains largely unresolved. In this study, we investigated 67 T1D and 71 T2D established genetic risk loci in a large cohort of LADA cases to assess where LADA is situated relative to these two well-characterized, classic forms of diabetes. We tested the association of these loci in 978 LADA cases recruited from the ActionLADA and German multicenter studies versus 1,057 healthy North American controls with European ancestry, and tested the difference between the LADA effect size versus that in T1D or T2D from the Wellcome Trust Case Control Consortium. We found that LADA is genetically more similar to T1D than to T2D, with the exception of an association at the T2D *HNF1A* locus (*P* = 3.4 x 10[-4]). Several T1D loci were associated with LADA (P < 7 x 10[-4]), including the major histocompatibility complex (MHC), as well as the *PTPN22*, *NAA25*, and *INS* loci. Contrary to previous studies, the key T2D risk allele at *TCF7L2* (rs7903146-T) was not associated with LADA and had a significantly lower frequency in LADA than in T2D cases (*P*difference = 5.21 x 10[-6]). A genetic risk score (GRS) weighted across T1D loci also better distinguished between LADA cases and controls than one constructed from T2D loci (AUC = 0.63 and 0.57, respectively). Furthermore, in LADA cases positive for two diabetes autoantibodies (GAD and IA2), the similarity between LADA and T1D became more apparent, both for individual variants and the performance of the T1D GRS (AUC = 0.71). Our results show that the genetic spectrum of T1D extends into adulthood and cases who do not initially require insulin; however, the genetic load of T1D risk alleles is less severe than in childhood-onset T1D. Additionally, T2D genetic risk also plays a small role in LADA, highlighting the potential for GRS in reclassifying and understanding diabetes subtypes.

1191F

Effect of genetic polymorphism of OCT and MATE transporters on metformin response in Korean type 2 diabetes mellitus patients. *N. Gu[1], J.E. Park[2], K.H. Shin[2].* 1) Department of Clinical Pharmacology and Therapeutics, Dongguk University College of Medicine and Ilsan Hospital, Goyang, Republic of Korea; 2) Pharmacotherapy & Translational Research Lab. College of Pharmacy & Research Institute of Pharmaceutical Sciences, Kyungpook National University, Daegu, Republic of Korea.

Background: Metformin is an oral antihyperglycemic agent, the most widely used to treat type 2 diabetes. It improves insulin sensitivity and decreases the insulin resistance. Metformin is transported into the hepatocytes and renal epithelium by organic cation transporter (OCTs) and then excreted into the bile and urine by multidrug and toxin extrusion (MATE). The current study was aimed to evaluate influence of genetic polymorphism of several transporters on metformin response in T2DM patients. **Methods:** Twenty Korean type 2 diabetic patients prescribed metformin were enrolled in the study. Their hemoglobin A1c (HbA1c), fasting plasma glucose (FPG) and insulin levels were measured at baseline, 3 months and 4 months after the first administration. We classified responders as follows; whose HbA1c levels at the end of 3 months decreased by more than 0.5% from the baseline. To evaluate the influence of genetic polymorphisms of OCT1, OCT2, OCTN1, MATE1 and MATE2-K, genomic DNA was extracted and analyzed using Taqman genotyping kit by real-time PCR. **Results:** The analysis was carried out for 20 patients with 7 responders and 13 non-responders. HbA1c %change (mean standard deviation) in responders and non-responders were -1.00 0.48, 0.003 0.34., respectively. For genotype frequencies of OCTN1 (rs272893), both CC and CT types were 43% in responders, otherwise CT type (84.62%) is the highest in non-responders. For MATE1 (rs2289669) genotype, the highest type was AG gene as 71% in responders and the next was AA type (50%) in non-responder group. **Conclusion:** Among the five selected genes, genetic polymorphisms of OCTN1 and MATE1 showed different pattern between responder and non-responder groups.

1192W

Prevalence of vitamin D receptor (*VDR*) gene polymorphisms in Kuwaiti Arab children with type-1 diabetes mellitus. *M.Z. Haider[1], M.A. Rasoul[1,4], M. Al-Mahdi[2], H. Al-Kandari[3], G.S. Dhaunsi[1,4].* 1) Dept Pediatrics, Fac Med, Kuwait Univ, Safat, Kuwait; 2) Dept Pediatrics, Al-Adan Hospital, Kuwait; 3) Dept Pediatrics, Farwania Hospital, Kuwait; 4) Dept Pediatrics, Mubarak Al-Kabeer Hospital, Kuwait.

Introduction & Objectives: Type-1 Diabetes Mellitus (T1DM) is a multifactorial disease in which a complex interplay of genetic and environmental factors modulate the immune system and result in destruction of insulin producing beta cells in pancreas. Recent evidence indicate that production and degradation of vitamin D is a major signaling component in both innate and adaptive immunity. We have determined the prevalence of four *VDR* gene polymorphisms and measured serum vitamin D levels in Kuwaiti children with T1DM and controls to evaluate their relationship with the disease onset. Methods: This study included 210 Kuwaiti children with T1DM and 136 ethnically matched controls. The ISPAD criteria was used for diagnosis of T1DM. The control subjects were healthy and were evaluated by a Diabetes specialist. The genotypes of four *VDR* gene polymorphisms (*Bsm*I, *Fok*I, *Apa*I and *Taq*I) were identified by PCR-RFLP. Serum vitamin D levels were determined by enzyme immunoassay method. The study was approved by KIMS-HSC Ethics Committee. Results: The genotype frequency of all four *VDR* gene polymorphisms was found to be significantly different between T1DM patients and controls. The genotype frequencies of all four polymorphisms were correlated with serum vitamin D levels in T1DM patients and controls. Serum vitamin D levels were significantly lower in T1DM patients compared to controls in the case of all genotypes except for bb genotype (minor allele) of the *VDR* gene *Bsm*I polymorphism. Conclusions: Our data demonstrate that four *VDR* gene polymorphisms (*Bsm*I, *Fok*I, *Apa*I and *Taq*I) show strong association with T1DM onset and with lower serum vitamin D levels in T1DM patients. Therefore *VDR* gene polymorphisms can be considered as important determinants of genetic predisposition of T1DM in Kuwaiti children.

1193T

Overall and central obesity with insulin sensitivity and secretion in a Han Chinese population: A Mendelian randomization analysis. *C. Hu.* Shanghai Diabetes Institute, Shanghai Jiao Tong University Affiliated Sixth People's Hospital, 600 Yishan Road, Shanghai, 200233, China.

Objective: We aimed to characterize the causal role of obesity in insulin sensitivity and secretion by using Mendelian randomization (MR) approach with genetic variants for measuring overall and central obesity. Research design and methods: We constructed two genetic risk scores (GRSs) based on 38 established loci for body mass index (BMI; a surrogate of overall obesity) and 13 waist-to-hip ratio (WHR; a surrogate of central obesity) to assess the causal effects of BMI and WHR on several glycemic-related traits in 2884 community-based Han Chinese individuals. Results: Both of BMI and WHR were observationally correlated with the glycemic-related traits, including insulin sensitivity and secretion indices. We demonstrated these associations were partly causal in MR analysis. A genetically determined one standard deviation (SD, 3.35 kg/m^2) higher BMI caused a unit of 178.18 pmol/L higher Stumvoll 1st phase and 35.52 pmol/L higher Stumvoll 2nd phase insulin secretion (P range from 0.001 to 0.002), which were even independent of central obesity (P range from 0.019 to 0.039). In contrast, a genetically determined 1 SD higher WHR (the change of 0.002 in WHR) caused a unit of 1.21 higher HOMA-IR and 18.40 lower Gutt index (representing the insulin sensitivity) (P=0.048 and 0.028, respectively). Conclusions: We provided the causal evidence that overall obesity affects to some extent compensatory insulin secretion but central obesity inversely links to insulin sensitivity in Han Chinese population.

1194F

Clinical whole exome sequencing in early onset diabetes patients. *S. Kwak[1], C. Jung[1], C. Ahn[1,2], J. Park[3], J. Chae[4], H. Jung[1], Y. Cho[1,2], D. Lee[5], J. Kim[4], K. Park[1,2,6].* 1) Department of Internal Medicine, Seoul National University Hospital, Seoul, South Korea; 2) Department of Internal Medicine, Seoul National University College of Medicine, Seoul, Korea; 3) New Business Division, SK Telecom, Seongnam, Gyeonggi-Do, Korea; 4) Department of Biomedical Sciences, Seoul National University College of Medicine, Seoul, Korea; 5) Department of Internal Medicine, Wonkwang University School of Medicine & Hospital, Iksan, Korea; 6) Department of Molecular Medicine and Biopharmaceutical Sciences, Graduate School of Convergence Science and Technology, Seoul National University, Seoul, Korea.

AIMS There could be an overlap of monogenic diabetes and early onset type 2 diabetes in those who are diagnosed before age of 30 years. Genetic diagnosis in these patients might improve quality of care. There are limited experience of using whole exome sequencing (WES) in Asian early onset diabetes patients and the clinical utility of WES is largely unknown. METHODS We performed whole exome capture and massive parallel sequencing in 28 early onset diabetes patients. Those who had strong family history of diabetes were preferentially enrolled. Rare and non-silent variants in 29 genes known to cause monogenic diabetes including 12 maturity-onset diabetes of the young (MODY) genes were investigated for its pathogenicity. RESULTS Average depth of on-target reads of WES was 97X. For the 29 genes of interest, 90% of sequences were covered for more than 20X. A total of four pathogenic or likely pathogenic rare missense variants (p.Leu319Pro of *HNF4A*, p.His103Tyr and p.Arg74Gln of *ABCC8*, and p.Leu139Val of *HNF1A*) in MODY genes were identified in three patients. Although four rare non-silent variants in MODY genes (p.Arg183Cys in *PAX4*, p.Val139Ile and p.Pro740fs in *CEL*, and p.Val147Ile in *HNF4A*) and two in monogenic diabetes genes (p.Glu169Lys in *WFS1*, and p.Pro407Gln in *GATA4*) were identified, their pathogenicity was uncertain. CONCLUSIONS WES could be an initial option for genetic testing in early onset diabetes patients. However, sufficient and universal coverage of genes of interest is required. In addition, there could be difficulties in interpreting variant pathogenicity and might require further validation.

1195W

Differential effects of genetic variants from across the allelic frequency spectrum at the 2q36.3-IRS1 locus on fasting insulin. *A. Leong[1], A.K. Manning[2], N. Nikpoor[3], CHARGE, T2D-GENES, GoT2D, and UK10K.* 1) Massachusetts General Hospital, Division of General Internal Medicine, 9th floor, Boston, MA, 02114, USA; 2) Massachusetts General Hospital, Richard B. Simches Research Center-7, 185 Cambridge St, Boston, MA, 02114, USA; 3) McGill University and Genome Quebec Innovation Centre, 740 Penfield, Room 6213, Montreal, Quebec, H3A 0G1, Canada.

Genome-wide association studies (GWAS) have identified a cluster of common single nucleotide variants (SNV) within a gene desert at 2q36.3 to be associated with fasting insulin (FI), type 2 diabetes, insulin resistance and cardiovascular disease. *IRS1*, residing ~500 kb away, has been implicated as the putative causal gene through long-range enhancer-promoter interactions. We hypothesize that rare and low-frequency SNVs at the 2q36.3-*IRS1* locus may have relatively large effects on FI. We sought to identify novel and potentially functional SNVs associated with FI after body mass index adjustment from across the allelic frequency spectrum at this locus. We examined sequencing data (5x-50x depth) at 2q36.3-*IRS1* from 8493 non-diabetic individuals in 7 studies, FHS, ARIC, CHS, RS, UK10K, GoT2D and T2D-GENES, and combined results in an inverse-variance weighted fixed effects meta-analysis. We then performed stepwise conditional analyses to identify additional distinct signals of SNVs with MAF≥1%. To examine the combined effects of SNVs, we piloted a haplotype analysis in FHS. We annotated SNVs using ENCyclopedia Of DNA Elements data to indicate regulatory sites. We used Madsen-Browning Burden tests and Sequence Kernel Association Tests to determine whether aggregated rare variants (MAF<1%) at regulatory sites were associated with FI. Of 331 SNVs with MAF≥1%, 30 reached $P<1.5 \times 10^{-4}$ (Bonferroni correction: 0.05/331); one was a low-frequency SNV (rs62188785; MAF=4.1%; $P=8 \times 10^{-5}$), 15kb upstream of the long-non coding RNA, LOC646736, near a putative enhancer, and 537kb away from *IRS1*. Conditioning on the most significant SNV (rs952227, MAF=32%, $P=4 \times 10^{-6}$), a known GWAS signal for FI, revealed that rs62188785 was a distinct signal (conditional $P=9 \times 10^{-4}$) whose minor allele had an effect in the opposite direction to the minor allele of rs952227. A generalized linear model regression analysis of FI on haplotypes showed that the haplotype containing the major allele at rs952227 and the minor allele at rs62188785 was associated with higher FI (HF=3.3%; $P=7 \times 10^{-3}$) compared to the most common haplotype (global P=0.03; N=842). Results from tests that aggregated rare variants at transcription factor binding sites, LOC646736, enhancers and *IRS1* were not statistically significant. In sum, through sequencing of 2q36.3-*IRS1*, we discovered a low-frequency SNV independent of the GWAS index SNP. Investigating the functional consequence of this SNV may identify a role for *LOC646736* on FI.

Genome-wide association study identifies new type 2 diabetes risk loci in Jordan subpopulations. *J. Li[1], R. Dajani[2], Z. Wei[3], Y. Khader[4], N. Hakooz[5], R. Fatahallah[6], M. El-Khateeb[6], A. Arafat[6], T. Saleh[2], A. Dajani[2], Z. Al-Abbadi[2], M. Abdul Qader[2], A. Shiyab[7], H. Hakonarson[1,8,9].* 1) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Department of Biology and Biotechnology, Hashemite University, Zarqa, Jordan; 3) Department of Computer Science, New Jersey Institute of Technology, Newark, NJ; 4) Department of Community Medicine, Public Health and Family Medicine, Faculty of Medicine, Jordan University for Science and Technology, Irbid, Jordan; 5) Department of Biopharmaceutics and Clinical Pharmacy Faculty of Pharmacy-University of Jordan, Amman, Jordan; 6) National Center for Diabetes, Endocrinology and Genetics, Amman, Jordan; 7) Department of Anthropology, Yarmouk University, Irbid, Jordan; 8) Division of Human Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA; 9) Department of Pediatrics, University of Pennsylvania School of Medicine, Philadelphia, PA.

Diabetes is among the most common chronic diseases globally and the prevalence is increasing. In Jordan, T2D affects 16% of the adults and another 23.8% with pre-diabetes. Type 2 diabetes (T2D) accounts for 90% of the diabetes cases in adults, causing a significant public health burden. Previous genome-wide association studies (GWAS) have identified over 90 susceptibility loci, but none of these studies have specifically investigated the Jodan populations. We genotyped genomic DNA of T2D cases and controls from Jordan, using the InfiniumII OMNI-Express BeadChip. After quality control filtering, 33 cases and 105 controls in the Circassian subgroup and 34 cases and 109 controls in the Chechen subgroup were left for analysis. We conducted GWAS on these two subpopulations in Jordan separately and further performed meta-analysis. We identified a novel T2D locus at chr20p12.2 at genome-wide significance (rs6134031, $P= 1.12 \times 10^{-8}$). It is located at an intergenic region, near gene *JAG1*. Another locus at chr12q24.31 (rs4758690, $P= 4.20 \times 10^{-5}$) was associated with T2D at suggestive significance level. Interestingly, the locus has a significant eQTL for gene *MLXIP* ($P=1.1 \times 10^{-14}$ for MLXIP expression in transverse colon; 4.2×10^{-7} for MLXIP expression in small intestine-terminal Ileum) and this SNP is also significantly associated with methylation level in MLXIP ($P=3.07 \times 10^{-5}$). MLXIP shows highest expression in colon and functions in transcriptional regulation of cellular glucose response, which makes it an interesting candidate target gene. Taken together, in the first GWAS of T2D cases constituting Jordan subpopulations, we identified novel susceptibility loci which may be unique risk factors in populations of the middle-east.

1197F

Integration of multi-tissue transcriptomic and genetic data in type 2 diabetes. *A. Ndungu[1], M. van de Bunt[1,2], A. Viñuela[3,4,5], S.C.J. Parker[6,7], N. Oskolkov[8], P.E MacDonald[9], H.K Im[10], M.L. Stitzel[11], InsPIRE Consortium.* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 2) Oxford Centre for Diabetes, Endocrinology and Metabolism, University of Oxford, Churchill Hospital, Old Road, Headington, Oxford, OX3 7LJ UK; 3) Department of Genetic Medicine and Development, University of Geneva Medical School, Geneva, Switzerland; 4) Swiss Institute of Bioinformatics, Geneva, Switzerland; 5) Institute of Genetics and Genomics in Geneva, University of Geneva, Geneva, Switzerland; 6) Department of Human Genetics, Medical School, University of Michigan, Ann Arbor, MI, USA; 7) Department of Computational Medicine and Bioinformatics, Medical School, University of Michigan, Ann Arbor, MI, USA; 8) Department of Clinical Sciences, CRC, Lund University, Malmö, Sweden; 9) Alberta Diabetes Institute, University of Alberta, Edmonton, Canada; 10) Section of Genetic Medicine, Department of Medicine, University of Chicago, Chicago, Illinois, USA; 11) The Jackson Laboratory for Genomic Medicine, Farmington, CT, USA.

C*is*-expression data are increasingly used to map non-coding GWAS signals to effector transcripts, usually through single variants (SV-eQTLs). Recently developed multi-variant (MV-eQTL) methods, such as PrediXcan integrate multiple *cis* variant effects and could prove more powerful genetic instruments e.g. for 2-sample Mendelian Randomisation experiments. We compared SV- and MV-eQTL methods in islet RNA-Seq data from 426 cadaveric donors. Initial results, comparing exon-level SV-eQTL and MV-eQTLs (PrediXcan), indicated MV-eQTLs generally accounted for more expression variation than the best SV-eQTL. This varied with gene; SV-eQTLs explained 0.13 of the variance in *DGKB* whilst MV-eQTLs accounted for 0.16. For *IGF2BP2,* the SV-eQTL accounted for 0.12 of phenotypic variance whilst MV-eQTLs accounted for 0.9. These differences could be a combination of genuine secondary signals and model over-fitting. Next, we compared SV-eQTL and MV-eQTLs in defining effector transcripts for T2D loci using DIAGRAM GWAS data. Of 6039 genes with a significant SV-eQTL (FDR <1%), 11 were highly correlated with T2D GWAS loci. Predicted expression from islet-derived MV-eQTL models identified 11 genes (10 at GWAS loci) significantly associated with T2D, 8 genes were implicated in T2D by both methods. MV-eQTLs identified putative effector transcripts at a further 3 genes with no SV-eQTL-GWAS overlap. We then compared T2D association results using predicted expression from islets to those from 36 tissues of broadly comparable sample sizes in GTEx v6. Compared to 11 significant signals (FDR<1%) from islets, muscle had 4 signals whilst other T2D-relevant tissues (liver, adipose, whole pancreas) had none: the most informative GTEx tissue was tibial artery (7 significant genes). Tissue-specificity varied; two genes in GWAS loci (*DGKB*, *UBE2E2*), had significant MV-eQTL signals evident from islet-generated models. In contrast, significant signals with *RCCD1* were evident for MV-eQTL analyses from 16 GTEx tissues and islets. *RCCD1* was significant in MV-eQTL analyses but not SV-eQTL. Whilst in principle, MV-eQTL based methods might be extensions of SV-eQTLs, complexities of these regions (multiple, overlapping signals) indicate that both have value in identifying candidate effector transcripts for further validation. The T2D MV-eQTL results reinforce the notion (consistent with physiological and genomic enrichment analyses) that events in the pancreatic islet are central to the pathogenesis of T2D. .

1198W

Identification of common drug targets for type 2 diabetes mellitus and cardiovascular diseases in Indian population using whole exome sequencing. *T. Prakash[1], A.M. Veerappa[1], N.B. Ramachandra[1], M.S. Basavaraj[2].* 1) Department of Studies in Genetics and Genomics, University of Mysore, Mysuru, Karnataka, India; 2) University Health Centre, University of Mysore, Mysuru, Karnataka, India.

The pathophysiology of the link between Type 2 Diabetes Mellitus (T2DM) and cardiovascular disease (CVD) is multifactorial. Diabetes is a prime risk factor for CVD and is also the most prevalent cause of morbidity and mortality among patients with T2DM. Understanding the profound mechanisms of these diseases can identify novel and effective drug targets. Current study was aimed at understanding the biological basis of the link between T2DM and CVD. We analyzed whole exome sequences of three individuals hailing from India and used custom variant identification pipeline, to identify and annotate pathological variants. We report the consequences of damaging novel and rare mutations in several genes for the shared pathophysiology that exists between T2DM and CVD. The findings indicate *PPARG*, *AKT2*, *APOB*, and *RELA* to be the prime drug targets in individuals with both T2DM and CVD pathology. The proposed mechanisms link hyperglycemia and intracellular metabolic changes of T2DM with oxidative stress, low-grade inflammation and endothelial dysfunction of CVD. The implications of the same will be discussed.

1199T

Genetics of diabetes in U.S. Hispanic/Latino individuals: Results from the Hispanic Community Health Study/Study of Latinos (HCHS/SOL).

Q. Qi[1], A.M. Stilp[2], T. Sofer[2], T. Wang[1], C.C. Laurie[2], M.C. Ng[3], I. Chen[4], K. Taylor[4], J. Pankow[5], M.L. Avilés-Santa[6], G. Papanicolaou[5], N. Schneiderman[7], J. Rotter[4], R.C. Kaplan[1], MEDIA consortium; HCHS/SOL. 1) Department of Epidemiology and Population Health, Albert Einstein College of Medicine, Bronx, NY; 2) Department of Biostatistics, University of Washington, Seattle, WA; 3) Center for Genomics and Personalized Medicine Research, Wake Forest School of Medicine, Winston-Salem, NC; 4) Los Angeles Biomedical Research Institute at Harbor-UCLA Medical Center, Torrance, CA; 5) Division of Epidemiology and Community Health, University of Minnesota, Minneapolis, MN; 6) Division of Cardiovascular Sciences, National Heart, Lung, and Blood Institute, Bethesda, MD; 7) Department of Psychology, University of Miami, Miami, FL.

A number of type 2 diabetes (T2D) genetic loci have been identified through recent genome-wide association studies (GWAS) in populations of European, Asian, and African ancestry, while few GWAS have been conducted in US Hispanic/Latinos who are disproportionately affected by diabetes. We conducted a GWAS (>25M SNPs) in 2499 diabetes cases (defined by medication use, fasting glucose≥126 mg/dL, post-OGTT glucose≥200 mg/dL, or HbA1c≥6.5%) and 5247 normal controls (excluding pre-diabetes) from 6 Hispanic/Latino background groups (Cuban, Dominican, Puerto Rican, Mexican, Central American, and South American) in the HCHS/SOL. Goals were to 1) search for novel diabetes genetic loci; and 2) examine 76 known T2D loci in US Hispanic/Latinos. Our GWAS identified two known loci (*TCF7L2* and *KCNQ1)*, but no novel signals, that reached genome-wide significance ($P<5×10^{-8}$). Conditional analysis suggested an additional independent signal at *KCNQ1*, represented by the SNP rs1049549 (MAF=0.06; OR=1.49 [95% CI 1.08, 1.27]; $P= 2.9 ×10^{-7}$), which might be an African ancestry-specific allele (Africans: MAF=0.28; Europeans: MAF=0.01). This association was replicated in African Americans from the MEDIA consortium ($P=0.006$). To examine overall genetic predisposition to diabetes in US Hispanic/Latinos, we calculated a genetic risk score (GRS) based on 76 known index SNPs and found that the GRS had a highly significant association with diabetes (OR=1.07 [1.06, 1.09]; $P=1.2×10^{-39}$), with relatively stronger effect in non-obese compared with obese (OR=1.10 [1.08, 1.12] vs 1.06 [1.05-1.08]; P for interaction =0.005). We also studied the generalization of 76 known index SNPs to the Hispanic/Latinos. Among 76 index SNPs, 66 SNPs showed consistency with the previously reported direction of associations (binomial test $P=7.8×10^{-75}$); and 14 SNPs were significantly generalized to the HCHS/SOL using the directional FDR r-values framework. In addition, a GRS based on the SNPs that did not pass generalization testing also showed a highly significant association with diabetes, suggesting that some of the non-generalized SNPs are in fact associated with diabetes in US Hispanics/Latinos and non-generalization might be due to lack of power. In summary, our study identified a novel independent signal suggesting an African ancestry-specific allele at *KCNQ1* locus for diabetes. Associations between known genetic loci and diabetes were shown in a large cohort of US Hispanic/Latinos of diverse background.

1200F

A novel 'metabolic syndrome' genetic risk score characterizes high-risk individuals independent of body mass index in the Diabetes Prevention Program.

S. Srinivasan[1,8], K. Jablonski[2], W. Knowler[3], S. Dagogo-Jack[4], S. Kahn[5], E. Boyko[5], G. Bray[6], E. Horton[12], M.F. Hivert[1,7,8], R. Goldberg[9], L. Chen[1], J. Mercarder[10], M. Harden[11], J.C. Florez[1,8,11], The Diabetes Prevention Program. 1) Massachusetts General Hospital , Boston, MA; 2) George Washington University, Washington, DC; 3) National Institute of Diabetes and Digestive and Kidney Diseases, Phoenix, AZ; 4) The University of Tennessee Health Science Center, Memphis, TN; 5) University of Washington, Seattle, WA; 6) Pennington Biomedical Research Center, Baton Rouge, LA; 7) Harvard Pilgrim Healthcare Institute, Boston, MA; 8) Harvard Medical School, Boston, MA; 9) University of Miami Leonard M.Miller School of Medicine, Miami, FL; 10) Barcelona Supercomputing Center, Barcelona, Spain; 11) Broad Institute, Cambridge, MA; 12) Joslin Diabetes Center, Boston, MA.

There is considerable heterogeneity in insulin resistance (IR), and phenotypic features of monogenic diseases can be used to understand potential mechanisms by which common variants act to induce IR. In the Diabetes Prevention Program (DPP), we tested a validated genetic risk score (GRS) consisting of 11 common genetic variants associated with a metabolic profile consistent with lipodystrophy including high triglycerides (TG), lower HDL cholesterol, and hepatic steatosis despite lower body mass index (BMI). We tested this GRS in 2,713 DPP participants who were at high risk for diabetes and had been randomized to intensive lifestyle intervention, metformin, or placebo. All measures were adjusted for age, sex, self reported ethnicity and baseline variable when applicable. At baseline and consistent with prior results, a higher GRS was associated with higher ln fasting insulin (µU/ml) (per allele β=0.012 [SE=0.005], $P=0.01$), higher ln TG (mg/dl) (β=0.02 [SE=0.005], $P<0.001$) and higher ln alanine transaminase levels (U/l) (β=0.009 [SE=0.008], $P<0.001$). In contrast and as expected, a higher GRS was associated with lower weight (kg) (β=-1.077 [SE=0.176], $P<0.001$), lower BMI (kg/m²) (β=-0.333 [SE=0.059], $P< 0.001$) and lower waist circumference (cm) (β=-0.659 [SE=0.128], $P<0.001$). Despite starting with lower weight and BMI at baseline, a higher GRS was associated with less reduction in weight (β=0.125 [SE=0.053], $P=0.018$) and BMI (β=0.047 [SE=0.019], $P=0.01$) at 1 year without significant interactions with treatment. Lifestyle intervention and metformin appeared to raise the insulin sensitivity index independent of genetic risk. In secondary analyses, we tested the association of the GRS with cardiovascular disease (CVD) endophenotypes in 2,708 participants. A higher GRS was associated with lower ln fibrinogen (mg/dl) (β=-0.006 [SE=0.002], $P=0.003$), lower ln C-reactive-protein (mg/dl) (β=-0.037 [SE=0.01], $P<0.001$), lower ln LDL peak-particle-density (Rf) (β=-0.005 [SE=0.001], $P<0.001$) and a lower ln ACC/AHA 10-year CVD risk score (β=0.04[SE=0.012], $P<0.001$) at baseline, reflecting lower adiposity. We found no association with coronary artery calcification scores. Among individuals with pre-diabetes, a higher GRS for IR with lower BMI was associated with lower CVD risk, in contrast to previous work showing increased coronary artery disease risk. Our results indicate that this GRS may have a differential effect on CVD in people with high metabolic risk at baseline.

1201W

Associations between *SLC16A11* variants and diabetes in the Hispanic Community Health Study/Study of Latinos (HCHS/SOL). *A.M. Stilp[1], B. Hidalgo[2], T. Sofer[1], Q. Qi[3], N. Schneiderman[4], Y.-D.I. Chen[5], R. Kaplan[3], L. Aviles-Santa[6], K.E. North[7], D. Arnett[8], A. Szpiro[1], J. Cai[9], K. Taylor[5], G. Papanicolaou[6], C.C. Laurie[1], J.I. Rotter[5].* 1) University of Washington, Seattle, Department of Biostatistics; 2) University of Alabama at Birmingham; 3) Albert Einstein College of Medicine, Department of Epidemiology and Population Health; 4) University of Miami, Department of Psychological and Behavioral Medicine Research Center; 5) Institute for Translational Genomics and Population Sciences, Los Angeles Biomedical Research Institute and Department of Pediatrics at Harbor-UCLA Medical Center; 6) National Institutes of Health, National Heart, Lung, and Blood Institute; 7) University of Chapel Hill, Department of Epidemiology; 8) University of Kentucky, College of Public Health; 9) University of North Carolina, Chapel Hill, Department of Biostatistics.

Five sequence variants in *SLC16A11* (rs117767867, rs13342692, rs13342232, rs75418188, and rs75493593), which occur in two non-reference haplotypes, were recently shown to be associated with type-2 diabetes in Mexicans and Mexican Americans analyzed by the SIGMA consortium (Williams et al. 2014). We analyzed these variants in 2492 diabetes cases and 5236 controls from the Hispanic Community Health Study/Study of Latinos (HCHS/SOL), which includes U.S. participants from six diverse background groups: Mexican, Central American, and South American (Mainland) and Puerto Rican, Cuban, and Dominican (Caribbean). We aimed to determine whether previous findings in Mexicans would replicate in the HCHS/SOL Mexican group and whether genotypic effects were similar in the other HCHS/SOL groups. The risk alleles occur in two non-reference haplotypes in HCHS/SOL, as in the SIGMA Mexicans. The haplotypes frequencies are very similar between SIGMA Mexicans and the HCHS/SOL Mainland groups, but are different in the Caribbean background groups. We found that *SLC16A11* sequence variants were significantly associated with risk of diabetes in the Mexican group (p<0.025), replicating the SIGMA findings. However, these variants were not significantly associated with diabetes in a combined analysis of all groups or in any of the five non-Mexican groups analyzed separately even though the risk variants were present at some frequency in all groups. Thus, the lack of replication in the combined analysis was likely not due to low power (85 % power to detect the previously-reported odds ratio). A sensitivity analysis in which younger controls were excluded (to better match the SIGMA studies) did not show qualitatively different results from the primary analysis. Recent results by Traurig et al. (2016) indicated that one of the SNPs, rs75493593, had a significant interaction with obesity in a sample of Native North Americans. We sought to explain the lack of replication by testing for a lower mean BMI in the Mexican group and for a similar interaction with obesity, but neither of these conditions was observed in the HCHS/SOL data. Therefore, the lack of replication is likely due to other factors, such as interaction with other Mexican-specific genetic variants or differing LD patterns in Mexicans compared to other Hispanic/Latino groups. These findings suggest the importance of recognizing the diversity of the Hispanic/Latino population in genetic analyses.

1202T

Genetic variants in *KCNB1* are modestly associated with type 2 diabetes in American Indians from the Gila River Indian Community. *M. Traurig, V. Ossowski, P. Chen, P. Piaggi, S. Kobes, R. Hanson, C. Bogardus, L. Baier.* NIH, Phoenix, AZ.

Pima Indians from the Gila River Indian Community (GRIC) have a high prevalence of type 2 diabetes (T2D) and we recently completed a genome-wide association study to identify determinants of this disease in 7701 community members using a custom designed Pima Indian specific Axiom Array. Based on whole-genome sequencing data on 266 full-heritage Pima Indians, we calculate that this array successfully tags (r^2 >0.85) 92% of all variation with a minor allele frequency (mAF) ≥0.05. Imputation was subsequently performed to capture remaining variations, and genotypes of novel variants in biological candidate genes with associations with T2D were prioritized for validation. One of these imputed variants was an intronic 16 bp deletion (mAF = 0.02) in the *KCNB1* gene (*KCNB1[16bpΔ]*). *KCNB1* encodes the potassium voltage-gated channel, Shab-related subfamily, member 1 which is involved in regulating insulin secretion. Genotyping of the deletion via fragment analysis in 7,351 Pima Indians confirmed the nominal association with T2D, where individuals with the deletion were protected from diabetes (OR = 0.51, 95%CI [0.34–0.77], $P = 1.2 \times 10^{-3}$ after genomic control, adjusted for age, sex, birth-year, and principal components 1-5). Analysis of other variation in this gene identified a common variant, rs3827088, (mAF = 0.31) directly genotyped by the Axiom array which also had a nominal association with T2D ($N = 7444$, OR = 1.17, 95%CI [1.05–1.30], $P = 4.9 \times 10^{-3}$). Genotyping of rs3827088 in an independent group of 3004 American Indians replicated the association with T2D (combined analysis; $N = 10448$, OR = 1.18, 95%CI [1.08–1.29], $P = 2.5 \times 10^{-4}$). Conditional analysis for the GRIC sample suggests that *KCNB1[16bpΔ]* and rs3827088 have independent effects on T2D; after conditioning for the other variant, the associations with T2D were essentially unchanged (*KCNB1[16bpΔ]*; OR = 0.55, 95%CI [0.39–0.77], $P = 3.2 \times 10^{-3}$ and rs3827088; OR = 1.18, 95%CI [1.08–1.30], $P = 2.8 \times 10^{-3}$). As expected, combining these 2 genetic variants showed that carriers of *KCNB1[16bpΔ]* and the non-risk (G) allele for rs3827088 are the most protected from diabetes, while those without the deletion and carrying the rs3827088 risk (A) allele are at the highest risk for diabetes. Studies of pathways potentially affected by *KCNB1* are ongoing.

1203F

Allelic variants associated with type 2 diabetes mellitus and related disorders in a Romanian cohort of elder male individuals. *G.F. Ursu[5], L.C. Bohiltea[1], P. Iordache[3], N. Cucu[4], V.E. Radoi[1,2], I. Craciunesc[5], C. Stiru[5], G. Chelu[2], C. Arsene[2], A. Voinoiu[3], V. Calota[3], C. Staicu[3], R.E. Bohiltea[3], C. Strugaru[1], D. Mates[3], A. Manolescu[6], V. Jinga[3], R.I. Ursu[1,2].* 1) Medical Genetics Department, "Carol Davila" University of Medicine and Pharmacy, Faculty of General Medicine, Bucharest, Romania; 2) SYNEVO Romania, Central Laboratory, Medical Genetics Department, Bucharest, Romania; 3) "Carol Davila" University of Medicine and Pharmacy, Bucharest, Romania; 4) Genetics Departmenr, Faculty of Biology, University of Bucharest, Romania; 5) "Prof. Dr. Agrippa Ionescu" Emergency Military Hospital, Bucharest, Romania; 6) University of Reykjavik, School of Science and Engineering, Reykjavik, Iceland.

   Background. Diabetes mellitus type 2 (t2D) is one of the world`s pandemics. This research wishes to determin high risk polymorphisms associated with t2D for the Romanian population. It is the first large diabetes-related genome-wide association study in Romania. It is a follow-up study of a previous PhD research involving the correlation between the FTO rs9939609 and ADRB3 rs4994 variants and obesity and diabetes in a cohort of 70 obese individuals. **Materials. Methods**. A GWAS was performed on a Romanian cohort of 750 males aged over 50 y.o. which have been divided into 2 study groups: 1. T2D group (250 individuals) 2. non-diabetic group (controls – 500 individuals) The research included 700000 SNPs. Genotyping results were analyzed in correlation with the presence of t2D and t2D-associated clinical parameters and disorders (weight, BMI, obesity level, flebitis, hypertension, prostate cancer). Lifestyle risk-factors were considered (environment, smoking, alcohol, coffee). Allele frequencies were calculated and compared with literature. **Results.** The results revealed a great number of allelic variants statistically corelated with t2D in the studied cohort. A cluster of SNVs (single nucleotide variants) on chromosome 6 (6 SNVs, 6q21, BVES gene) showed the highest association (p-values of 10^{-6}). Several variants on chromosomes 12, 13, 16, 18, 2, 4, 11, 19, 1, including SNVs in the previously reported FTO, MC4R, POMC, TMEM18, LEPR, BDNF, ADIPOQ, INSR, GHRH genes, also showed important correlations with t2D. Among the analyzed t2D parameters and comorbidities, obesity (including weight and BMI) and hypertension revealed the strongest association, SNVs on chromosomes 16, 6, 12, 13, 11, 4, 1 being correlated with these conditions. Over 50 SNPs were correlated with prostate cancer, 28 reavealing the strongest results (chromosomes 4,8,13,16,2,6). **Conclusions.** The study identified several gene clusters correlated with t2D and comorbidities. The implications of these variants for the Romanian population need to be further analyzed, replication studies having to be undertaken for confirmation (follow-up study under way - EU FP7 ROMCAN project, 5000 Romanian individuals). **Acknowledgemets.** The research is part of EU FP7 ProMark project.

1204W

Gene enrichment evaluation of glucocorticoid pathways for a role in type 2 diabetes pathogenesis. *L.N. Brenner, L. Chen, J.C. Florez.* Massachusetts General Hospital, Boston, MA.

   Glucocorticoids are used to treat many types of diseases. Notwithstanding their many therapeutic uses, they often cause hyperglycemia or worsening of pre-existing diabetes: up to 50% of patients who receive glucocorticoids have glucocorticoid-induced hyperglycemia. The mechanism of this intolerance is thought to be due to decreased insulin sensitivity, as well as decreased insulin secretion. However, the factors that predispose certain individuals to glucocorticoid-induced hyperglycemia are not known. To further evaluate whether genes in glucocorticoid pathways contribute to type 2 diabetes pathogenesis, we conducted a gene set enrichment analysis of different cohort results using the program Meta-Analysis Gene-set Enrichment of variant Associations (MAGENTA) deployed in publicly available genome-wide association meta-analyses for type 2 diabetes (DIAGRAM) and quantitative glycemic traits (MAGIC). We constructed three gene sets: one from an Online Mendelian Inheritance in Man (OMIM) literature search for "glucocorticoid," one from a published set of glucocorticoid-related expression changes and one including all genes in the glucocorticoid biosynthesis pathway. The different glucocorticoid-related gene sets show enrichment in both the type 2 diabetes and glycemic trait analyses. Using a stringent 95% cutoff, the gene sets derived from the OMIM literature-search and the glucocorticoid biosynthesis pathway show an enrichment for type 2 diabetes genetic associations (p=0.02 for both). The glucocorticoid synthesis gene set is also enriched for genetic associations with fasting insulin adjusted for BMI (p=0.02). The glucocorticoid-related expression gene set demonstrates enrichment for genetic associations of fasting glucose (p=0.03). A less stringent cutoff of 75% reveals additional significant enrichment for associations for the OMIM gene set with fasting insulin, with (p=0.04) and without (p=0.01) BMI adjustment, and with the Homeostatic Model Assessment of Insulin Resistance (HOMA-IR; p=0.009). At this lower 75% threshold, the published expression gene set also shows enrichment for the corrected insulin response (p=0.03). Overall, this suggests that genetic variation in the glucocorticoid pathway contributes to hyperglycemia and type 2 diabetes. Further investigation is needed to identify the specific genes involved and to develop better prediction algorithms to distinguish patients who will and will not develop glucocorticoid-induced hyperglycemia.

1205T

Exome sequencing in DiscovEHR identifies rare variants in anion transporter genes that exert large effects on uric acid levels and gout. *J. Freudenberg, S. Mukherjee, C. O' Dushlaine, A. Li, GHS RGC DiscovEHR, J. Overton, J. Reid, L. Mitnaul, I. Borecki, A. Baras, O. Gottesman, F. Dewey, A. Shuldiner.* Regeneron Genetics Center, Tarrytown, NY.

Genome-wide association studies of uric acid level and gout have found associations with common variants kidney expressed anion transporter genes (*SLC22A12, SLC2A9, ABCG2*). *SLC22A12* and *SLC2A9* function in uric acid re-absorption, whereas *ABCG2* functions in uric acid excretion. We comprehensively evaluated the role of rare protein altering variants in these genes by exome sequencing of 3357 cases of gout and 35,721 controls without a history of gout, including 8677 individuals with measurements of serum uric acid. All individuals were of European ancestry and from the Geisinger Health System DiscovEHR cohort. Common variant associations were replicated at the anion transporter loci. Nonsynonymous variants were aggregated for gene-based analyses based on the prediction to be damaging by five bioinformatics methods (nsStrict), or alternatively one out of the five methods combined with minor allele frequency less than 1% (nsBroad). A strong association of rare variant burden was observed for *SLC22A12* with lower uric acid level (nsStrict: Beta=-0.26, P=1e-10; nsBroad: Beta=-0.21, P=1.7e-21) and decreased risk of gout (nsStrict: OR=0.27, P=6e-4; nsBroad: OR=0.39, P=8.2e-7). Similarly, rare variant burden in *SLC2A9* was associated with lower with uric acid levels (nsStrict: Beta=-0.19, P=5.5e-4; nsBroad: Beta=-0.12, P=1.6e-4) and decreased gout risk (nsStrict: OR=0.32, P=4.7e-2; nsBroad: OR=0.65, P=1.1e-1). In contrast, rare variant burden at *ABCG2* was associated with higher uric acid levels (nsStrict: Beta=0.075, P=4.5e-3; nsBroad: Beta=0.042, P=7.8e-3) and increased risk of gout (nsStrict:OR=1.58, P=3.3e-3; nsBroad: OR=1.32, P=4.6e-3). In summary, in addition to known common variant associations, we find strong rare variant effects at uric acid transporter genes. We hypothesize that drugs that block uric acid re-absorption might work best among individuals where uric acid excretion is impaired due to damaging variants in *ABCG2*, whereas such drugs may work poorly among individuals where re-absorption is already impaired due to damaging variants in *SLC22A12* or *SLC2A9*. Further, these findings suggest that given the strong effects of the multiple rare variants in these genes, drugs interfering with uric acid excretion, such diuretics or salicylates, may be used more carefully in those individuals.

1206F

Family-based linkage and association analysis of whole exome sequencing data with cardiometabolic phenotypes in Hispanic Americans: The Insulin Resistance Atherosclerosis Family Study. *N.D. Palmer[1,2,3,4,5], K.L. Tabb[1,2,3], J.N. Hellwege[6,7], L. Dimitrov[2], S. Sajuthi[4,5,8], K.D. Taylor[9], M.C.Y. Ng[2,3], G.A. Hawkins[2,4], Y.I. Chen[9], W.M. Brown[4,8], D. McWilliams[4,8], A. Williams[4,8], C. Lorenzo[10], J.M. Norris[11], J. Long[6,7], J.I. Rotter[9], J.E. Curran[12], J. Blangero[12], L.E. Wagenknecht[4,13], C.D. Langefeld[4,8], D.W. Bowden[1,2,3].* 1) Department of Biochemistry, Wake Forest School of Medicine, Winston-Salem, NC; 2) Center for Genomics and Personalized Medicine Research, Wake Forest School of Medicine, Winston-Salem, NC; 3) Center for Diabetes Research, Wake Forest School of Medicine, Winston-Salem, NC; 4) Center for Public Health Genomics, Wake Forest School of Medicine, Winston-Salem, NC; 5) Molecular Genetics and Genomics Program, Wake Forest School of Medicine, Winston-Salem, NC; 6) Division of Epidemiology, Department of Medicine, Vanderbilt University Medical Center, Nashville, TN; 7) Vanderbilt Genetics Institute, Vanderbilt University Medical Center, Nashville, TN; 8) Department of Biostatistical Sciences, Wake Forest School of Medicine, Winston-Salem, NC; 9) Institute for Translational Genomics and Population Sciences and Department of Pediatrics, Los Angeles BioMedical Research Institute at Harbor-UCLA Medical Center, Torrance, CA; 10) Department of Medicine, University of Texas Health Science Center, San Antonio, TX; 11) Department of Epidemiology, Colorado School of Public Health, University of Colorado Denver, Aurora, CO; 12) South Texas Diabetes and Obesity Institute, University of Texas Rio Grande Valley School of Medicine, Brownsville, TX; 13) Division of Public Health Sciences, Wake Forest School of Medicine, Winston-Salem, NC.

Linkage methods can be a powerful tool to elucidate low frequency/high impact variants in extended families, particularly when used to compliment conventional association analysis. We utilized two-point linkage and single variant association analysis using whole exome sequencing (WES) data to distinguish variants which are strongly linked and/or associated with cardiometabolic traits. WES of 1205 Hispanic Americans (78 families) from the Insulin Resistance Atherosclerosis Family Study identified 555,651 variants. Linkage among variants with a minor allele frequency greater than 0.5% (n=211,612) with 50 metabolic traits yielded 10,580,600 LOD scores with 1148 LOD scores ≥3, 183 LOD scores ≥4, and 29 LOD scores ≥5. The highest LOD score was 17.65 at rs200573126 with serum adiponectin levels. This missense variant (G45R) in *ADIPOQ* was also significantly associated with adiponectin levels (*p*=4.53×10[-41]) as previously reported. The maximal novel LOD score detected was 5.50 for rs2289043 in *UNC5C* with subcutaneous adipose tissue measurements. *UNC5C* encodes a netrin-1 receptor; expression of netrin-1 has been reported to be higher in obese, but not lean, adipose tissue. Additional strong linkage signals included: *GAS2L3* with gamma-glutamyl transpeptidase levels (LOD=5.33), *AQP12B* with adiponectin levels (LOD=5.30), and *GPX6* and *FAM109A* with waist/hip ratio adjusted for BMI (LOD=5.13 and 5.02, respectively). Thirteen variants attained genome-wide significance, with the strongest association between rs651821, a 5′-UTR variant in *APOA5*, and triglyceride levels (*p*=3.67×10[-10]). APO AV is known to be involved in the regulation of plasma triglycerides. Other genes containing variants significantly associated with cardiometabolic phenotypes included *PNPLA3* with liver density (*p*=2.17×10[-09]), *CCDC115* with glucose effectiveness (*p*=4.25×10[-09]), and *IDH1* with waist circumference (*p*=2.45×10[-08]). Two genes contained variants showing coincident linkage and association: rs189547099 in *FNIP2* and a novel locus in *GLRB* with triglyceride levels (*p*=6.31×10[-08], LOD=3.13; both variants). *FNIP2* suppresses *PPARGC1a* RNA and is expressed in liver, pancreas, and adipose tissue; *GLRB* encodes the b unit of the glycine receptor. Overall, WES data provided insights that were not observed in exome chip data analysis and thus enabled identification of novel signals contributing to cardiometabolic traits when integrating results from two-point linkage and single-variant association analyses.

1207W

Genome-wide association studies identify two novel susceptibility loci to diabetic retinopathy in Japanese patients with type 2 diabetes. *M. Imamura[1,2,3], M. Taira[3], A. Takahashi[4,5], Y. Kamatani[4], M. Kubo[6], S. Maeda[1,2,3].* 1) Department of Advanced Genomic and Laboratory Medicine Graduate School of Medicine, University of the Ryukyus; 2) Division of Clinical Laboratory and Blood Transfusion, University of the Ryukyus Hospital; 3) Laboratory for Endocrinology, Metabolism and Kidney Diseases, RIKEN Center for Integrative Medical Sciences; 4) Laboratory for Statistical Analysis, RIKEN Center for Integrative Medical Sciences; 5) National Cerebral and Cardiovascular Center, Omics Research Center; 6) RIKEN Center for Integrative Medical Sciences.

Several reports have shown familial aggregations of diabetic retinopathy (DR) or advanced DR among patients with type 1 or type 2 diabetes, suggesting genetic susceptibility contributes to the development and/or progression of DR. However, the genes involved in the susceptibility to DR are still unknown. To identify novel genetic loci associated with the susceptibility to DR, we performed a meta-analysis of genome-wide association studies (GWAS) for DR in Japanese patients with type 2 diabetes registered in BioBank Japan (Study-1; 4,839 DR cases and 4,041 controls, Study-2; 693 DR cases and 1,524 controls). DR cases were patients having any stages of DR and controls were type 2 diabetes patients who did not have any sign of DR with long duration of diabetes (≥5 years) or with diabetic nephropathy. We analyzed the association with DR of ~7.5 million single nucleotide polymorphisms (SNPs) from directly genotyped data (Study-1; Omni-express exome, Study-2; Illumina 610K) and genotype imputation using MACH and minimac. We have identified 85 loci showing suggestive association with DR ($p < 1 \times 10^{-4}$) through the GWAS meta-analysis. These loci were further evaluated in an independent case-control study (Study-3; 2,260 DR cases and 723 controls, BioBank Japan). After combining all the association data (Study-1, 2 and 3) by a meta-analysis, the association of two loci reached genome-wide significance level; rs12630354 on Ch3: $p = 1.62 \times 10^{-9}$, Odds ratio [OR] = 1.17, 95% Confidence Interval [CI] 1.11-1.23, rs140508424 on Ch9: $p = 4.19 \times 10^{-8}$, OR = 1.61, 95% CI 1.36-1.91. None of the association with advanced DR reached genome-wide significance ($p > 5.0 \times 10^{-8}$) in a sub-group analysis: excluding patients with simple DR (DR cases n = 2,003, 368 and 1,260 for Study-1, Study-2 and Study-3, respectively). In conclusion, we have identified two novel loci contributing to DR susceptibility, although further replication studies are required to validate the association of these loci with DR.

1208T

Genome-wide associations of objective activity-monitor derived measures of sleep patterns. *S.E. Jones[1], A.R. Wood[1], H. Yaghootkar[1], J. Tyrrell[1], M.A. Tuke[1], K.S. Ruth[1], R.N. Beaumont[1], R.M. Freathy[1], A. Murray[1], V.H. Stiles[2], M. Hillsdon[2], T.M. Frayling[1], M.N. Weedon[1].* 1) Genetics of Complex Traits, Medical School, University of Exeter, Exeter, Devon, United Kingdom; 2) Sport and Health Sciences, University of Exeter, Exeter, Devon, United Kingdom.

Sleep is a fundamental component of our daily lives. Poor quality sleep, lack of or excessive sleep and disrupted sleep timings are important risk factors for diseases such as obesity, type 2 diabetes and cardiovascular disease. Until recently, little was known about the genetic factors that influence sleep patterns. Using data from 23andMe and UK Biobank, we and others recently identified 22 variants influencing chronotype (whether you are a morning or evening person) and three loci influencing sleep duration. The identification of additional variants associated with sleep will provide further insight into the biology of this essential biological requirement. The use of objective measures of sleep may provide more power to identify variants than self-report measures of sleep, which may be subject to reporting bias.   We aimed to derive objective measures of sleep using data from activity monitors worn by ~103,000 of the 500,000 UK Biobank individuals for ten days. We aimed to identify genetic variants associated with sleep and validate variants recently identified by self-report measures. We present preliminary GWAS results of sleep duration and sleep midpoint using the ~22,000 white British UK Biobank individuals that have both actigraphy data and genetic data available.   Objective, actigraphy derived sleep measures were correlated with self-report measures: sleep duration r=0.18, chronotype (derived from midpoint of sleep) r=0.24.   Of the 22 variants associated with self-report chronotype, 21 had directionally consistent effects (binomial P=2.4x10-7) in objective actigraphy-based measures, and six replicate at P<0.05, including variants in the *PER2* and *AK5*/*PIGK* loci. Using a GRS (genetic risk score) of the 22 lead chronotype variants, we saw strong associations between sleep midpoint and chronotype (P=3.6x10-10, P=5.9x10-8 and P=8.6x10-9 for average over all nights, weekday nights and weekend nights respectively). The strongest self-report sleep duration signal in *PAX8* was reproduced in the actigraphy sleep duration GWAS (P=1.9x10-4) with almost identical effect size (2.3mins per allele for both).   In conclusion, we have performed the first large-scale GWAS study of objective measures of sleep patterns. We validate known self-report sleep duration and chronotype signals. With the upcoming release of the full UK Biobank cohort, we aim to identify further signals associated with these objective sleep pattern phenotypes.

Genome-wide association study of 1,5-anhydroglucitol in adults without diabetes: Results from the Atherosclerosis Risk in Communities Study.
M. Li[1,2], N. Maruthur[1,3,4], S. Loomis[1], K. North[5], H. Mei[6], A. Morrison[7], J. Pankow[8], E. Boerwinkle[7,9], E. Selvin[1,3,4], A. Kottgen[1,10]. 1) Department of Internal Medicine, University of Utah, Salt Lake City, UT; 2) Department of Epidemiology, Johns Hopkins University, Baltimore, MD; 3) Department of Medicine, Division of General Internal Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 4) The Welch Center for Prevention, Epidemiology, and Clinical Research, Johns Hopkins University, Baltimore, MD; 5) Department of Epidemiology, University of North Carolina, Chapel Hill, NC; 6) Center of Bio-statistics & Bioinformatics, University of Mississippi Medical Center, Jackson, MS; 7) Human Genetics Center, School of Public Health, University of Texas Health Science Center at Houston, Houston, TX; 8) Division of Epidemiology and Community Health, School of Public Health, University of Minnesota, Minneapolis, MN; 9) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 10) Division of Genetic Epidemiology, Institute for Medical Biometry and Statistics, Medical Center – University of Freiburg, Faculty of Medicine, University of Freiburg, Germany.

1,5-anhydroglucitol (1,5-AG) is a marker of glucose peaks over 1-2 weeks and has been shown to predict diabetes-related outcomes. Lower levels of 1,5-AG are indicative of hyperglycemia. To gain additional insights into the genetic underpinnings of hyperglycemia, we aimed to identify genetic variants associated with 1,5-AG and to examine their relationship with the most commonly used clinical glycemic markers, HbA1c and fasting glucose. We conducted genome-wide association studies of 1,5-AG in 7,550 European ancestry and 2,030 African American participants without diagnosed diabetes from the Atherosclerosis Risk in Communities (ARIC) Study. Variants that were significantly associated with serum 1,5-AG concentrations were evaluated for replication in a study of blood metabolite concentrations among 7,824 European individuals. In the ARIC study, mean 1,5-AG levels were lower in African American than European ancestry participants (17.3 vs 18.9 ug/mL; $P<0.0001$). Genome-wide significant associations ($p<5 \times 10^{-8}$) among European ancestry participants were identified for single nucleotide polymorphisms (SNPs) in or near *EFNA1*, *MCM6*, *SI*, *MGAM/MGAM2*, *SLC5A10*, and *SLC5A1*. Among the smaller African American sample, no genome-wide significant associations were observed. The index SNPs at each of the six loci together explained 4.2% of the variation in 1,5-AG levels. A common theme among the genes mapping into the identified loci is their role in intestinal glucose digestion as well as glucose and 1,5-AG reabsorption in gut and kidney. None of the SNPs were significantly associated with traditional glycemic markers (fasting glucose and HbA1c) or other nontraditional glycemic markers (fructosamine and glycated albumin). Four of the six loci were successfully replicated in an external European population study. We have identified, for the first time, genes that influence 1,5-AG in non-diabetic adults suggesting genetic variation related to glucose reabsorption and metabolism as a strong influence on 1,5-AG levels and highlight mechanisms that influence the body's ability to metabolize glucose.

Novel locus discovery through trans-ethnic association analyses of glycemic traits using densely imputed genetic data. *G. Marenne on behalf of the Meta-Analyses of Glucose and Insulin-related traits Consortium (MAGIC) Investigator.* Human Genetics, Wellcome Trust Sanger Institute, Hinxton, Cambridge, United Kingdom.

Previous large-scale glycemic trait genetic association analyses, by us (MAGIC) and others, have identified more than 120 loci associated with fasting glucose (FG), fasting insulin (FI), glycated hemoglobin (HbA1c) and 2-hour glucose (2hG), focusing on European descent populations. Here, we extended meta-analyses to five ancestries (71% Europeans, 13% East Asian, 7% Hispanic, 6% African-American and 3% South Asian), and used genetic data imputed to the 1000 Genomes Project (phase 1 v3, March 2012, or later) to aid additional locus discovery and fine-mapping. We report preliminary association results for FG, FI, HbA1c, and 2hG levels in up to 281,416 individuals without diabetes from 144 cohorts. Genetic association analyses were performed using an additive model, and inverse normal transformation for each trait. FG, FI and 2hG were further adjusted for body mass index. Individual cohort results were combined by fixed-effect ancestry-specific meta-analyses. Trans-ethnic meta-analyses were then performed using MANTRA which allows for heterogeneity in allelic effects between diverse ethnic groups, with a $\log_{10}$ Bayes factor ($\log_{10}BF$) threshold of 6 used to identify genome-wide significant signals. Lastly, GARFIELD was used to perform functional enrichment analysis. Preliminary results identified 132 regions associated with FG, of which 93 did not overlap previously established FG-associated regions. New FG loci include those at *CDK14* and *GAD2* genes ($\log_{10}BF=19.75$ and 16.44). We also identified 78 FI-associated regions (61 novel), 189 HbA1c-associated regions (138 novel) and 31 2hG-associated regions (23 novel). The most significant FI, HbA1c and 2hG novel signals fall within *BCL2*, *HBB* and *DVL2* genes ($\log_{10}BF$ = 11.56, 25.28 and 11.10, respectively). Enrichment analysis showed that HbA1c signals were mostly enriched in open chromatin seen in blood cell type, whereas FG and 2hG signals were mostly enriched in liver cell type, and FI signals were mostly enriched in fetal lung cell type. In conclusion, this large international effort has identified over a hundred novel loci, and suggested new hypotheses about the biology and the genetic architecture underlying glycemic traits.

1211T

Genome-wide association study of iron traits in relation to diabetes mellitus in the Hispanic Community Health Study/Study of Latinos (HCHS/SOL): Potential genomic intersection of iron and glucose regulation. *L.M. Raffield[1], T. Louie[2], T. Sofer[2], D. Jain[2], E. Ipp[3], K.D. Taylor[4], G.J. Papanicolaou[5], L. Avilés-Santa[5], L.A. Lange[1], C.C. Laurie[2], M.P. Conomos[2], T.A. Thornton[2], Y.I. Chen[4], B. Thyagaran[6], A.P. Reiner[7], N. Schneiderman[8], H.J. Lin[4], J.I. Rotter[4].* 1) Department of Genetics, University of North Carolina at Chapel Hill, Chapel Hill, NC; 2) Department of Biostatistics, University of Washington, Seattle, WA 98195; 3) Department of Medicine and Division of Endocrinology, Harbor-UCLA Medical Center, Torrance, CA 90502, and the David Geffen School of Medicine at UCLA, Los Angeles, CA; 4) Institute for Translational Genomics and Population Sciences, Los Angeles Biomedical Research Institute and Department of Pediatrics, Harbor-UCLA Medical Center, Torrance, CA 90502, and the David Geffen School of Medicine at UCLA, Los Angeles, CA; 5) Division of Cardiovascular Sciences, NHLBI, NIH, Bethesda, MD 20892; 6) Department of Laboratory Medicine and Pathology, University of Minnesota, Minneapolis, MN 55455; 7) Department of Epidemiology, University of Washington, Seattle, WA 98195; 8) Department of Psychology and Behavioral Medicine, University of Miami, FL 33124.

Genetic variants are known to affect iron stores in the body, and both iron overload and deficiency can adversely affect human health. For example, elevated iron storage has been associated with increased diabetes risk, although exact mechanisms are still being investigated. We conducted the first genome-wide association study (GWAS) of ferritin, serum iron, total iron binding capacity (TIBC), and transferrin saturation in a Hispanic/Latino population, the Hispanic Community Health Study/Study of Latinos (HCHS/SOL; >12,000 participants with iron measures; mean age 46.1; 58.6% female). We identified variants associated with iron traits and then evaluated associations with type 2 (apparently >95% in HCHS/SOL) diabetes and related glycemic traits. Genotyping was done using an Illumina array (>2.5 million variants from the HumanOmni2.5-8v1-1 array and custom content), with imputation to the 1000 Genomes phase 1 version 1 reference panel. Associations were assessed using a mixed model approach (the GENESIS R package) adjusting for sex, age, cigarette use, heritage group, sampling design, kinship, household, census block, recruitment center, and five ancestry principal components. A novel association between TIBC and an intergenic variant near the gene for protein phosphatase 1, regulatory subunit 3B (*PPP1R3B*), was observed (rs4841132, β= -0.116, P = 7.44 x 10^{-8}, effect allele frequency=18.2%), which strengthened when iron deficient individuals were excluded (β= -0.121 P = 4.78 x 10^{-9}). Genome-wide significant associations (P<5 x 10^{-8}) were also identified between iron traits and four previously known loci -- transferrin (*TF*), hemochromatosis (*HFE*), fatty acid desaturase 2 (*FADS2*)/myelin regulatory factor (*MYRF*), and transmembrane protease, serine 6 (*TMPRSS6*). Eight of twelve European GWAS loci and two of four African American GWAS loci generalized to HCHS/SOL (P<0.05, after correction for false discovery rate). Regarding glucose homeostasis, the iron-raising variant of *TMPRSS6* (rs855791, Val736Ala) was associated with lower HbA1c (P = 8.66 x 10^{-10}), and the iron-raising allele of rs4841132 (near *PPP1R3B*) was associated with elevated fasting glucose (P = 7.70 x 10^{-7}) and elevated fasting insulin (P = 4.79 x 10^{-6}). Adjustment for TIBC did not attenuate these *PPP1R3B* associations, so iron is not likely the mediator. These results provide new genetic information on iron traits and on the connection between iron and glucose homeostasis.

1212F

Genome-wide association analysis identifies novel loci associated with circulating visfatin levels. *S.N. Adebamowo[1], A.A. Adeyemo[1], A.P. Doumatey[1], F. Tekola-Ayele[1], A.R. Bentley[1], G. Chen[1], H. Huang[1], J. Zhou[1], D. Shriner[1], O. Fasanmade[2], G. Okafor[3], B. Eghan[4], K. Agyenim-Boateng[4], A. Owusu[5], A. Amoah[5], J. Acheampong[4], T. Johnson[2], J. Oli[3], C.A. Adebamowo[6], F. Collins[7], G. Dunston[8], C.N. Rotimi[1].* 1) National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 2) University of Lagos, Lagos, Nigeria; 3) University of Nigeria Teaching Hospital, Enugu, Nigeria; 4) University of Science and Technology, Kumasi, Ghana; 5) University of Ghana Medical School, Accra, Ghana; 6) Department of Epidemiology and Public Health, School of Medicine, University of Maryland, Baltimore, MD; 7) National Institutes of Health, Bethesda, MD; 8) National Human Genome Center at Howard University.

Background: Visfatin is an adipokine produced by multiple tissues but primarily by brown adipose tissue. Animal experiments and epidemiological studies have suggested a role for visfatin in insulin secretion; type 2 diabetes (T2D) and obesity. However, the genetic factors influencing circulating visfatin levels have not yet been identified. We conducted a genome wide association study (GWAS) for circulating visfatin in individuals of African ancestry. **Methods:** The study participants were drawn from two independent studies, an African cohort (n=1382) enrolled in Nigeria, Ghana and Kenya and an African-American cohort (n=2109) enrolled from the Washington DC metropolitan area. Serum visfatin was measured on fasting samples using the BioRad Bio-Plex Pro™ Human Diabetes Immunoassay. Samples were genotyped on the Affymetrix Axiom® PanAFR SNP array and the Affymetrix Axiom® Exome 319 Array, followed by imputation into the 1000 Genomes Phase 1 v.3 cosmopolitan reference. Association tests were done for visfatin levels under an additive genetic model with adjustment for age, sex, body mass index, T2D status and the first 3 principal components of the genotypes. **Results:** In the African cohort, the GWAS yielded a significant cluster of 4 SNPs ~30kb upstream of the *CNTNAP2* gene on chromosome 7: rs112623225 (p = 2.6 x 10^{-9}), rs17480133 (p = 2.5 x 10^{-9}), rs4726781 (p = 5.1 x 10^{-9}) and rs4726782 (p = 4.2 x 10^{-8}). These variants alter several regulatory motifs in key transcriptional factors including *ARID5A*, which is overexpressed in adipocytes and whole blood, the two primary sites of visfatin abundance. In the African-American cohort as well as in a meta-analyses of both cohorts, there was a genome-wide significant variant (rs2238776, p = 1.9 x 10^{-12}) in the *TBX1* gene. This intronic variant is in enhancer histone marks in several tissues and alters the motifs Ets*, HNF1, TCF12*, most of which are expressed in adipocytes. However, this variant is less common in African populations (YRI MAF=0.004), compared to African-Americans (ASW MAF 0.04). This may explain, in part, why it was not observed among continental Africans included in this study. **Conclusions:** We identified novel genetic variants near *TBX1* and *CNTNAP2* that influence circulating visfatin levels. These findings should be investigated further in other global populations. Mechanistic studies examining how these loci regulate circulating visfatin levels should also be conducted.

1213W

From genetic informatics to a biological model: Analysis of genetic variants of *SLC5A. J.C. Fox[1], B.A. Hoch[2], J. Mayer[2], H. Ye[2], E.W. McPherson[1], S.J. Hebbring[1].* 1) Center for Human Genetics, Marshfield Clinic Research Foundation, MARSHFIELD, WI; 2) Bioinformatics Research Center, Marshfield Clinic Research Foundation, MARSHFIELD, WI.

SLC5A2 encodes the sodium/glucose co-transporter 2 (SGLT2). Primarily found in the kidneys, this protein plays a vital role in glucose transport and regulation of blood glucose levels. SGLT2 variants are implicated in a disorder known as glycosuria, which is characterized by an increased secretion of glucose in the urine. SGLT2 has become a popular target for type 2 diabetes (T2D) therapeutics. However, many individuals using these drugs develop side effects that include ketoacidosis, a condition that is not normally found in individuals with glycosuria. Using Phenome Wide Association Studies, we have identified 2 novel and likely clinically relevant variants within the gene *SLC5A2*. Herein, we present a study that begins with the identification of two biologically-relevant genetic variants and describe the experimental design to analyze their functional consequences. Additionally, we will test the impact of functional variants on commercially-available SGLT2 inhibitors. From these studies, we can begin to develop a pharmacogenetic model that may link SGLT2 inhibitors to variant-specific outcomes that may affect their use in patients with T2D. As precision medicine takes precedence in health care it is hoped that studies like these, which begin with a genetic informatics approach, will have a clinical impact on patient care.

1214T

Opposite effects of maternal and paternal alleles on body mass index in the Hutterites. *S. Mozaffari[1], D. Nicolae[2], C. Ober[1].* 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) Departments of Medicine and Statistics, University of Chicago, Chicago, IL.

Genome Wide Association Studies (GWAS) typically treat alleles inherited from the mother and from the father as equivalent, although it is possible that variants can affect traits differently depending on whether they are maternal or paternal in origin. Many studies have utilized pedigree information to test for parent of origin effects (POEs) on phenotypes and gene expression to uncover new imprinted loci. However, none have investigated whether variants can have opposite effects depending on the parental origin. We developed a novel statistical model that compares the effects of the maternal and paternal variants on trait values, including effects that are opposite. We tested for POEs with 10 common quantitative traits in >1000 Hutterites, who are members of a single pedigree, using ~5M variants (MAF>5%) imputed and phased from Hutterite whole genome sequences. Although a standard GWAS of body mass index (BMI) in the Hutterites did not yield any significant associations, our new method revealed SNPs in 12 independent regions with POEs that surpassed genome wide significance ($p<10^{-9}$); all were due to opposite effects of paternally and maternally inherited alleles. Four regions include known or predicted imprinted genes: paternally expressed *FAM50B* and *GATA3* and maternally expressed *CTNNA3* and *ABCC9*. The two most significant associations were not in known imprinted regions. The lead SNP in one region (rs114757733 A/G, $P=7.17\times10^{-15}$) is in the intron of the *DIET1* gene, which modulates bile acid and lipid levels. At this SNP, the paternally inherited A allele is associated with increased BMI whereas the maternally inherited A allele is associated with decreased BMI. The lead SNP in the second region (rs113661800 G/del, $P=1.75\times10^{-14}$) is intergenic between a long noncoding RNA gene, *LINC0449*, and a gene involved in metabolic function, *CCRN4L*. LINC genes are often found in imprinted regions. The G allele at this SNP is associated with increased BMI when inherited from the father but decreased BMI when inherited from the mother. Five of the other nine phenotypes showed significant POEs, but none with opposite effect alleles. Thus, BMI is unique in this respect and fits with the theory that imprinted loci are primarily involved in metabolic functions related to growth. In summary, our new method revealed extensive opposite POE on BMI, potentially identifying new imprinted regions and potential risk alleles for metabolic disorders. Supported by HL085197. .

Joint effects of common genetic variants for type 2 diabetes on the risk of gestational diabetes. *V.K. Kawai[1], R.T. Levinson[2], A. Adefurin[1], D. Kurnik[1,3,4], S. Collier[5], D. Conway[5], C.M. Stein[1].* 1) Division of Clinical Pharmacology, Department of Medicine, Vanderbilt University Medical Center, Nashville, TN, USA; 2) Vanderbilt Genetics Institute, Vanderbilt University School of Medicine, Nashville, TN, USA; 3) Clinical Pharmacology Unit, Rambam Medical Center, Haifa, Israel; 4) Rappaport Faculty of Medicine, Technion - Israel Institute of Technology, Haifa, Israel; 5) Vanderbilt Institute of Clinical and Translational Research, Vanderbilt University Medical Center, Nashville, TN, USA.

Gestational diabetes (GDM) is characterized by maternal glucose intolerance that occurs only during pregnancy. Because GDM resembles closely type 2 diabetes (T2DM) in its pathophysiology and risk factors, shared genetic predisposition is likely but has not been established. Here, we test the hypothesis that a genetic risk score (GRS) that included variants known to be associated with T2DM is associated with the risk of GDM. **Methods**: We conducted a case-control study using BioVU, a DNA biobank linked to de-identified electronic medical records at Vanderbilt Medical Center. To calculate a simple-count (0, 1, 2 for each risk allele) GRS, we selected 34 SNPs previously associated with T2DM or fasting glucose in two or more genome wide association studies ($P < 5 \times 10^{-8}$) in the general population. Using bioinformatic algorithms and manual review in women without diabetes, we identified 458 cases of GDM and 1537 pregnant controls of European ancestry. We defined a case of GDM as having a positive 100g oral glucose tolerance test during pregnancy using Carpenter and Coustan criteria, or a physician's diagnosis, or an ICD9 billing code for glucose intolerance in pregnancy with an intervention for GDM (nutritional or antidiabetic drug); controls were pregnant women with a normal 50g glucose challenge test. We performed a logistic regression analysis adjusting for maternal age, parity, and maternal body mass index (BMI) to assess the effect of the GRS on the risk of GDM and we calculated the area under the curve (AUC) for the receiver-operating characteristic curve (ROC) for the logistic regression model. **Results**: GDM cases had a higher number of risk alleles compared to controls (38.9 ± 4.0 risk vs. 37.4 ± 4.0 risk alleles, P<0.0001). The odds ratio (OR) for GDM associated with an increase of 1 risk allele in the GRS was 1.10 (95%CI 1.07 - 1.13) after adjustment for maternal age, parity, and BMI. Women in the top quintile of the GRS (≥ 42 risk alleles) had an OR=3.19 (95%CI 2.17 - 4.71) for GDM when compared with women in the bottom quintile (≤ 34 risk alleles). The AUC for the ROC curve for predicting GDM was 0.67 (95% CI 0.64 - 0.70) for clinical covariates alone and 0.70 (95%CI 0.67 - 0.73) for clinical covariates and the GRS. **Conclusions**: The main finding was that a GRS, which incorporated the effects of common genetic variants for T2DM, was associated with the risk of GDM.

1216W

Circulating aromatic amino acids modify the *GCKR* genotype on changes of glucose metabolism in response to weight-loss diets: The POUNDS Lost trial. *Y. Heianza[1], W. Ma[2], Y. Zheng[3], G.A. Bray[4], F.M. Sacks[3], L. Qi[1,2,3,5].* 1) Department of Epidemiology, School of Public Health and Tropical Medicine, Tulane University, New Orleans, LA; 2) Department of Epidemiology, Harvard T.H. Chan School of Public Health, Boston, MA; 3) Department of Nutrition, Harvard T.H. Chan School of Public Health, Boston, MA; 4) Pennington Biomedical Research Center, Louisiana State University, Baton Rouge, LA; 5) Channing Laboratory, Brigham and Women's Hospital and Harvard Medical School, Boston, MA.

The type 2 diabetes (T2D) associated glucokinase regulatory protein gene (*GCKR*) variant was recently found to be related to circulating levels of amino acids, including branched-chain amino acids (BCAAs) and aromatic amino acids (AAAs) that are predictors of T2D. We investigated whether blood BCAAs and AAAs levels modified associations of the *GCKR* variant on changes in glucose metabolism among overweight or obese individuals who participated in the POUNDS Lost trial, a 2-year weight-loss diet intervention study. This study included 691 participants with genotyping data on *GCKR* variant rs780094 and blood BCAAs (valine, leucine and isoleucine) and AAAs (tyrosine and phenylalanine). We found that plasma phenylalanine significantly modified association of the *GCKR* genotype with 6-month changes in fasting glucose ($P_{interaction}$=0.019) regardless of body mass index at baseline. Among individuals with high phenylalanine levels at baseline, increasing number of the diabetes-risk-reducing A allele was associated with increase in glucose concentration (β [SE], 1.56 [0.69]; *p*=0.02). Conversely, among those with low phenylalanine levels, carrying the A allele showed a significant reduction (β [SE], −1.46 [0.65]; *p*=0.03). Similar but less significant interaction patterns were also observed at 2 years. Blood BCAAs did not interact with *GCKR* for the changes in glucose concentrations. In conclusion, blood AAA modified associations of the *GCKR* variant on changes in glucose after the diet intervention. Our study suggests that low phenylalanine levels improve glucose metabolism in response to weight-loss diets for overweight or obese individuals with the diabetes-risk-reducing *GCKR* A allele.

Adiponectin isoform distribution in carriers of ethnic-specific *ADIPOQ* **mutations: The Insulin Resistance Atherosclerosis Family Study (IRASFS).** *K.L. Tabb[1,2,3], C. Gao[2,3,4,5], G.A. Hawkins[2,5], J.I. Rotter[6], Y.-D.I. Chen[6], J.M. Norris[7], C. Lorenzo[8], B.I. Freedman[2,3,5,9], D.W. Bowden[1,2,3], N.D. Palmer[1,2,3,4,5].* 1) Dept of Biochemistry, Wake Forest School of Medicine, Winston-Salem, NC; 2) Center for Genomics & Personalized Medicine, Wake Forest School of Medicine, Winston-Salem, NC; 3) Center for Diabetes Research, Wake Forest School of Medicine, Winston-Salem, NC; 4) Molecular Genetics and Genomics Program, Wake Forest School of Medicine, Winston-Salem, NC; 5) Center for Public Health Genomics, Wake Forest School of Medicine, Winston-Salem, NC; 6) Inst for Translational Genomics and Population Sciences/ Dept of Pediatrics, LA BioMed-UCLA Med Center, Torrance, CA; 7) Dept of Epidemiology, Colorado School of Public Health, University of Colorado Denver, Aurora, CO; 8) Dept of Medicine, University of Texas Health Science Center, San Antonio, TX; 9) Dept of Internal Medicine, Wake Forest School of Medicine, Winston-Salem, NC.

   Adiponectin, an adipokine synthesized and secreted specifically by adipocytes, is found in human serum in three distinct multimers (high, medium, and low molecular weight). The high molecular weight (HMW) multimer has been reported to be the most biologically active isoform. Our laboratory has previously reported two ethnic-specific variants in *ADIPOQ*, G45R in Hispanic Americans and R55C in African Americans. In our original report, carriers of both variants had mean adiponectin levels, measured by radioimmunoassay (RIA), that are approximately 19% of those of non-carriers. While adiponectin levels are observed to be inversely correlated with cardiometabolic disease, heterozygous mutation carriers were not clinically different from non-carriers. In this study, we used western blotting to explore the multimeric distribution of adiponectin in carriers of each variant to elucidate the lack of a clinical phenotype associated with cardiometabolic disease. Using a native PAGE protocol, serum proteins of archived human serum samples from the Insulin Resistance Atherosclerosis Family Study (Hispanic American, n=125; African American, n=47) were separated and transferred to a nitrocellulose membrane for antibody-based detection and densitometry analysis. Fluorescent imaging of the membranes showed an absence of the HMW isoform and a marked (>90%) reduction in the medium molecular weight isoform in serum samples from G45R and R55C carriers compared to those of non-carriers. There was a corresponding 20% increase (p<0.01) in the amount of the low molecular weight isoform (LMW) compared to non-carriers. This is in contrast to our original findings and is likely due to the preferential detection of the HMW by the antibody used in the RIA. These results challenge the current understanding of the importance of the HMW multimer, suggesting that the increase in the LMW isoform, and thus total serum adiponectin, may functionally compensate for the loss/reduction of the higher order multimers in carriers of the G45R and R55C *ADIPOQ* variants and could therefore explain the clinically normal phenotype of these individuals. These results have implications for efforts to use adiponectin therapeutically.

New insights into the control of obesigenic pathways - A comprehensive proteomics and genetics data integration approach. *J. Carayol[1], A. Valsesia[1], S. Métairon[2], P. Descombes[2], J. Hager[1].* 1) Nutrition and Metabolic Health, Nestlé Institute of Health Sciences SA, Lausanne, Vaud, Switzerland; 2) Functional Genomics, Nestlé Institute of Health Sciences SA, Lausanne, Vaud, Switzerland.

   Many genes and proteins influencing bodyweight, like leptin or adiponectin have been identified and characterized. While they have considerably enriched our understanding of the pathways involved in obesity, many aspects of how these genes/proteins are controlled on the molecular level remain unknown. Many of these proteins show large inter-individual variability and/or changes during weight loss interventions. It is not clear if these changes mainly stem from environmental influences or systemic biological differences. Availability of high-throughput omics technologies including genomics and proteomics should allow the characterization of the molecular mechanisms underlying obesity and their regulation. We performed the first large-scale proteomics screen combined with analysis of variation in the genome in one of the largest multi-centric weight loss intervention trials, the Diogenes study. Information from 1,129 proteins and 4 million SNPs was available for 498 participants before and after a low calorie diet (LCD) intervention. Association was tested first between BMI and proteins levels, both for baseline and fold changes during LCD intervention. For proteins associated with BMI variations before and during LCD, protein Quantitative Trait Locus (pQTL) analysis was performed using a linear mixed model. At baseline out of 146 proteins associated with BMI, 50 had pQTL signals (29 cis-acting and 21 trans-acting loci). In contrast among 127 proteins associated with BMI change during LCD, only trans-acting pQTLs (n=28) were identified, even at a relaxed suggestive association pvalue cutoff set to 1e-06. One of the strongest trans-acting pQTL signals for weight loss associated proteins was for leptin plasma levels. The SNPs for this pQTL are in a region on chromosome 6 (SNP rs1336257, p = 1.1e-7) that is enriched in transcription factor binding sites and close to the BCKDHB gene involved in branched chain aminoacid catabolism. We hypothesize that this or other genes in this region may be new regulators of leptin levels during weight loss. To our knowledge, we performed the first pQTL analysis in obesity and provide novel insight into the regulation of gene's protein product before and after weight-loss in subjects with overweight and obesity.

1219W

Association of *ENPP1* K121Q polymorphism with common obesity in North Indian Punjabi population. *H. Kaur[1], B. Doza[1,2], M. Singh[1], J. Kaur[1].* 1) Human Genetics, Guru Nanak Dev University, Amritsar, India; 2) Director, Aligarh Muslim University off-campus, Murshidabad, West Bengal.

Obesity is a complex phenotype resulting from the combined effects of genes, behavioral factors, and their interactions. A large number of genetic association studies suggest that polymorphic variants in genes are associated with BMI. Genetic variants of the *ENPP1* are reported to be associated with obesity in different ethnic populations. The aim of the present study was to examine the association of *ENPP1*(K121Q) polymorphism with obesity and obesity related phenotypes in Punjabi population. A total of 200 subjects, 100 obese (50 male/ 50 female) and 100 gender matched non obese were included from Amritsar region of Punjab. Various anthropometric and physiometric measurements were taken for all the subjects. Genotyping of *ENPP1*gene K121Q polymorphism was performed by the PCR-RFLP method, PCR products digested with restriction enzyme Ava Π, followed by Agarose Gel Electrophoresis. The genetic effects were analyzed according to gender (male and female). Deviation from Hardy- Weinberg Equilibrium (HWE) was observed for this gene variant within both the male cases (p= 0.05) and control (p=0.001) groups , whereas in female group controls showed significant deviation (p= 0.001). In males the association in dominant model was the highest but not significant (OR: 1.44; p=0.673), no significant associations were observed in the recessive, co-dominant and dominant mode of inheritance whereas in females the association in dominant model was very negligible and significant (OR:6.47; p=0.014) and the association in co-dominant model (QQ vs. KQ) = (KQ vs. KK) was found comparatively higher (OR: 3.26; p= 0.038) as compared to recessive model (QQ vs. KK/KQ) (OR: 2.09; p=0.548).The Q allele did not differ between obese cases and control subjects in both male(OR: 0.2263; 95%CI 0.0589-0.8689 ; p= 0.0304) and females (OR: 0.4681; 95%CI: 0.11-1.99; p= 0.2358). Further in females the Q allele was found to have significant association with BMI (p=0.0038). The estimates of relative risk (odds ratio) for the *ENPP1* K121Q polymorphism in obese subjects and normal control subjects for both genotypic and allelic frequencies were observed to be statistically significant (genotypic frequencies: OR: 0.1546; 95%CI: 0.03-0.81; p=0.0275; allelic frequencies: OR: 0.2263, 9s5%CI: 0.06-0.87; p=0.0304) in females. In conclusion *ENPP1/PC-1* K121Q polymorphism influences the risk of obesity in north Indian Punjabi female population whereas no association was found in Male population.

A study on genetic variation associated with visceral adipose tissue and interaction of life style on the expression of genetic variation. *H. Kwon, J. Park, B. Cho, J. Yoon.* Family Medicine, Seoul National University Hospital, Seoul, South Korea.

Introduction : Obesity, especially abdominal obesity is known as a risk factor for various diseases, and also to increase mortality. Among components of abdominal obesity, visceral adipose tissue (VAT) is a risk for various metabolic diseases and mortality. Genetic variations affecting abdominal obesity have been identified, and interactions between genetic variations and lifestyle factors also have been studied. But there has been no study on genetic variations altering VAT in Koreans, nor study on interaction between genetic variations and life style factors affecting VAT in Koreans. In this study, I have tried to find the association of VAT and SNPs which were previously known to be associated with obesity, and also to test the interaction of life style such as smoking, alcohol drinking and physical activity on the association of VAT and SNPs. Methods : I have selected 17 SNPs previously known to be associated with obesity, and analyzed selected SNPs through realtime PCR from the blood of Korean men aged 20 to 65 who took comprehensive health checkup programs including abdominal fat analysis with CT scan. I have tested the association between selected SNPs and obesity traits including VAT with linear regression analysis, and also checked interaction of life style factors on the association. I also tried stratified analysis with the criteria of body mass index 25kg/m2. Results : Rs9939609 was associated with VAT in dominant model, with AT/AA allele type tends to 6.8cm2 higher in VAT, 0.6kg/m2 higher in body mass index, 1.4cm thicker in waist circumference, 0.7% more in body fat, and 11.2cm2 higher in abdominal subcutaneous fat. On interaction analysis, rs1514175, rs2112347, rs10767664 were affected by alcohol drinking, and rs1718537 and rs3817334 were affected by physical activity on their association with VAT, but on stratified analysis by life style factors there was no significant difference in VAT according to allele type. On stratified analysis by body mass index, rs713586 and rs3810291 were associated with VAT only in subjects with body mass index higher than 24kg/m2 Conclusions : Rs9939609, rs713586 and rs3810291 were associated with VAT in Korean male, and this finding could be implemented in practice and study in the field of obesity.

1221F

Variants in fat mass and obesity gene are associated with variability of body mass index from childhood to adulthood. *S. Li, T. Zhang, C. Fernandez.* Epidemiology, Tulane School of Public Health and Tropical Medicine, New Orleans, LA.

Variants in the fat mass and obesity gene (*FTO*) have been associated with phenotypic variability of body mass index (BMI) in large-scale genome-wide association studies. However, no studies have examined associations between the *FTO* variants and BMI variability across the life course. Taking advantage of a longitudinal black-white cohort beginning in early childhood (n=1,201with 10,313 observations; age: 4.0-51.0 years with an average follow-up period of 31.4 years), we examined the variant rs994134 in the *FTO* gene with BMI variability from childhood to adulthood. BMI residual standard deviation (RSD) derived from mixed models was used as a measure of BMI variability. The association of rs994134 with BMI and RSD was similar in blacks and whites (P>0.49 for interactions with race). On average, the T allele was associated with 0.60 kg/m^2 increase in BMI (P=0.005) and 0.09 kg/m^2 (P=0.008) increase in RSD, relative to the C allele after adjusting for race and sex. The association of rs994134 with BMI RSD persisted (P=0.04) when RSD was adjusted for absolute BMI values. In conclusion, the BMI-increasing allele of the *FTO* variant rs994134 is also associated with BMI variability from childhood to adult life.

1222W

Assessment of copy number variation in two protocadherin genes and its effect on childhood obesity predisposition in Koreans. *S. Moon, M.Y. Hwang, B.J. Kim.* Korea National Intsitute of Health, Cheongwon-gun, Chungcheongbuk-, South Korea.

Recently, the prevalence of childhood obesity has significantly increased in industrialized countries, including Korea, and now controlling obesity is becoming an economic burden. However, knowledge of the risk factors associated with obesity is still limited. In this study, we aimed to discover additional obesity-associated loci in children. To achieve this, we conducted a genome-wide association study of copy number variation (CNV) using whole-exome sequencing (WES) data from 102 extremely obese and 86 normal weight children.Using a logistic regression analysis, we identified a CNV locus that overlapped two protocadherin genes, PCDHB7 and PCDHB8, which are brain function–related genes (P-value = 6.40 × 10^{-4}, odds ratio = 2.2189). A subsequent replication analysis using WES data from 203 obese and 291 normal weight children showed that this CNV region satisfied the genome-wide significance standard (Fisher's combined P-value = 7.29 × 10^{-5}). Moreover, correlation test using 199 additional samples supported significant association between CNV and increased body mass index. This region also showed a meaningful, although not enough significant, association with obesity in 4,694 community-based adult samples. Our findings suggest that differences in the common CNV region at 5q31.3 may have an impact on the pathophysiology of obesity.

1223T

Assessing variation across 98 established loci for body mass index in American Indians. *Y.L. Muller, P. Piaggi, P. Chen, G. Wiessner, C. Okani, G. Skelton, S. Kobes, M. Hohenadel, W.C. Knowler, C. Bogardus, R.L. Hanson, L.J. Baier. NIDDK, NIH, Phoenix, AZ.*

Meta-analyses of genome-wide association studies (GWAS) have identified ~98 established ($p < 5 \times 10^{-8}$) loci for Body Mass Index (BMI). The GWAS data included in these meta-analyses were predominately derived from individuals of European ancestry. To assess the role of these established BMI loci in American Indians who have a high prevalence of obesity, we analyzed the lead SNPs at these loci in a longitudinally studied population of full heritage Pima Indians who were informative for BMI in adulthood (maximum BMI recorded at age ≥15 years, n=3412), BMI z-score in childhood (maximum age-and-sex specific z-score at age 5-20 years, n=2296) and percent body fat in adulthood (n=555). Among the 98 lead SNPs, 16 were monomorphic or had a minor allele frequency (mAF) <0.01 in Pima Indians. Of the remaining 82 SNPs (mAF≥0.01) analyzed, 11(*TMEM18, MRPS33P4, TCF7L2, ZFP64, LMX1B, PRKD1, FTO, GRP, NLRC3, TAL1, RPTOR*) nominally associated with BMI in Pima Indian adults (p=1.6 x 10^{-4} to 0.05) in a direction consistent with that reported in the European meta-analyses. A multi-allelic genetic risk score (GRS), which summed the risk alleles for all 82 SNPs, showed a significant trend for the relationship between increasing number of risk alleles in Pima Indians and BMI in adulthood (β=0.16 kg/m^2 per risk allele, p=2.8 x 10^{-8}), BMI z-score in childhood (β=0.024 SD, p=6.8 x 10^{-9}) and % body fat (β=0.17 %, p=3.0 x10^{-4}). To determine whether different variants at these loci also contribute to BMI in American Indians, ~6000 SNPs which tag (r^2≥0.85) common variation (mAF ≥0.05) detected in whole genome sequence data from 295 Pima Indians across all 98 loci were evaluated in an expanded population-based sample of 7710 Pima Indians (including mixed heritage individuals). Tag SNPs in 26 of 98 loci had additional variants that associated with BMI (p=8.1x10^{-6} to 0.002) after accounting for the number of tag SNPs at each locus using the Sidak correction. The strongest BMI signal was in *GPR* (rs1563713, p=8.1 x 10^{-5}). In conclusion, nominal but directionally consistent replication of established BMI variants was observed in Pima Indians. In aggregate these SNPs had a notable effect on BMI in both adulthood and childhood, suggesting that these variants, or nearby functional variants, influence BMI in American Indians. Analysis of additional variation in these loci provided evidence for additional variants in some of the loci.

1224F

Genome-wide gene-based SNP analyses identify mir-486 as a predictive marker of weight loss in obese, non-diabetic patients upon low-caloric diet intervention. *A. Valsesia[1], J. Carayol[1], N. Gheldof[1], G. Lefebvre[1], S. Metairon[1], C. Chabert[1], N. Viguerie[2], D. Langin[2], P. Descombes[1], M.E. Harper[3], R. Mc Pherson[4], R. Dent[5], A. Astrup[6], W. Saris[7], J. Hager[1]. 1) Nestlé Institute of Health Sciences, Lausanne, Switzerland; 2) INSERM UMR1048, Obesity Research Laboratory, Institute of Metabolic and Cardiovascular Diseases, University of Toulouse, France; 3) Department of Biochemistry, Microbiology and Immunology, Faculty of Medicine, University of Ottawa; 4) Atherogenomics Laboratory, University of Ottawa Heart Institute, Ottawa, Canada; 5) Ottawa Hospital Weight Management Clinic, The Ottawa Hospital, Ottawa, Canada; 6) University of Copenhagen, Department of Nutrition, Exercise and Sports, Faculty of Science, Copenhagen, Denmark; 7) Department of Human Biology, NUTRIM, School of Nutrition and Translational Research in Metabolism, Maastricht University Medical Centre + (MUMC+), Maastricht, The Netherlands.*

Obesity is a major risk factor for a number of co-morbidities including cardiovascular disease, dyslipidemia, hypertension, insulin resistance and type 2 diabetes (T2D) as well as cancer. Multiple studies have shown that weight loss through energy-restricted dietary interventions improves the metabolic dysfunctions involved in metabolic syndrome. Nevertheless, large inter-individual variability is observed regarding the capacity to lose and maintain weight. In addition, initial BMI has been shown to have some predictive value but is not useful in obesity intervention studies where subjects have similar starting BMI's. Here, we present a gene-based genome-wide association analysis of two large dietary intervention studies: the Ottawa weight maintenance program (n=1166), used as discovery cohort; and the DiOGenes randomized clinical trial (n=798, NCT00390637), used as validation cohort. Our analyses aimed at identifying SNPs associated with weight loss upon a low-caloric diet (LCD) intervention. Using a two-stage approach, we found that SNPs nearby the mir-486 gene were associated with weight loss (FDR=5.5% in the validation cohort). Nominal gene-based p-values were as follows: p=1.9e-4 in the discovery cohort, p=5.2e-3 in the validation cohort and p=1.1e-5 from meta-analysis. Quantification of mir-486 levels in adipose tissue biopsies (n = 440) in the validation cohort showed that baseline levels were associated with clinical outcomes both for weight and glycemic control. Upon LCD, we observed significant association between baseline mir levels with weight loss (p=0.019) and marginal association with improvement in glycemic control (p=0.10). Six months after the LCD, the association was significant for both endpoints (p=0.034 and 0.021, respectively for weight and glycemic control). In conclusion, our analyses identified SNPs, encompassing the mir-486 locus, associated with weight loss upon low-calorie diet. Analyses of baseline mir-RNA levels from adipose tissue biopsies showed association with long-term clinical improvements, both for weight and glycemic outcomes. Our study identified a potential biomarker for stratification of obese, non-diabetic subjects prior to weight loss intervention.

1225W

A meta-analysis of genome-wide association studies for susceptibility loci to diabetic nephropathy in Japanese patients with type 2 diabetes. *M. Taira[1], M. Imamura[1,4,5], A. Takahashi[2,6], Y. Kamatani[2], M. Kubo[3], S. Maeda[1,4,5].* 1) Laboratory for Endocrinology, Metabolism and kidney Diseases, RIKEN Center for Integrative Medical Sciences, Kanagawa, Japan; 2) Laboratory for Statistical Analysis, RIKEN Center for Integrative Medical Sciences, Kanagawa, Japan; 3) RIKEN Center for Integrative Medical Science, Kanagawa, Japan; 4) Department of Advanced Genomic and Laboratory Medicine Graduate School of Medicine, University of the Ryukyus, Okinawa, Japan; 5) Division of Clinical Laboratory and Blood Transfusion, University of the Ryukyus Hospital, Okinawa, Japan; 6) National Cerebral and Cardiovascular Center, Omics Research Center, Osaka, Japan.

   Background: Diabetic nephropathy (DN) is a leading cause of end-stage renal disease in Western countries as well as in Japan. Although several reports have shown that genetic factors play a pivotal role in the development and progression of DN, worldwide efforts to identify susceptibility loci for DN have not been successful so far. To explore novel genetic loci associated with the susceptibility to DN, we performed a meta-analysis of genome-wide association studies (GWAS) for DN in Japanese patients with type 2 diabetes (T2DM). **Methods**: We divided Japanese patients with T2DM registered in Bio-Bank Japan, who had been analyzed in previously reported GWAS for T2DM (Set-1: 9,343, Set-2: 3,607), into two groups; 1) DN cases, defined as patients having overt nephropathy or end-stage renal disease, 2) controls, who did not have any sign of DN and with diabetic retinopathy or with long duration of diabetes (> 5 years). As our discovery stage, we examined two independent case-control groups (Study-1: 2,380 DN cases and 5,238 controls, Study-2: 429 DN cases and 358 controls) obtained by genotype imputation using 1000 genomes reference data (phased JPT+CHB+CHS, March 2012). Results of the two GWAS were combined with an inverse variance method. **Results:** We did not observe any loci showing genome-wide significant association with DN in the initial GWAS meta-analysis, and we selected candidate SNP loci (p-value < 1.0×10^{-4}) for further analysis. Subsequently, we performed *de novo* genotyping for the candidate SNP loci by Multiplex-PCR Invader assay in an independent case-control study (Set-3: 1,213 DN cases and 1,298 controls) and all association data (Set-1, Set-2 and Set-3) were combined with a meta-analysis. After integrating all association data by a meta-analysis, we identified that the association of one SNP locus reached a genome-wide significance level (combined *P*-value =7.74×10^{-10}, odds ratio 1.23) and six SNP loci showed borderline association with DN (5×10^{-8} < combined *P*-value < 5×10^{-7}). There is no overlap between the above seven SNP loci and previously-reported loci for susceptibility to DN. **Conclusion**: We have identified a novel locus for conferring susceptibility to DN. Further studies using independent case-control groups are required to confirm the association of this locus with DN. .

Expression QTL analysis reveals *RHBDF2* as a candidate gene for Non-Alcoholic Steatohepatitis. *M. Olivier[1], E. Drigalenko[1], M.I. Goldblatt[2], J.R. Wallace[2], H.H.H. Göring[1,5], D.E. Kleiner[3], S. Gawrieh[4].* 1) Department of Genetics, Texas Biomedical Research Institute, San Antonio, TX; 2) Department of Surgery, Medical College of Wisconsin, Milwaukee, WI; 3) Laboratory of Pathology, National Cancer Institute, Bethesda, MD; 4) Department of Medicine, Indiana University, Indianapolis, IN; 5) current affiliation: South Texas Diabetes and Obesity Institute, University of Texas Rio Grande Valley, Brownsville, TX.

   Nonalcoholic fatty liver disease (NAFLD) is characterized by hepatic steatosis in the absence of significant alcohol use. Some patients with NAFLD have nonalcoholic steatohepatitis (NASH), which may progress to cirrhosis and liver failure. Both genetic and environmental factors contribute to the development and progression of the disorder, but only few genes have been identified so far that contribute to NAFLD or NASH. We collected liver biopsy samples from 76 morbidly obese patients of Northern European descent undergoing bariatric surgery. All biopsies were evaluated according to the NASH Clinical Research Network system the NAFLD Activity Score (NAS) was recorded. 30 individuals had unremarkable histology and served as controls, 28 had NAFLD but not steatohepatitis, 9 as borderline steatohepatitis, and 9 individuals were diagnosed with definite NASH. Gene expression in the liver was analyzed using Illumina BeadChip arrays, HumanWG-6. In the 76 samples, expression levels of 23 genes were significantly associated with NAS scores, including *TGFBI*, *FABP4*, and several collagen genes. To identify sequence variants associated with these changes in gene expression (eQTL), SNPs were selected from Affymetrix SNP6 chop data within 100 kb of the expression probes for these 23 genes, and analyzed for association with the respective gene expression level. Two sequence variants upstream of the transcription start site of the gene *RHBDF2* on chromosome 17 were significantly associated after correction for multiple testing ($p<1 \times 10^{-3}$), and four additional variants were nominally associated ($p<0.05$). This gene (Rhomboid 5 Homolog 2) has not previously been reported to contribute to the development or progression of NAFLD. *RHBDF2* has been associated with esophageal cancer, and related pathways include immune system and signaling by GPCR. GO annotations related to this gene include serine-type endopeptidase activity and growth factor binding. Interestingly, the expression of its paralog gene, *RHBDF1*, is also significantly associated with NAS score. Our analysis suggests that *RHBDF2* (and possibly *RHBDF1*) may contribute to NAFLD and NASH, however, the specific role(s) of *RHBDF1* and *RHBDF2* remain to be elucidated.

1227F

SUGP1 is a novel regulator of cholesterol metabolism. *M.W. Medina[1], M. Kim[1], C.Y. Yu[1], E. Theusch[1], D. Naidoo[1], K. Stevens[1], Y.L. Kuang[1], E. Schuetz[2], A. Chaudhry[2]. 1) Children's Hospital Oakland Research Institute, Oakland, CA; 2) Department of Pharmaceutical Sciences, St. Jude Children's Research Hospital, Memphis, TN.*

A large haplotype on chromosome 19p13.11, tagged by rs10401969 in intron 8 of SURP and G patch domain containing 1 (*SUGP1*), has been associated with a number of cardiometabolic phenotypes including plasma total cholesterol, LDL-cholesterol, and triglycerides as well as incidence of coronary artery disease, hepatic steatosis and nonalcoholic fatty liver disease. Several recent studies have suggested that transmembrane 6 superfamily member 2, *TM6SF2*, is the causal gene within the locus. However, in individuals of European ancestry, the 19p13.11 haplotype spans ~360kb, contains 16 protein-coding genes, and harbors several SNPs in perfect or near perfect linkage disequilibrium ($r^2 > 0.95$, D'=1) with rs10401969. Thus, we postulated that this locus may harbor additional risk genes, including the putative splicing factor *SUGP1*. Using a mini-gene construct, we found that rs10401969 regulates *SUGP1* exon 8 skipping, causing nonsense-mediated mRNA decay. Through an RNA electrophoretic mobility shift assay (EMSA), we observed altered binding of HNRNPA1, a well-known splicing factor, depending on rs10401969 allele. Hepatic *Sugp1* overexpression in CD1 male mice increased plasma cholesterol levels 20-50%. In human hepatoma cell lines, *SUGP1* knockdown stimulated 3-hydroxy-3-methylglutaryl-CoA reductase (*HMGCR*) alternative splicing and decreased *HMGCR* transcript stability. HMGCR encodes the rate-limiting step of cholesterol biosynthesis, thus *SUGP1* knock-down also caused reduced cholesterol synthesis and increased LDL uptake, consistent with the change in plasma cholesterol observed *in vivo*. Furthermore, the directionality of the effects from modulating SUGP1 both *in vivo* and *in vitro* was also consistent with the original GWAS finding that the rs10401969 minor allele is associated with reduced plasma LDL-cholesterol. Our results strongly support a role for SUGP1 as a novel regulator of cholesterol metabolism and suggest that it contributes to the relationship between rs10401969 and plasma cholesterol. Thus, our findings highlight the possibility that a GWAS locus may harbor more than one causal gene.

1228W

The impact of genetic risk on effectiveness of lifestyle intervention in a general population. *M. Conomos, J.C. Lovejoy, A.T. Magis. Arivale, Seattle, WA.*

With increased focus on personalized and precision medicine in the media, public interest in lifestyle intervention aimed at improving biomarker levels associated with disease risk that is tailored to personal genetics has grown considerably in the past few years. However, it is well known that an individual's phenotype for many complex traits is determined by both a heritable genetic component that cannot be altered, as well as an environmental component that may be modifiable. In this study, we investigate the impact of genetic risk on the effectiveness of lifestyle intervention aimed at improving clinical markers of cardiovascular risk. Blood lipid levels were regularly collected and used for lipid profiling, and whole genome sequencing was performed on a cohort of more than 1000 individuals who were enrolled in a lifestyle intervention program for at least six months. Using previously published GWAS data from the entire genome, we construct polygenic scores predictive of total cholesterol, LDL and HDL cholesterol, and triglyceride levels that are used to partition individuals into genetic risk strata for having unhealthy lipid levels. Taking advantage of the longitudinal blood measurements collected, we are able to quantify the improvement of lipid levels over time in the cohort as a whole, as well as within the genetic risk strata. This allows us to test the hypothesis that, among individuals with unhealthy baseline lipid levels, lifestyle intervention can more effectively improve lipid levels for individuals in low genetic risk strata than individuals in high genetic risk strata. This study provides insight into strategies for genetics-based personalization of lifestyle intervention to improve specific clinical markers and optimize wellness.

1229T

Identifying genetic variants for serum lipoprotein(a) independent of kringle repeat polymorphism. *S.M. Hosseini[1,2], J.K. Snell-Bergeon[3], A.P. Boright[4], A.J. Canty[5], L. Sun[6,7], S.B. Bull[6,8], S.M. Marcovina[9], J.D. Brunzell[9], A.D. Paterson[2,6], the DCCT/EDIC Research Group.* 1) Ted Rogers Cardiac Genome Clinic, Hosp Sick Children, Toronto, ON, Canada; 2) Genetics and Genome Biology Program, The Hospital for Sick Children Research Institute, Toronto, Canada; 3) Barbara Davis Centre for Diabetes, University of Colorado, Aurora, CO, USA; 4) Department of Medicine, University of Toronto and LMC Diabetes & Endocrinology, Toronto, Canada; 5) Department of Mathematics & Statistics, McMaster University, Hamilton, Canada; 6) Dalla Lana School of Public Health, University of Toronto, Toronto, Canada; 7) Department of Statistical Sciences, University of Toronto, Toronto, Canada; 8) Lunenfeld-Tanenbaum Research Institute of Mount Sinai Hospital, Toronto, Canada; 9) Northwest Lipid Metabolism and Diabetes Research Laboratories, Division of Metabolism, Endocrinology and Nutrition, Department of Medicine, University of Washington, Seattle, WA, USA.

Lipoprotein(a) [Lp(a)] is a highly heritable, independent risk factor for cardiovascular diseases (CVD). Lp(a) level is mainly determined by variation in the *LPA* region with significant contribution from a VNTR (variable number tandem repeat) in *LPA* coding for the KIV-2 (kringle IV type 2) domain of apolipoprotein(a). Diabetes is an important CVD risk factor and may also influence Lp(a) metabolism. To investigate genetic determinants of Lp(a) in diabetes and identify novel quantitative trait loci (QTL) for Lp(a) independent of KIV-2 copy number (KCN) we studied two cohorts of white European ancestry with type 1 diabetes (T1D): The Diabetes Control and Complications Trial (DCCT) and Coronary Artery Calcification in T1D (CACTI). Both cohorts were genotyped using Illumina arrays, with imputation of untyped SNPs using the 1000 Genomes data for the conditional GWAS. Here, we report four major findings. First, in the univariate GWAS, 56 genotyped SNPs in the *LPA* region show genome-wide significant ($p<5\times10^{-8}$) association with Lp(a) in DCCT, all of which replicate in CACTI ($3.5\times10^{-7}<p<0.01$). Second, KCN alone, determined using multiplex qPCR, explains 19% of Lp(a) variation in DCCT. 38 SNPs in the *LPA* region show association with KCN ($p<5\times10^{-8}$), with evidence for 15 independent signals in multivariate linear regression, capturing >41% of KCN variation. A genetic risk score for KCN, calculated based on these 15 SNPs, explains 14% of variation in Lp(a) in CACTI. Third, after adjusting for the effect of KCN on Lp(a) in DCCT, 63 SNPs from *LPA* region are still associated with Lp(a) ($p<5\times10^{-8}$), of which 15 showed independent evidence in multivariate analysis (5 with $p<5\times10^{-8}$). Fourth, conditional GWAS accounting for the main *cis* effects, revealed no genome-wide significant association in DCCT, but discovered one in CACTI (rs111850011, $p=3\times10^{-8}$). This SNP is located 26 kb upstream of steroid-5-alpha-reductase, alpha polypeptide 2 (*SRD5A2*). 5α-reductase is an important regulator of lipoprotein metabolism. The SNP shows consistent direction of effect in DCCT without being significant ($p=0.6$). Attempts at replication in independent populations are underway. In conclusion, consistent with studies in non-diabetics, we identify several SNPs in the *LPA* region that contribute to serum Lp(a) in T1D. We show that these variants exert their effect either independent of KIV-2 VNTR or as its proxies. Finally, we identify a novel genome-wide significant *trans* QTL for Lp(a).

1230F

Multiplexed targeted resequencing identifies rare noncoding variants associated with high HDL cholesterol. *S.A. Khetarpal[1,2,4], P.L. Babb[2,3,4], W. Zhao[1,2], S. DerOrhannessiani[1,2], W.F. Hancock-Cerutti[1,2], S. Elwyn[1,2], T. Tran[1,2], C.D. Brown[2], B.F. Voight[2,3,4], D.J. Rader[1,2,4].* 1) Department of Medicine, Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA; 2) Department of Genetics, Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA; 3) Department of Pharmacology, Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA; 4) equal contribution.

Genome-wide studies in large populations have uncovered many loci influencing levels of high-density lipoprotein cholesterol (HDL-C), a biomarker for risk of heart disease. However, the contribution of the identified genes is unknown and difficult to ascertain from current genotyping studies of common variants with relatively small effects, prompting the need for efficient, cost-effective methods to identify rare variants with putatively larger impact. Here, we utilized a multiplexed inversion probe (MIP) target capture approach to resequence seven HDL-C associated loci in 797 individuals with extremely high HDL-C (>95th percentile for age and gender) vs. 735 normal HDL-C controls. Our targets included the coding regions of *APOC3*, *SCARB1*, *CETP*, *LIPG*, *CCDC92*, *ZNF664*, and *GALNT2* (>29 kb), along with regulatory features in the noncoding genome (>16 kb). Validation in 1,119 of the 1,532 participants on the Exome Array resulted in >95% genotyping concordance across SNPs. From our resequencing, we first identified known GWAS signatures in *GALNT2*, *CETP*, and *LIPG* and found consistent associations with high HDL-C as reported in the larger GWAS, thus supporting our study design involving HDL-C phenotypic extremes. Second, we discovered multiple novel, rare, noncoding variants individually associated with increased HDL-C ($P<1.74\times10^{-05}$, Score Test). Additionally, gene-burden testing of aggregated coding variants across each region with HDL-C identified a significant excess of variants in *SCARB1* associated with high HDL-C levels, consistent with recent discoveries in humans with complete *SCARB1* loss-of-function. Our targeted resequencing at the extremes of HDL-C thus revealed multiple novel noncoding variants for further study and supports the rationale for larger efforts to resequence the noncoding genome to find rare variants for complex traits.

Replication of a single nucleotide polymorphism variant in *CETP* gene associated with large-HDL particle in the ClinSeq® Study. *H. Sung[1], M. Sampson[2], K. Lewis[3], D. Ng[3], S.G. Gonsalves[3], J.C. Mullikin[4,5], A. Remaley[6], A.F. Wilson[1], National Institutes of Health Intramural Sequencing Center(NISC).* 1) Genometrics Section, Computational and Statistical Genomics Branch, National Human Genome Research Institute, NIH, Baltimore, MD, USA; 2) Clinical Center, NIH, Bethesda, MD, USA; 3) Medical Genomics and Metabolic Genetics Branch, National Human Genome Research Institute, NIH, Bethesda, MD, USA; 4) National Institutes of Health Intramural Sequencing Center(NISC), National Human Genome Research Institute, NIH, Bethesda, MD, USA; 5) Comparative Genomics Analysis Unit, Cancer Genetics and Comparative Genomics Branch, National Human Genome Research Institute, NIH, Bethesda, MD, USA; 6) Lipoprotein Metabolism Section, National Heart, Lung, and Blood Institute, NIH, Bethesda, MD, USA.

ClinSeq® is a large-scale medical sequencing study designed to investigate associations of rare sequence variants with traits related to Coronary Artery Disease (CAD). The study currently includes more than 1000 non-smoking participants between the ages of 45 to 65 with normal to severe coronary artery calcification scores. About 200 CAD-related traits were measured at the NIH Clinical Research Center in Bethesda, MD. Whole-exome sequencing was performed with the Agilent SureSelect 38Mb and 50Mb capture kits for 387 and 325 individuals, respectively, at the NIH Intramural Sequencing Center. Single nucleotide variants (SNVs) common to both capture regions with a call rate > 98% and minor allele frequency (MAF) > 1% were used to check for cryptic relatedness and for mis-specified population stratification by multidimensional scaling analysis – 635 unrelated European Americans (EAs) remained. For each capture kit with EAs only, SNVs with at least one homozygote and a call rate greater or equal to 50% were included. The two capture regions with only SNVs in common were merged, yielding 439,807 SNVs. Of these SNVs, 74% and 46% had MAFs < 0.01 and < 0.001, respectively. The SNVs with MAF < 0.01 were collapsed into a single derived variant for each genomic region defined by hotspot blocks. Collapsed variants were coded as the proportion of minor allele occurring within each region; common variants were coded as the number of minor alleles (scaled from 0 to 1). Lipoprotein particle profiles including High Density Lipoprotein particle (HDLp) by nuclear magnetic resonance spectroscopy were measured at LipoScience/LabCorp Global Research Services. In this study, tests of association of each SNV with each classified HDLp were performed on untransformed, log-transformed and rank-inverse transformed HDLp with simple linear regression, adjusting for age, sex, BMI, use of medication. The SNVs rs1532625 and rs7205804 in the intron of *CETP* gene were associated (P = 1e-05) for all untransformed and transformed large-HDLp traits (combining the HDLp with estimated particle diameters of 9.7, 10.5 and 12 nm) after Bonferroni correction. This finding replicates the association by Reilly et al.(2013) between rs1532625 and HDL level.

1232T

Genome-wide association study identifies *TRAF3* as a novel susceptibility locus for Gallstone disease in Latin Chilean population. *B. Bustos[1], E. Pérez-Palma[1], S. Buch[2], L. Azócar[3], E. Riveras[3], C. Moraga[4], M. Toilat[5], J. Hampe[2], P. Nürnberg[5], R.A. Gutierrérrez[4,6], G.V. De Ferrari[1,6], J.F. Miquel[3,6].* 1) Centro de Investigaciones Biomédicas, Universidad Andres Bello, Santiago, Chile; 2) Medical Department I, University Hospital Dresden, TU Dresden, Dresden , Germany; 3) Depto. de Gastroenterología, Facultad de Medicina, Pontificia Universidad Católica de Chile, Santiago, Chille; 4) Depto. Genética Molecular y Microbiología, Facultad de Ciencias Biológicas, Pontificia Universidad Católica de Chile, Santiago, Chile; 5) Cologne Center for Genomics, University of Cologne, Cologne, Germany; 6) FONDAP Center for Genome Regulation (CGR).

Gallstone disease (GSD) is a gastrointestinal disorder with high prevalence in western countries. Genome-wide association studies and meta-analysis approach on GSD have reported a handful of lithogenic variants, being the most important the sterolin transporter ABCG8 (p.D19H). This signal has been replicated in different populations across the world, including Latin Chileans, however it only explains a small portion of the population attributable risk. The Chilean population has one of the highest prevalence of GSD in the world, but has been the target of only a few genetic studies. Here, we show the results from the first GWAS performed on the Chilean population. Subjects were recruited from community medical centers in Santiago de Chile. Status of GSD (cases or controls) was diagnosed by abdominal ultrasonography. Genotyping was done using Affymetrix Axiom LAT 1 World array Plates. Genome-wide Imputation was performed with IMPUTE2 using the 1000 Genomes Project Phase 3 reference panel. Association analyses were done using SNPTEST. Replication and gene expression analyses were performed using RT-qPCR with TaqMan probes and custom DNA primers, respectively. We selected 10 candidate loci surpassing suggestive genome-wide significance (p < 1×10^{-5}) in a discovery cohort of 1,095 individuals (529 cases, 566 controls). Replication was done in a cohort of 1,868 individuals (707 cases and 1,161 controls). We successfully replicated 2 signals: the previously known ABCG8 locus (discovery p=5.26×10^{-6}, OR=1.88; replication p=0.001, OR=1.58) and a novel signal on chromosome 14 (discovery p=4.9×10^{-6}, OR=1.50; replication p=0.003, OR=1.29) inside the TNF receptor-associated factor gene (TRAF3). Gene expression analysis in 22 RNA samples from human gallbladder tissues (11 cases, 11 controls) showed a significant decrease of TRAF3 levels in cases versus controls (fold change=0.51, p=0.015). Same results were observed in 41 RNA samples from duodenum tissue (19 cases, 22 controls; fold change=0.50, p=0.001). TRAF3 regulates pathways leading to the activation of NF-kappa-B and their lower expression levels could be linked to enhanced chronic and acute gallbladder inflammation observed in gallstone patients, which is implicated both in the pathogenesis as in development of symptoms in GSD. These results provide new insights into the genetic susceptibility of this prevalent disease in a high risk Latin population. **Funding:** FONDECYT #1130303-JFM, #1140353-GVD, FONDAP #1509000.

1233F

Genetic and environmental determinants of the susceptibility of hyperlipidemia in Taiwanese using Taiwan Biobank dataset. *C.N. Hsiung[1,2], C.Y. Shen[1,2].* 1) Taiwan Biobank, Academia Sinica, Taipei, Taipei, Taiwan; 2) Institute of Biomedical Sciences,Academia Sinica, Taipei, Taipei, Taiwan.

Hyperlipidemia is an important risk factor for cardiovascular disease and is affected by both genetic and environmental factors. Recent genome wide association studies (GWAS) have identified several loci associating with lipid level, but these have been identified mainly in European populations. We used Taiwan biobank database in order to identify not only environmental factors but also genetic markers predicting hyperlipidemia in a Taiwanese population The Taiwan biobank database has collected information from over 56,000 participants and whole-genome typing has been performed in 14,432 individuals. We used logistic regressions to build prediction models for hyperlipidemia. Whole-genome genotyping using TWBv1.0 chip (653,291 single-nucleotide polymorphisms, SNPs, specifically for the Han Chinese in Taiwan) is performed to generate polygenic scores. Our findings show that the model based on conventional risk factors resulted in good prediction with high efficiency area under the receiver operating characteristic (ROC-AUC=0.72). We then examined the risk associated with 55 SNPs for hyperlipidemia detected by GWAS, and resulted in a polygenic score, which increased the risk of hyperlipidemia (OR=2.64, 95% C.I. =2.477-2.828). The full prediction model, based on environmental risk factor and polygenic score together, led to better efficiency (ROC-AUC=0.82, P<0.0001). This study builds a prediction model, including environmental risk factors and polygenic score, for hyperlipidemia. On the basis of this finding, further measures aiming at public health intervention are designing to decrease the incidence of hyperlipidemia and cardiovascular disease in Taiwan population.

1234W

Meta-analysis of genome-wide association studies in Chinese and European populations identify novel loci associated with circulating monounsaturated fatty acids. *H. Li[1], H. Yao[1], J. Zhu[1], T. Monounsaturated fatty acids (MUFAs) have been suggested to have protective effects against cardio-metabolic disorders including metabolic syndrome, type 2 diabetes (T2D), and cardiovascular disease (CVD). Previous genome-wide association studies (GWAS) have identified loci for plasma phospholipid and erythrocyte palmitoleic acid (16:1n-7) and oleic acid (18:1n-9) levels in populations of European origin. To identify loci for other MUFAs, including vaccenic aicd (18:1n-7), gondoic acid (20:1n-9), erucid acid (22:1n-9), and nervonic acid (24:1n-9), we performed ethnic-specific GWAS meta-analyses and trans-ethnic meta-analyses in over 15,000 participants from nine cohorts of Chinese- and European-ancestry. Ten loci were genome-wide significant ($\log_{10}$Bayes factor)>6) in the trans-ethnic meta-analysis, including five novel loci (*PCDH15*, *STARP1*, *GGCT*, *IQCA1* and *ST8SIA5*), and five previously reported ones (*FADS1/2*, *PKD2L1*, *GCKR*, *HIF1AN* and *LPCAT3*). Novel associations were added to previously reported loci (*FADS1/2*, *PKD2L1* and *GCKR*) in our study. The previously reported associations of *PKD2L1*, *FADS1/2*, *GCKR* and *HIF1AN* with 16:1n-7 and of *FADS1/2* and *LPCAT3* with 18:1n-9 were confirmed in the Chinese populations and in the trans-ethnic meta-analysis. Additional genes and novel pathways were identified in the

gene- and pathway-based analysis. Our findings provide novel insight into the genetic basis for MUFA metabolism and emphasize the benefits of trans-ethnic meta-analysis for complex traits by discovering additional novel variants and testing for the difference of the identified loci across ethnic groups.

1235T

Parent-of-origin effects analysis of NMR metabolites. *N. Pervjakova[1,2], T. Haller[1], K. Kristiansson[4,6], A. Joensuu[3,4,5], M. Perola[4,6], R. Mägi[1].* 1) Estonian Genome Center University of Tartu, Tartu, Tartumaa, Estonia; 2) Department of Biotechnology, Institute of Molecular and Cell Biology, University of Tartu, Tartu 51010, Estonia;; 3) Institute for Molecular Medicine (FIMM), University of Helsinki, Biomedicum 2, Tukholmankatu 8, 00290 Helsinki, Finland; 4) Genomics and Biomarkers Unit, Department of Health, National Institute for Health and Welfare (THL), Biomedicum 1, Haartmaninkatu 8, 00290 Helsinki, Finland; 5) Diabetes and Obesity Research Program, Research Programs Unit, University of Helsinki, Haartmaninkatu 8, 00290 Helsinki, Finland; 6) Institute for Molecular Medicine Finland (FIMM), Helsinki, Finland.

   Parent-of-origin effect (POE) occurs when the allelic effect on phenotype depends on whether the allele is inherited from mother or father. POE can be mediated through several mechanisms, such as genomic imprinting, trans-generational effects, *in utero* effects and the maternal environment. The aim of this study was to identify POE of common variants in NMR metabolites. We considered 5,853 individuals from Estonian Biobank (EGCUT) for 82 NMR metabolites. Individuals were imputed to the 1000 Genomes Project reference panel (March 2012 release). POE analysis was conducted using POE method in QUICKTEST using markers with MAF ≥ 1%, and imputation quality ≥ 0.8. As the next step similar approach have been used for analysing two additional cohorts DILGOM (500 individuals) and FINRISK1997 (10,000 individuals) from Finland. All three cohorts were meta-analysed using fixed-effect inverse variance based meta-analysis in GWAMA. We observed evidence of novel POE variants for 7 metabolites - Identified variants are associated with lipids and lipoproteins. Two of the found variants (rs1330350 and rs189194743) located in *TNC* and *PTPRD* genes, respectively, which are associated with signaling molecules, regulating a variety of cellular processes, such as neuronal regeneration, mitotic cycle, cell growth, neurons and axons migration during development. These regulatory features provide normal embryonic growth and therefore it suggests that identified POE may be mediated through genomic imprinting. This idea motivated us to perform further steps, such as allele-specific expression analysis, epigenome-wide association analysis with further replication in an independent cohort and methylation QTL to investigate mechanisms underlying POE and its association with genomic imprinting. We believe that our results will highly contribute to uncovering complex relations between genetic variants and common traits and help to reveal some of the hidden heritability.

1236F

Gene-smoking interactions in 133,802 multi-ethnic subjects identifies novel loci for high-density lipoprotein cholesterol. *A.R. Bentley[1], C.N. Rotimi[1], L.A. Cupples[2], CHARGE Gene-Lifestyle Interactions Working Group.* 1) Center for Research on Genomics and Global Health, NHGRI, National Institutes of Health, Bethesda, MD; 2) Department of Biostatistics, Boston University, Boston, MA.

High-density lipoprotein cholesterol (HDLC) concentration is associated with smoking, but it is unknown to what extent smoking may modify genetic associations with HDLC. We investigated whether accounting for the interaction of current smoking and genetic variants may help identify HDLC loci in 133,802 individuals of European (n=90,266), African (n=23,745), Asian (n=13,171), and Hispanic ancestry (n=6,620), using 1000G imputed data. To maximize statistical power, in addition to testing the interaction with a 1 degree of freedom (df) test, we employed a joint 2 df test that simultaneously evaluates the SNP and interaction effects. Two models of the genetic main effect with and without smoking adjustment were considered so that we could determine what loci identified in the interaction could also be identified in a main effect analysis. Meta-analyses were conducted for each ancestry, and then all groups were meta-analyzed. In multi-ethnic meta-analysis, we identified 3 novel loci with a main effect on HDLC: gene-rich regions on chromosome 15 (e.g. *UBR1*, *TGM7*, *ADAL*, *TUBGCP4*, *TP53BP1*) and chromosome 1 (e.g. *TMED5, CCDC18, DR1)*, and non-coding variants in *PTPRJ*. Three additional novel loci were identified in the ancestry-stratified meta-analyses: rs9935936 (*GNAO1*) and rs143691761 (*CTNNA1*) in European and rs2160394 (*PRKD3*) in Asian ancestry individuals. Using the 2 df interaction test in multi-ethnic meta-analysis, a smoking interaction was observed for a novel locus near *STOML3*. These variants were African ancestry-specific and reached statistical significance in the meta-analysis limited to African ancestry studies. Two additional smoking interactions were observed using the 1 df test: rs10743071 (*STK33*) in African ancestry individuals, and rs17311510 (*TGM*) in European ancestry and multi-ethnic meta-analyses. In addition to these novel results, our meta-analyses confirmed associations for 50 previously-identified lipids loci. Further work is ongoing to replicate these loci and to understand the biological mechanisms underlying these associations which may lead to novel drug targets and/or therapeutic interventions. In summary, large multi-ethnic meta-analyses of a genome-wide interaction study of HDLC and current smoking reveals 9 novel loci across and within ancestry groups.

1237W

Novel rare variants in *GCKR* affect triglyceride concentrations and increase the risk for type 2 diabetes. *D. Sanghera[1], B. Sapkota[1], H. Mussa[2], D. Goins[4], C. Borga[3], P. Whitby[2], C. Sansam[4], K. Frazer[3].* 1) Department of Pediatrics, Section of Genetics, University of Oklahoma Health Sciences Center, Oklahoma City, Oklahoma; 2) Department of Pediatrics, Section of Infectious Diseases, University of Oklahoma Health Sciences Center, Oklahoma City, Oklahoma; 3) Department of Pediatrics, Section of Pediatric Hematology-Oncology, University of Oklahoma Health Sciences Center, Oklahoma City, Oklahoma; 4) Cell Cycle & Cancer Biology Research Program, Oklahoma Medical Research Foundation, Oklahoma City, Oklahoma, USA.

Dyslipidemia is a well-established risk factor for cardiovascular disease and a principal cause of mortality in individuals with type 2 diabetes (T2D). Despite the high heritability (50-80%) of lipid traits, previous genome-wide association studies (GWAS) have only been able to account for a fraction of this heritability (<10%) in genes involved in lipid metabolism. In this study, we aim to identify the rare functional variants in known candidate genes for diabetic dyslipidemia. Here, we performed targeted sequencing of 14 confirmed candidate genes (~215 kb) for 940 diabetic dyslipidemia individuals [572 cases with high serum triglycerides (TG) (>150 mg/dl) and 368 controls with low TG (<100 mg/dl)] from the Asian Indians Diabetic Heart Study. Of a total of 2361 high-quality variants analyzed, 953 variants (40%) were unique to high TG cases and 321 variants (13.6%) were unique to controls. Further analysis of variants within the *GCKR* gene using the Combined Multivariate and Collapsing methods revealed clustering of 13 functionally damaging and deleterious rare mutations near Fructose Binding site and Glucokinase (GCK) Binding sites at the sugar isomerase domains. The *GCKR* encodes glucokinase regulatory protein that regulates GCK (a known T2D gene) by forming a complex, which plays a role in the control of blood glucose homeostasis. The lead variant with a missense mutation of Serine/Asparagine was restricted to individuals with high TG. More than 60% of the carriers were diabetic and 90% of carriers had high TG (ranging from 182 mg/dl to 560 mg/dl). However, this variant was absent in Caucasians (n=33,370), Africans (n=5,203), Hispanic/Latinos (5,789), and East Asians (n=4,327) in a large Exome Aggregation Consortium (ExAC) dataset of multiethnic populations. We have designed a transgenic zebrafish (*Danio rerio*) and will be testing the phenotypic effects of these variants to evaluate metabolic consequences *in vivo.* Taken together, our findings have the potential to find novel pathway for diabetes linked with hypertriglyceridemia.

1238T

An insertion-deletion polymorphism within *FADS2* is associated with fatty acid levels and dietary pattern in Chinese Hans. *L. Xu[1], H. Yao[1], H. Shaofeng[1], Y. Kaixiong[2], G. Zhenglong[2], L. Huaixing[1].* 1) Key Laboratory of Nutrition and Metabolism, Institute for Nutritional Sciences, Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, University of the Chinese Academy of Sciences, Shanghai, People's Republic of China; 2) Department of Biological Statistics and Computational Biology, Cornell University, Ithaca, New York.

A recent study has suggested that different dietary patterns may contribute to individual variability in response to polyunsaturated fatty acid (PUFA) composition and allele frequencies of SNP rs66698963 (an insertion-deletion polymorphism) at *FADS2* locus. The I/I genotype frequency was higher in traditional vegan/vegetarian populations and was associated with 8% higher basal plasma phospholipid arachidonic acid (AA, 20:4n-6) level. In this study, we aimed to examine whether the reported insertion-deletion variant exhibits different allele frequencies and effect sizes on PUFA levels in the Beijing and the Shanghai individuals of Chinese Hans, who are supposed to have different dietary patterns, from the Nutrition and Health of Aging Population in China (NHAPC) study. The insertion-deletion polymorphism rs66698963 was successfully imputed using the 1000 Genome Project Phase 3 data as the reference panel (info=0.85). The frequencies of rs66698963-insertion (0.81 and 0.71 in Beijing and Shanghai, respectively) and its proxies (r²≥0.6) were significantly higher in participants from Beijing ($P \leq 3.07E10^{-15}$) compared with those from Shanghai. Consistent with previous findings, rs66698963 was significantly associated with multiple PUFA levels including 18:2n-6, 18:3n-6, 20:3n-6, 20:4n-6, 22:4n-6, 20:5n-3 and 22:5n-3 ($P \leq 7.95E10^{-8}$). Moreover, rs66698963 exerted significantly larger impact on 20:3n-6 level in Beijing populations ($P_{heterogeneity}=2.28E10^{-7}$) while it exerted larger impact on 18:3n-6 and 20:5n-3 levels in Shanghai populations ($P_{heterogeneity} \leq 0.016$). The deletion allele frequency is higher in Shanghai individuals (D=0.29) who consume more seafood than in Beijing individuals (D=0.19) who consume less seafood. In conclusion, we replicated the previous findings that this genetic variant is associated with fatty acid composition and the deletion allele has higher frequency in individuals who consume more seafood.

1239F

Large-scale meta-analysis of lipids traits in Hispanic population. *L.E. Petty[1], M. Graff[2], X. Guo[3], Y. Hai[3], J. Yao[3], A. Manichaikul[4], X.Q. Wang[4], A.E. Justice[2], L.S. Emery[5], T. Sofer[6], H.M. Highland[2], J.E. Below[1], Hispanic LIpids Consortium.* 1) Human Genetics Center, University of Texas Health Science Center at Houston, Houston, TX; 2) Dept. of Epidemiology, University of North Carolina, Chapel Hill, NC; 3) HARBOR-UCLA Medical Center, Torrance, CA; 4) Center for Public Health Genomics, University of Virginia, Charlottesville, VA; 5) Department of Genome Sciences, University of Washington, Seattle, WA; 6) Department of Biostatistics, University of Washington, Seattle, WA.

To date, genome wide association studies have successfully identified many (>150) loci associated with lipid levels. These studies have primarily been performed in Caucasian samples, yet dyslipidemia, a major risk factor for the development of cardiovascular disease, disproportionately affects Hispanic/Latinos (HL). Therefore, this inordinately affected ancestry group is a target population for additional, large-scale GWAS and holds promise for further discovery, as evidenced by recent, smaller GWAS in HL identifying novel loci and population-specific alleles. In this pursuit, we assembled a HL lipids consortium of >50,000 samples. Here we present preliminary results in a subset including Hispanic Community Health Study / Study of Latinos, Women's Health Initiative, Starr County, and two data sets from Mexico City (N=19,696). Imputation to 1000 Genomes Project phase 3 or phase 1 reference data was completed for each study. Association testing for four lipids phenotypes (total cholesterol, HDL, LDL, and triglycerides) using SNPTEST or MACH was performed in each study adjusting for principal components as necessary, age, sex, and any study-specific covariates. Meta-analysis was performed using METAL. Variants with IMPUTE2 quality scores less than 0.8 or MAC < 5 were excluded from meta-analysis. For total cholesterol, we identified 16 genome-wide significant loci, including 12 loci that map to genes that have not been published before in HL populations. For example, sentinel SNP rs1260326 maps to *GCKR*, which has been previously observed in HL populations. However, another sentinel SNP rs35529421 maps to *DOCK7*, which has been reported in European populations, but never HL. For HDL, LDL, and triglycerides, we identified 14, 12, and 9 significant loci, respectively, of which 8, 9, and 6 map to genes that have not been observed in HL populations. All of these findings not previously seen in HL populations have been published in other ancestry groups. Our future work will include additional HL samples to more than double the sample size. We anticipate that this increase in sample size will likely allow for identification of loci that map to novel genes for each lipid trait. Additionally, we explored linkage disequilibrium patterns around top findings and report genome-wide significant population-specific allelic effects in HLs independent of previously published alleles in European populations.

1240W

The interaction between common markers and menopausal hormone therapy influencing lipid levels. *J. Rich[1], A. Reiner[2,3], C. Kooperberg[3], P. Auer[1].* 1) School of Public Health, University of Wisconsin Milwaukee, Milwaukee, WI; 2) Department of Epidemiology, University of Washington, Seattle, WA; 3) Division of Public Health Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA.

Sex steroid hormones and their receptors are critical determinants of plasma lipid levels. In addition to the effects of estrogen on low-density lipoprotein cholesterol (LDL-C), high-density lipoprotein cholesterol (HDL-C), and triglycerides (TG), plasma lipid concentrations are also highly influenced by genetic variation. In this study, we sought to identify genetic variants that interact with menopausal hormone therapy to influence lipid levels. We imputed low-depth (8x) whole genome sequencing (WGS) data from the UK10K project into a total sample of 11,150 post-menopausal women that participated in the Women's Health Initiative. Exposure to hormone replacement therapy (HRT) was defined as currently taking hormone therapy versus not. We followed a two-stage approach to the gene-by-environment interaction analyses: stage 1 consisted of marginal analyses between all imputed variants with a minor allele frequency > 5%; variants with a p-value of association less than 5×10^{-7} were brought forward to the stage 2 interaction analyses. In stage 2, we tested for interaction between imputed variants and hormone replacement therapy (HRT) on LDL-C, HDL-C, and TG levels for the 2,101 variants brought forward from stage 1. The 2-stage approach identified a common marker (rs375372) that interacts with HRT to influence TG levels ($P=5.2 \times 10^{-4}$). For HRT users, the additive effect of the rs375372 alternate allele increases TG levels by 4.5%. This effect was not observed in individuals that were not taking HRT, suggesting that the effect of the rs375372 alternate allele on TG levels is specific to those that use HRT. The rs375372 variant was located in a putative 5' promoter for the *LIPC* gene, indicated by the H3K4me3 histone mark in adult Liver tissue from the RoadMap Epigenome project. *LIPC* is expressed in the liver, encodes a hepatic triglyceride lipase, and has been previously implicated in hyperlipidemia. The rs375372 variant is not in linkage disequilibrium ($R^2 > 0.6$) with any known variant association for TG. Though gene-by-environment (GxE) interactions may play an important role in explaining the heritability of lipid traits, there are limited examples of robustly associated GxE interactions. These results provide strong evidence for a new locus that interacts with an environmental exposure to influence TG.

1241T

Genome by lipidome analyses in a Singaporean cohort. *M.K. Lin[1,2], H. Begum[1,3], F. Torta[1,2], P. Narayanaswamy[1], P.A. Mundra[3], W.Y. Saw[4,5], E. Tantoso[4], P.F. Little[5], P.J. Meikle[3], Y.Y. Teo[4,5,6,7,8], M.R. Wenk[1,2].* 1) Singapore Lipidomics Incubator, Life Science Institute, National University of Singapore, Singapore; 2) Department of Biochemistry, Yong Loo Lin School of Medicine, National University of Singapore, Singapore; 3) Baker IDI Heart and Diabetes Institute, Melbourne, Australia; 4) Saw Swee Hock School of Public Health, National University of Singapore, Singapore; 5) Life Science Institute, National University of Singapore, Singapore; 6) Genome Institute of Singapore, Agency for Science, Technology and Research, Singapore; 7) NUS Graduate School for Integrative Science and Engineering, National University of Singapore, Singapore; 8) Department of Statistics and Applied Probability, National University of Singapore, Singapore.

Metabolic diseases, such as obesity and cardiovascular disorders, are associated with perturbations in lipid homeostasis. Clinical manifestations of metabolic diseases can be heterogenous, resulting from an interplay of environmental and genetic factors. The present study is based upon the hypothesis that the relevant clinical 'lipid' phenotype, high/low density lipoprotein and total triglyceride levels, are influenced by precursor molecules which define these clinical lipids, and there are underlying genetic variations influencing precursor lipid molecular levels. A Singaporean pilot cohort comprising of 105 Malay, 102 South Indian, and 109 South Chinese healthy subjects was recruited. These three ethnic groups made up approximately 98% of Singapore's ethnic-diverse population. Average age of the cohort was 51.9 years (SD ±6.0 years), with mean body mass index of 25.5 (SD ±4.4). There was no known metabolic disorders reported by the subjects during sample collection. Seemingly healthy subjects were selected based on the hypothesis that genetic features driving changes at lipid molecular level can act as biomarkers in prevention of metabolic diseases through life-style modification. Large-scale lipid profiling was performed. 283 lipid molecules were measured using targeted liquid-chromatography mass spectrometry in multiple reaction monitoring. The lipidomic data was independently validated at two distinct locations (Singapore and Australia) on different experimental platforms. All individuals were genotyped on Illumina® Omni 2.5 and exome chip. Association analyses utilizing PLINK was carried out for 2.5 million SNPs and variation in lipid molecule levels. Despite the small sample size, significant association signals (*p*-value ≤ 5.0×10^{-8}) after Bonferroni correction were detected for lipid molecules within the top ten coefficient of variation within each ethnic group. SNPs were found significantly associated to lipid classes, triglyceride and phosphatidylcholine. These SNPs are located in plausibly lipid biological pathway-related genes. Results were ethnic-specific. Results will be validated in a larger Singaporean population comprising of healthy controls and patient groups with various metabolic disorders. Implication of the validated results will help uncover metabolic biomarkers specific to Singapore's population, allowing more precise and efficient diagnoses to advise (potential) patients.

1242F

Rare alleles in Europeans are associated with low density lipoprotein cholesterol (LDL-C) and triglycerides (TG) levels in the Hutterites. *C. Igartua[1], D.L. Nicolae[1,2,3], C. Ober[1].* 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) Department of Statistics, University of Chicago, Chicago, IL; 3) Department of Medicine, University of Chicago, Chicago, IL.

Founder populations offer unique opportunities to study the clinical effects of alleles that are rare in outbred populations but occur at higher frequencies in these isolated populations. Whole genome sequencing in 98 South Dakota Hutterites, a founder population of European descent, revealed 1,037,333 variants that are rare (<1%) or absent in European populations, but occur at frequencies of up to 50% in the Hutterites. We conducted a GWAS of lipid levels with these "rare in European variants" (REVs). Plasma levels of LDL-C, high-density lipoprotein cholesterol (HDL-C), TG and total cholesterol (TC) were measured in 828 adult Hutterites who are related to each other in a 13-generation pedigree with 64 founders. Variants present in the whole genome sequences were previously imputed to these individuals using PRIMAL (Livne et al. *PLoS Comp Biol* 2015; 11:e1004139). We tested for associations with 322,934 REVs with MAF>1% in the Hutterites and imputation call rates >75% in this sample using a linear mixed model (GEMMA), including age and sex as fixed effects and kinship as a random effect. After Bonferroni correction for 4 phenotypes and 322,934 variants, we identified associations between increased LDL-C and 44 variants in a 7.6 Mb region flanking the LDL receptor gene (*LDLR*) on chromosome 19. These variants had minor allele frequencies of 0.03-0.04, and most are private to the Hutterites, including a missense variant in *ZNF439* ($p=5.55 \times 10^{-12}$, OR= 2.6 [2.0,3.4]), and a noncoding RNA in an intron of LOC100652768 ($p=9.84 \times 10^{-9}$, OR= 2.6 [1.9,3.6]). These variants are not in LD with common variants at *LDLR* previously associated with LDL-C (rs688, $r^2=0.02$; $p=2.92 \times 10^{-4}$, OR= 1.2 [1.1,1.3], AF 0.58 in the Hutterites). 12 REVs (MAFs 2.0%-2.4%) on chromosome 11 were associated with reduced TG levels (rs114977169, $p=9.49 \times 10^{-13}$, OR=0.28 [0.2,0.4]). These variants are in LD with a variant predicted to disrupt splicing of the first exon in *APOC3*, and which was previously associated with TG levels in the TwinsUK cohort (rs138326449; MAF=0.0025 in TwinsUK). These results provide examples of rare variants with large effects on LDL-C and TG levels in the Hutterites. The REVs flanking the *LDLR* gene have effects on LCL-C that are independent of known common variation at this locus, either through long-range regulatory effects on the *LDLR* gene itself or due to their effects on other novel genes in this region. This work was supported by R01 HL085197.

1243W

Overlap of lipid GWAS and adipose eQTL loci identifies 18 lipid loci with candidate regulatory variants. *M. Alvarez[1], E. Nikkola[1], C. Raulerson[2], K. Mohlke[2], M. Laakso[3], P. Pajukanta[1,4].* 1) Department of Human Genetics, David Geffen School of Medicine at UCLA, Los Angeles, USA; 2) Department of Genetics, University of North Carolina, Chapel Hill, North Carolina, USA; 3) Department of Medicine, University of Eastern Finland and Kuopio University Hospital, Kuopio, Finland; 4) Molecular Biology Institute at UCLA, Los Angeles, USA.

High serum lipids levels are a major risk factor for cardiovascular disease (CVD) that present a major public health problem worldwide. Genome-wide association studies (GWAS) have identified >157 loci significantly associated with lipid levels. Although the molecular mechanisms underlying several of these loci have been characterized, for many loci the causal variants, genes, and functional mechanisms remain to be elucidated. We hypothesize that for some of these loci, associated variants affect transcriptional processes of genes relevant to lipid metabolism. To identify variants and genes for the uncharacterized lipid loci, we overlapped expression quantitative trait loci (eQTL) with the lipid GWAS loci. Using RNA sequencing of subcutaneous adipose tissue and genotype data of 494 individuals from the METabolic Syndrome In Men (METSIM) cohort, we assessed gene expression and allele-specific expression. To identify eQTLs we used the RASQUAL software and found 5,109 genes with a lead eQTL SNP passing a genome-wide Bonferroni threshold (p-value$<3.2 \times 10^{-6}$). To overlap eQTL and lipid-GWAS loci, we required the lead eQTL and the lead GWAS SNP to be in linkage disequilibrium (LD) ($r^2 \geq 0.75$), and observed 14, 4, 6, and 2 of HDL-C, LDL-C, total cholesterol (TC) and triglyceride (TG) loci overlapped with an eQTL, respectively. A combined total of 18 (11.5%) lipid GWAS loci overlapped with a significant eQTL. To further investigate causal regulatory SNPs, we annotated variant proxies in LD with both the eQTL and GWAS lead SNPs ($r^2 \geq 0.75$) using ENCODE and Roadmap Epigenomics data. Among the signals, we followed up on the HDL-C/TC *LILRA3* locus because of its lack of characterization and tight LD between the lead eQTL and TC GWAS SNP ($r^2=0.99$). We identified rs383925 as a likely causal variant since it lies in a region with promoter and enhancer histone marks in several cell and tissue types, including blood and adipose. The variant rs383925 is also predicted to alter the regulatory motif of PU.1, a transcription factor that may be involved in activation of macrophages. In addition, this SNP is a strong eQTL for *LILRA3* in subcutaneous adipose and blood tissue in GTEx, providing additional evidence to its association with *LILRA3* expression. As *LILRA3* encodes a soluble receptor for class I antigens and is predominantly expressed in blood, we predict this GWAS signal to act in a monocyte/macrophage specific manner in obesogenic adipose tissue to affect HDL-C and TC levels.

1244T

Evidence for modification of genetic risk in autoimmunity by exposure to pregnancy using case-only study design. *C. Adams[1], G.I. Cruz[1], X. Shao[1], H. Quach[1], K. Taylor[2,3], J. Nititham[2,3], C. Schaefer[4,5], T. Olsson[6], I. Kockum[6], L. Alfredsson[7,8], L.A. Criswell[2,3], L.F. Barcellos[1,4,5].* 1) GEGL Lab, School of Public Health, University of California, Berkeley, Berkeley, CA; 2) Institute for Human Genetics, University of California, San Francisco, San Francisco, CA; 3) Rosalind Russell/Ephraim P. Engleman Rheumatology Research Center, Department of Medicine, University of California, San Francisco, San Francisco, CA; 4) Kaiser Permanente Division of Research, Oakland, CA; 5) Research Program on Genes, Environment and Health, Kaiser Permanente, Oakland, CA; 6) Department of Clinical Neuroscience and Center for Molecular Medicine, Karolinska Institutet at Karolinska University Hospital, Stockholm, Sweden; 7) Institute of Environmental Medicine, Karolinska Institutet, Stockholm, Sweden; 8) Centre for Occupational and Environmental Medicine, Stockholm County Council, Stockholm.

Multiple sclerosis (MS) [MIM 126200], Rheumatoid arthritis (RA) [MIM 604302], Systemic lupus erythematosus (SLE) [MIM 152700], and Sjögren's syndrome (SS) [MIM 270150] are autoimmune diseases (AD) that predominately affect women. Pregnancy can affect the activity of AD and may also contribute to risk of AD onset later in life. Both genetic and environmental factors are believed to contribute to AD. Genes within the major histocompatibility complex (MHC) contribute substantially to the risk of AD. Genome-wide association studies (GWAS) have identified additional loci. However, whether genetic risk of developing AD is modified by pregnancy is unknown. We utilized a powerful case-only GxE study design to investigate whether exposure to pregnancy was associated with genotype for established genetic AD risk factors in MS, RA, SLE, and SS cases. All cases were adult females with confirmed disease selected from the Mother-Child Immunogenetic Study (RA n=1000; SLE n=2500) at University of California, San Francisco, the Sjögren's International Collaborative Clinical Alliance registry (SS n=3500), Kaiser Permanente Northern California (KPNC; MS n=900), and a Swedish cohort (MS n=2000). Comprehensive reproductive history, genetic ancestry, and other potential confounder and covariate data were collected for all cases. Several pregnancy exposure models comprised of different groupings of disease onset before and after first live birth pregnancy and no live birth pregnancy were tested. Logistic regression was used to test for association between pregnancy exposure and genotype for non-HLA disease risk GWAS variants and the MHC variants adjusting for genetic ancestry and confounders. Genotype data for all cases were obtained through whole-genome or ImmunoChip profiling and imputation. Results for MS, to date, demonstrate evidence for a significant association between disease onset after first live birth pregnancy and *PVT1* genotype (OR=1.53; 95% CI, 1.22-1.92; $P_{FDR-adj}$<0.05). Specifically, among KPNC MS cases, the odds of onset of MS after the first live birth pregnancy were 1.53 times the odds of onset of MS before a live birth pregnancy for each additional rs4410871 T allele. No evidence for association was found for SNPs in the MHC. *PVT1* encodes a long, non-coding mRNA that has been previously identified as a non-HLA MS risk GWAS risk locus. This study is the first to characterize the association between exposure to pregnancy and AD genetic risk factors.

1245F

Large-scale imputation of KIR genes in psoriasis case-control cohorts. *R.S. Ahn[1], D. Vukcevic[2,3,4], A. Motyer[2,3], D. Ellinghaus[5], L.C. Tsoi[6], R.P. Nair[6], J. Oksenberg[7], C. Palmer[8], J. Foerster[9], J.T. Elder[6], A. Franke[5], S. Leslie[2,3,4], W. Liao[1].* 1) Dept. of Dermatology, University of California, San Francisco, San Francisco, CA; 2) School of Mathematics and Statistics, University of Melbourne, Parkville, Australia; 3) School of BioSciences, University of Melbourne, Parkville, Australia; 4) Data Science, Murdoch Childrens Research Institute, Parkville, Australia; 5) Institute of Clinical Molecular Biology, Kiel University, Kiel, Germany; 6) Dept. of Dermatology, University of Michigan, Ann Arbor, MI; 7) Dept. of Neurology, University of California, San Francisco, San Francisco, CA; 8) Division of Cardiovascular & Diabetes Medicine, University of Dundee, Dundee, United Kingdom; 9) College of Medicine, Dentistry, and Nursing, University of Dundee, Dundee, United Kingdom.

Killer cell immunoglobulin-like receptors (KIR) are expressed on the surface of natural killer cells and regulate innate immune response by interacting with HLA molecules expressed on the surface of antigen presenting cells. KIRs are encoded by 14 genes that are located on chromosome 19. In the autoimmune skin disorder, psoriasis, previous studies have shown that copy number of several KIR genes, including *KIR2DS1*, *KIR2DS4*, and *KIR3DL1*, are associated with psoriasis. However, these studies had limited power to detect an association because of their small sample sizes. To overcome the time and expense of directly genotyping KIR genes, we implemented a state-of-the-art method, KIR*IMP, to impute KIR copy number from SNPs on chromosome 19 from a cohort from UCSF (n = 1261) as well as US, Canadian, German, and Estonian cohorts from the PAGE consortium (n = 9482). All samples were genotyped on either the Affymetrix Axiom UK Biobank chip (UCSF) or the Illumina Immunochip (PAGE consortium). Univariate logistic regression was implemented to test for association between imputed KIR copy number and psoriasis in each cohort followed by a pooled association test. Pooled association testing revealed that *KIR2DS4* Deletion variant and *KIR3DL1* exon 4 were associated with psoriasis under a dominant model (p < 0.05). We also found suggestive evidence (p < 0.1) of association between psoriasis and *KIR2DS4* and *KIR3DL1* exon 9 under a dominant model and for *KIR2DS4* deletion variant and *KIR3DS1* under an additive model. This is the first large-scale study of imputed KIR copy number in psoriasis. We discovered that several previously reported KIR gene associations are replicated when several cohorts are pooled together. Our study suggests that future studies of typed and imputed KIR copy number in psoriasis and other autoimmune diseases are warranted.

1246W

Novel SLE risk variant at non-coding RNA (SMG7-AS1) modulating the expression of SMG7. *F. Alasti[1], C. Sun[1], B. Singh[1], P. Borden[2], P. Raj[3], J. Guthridge[1], J. James[1], P.M. Gaffney[1], J. Harley[4], E. Wakeland[2], L. Looger[2], M. Alaecon[1], S.K. Nath[1].* 1) Arthritis and Clinical Immunology Research Program, Oklahoma Medical Research Foundation, Oklahoma City (OMRF), OK, USA; 2) Howard Hughes Medical Institute, Janelia Farm Research Campus, Ashburn, VA, USA; 3) Department of Immunology, University of Texas Southwestern Medical Center, Dallas, TX, USA; 4) Cincinnati Children's Hospital Medical Center, Cincinnati, OH, USA.

Introduction: Systemic lupus erythematosus (SLE) is a progressive complex autoimmune disease characterized by the production of a range of auto-antibodies. SLE is influenced by both genetic and environmental factors; however, the exact etiopathology of SLE is not clearly understood. Several studies have identified multiple susceptibility loci for SLE, including *NCF2*. We recently reported multiple SLE risk variants at this gene. To identify additional novel variants within this region, we conducted a follow-up study in ethnically diverse populations. We subsequently found novel SNPs at neighboring genes (like *SMG7*). We hypothesize that these SNPs can modulate the expression of *SMG7*. **Methods:** The confirmation of our SNPs was done by genotyping and sequencing followed by imputation-based analysis and conditional analysis. We assessed allele specific functions using luciferase promoter assay, quantitative real-time PCR and Western blot analysis. **Results:** We discovered a novel SNP located at the non-coding part of anti-sense RNA (*SMG7-AS1*) consistently associated with individuals with European and Hispanic ancestry (OR = 0.79, 95% CI: 2.58 [2.32-2.94], P_{meta} = 1= 4.05 x 10 -61). In order to figure out if any of our associated SNPs can affect the expression of *SMG7*, we performed dual Luciferase assays in which the best candidate SNP showed strong effect on the promoter activity, to be significantly decreased by switching to the risk alleles. To examine whether the RNA expression levels of *SMG7* gene is affected by our associated SNP, we assessed a qRT-PCR on 7 individuals homozygous for the risk allele versus >10 homozygous for the protective allele. Our data showed that the RNA expression levels of *SMG7* in homozygous risk group compared to the protective group is significantly lower (P< 0.01). In addition, our protein Western blot analysis also supported our RNA quantitative results. The novel imputed SNP was confirmed by Taqman genotyping and sequencing. It is known that SMG7 has a major role at NMD pathway. To follow up our current study, we need to find out if our SNP is affecting the NMD pathway and also show how it is causing the SLE susceptibility. **Conclusion:** This study identified a novel functional SNP at SMG7-AS1 and confirmed its regulatory roles in SMG7 expression by affecting the promoter activity of *SMG7* gene. Decreased expression level of *SMG7* with the risk alleles versus the protective alleles may contribute to SLE susceptibity.

1247T

Joint pathway analysis and histone mark enrichment unravels hidden biological processes underlying celiac disease pathogenesis. *L. Bossini-Castillo[1], P. Carbonetto[2], C. Wijmenga[3], M. Stephens[4], G. Trynka[1].* 1) Wellcome Trust Sanger Institute, Hinxton, Cambridge, United Kingdom; 2) Ancestry.com DNA, LLC, San Francisco, CA; 3) Department of Genetics, University of Groningen, University Medical Center, Groningen, The Netherlands; 4) Department of Human Genetics, University of Chicago, Chicago, Illinois, United States of America.

Celiac disease (CeD) is a complex autoimmune disorder of the gut triggered by gluten ingestion. CeD affects close to 3% of the European population. Up to 45 CeD genetic risk factors have been identified to date. Here, we show that a combined analysis of pathways and cell-specific regulatory annotations in a previously published dataset of 3,149 CeD cases and 6,325 controls (Dubois 2010 *Nat Genet*) yields novel insights into disease-relevant biological processes, and implicates disease-causal cell types. In this study, we assessed enrichment of SNPs annotated to 3,159 candidate pathways from 8 databases. The applied pathway enrichment method builds on multivariate regression to model disease risk as the combined additive effect of multiple markers (Carbonetto 2013 *PLOS Genet*). We identified five pathways with strong support for enrichment of CeD risk factors, including IL-12 signaling, expression of chemokine receptors, cytokine-cytokine receptor, E-cadherin adherens junction and Th1/Th2 differentiation. While the role of the immune pathways has been previously explored in CeD, the implication of the E-cadherin adherens junction pathway, which regulates adhesion of endothelial cells and epithelial inflammation, was novel. The enriched pathways replicated in an independent US cohort comprising 1,596 cases and 2,965 controls, with an inflation factor (lambda) of 1.13 - 1.64 for the pathway assigned SNPs. One advantage of taking a modeling approach to interrogate enriched pathways is that it can be used to inform which SNPs are associated with the phenotype. Using SNPs with posterior probability > 0.01, assigned to the significant pathways, we tested for enrichment with active promoters (using the H3K4me3 mark) in a set of 118 tissues. We observed that associations informed by different pathways pointed to distinct cell types, and these cell types were not detected from the association signal under the null hypothesis of no pathway enrichment. We observed that SNPs from E-cadherin adherens junction pathway were enriched in rectal and stomach smooth muscle, psoas muscle and different T cells, further supporting the role of adhesion of endothelial cells and epithelial inflammation in CeD pathogenesis. In summary, by analysing the accumulation of genetic variants in gene pathways jointly with cell specific regulatory annotations we were able to gain valuable novel insights into disease mechanisms and implicate relevant cell types for a complex trait.

Replication of ImmunoChip array and genome-wide linkage identified variants of Kawasaki disease in Taiwanese children. *T. Chang[1], M. Chen[2], Y. Lee[1,2], W. Chen[1], N. Chiu[2].* 1) Med Res Dept, Mackay Memorial Hospital, New Taipei, Taiwan; 2) Pediatrics, Mackay Memorial Hospital, Taipei, Taiwan.

Genetic epidemiological studies show that genetic factors contribute significantly to Kawasaki disease pathogenesis. However, genetic studies are often inconsistent and the associations are often race or ethnicity specific. The aim of this study is to replicate 4 novel single nucleotide polymorphisms (SNPs) identified by either fine-mapping ImmunoChip array or linkage analysis, which were associated with Kawasaki disease in Caucasians. The rs7320375 *A/G*, rs4021 *A/G*, rs392775 *A/T*, and rs9847915 *A/T* SNPs were genotyped in 690 Taiwanese children with Kawasaki disease and 562 ethnically matched healthy controls by using the Pre-Developed TaqMan Allelic Discrimination Assay. In our replication study, no significant associations between these 4 SNPs and susceptibility of KD were found. In addition, no evidence for associations between these SNPs and development of coronary artery lesions (CALs) was found. In summary, our findings provide little support to validate these fine-mapping discovered novel SNPs in the susceptibility or CAL development of KD in Taiwanese children.

1249W

Low-frequency coding variants explain a fraction of multiple sclerosis heritability and identify four new susceptibility genes. *C. Cotsapas, International Multiple Sclerosis Genetics Consortium* . Neurology, Yale School of Medicine, New Haven, CT.

Multiple sclerosis (MS) is an autoimmune disease in which the myelin sheath surrounding brain neurons is destroyed by the immune system, leading to progressive physical and cognitive morbidity and shortened life expectancy. Over the last decade we have conducted a series of genome-wide association studies, discovering 200 common variant risk associations explaining over 50% of the heritability. To complement these efforts we have genotyped 250,000 low-frequency non-synonymous (NS) coding variants across all exons. Following stringent quality control we meta-analyzed 29,746 cases and 35,066 controls in 14 country-level strata, using linear mixed models to control for population stratification. We find seven low-frequency NS variants (MAF < 0.05) show convincing evidence of association ($p < 6.25 \times 10^{-7}$, Bonferroni-adjusted $p < 0.05$ for number of variants tested). These variants are located in six genes, including four outside risk loci identified by common variant GWAS. These four genes – PRF1, HDAC7, NLRP8 and PRKRA – identify new immune functions mediating risk, and implicate both variation in genome regulation and in heterologous cell killing in pathogenesis. The PRF1 A91V variant (overall MAF = 0.049, association $p = 3.9 \times 10^{-11}$) is a hypomorph, with CD8+ cytotoxic T cells from heterozygous donors showing 30% lower efficiency in effector T cell killing than donors homozygous for the major allele (PMID 25776844). We next assessed if more effects are present in our data and to estimate the heritability attributable to low-frequency variation in MS, using polygenic risk scores. We find significant evidence of polygenicity with low frequency (MAF < 0.01) NS variation, and estimate that approximately 5% of disease heritability is attributable to this fraction of the allelic spectrum. Our effect size estimates are in line with those for common variants, and we do not observe any odds ratios >1.5. Thus, we conclude that low frequency variation explains a small but significant fraction of MS heritability, and can identify new pathogenic genes that may otherwise not have been found. However, our results also suggest that assessing the contribution of low frequency variation either by genotyping or sequencing will require large sample sizes due to modest effect size. .

In sickness and in health? Mate's genes and risk of female autoimmunity in a study of 6,200 individuals. *G.I. Cruz[1], X. Shao[2], C.J. Adams[1], H. Quach[2], K. Ho[3], K. Sterba[3], J.A. Noble[4], N.A. Patsopoulos[5], M.P. Busch[6], D.J. Triulzi[7], W.S.W. Wong[8], B.D. Solomon[8], J.E. Niederhuber[8], L.A. Criswell[3], L.F. Barcellos[1,2].* 1) School of Public Health, University of California Berkeley, Berkeley, CA; 2) Genetic Epidemiology and Genomics Lab, California Institute for Quantitative Biosciences (QB3), University of California Berkeley, Berkeley, CA; 3) Rosalind Russell / Ephraim P. Engleman Rheumatology Research Center, Department of Medicine, University of California San Francisco, San Francisco, CA; 4) Children's Hospital Oakland Research Institute, Oakland, CA; 5) Program in Translational NeuroPsychiatric Genomics, Institute for the Neurosciences, Department of Neurology, Brigham & Women's Hospital, Boston, MA; Division of Genetics, Department of Medicine, Brigham & Women's Hospital, Harvard Medical School, Boston,; 6) Blood Systems Research Institute, San Francisco, CA; 7) Institute of Transfusion Medicine and Department of Pathology, University of Pittsburgh, Pittsburgh, PA; 8) Division of Medical Genomics, Inova Translational Medicine Institute, Falls Church, VA.

The causes of sexual dimorphism observed in autoimmune disorders (AD) are not entirely understood. Women are disproportionately affected, raising interest in female-specific factors as possible mechanisms. Pregnancy involves immunological changes in the mother. It is well known that pregnancy affects activity of pre-existing rheumatoid arthritis (RA) [MIM 604302] and systemic lupus erythematosus (SLE) [MIM 152700]. It is possible exposure to paternal antigens through the fetus could influence the development of AD in women without the disease. As not all pregnancies result in a live birth, we investigated if mating partners who carry RA- and SLE-associated risk alleles increase the risk of disease of the mother. We investigated the association between a mating partner's human leukocyte antigen (HLA) genotype and maternal AD in 155 RA and 151 SLE cases and 895 controls from the Mother-Child Immunogenetic Study (MCIS). Female cases, their children and their children's fathers were recruited at UC San Francisco; controls and their families were recruited from the Blood Centers of the Pacific, the Institute for Transfusion Medicine at the University of Pittsburgh, and from studies at the Inova Translational Medicine Institute (ITMI); a population-based sample of 5000 males matched on genetic ancestry were included for comparison. HLA alleles were imputed from genotype and whole genome sequencing data using SNP2HLA. We categorized mating partners' *DRB1* genotype as carriers of an allele or group of alleles of interest (AOI) for each disease. RA AOI tested include the *DRB1* "shared epitope" (SE) and alleles coding for high-risk amino acids (AA) at positions 11 (valine), 71 (lysine), and 74 (alanine); SLE AOI *DRB1*03:01*, **15:01*, **08:01*. We used logistic regression models to estimate odds ratios (ORs) and 95% confidence intervals (CIs) for the association between RA and SLE separately and a mating partner's *HLA* risk alleles. In addition, we estimated each couple's relatedness coefficient, *R,* to investigate non-random mating effects in AD. We found increased risk of RA associated with SE carrier status (OR 1.5; 1.1-2.1) and AA 71 (OR 1.4; 95% CI, 1.0-2.0); however, AA 74 was associated with reduced risk (OR 0.6; 95% CI, 0.4-0.8). We did not find any significant associations between AOIs investigated and SLE. These findings support the hypothesis that a mating partner's genotype may contribute to risk of some female AD, possibly through exposure to pregnancy.

Three novel susceptibility loci were identified through a meta-analysis of immunochip data from Korean and East Asian patients with inflammatory bowel disease. *M. Hong[1], H. Oh[1], S. Jung[1], S.J. Ahn[1], B.D. Ye[2], S.H. Park[2], S.K. Yang[2], K. Song[1].* 1) Department of Biochemistry and Molecular Biology, University of Ulsan College of Medicine, Seoul, Korea; 2) Department of Gastroenterology, Asan Medical Center, University of Ulsan College of Medicine.

Most Asian GWAS on IBD genetics analyzed CD and UC separately, giving insights into the genetic architecture of each single disease, but not a broad view of the genetic basis of IBD in Asians. A recent study on IBD in Japanese successfully confirmed associations at several known loci, but did not find new loci possibly due to the limited sample size. We previously reported association analyses for CD and UC separately using immunochip data. To identify additional IBD susceptibility loci in Asian, we first performed immunochip analysis of IBD in Koreans (1332 cases, 1185 controls) followed by a meta-analysis combining Korean and East Asian IBD immunochip data sets (2824 cases, 3719 controls). In the Korean IBD Immunochip analysis, we did not find any novel loci with genome-wide significance. In a meta-analysis using immunochip data of Korean and East Asian IBD, SNPs with association $P < 1 \times 10^{-3}$ in the discovery cohort were confirmed in the Korean IBD GWAS (730 cases, 3739 controls) data set. Three novel loci reached genome-wide significance ($0.05/80,279 = 6.23 \times 10^{-7}$) in the discovery and GWAS replication cohorts combined including rs2072711 in *NCF4-CSF2RB* (OR = 1.20, P_combined = 3.34×10^{-10}), rs12928665 near *CIITA* (OR = 0.86, P_combined = 1.31×10^{-8}), and rs3138056 near *NFKBIA* (OR = 0.87, P_combined = 6.12×10^{-7}). Our results provide new biological insight to IBD in East Asians.

1252W

Genome-wide association study identifies *PRKCB* as a novel genetic factor for primary biliary cirrhosis in the Japanese population. *M. Kawashima[1,2], Y. Hitomi[2], N. Nishida[2,3], K. Kojima[4], Y. Kawai[4], H. Nakamura[5], M. Yasunami[6], K. Chayama[7], Y. Aiba[5], M. Nagasaki[4], K. Tokunaga[2], M. Nakamura[5,8], PBC Consortium in Japan (PBCCSJ).* 1) National Bioscience Database Center, Japan Science and Technology Agency, Tokyo, Japan; 2) Department of Human Genetics, Graduate School of Medicine, The University of Tokyo; 3) The Research Center for Hepatitis and Immunology, National Center for Global Health and Medicine; 4) Division of Biomedical Information Analysis, Department of Integrative Genomics, Tohoku Medical Megabank Organization, Tohoku University; 5) Clinical Research Center, National Hospital Organization (NHO) Nagasaki Medical Center; 6) Department of Clinical Medicine, Institute of Tropical Medicine, Nagasaki University; 7) Department of Gastroenterology and Metabolism, Applied Life Sciences, Institute of Biomedical & Health Sciences, Hiroshima University; 8) Department of Hepatology, Graduate School of Biomedical Sciences, Nagasaki University.

Primary biliary cirrhosis (PBC) is a chronic and progressive cholestatic liver disease, presumably caused by autoimmune reactions against biliary epithelial cells leading to liver cirrhosis and hepatic failure. PBC primarily affects women (female-to-male ratio, 7:1) between 50 and 60 years of age. The high concordance rate in monozygotic twins compared to dizygotic twins indicates strong genetic factors are involved in predisposing to PBC. ;Previously, we performed a genome-wide association study (GWAS) in 963 Japanese individuals (487 PBC cases and 476 healthy controls) and identified two significant susceptibility loci, *TNFSF15* (rs4979462) and *POU2AF1* (rs4938534). In this study, we performed extended GWAS in an additional 1,923 Japanese individuals (894 PBC cases and 1,029 healthy controls), and combined the results with the previous GWAS data. This GWAS, together with a subsequent replication study in an independent set of 7,024 Japanese individuals (512 PBC cases and 6,512 healthy controls), identified *PRKCB* (rs7404928) as a novel susceptibility gene for PBC (odds ratio [OR] = 1.26, P = 4.13 × 10^{-9}). Furthermore, primary functional variants of *PRKCB* (rs35015313) were identified by genotype imputation using a phased panel of 1,070 Japanese individuals from a prospective, general population cohort study by the Tohoku Medical Megabank Organization, and subsequent in vitro functional analyses. These results may lead to improved understanding of the disease pathways involved in PBC, forming a basis for prevention of PBC and development of novel therapeutics.

1253T

Confirmation of 5 novel susceptibility loci for Systemic Lupus Erythematosus (SLE) and integrated network analysis with 75 SLE loci. *J.E. Molineros[1], C. Sun[1], W. Yang[2], S.C. Bae[3], Y. Okada[4,5], N. Shen[6], X.J. Zhou[7], S.K. Nath[1].* 1) Arthritis and Clinical Immunology, Oklahoma Medical Research Foundation, Oklahoma City, OK; 2) Department of Paediatrics and Adolescent Medicine, Scientific Staff, Centre for Genomic Sciences,LKS Faculty of Medicine, The University of Hong Kong; 3) Department of Rheumatology, Hanyang University Hospital for Rheumatic Diseases, Seoul, Korea; 4) Department of Human Genetics and Disease Diversity, Graduate School of Medical and Dental Sciences, Tokyo Medical and Dental University, Tokyo, Japan; 5) Laboratory for Statistical Analysis, RIKEN Center for Integrative Medical Sciences, Yokohama, Japan; 6) Shanghai Institute of Rheumatology, Renji Hospital, School of Medicine, Shanghai Jiao Tong University, Shanghai, China; 7) Renal Division, Peking University First Hospital, Peking University Institute of Nephrology, Key Laboratory of Renal Disease, Ministry of Health of China and Key Laboratory of Chronic Kidney Disease Prevention and Treatment (Peking University), Ministry o.

Introduction: We recently identified 10 novel SLE susceptibility loci in Asian populations, and uncovered some novel loci that required further replication. In this follow-up study, we attempted to replicate 5 loci, and perform a joint analysis together with all previously known SLE loci to identify gene sub-networks among these loci. *Objectives*: The objectives of this study are to (a) assess the replication of five previously identified suggestive loci, followed by meta-analysis in 7 Asian and European cohorts; (b) identify how these candidate loci fit within the context of the current set of SLE loci. *Data and Methods*: We genotyped 5 SNPs from 5 loci in Hong Kong (1,456 cases and 955 controls). We augmented this data with our previously reported Asian data and published data from an European cohort, and performed a meta-analysis (9,999 cases and 27,410 controls). *Results*: All 5 loci passed the genome-wide significance threshold: *MYNN* (rs10936599 P$_{meta}$=5.14x10^{-14}), *ATG16L2* (rs11235604, P$_{meta}$=1.31x10^{-9}), *CCL22* (rs223881, P$_{meta}$=2.81x10^{-14}), *ANKS1A* (rs2762340, P$_{meta}$=1.96x10^{-11}) and *RNASEH2C* (rs1308020, P$_{meta}$=7.32x10^{-18}). Functional analysis indicated that 3 non-coding loci (rs223881, rs2762340 and rs1308020) are eQTLs targeted for multiple genes. Additionally, all these loci co-located with enhancer/promoter marks, indicating their possible roles in gene regulation. With these 5 novel loci, the total of SLE susceptibility loci increased to 75. These loci share pathway memberships, gene ontology, and protein domains that suggest common modes of action among SLE genes. All 5 loci (together with known SLE loci) had an over-representation of *E2F1* TFBS (P=3.5x10^{-5}), which implicated them in the regulation of p53 dependent/independent apoptosis. We also identified that 35 SLE loci (including *CCL22*, *MYNN* and *ATG16L2*) were directly implicated in differential expression (P<5x10^{-3}) of nearby genes (1 Mb boundary). Conclusion: We confirmed 5 novel SLE susceptibility loci that share common functional traits with many others currently established loci. We identified functional variants that directly affect gene expression, disrupt binding of key transcription factors, and share functional characteristics with known SLE loci. With this evidence, we not only increased the number of SLE loci, but also expanded knowledge of SLE pathobiology.

1254F

Exome sequencing followed by genotyping identifies a rare variant in *NLRP7* **associated with inflammatory bowel disease.** *A. Onoufriadis[1], A. Amar[1], Y. Omar[1], K. Stone[1], K. Taylor[1], M.A. Simpson[1], J. Sanderson[2], N.J. Prescott[1], C.G. Mathew[1].* 1) Medical and Molecular Genetics, King's College London, London, United Kingdom; 2) Department of Gastroenterology, Guy's and St Thomas' NHS Foundation Trust, London, United Kingdom.

Genome-wide association scans (GWAS) have now identified more than 200 genomic regions that influence susceptibility to the two forms of inflammatory bowel disease (IBD), Crohn's disease (CD) and ulcerative colitis (UC). Despite these successes, a substantial fraction of IBD heritability remains unaccounted for. This is likely to reflect an intrinsic limitation of GWASs, which are designed to identify common variants of small effect and are unlikely to detect associations with rare susceptibility alleles. Given that disorders segregating in pedigrees are typically caused by rare and highly penetrant mutations, we sequenced the exomes of 29 affected individuals across 13 families with multiple affected individuals. We followed a stepwise filtering process of the exome variant profiles generated, retaining all heterozygous co-segregating variants that were protein altering with a MAF<1% in either the 1000 genomes data or 1000 non-IBD individuals sequenced in-house. Based on the notion that genes carrying common disease associated variants may also harbour rare susceptibility alleles, we focused on 294 key genes that lie on 162 GWAS hits and were prioritised via gene ontology and pathway analyses (Jostins et al 2012). This analysis revealed two families with two different rare missense variants in the *NLRP7* gene co-segregating with disease, p.R801H and p.S361L. We followed up these variants (rs143169084 and rs140797839) by genotyping them in 6293 IBD cases and 7239 controls. Whilst we observed both variants at a higher frequency in IBD cases compared to controls, only p.S361L (rs143169084) was significantly associated with IBD (p=0.02822), whereas the rarer variant p.R801H (rs140797839, 0.014% controls) failed to achieve significance. The NLRP7 protein is a component of the inflammasome, which leads to induction of caspase-1 and IL-1B secretion during the innate immune response.

Molecular characterization, pathogenesis and tissue susceptibility of human systemic lupus erythematosus (SLE) by expression and eQTL analysis. *N.I. Panousis[1,2,3], G. Bertsias[4], I. Gergiannaki[4], M. Tektonidou[5], M. Trachana[6], A. Banos[7], A. Fanouriakis[8], C. Pamfil[9], E.T. Dermitzakis[1,2,3], D. Boumpas[7,8].* 1) Department of Genetic Medicine and Development, University of Geneva Medical School, Geneva, Switzerland; 2) Institute of Genetics and Genomics in Geneva (iG3), University of Geneva Medical School, Geneva, Switzerland; 3) Swiss Institute of Bioinformatics, Geneva, Switzerland; 4) Department of Rheumatology, University of Crete, Faculty of Medicine, Crete, Greece; 5) Department of Rheumatology, University of Athens, Faculty of Medicine, Athens, Greece; 6) Department of Pediatrics, Aristotle University of Thessaloniki, Faculty of Medicine, Thessaloniki, Greece; 7) Biomedical Research Foundation of the Academy of Athens, Athens, Greece; 8) Department of Rheumatology, Attikon Hospital, Athens, Greece; 9) Iuliu Haţieganu University of Medicine and Pharmacy, Cluj-Napoca, Romania.

Systemic lupus erythematosus (SLE) is a complex autoimmune disease characterized by remarkable immunological and clinical heterogeneity. Assessing the molecular and genetic basis of this variability is of great importance to understand the risk stratification of patients and applications of targeted therapies. By studying patterns of gene expression and genetic variation in whole blood we can develop a functional understanding of how genetic variants can alter risk of SLE and its complications. We report RNA-seq analysis of 142 genotyped and deeply phenotyped with varying levels of disease activity/severity- SLE patients and 48 control matched individuals. We found 4650 (1% FDR) differentially expressed genes (DEGs) between unaffected and SLE individuals with several molecular pathways being associated with predisposition to SLE and disease severity. By exploring DEGs within sub-categories of SLE activity and healthy individuals we defined different modules of genes associated with the pathogenesis and the disease progression. We explored organ involvement in disease progression/severity. When comparing patients with Active Lupus Nephritis (LN) with inactive LN we identified 1070 (1%FDR) DEGs with pathways such as interferon signaling, cell cycle regulation and oxidative phosphorylation to be over-expressed in active LN. PCA analysis differentiated active LN from inactive demonstrating robust differences in expression and indicating that LN is an extreme phenotype among SLE. By exploring the sub-groups of individuals according to their organ activity (i.e serological, cardiorespiratory, vasculitis) we identified genes and pathways that predispose to the specific organ affected. We further explored genetic regulation of blood expression, in the context of variants associated with gene expression in SLE. We mapped 3178 (5% FDR) genetic variants related with differences in gene expression (eQTLs). We further mapped 37 SLE-specific eQTLs, the majority of them being exome variants providing novel insights into genes and genetic variation contributing to SLE pathogenesis. Enrichment of eQTLs from the GTEx consortium and SLE GWASs revealed several loci where the eQTL and GWAS were tagging the same functional variant across different tissues, thus providing insights to the most relevant tissues implicated in the disease. All the results above provide a unique framework for SLE patient stratification, analysis of which is in progress.

Novel genetic associations of autophagy gene *MAP1LC3B* and *ARMBA1* in systemic lupus erythematosus. *Y.Y. Qi[1], S.K. Nath[2], C.L. Sun[2], Y.M. Zhang[1], F.J. Cheng[1,3], P. Hou[1], R. Mu[4], C. Li[4], J.P. Guo[4], Z.G. Li[4], F. Yu[1], M.H. Zhao[1], X.J. Zhou[1], H. Zhang[1].* 1) Renal Division, Peking University First Hospital;Peking University Institute of Nephrology; Key Laboratory of Renal Disease, Ministry of Health of China; Key Laboratory of Chronic Kidney Disease Prevention and Treatment (Peking University), Ministry of Ed; 2) Arthritis and Clinical Immunology Research Program, Oklahoma Medical Research Foundation, Oklahoma City, Oklahoma, USA; 3) Shandong Provincial Hospital Affiliated to Shandong University, Jinan, Shandong Province, People's Republic of China; 4) Department of Rheumatology and Immunology, Peking University People's Hospital, Beijing, China.

Objective Emerging evidences from genetic, cell biology and model animal studies suggested a pivotal role of autophagy in mediating the occurrence and development of SLE. This study analyzed variations in autophagy genes for association with SLE with Chinese ancestry. **Methods** In the first stage, 342 variants from 26 autophagy genes were used to perform genetic association analysis of a GWAS dataset using ImmunoChip in 1000 Chinese individuals. The second stage involved genetic replications in additional 4824 Chinese individuals and functional annotations of associated variants. Functional annotations of the associated variants were further examined by the *in silico* method as well as by expression quantitative trait loci (eQTL) analysis with mRNA. Luciferase reporter assay and electrophoretic mobility shift assay (EMSA) were performed to confirm the functional effects in HEK293T and Jurkat cell lines. **Results** By the two-stage analysis, *MAP1LC3B* rs933717 ($P_{discovery}=7.57*10^{-3}$, $P_{replication}=5.76*10^{-5}$ and $P_{combination}=2.35*10^{-6}$) and *ARMBA1* rs12574250 ($P_{discovery}=2.39*10^{-2}$, $P_{replication}=1.62*10^{-4}$ and $P_{combination}=8.61*10^{-6}$) were observed to be consistently associated with SLE. Risk genotypes of rs933717 were correlated with higher *MAP1LC3B* transcription levels in eQTL analysis (rs933717CC vs. TT $p=0.012$; rs933717CT vs. TT $p=0.003$). And higher *MAP1LC3B* mRNA expression was observed in the peripheral blood mononuclear cells of SLE ($p=1.28*10^{-9}$). Increased transcriptional activity of rs933737C (risk allele) by luciferase reporter assay was confirmed in two cell lines ($p=0.014$ in HEK293T, $p=0.022$ in Jurkat). rs933717C (risk allele) also showed greater affinity for HEK293T and Jurkat nuclear protein-DNA complex by EMSA directly. **Conclusion** We observed novel loci implicated in autophagy pathway associated with susceptibility to SLE, which might shed new insight into etiological basis of autophagy in SLE.

1257F

Decreased severity of experimental autoimmune arthritis in peptidylarginine deiminase type 4 knock-out mice. *A. Suzuki[1], Y. Kochi[1], H. Shoda[2], K. Fujio[2], K. Yamamoto[1,2].* 1) IMS, RIKEN, Yokohama City, Japan; 2) Division of Allergy and Rheumatology, University of Tokyo.

Objective. Previously, peptidylarginine deiminase type 4 (PADI4) was identified as a susceptibility gene for Rheumatoid arthritis (RA) by genome-wide association studies. PADI4 is highly expressed in bone marrow, macrophages, neutrophils, and monocytes. Peptidyl citrulline is an interesting molecule in RA because it is a target antigen of anti-citrullinated peptide antibodies (ACPAs), and only PADs (translated protein from PADI genes) can provide peptidyl citrulline via modification of protein substrates. The aim of this study was to evaluate the importance of the PADI4 gene in the progression of RA. *Methods.* We generated Padi4 knockout (Padi4−/−) DBA1J mice. Padi4−/− DBA1J and wild-type mice were immunized with bovine type II collagen (CII) to develop collagen-induced arthritis (CIA). Expression of various inflammatory cytokines and Padi genes in immune cells was detected by real-time TaqMan assay. Cytokine concentration in sera was measured by enzyme-linked immunosorbent assay. Localization of PAD4 and PAD2 protein was indicated by immunohistochemistry. *Results.* We demonstrated that the clinical disease score was significantly decreased in Padi4−/− mice and Padi4 expression was induced by CII immunization. In Padi4−/− mice sera, serum anti-type II collagen (CII) IgM, IgG, and inflammatory cytokine levels were also significantly decreased compared with those in wild-type mice sera. Interestingly, Padi2 expression was compensationally induced in CD11b+ cells of Padi4-/- mice. *Conclusion.* On the basis of these studies, it appears that Padi4 enhances collagen-initiated inflammatory responses. Our results revealed that PAD4 affected on expression of various cytokines and also controlled Padi genes.

Rheumatoid arthritis (RA) is a chronic autoimmune joint-destructive disease. Multiple anti-citrullinated peptide antibodies (ACPA) are seen specifically in ~70% of RA patients; the presence of ACPA is clinically used as a diagnostic tool. Residues at amino acid (AA) position 11 in the HLA-DRB1 is the strongest susceptibility position in the HLA locus to ACPA(+) RA. Here, we investigated whether different individual ACPA have distinct genetic factors. We phenotyped RA cases with a multiplex peptide array to quantify 18 fine-specific ACPA as well as 2nd generation cyclic ctrullinated peptide antibody (CCP2), the representative method to quantify ACPA. We queried 6,267 patients and 12,054 controls in 3 independent cohorts. Clustering analysis of fine ACPA demonstrated that ACPA could be classified into 2 distinct clusters. The 12 antibodies (Ab) in cluster 1 included CCP2 and an Ab recognizing a peptide derived from fibrinogen beta AA position 60 to 74 with positions 60, 72 and 74 citurillnated (Fibbeta60.74Ab) which showed the strongest correlation with CCP2. Cluster 2 included Fib72Ab, which reacts to a peptide sharing 12 AA sequences to the Fibbeta.60.74Ab peptide but strikingly differs only in citrullination at only one AA position. We imputed HLA genotypes and tested for MHC associations with specific ACPA with logistic regression models correcting for 10 principal components and cohort effects. Position 11, with 6 possible residues, had the strongest association to 14 ACPA, including all Ab in cluster 1 among cases (omnibus $p \leq 1.1 \times 10^{-33}$). Intriguingly, Fib72Ab, the cluster 2 Ab showed distinct association patterns of AA residues at the position 11 ($p = 1.1 \times 10^{-50}$) from cluster 1 associations. We previously showed that HLA-DRB1 alleles interact to confer risk of ACPA(+) RA (Lenz et al Nat Gen 2015); we assessed whether allelic interactions influence expression of specific ACPA. We identified two novel allelic combinations specifically showing interactive effects on fine-specific ACPA, including an interaction between DRB1*13:01 and 11:01 which influences expression of another Ab in cluster 2. These findings suggest that specific HLA-DRB1 alleles, and their interacting combinations lead to a different repertoire of Ab, with reactivities to different citurillnated peptide sequences. They suggest that reactivity to multiple antigen sets might independently lead to RA.

Trans-ethnic genetic association studies facilitate the mapping of novel psoriasis susceptibility loci with higher resolution. *L.C. Tsoi[1,2,3], R.P. Nair[1], M. Ghosh[4], M. Kabra[4], T. Tejasvi[1], P.E. Stuart[1], J.J. Voorhees[1], X. Wen[3], H.M. Kang[3], G.R. Abecasis[3], V.K. Sharma[4], J.T. Elder[1,5] on behalf of an international group of investigators studying psoriasis genetics.* 1) Dermatology, University of Michigan, Ann Arbor, MI, USA; 2) Dept of Computational Medicine & Bioinformatics, University of Michigan, Ann Arbor, MI, USA; 3) Dept of Biostatistics, University of Michigan, Ann Arbor, MI, USA; 4) All India Institute of Medical Sciences, New Delhi, India; 5) Ann Arbor Veterans Hospital, Ann Arbor, MI, USA.

Psoriasis is a chronic autoimmune disease of skin with a complex genetic architecture, and it affects over 100 million people worldwide. Genetic association studies have revealed over 80 psoriasis susceptibility regions to date; however, most of these efforts have focused on European-origin and Chinese populations. Identification of disease variants in other populations may facilitate the prioritization of causal genetic variants by exploiting the differences in haplotype structure. To this end, we performed GWAS in an Indian sample consisting of 2,599 cases and 1,734 controls. Indicative of common disease signals and mechanisms across the two populations, effect sizes of the known psoriasis susceptibility regions were highly correlated in the Indian and European datasets (Sperman r = 0.65; $p = 3 \times 10^{-9}$). Based on this observation, we performed a meta-analysis aggregating the Indian cohort with genetic association results of a meta-GWAS of European-origin individuals consisting of over 30,000 individuals. We identified three new loci achieving genomewide significance (1p36.22, 1q24.2, and 13q14.2), including one locus that has been identified in a previous Chinese study (1p36.22) but never established at genomewide significance in European studies. Finally, we utilized a Bayesian approach to compute the posterior probability of being a causal variant for each of the known and novel loci. By identifying sets of SNPs residing in 95% credible intervals, we were able to provide higher resolution (mean reduction in 95% credible interval = 20,000 bp) and to reduce the number of potential causal variants (mean reduction = 10) in the trans-ethnic study when comparing with the European-based study for all novel loci. Our study reveals elements of common genetic architecture shared across ethnicities in psoriasis, and highlights the value of trans-ethnic meta-analysis to uncover new disease-associated variants and to enhance the fine-mapping of susceptibility loci.

1260F

Genetic factors for lupus nephritis in Asian populations. *W. Yang, H. Zhang, Y. Zhang, Y.F. Wang, T.Y. Wang, J. Yang, Y.L. Lau.* Department of Paediatrics & Adolescent Medicine, Faculty of Medicine, University of Hong Kong, Pokfulam, Hong Kong.

Systemic lupus erythematosus (SLE) is a prototype autoimmune disease characterized by autoantibody production and multi-organ damage, which predominantly affects women in child bearing age. Lupus nephritis(LN) is a common manifestation of SLE and an important feature for the morbidity and mortality of the disease and a major cause of end-stage organ failure in SLE patients. Asian patients were reported to have higher rates of LN and more active glomerulonephritis compared to White patients. Previously, it was reported some genetic loci are more strongly associated with LN than with SLE patients without LN, including HLA-DRB1, STAT4, ITGAM and TNFSF4. A patient only GWAS comparing LN patients with SLE patients without LN also reported association for LN of PDGFRA, SLC5A11, ID4, and HAS2. However, all these studies were conducted on European populations and studies focusing on Asian samples who have more LN and more severe LN are scarce. Here we analyzed our Hong Kong GWAS data (paed.hku.hk/genome) by comparing LN patients with controls and SLE patients without LN with controls, and compared the results of the two analyses. We observed a clearly stronger association for patients with LN for NCF2, ITGAM, TNFAIP3, ELF1, ETS1, SLC15A4 and WDFY4. The only known susceptibility gene that may be protective against LN is CD80. Our analyses suggest potential population differences on the genetic variants that predispose to LN in Asian populations than in European populations. Studies focusing on subphenotype differences with big enough sample size and diverse ethnicity background are needed to confirm the differences and to identify novel loci for LN susceptibility. We also elaborate the pitfalls in subphenotype analysis by proposing always including controls in the analysis to reduce false positive detection and always evaluating a locus comprehensively by focusing on top and independent variants from a locus for valid conclusions on subphenotype association.

1261W

Impact of violence on allostatic load in African American young adults. *L. Jackson[1,2], F. Saadatmand[2], M. Shestov[3], G. Dunston[1], J. Wright[2].* 1) National Human Genome Center, Howard University, Washington, DC; 2) Pediatrics, Howard University, Washington, DC; 3) Genomics and Computational Biology, Biomedical Graduate Studies, University of Pennsylvania, Philadelphia, PA.

Allostatic load, the chronic stress-induced wear and tear on the body, has a cumulative deleterious effect in individuals over their lifetime. Recent studies have suggested that socioeconomic status, psychological determinants and biomedical health cumulatively contribute to allostatic load in young adults. While these finding individually suggest that African American children may be particularly susceptible to the effects of allostatic loading due to racially based discrimination and economic instability, few studies have shown the effect of exposure to violence on the allostatic load carried by young African Americans. The Biological and Social Correlates of Drug Use in African American Emerging Adults or BADU dataset is composed of young African Americans (N=557 individuals) living in the Washington DC area, collected from 2010 to 2012. Study participants were sought equally between males and females (N_{MALES}= 283, $N_{FEMALES}$=274). This dataset provides a rich source of information on the behavioral, mental, and physical health of African American young adults (18-25 year olds) living in the Washington DC area. This includes exposure to community, interpersonal and intimate partner violence. Analysis of six biomedical markers measured in BADU study participants: C Reactive Protein, Cortisol, Epstein Barr Virus IgG, IgE, IgA and IgM, known to be associated with allostatic load show that cortisol is positively correlated to reported emotional state(R=0.072) and perceived individual discrimination (R=0.059). Allostatic load appears to be high in individuals who self-report exposure to violence. These findings suggest that allostatic load is an important factor in health and disease outcomes for young African Americans.

1262T

The genetics of red blood cell density in sickle cell disease patients. *Y. Ilboudo[1], P. Bartolucci[2], F. Galacteros[2], S. Alper[3], C. Brugnara[4], G. Lettre[1,5].* 1) Biochemistry, University of Montréal, Montréal, Québec, Canada; 2) Red Cell Genetic Disease Unit, Hôpital Henri-Mondor, Assistance Publique–Hôpitaux de Paris (AP-HP), Université Paris Est IMRB - U955 - Equipe n°2, Créteil, France; 3) Division of Nephrology, Beth Israel Deaconess Medical Center, Boston, USA Department of Medicine, Harvard Medical School, Boston, USA; 4) Department of Laboratory Medicine, Boston Children's Hospital, Boston, Massachusetts, USA; 5) Department of Medicine, Université de Montréal, Montréal, Québec, Canada.

Sickle cell disease is a monogenic blood disorder caused by mutations in the β-globin gene. Although a single gene is involved in this disorder, the clinical symptoms are heterogeneous. Dehydrated red blood cell density (DRBC) is a typical attribute of sickle cell disease (SCD) patients. Recent studies have linked higher percentage of DRBC with increased incidence of SCD-related pathophysiologies caused by the deformation of erythrocytes in blood vessels. Based on these novel findings, we sought to identify the genetic determinants of DRBC in SCD patients. We conducted a genome-wide association study (GWAS) in 405 SCD patients from the GEN-MOD study. These participants are of recent African descent and were recruited in France. Genotyping was done on the Illumina HumanOmni2.5Exome array and imputation was performed using 1000 Genomes Phase 3 haplotypes (v.5). We also performed gene-based tests (SKAT & VT), focusing on non-synonymous and splice site variants with a minor allele frequency <5%. DRBC was analyzed using an additive linear regression model, correcting for age, sex, and the first 10 principal components. Finally, we selected 65 patients from the GEN-MOD study for whole-exome sequencing (WES), and investigated the association between DRBC and rare detrimental mutations in strong candidate genes that play a role in red blood cell biology. The GWAS analyses were inconclusive as none of the variants reached array-wide significance ($P<2x10^{-7}$). This lack of association probably reflects our modest sample size to find association between DRBC and common variants of weak effects. The WES experiment identified 230 mutations in 50 candidate genes. Of interest, we found that the patient with the highest percentage of DRBC (37%) had a missense mutation in *ATP1B2*, the beta2 subunit of the ouabain-sensitive Na+/K+ -ATPase. This gene is also known as *AMOG* (Ca2+-dependent adhesion molecule of glia) and is expressed abundantly in the brain and the retina. It binds to retinoschisin, a retinal degeneration gene for X-linked human juvenile retinoschisis. We present the first genetic study of DRBC, a biomarker and potential modifier of severity in SCD. We found no evidence of common variants with strong effect on DRBC variation. Our candidate-gene approach based on WES highlighted several promising candidate mutations, although functional validation is required to confirm their mechanistic effect.

1263F

Polymorphisms in *IL18* gene are associated with person-to-person variation in IL18 levels in individuals with HCV and/or HIV infection. *C. Vergara[1], C.L. Thio[1], R. Latanich[1], G. Kirk[2], S. Mehta[2], A. Cox[1], A. Kim[13], G. Lauer[13], M. Busch[3], E. Murphy[3,4], M. Villacres-Cevallos[5], M. Peters[4], A. French[6], E. Golub[2], J. Eron[7], C.D. Lahiri[8], S. Shrestha[9], D. Gustafson[10], M. Young[11], K. Anastos[12], B. Aouizerat[14], D. Thomas[1], P. Duggal[2].* 1) Division of Infectious Diseases, Johns Hopkins University, Baltimore, MD. USA; 2) Johns Hopkins University Bloomberg School of Public Health, Baltimore, MD.,USA; 3) Blood Systems Research Institute, San Francisco, CA.,USA; 4) University of California, San Francisco, CA.,USA; 5) Keck School of Medicine of the University of Southern California, Los Angeles, CA., USA; 6) CORE Center/Stroger Hospital of Cook County, IL., USA; 7) University of North Carolina at Chapel Hill, NC.,USA; 8) Emory University School of Medicine, Atlanta, GA, USA; 9) The University of Alabama at Birmingham, AL., USA; 10) State University of New York - Downstate Medical Center, NY, USA; 11) Georgetown University Medical Center, Washington, DC.,USA; 12) Albert Einstein College of Medicine and Montefiore Medical Center, NY.USA; 13) Massachusetts General Hospital, Boston, MSS.,USA; 14) New York University, NY.,USA.

Inflammasomes are multi-protein cytosolic complexes that integrate several pathogen-triggered signaling cascades ultimately leading to caspase-1 activation and the generation of the pro-inflammatory cytokine interleukin (IL)-18. Hepatitis C virus (HCV) and human immunodeficiency virus-1 (HIV) infections are associated with elevated plasma levels of IL18 suggesting inflammasome activation. However, there is marked person-to-person variation in the inflammasome response to HCV and HIV as demonstrated by varying blood levels of IL18. We hypothesized that there is a genetic basis for this variation. To test this hypothesis, we analyzed the associations of plasma IL18 levels and polymorphisms in 10 genes that were identified to participate in various stages of the inflammasome signaling cascade and/or IL18 production. We studied 1538 subjects with active HCV and/or HIV infection including 386 individuals of European ancestry, 796 individuals of African ancestry and 356 individuals of Hispanic ancestry. Samples were genotyped using the Illumina Human Omni-Quad and Omni.2.5. IMPUTE2 was used for imputation to 1000 genomes Phase III and PLINK was used test the association of variants with LogIL18 levels using an additive model. HCV and HIV infection status and HIV RNA, plus 2 principal components were included as covariates. The results obtained in the three ethnic groups were meta-analyzed with META. We observed significantly associated variants in the *IL18-BCO2* region on chromosome 11 in two imputed intronic SNPs: rs111311302 and rs80011693 in the meta-analysis. The presence of one G allele in rs111311302 confers a decrease of 0.06 units of LogIL18 levels in comparison with the C allele (β for G allele = -0.06, SE: 0.02, P value= $2.7 x 10^{-4}$). Both variants are in high linkage disequilibrium (LD), r2=0.98-1 in the three ethnic groups and the same values were observed for rs80011693 (T>C). No associations were detected between IL18 levels and polymorphisms in *IL-1β*, *ASCC1*, *NLRP3*, *NFKB1*, *NFKB2*, *CASP1*, *TLR7*, *TLR8* and *MYD88*. In conclusion, person to person variation in DNA of IL18 appears to modify IL18 production in response to HIV and HCV infections. While additional research is needed to demonstrate the mechanism, these data may help explain variability in the long-term inflammatory outcomes of chronic viral infections.

1264W

Integration of GWAS and lung eQTL to identify asthma genes. *J. Berube[1], M. Lamontagne[1], M. van den Berge[2], D.D. Sin[3], K. Hao[4], D.C. Nickle[5], W. Timens[2], P.D. Paré[3], M. Laviolette[1], Y. Bossé[1,6].* 1) Institut universitaire de cardiologie et de pneumologie de Québec, Quebec City, Canada; 2) University of Groningen, University Medical Center Groningen, GRIAC Research Institute, Groningen, Netherlands; 3) The University of British Columbia Centre for Heart Lung Innovation, St Paul's Hospital, Vancouver, Canada; 4) Icahn School of Medicine at Mount Sinai, New York, NY, United States; 5) Merck & Co, MRL, Seattle, Washington, United States; 6) Department of Molecular Medicine, Laval University, Quebec City, Canada.

   Several genetic variants associated with asthma have been identified through GWAS. An integration of asthma GWAS data with lung expression quantitative trait loci (eQTL) has the potential to reveal the most likely causal genes in asthma susceptibility loci. Here, we leverage the results of the largest publically available GWAS data on asthma and a large-scale eQTL study performed in human lung tissues to elucidate causal genes in asthma susceptibility loci. First, the summary statistics of the 10,365 asthmatic subjects and 16,110 controls from the GABRIEL consortium were obtained for five loci that showed genome-wide significance and two additional borderline significant loci. Missing summary statistics were imputed using the ImpG software and the 1000 genomes European genotypes. Second, the lung eQTL dataset summary statistics were calculated 1 Mb up- and down-stream of the sentinel asthma associated SNPs for 1,038 individuals with genome-wide genotyping and gene expression data. Colocalisation analyses were then performed using the R package COLOC with a $p_{12}=10^{-5}$. For the 17q21 locus, the gene *GSDMA* demonstrated a 96.9% posterior probability that the asthma and the lung eQTL signals colocalized, suggesting that the genetic association and lung eQTL signals shared causal variants. The most likely SNP is rs4580194 with an imputed p-value for asthma of 1.04e-11 and an eQTL p-value with *GSDMA* of 1.54e-83. For the other asthma loci on chromosomes 2 (*IL18R1*), 5 (*SLC22A5* and *IL13*), 9 (*IL33*), 15 (*SMAD3*), 15 (*RORA*) and 22 (*IL2RB*), the highest posterior probabilities for genes surrounding asthma SNPs were between 2 and 3%. This study supports *GSDMA* as the most likely asthma gene on chromosome 17q21. Other GWAS-nominated asthma loci will require further investigation.

1265T

Genome-wide association analysis reveals variants on chromosome 19 that contribute to childhood risk of chronic otitis media with effusion. *E. Einarsdottir[1,2], L. Hafrén[3], E. Leinonen[1], M.F. Bhutta[4], E. Kentala[3], J. Kere[1,2], P.S. Mattila[3].* 1) Folkhälsan Institute of Genetics, and Molecular Neurology Research Program, University of Helsinki, Helsinki, Finland; 2) Department of Biosciences and Nutrition, Karolinska Institutet, Huddinge, Sweden; 3) Department of Otorhinolaryngology, Helsinki University Hospital, Helsinki, Finland; 4) Children's Surgical Centre, Phnom Penh, Cambodia.

   We performed a genome-wide association (GWA) study to identify genetic risk factors underlying childhood otitis media (OM [MIM166760]). The study included 829 Finnish affected children and data from 2118 controls genotyped previously. The most significant findings were validated on an independent platform. An association was found to a locus on chromosome 19 (best P = 1.77×10^{-7}, OR = 1.59). This locus harbors six genes in strong linkage disequilibrium. In a sub-phenotype analysis of the 509 patients with chronic otitis media with effusion (COME), one marker reached genome-wide significance (P = 2.92×10^{-8}). This association, albeit to the opposite allele, was replicated in a UK family cohort of 4860 subjects (best P = 1.62×10^{-4}, OR = 0.71). Our study is the largest reported association study performed on OM. Its main strength is the large sample size and the homogeneous Finnish population from which it is derived. We hypothesize that the genomic region on chromosome 19 is important for OM, and particularly COME, risk in both the Finnish and UK populations. Although the precise risk variants and mechanism remain unclear, our study suggests that the identified region on chromosome 19 includes a novel and previously uncharacterized risk locus for OM.

1266F

GWAS for serum galactose-deficient IgA1 (Gd-IgA1) points to critical genes of the O-glycosylation pathway. *K. Kiryluk[1], Y. Li[1], Z. Moldoveanu[2], H. Suzuki[3], J. Xie[4], N. Mladkova[1], R. LeDesma[1], P. Hou[5], I. Ionita-Laza[1], N. Chen[4], H. Zhang[5], J. Novak[2], A.G. Gharavi[1].* 1) Columbia University, New York, NY; 2) University of Alabama at Birmingham, Alabama, USA; 3) Juntendo University Faculty of Medicine, Tokyo, Japan; 4) Ruijin Hospital, Shanghai Jiao Tong University School of Medicine, Shanghai, China; 5) Peking University First Hospital, Peking University Institute of Nephrology, Beijing, China.

Background: IgA1 O-glycosylation defects are universally detected among patients with IgA nephropathy (IgAN), the most common form of primary glomerulonephritis worldwide. Serum level of galactose-deficient IgA1 (Gd-IgA1) represents a known heritable biomarker for IgAN, but specific genetic factors involved in its determination are not known. **Methods:** We performed a quantitative GWAS for serum Gd-IgA1 in 2,633 individuals of Asian and European ancestry. In the discovery phase, we used HAA-lectin based ELISA to analyze sera of 1,195 individuals of East Asian and European ancestry genotyped with Illumina 610-quad and 550v3 platforms, respectively. We used a linear model with individual SNPs coded as additive genetic predictors and the outcome defined as standardized residuals of serum Gd-IgA1 after adjustment for age and sex. Each cohort was additionally adjusted for significant PCs of ancestry. Suggestive loci were followed by targeted genotyping in 1,438 additional individuals of East Asian and European ancestry. Subsequently, all cohorts were meta-analyzed jointly to identify novel genome-wide significant loci. **Results:** The strongest association signal was located within a 200-kb interval on chr.7p21.3 containing *C1GALT1* gene (rs13226913, P = 3.2 x 10^{-11}). The protein encoded by *C1GALT1* generates the common core 1 O-glycan structure by the transfer of galactose (Gal) from UDP-Gal to GalNAc-alpha-1-Ser/Thr. Core 1 is a precursor for O-glycans in the hinge region of circulating IgA1, as well as in many extended mucin-type O-glycans on cell surfaces. Notably, rs13226913 has a highly significant cis-eQTL effect on *C1GALT1* mRNA levels (P = 3.9 x 10^{-23}, the Gd-IgA1-increasing allele is associated with lower levels of mRNA expression). The second locus comprises a 100-kb interval on chr.Xq24 and contains *C1GALT1C1* gene (rs5910940, P = 2.7 x 10^{-8}), the molecular partner of C1GALT1 essential for its proper enzymatic activity. We demonstrate that non-coding variants in *C1GALT1* and *C1GALT1C1* genes jointly explain up to 7% of the overall variability in circulating Gd-IgA1. **Conclusions:** In the first GWAS for serum Gd-IgA1 we discovered two genome-wide significant loci that encode the molecular partners involved in the critical step of IgA1 *O*-glycosylation. Our findings provide new insights into the genetic regulation of O-glycan synthesis and are potentially relevant to several human diseases, including IgAN, inflammatory bowel disease, hematologic disease, and cancer.

1267W

The psoriasis risk allele *HLA-C*06:02* shows evidence of association with chronic and recurrent tonsillitis. *L.L.E Koskinen[1], K. Haapasalo[1], J. Suvilehto[2], P. Jousilahti[3], A. Wennerström[3], S. Suomela[4], R. Trembath[5], J. Barker[5], J. Vuopio[6,7], J. Kere[8,9], T.S. Jokiranta[1], P. Saavalainen[1].* 1) Research Programs Unit, Immunobiology, University of Helsinki, Helsinki, Finland; 2) Department of Otorhinolaryngology, Helsinki University Central Hospital, Helsinki, Finland; 3) Department of Health, National Institute for Health and Welfare, Helsinki, Finland; 4) Department of Dermatology, University of Helsinki and Helsinki University Hospital, Helsinki, Finland; 5) Division of Genetics and Molecular Medicine, Faculty of Medicine and Life Sciences, Kings College London, SE1 9RT, UK; 6) Medical Microbiology and Immunology, University of Turku, Turku, Finland; 7) Bacterial Infections Unit, National Institute for Health and Welfare, Helsinki, Finland; 8) Department of Biosciences and Nutrition, Karolinska Institutet, Huddinge, Sweden; 9) Research Programs Unit, Molecular Neurology, University of Helsinki, Helsinki, Finland.

Pharyngeal tonsillitis is one of the most common upper respiratory tract disorders in humans where Group A streptococcus is considered to be clinically the most important bacterial pathogen. While many patients experience only occasional throat infections with a relative short duration, a subset of patients suffer from chronic or recurrent tonsillitis. The reason for this is not yet fully understood. Susceptibility to tonsillitis has been suggested to have a genetic component. To search for new genetic biomarkers in pharyngeal tonsillitis, we performed an association study using the ImmunoChip (Illumina Infinium SNP array). Over 190,000 SNPs were genotyped in 96 Finnish patients subjected to tonsillectomy due to chronic or recurrent tonsillitis. 504 controls from the DILGOM/FINRISKI 2007 cohort were previously genotyped with ImmunoChip. The data was analyzed for association with PLINK. Classical alleles and amino acids of the HLA class I and II genes were imputed from the SNP genotypes with SNP2HLA. ImmunoChip data (from the Genetic Analysis of Psoriasis Consortium) and *HLA-C*06:02* genotype information from 163 Finnish patients with psoriasis were used in comparing the results with the tonsillitis data. For tonsillitis, the strongest association was identified on chromosome six at the MHC locus nearby genes *RNF39*, *TRIM31*, *HLA-C* and *HLA-B* (p=3.07E-6). Association analysis of the imputed HLA alleles suggested *HLA-C*06:02* as a risk factor for tonsillitis (p=5.0E-4, OR 2.3). Haplotype analysis pointed towards *HLA-C*06:02/HLA-B*5701* as the haplotype conferring the strongest risk for tonsillitis (p=8.0E-3, OR 5.5). Comparison of the tonsillitis and psoriasis genotype data at the HLA locus showed that the same haplotype increased the risk of both diseases.   We identified evidence of association with recurrent/chronic tonsillitis at the HLA locus, with the *HLA-C*06:02* haplotype conferring the highest disease risk. Interestingly, this haplotype is a known risk haplotype in psoriasis also. Our finding suggests a novel genetic explanation for the known link between streptococcal throat infections and onset and pathogenesis of psoriasis. The result supports the theory of molecular mimicry between streptococcal M protein and skin keratins, and points to presentation of shared antigenic T cell epitopes by HLA-Cw6 in both diseases.

1268T

Combining eQTL analyses with CRISPR/Cas9 experiments to fine-map causal variants that regulate *ATP2B4*, a gene associated with red blood cell traits and malaria resistance. *S. Lessard[1], E. Stern[2,3], D.E. Bauer[2], G. Lettre[1].* 1) Department of Medicine, Université de Montréal, Montreal Heart Institute, Montreal, Quebec, Canada; 2) Boston Children's Hospital, Dana-Farber Cancer Institute, Harvard Medical School, Harvard Stem Cell Institute, Boston, Massachusetts; 3) Tufts University School of Medicine, Boston, Massachusetts.

A major challenge arising from the success of genome-wide association studies (GWAS) is to link associated non-coding variants to causal genes. This information is essential to translate genetic discoveries into therapeutic breakthroughs. Here, we explore how to combine expression quantitative trait loci (eQTL) mapping and the CRISPR/Cas9 genome-editing tool to dissect the *ATP2B4* GWAS locus associated with red blood cell (RBC) traits and malaria resistance.Using RNA-seq and genotype data from human erythroblasts, we identified 534 genes with strong evidence of allelic imbalance (AI, binomial P<1.6x10^{-5}). For 215 of these genes, we identified at least one significant eQTL at a false discovery rate <5%. Although most of these eQTL associations are replicated in other tissues from GTEx, our results highlighted 64 eGenes that are specific to erythroblasts. We found an enrichment of erythroblast eQTL in erythroid enhancers and ChIP-seq peaks for the erythroid transcriptional master regulator GATA1.Of particular interest, we identified a cluster of SNPs on chromosome 1 in strong linkage disequilibrium that are eQTL for *ATP2B4* (P=5x10^{-6}), which encodes the main plasma membrane calcium-transporting ATPase in RBCs. These SNPs overlap an erythroid-specific DNase I hypersensitive site (DHS) and are associated with RBC traits and malaria resistance. Using the CRISPR/Cas9 system in a human erythroid cell line, we deleted this DHS and observed a dose-dependent effect on *ATP2B4* expression levels, where cells with bi-allelic deletions displayed almost no *ATP2B4* expression. Smaller deletions narrowed down the essential regulatory sequence to a 98 bp region that contains 5 GATA1 binding motifs overlapping several eQTL. Individual disruptions of these motifs suggested cooperative regulation of *ATP2B4* by constituent GATA1 binding sites. Overall, this data suggests that the biological basis of the *ATP2B4* GWAS associations is through modulation of core erythroid enhancer function by common haplotypes. We are now exploring the effect of *ATP2B4* deficiency on calcium transport, hemoglobin concentration, and plasmodium invasion.Our study provides a proof-of-concept that eQTL mapping followed by genome editing in relevant cells facilitates the molecular characterization of GWAS signals. The *ATP2B4* minimal regulatory sequence would have been missed if we had not mapped eQTL specifically in erythroid cells, emphasizing the importance of employing the appropriate cell model.

1269F

A synonymous variant in *IL10RA* affects RNA splicing in pediatric patients with refractory inflammatory bowel disease. *S. Oh[1], J. Baek[2], H. Liany[3], J.N. Foo[3], K.M. Kim[1], S.C. Yang[2], J.J. Liu[3], K. Song[2].* 1) Pediatrics, Asan Medical Center Children's Hospital, University of Ulsan College of Medicine, Seoul, South Korea; 2) Biochemistry and Molecular Biology, University of Ulsan College of Medicine, Seoul, Korea; 3) Human Genetics Group, Genome Institute of Singapore, Singapore.

Interleukin-10 receptor (*IL10R*) mutations are associated with severe childhood inflammatory bowel disease (IBD). Two unrelated patients who died of very early-onset severe IBD and sepsis were identified to harbor the same compound heterozygous mutations in *IL10RA* (p.R101W; p.T179T). A third patient was found to be homozygous for p.T179T. The missense change of p.R101W has been reported. The synonymous change of p.T179T, with a minor allele frequency of 0.035% in the population, was novel. The p.T179T mutation was located before the 5′ splice donor site, leading to exon skipping and out-of-frame fusion of exons 3 and 5, causing altered STAT3 phosphorylation in IL10-induced peripheral blood mononuclear cells. The patient developed colitis at six years of age, the oldest reported age of onset among patients with *IL10RA* mutations, and did not suffer from perianal disease. We report three pediatric patients with a rare, synonymous p.T179T variant causing a splicing error in *IL10RA*.

1270W

Human genetic determinants of the humoral immune response to common pathogens. *P. Scepanovic[1,2], C. Alanio[3,4], C. Hammer[1,2], D. Duffy[3,4], J. Antonsson[5,6], L. Abel[7,8], L. Quintana-Murci[9,10], M. Albert[3,4,11], J.    Introduction. Immunological responses to latent infections and vaccinations vary among individuals, and this is thought to be highly influenced by host genetics. To unravel the mechanisms of genetic control of the immunoglobulin G (IgG) responses to common latent pathogens and vaccines, we conducted genome-wide association studies (GWAS) in a well characterized population of 1000 healthy individuals recruited by the *Milieu Intérieur* Consortium. **Methods.** The *Milieu Intérieur* (MI) project is a population-based study that aims at assessing the determinants of immunological variance within a healthy population. To achieve this, 1000 healthy individuals, with a 1:1 sex ratio, and stratified across five-decades of life (age 20 – 69) were recruited. Serum from these donors were used for qualitative (serostatus: seropositive/seronegative) and quantitative assessment of IgG responses against Cytomegalovirus (CMV), Epstein-Barr virus (EBV), Herpes simplex virus 1 & 2 (HSV-1 & 2), Varicella zoster virus (VZV), *Helicobacter pylori*, *Toxoplasma gondii*, Influenza A virus, Measles, Mumps, Rubella, and Hepatitis B virus. We used the Illumina OmniExpress and HumanExome arrays to genotype the 1,000 MI donors. After imputation with IMPUTE2, logistic or linear regressions were performed to detect associations between 5 million human polymorphisms and antibody responses.   **Results and discussion.** No genome-wide significant associations ($P < 5 * 10^{-8}$) were found for serostatus. In contrast, genome-wide significant associations were observed for the levels of IgG mounted against EBV, Rubella, and HSV-1. For EBV (EBNA antigen) and Rubella the most relevant association concerns the MHC locus on chromosome 6 ($P = 1.1 * 10^{-9}$ and $P= 7.7 * 10^{-10}$ respectively) and confirms previous observations. By imputing classical HLA alleles and amino acids, we found that these associations rely on variations in amino acid composition of HLA-DRβ1 and HLA-DPβ1 molecules respectively. In parallel, we report new associations of (i) EBV EBNA IgG levels with *LOC646241* ($P = 3.4 * 10^{-9}$), (ii) EBV VCA IgG levels with *SND1* ($P = 2.7 * 10^{-9}$) and *LINC01090* ($P = 3.11 * 10^{-9}$), and (iii) HSV1 IgG levels with *CTNNA3* ($P = 7 * 10^{-12}$). Together our results provide new possible insights into mechanisms determining response to these viral antigens and encourage further genetic and functional work.

   Genome-wide association testing of single nucleotide polymorphisms (SNPs) is limited to detect the complete genetic variance of human diseases. One reason is the correction for multiple testing of large numbers of independent markers. In this instance, candidate gene studies that focus on confined chromosomal regions may be advantageous. An ideal mapping strategy takes account of the advantages of both approaches, but requires a system for an unbiased *de novo* generation of hypotheses on candidate genes. Herein, we describe a systems genetics approach, which exploits murine genome variability to systematically generate candidate genes that can be tested in human samples. Periodontitis (PD) has a high global prevalence rate of 11% for the severe forms but the genetic etiology is currently very poorly understood. In a previous study, we crossed the mouse lines A/J and BALB/cJ (resistant and susceptible to bacteria induced PD) into the F$_2$ generation and identified two QTLs of genomewide significance. Here, we performed RNA sequencing of hemi-maxilla of the extreme phenotypes of the F$_2$ offspring (HiSeq system, Illumina). Four differently expressed genes at the previously identified QTLs were detected using the software tools Cufflinks and DESeq. (*Ugt2a1*, *Pf4*, *Sult1d1*, *Stoml3*). The human orthologous were analysed for disease associated SNPs in imputed genotypes (1000G Phase3 EUR) of a German case-control sample of the very severe, rare, and early-onset phenotype aggressive PD (AgP; 717=cases, 4,079=controls, genotyped on OmniExpress Bead Chips, Illumina). Two haplotype blocks suggested association with PD and were located upstream *UGT2A1* (tagging SNP rs146712414, $P=9.1x10^{-5}$, odds ratio [OR]=1.34, 95% confidence interval [CI]=1,16-1.56) and at *PF4* (SNP rs1595009, $P=2.8x10^{-4}$, OR=0.77 [0.67-0.89]). These associations were tested in a sample of white US-Americans, diagnosed for the widespread but moderate chronic PD, (CP; 1,961=cases, 1,864=controls). With this sample, only the haplotype at *PF4* was associated with CP (rs1595009, p=0.029; $P_{pooled}=1.2x10^{-4}$). eQTL analysis (Haploreg, GTEx) showed that the risk G-allele was highly significant associated with elevated expression of the distant gene *PF4V1* ($p=3.7^{-10}$) and *CXCL5*, located *in cis* ($p=6.5x10^{-6}$). Our data show that expression patterns in mouse models can recapitulate human conditions and allow narrowing down a limited number of genes, which can be tested successfully for disease association in the human genome.

The role of rare variants in a pediatric inflammatory bowel disease cohort. *K. Shaw[1], D. Cutler[2], D. Okou[3], L. Denson[4], S. Kugathasan[3], M. Zwick[2].* 1) Genetics and Molecular Biology Program, Emory University, Atlanta, GA; 2) Department of Human Genetics, Emory University, Atlanta, GA; 3) Department of Pediatrics, Emory University, Atlanta, GA; 4) Division of Gastroenterology, Hepatology and Nutrition, Cincinnati Children's Hospital Medical Center, Cincinnati, OH.

The two most common forms of inflammatory bowel disease (IBD) are Crohn's disease (CD) and ulcerative colitis (UC). CD and UC are severe chronic diseases characterized by relapsing-remitting gastrointestinal inflammation. Around 5% of existing IBD cases in the United States are patients under the age of 20. Studies of these pediatric cohorts can provide unique insights into the genetic architecture of IBD. Large genome-wide association studies of IBD have found 200 loci associated with disease but explain only 13.1% of variance in disease liability for CD and 8.2% for UC. In this study we found rare, nonsynonymous variants at well-conserved loci (CADD score >10) that were significantly more frequent in exome sequencing of 376 pediatric IBD patients than in publicly available Exome Aggregation Consortium (ExAC) data. We calculated the proportion of variance explained by these sites and performed pathway enrichment analysis of genes containing significant sites. We found 178 sites enriched in our pediatric IBD patients. Some sites overlapped with known CD and UC-associated genes, including NOD2 and several genes in the HLA system. Pathway enrichment analysis implicated many immune-related pathways consistent with our understanding of IBD such as detection of bacterium, antigen processing and presentation, toll-like receptor signaling, and interferon-gamma and interleukin-6 production. Other enriched pathways included those involved in metabolism of drugs and xenobiotics, as well as trafficking of metabolites.

Copy number variation of *ADAM3A* gene in systemic lupus erythematosus. *F.B. Barbosa[1], M. Simioni[2], C.E.V. Wiezel[1], F.R. Torres[2], M.C. Molck[2], E.A. Donadi[3], V.L. Gil-da-Silva-Lopes[2], A.L. Simões[1].* 1) Department of Genetics, Ribeirão Preto Medical School, University of São Paulo, Ribeirão Preto - SP, Brazil; 2) Department of Medical Genetics, Faculty of Medical Sciences, University of Campinas, Campinas - SP, Brazil; 3) Division of Clinical Immunology, Department of Medicine, Ribeirão Preto Medical School, University of São Paulo, Ribeirão Preto - SP, Brazil.

Systemic lupus erythematosus (SLE [MIM: 152700]) is an autoimmune disease with a strong genetic background characterized by chronic inflammation and autoantibody production. Copy number variations (CNVs), deletions or duplications usually greater than 1 Kb in genomic DNA, can contribute to the variability of the risk for complex diseases including SLE. Blood cell lymphocytes from 23 unrelated SLE patients and 110 healthy subjects were submitted to the genome-wide human Cytoscan HD Array (Affymetrix®) to screen for CNVs in genomic DNA. Low copy number (<2 copies) of *ADAM3A* gene was identified as potential candidate to SLE susceptibility (p = 0.0297, Odds Ratio [OR] = 3.6, 95% confidence interval [CI] = 1.0—16.0). *ADAM3A* gene is inserted in a cluster with other genes of *ADAM* family involved in several inflammation processes. *ADAM3A* have been related to some types of cancer and autoimmune diseases. The purpose of this study was to confirm the role of the *ADAM3A* CNV in SLE using a target-specific methodology in a larger sample size. A total of 134 unrelated SLE patients and 201 healthy controls were genotyped by SYBR green-based quantitative PCR (qPCR) using the StepOnePlus instrument and software (Applied Biosystems). Fisher's Exact test was applied for comparing the frequencies of *ADAM3A* copy number states between SLE and healthy controls using R. The genotypes of individuals determined by both Cytoscan HD Array and qPCR were 100% and 90% concordant in case and control groups, respectively. Individuals with discordant genotypes in the two methodologies were excluded from the statistical analysis. The copy number state of *ADAM3A* varied from 0 to 3 in the SLE group, while it ranged from 0 to 8 copies in controls. No evidence of association of the *ADAM3A* deletion with SLE susceptibility was found (p = 0.4762, OR = 0.8, 95% CI = 0.5—1.4). However, high copy number of *ADAM3A* (>2 copies) were described as a protective factor against susceptibility to SLE (p = 0.0277, OR = 0.3, 95% CI = 0.1—0.9). Our findings suggest that common duplications in immunoregulatory genes may be a protective factor against the development of SLE. Background: The high variability in the genome of Human Immunodeficiency Virus (HIV) is due to its rate of replication and inability of the reverse transcriptase to correct errors. These errors generate mutations that in some cases back to their wild type. Such as resistance mutations like T215Y/F and its revertants in treat-naive and with antiretroviral therapy (ART) patients. The objective was to compare the frequencies of variants of the reverse transcriptase gene of HIV-1 at codon 215 revertants mutations between 2000-2009 and 2010-2014 in the patients with ART or naive-treat. **Methods:** Were selected plasma samples from 473 patients with HIV-1 from 2000 to 2014, who attended the Laboratory of Immunodeficiencies and Human Retrovirus, Western Biomedical Research Center, Mexican Institute of Social Security. They were divided into four groups of patients: 1) ART-naive from 2000 to 2009 (n=95); 2) ART-naive from 2010 to 2014 (n=134); 3) ART-treat from 2000 to 2009 (n=121) y 4) ART-treat from 2010 to 2014 (n=123). Extraction of viral RNA was performed, an RT-PCR reaction and subsequently sequencing for reverse transcriptase. Genotyping was performed with Trugene HIV-1 system with kit the OpenGene DNA Sequencing System (Siemens; Ontario, Canada). The sequences were analyzed with the database of Stanford University and the revertants mutations were determined. Chi-square test was used to compare frequencies in SPSS version 22. **Results:** We found the frequency of mutations at codon 215 between 1 and 2 of 3.16% and 4.48% respectively. For T215Y only found in the group 1 at 1.05%. The variants of the revertant mutation for group 1 was T215A/C with a frequency of 1.05% for each variant, and group 2 was T215S/D/L/P with 1.49% for S/L and 0.75% for D/P. Group 3 had a mutation frequency of 48.76%, where T215Y was 33.88%, T215F 6.61% and the revertant mutation T215C 2.48%. T215V of 1.65% and T215S/D/L/H of 0,83% each one; in the group 4 frequency was 47.97% mutations, where T215Y was 23.58%, T215F 17.07% and the revertants mutations T215D/E 2.44% and T215C/V/I 0.81%. There are significant differences in T215Y/F between 1-3 and 2-4 groups (p<0.05). In revertant mutations there were no differences between periods, as well as naive and treated with antiretroviral drugs. **Conclusion:** The frequency of mutation variants have changes T215 showing that the virus is returning to its wild type.

1275F

Identification of the primary functional variants for primary biliary cirrhosis (PBC) susceptibility loci by high-density association mapping and *in silico/in vitro* functional analyses.

Y. Hitomi[1,10], K. Kojima[2,3,10], M. Kawashima[1,4], Y. Kawai[2,3], N. Nishida[1,5], Y. Aiba[6], M. Yasunami[7], M. Nagasaki[2,3,8], M. Nakamura[6,9], K. Tokunaga[1]. 1) Department of Human Genetics, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan; 2) Department of Integrative Genomics, Tohoku Medical Megabank Organization, Tohoku University, Sendai, Japan; 3) Graduate School of Medicine, Tohoku University, Sendai, Japan; 4) Japan Science and Technology Agency (JST), Tokyo, Japan; 5) The Research Center for Hepatitis and Immunology, National Center for Global Health and Medicine, Ichikawa, Japan; 6) Clinical Research Center, National Hospital Organization, Nagasaki Medical Center, Omura, Japan; 7) Department of Clinical Medicine, Institute of Tropical Medicine, Nagasaki University, Nagasaki, Japan; 8) Graduate School of Information Sciences, Tohoku University, Sendai, Japan; 9) Department of Hepatology, Nagasaki University Graduate School of Biomedical Sciences, Nagasaki, Japan; 10) These authors contributed equally to this work.

Primary biliary cirrhosis (PBC) is a chronic and cholestatic liver disease that is caused by autoimmune destruction of intrahepatic small bile ducts, eventually leading to liver cirrhosis and hepatic failure. Recently, *Human Leukocyte Antigen (HLA)*, *tumor necrosis factor superfamily member 15 (TNFSF15)*, *POU class 2 associating factor 1 (POU2AF1)*, and other genes have been identified as susceptibility genes to PBC in the Japanese population by our previous genome-wide association study (GWAS). However, especially for a gene region that is located in a large linkage disequilibrium (LD) block such as chromosome 17q12-21 (*ORMDL3-GSDMB-ZPBP2-IKZF3*), primary functional variants in these gene loci and their molecular mechanisms for disease susceptibility to PBC have not been clarified. In the present study, in order to identify the primary functional variants in chr.17q12-21, high-density association mapping was carried out based on SNP imputation analysis by IMPUTE2 (ver. 2.3.1), using the whole-genome sequence data from a reference panel of 1,070 Japanese individuals (1KJPN), together with genotype data from our previous GWAS (PBC patients: n = 1,389; healthy controls: n = 1,508). Among 95 SNPs that showed genome-wide significant associations ($P < 5.0 \times 10^{-8}$) by this high-density association mapping, candidate functional SNPs that potentially regulate the gene expression efficiencies were selected by *in silico* analysis based on the Regulome DB database and the UCSC genome browser. Primary functional variants for disease susceptibility were identified by *in vitro* functional analysis (Luciferase assay and EMSA) using the human bile duct cell line HuCCT1 and the human T cell line Jurkat. Additionally, e-QTL data from the GTEX-portal database supported the regulations of expression efficiencies by these functional variants ($P = 3.80 \times 10^{-21}$ in whole-blood, n = 338). These results suggested that high-density association mapping based on SNP imputation analysis and on *in silico / in vitro* functional analysis can identify primary functional variants in disease susceptibility genes. This study illustrated a systematic methodology for identification of primary functional variants from a pool of suggestive SNP associations, and this methodology may eventually contribute to novel diagnostic and therapeutic methods for PBC.

1276W

Prediction of Type 1 diabetes status with high precision, based on GWAS identified SNPs. *J.D. Roizen[1], A.M. Casella[1], J.P. Bradfield[2], H. Hakonarson[3].* 1) Division of Endocrinology and Diabetes, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Quantinuum Research LLC, San Diego, CA, United States; 3) 3Center for Applied Genomics, The Children's Hospital of Philadelphia, Philadelphia, PA, University of Pennsylvania Perelman School of Medicine, Philadelphia, PA, United States.

Type 1 diabetes mellitus (T1DM) is the third most common chronic disease of childhood and the most common autoimmune disease in pediatrics with a prevalence of 1 in 500 children in the United States. Among childhood diseases not due to a single gene mutation, T1DM has a uniquely high proportion of genetically inherited risk. Genome wide association studies have identified 68 variants associated with increased risk for T1DM; approximately 50% of the genetic risk for T1DM is due to high risk HLA alleles (DR3 or DR4 in combination with DQ8). The non-HLA contribution of genetic predisposition towards diabetes has been well defined, however, they have been unused either for risk identification to identify prospective study participants or for risk stratification of study participants. Thus, a critical gap in type 1 diabetes research is that known inheritable contributors to type 1 diabetes have not been used to predict type 1 diabetes genetic risk. We used the currently identified single nucleotide polymorphisms (SNPs) identified as associated with T1DM risk to generate a risk score for individuals in a large T1DM dataset genotyped on Illumina human genotyping arrays (n = 18186; 6490 cases, 11696 controls). We used standard quality control measures for genotyping (minor allele frequency > 0.01, Hardy-Weinberg equilibrium 0.000001, and maximum per-person missing genotyping frequency of 0.05). We imputed HLA genotypes using SNP2HLA for imputation of non-HLA SNPs we used IMPUTE2. We used the approach described by Hu et al., including the use of three critical amino acids in the HLA for the aggregate of HLA risk score. We used the ProbABEL package in R to score all individuals and evaluate a SNP-based risk score. Applying this score on this dataset with the initial five eigenvectors to account for genetic background generated a receiver-operator curve (ROC) with an area under the curve (AUC) of 0.915; a re-regression of the betas for these inputs generates and ROC with an AUC of 0.926. Thus, we report a substantial improvement in our ability to predict T1DM and a milestone in GWAS – moving from identifying alleles to using alleles to highly-accurately stratify risk. The objective of this study has been a long-standing goal of the diabetes research community and is an essential element to intervene with preventive or curative therapy.

Rheumatoid arthritis (RA) and Type 1 diabetes (T1D) are seropositive autoimmune diseases in which destruction of joints (RA) and pancreatic beta-cells (T1D) respectively lead to chronic diseases with disability and decreased life expectancy. Genome-wide association studies (GWAS) have identified 101 loci associated with RA (Okada *et al*, *Nature*, 2014) and 53 loci associated with T1D (Onengut-Gumuscu *et al*, *Nat Genet*, 2015). However, array-based genotyping used in GWAS captures limited sets of variants, potentially missing causal variants. We therefore performed imputation on the 184 non-MHC ImmunoChip loci using the European (EUR) and cosmopolitan (COSMO) populations in 1000 genomes, and the Haplotype Reference Consortium (HRC) as reference. To ensure selection of the best imputation strategy for finemapping, we objectively assessed imputation quality by sequencing 900 1kb regions within 55 ImmunoChip loci in 744 individuals. Out of the 510 variants with minor allele frequency (MAF) > 1%, 72% (EUR), 72% (COSMO), and 50% (HRC) were imputed, of which 76% (EUR), 77% (COSMO) and 78% (HRC) were imputed with high quality (correlation of genotyped vs imputed dosage R^2 > 0.8). Based on these findings, we used the COSMO imputed ImmunoChip data for all 11,475 cases and 15,870 controls for RA, and 12,097 cases and 14,342 controls for T1D. We performed logistic regression on the imputed dosages (MAF > 0.5%, Hardy-Weinberg p > 10^{-5}; INFO > 0.3) and examined 33 RA loci RA and 48 T1D loci associated with disease in our samples (disease association p < 10^{-5}). Performing conditional logistic regression on these loci, we showed that 4 RA loci and 9 T1D loci harbor multiple independent variants (p < 10^{-5}). We then performed Bayesian fine-mapping (Wakefield, *Am J Hum Genet* 2007; Maller *et al*, *Nat Genet,* 2012), created credible sets of variants spanning 90% of the posterior probability, and identified 8 loci for RA and 13 loci for T1D having ≤ 5 variants in their credible set. This method identified a single, putatively causal variant at loci contributing to RA (*REL*) and T1D (*IL2RA*, *PTPN2, SH2B3*). In conclusion, our approach of dense genotyping, high-quality imputation, Bayesian fine-mapping, and logistic regression has pinpointed a set of putative causal variants in 8 loci for RA and 13 loci for T1D. These variants will guide future validation and functional studies. .

Multiple sclerosis (MS) [MIM 126200] is an autoimmune disease with both genetic and environmental risk factors. Recent studies indicate childhood and adolescent obesity double the risk of MS, but this association may reflect unmeasured confounders rather than causal effects of obesity. We utilized separate-sample Mendelian randomization (MR) to estimate the causal effect of body mass index (BMI) on both pediatric and adult onset MS susceptibility. For non-Hispanic white members of Kaiser Permanente, Northern California (1,104 adult MS cases and 10,536 controls) and a replication dataset from Sweden (5,133 MS adult cases and 4,718 controls), a weighted genetic risk score (GRS) was calculated as an instrumental variable using 97 variants previously established to predict BMI (R^2= 2.7%). Models were adjusted for birth year, sex, education, smoking, ancestry, and genetic predictors of MS including *HLA-DRB1*15:01* and 110 non-HLA variants. We also examined this relationship in non-Hispanic white pediatric cases and controls from over 15 sites across the U.S. (total sample size: 394 pediatric MS cases, 10,875 controls). Adjusted MR estimates suggested higher genetically induced BMI predicted greater MS susceptibility in adult KPNC and Swedish datasets (odds ratio [OR] = 1.13, 95% CI 1.04, 1.22 and OR=1.09, 95% CI 1.03, 1.15, respectively). A significant causal association between BMI GRS and pediatric MS was also demonstrated (OR = 1.20, 95% CI 1.06, 1.36; p=0.004) after adjusting for sex, ancestry, *HLA-DRB1*15:01,* and 110 non-HLA MS risk variants. Although the mechanism remains unclear, these findings support a causal effect of increased BMI on both adult and pediatric onset MS and suggest a role for inflammatory pathways that characterize both autoimmune disease and obesity.

1279W

Identifying T1D risk loci with parent-of-origin effects. *S. Onengut-Gumuscu[1,2], W-M. Chen[1,2], E. Farber[1], P. Concannon[3,4], S.S. Rich[1,2], Type 1 Diabetes Genetics Consortium (T1DGC).* 1) Center for Public Health Genomics, University of Virginia, Charlottesville, Virginia, USA; 2) Public health Sciences, University of Virginia, Charlottesville, VA; 3) Department of Pathology, Immunology and Laboratory Medicine, University of Florida, Gainesville, FL; 4) Genetics Institute, University of Florida, Gainesville, FL.

Type 1 diabetes (T1D) is an autoimmune disease that arises from the action of both genetic and environmental factors. T1D is the most common type of diabetes in children affecting up to 1 in 300 individuals. Fathers with T1D are more likely to transmit the disease to their offspring than mothers with T1D. On average, 5-10% of the offspring of affected fathers develop T1D, while only 2-5% of offspring of affected mothers develop T1D. This long-recognized epidemiologic observation suggests that DNA regulatory (epigenetic) factors could play an important role in T1D risk. In addition to parent-of-origin (POO) effects in T1D, these effects have been implicated in bipolar disease, cancer, and type 2 diabetes. To date, there are few large-scale family-based studies of autoimmune disorders that provide the data necessary to determine differential parental transmission of risk alleles. Over 2,000 affected sibpair (ASP) families were collected by the Type 1 Diabetes Genetic Consortium (T1DGC) with ImmunoChip (and other) genotyping data. We performed association analysis of T1DGC ASP families using the parent-of-origin test (TDT-POO) as incorporated in PLINK. These results support POO effects at several T1D loci, including 14q32.2, a well-established T1D risk locus, positioned in an imprinted region of the genome (*MEG3*). The 14q32.2 T1D locus shows paternal POO effects (P_{PAT} = 2.43x10⁻⁵, P_{MAT} = 0.7). The 16p13 locus is highly enriched for transcription factor binding events and has been shown to contain T1D-associated risk variants that regulate gene expression (*CLEC16A/DEXI*). Transmission of alleles from parents to affected offspring exhibit disease association with paternal transmission (P_{PAT} = 8.55x10⁻⁵, P_{MAT} = 0.01). The 20p13 locus (*SIRPG*) exhibits T1D risk associated with maternal transmission (P_{PAT} = 0.6, P_{MAT}= 3.11x10⁻⁶). Further studies examining the SNPs implicated in POO effects and the role of those SNPs on gene regulation and signaling are needed to understand the mechanisms underlying T1D risk.

1280T

Dissecting complex asthma phenotypes by mapping the *IL1RL1* 2q12 region to three genes and two cell types. *S. Ghosh[1], D. Mayhew[1], A. Yeo[2], M. Magid-Slav[1], G. Livi[3], Q. Lu[3], J. Betts[2].* 1) GlaxoSmithKline, King of Prussia, PA; 2) GlaxoSmithKline, Stevenage, Herts, UK; 3) GlaxoSmithKline, Collegeville PA.

Asthma is a heterogeneous disease characterized by recurrent wheezing, which is a manifestation of reversible airways narrowing, commonly to environmental stimulants. Many genes associated with asthma transmit danger signals of airways epithelial damage to the immune system that underpin the pathways for allergic asthma. *IL33*, which helps induce T helper type 2 [Th2] cytokines and its receptor, *IL1RL1* (expressed on mast cells, Th2, Tregs, macrophages), represent such a system. However, non-allergic asthma, about 50% of cases, can be driven by neutrophilic, Th17-dependent pathways that arise when infective agents activate IL1 and IL18 cytokines *via* the inflammasome. In the absence of a large meta-analysis and genetic fine mapping of European asthma samples, we used *in silico* approaches to identify potential effector genes in the strongly associated, noncoding, 2q12 region surrounded by the *IL1RL1, IL18R1* and *IL18RAP* genes. The cis-regulatory elements controlling expression of *IL1RL1*, *IL18R1*, and *IL18RAP* are within two adjacent, asthma-associated, linkage disequilibrium regions using the dataset of FANTOM5. The first associated region had enhancers active in neutrophils (correlating with *IL18RAP* and *IL18RL1* expression) and mast cells (correlating with *IL1RL1* expression). In contrast, the second associated region had an eQTL (rs13015714) for *IL18RAP* as well as asthma-associated SNPs (e.g. intronic rs3771166) that are in perfect LD with *IL1RL1* coding SNPs. We are locating open chromatin in the two asthma regions in stimulated neutrophils and mast cells, respectively, to narrow down to the etiological SNPs. Finally, we will use genetically modified cell lines that secrete any/all of these cytokines. Our aim is replace protective with susceptibility variants and measure real-time expression of each of these cytokines as well as signal transduction of IL1RL1 when coding SNPs are thought etiological. Thus, three genes in two cell types are implicated for the 2q12 association region, explaining the Th2 (mast cell) and Th17 (neutrophilic) phenotypes that are part of the clinical heterogeneity in asthma. Performing a similar dissection in other asthma-associated regions will clarify the degree to which these and other cellular mechanisms contribute to this disease. This will ultimately identify asthma subtypes for precision therapy.

1281F

A pilot study of blastomycosis susceptibility in a high risk population. *M.B. O'Neill, D. Xiong, B.S. Klein, C.S. Pepperell.* University of Wisconsin - Madison, Madison, WI.

Blastomycosis is a rare infection caused by the dimorphic fungus *Blastomyces dermatitidis*. The outcomes of infection with *B. dermatitidis* vary dramatically - many people are unaffected while others develop an invasive fungal infection that can result in respiratory failure, neurological damage and death. During recent blastomycosis outbreaks in Wisconsin, marked disparities in incidence rates were identified between residents of Hmong and European ethnicity (168 vs. 13 per 100,000, respectively). There is no evidence of differential exposure to the fungus nor of differences in co-morbidities that alter susceptibility, which suggests the disparity may have an underlying genetic basis. Hmong populations are expected to have high levels of autozygosity due to historically high rates of within-group marriage (endogamy) and recent population bottlenecks caused by repeated migrations, geographic dispersal, and population losses from military conflict. We hypothesize that individuals of Hmong-ancestry have increased susceptibility to blastomycosis as a result of homozygous variants that affect immune responses to the fungus, which are rare or absent in European-ancestry populations. In a pilot study, we used a disease mapping strategy designed to exploit the predicted high rates of autozygosity in Hmong populations to uncover potential loci mediating variable susceptibility to infection. PLINK was used to identify runs of homozygosity (ROH) in the whole genome sequence of five persons of Hmong-ancestry who developed blastomycosis during an outbreak in Marathon County, Wisconsin. Loci within ROH shared by all infected individuals ('consensus ROH') were annotate and cross-referenced with the 1000 Genomes, Genotype-Tissue Expression (GTEx), and Immune Variation (ImmVar) projects to determine the frequency of each single nucleotide polymorphism (SNP) across human populations, as well as their predicted or demonstrated effects on function. Variants within consensus ROH that were fixed in the five Hmong cases and found at 0-20% in the European superpopulation of the 1000 Genomes Project were inspected further for promise as disease susceptibility loci; SNPs identified as expression QTLs in the GTEx or ImmVar projects, SNPs annotated as regulatory, and/or SNPs with high FUNSEQ scores were deemed candidate disease susceptibility loci.

1282W

Whole genome sequence analysis of asthma in families from Barbados.
N. Rafaels[1], M. Daya[1], M. Boorgula[1], S. Chavan[1], C. Foster[2], P. Maul[3], T. Maul[3], H. Watson[4], I. Ruczinski[5], T.H. Beaty[6], R.A. Mathias[2], K.C. Barnes[1]. 1) University of Colorado Anschutz Medical Campus, Aurora, CO; 2) Johns Hopkins Asthma & Allergy Center, Johns Hopkins University School of Medicine; 3) Genetics and Epidemiology of Asthma in Barbados, The University of the West Indies; 4) School of Clinical Medicine and Research, Queen Elizabeth Hospital, The University of the West Indies; 5) Department of Biostatistics, School of Public Health, Johns Hopkins University; 6) Department of Epidemiology, School of Public Health, Johns Hopkins University.

Asthma is a complex disease with striking disparities between ethnicities, and asthmatics of African descent have more severe asthma, poorer response to therapy, and higher IgE levels compared to asthmatics of European ancestry. Genetics of asthma research has been conducted in the Barbados Asthma Genetics Study (BAGS) for >2 decades focused on a population of African descent. As part of the NHLBI's Trans-Omics for Precision Medicine (TOPMed) Program, high coverage whole genome sequencing (WGS; 39.4 average depth) was performed on samples collected from 190 families (mean pedigree size of 5.7 individuals, ranging from 1 to 56 individuals). Sequencing was 99.5% concordant with samples genotyped on the Illumina OMNI 2.5 array. The average Yoruba (YRI) component in Barbados is 88%. There were 41.9 million (M) variants observed, of which 6.3M (15%) were private. 59.8% (~25.1M) with an minor allele frequency (MAF) ≤1%, 17.2% (~7.2M) with a MAF 1-5%, and only 23.0% (~9.6M) were common (MAF>5%). On average, individuals had 4.3M variants different from reference (NCBI37), of which 1.6M (38.4%) were in genes, and ~24,000 (0.6%) were coding. This data set provides us with the opportunity to investigate the role that structural and rare variants may have in allergic disease and asthma. To illustrate the utility of the data set and to hone in on rare variation associated with disease, we examined one of the largest and well-characterized pedigrees of 31 individuals to determine how private variants may play a role in asthma pathogenesis. Among 226,498 variants private to this family, a novel missense variant predicted to be damaging by both polyphen2 and SIFT in the ADAMTS12 gene, a gene previously associated with asthma in linkage studies, is found in 15 of 31 individuals in this family. We discuss our quality control and analysis pipeline and showcase preliminary results.

1283T

Exploring causal regulatory variation underlying GWAS signals for generalized vitiligo.
G. Andersen[1], Y. Jin[1,2], D. Yorgov[3], T. Ferrara[1], S. Santorico[1,2,3], R. Spritz[1,2]. 1) Human Medical Genetics and Genomics, University of Colorado, Anschutz Medical Campus, Aurora, CO; 2) Department of Pediatrics, University of Colorado School of Medicine, Aurora, Colorado, USA; 3) Mathematical and Statistical Sciences, University of Colorado, Denver, USA.

From meta-analysis of three genome-wide association studies (GWAS) of vitiligo in European-derived whites, we have identified and replicated 48 loci, establishing a pathobiological framework for melanocyte-directed autoimmunity. At 42 (87.5%) of the vitiligo-associated loci, the most significant "lead SNPs" reside in non-coding regions, suggesting that many may alter gene expression. To investigate potential regulatory roles of variants at vitiligo susceptibility loci, we performed conditional logistic regression to identify likely causal variants, studied variant annotation from ENCODE regulatory datasets, applied PrediXcan to assess predicted gene expression differences between vitiligo cases and controls, and assessed co-localization of vitiligo associations and expression quantitative trait loci (eQTLs) with a Bayesian analysis. Specifically, we carried out conditional logistic regression to identify potential causal variation at each vitiligo susceptibility locus, and we annotated the most-associated "lead variants" against ENCODE datasets for multiple immune cell types and melanocytes. These analyses showed that many lead variants reside in DNase hypersensitivity sites and/or chromatin marks that represent active transcriptional enhancers and promoters. We used a Bayesian approach to assess co-localization of the vitiligo association peaks and eQTL peaks in purified blood monocytes, which mediate many aspects of the autoimmune response. This analysis indicated that 8 of the vitiligo associations correspond to *cis*-eQTLs that control expression of specific genes in the vicinity. To assess correspondence of the confirmed vitiligo association signals with differential gene expression in vitiligo cases versus controls, we used PrediXcan to predict expression of 11,553 genes for all 2,853 cases and 37,412 controls in our GWAS meta-analysis cohort. PrediXcan identified 83 genes with significant differential predicted expression in vitiligo cases versus controls following Bonferroni correction. Over 90% of these were located within 1 Mb of a confirmed vitiligo susceptibility locus. Together, our results indicate that for vitiligo as for other complex diseases, there is enrichment of causal variations that alter gene expression. This may bode well for identifying potential therapeutic targets, as pharmacologic modulation of dysregulated biological pathways may prove more tractable than attempting to target proteins impacted by amino acid substitutions.

1284F

First GWAS of inflammatory bowel disease in African Americans identifies *ZNF649* **and** *LSAMP* **as novel, African specific loci, and replicates and defines established inflammatory bowel disease loci for African Americans.** *S.R. Brant[1], D.T. Okou[2], C.L. Simpson[3], D.J. Cutler[2], T. Haritunians[4], J.P. Bradfield[5], P. Chopra[2], J. Prince[2], F. Begum[6], J.H. Cho[7], H. Hakonarson[5], M.E. Zwick[2], D.P.B. McGovern[4], S. Kugathasan[2].* 1) Meyerhoff IBD Center, Johns Hopkins University School of Medicine, Baltimore, MD; 2) Emory University School of Medicine, Atlanta, GA; 3) The University of Tennesse Health Science Center, Memphis, TN; 4) F. Widjaja Foundation Inflammatory Bowel and Immunobiology Research Institute, Cedars-Sinai Medical Center, Los Angeles, CA; 5) Center for Applied Genomics, Abramson Research Center, The Children's Hospital of Philadelphia, Philadelphia, PA; 6) Dept of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 7) Dept of Medicine, Icahn School of Medicine at Mount Sinai, New York, NY.

   INTRODUCTION: The inflammatory bowel diseases (IBD), comprising ulcerative colitis (UC) and Crohn's disease (CD), are chronic gastrointestinal diseases associated with significant morbidity and rising prevalence, particularly in the African American (AA) population. We previously found evidence in AAs, by genotyping IBD cases and controls using the Immunochip platform for 8 of the 200 established European IBD, but none was genome wide significant, and we found no significant evidence for novel loci. We therefore performed this first AA IBD GWAS. METHODS: We genotyped two AA cohorts: 1258 AA IBD cases coordinated by Johns Hopkins and Cedars Sinai IBD Genetic Centers genotyped on Omni2.5 and used dbGAP data from the Health Retirement Study on 1678 AA controls; and 1087 IBD cases coordinated by Emory University IBD Genetics Center genotyped on Affymetrix Axiom Genome-Wide Pan AFR World Array and 3324 previously genotyped Kaiser controls. We imputed 11.4 million common SNPs and performed meta-analysis of the 2 GWASs (2345 IBD, 5002 controls). RESULTS: Genome wide significant (GWS) associations were detected (p<5.0x10⁻⁸) for SNPs at *HLA-DRB1*, *ZNF649* (19q31), and *LSAMP* for UC, and *USP25* for IBD. Furthermore, GWS associations spanning *BTNL2* to *HLA-DQA1* were identified for all IBD, by conditioning on the top UC HLA association. *ZNF649 (*a gene influencing NF-kB and TNFa activation) and *LSAMP* (expressed in colon) represent novel IBD loci. Their associated SNPs are monomorphic in non-African populations, suggesting these loci are African specific. We found strong evidence (p<1.5x10⁻⁶) for SNPs at 8 additional established IBD loci (4 <u>novel</u> for the AA population) proximal or at genes <u>KCNQ2</u> for UC*; NOD2* and *IL23R for CD;* and *PTGER4,* <u>TNC</u>*, IL12B,* <u>CXCR6</u>, and <u>ADCY3</u> for IBD. Several, like *TNC* (p=9.6x10⁻⁸) a gene regulating intestinal barrier function and T-cell activation 200kb from the major Asian CD locus *TNFSF15,* showed unique patterns of association with African-specific alleles. Among 231 SNPs maximally and independently associated at established European loci, 104 showed evidence of replication (p<0.05) in AAs. CONCLUSIONS: The detection of novel IBD loci, African-specific ancestral alleles for both novel and established loci, and unique patterns of association, demonstrates the importance of high-density, gene mapping for IBD in the AA population. It remains vital to expand GWASs to understudied and unique populations to define genetic architecture for complex diseases.

1285W

Identification of three new susceptibility loci for inflammatory bowel disease in Koreans. *H. Oh[1], M. Hong[1], S. Jung[1], S.J. Ahn[1], C.H. Lee[2], E. Kim[2], B.D. Ye[3], S. Park[3], J. Liu[4], D.P.B. McGovern[5], B. Han[2], S.K. Yang[3], K. Song[1].* 1) Biochemistry and Molecular Biology, University of Ulsan College of Medicine, Seoul, South Korea; 2) Convergence Medicine, University of Ulsan College of Medicine & Asan Institute for Life Sciences, Asan Medical Center; 3) Gastroenterology, Asan Medical Center, University of Ulsan College of Medicine; 4) Genome Institute of Singapore, Singapore; 5) The F. Widjaja Foundation Inflammatory Bowel and Immunobiology Research Institute; Cedars-Sinai Medical Center, Los Angeles, USA.

   Recent meta-analysis of the genome-wide association studies (GWAS) identified over 200 IBD associated regions. However, identified common variants account for only a fraction of IBD heritability. Moreover, despite of observed differences in clinical characteristics of IBD among different ethnicities, there have been limited studies in non-European populations. We performed a genome-wide association study on IBD in Koreans. We used 1505 cases (922 CD, 583 UC) and 4041 controls for the discovery stage followed by replication in an additional 1,989 cases (993 CD, 996 UC) and 3,491 controls. We identified three new susceptibility loci for IBD at genome-wide significance: a SNV at 1q21 (odds ratio [OR] = 1.35, 95% CI = 1.22-1.49, combined *P* = 1.96 x 10⁻⁹), a SNV at 22q13 (OR = 1.23, 95% CI = 1.14-1.32, combined *P* = 2.48 x 10⁻⁸), and a SNV at 9p21 (OR = 1.17, 95% CI = 1.11-1.24, combined *P* = 5.45 x 10⁻⁸). In addition, we confirmed significant associations of 28 previously known IBD loci (*P*<2.16 x 10⁻⁴). Together, the loci we identified and replicated accounted for 6.82% and 5.53% of the total disease variance for CD and UC risk in Koreans, respectively. Estimate of the genetic correlation in risk between CD and UC was 0.47 (SE 0.08). Our study provides new biological insight to IBD in East Asians and supports the complementary value of genetic studies in different populations.

1286T

Cross-talks between autism and atopy: Perspectives from shared genetic etiology. *P. Lin, C. Cassidy, S. Berry, T. Mersha.* Pediatrics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH.

   Individuals with autism spectrum disorder (ASD) might have a higher risk of atopic diseases. It has been speculated that immune dysregulation may play a role in the link between ASD and atopy. In this study, we searched for 16 million PubMed abstracts to extract lists of shared risk genes for ASD and three atopy-related diseases (i.e., asthma, COPD, and psoriasis). We have calculated inclusion index (ratio of overlapped genes to the reference list) to evaluate the relative contribution of overlapped genes to the etiologies of ASD. Additionally, we assess whether overlapped genes were over-represented in ASD-related gene networks, Finally, we used Panther web-tool to identify functional ontologies of the overlapped genes. We found more shared networks than expected by chance alone (hypergeometric p-value < 5×10^{-6} for all disease pairs, i.e., ASD-asthma, ASD-COPD, ASD-psoriasis). The inclusion indexes for all three of the "ASD-atopic disease" pairs were 0.25~0.3. Furthermore, the results reveal that the overlapped genes for ASD and asthma were significantly over-represented in the endogenous cannabinoid signaling pathway (fold enrichment = 19.3, p-value = 1.4×10^{-3}). The overlapped genes for ASD and COPD were significantly over-represented in the hopxia response via HIF activation pathway (fold enrichment = 26.8, p-value = 2.7×10^{-3}). The overlapped genes for ASD and psoriasis were significantly over-represented in the endogenous interferon-gamma signaling pathway (fold enrichment = 18.1, p-value = 1.2×10^{-2}). An improved understanding of these shared networks/pathways could provide valuable insights into the causal pleiotropic effects that may contribute to comorbidity between ASD and atopy.

1287F

Whole genome sequencing-based detection of a common African structural variant of the alpha-globin gene cluster and its interaction with sickle cell trait on red cell and kidney phenotypes: The NHLBI TOPMed Project. *A.P. Reiner[1,10], R.E. Handsacker[2,3], S.A. McCarroll[2,3], P.L. Auer[10,11], L.A. Lange[7], G. Lettre[4,5], A. Correa[9], C. Jaquish[12], H. Kang[8], G. Abecaisis[8], C. Laurie[1], J.D. Smith[1], D.A. Nickerson[1], R. Naik[6], J.G. Wilson[9], NHLBI TOPMed Project.* 1) University of Washington, Seattle, WA, 98195, USA; 2) Harvard Medical School, Boston, Massachusetts, USA; 3) Broad Institute of MIT and Harvard, Cambridge, Massachusetts, USA; 4) Université de Montréal, Montréal, QC H3T 1J4, Canada; 5) Montreal Heart Institute, Montréal, QC H1T 1C8, Canada; 6) Johns Hopkins University School of Medicine, Baltimore, MD 21205, USA; 7) University of North Carolina at Chapel Hill, Chapel Hill, NC 27514, USA; 8) University of Michigan, Ann Arbor, MI 48108, USA; 9) University of Mississippi Medical Center, Jackson, MS 39216, USA; 10) Fred Hutchinson Cancer Research Center, Seattle, WA 98109, USA; 11) University of Wisconsin-Milwaukee, Milwaukee, WI 53205, USA; 12) National Heart, Lung, and Blood Institute, NIH, Bethesda, MD.

   Heterozygosity or carrier status for two of the clinically most well-characterized recessive genetic disorders among African ancestral populations, sickle cell *HBB* rs334 (p.V6L) on chromosome 11 (sickle cell trait or SCT) and a common 3.7 kb deletion structural variant (SV) of the alpha-globin gene cluster on chromosome 16p (alpha thalassemia trait), have not been adequately characterized with respect to phenotypic consequence in large studies. Only recently was SCT associated with a 1.5- to 2-fold risk of chronic kidney disease (CKD) among African Americans. Notably, the presence of the alpha-globin 3.7kb deletion lowers the concentration of sickle hemoglobin, and thereby can modify the clinical manifestations of sickle cell disease. Whether the alpha-globin 3.7 kb deletion modifies the risk of CKD among SCT carriers is unknown. We applied the Genome STRiP multi-sample algorithm for simultaneous discovery and genotyping of structural variations to 30x whole genome sequence (WGS) generated in the NHLBI TOPMed project on 3,020 African Americans from the Jackson Heart Study (JHS). We further examined the association of SCT in the presence or absence of the 3.7 kb deletion variant on red cell and CKD phenotypes. Overall, 67% of JHS African Americans had two diploid copies of the SV, 28% were heterozygous, and 4% were homozygous for the 3.7 kb deletion, while 1% carried extra copies (3 or 4). When adjusted for age, sex, and genetic ancestry, carrying one or two copies of the 3.7 kb deletion was strongly associated with anemia and microcytic red cells (mean cell volume or MCV<80 fl) (p<0.00001). SCT was associated with a 1.8-fold increased risk of low MCV (p=0.001), regardless of alpha-globin gene status. By contrast, SCT was associated with 1.5-fold increased risk of anemia only among individuals carrying the normal diploid copy number of the alpha-globin SV (p for interaction <0.05). Similarly, among the 1,800 participants with normal diploid copy number of the alpha globin SV, SCT was associated with 2.4-fold increased risk of CKD (defined as eGFR<60mL/min); but there was no increased risk of CKD associated with SCT (relative risk=1.0) among the 876 individuals carrying at least one copy of the alpha-globin deletion (p for interaction <0.03). If validated in independent samples, the observation that a common alpha-globin deletion reduces the risk of CKD associated with SCT has potentially important implications for public health screening and therapy.

1288W

Recessive coding and regulatory mutations in *FBLIM1* underlie the pathogenesis of Chronic Recurrent Multifocal Osteomyelitis (CRMO). *A. Cox[1], B. Darbro[1], R. Laxer[2], X. Bing[1], A. Finer[1], A. Bassuk[1], P. Ferguson[1].* 1) Pediatrics, University of Iowa, Iowa City, IA; 2) Hospital for Sick Kids, Toronto, ON, Canada.

Chronic recurrent multifocal osteomyelitis (CRMO) is a rare, autoinflammatory bone disease presenting in infancy and childhood. While CRMO is characterized by painful bone lesions, it is often comorbid with psoriasis or Crohn disease and many patients have close relatives with either of the more common disorders. Some syndromic cases of CRMO are caused by truncation mutations in the interleukin-1 receptor agonist (*IL-1RA*) gene and these children respond very well to treatment with recombinant *IL-1RA*. However, most cases of CRMO are non-syndromic with an unknown genetic cause, although many patients respond to TNF-α blocking agents, implicating the pathway in the disease. Via whole-exome sequencing, we determined a rare, coding, homozygous mutation in 25 genes in a child with CRMO from consanguineous parents. Of these genes, *FBLIM1* stood out as it was the most differentially expressed gene in a mouse microarray experiment using the *cmo* mouse model of CRMO. We sequenced *FBLIM1* in 96 CRMO subjects and found a second proband with a novel frameshift mutation in exon 6 and a rare regulatory variant in the third intron. Complementary enhancer and repressor activities of a 1-kb region around the regulatory mutation were validated by luciferase assay in SaOS2 cells and Thp1 macrophages, as was the effect of the mutation on regulatory activity. We conclude that mutations in *FBLIM1* are implicated in CRMO and autoinflammatory disease and our finding suggest that CRMO is a disorder of imbalanced bone remodeling.

1289T

Design of diagnostic algorithm for Primary Immune Deficiencies and validation of NGS panel: From traditional immunophenotyping and polymorphism studies to the next generation sequencing. *A. Bisgin[1], M. Yilmaz[2].* 1) Department of Medical Genetics, Cukurova University Faculty of Medicine, Adana, Turkey; 2) Department of Pediatric Allergy & Immunology, Çukurova University Faculty of Medicine, Adana, Turkey.

Objective: Primary immune deficiency disorders (PIDs) are a group of diseases with profound defects in immune cells. The traditional diagnostics have evolved from clinical evaluation, flow cytometry, western-blotting and Sanger-sequencing focus on small groups of genes. However, this is not sufficient to confirm the suspicion of certain PIDs. Our innovative approach to diagnostics outlines the algorithm for PIDs and the clinical utility of immunophenotyping with a custom-designed gene panel. **Methods:** We have designed a diagnostic algorithm based on polymorphism and flow cytometry studies. Metaanalysis were used to select the genes associated with PIDs and spesific immune phenotypes for NGS panel development. Then, the test panels for severe-combined-immune-deficiency (SCID), common-variable-immune-deficiency (CVID) and chronic-granulomatous-disease (CGD) via next-generation-sequencing by MiSeqSystem (Illumina) were customized. In-silico analysis for mutations was carried out using SIFT, Polyphen2 and Mutation-Taster. Clinical evaluation and primary consideration for testing was done by experienced medical geneticist in immunogenetics. **Results:** NGS identified more than 15000 sequence variants. The causative mutation was identified in 52% of PIDs (78% efficiency on CGD) with 20% of novel mutations detected. In the validation study, NGS and Sanger-sequencing were 100% concordant for the variants across all genes selected from polymorphism studies. Based on these results, this new algorithm including immune phenotyping and NGS for PIDs were started to use for clinical assessments. **Conclusion:** This study provides a thorough validation of diagnositc algorithm and indicates that still the traditional researches can be used to collect significant information related to design of most current diagnostics. The benefits of such testings are for diagnosis, prevention including the prenatal and pre-implantation diagnosis, prognosis, treatment, and research.

Genome-wide association study identifies a sequence variant in *HORMAD2* associated with tonsillectomy. *B. Feenstra[1], P.M. Bager[1], X. Liu[1], H. Hjalgrim[1], E.A. Nohr[2], D.M. Hougaard[3], F. Geller[1], M. Melbye[1,4,5].* 1) Department of Epidemiology Research, Statens Serum Institut, Copenhagen, Denmark; 2) Research Unit of Gynaecology & Obstetrics, Institute of Clinical Research, University of Southern Denmark, Odense, Denmark; 3) Danish Centre for Neonatal Screening, Department of Clinical Biochemistry, Immunology and Genetics, Statens Serum Institut, Copenhagen, Denmark; 4) Department of Clinical Medicine, University of Copenhagen, Copenhagen, Denmark; 5) Department of Medicine, Stanford University School of Medicine, Stanford, California, USA.

Inflammation of the tonsils is a normal response to infection, but some individuals experience recurrent, severe tonsillitis and massive hypertrophy of the tonsils in which case surgical removal of the tonsils may be considered. To identify genetic variants underlying an exaggerated tonsillar immune response, we used tonsillectomy information from Danish health registers and carried out a genome-wide association study comprising 1,464 patients and 12,019 controls of Northwestern European ancestry, with replication in an independent sample set of 1,567 patients and 1,367 controls. The variant rs2412971, intronic in *HORMAD2* at chromosome 22q12, was significantly associated with tonsillectomy (OR = 1.22; P = 1.48 × 10^{-9}) and is highly correlated with SNPs previously found to be associated with IgA nephropathy, Crohn's disease (CD) and early-onset inflammatory bowel disease (IBD). The risk allele for tonsillectomy corresponded to increased risk of IgA nephropathy and decreased risk of CD and IBD. We further performed lookup analyses of the top SNP for outcomes related to tonsillectomy in the combined discovery and replication sample and found that rs2412971 was associated with acute tonsillitis (OR = 1.19; P = 7.82 × 10^{-4}), chronic disease of the tonsils (OR = 1.19; P = 2.32 × 10^{-6}) and appendectomy (OR = 1.18; P = 1.13 × 10^{-3}). Further functional investigation is required to illuminate whether the molecular mechanisms underlying the genetic associations at this locus involve general lymphoid hyper-reaction throughout the mucosal-associated lymphoid tissue (MALT) system.

1291W

A cancer-related mucin 1 splice site variant regulates IgG antibody response against polyomaviruses. *C. Hammer[1,2,3], P. Scepanovic[1,2], T. Waterboer[4], M. Pawlita[4], H. Ehrenreich[3], J. Fellay[1,2].* 1) School of Life Sciences, École Polytechnique Fédérale de Lausanne, Lausanne, Switzerland; 2) Swiss Institute of Bioinformatics, Lausanne, Switzerland; 3) Clinical Neuroscience, Max Planck Institute of Experimental Medicine, Göttingen, Germany; 4) Division of Molecular Diagnostics of Oncogenic Infections, Infections and Cancer Program, German Cancer Research Center, Heidelberg, Germany.

Polyomaviruses have been shown to play a role in human diseases, mainly in immunocompromised individuals. However, several members of this family could not yet be reliably associated with specific pathologies. One way to obtain more insight into possible mechanisms is to identify human genes that play a role in the immune response to infection. The magnitude of the human antibody response to viral antigens is highly variable, and a significant part of this variation is heritable and can be attributed to differences in the host genome. To explore the impact of human genetic variation on humoral immunity against polyomaviruses, we performed genome-wide association studies of immunoglobulin G (IgG) response to KIPyV, WUPyV, HPyV6, and HPyV7, in 2,363 immunocompetent adults. Seroprevalence rates for all viruses were between 64% and 96%. Compatible with previous results for a wide range of viruses, significant associations were found in the HLA class II locus on chromosome 6, implicating different *HLA-DRB1* haplotypes in the regulation of anti-polyomavirus IgG levels. In addition, we discovered a genome-wide significant association signal on chromosome 1, located in the mucin 1 (*MUC1*) gene. The T allele of rs4072037 was found to be strongly associated with increased IgG response to polyomavirus infection (P = 6.6 x 10^{-13}). The same variant has been been implicated before in gastric cancer and *H.pylori* positive gastritis. Using Oxford Nanopore MinION full-length sequencing of *MUC1* short isoforms, amplified from gastric tissue RNA obtained from the Genotype-Tissue Expression Project (GTEx), we confirmed that rs4072037 affected splice site selection in intron 1, and showed that it had no further impact on additional splicing patterns. Functional follow-up analyses investigating the potential link between *MUC1* and polyomaviruses are currently ongoing.

QTL mapping of cytokine responses to LPS in peripheral blood leukocytes (PBLs). *M. Stein[1], C. Hrusch[2], C. Igartua[1], A. Sperling[2], C. Ober[1].* 1) Human Genetics, University of Chicago, Chicago, IL; 2) Department of Medicine, Section of Pulmonary and Critical Care Medicine, and the Committee on Immunology, University of Chicago, Chicago, IL.

Inter-individual variation in gene expression has been extensively studied across tissues, populations, and treatments, but relatively few studies have explored genome-wide variation on protein levels or response to treatments. We undertook this study to identify genetic variants that influence cytokine levels after PBL stimulation with lipopolysaccharide (LPS), a component of the Gram-negative bacterial cell wall, and whose exposure levels are associated with asthma risk. Whole blood samples were collected from 107 South Dakota Hutterites. Cells were incubated with media+LPS in a closed system (TruCulture®, Myriad RBM) for 30 hours. 25 cytokines were measured in the supernatants in duplicate using the Milliplex Th17 Magnetic Bead Panel (EMD Millipore); 17 cytokines had measurements within the range of detection in >70% individuals and were retained for analysis. We performed a genome-wide cytokine QTL study with ~5M variants (MAF>5%) imputed from Hutterite whole genome sequences using a linear mixed model (GEMMA). We included kinship as a random effect to correct for relatedness, and sex and age as fixed effects. Only interleukin 10 (IL-10), IL-12 (p70) and IL-23 responses were associated with SNPs at a Bonferroni-corrected threshold ($P=3.9 \times 10^{-7}$, after pruning for LD). SNPs on chromosomes 3p and 22q were associated with IL-10 response, on chromosome 3q with IL-12 response, and SNPs on chromosomes 4q and 9q were associated with IL-23 response. Notably, an intergenic SNP on chromosome 9 that was associated with IL-23 response (rs4476017, $P=3.5 \times 10^{-7}$) is located in a region with histone marks consistent with enhancer activity in peripheral blood neutrophils and monocytes (Epigenome Roadmap). One other SNP associated with IL-23 response on chromosome 4 (rs75627478, $P=1.76 \times 10^{-7}$) is in an intron of the glycine receptor alpha 3 (*GLRA3*) gene and in LD ($r^2=0.66$ in the Hutterites) with a SNP that is also in an enhancer region in peripheral blood neutrophils and monocytes. These results suggest involvement of regulatory regions in cytokine response to LPS, and identifies potential candidate SNPs for immune-mediated diseases. Funded by R01 HL085197.

Evidence for a heritable response to infection for immunological traits associated with Chagas disease. *N.B. Blackburn[1,2], R. Corrêa-Oliveira[3], V.P. Diego[1], J.M. Peralta[1], J. Blangero[1], J.L. VandeBerg[1], S. Williams-Blangero[1].* 1) South Texas Diabetes and Obesity Institute, University of Texas Rio Grande Valley, Brownsville, TX; 2) Menzies Institute for Medical Research, University of Tasmania, Hobart, Australia; 3) Centro de Pesquisas Rene Rachou, FIOCRUZ, Belo Horizonte, MG, Brazil.

Chagas disease (CD) is a neglected tropical disease caused by infection with *Trypanosoma cruzi*, a parasite transmitted by triatomine bugs. Despite successful vector control programs in areas where *T. cruzi* infection and CD are endemic, CD is still a leading cause of heart disease in Latin America, and WHO estimates that 8-10 million worldwide are infected with *T. cruzi*. Individuals who are seropositive for *T. cruzi* infection display significant variation in progression of CD. Some individuals remain asymptomatic throughout their lives, while others develop cardiac disease or gastrointestinal involvement. Research from our group previously has demonstrated that seropositivity is heritable in a large family cohort from the Posse region of Goiás, Brazil. Chagas disease is endemic to the rural Posse region of Brazil, with approximately 50% of the adult population being seropositivity for *T. cruzi*. Our current work in this cohort involves the assessment of six immunological traits (the cytokines IL-2, IL-4, IL-6, IL-10, TNFα, and IFNγ, measured in serum) and their relationship to seropositivity. The focal population consists of 1417 study participants (50.5% male). 83% of the study participants are part of a seven generation pedigree of 2572 individuals with 65% of the assayed individuals being seropositive for *T. cruzi*. Our hypothesis was that by modelling seropositivity as an 'environment' we would be able to detect genotype-by-environment interactions, indicating a heritable response to *T. cruzi* infection. The pedigree design enabled us to observe the same genotypes in relatives who were and were not seropositive (i.e., in each 'environment'). Analyses were conducted in SOLAR. Cytokine measurements were residualized with age, sex (and their interactions), and seropositivity as covariates, and inverse normalized to prevent non-normal distribution errors. All traits showed significant heritabilities; they ranged from 13% for IFNγ ($P=7.02 \times 10^{-4}$) to 27% for IL-2 ($P=2.5 \times 10^{-12}$), indicating a genetic basis to variation in these traits across the cohort. Further, IL-4 and IFNγ exhibited significant genotype-by-environment interactions. IL-4 displayed evidence of different variances in each environment ($P=0.03$), while different genes influence IFNγ levels in each environment ($P=0.04$). Our findings demonstrate that cytokine response to infection is itself heritable in the Posse Family Study population.

Genome wide association study for identification of genetic suscep-tibility loci for meningeal tuberculosis. *E. Png[1,9], T.T.T. Nguyen[2,3,9], Z. Li[4], K.S. Sim[4], D.B. Nguyen[5], T.T.H. Chau[6], T.H.M Nguyen[6], M. Caws[7], C.C. Khor[4], D. Heemskerk[2,3], G. Thwaites[2,3], M.L. Hibberd[1,9], S.J. Dunstan[8,9].* 1) Infectious Diseases, Genome Institute of Singapore, Singapore, Singapore; 2) Oxford University Clinical Research Unit, Hospital for Tropical Diseases, 764 Vo Van Kiet, District 5, Ho Chi Minh City, Vietnam; 3) Centre for Tropical Medicine, Nuffield Department of Clinical Medicine, Oxford University, OX37LJ, United Kingdom; 4) Human Genetics, Genome Institute of Singapore, Singapore; 5) Pham Ngoc Thach Hospital for Tuberulosis and Lung Disease, District 5, Ho Chi Minh City, Vietnam; 6) Hospital for Tropical Diseases, 764 Vo Van Kiet, District 5, Ho Chi Minh City, Vietnam; 7) Liverpool School of Tropical Medicine, Liverpool, UK; 8) Peter Doherty Institute for Infection and Immunity, The University of Melbourne, Australia, 3010; 9) Joint authors, who equally contributed to this work.

   Tuberculosis (TB) remains a leading cause of infection-associated mortality, with close to 10 million new cases and 2 million deaths annually. Although *Mycobacterium tuberculosis* (MTB) is thought to have infected around a third of the world's population, only 10% of those infected develop active disease during their lifetime. Despite apparently similar exposures to MTB, there are substantial variation in progression to TB disease. Furthermore, while a majority of active TB leads to pulmonary disease (PTB), in a minority of cases, extra-pulmonary TB can develop in other organs, with tuberculous meningitis (TBM) the most severe form, occurring in approximately 1% of all TB cases. Although PTB is largely curable, TBM is known to have poor outcomes and kills or severely disables about half of the people affected. The underlying mechanisms leading to TBM are largely unknown, but their elucidation will aid the development of more effective interventions. Recent genome wide association studies (GWAS) have convincingly shown SNPs associated with PTB, this has encouraged us to conduct GWAS for genes relevant to TBM disease, since TBM and PTB may have distinctive mechanisms. Following imputation from the Illumina Human660W-Quad and Infinium OmniExpress-24 arrays, we obtained genotypes for 4 million SNPs that passed genotype cluster plot inspection or imputation call threshold ≥ 0.9 and quality control filters; for call rate ≥ 95%, minor allele frequency ≥ 5%, Hardy Weinberg Equilibrium (in controls) P ≥ 1 x 10[-7], in 441 TBM and 2000 population controls from Vietnam. We observed minimal genome-wide inflation of the single-SNP association test statistics (λGC= 1.03), and found an excess of 80 significant *P*-values (*P* ≤ 1 x 10[-5]) at the tail end of the distribution, suggesting that at least some of these significant *P*-values could represent true associations. We next plan to replicate these associations by genotyping these variants in an independent sample set from Vietnam as well as other populations.

1295T

Host genetic determinants of HIV-1 broadly neutralizing antibody induc-tion. *C.W. Thorball[1,2], C. Hammer[1,2], P. Rusert[3], R.D. Kouyos[3,4], M. Schanz[3], M. Huber[3], H.F. Günthard[3,4], A. Trkola[3], J. Fellay[1,2], the Swiss HIV Cohort Study.* 1) School of Life Sciences, École Polytechnique Fédérale de Lausanne, Lausanne, Switzerland; 2) Swiss Institute of Bioinformatics, Lausanne, Switzerland; 3) Institute of Medical Virology, University of Zurich, Zurich, Switzerland; 4) Division of Infectious Diseases and Hospital Epidemiology, University Hospital Zurich, Zurich, Switzerland.

   The induction of broadly neutralizing antibodies (bnAbs) is considered essential in the development of an effective vaccine against HIV-1 due to their potent activity against divergent HIV-1 strains. During the course of natural infection, 10-25% of all individuals infected with HIV-1 produce antibodies with limited neutralization breadth, while only 1% of all infected individuals become capable of producing highly potent antibodies with a broad, elite neutralization activity. But why these highly potent bnAbs are only successfully induced in a fraction of HIV-1 infected individuals remains unknown. To identify host genetic variants associated with the ability to produce HIV-1 broadly neutralizing antibodies, we performed whole-exome sequencing (WES) of 63 patients with elite neutralization activity and 273 patients with no or weak cross neutralization activity. Neutralization breadth in patients was identified in a stringent 8-virus panel neutralization screen of 4484 HIV-1 positive plasma samples with matched disease progression in the Swiss HIV Cohort Study (SHCS) and the Zurich Primary HIV Infection Study (ZPHI). Variant calling was performed using GATK (v3.5) following the GATK Best Practices. In order to further improve data quality, the dataset was imputed with PBWT and the Haplotype Reference Consortium reference panel (r1.1). Only variants with INFO score above 0.8 and patients of Caucasian ancestry were retained for further analyses. Variants associated with the ability to produce highly potent bnAbs were identified using the recently developed logistic mixed model association test GM-MAT. Significant genome-wide associations (p < 5x10e-8) were identified for 9 variants, despite the limited power of this study, in *HLA-DRB1* (rs35445101), *PABPC3* (rs11619791, rs9511646), *EPG5* (rs78940552, rs73436059, rs73436053, rs3744999, rs56159632) and *NUP85* (rs193149375). Analysis of GTEx data showed that in whole blood, rs35445101 is an eQTL affecting in particular the other HLA class II genes *HLA-DQA2* (p = 2.8e-53) and *HLA-DRB6* (p = 1.4e-44) indicating that the contribution of the HLA class II locus to the induction of bnAbs might go beyond *HLA-DRB1*. These results, although preliminary, identify multiple host genetic factors influencing the ability of HIV-1 patients to successfully produce highly potent bnAbs.

Introduction Tuberculosis (TB [MIM 607948]) is chronic respiratory infection with high burden to global health. Human leukocyte antigen (HLA) is significantly associated with TB in Icelandic population, where *HLA-DQA*03:01* and *HLA-DRB1*12:02* were associated with TB. *HLA* class I was detected to show significant association with TB caused by specific lineage of the pathogen of TB, *Mycobacterium tuberculosis* (MTB). This study aims to further investigate associations between HLA class I and II alleles imputed from GWAS data with TB in Thais. Overall, 1,554 TB cases and 834 controls were selected and GWAS data was obtained by Illumina Human610-Quad BeadChip (724 cases and 834 controls) and HumanOmniExpress BeadChip (830 cases). From these TB cases, 951 MTB isolates were classified by spoligotyping based on lineages of MTB into Beijing, EAI and non-Beijing non-EAI. Imputation of *HLA-A, -B, -C, -DPB1, -DQA1, -DQB1* and *-DRB1* were conducted by HIBAG. After quality control processes and outliers exclusion based on principal component analysis, 1,792 samples were included for the association analysis. Two cases groups were defined as discovery and replication set, and the controls were utilized as common control. HLA alleles with frequency higher than 5% were subjected to Fisher's exact test and *P*-values (*Pc*) was empirical significant level corrected by Bonferroni correction. Results We could not detect association between HLA class I and TB in this group of samples. However, *HLA-DRB1*14:01* showed significant protective association in discovery set (*Pc*: 1.04E-02 and odds ratio (OR): 0.4 (0.2-0.73) with confirmation in replication set (*Pc*: 1.93E-04 and OR: 0.27(0.12-0.54)) in positivity model. The protective effect is stronger in TB cases with Beijing lineage comparing with TB cases with the other lineages. Disussion This result suggested that HLA class II was more critical than HLA class I associated with TB and consideration for lineage information was important to reveal pathogenesis of TB. HLA class II alleles interacting with lineage based variations might be important in host-pathogen interactions in TB.

1297W

Associations between mitochondrial variants and asthma in a multi-ethnic cohort. *K.M. Magnaye[1], C. Igartua[1], J. Hartiala[2], Z. Chen[2], H. Allayee[2], F.D. Gilliland[2], C. Breton[2], D.L. Nicolae[1,3], C. Ober[1], EVE Consortium.* 1) Human Genetics, University of Chicago, Chicago, IL; 2) Preventive Medicine, University of Southern California, Los Angeles, CA; 3) Medicine and Statistics, University of Chicago, Chicago, IL.

Asthma is a common chronic inflammatory disease of the airways, affecting over 230 million people worldwide. One of the strongest risk factors for childhood onset asthma is maternal asthma. One possible explanation for this maternal risk may be the presence of asthma-associated variation in the maternally-inherited mitochondrial genome. To test this hypothesis, we performed meta-analyses of mitochondrial single variants, as well as with gene- and complex-based analyses, on asthma risk in participants in the EVE Consortium on the Genetics of Asthma, which consists of 3,611 asthmatics and 3,623 non-asthmatic controls of European, African American, Latino and African Caribbean ancestries from 7 studies. Subjects were genotyped using the Illumina Infinium HumanExome BeadChip array, which yielded 160 mitochondrial markers after quality control checks; 41 variants had MAF >1%. To evaluate the effects of individual variants with MAF >1% on asthma risk, we used a linear mixed model (GEMMA), correcting for sex and the first 10 autosomal principal components (PCs) within each study, and combined the effects across studies within each ethnic group in meta-analyses. For the meta-analyses, we required each variant to be present and with a MAF >1% in at least two groups. After adjusting for the number of variants tested, one missense mutation in each of the *ND3* and *ATP6* genes was significant in the Latinos (OR =1.04, p = 3.63x10[-5]; OR = 1.04, p = 8.68x10[-5]) and one missense mutation in the *CYB* gene was significant in the European Americans (OR = 1.04, p = 6.20x10[-4]). We next performed gene-based and complex-based tests of all 160 variants, using SNP-set Kernel Association Test (SKAT), also adjusting for sex and the first 10 autosomal PCs, and combined the results across groups using MetaSKAT. Only the D-loop regulatory region, defined by three variants, was associated with asthma in the African Caribbean sample after correcting for 15 tests (SKAT p = 2.81 x 10[-3]). No mitochondrial complexes were significantly associated with asthma in any of the meta-analyses. Our results suggest that associations with mitochondrial variants and genes are ethnic specific. Moreover, this study did not reveal any large-effect functional mitochondrial variants or genes in the etiology of asthma or support the hypothesis that the risks associated with maternal asthma are due to genetic variation inherited in the mitochondrial genome. Supported by HL101651. .

1298T

An inframe deletion in *NUDT15* is a common cause of thiopurine-induced myelosuppression. *J.W. Harrison[1], G. Heap[1], G. Jones[1], C. Bewshea[1], P. Irving[2], C. Mowat[3], J. Simmons[4], M. Parkes[5], F. Cummings[6], S. Sebastian[7], R. Chaudhry[8], R. Russell[9], C.W. Lees[10], T. Creed[11], R. Fedorak[12], C. Hawkey[13], M.J. Weedon[1], T. Ahmad[1].* 1) RILD Building, University of Exeter Medical School, Exeter, Devon, United Kingdom; 2) Guy's and St Thomas' Hospital; 3) Ninewells Hospital & Medical School, Dundee; 4) Royal Berkshire NHS Foundation Trust; 5) Addenbrookes NHS Foundation Trust; 6) Southampton NHS Foundation Trust; 7) Hull and East Yorkshire Hospitals NHS Trust; 8) Watford General Hospital Trust; 9) Royal Hospital for Sick Children, Glasgow; 10) Western General Hospital, Glasgow; 11) Bristol Royal Infirmary; 12) University of Alberta Edmonton, Alberta; 13) Nottingham Digestive Diseases Centre.

The thiopurines azathioprine and mercaptopurine are common medications used in the treatment of inflammatory bowel disease and other autoimmune disorders. Despite their widespread use 40% of patients fail to tolerate these medications. Previously identified variants in the TPMT gene have been shown to strongly predispose individuals to this serious condition. However, despite widespread adoption of TPMT screening, up to 10% of patients still experience severe myelosuppression necessitating drug withdrawal. Common variants in the *NUDT15* gene have recently been reported to strongly predispose individuals in Asian populations to thiopurine-induced myelosuppression (e.g. Japanese populations: R139C OR = 5.82). The reported variants are, however, rare within European populations (MAF= 0.0046). Here we performed exome sequencing in 290 cases of thiopurine-induced myelosuppression and 767 thiopurine tolerant controls all of Caucasian European-descent to identify novel variants associated with myelosuppression. We performed single variant genome-wide association studies for 843,893 variants and identified a novel 6-base pair inframe deletion in the NUDT15 gene which was present in 14 cases and only 1 control (OR=38.8, P= 1.226×10^{-07}, 5.08-1631.3, 95% confidence interval, MAF=0.014). We confirmed sequence accuracy by Sanger sequencing. These data suggest this novel variant is strongly associated with the development of this potentially life-threatening reaction to thiopurine treatment. In conclusion we have identified a novel variant in *NUDT15*, a gene already shown to be important in the metabolism of thiopurines. This novel variant is strongly associated with the development of thiopurine-induced myelosuppression. *NUDT15* variants are as important as *TPMT* variants in determining whether a patient develops myelosuppression during thiopurine treatment in European populations. The addition of this and other NUDT15 variants to established genetic screening will further improve the personalising of thiopurine treatment and thus increasing its effectiveness in European populations.

1299F

Pharmacogenetics to inform global drug development: Utilizing data from Western countries to predict PK and tolerability in Eastern countries. *L. Parham[1], Z. Xue[1], S. Ford[2], Y. Lou[3], D. Margolis[4], A. Hughes[1], W. Spreen[4], P. Patel[4].* 1) Genomic Medicine, PAREXEL, Durham, NC; 2) Quantitative Clinical Development, PAREXEL, Durham, NC; 3) Biostatistics, PAREXEL, Durham, NC; 4) ViiV Healthcare, Research Triangle Park, NC.

In global drug development, extensive pharmacokinetic (PK) data from early phase studies may be limited to Western countries. The ability to extrapolate what PK profiles might be expected when expanding into other racial populations and ethnicities is of great value. Utilizing available subject data and knowledge of drug metabolism/disposition pathways, along with pharmacogenetics (PGx), can inform expectations of PK effects due to regional genetic differences. Many genes implicated in drug metabolism have known genetic polymorphisms that vary by ancestry which can impact enzyme activity, and may lead to clinically important differences in exposure. UGT1A1 is responsible for the glucuronidation of multiple medicines and known alleles result in decreased UGT1A1 enzyme activity. Carriage of known alleles varies by ancestry group with *28 being common among all populations, *37 common among those with African ancestry, and *6 being commonly observed in East Asians. The impact of reduced UGT1A1 activity varies by medicine. Cabotegravir (CAB) is an integrase strand transfer inhibitor in development for the treatment and prevention of HIV-1 infection and is primarily metabolized by UGT1A1. An analysis was conducted utilizing 347 subjects who received CAB across 4 phase I and 2 phase II clinical studies to evaluate the genetic effects of *UGT1A1* genotypes on oral PK parameters, including C_τ (plasma concentration at end of the dosing interval). The majority of subjects available were of European, or African American/African heritage; less than one percent were self-reported as Asian. Genetically predicted UGT1A1 activity (determined by carriage of *28, *37 and/or *6) was significantly associated with CAB C_τ (p=4.89×10^{-11}). Comparing subjects with a low vs. normal genetically predicted UGT1A1 activity, a 1.5-fold increase in mean C_τ was observed. Increased CAB exposure in carriers of UGT1A1 reduced function polymorphisms is not clinically significant based on the cumulative safety data available and no dose adjustment in these individuals is required. Three subjects carried *6, the reduced function UGT1A1 allele that is commonly observed in Asians. While sample sizes were limited, CAB C_τ values observed for these 3 subjects were within the range of others in the same predicted activity classes due to other functional alleles. This PGx analysis provided useful information to support accelerated clinical development timelines in Eastern countries.

HLA imputation from whole genome sequencing data and association with disease severity and treatment response to Golimumab in rheumatoid arthritis. *K.A. Standish[1,2], C.C. Huang[3], S. Lamberth[3], K.A. Campbell[3], M. Curran[3], N.J. Schork[1,2].* 1) Human Biology, J. Craig Venter Institute, La Jolla, CA; 2) University of California, San Diego; 3) Janssen R&D, LLC, Springhouse, PA.

The highly polymorphic human leukocyte antigen (HLA) region on chromosome 6 encodes the major histocompatibility complex (MHC) proteins. These cell-surface proteins are responsible for antigen presentation to the adaptive immune system and play critical roles in host defense, tissue compatibility, and immune regulation. Polymorphisms in this region have been linked to several autoimmune diseases; for example, the HLA-DRB1 "shared epitope" harbors several polymorphisms strongly associated with susceptibility to rheumatoid arthritis. Using whole-genome sequencing (WGS) data from a cohort of moderate-to-severe RA patients in a phase 3 clinical study, we explored different computational HLA imputation methods and built a robust pipeline to determine HLA type and primary protein sequence with high confidence. We then profiled different HLA-DRB1 haplotypes by classic 4-digit type (e.g. 04:01) as well as individual and combinations of amino-acids at various polymorphic residues (positions 11, 70 - 74). Using traditional response measurements before and after treatment, as well as with a more sophisticated approach employing the use of longitudinal trial design, we recapitulated a previous observation that haplotypes associated with more severe disease states are also associated with greater treatment responses. This trend was observed for the collapsed haplotypes defined by residues 11, 71, and 74, as well as positions 70 to 74 (shared epitope) in HLA-DRB1. However, no significant association was observed between any particular haplotype and disease severity or treatment response. Our approach of using WGS data to assign patients HLA haplotypes at varying levels of resolution and linking them to clinical phenotypes provides added utility to sequencing data in an era when sequencing is increasingly becoming available to general public.

1301T

Genetic risk prediction and subtyping for generalized vitiligo. *S.A. Santorico[1,2,3], S. Paul[1], D. Yorgov[1], Y. Jin[2,4], T. Ferrara[2], R.A. Spritz[2,4].* 1) Mathematical and Statistical Sciences, University of Colorado, Denver, USA; 2) Human Medical Genetics and Genomics Program, University of Colorado School of Medicine, Aurora, Colorado, USA; 3) Department of Biostatistics and Informatics, Colorado School of Public Health, University of Colorado, Aurora, Colorado, USA; 4) Department of Pediatrics, University of Colorado School of Medicine, Aurora, Colorado, USA.

Generalized vitiligo (GV) is an autoimmune disease in which white patches of skin and hair result from destruction of melanocytes. GV patients have ~20% risk of other autoimmune diseases, pointing to shared genetic risk factors and perhaps environmental triggers. In previous work, we discovered and replicated 46 autosomal GV loci via meta-analysis of three genome-wide association studies, with independent replication, consisting of a total of 4,680 vitiligo cases and 39,586 controls of European (EUR) ancestry with genotypes for 8,801,562 variants. Loci mostly encode immune regulators and apoptotic regulators, some of which are also associated with other autoimmune diseases, as well as several melanocyte regulators. Working towards our long-term goal of accurately targeting preventive measures and ensuring the use of the most effective interventions and treatment approaches, we have created a "polygenic risk score" for vitiligo, optimizing the set of variants for inclusion, and compared the predictive ability to a "major loci risk score" based on our 46 replicated autosomal GV loci. The polygenic risk score is built from estimated logistic regression coefficients, after adjustment for ancestry. Variants were included in risk scores for levels of significance, α, in {5×10^{-8}, 0.001, 0.002, ..., 0.009, 0.01, 0.02, ..., 0.09, 0.1} after LD clumping with an index variant P value of 0.1. Performance was assessed by 10-fold cross-validation. Over this range of significance levels, the maximal area under the curve (AUC) of 0.769 occurred at an inclusion α of 0.008; however, this was lower than the AUC for the major loci risk score of 0.776. As a preliminary analysis to explore disease subtypes, recursive partitioning was applied to the 46 replicated autosomal GV loci. Six loci were found to best separate cases and controls into subgroups. These loci included *HLA-A*, *PTPN22*, *CD44*, *GZMB*, *TYR*, and *MC1R*. Additional methods of clustering are being considered and will be compared to the results of recursive partitioning. Long term these will be correlated with vitiligo sub-phenotypes, occurrence/non-occurrence of other autoimmune diseases, age of vitiligo onset, and self-reported treatment histories. Work will be presented through the lens of our long-term goal: optimized prediction of vitiligo risks and subtypes to facilitate clinical application of optimal therapies based on genetic subtyping of disease.

1302F

Novel genetic variants associated with asthma exacerbations in African American youth. *P. Goddard[1], M.J. White[1], O. Risse-Adams[1,2], J. Adams[1], M.G. Conteras[1,3], D. Hu[1], C. Eng[1], A. Davis[4], E. Brigino-Buenaventura[5], M.A. LeNoir[6], M. Seibold[7], N. Thakur[1], J. Galanter[1], S.S. Oh[1], K. Bibbins-Domingo[1], M. Pino-Yanes[8,9], E. Burchard[1,10].* 1) Department of Medicine, University of California, San Francisco, San Francisco, CA; 2) Lowell Science Research Program, Lowell High School, San Francisco, CA, USA; 3) SF BUILD, San Francisco State University, San Francisco, CA, USA; 4) Children's Hospital and Research Center Oakland, Oakland, CA, USA; 5) Department of Allergy and Immunology, Kaiser Permanente Vallejo Medical Center, Vallejo, CA, USA; 6) Bay Area Pediatrics, Oakland, CA, USA; 7) Integrated Center for Genes, Environment, and Health; Department of Pediatrics, National Jewish Health, Denver, Colorado, USA; 8) Research Unit, Hospital Universitario N.S. de Candelaria, Tenerife, Spain; 9) CIBER de Enfermedades Respiratorias, Instituto de Salud Carlos III, Madrid, Spain; 10) Department of Bioengineering and Therapeutic Sciences, University of California, San Francisco, CA, USA.

There are major disparities in asthma prevalence, mortality, and morbidity among racial/ethnic groups in the U.S. African Americans carry a heavier disease burden than their European and Mexican American counterparts. Asthma exacerbations, characterized by oral steroid use, and/or hospital visits, account for a significant portion of the cost and morbidity associated with asthma in the U.S. There have been limited studies exploring the genetic variation underlying susceptibility to asthma exacerbations in minority populations. It is vital that the genetic variation underlying susceptibility to asthma exacerbations in African American youth with asthma be evaluated in order to identify novel treatments and therapeutic interventions for this "at risk" population. The main aim of this study is to identify genetic variants that are associated with asthma exacerbations in a pediatric cohort of African American asthmatics.Our study population consists of asthma cases from the Study of African Americans, Asthma, Genes, and Environments (SAGE II). An asthma exacerbation was defined as the recent occurrence of at least one of the following events: use of oral corticosteroids, a hospital visit or an ER visit for an asthma related ailment. Exacerbation incidence was determined by self-reported responses to a questionnaire. LAT1 Axiom array was used for genotyping. 812 individuals and 519,236 SNPs were analyzed following quality control. Logistic regression analysis was performed to evaluate the association between SNP genotype and asthma exacerbation occurrence with adjustments for body mass index (BMI), age, gender, and global African ancestry.Logistic regression analysis revealed several novel SNPs associated with acute asthma exacerbations in African Americans. Our most significant result was rs67267432, located on chromosome 2 (OR: 1.984, p-value = 7.56×10^{-7}). Of note, another of our suggestive results on chromosome 17, rs4789054 (OR: 1.678, p-value = 1.11×10^{-5}) is located proximal to *DNAI2* (Dynein Intermediate Chain 2) encoding a lung ciliary protein. *DNAI2* is regulated by the interferon viral response system and has been implicated in other respiratory diseases. Our results failed to replicate variants previously associated with asthma exacerbations in populations of European-origin, suggesting that these may be population-specific effects. Further research is underway to evaluate our findings in the context of air pollution exposure and pathway enrichment.

1303W

Eosinophilic esophagitis risk variant at 2p23 dampens IL-13-induced calpain-14 promoter activity in a STAT6-dependent manner. *L. Kottyan[1,2], D. Miller[1], A. Maddox[1,2], A. Lynch[1], J. Lee[1], C. Schroeder[1], M. Brusilovsky[2], M. Weirauch[1,3], M. Rothenberg[2].* 1) Center for Autoimmune Genomics and Etiology, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 2) Division of Allergy and Immunology, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 3) Divisions of Biomedical Informatics and Developmental Biology, Cincinnati Children's Hospital Medical Center, Cincinnati, OH.

Eosinophilic esophagitis (EoE) is a chronic, food-driven, esophageal, inflammatory allergic disease characterized by marked mucosal eosinophil accumulation. We have recently found that, in addition to genetic risk loci for allergic sensitization, EoE susceptibility is linked to a tissue-specific genetic factor(s) at 2p23, encoding the *CAPN14* gene. In our initial studies, we showed that *CAPN14* is dynamically up-regulated as a function of EoE disease activity as well as after exposure of epithelial cells to IL-13, a critical regulator of esophageal inflammation in EoE. Patients with EoE and the 2p23 risk haplotype express decreased *CAPN14.* Furthermore, shRNA-mediated knockdown of *CAPN14* disrupts the regulation of IL-13-mediated esophageal epithelial cell inflammation. Together, these data underscore calpain-14 as a regulator of esophageal inflammation in EoE. This genetic linkage has been replicated at genome-wide significance in multiple cohorts, as well as in a recent independent study, adding credence to the importance of the 2p23 genetic association. In the current study, we performed a replication and fine-mapping study of the 2p23 locus in an additional cohort of subjects with and without EoE. Using this independent cohort, we further replicated this locus (rs76562819 $p_{meta} < 10^{-14}$, Odds Ratio=1.98) and performed fine mapping using Bayesian and frequentist strategies, identifying five genetic variants most likely to be causal for increased EoE risk. We used DNA affinity precipitation analysis and electromobility shift assays to identify proteins that differentially bound specific variants, and confirmed STAT6 binding to the three putative binding sites in the promoter and first intron. Using luciferase reporter assays, we demonstrated that the risk variant of rs76562819 was sufficient to reduce promoter activity of *CAPN14* by 50% in IL-13 treated esophageal epithelial cells - similar to the allelic decrease seen in patient biopsies. Each of the three STAT6 elements were required for the 10-fold increase in IL-13 induced promoter activity and for the 50% reduction in genotype-dependent expression. Our work establishes a candidate molecular mechanism for EoE disease etiology in which the risk variant rs76562819 at 2p23 dampens IL-13-induced calpain-14 promoter activity in a STAT6-dependent manner.

1304T

Association of *STAT4 rs7574865* polymorphism with susceptibility to systemic lupus erythematosus. *V.E. Maso[1], F.B. Barbosa[1], C.E.V. Wiezel[1], M. Simioni[2], F.R. Torres[2], M.C. Molck[2], E.A. Donadi[3], V.L. Gil-da-Silva-Lopes[2], A.L. Simões[1].* 1) Department of Genetics, Ribeirão Preto Medical School, University of São Paulo, Ribeirão Preto, SP, Brazil; 2) Department of Medical Genetics, Faculty of Medical Sciences, University of Campinas, Campinas, SP, Brazil; 3) Division of Clinical Immunology, Department of Medicine, Ribeirão Preto Medical School, University of São Paulo, Ribeirão Preto, SP, Brazil.

   Systemic lupus erythematosus (SLE [MIM: 152700]) is a multisystem autoimmune disease characterized by autoantibody production and immune complex deposition in several tissues. Beyond the immunological factors related to the loss of self-tolerance, genetic factors also strongly contributed to the SLE etiology. Regarding single nucleotide polymorphisms (SNPs) implicated in SLE etiology, the *rs7574865* SNP located in the *STAT4* (MIM: 600558) gene has been observed to have a consistent association with SLE and other autoimmune diseases. Considering that ancestral composition of populations can modify the results of association tests, the study of SNPs in admixed populations can produce different even conflicting results compared with those reported. The aim of this study was to compare allelic frequencies of the *STAT4 rs7574865* G/T polymorphism between SLE Brazilian patients and healthy individuals. A total of 139 unrelated SLE patients and 156 healthy controls were genotyped by TaqMan-based quantitative PCR using the StepOnePlus instrument (Applied Biosystems). SNP allelic/genotypic frequencies and Hardy-Weinberg equilibrium (HWE) were calculated by Plink v. 1.07. Statistical analysis was performed using R v. 3.2.3. No deviation from the HWE were found in patient (p = 0.85) and control (p = 0.81) groups. The *rs7574865* T allele and TT genotype were significantly increased in SLE in comparison to the healthy controls (p = 0.0001, odds ratio [OR] = 2.0, 95% confidence interval [CI] = 1.4—3.0 and p = 0.0051, OR = 3.7, 95% CI = 1.3—11.7, respectively). G allele and GG genotype were found as a protective factor against susceptibility to SLE (p = 0.0001, OR = 0.5, 95% CI = 0.3—0.7 and p = 0.0007, OR = 0.4, 95% CI = 0.3—0.7, respectively). These findings demonstrated that the association of *STAT4 rs7574865* SNP with SLE were effectively replicated in the Brazilian population. Our data highlighted the role of *STAT4* in SLE pathogenesis regardless of the studied population. Support: FAPESP (2013/17062-9, 2011/23794-7), CNPq (312547/2009-9, 304455/2012-1), and FAEPA.

Genetic variants of SMADs affect susceptibility to ulcerative colitis through their alternative expressions in Japanese patients. *S. Taniguchi[1], S. Suzuki[1], T. Inamine[1], A. Yamashita[1], S. Fukuda[1], S. Kondo[1], H. Isomoto[2], K. Tsukamoto[1].* 1) Dept Pharmacotherapeutics, Nagasaki Univ Grad Sch, Nagasaki, Nagasaki, Japan; 2) Division of Medicine and Clinical Science, Department of Multidisciplinary Internal Medicine, Tottori University Faculty of Medicine, Yonago, Japan.

   PURPOSE Inflammatory bowel diseases, comprised of ulcerative colitis (UC) and Crohn's disease, are attributed to inappropriate inflammatory response in the intestinal epithelia of patients. TGF-b/SMAD signals play a key role in differentiation of naive CD4+ T cells to Th17 cells or regulatory T (Treg) cells. In order to identify genetic determinants of UC, we investigated an association between susceptibility to UC and polymorphisms of SMADs in the Japanese population.   METHODS The study subjects consisted of 108 patients with UC and 199 unrelated healthy control subjects. A total of 21 tag single nucleotide polymorphisms (SNPs) in four genes (*SMAD2, SMAD3, SMAD4,* and *SMAD7*), which are involved in the TGF-b/SMAD signaling pathway, was genotyped by PCR-restriction fragment length polymorphism, PCR-direct DNA sequencing, or PCR-high resolution melting curve analysis. The frequencies of alleles and genotypes were compared between UC patients and control subjects by chi-square test or Fisher's exact test in three inheritance models: the allele, the minor allele dominant, and the minor allele recessive models. In addition, in order to investigate whether the risk allele of rs7229678 in *SMAD4* affects its gene expression, the DNA sequence including this SNP site was integrated into pGL3-promoter plasmid and reporter gene assay was performed in Jurkat and Caco-2 cell lines.   RESULTS Five SNPs of *SMAD2*, one SNP of *SMAD3*, two SNPs of *SMAD4*, and one SNP of *SMAD7* showed a close and significant association with susceptibility to UC. Moreover, the reporter gene assay demonstrated that the transcriptional activity of the risk allele of rs7229678 in *SMAD4* was lower than that of the non-risk allele in both Jurkat and Caco-2 cell lines.   CONCLUSION Genetic variants of SMAD signaling molecules in the TGF-b/SMAD pathway may disturb the signal transduction and alter the balance of differentiation to Th17 or Treg cells, thereby leading to dysregulation of immune response and eventually resulting in the development of UC.

1306W

Candidate genes predisposing to primary biliary cirrhosis/cholangitis. *G. Macintyre[1,2], D.A. Bugbee[2], P. Nuin[1], P.M.K. Gordon[4], B. Eksteen[5], E. Carpenter[2], J. Reeve[3], G. Wong[2], A. Mason[2].* 1) Medical Genetics, Faculty of Medicine & Dentistry, University of Alberta, Edmonton, Alberta, Canada; 2) Medicine, Faculty of Medicine & Dentistry, University of Alberta, Edmonton, Alberta, Canada; 3) Laboratory Medicine and Pathology, Faculty of Medicine & Dentistry, University of Alberta, Edmonton, Alberta, Canada; 4) Alberta Children's Hospital Research Institute, Calgary, Alberta, Canada; 5) Department of Medicine, University of Calgary, Calgary, Alberta, Canada.

Primary Biliary Cirrhosis/Cholangitis (PBC) is a rare liver disease (prevalence 1:2,500 to 1:100,000) that is more common in women, particularly in middle-age. However, several cases of females with early age of onset (<22 years) have now been recognized with more severe and progressive disease. PBC is characterized by bile duct destruction and is considered an autoimmune disease as 95% of patients make anti-mitochondrial antibodies (AMA) that are highly specific for diagnosis. Our previous studies indicate that a genetic predisposition and specific beta-retroviral infection may result in PBC. We have performed a whole exome analysis on a single family: affected mother and daughter, healthy father and healthy daughter. Both affected mother and daughter exhibited severe symptoms, the daughter in her teens, and each required a liver transplant. Both mother and daughter have developed recurrent PBC in the allograft and the daughter has required anti-retroviral therapy to prevent progressive disease. A preliminary analysis of variants displaying a dominant mode of inheritance implicates several rare variants including a deletion in the angiomotin gene (*AMOT*) as a possible candidate for PBC. AMOT is important in angiogenesis, hepatic epithelial cell proliferation and migration, and is implicated in viral infection. We also analyzed known GWAS variants from previous studies of rare liver diseases and have identified many that are homozygous and follow a recessive mode of transmission. These include several genes including fucosyltransferase-2 (*FUT2*), and genes encoding toll-like receptors (*TLR2, TLR3*). The candidate genes provide support for the gene-plus-infection hypothesis and implicate possible alterations in key immune pathways in PBC in this family.   .

1307T

Interplay of genetic and environmental factors, N-glycosylation of plasma immunoglobulin G (IgG) and immune traits in autoimmune thyroid diseases (AITD). *T. Martin[1], M. Simurina[2], M. Autoimmune thyroid disease (AITD) is one of the most common autoimmune diseases, affecting about 5% of Europeans, with a heritability of 75%. AITD is caused by abnormal thyroid autoantibodies (e.g. thyroperoxidase antibody: TPOAb) and T cells that damage the thyroid cells. Variation in the levels of immune traits, immunoglobulins (Ig) and glycans in the blood are also strongly heritable and can play key roles in AITD, driven by underlying genetic variation. Our aims were (1) to assess the association of plasma IgG glycome composition and immune cell traits with AITD or TPOAb levels (2) to explore the interaction of IgG glycans with immune traits and (3) to explore the role of genetic and environmental factors on these potential interactions. AITD was assessed clinically. TPOAb was measured using chemiluminescent immunoassays and glycans using hydrophilic interaction chromatography-UPLC. Immunophenotyping was done by flow-cytometry. Genome-wide scans on different omics for AITD status and interaction networks were conducted in the TwinsUK cohort (4,473 twins for 76 IgG glycans, 487 twins for 23,485 immune traits). Glycan findings were replicated in 2 independent cohorts and validated by lectin analysis on a subset (11 Hashimoto's disease samples and 13 healthy donors). We identified 10 glycans significantly associated with AITD in the TwinsUK samples, of which 7 replicated. These observed associations indicated a depletion of core fucose on IgG N-glycans in AITD that was then validated. No significant association between any blood immune trait and AITD could be detected. Tobacco smoking appeared to enhance IgG core afucosylation and to alter the associations of glycans with natural killer (NK) cells and B IgG cells. However, no shared SNPs between these parameters could be found. Our study shows for the first time a depletion of core fucose in the IgG glycome in AITD patients with a potential functionally relevant interaction with NK cells independent of age and sex. IgG core afucosylation in AITD seems unlikely to be directly triggered by common genetic variation. Smoking however appears to enhance the core afucosylation in AITD and modify the associations between IgG glycans and NK cells as well as B IgG cells. Further studies on the glycosylation of TPOAb and thyroglobulin antibodies and their interactions with immune traits and thyroid cells will help elucidate their roles in thyroid disease and to determine their potentials in next-generation therapeutics.

1308F

GWAS of Danish Hirschsprung disease using pathology confirmed cases detects novel associations and makes case/control prediction with high accuracy. *J. Fadista[1], M. Lund[1], F. Geller[1], P. Nandakumar[2], S. Chatterjee[2], L. Carstensen[1], J. Grauholm[3], D. Hougaard[3], A. Chakravarti[2], M. Melbye[1,4,5], B. Feenstra[1].* 1) Dept Epidemiology Research, Statens Serum Institut, Copenhagen, Copenhagen, Denmark; 2) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, Maryland, USA; 3) Danish Centre for Neonatal Screening, Department of Clinical Biochemistry, Immunology and Genetics, Statens Serum Institut, Copenhagen, Denmark; 4) Department of Clinical Medicine, University of Copenhagen, Copenhagen, Denmark; 5) Department of Medicine, Stanford University School of Medicine, Stanford, California, USA.

   Hirschsprung disease (HSCR) is a congenital disorder with a population incidence of ~1/5000 live births, defined by an absence of enteric ganglia along a variable length of the colon. The condition results from failure in the migration, survival, proliferation or differentiation of ENCCs (enteric neural crest-derived cells) in the intestinal tract. Recent HSCR GWAS have found common associated variants at *RET*, *SEMA3* and *NRG1* but they explain only a small proportion of HSCR heritability. We performed a GWAS with 170 cases identified from the National Patient Registry (ICD-8:75139 or ICD-10:Q43.1) and from the Pathology Registry (SNOMED: S62590) and 4,717 controls from other projects, all genotyped on the Illumina HumanOmniExpressExome array. The analysis was based on 6.2 million variants imputed from the Haplotype Reference Consortium panel (info score ≥ 0.9; MAF > 1%), using logistic regression on imputed SNP dosages under an additive genetic model. In addition to known variants at the *RET* and *SEMA3* loci, we found four new loci with variants at genome-wide significance ($P<5\times10^{-8}$) or close to it ($P<1\times10^{-7}$) in our discovery analysis. Doing *in silico* replication in an independent cohort of 189 probands and 484 controls replicated one of these new loci, with the closest RefSeq gene being *PCDH10*, a neuronal receptor that regulates cell migration and is mostly expressed in fetal brain. We show that, in the mouse, *Pcdh10* is also expressed in the gut during gut development. The top SNP at this locus has a risk allele frequency of 25%, with a combined discovery and replication OR=1.67 ($P=7.6\times10^{-9}$) in comparison with OR=5.1 ($P=6.4\times10^{-77}$) for the known RET locus. Using the GCTA method on all genotyped SNPs, we estimated the heritability of HSCR to be 88%, close to classical family-studies-based estimates. Moreover, by using LASSO regression on all variants with $P<0.01$, we were able to assign case/control labels with 94% accuracy using 191 LASSO SNPs. Furthermore, we detected an enrichment of regulatory regions in neural progenitor cells (MAF-matched 10K permutations & Bonferroni corrected for 127 ENCODE/Roadmap tissues). In conclusion, we detected one novel locus associated with HSCR and were able to predict case/control status with high accuracy based on a subset of less than 200 SNPs.

1309W

EHR data illuminates patient subtypes in obstructive lung diseases yielding new insights for genetic discovery. *N. Banerjee[1], C. Van Hout[1], B. Cajes[1], N. Abul-Husn[1], N. Karra[1], H. Kirchner[2], J. Overton[1], J. Reid[1], I. Borecki[1], F. Dewey[1], A. Shuldiner[1], A. Baras[1], O. Gottesman[1], S. Bruse[1], Geisinger-Regeneron DiscovEHR collaboration.* 1) Regeneron Genetics Center, Regeneron Pharmaceuticals, Tarrytown, NY; 2) Geisinger Health System, Danville, NY.

   Asthma and chronic obstructive pulmonary disease (COPD) are heterogeneous diseases that include several shared and distinct clinical and pathophysiological features. The intrinsic heterogeneity and shared features of these diseases complicates their clinical diagnosis and the downstream classification of patients into case-control cohorts for the purposes of genetic discovery. We hypothesized that data-driven classification methods using multiple dimensions of information - diagnosis codes, laboratory tests and other quantitative measures - could generate more granular and more homogeneous classifications of asthma and COPD patients that would be more suited for genetic discovery than using diagnosis codes alone. We focused on 6494 COPD patients and 7997 asthma patients from the Regeneron Genetics Center-Geisinger Health System DiscovEHR collaboration. All patients have exome-sequence data in additional to rich longitudinal electronic health records. Initial assignment to asthma or COPD was defined by ICD-9 codes. EHR-derived phenotypes used for further classification included all ICD-9 codes and quantitative measures such as blood test results and lung function testing. Through principal component analysis, we observed that even though there was substantial overlap between asthma and COPD patients, there were distinct subgroups. To investigate further, we used information gain analysis to identify feature pairs that are important in each disease and utilized an ensemble learning method to classify between COPD and asthma patients. We identified relevant traits such as BMI, monocytes, leukocytes and neutrophils that contributed significantly toward classifying the two groups with an area under the ROC curve of ≥ 0.85. This distinction is independent of the contribution of known classifiers like age and smoking status. In preliminary exome-wide association analyses, utilizing cluster members as cases and non-cluster members as controls, we observed suggestive evidence of association with multiple variants in the NWD1 gene (most significant variant $p=4.23\times10^{-7}$), with a cluster comprised of predominantly COPD-diagnosed patients (n=494). This gene has been previously implicated by a published GWAS of bronchodilator response in COPD patients. Our findings highlight the potential of leveraging a broader landscape of quantitative and binary phenotypes to refine the classification of obstructive airway diseases for the purposes of genetic discovery.

1310T

Whole exome sequencing in atypical hemolytic uremic syndrome patients suggests involvement of cell adhesion and signaling genes.

F. Bu[1,2], M. Lemaire[3], K. Frees[1], N. Ghiringhelli Borsa[1], C. Nishimura[1], C.M. Nester[1,7], R.P. Lifton[4], V. Fremeaux-Bacchi[5,6], R.J.H. Smith[1,7]. 1) Molecular Oto-laryngology and Renal Research Laboratories, University of Iowa, Iowa City, IA, USA; 2) Medical Genetics Center, Southwest Hospital, Chongqing, China; 3) Department of Paediatrics, University of Toronto, Toronto, Ontario, Canada; 4) Department of Genetics, Yale University School of Medicine, New Haven, CT, USA; 5) Laboratoire d'Immunologie Biologique, Hôpital Européen Georges Pompidou, AP-HP, Paris, France; 6) INSERM UMRS 1138, Cordeliers Research Center, Complement and Diseases Team, Paris, France; 7) Rare Renal Disease Clinic, Departments of Pediatrics and Internal Medicine, Carver College of Medicine, University of Iowa, Iowa City, IA, USA.

   Introduction: Atypical hemolytic uremic syndrome (aHUS) is an ultra-rare disease characterized by hemolytic anemia, thrombocytopenia, and renal failure. More than half of aHUS patients carry mutations in complement genes that predispose to uncontrolled activation of the alternative pathway of complement at glomerular endothelial surface. The penetrance of mutations in genes known to be associated with aHUS is extremely variable, ranging from 12.5% to 100%. An underlying genetic association is lacking for the other half of patients. We hypothesize that other genes/pathways contribute to aHUS pathogenesis in patients without molecular diagnosis. **Patients & Methods:** We completed whole-exome sequencing (WES) in 106 aHUS patients negative for complement gene mutations, DGKE and Factor H-autoantibodies. We excluded 13 patients because they failed the relatedness or population stratification tests. In the remaining 93 patients, GATK Variant Quality Score Recalibration (VQSR) was used to filter variants with a 99.5% sensitivity threshold for SNVs and 99.0% for indels. The top 0.5% of exonically variable genes (n=94) and the top 0.2% of variable exons were excluded. Remaining variants were annotated and filtered on the basis of missing genotype rate, minor allele frequency and predicted functional consequence. Gene burden was tested using Sequence Kernel Association Test (SKAT) implemented in Ingenuity Variant Analysis (IVA). Genes with P<0.05 were included in pathway analyses using WebGestalt. The control group is comprised of WES data generated locally from 300 adults without kidney disease. **Results:** In total, WES data from 93 aHUS patients and 300 controls yielded 18,322 ultra-rare/novel variants that passed all filtering steps. Pathway analysis was performed with the 120 genes that had p-values < 0.05 in a gene burden analysis. Of these, 13 genes (P<0.01) are bona fide candidates for functional studies. Significant gene enrichment was observed in cell adhesion and signaling pathways, including E-cadherin and N-cadherin signaling events (Hypergeometric, FDR adjusted p-values of 0.0032 and 0.0076, respectively). **Summary:** These preliminary findings show enrichment for ultra-rare/novel variants in cell adhesion and signaling pathways in this aHUS cohort. These data suggest that a novel pathophysiologic path to aHUS is driven by mutated adhesion proteins expressed at the surface of endothelial cells.

1311F

Rare variants in 5α-reductase-2 and GWAS susceptibility loci are associated with elevated androgen levels in polycystic ovary syndrome.

M. Dapas[1], R. Sisk[1], R.S. Legro[2], M. Urbanek[1], A. Dunaif[1], M.G. Hayes[1,3,4]. 1) Division of Endocrinology, Metabolism and Molecular Medicine, Department of Medicine, Northwestern University Feinberg School of Medicine, Chicago, IL 60611; 2) Department of Obstetrics and Gynecology, Penn State College of Medicine, Hershey, PA 17033; 3) Department of Anthropology, Northwestern University, Evanston, IL 60208; 4) Center for Genetic Medicine, Northwestern University Feinberg School of Medicine, Chicago, IL 60611.

   Polycystic ovary syndrome (PCOS) is a common endocrine disorder affecting ~7% of premenopausal women worldwide. Analogous to other complex diseases, common genetic susceptibility variants for PCOS account for little of the observed heritability. We tested the hypothesis that this deficit in heritability was due to rare genetic variants with larger biological effects. Whole genome sequencing was performed on 64 two-generation families with one or more daughters with PCOS. Variants were filtered according to allele frequency (MAF≤2%), call quality, consistency with Mendelian inheritance, and predicted deleteriousness. Associations between sets of rare variants and PCOS and its quantitative hormonal traits were assessed with burden tests, grouping variants at the gene-level (including 3' UTR and 7.5kb upstream of 5' TSS) and in sliding windows across the genome, accounting for relatedness, and adjusting for age and BMI. After correcting for multiple testing (P_{adj}), significant associations with testosterone (T) levels were found for rare variants in *SRD5A2* ($P=7.16 \times 10^{-7}$, $P_{adj}=0.012$), *CAMK4* ($P=5.98 \times 10^{-8}$, $P_{adj}=0.0074$), and an intergenic region in 9p23 ($P=2.29 \times 10^{-7}$, $P_{adj}=0.035$). Significant associations were also found with dehydroepiandrosterone (DHEAS) levels for rare variants in *PTCH1* ($P=1.11 \times 10^{-7}$, $P_{adj}=0.017$) and *CAMKMT* ($P=1.51 \times 10^{-7}$, $P_{adj}=0.016$). These genes are both in linkage disequilibrium (LD) with the previously identified PCOS risk alleles in or near *C9orf3* and *THADA*, respectively. No significant associations were found with PCOS diagnosis or with fasting insulin, luteinizing hormone, or sex hormone binding globulin levels. *SRD5A2* encodes 5α-Reductase-2, which modulates target tissue androgen action by converting T to its more potent metabolite, dihydrotestosterone. Increases in 5α-Reductase activity have been found in PCOS, and functional *SRD5A2* SNPs have been associated with PCOS. Further, we recently reported increases in global 5α-Reductase activity in infant daughters of affected women, suggesting that these changes play a primary role in disease pathogenesis. The rare variants associated with DHEAS levels in *PTCH1* and *CAMKMT*, which encode Patched-1 and Calmodulin-Lysine N-Methyltransferase, respectively, are in LD with two nearby PCOS GWAS susceptibility loci, suggesting that they are causal variants contributing to signals at these loci. Collectively, our findings suggest that rare variants contribute to elevated androgen levels in PCOS.

1312W

Effects of *NRG1* variants in Hirschsprung patients. *D.R. Gunadi[1], M. Sunardi[2], N.Y.P. Budi[2], A.S. Kalim[2], K. Iskandar[3], A. Makhmudi[1].* 1) Pediatric Surgery Division, Department of Surgery, Faculty of Medicine, Universitas Gadjah Mada/Dr. Sardjito Hospital, Yogyakarta, Indonesia; 2) Molecular Biology Laboratory, Faculty of Medicine, Universitas Gadjah Mada, Yogyakarta, Indonesia; 3) Department of Child Health, Faculty of Medicine, Universitas Gadjah Mada/UGM Hospital, Yogyakarta, Indonesia.

   Purpose: Hirschsprung disease (HSCR) is a neurocristopathy characterized by absence of intramural ganglion cells along variable lengths of the intestines in neonates. The *NRG1* gene, encoding neuregulin 1, is implicated in the development of the enteric nervous system (ENS), and seems to contribute by both common and rare variants. In this study, we analyzed the *NRG1* common and rare variants in Indonesian HSCR patients. **Methods:** We diagnosed a HSCR in our hospital based on the clinical manifestation, contrast enema, and/or histopathology findings. The Hematoxillin & Eosin staining and/or S100 immunohistochemistry were utilized for the histopathology diagnosis of HSCR. Sixty isolated HSCR patients and 124 controls were ascertained for *NRG1* common variant study. The two genetic markers, rs7835688 and rs16879552, within intron 1 of *NRG1* were examined using TaqMan Genotyping Assays in genomic DNA for association studies. To identify a rare variant of *NRG1* in forty HSCR patients, Sanger sequencing method was performed using a BigDye Terminator Cycle Sequencing Kit. **Results:** *NRG1* rs7835688 was associated with HSCR by case–control analysis (OR = 2.0, 95% CI = 1.3-3.3; p = 4.3 × 10^{-3}), whereas rs16879552 demonstrated no association (OR = 1.6, 95% CI = 0.9-2.7; p = 0.097). Further, the transmission disequilibrium tests (TDT) showed that neither of the two *NRG1* common variants was significant, with the transmission rates were at ~62% for both variants. We identified a missense mutation, c.397G>C, in exon 7, which led to a substitution of valine with leucine in the neuregulin 1 (p.V133L). Further, the analysis of *NRG1* coding sequences in this study was not finished yet due to time constraint. **Conclusions:** *NRG1* rs7835688 variant is a common susceptibility factor for HSCR in Indonesia. The *NRG1* rare variant might also have a significant impact in Indonesian HSCR.

1313T

Impact of *Semaphorin 3* variants in patients with Hirschsprung disease. *K. Iskandar[1], N.Y.P. Budi[2], A.S. Kalim[2], M. Sunardi[2], A. Makhmudi[3], . Gunadi[3].* 1) Department of Child Health, Faculty of Medicine, Universitas Gadjah Mada/UGM Hospital, Yogyakarta, Indonesia; 2) Molecular Biology Laboratory, Faculty of Medicine, Universitas Gadjah Mada, Yogyakarta, Indonesia; 3) Pediatric Surgery Division, Department of Surgery, Faculty of Medicine, Universitas Gadjah Mada/Dr. Sardjito Hospital, Yogyakarta, Indonesia.

   Purpose: Recently, common and rare variants within a locus on 7q21.11 containing the *Semaphorin* (*SEMA*) *3A, SEMA3C,* and *SEMA3D* genes were reported to be associated with Hirschsprung disease (HSCR). Here, we investigated three genetic markers, rs1583147, rs12707682, and rs11766001, at this locus and *SEMA3D* rare variants to determine their potential contributions to the susceptibility of Indonesian HSCR patients. **Methods:** Sixty isolated HSCR patients and 118 ethnicity-matched controls were ascertained for *SEMA3* common variant study. The three genetic markers were examined using TaqMan Genotyping Assays in genomic DNA for association studies. To identify a rare variant of *SEMA3D* in forty HSCR patients, Sanger sequencing method was performed using a BigDye Terminator Cycle Sequencing Kit. **Results:** The risk allele frequencies of *SEMA3* rs12707682 (allele C) and rs1583147 (allele T) is higher in cases, 53% and 23%, than in controls, at 42% and 13%, respectively. However, these frequency differences were not statistically significant with p-value of 0.06 and 0.023, respectively. These findings were consistent with transmission disequilibrium test (TDT) results with p-values of 0.041 and 0.11 for rs12707682 and rs1583147, respectively. Furthermore, the frequency of *SEMA3* rs11766001 risk allele in HSCR cases and controls were 1.7% and 0.8%, respectively. We were unable to find any rare variant in the first five exons of the *SEMA3D* gene in Indonesian HSCR patients. **Conclusions:** *SEMA3* rs12707682 and rs1583147 variants are not common risk factors for HSCR in Indonesia. The rarity of the *SEMA3* rs11766001 polymorphism in Indonesian population might be due to a founder effect. Furthermore, the effects of *SEMA3D* rare variant in Indonesian HSCR could not be determined since the sequencing analysis was not completed yet due to time limit. .

1314F

Copy number gains encompassing genes *SLC2A14* and *OR4K1* are significantly associated with spirometric measures of Chronic Obstructive Pulmonary Disease (COPD). *F. Begum[1], L. Jiang[1], I. Ruczinski[2], M. Cho[3], M. Parker[3], J. Crapo[4], E. Silverman[3], T. Beaty[1], COPDGene Investigators.* 1) Department of Epidemiology, Johns Hopkins University, Baltimore, MD; 2) Department of Biostatistics, Johns Hopkins Bloomberg School of Public Health, Maryland, USA; 3) Channing Division of Network Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, Massachusetts, USA; 4) Department of Medicine, National Jewish Health, Denver, USA.

Chronic Obstructive Pulmonary Disease (COPD) is the third leading cause of death in the United States. Besides cigarette smoking, a major environmental factor, it is crucial to understand the genetic underpinning of COPD, as multiple genetic factors have been identified from large-scale genetic studies of COPD. Spirometry is the defining pulmonary function test (PFT) for diagnosing COPD, especially FEV1 (forced expiratory volume in 1s) and the ratio of FEV1 to FVC (forced vital capacity). Previous large genome-wide association studies (GWAS) have identified several genes and pathways associated with quantitative measures of pulmonary function. A genome-wide sequencing study by Govindan et al. (2012) validated structural variants, which may also contribute to lung adenocarcinoma. Begum et al. (2016) reported a hemizygous deletion at 5q35.2 among African Americans (AA) associated with reduced total lung capacity using COPDGene study. In this study we extended our search for association between spirometric measures with both amplification and deletions. We used PennCNV to estimate CNVs on 9,076 cigarette smokers with and without COPD from the COPDGene study exploiting Illumina's Omni-Express genome-wide marker data. Among these 9,076 subjects, 2,889 subjects are AAs and the remainder are Non-Hispanic Whites. In a race-stratified analysis, we tested for association between estimated CNV components (defined as disjoint intervals of copy number regions) and multiple spirometric measures. We observed a large region of polymorphic CNVs (mostly amplifications) spanning the ~71kb region encompassing the *SLC2A14* gene on chromosome 12, and ~19kb region of chr14q11.2 involving the *OR4K1* gene achieved genome-wide significance (p-value=9.38E-06 & p-value=2.33E-05) in tests of association with multiple spirometric measures (FEV1 percent predicted, FVC, pre-bronchodilator FEV1 and FVC, and FEV6) among AAs. The *SLC2A14* gene is a glucose transporter gene involved with cell proliferation and is included in multiple cancer pathways. Moreover, it has been previously reported in the literature that copy number gain in the chr12p13.31 region showed overexpression of 13 novel asbestos-related miRNAs among lung cancer patients. *OR4K1* is an olfactory receptor. We are currently following up on these association signals using data from other studies including the Atherosclerosis Risk in Communities (ARIC) study and the lung carcinoma data from The Cancer Genome Atlas (TCGA). .

1315W

Disease associations of common and rare calcium sensing receptor variants in the 50K DiscovEHR cohort. *G. Breitwieser, R. Metpally, S. Krishnamurthy, D. Smelser, J. Robishaw, D. Carey, Geisinger-Regeneron DiscovEHR collaboration.* Weis Center for Research, Geisinger Clinic, Danville, PA.

Calcium sensing receptor (*CASR*) variants contribute to serum calcium regulation. Unfortunately, our current understanding of the impact of *CASR* genetic variants is restricted to narrowly focused studies on patients having severe calcium perturbations. The overall impact of more modest alterations in serum calcium on disease prevalence is unknown. Our goals in this study were to determine the prevalence of *CASR* common and rare variants in an unselected population, and assess the impact on disease. <u>Methods</u>. We analyzed whole exome sequences from 51,289 individuals in the DiscovEHR cohort who consented to participate in the MyCode Community Health Initiative. Common *CASR* tri-locus haplotypes were tested for association with serum calcium levels. *CASR* haplotype association with disease phenotypes was determined by Phenome-wide Association Study (PheWAS), comparing the haplotype with highest serum calcium with the reference haplotype. Rare coding variants in *CASR* were functionally classified as benign, loss or gain of function using bioinformatics plus serum calcium measures from the electronic health record. Optimized sequence kernel association tests (SKAT-o) were used to detect rare variant disease associations. <u>Results</u>. Of the common tri-locus haplotypes, S986/R990/E1011 was associated with the highest serum calcium. The SRE/SRE haplotype (present in 1.4% of cohort) predisposed to cardio-renal diseases. A total of 2116 individuals (1/24) carried rare (MAF<1%) *CASR* variants. Fourteen rare *CASR* variants (1/2100 individuals) significantly altered serum calcium in the heterozygous state (2 gain of function, 4 strong loss of function and 8 mild loss of function variants). Rare variant tests showed significant association of loss of function variants with cardiovascular diseases, sleep disturbances, epilepsy, and skin and breast cancer phenotypes. <u>Conclusions</u>. Rare and common *CASR* variants influence total serum calcium levels and represent a significant disease risk factor. Supported by funds from GHS and REGN.

1316T

GWAS of thyroid function markers identifies novel loci and highlights connections to metabolic phenotypes and thyroid disease. *A. Teumer[1,2], L. Chaker[3,4], M. Medici[3], A. Köttgen[5], H. Völzke[1,2], R. Peeters[3] on behalf of the CHARGE thyroid function working group.* 1) Institute for Community Medicine, University Medicine Greifswald, Greifswald, Germany; 2) DZHK - German Center for Cardiovascular Research, partner site Greifswald, Greifswald, Germany; 3) Department of Internal Medicine and Rotterdam Thyroid Center, Erasmus Medical Center Rotterdam, Rotterdam, The Netherlands; 4) Department of Epidemiology, Erasmus Medical Center Rotterdam, Rotterdam, The Netherlands; 5) Division of Genetic Epidemiology, Medical Center - University of Freiburg, Germany.

Overt and subclinical thyroid dysfunction are associated with several diseases. Circulating concentrations of the thyroid-stimulating hormone (TSH) and free thyroxin (FT4) have a strong heritable component, but previously identified loci only explain 19% and 10% of their estimated genetic variance, respectively. To find novel loci associated with thyroid function, we performed sex-stratified 1000Genomes imputation-based genome-wide association studies (GWAS) in euthyroid subjects of European-ancestry from 23 population-based cohorts (n=54,288 for TSH and n=49,269 for FT4). Additionally, we conducted GWAS to reveal susceptibility loci for hypo- and hyperthyroidism defined by increased (n=3,340 cases) and decreased (n=1,840 cases) TSH levels, respectively. After the discovery stage, we revealed 24 and 22 novel genome-wide significant loci for TSH and FT4, respectively. The explained genetic variance increased to 33% for TSH and 22% for FT4. All 30 previously associated loci with thyroid hormones were replicated. Among the novel loci associated with TSH were the genes encoding for the TSH receptor and thyroglobulin, and the thyroid hormone degrading enzyme *DIO2* associated with FT4. Although all loci associated with hypo- or hyperthyroidism were also associated with TSH, only some overlapped with both hypo- and hyperthyroidism (*PDE8B, PDE10A, FOXE1, CAPZB*). No significant gene-by-sex interactions were found. Genetic risk scores (GRS) built from the significant loci for TSH and FT4 were associated with goiter and body height. The GRS for TSH was also associated with TPO-antibody positivity, Graves' disease, hypo- and hyperthyroidism, type 2 diabetes, kidney function and schizophrenia, whereas the GRS for FT4 was additionally associated with body mass index. The most significant pathways were related to regulation of phosphate metabolism and body length for the TSH, and to the amount of body fat for the FT4 associated loci. Replication of the new associations among ~17,000 independent samples will be completed soon. The results of this GWAS highlight the close connection of thyroid function to metabolic phenotypes and suggest a relation of thyroid function and schizophrenia. They provide a basis for functional follow-up studies and assessment of the causality of associations between thyroid function and other diseases using Mendelian randomization. Together, this will facilitate an improved understanding of the systemic effects of thyroid hormones.

1317F

SERPINA1 **Z variant heterozygosity increases risk for lung and liver disease in a large clinical care cohort.** *S. Bruse[1], N. Abul-Husn[1], J. Leader[2], H. Kirchner[2], C. Van Hout[1], J. Overton[1], J. Reid[1], A. Baras[1], M. Murray[2], A. Shuldiner[1], F. Dewey[1], O. Gottesman[1], Geisinger-Regeneron DiscovEHR collaboration.* 1) Regeneron Genetics Center, Tarrytown, NY; 2) Geisinger Health System, Danville, PA.

The *SERPINA1* ZZ genotype is the most common cause of alpha-1-antitrypsin (AAT) deficiency, with associated increased risk of chronic obstructive pulmonary disease (COPD) and liver disease. While heterozygosity for the *SERPINA1* Z variant (principally the MZ genotype) is suspected to confer disease risk, this has not been definitively established. We leveraged the rich source of electronic health record (EHR) and exome sequencing data from the Regeneron Genetics Center–Geisinger Health System DiscovEHR collaboration to determine the association of MZ genotype with lung and liver disease in a clinical care cohort. In 49,176 sequenced adults of European ancestry, we examined the association of MZ genotype with EHR-extracted measures of AAT (n=1,360), alanine aminotransferase (ALT; n=40,505), aspartate aminotransferase (AST; n=39,904), alkaline phosphatase (ALP; n=39,533), and spirometry (n=9,126). MZ genotype was also tested for association with alcoholic (n=180) and non-alcoholic (n=3,316) liver disease, asthma (n=7,129), COPD (n=5,858), and COPD-specific diagnoses of emphysema (n=1,422) and chronic bronchitis (n=2,267), as defined by ICD9 diagnosis codes. The common S variant (MS, SS, and SZ genotype carriers; n=3,482) was excluded from these analyses. We identified 1618 MZ genotype carriers in the cohort (3.3%). MZ genotype was associated with a 33% reduction in AAT ($p=1.2 \times 10^{-80}$), and with increased ALT (9.8%; $p=2.0 \times 10^{-19}$), AST (6.3%; $p=2.1 \times 10^{-19}$), and ALP (7.3%; $p=1.1 \times 10^{-21}$) levels. There was no association with spirometry. In case/control analyses, MZ genotype was associated with alcoholic and non-alcoholic liver disease (odds ratio [OR] 2.6, p=0.0006; OR 1.26, p=0.03, respectively), COPD (OR 1.27, p=0.009), and emphysema (OR 1.42, p=0.02). When restricting analyses to COPD (n=1,858) and emphysema (n=668) patients with spirometry-confirmed airway obstruction, MZ remained significantly associated with disease (OR 1.47, p=0.004; OR=1.77, p=0.003 for COPD and emphysema respectively). There was no association with asthma or chronic bronchitis. Thus, in a large clinical care cohort, *SERPINA1* MZ genotype was significantly associated with increased liver enzyme levels, and with increased risk of COPD, emphysema, and liver disease. To our knowledge, this is the first study to clearly demonstrate the association of Z heterozygosity in *SERPINA1* with clinical disease risk, which has important implications given the high population frequency of the Z variant.

1318W

Whole exome sequencing and linkage analysis identified *TTK* as a candidate gene for pulmonary nontuberculous mycobacterial lung disease. *F. Chen[1], E.P. Szymanski[2], K.N. Olivier[3], X. Liu[4], H. Tettelin[4], S.M. Holland[2], P. Duggal[1].* 1) Department of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 2) Laboratory of Clinical Infectious Diseases, NIAID, NIH, Bethesda, MD; 3) Cardiovascular and Pulmonary Branch, NHLBI, NIH, Bethesda, MD; 4) Institute for Genome Sciences, University of Maryland School of Medicine, Baltimore, MD.

   Background: Pulmonary nontuberculous mycobacterial (PNTM) lung disease is caused by nontuberculous mycobacteria (NTM) ubiquitous in the environment, but only a fraction of immunocompetent individuals develop the disease. A distinct group of individuals affected by PNTM are white postmenopausal women, with a tall and lean body habitus and higher rates of scoliosis, pectus excavatum, mitral valve prolapse, and mutations in the *CFTR* gene. These clinical features and the familial clustering of the disease suggest an underlying genetic mechanism. **Methods and Results:** To map the genes associated with PNTM, whole-exome sequencing (WES) was conducted in 10 PNTM families and 57 sporadic cases recruited at the NIH Clinical Center during 2001-2013. Eighty-five percent of PNTM cases in this cohort were women of European ancestry. We carried out a variant-level and a gene-level parametric linkage analysis on nine PNTM families (16 affected and 20 unaffected) under a recessive disease model. We performed multipoint linkage analysis in MERLIN with 4,328 independent (pairwise $r^2 < 0.10$) genome-wide common variants, and identified a 20 cM region on chromosome 6q12-6q16 (HLOD=3.9) with 100% penetrance and a risk allele frequency of 5%. To determine the gene(s) underlying the linkage signal on chromosome 6, all sequenced variants in each gene region were collapsed to construct haplotypes using the collapsed haplotype pattern (CHP) method implemented in SEQLinkage, and genes were then tested as regional markers in a single-point linkage analysis in MERLIN. In this gene-level linkage analysis, the TTK protein kinase (*TTK* [MIM 604092]) gene on chromosome 6q14.1 was found to be most significant (HLOD=3.38). Evidence of suggestive linkage was also found in the same linkage region on chromosome 6 for gene trophoblast glycoprotein (*TPBG* [MIM 190920], HLOD=3.08), origin recognition complex subunit 3 (*ORC3* [MIM 604972], HLOD = 3.10), and ankyrin repeat domain 6 (*ANKRD6* [MIM 610583], HLOD = 3.02). **Conclusion:** *TTK* encodes a protein kinase that is essential for mitotic checkpoints and the DNA damage response. Dysfunction in DNA repair is a common finding in patients with chronic obstructive pulmonary disease (COPD) and tuberculosis (TB). Inhibition of *TTK* expression has been associated with compromised DNA repair and cell survival, which may contribute to the progression from NTM infection to the occurrence of pulmonary disease.

1319T

Identifying modifying genes to explain the variation in severity of fragile X-associated primary ovarian insufficiency. *C.E. Trevino, E.G. Allen, P. Jin, H.R. Johnston, D.J. Cutler, M.E. Zwick, S.T. Warren, S.L. Sherman.* Human Genetics, Emory University, Atlanta, GA.

   Primary ovarian insufficiency (POI) is a condition characterized by symptoms of early menopause and infertility that affects 1% of the general population, making it a leading cause of infertility in women. Patients with this condition also display elevated follicle stimulating hormone, low anti-Müllerian hormone levels and early estrogen deficiency. Women who carry the *FMR1* premutation, a CGG repeat expansion in the range of 55-200 repeats in the 5'UTR of the X-linked *FMR1* gene, are at a significantly increased risk for POI: about 20% of carriers are diagnosed with fragile X-associated POI (FXPOI). Although the risk for FXPOI is significant, not all carriers experience the disorder, and among those who do, the range of severity is broad. We hypothesize that there are other genetic variants, in addition to premutation repeat number, that modify the age of onset and severity of FXPOI. To test this hypothesis, we are currently conducting a whole genome sequencing (WGS) study among women with the premutation, comparing those who had FXPOI diagnosed before age 35 with those who had menopause after age 50. Currently, we have sequence data on 50 in each group and variants from the WGS are being prioritized using a well-established pipeline. From these data, we will take the top candidate genes and screen them using *Drosophila* models as a high-throughput, whole organism functional screen. Models will include the KO of the candidate gene and the KO on a premutation background (90 CGG repeats). The premutation *Drosophila* model has been shown to have reduced fecundity compared with the control flies. Using both models will allow us to determine whether there are modifying effects of the candidate gene specifically with the premutation. We will present results from the WGS and from the *Drosophila* models based on the top 5 candidate genes. The overall goal of this project is to elucidate novel molecular mechanisms for FXPOI to facilitate early risk assessment and diagnosis, allowing more informed choices about family planning and fertility options. In addition, the identified genes may also play a role in idiopathic POI and lead to a new understanding of possible treatment targets.

1320F

Allelic imbalance in regulation of *ANRIL* through chromatin interaction at 9p21 endometriosis risk locus. *H. Nakaoka, A. Gurumurthy, T. Hayano, S. Ahmadloo, W. Omer, C. Hata, T. Kimura, K. Hosomichi, I. Inoue.* Division of Human Genetics, National Institute of Genetics, Mishima, Shizuoka, Japan.

A large number of variants associated with human complex diseases have been discovered by genome-wide association studies (GWASs). These discoveries have been anticipated to be translated into the definitive understanding of disease pathogeneses; however, functional characterization of the disease-associated SNPs remains a formidable challenge. Here we explored regulatory mechanism of a SNP on chromosome 9p21 associated with endometriosis by leveraging "allele-specific" functional genomic approaches. By scrutinizing linkage disequilibrium structure and DNase I hypersensitive sites across the risk locus, we prioritized rs17761446 as a candidate causal variant. Chromosome conformation capture followed by high-throughput sequencing revealed that the protective G allele of rs17761446 exerted stronger chromatin interaction with *ANRIL* promoter. We demonstrated that the protective allele exhibited preferential binding affinities to TCF7L2 and EP300 by bioinformatics and chromatin immunoprecipitation (ChIP) analyses. ChIP assays for histone H3 lysine 27 acetylation and RNA polymerase II reinforced the enhancer activity of the SNP site. The allele specific expression analysis for eutopic endometrial tissues and endometrial carcinoma cell lines showed that rs17761446 was a *cis*-regulatory variant where G allele was associated with increased *ANRIL* expression. Our work illuminates the allelic imbalances in a series of transcriptional regulation from factor binding to gene expression mediated by chromatin interaction underlie the molecular mechanism of 9p21 endometriosis risk locus. Functional genomics on common disease will unlock functional aspect of genotype-phenotype correlations in the post-GWAS stage.

1321W

Genome-wide association study identified new susceptible genetic variants in HLA class I region for hepatitis B virus-related hepatocellular carcinoma. *H. Sawai[1], N. Nishida[1,2], M. Sugiyama[2], S-S. Khor[1], M. Mizokami[2], K. Tokunaga[1].* 1) Department of Human Genetics, The University of Tokyo, Tokyo, Japan; 2) Genome Medical Sciences Project, National Center for Global Health and Medicine, Chiba, Japan.

Recent genome-wide association studies (GWAS) of chronic hepatitis B virus (HBV) carriers with or without hepatocellular carcinoma (HCC) in China reported that SNPs in *KIF1B*, *HLA-DQA1/DRB1*, *GRIK1*, *STAT4* and *HLA-DQ* were associated with HBV-related HCC susceptibility. In this study, we performed a GWAS using 473 Japanese HBV-positive HCC patients and 516 HBV carriers including chronic hepatitis (CH) and asymptomatic carrier (ASC) individuals to identify new host genetic factors associated with HBV-derived HCC in Japanese and other East Asian populations. There were 110 SNPs with P values < 10^{-4} with 65 and four SNPs located within the HLA class I and II regions, respectively. In a subsequent replication analysis, three SNPs in the HLA class I region were genotyped in four independent population-based replication sets (Japanese, Korean, Hong Kong Chinese, and Thai). The meta-analysis with the combined Japanese samples and three other replication sample sets confirmed the association for the SNPs (SNP1: OR = 1.63, P = 6.17×10^{-11}; SNP2: OR = 1.70, P = 4.79×10^{-13}; and SNP3: OR = 1.70, P = 4.61×10^{-9}). We performed two-field HLA genotype imputation for five HLA loci (*HLA-A, B, DRB1, DQB1* and *DPB1*) using GWAS SNP typing data to investigate the association of HLA alleles. A subsequent HLA allele association test revealed that a particular HLA class I allele was significantly associated with disease progression to HCC (OR = 1.97, P = 4.58×10^{-4}). Conditioning analysis of each of the three SNPs on the HLA class I region abolished the association of the HLA allele (P > 0.05). However, conditioning the HLA allele could not eliminate the association of the three SNPs (SNP1: OR = 1.67, P = 6.53×10^{-4}; SNP2: OR = 1.72, P = 2.49×10^{-4}; and SNP3: OR = 1.48, P = 1.02×10^{-2}), suggesting that additional genetic factors may exist in the HLA class I region.

1322T

Developmental genes modify the pathological picture of Biliary Atresia but are not the predominant cause of the disease. *G. Cheng[1], M.M. Garcia-Barceo[1], P.H.Y. Chung[1], E.W.K. Tang[1], J.M.T. So[1], E.K.W. Chan[2], D.N. Ngo[5], N.S. Tran[4], P.A.H. Nguyen[3], S. Cherney[6], P.S. Sham[6], J.M. Nicholls[7], P.K.H. Tam[1].* 1) Surgery, University of Hong Kong, Hong Kong, Hong Kong, Hong Kong; 2) Surgery, The Chinese University of Hong Kong, Hong Kong, Hong Kong, Hong Kong; 3) Hepatology, the National Hospital of Pediatrics, Hanoi, Vietnam; 4) Surgery, the National Hospital of Pediatrics, Hanoi, Vietnam; 5) Genetics, the National Hospital of Pediatrics, Hanoi, Vietnam; 6) Psychiatry, University of Hong Kong, Hong Kong, Hong Kong, Hong Kong; 7) Pathology, University of Hong Kong, Hong Kong, Hong Kong, Hong Kong.

Biliary atresia (BA) is rare but is the most common indication for pediatric liver transplantation (LT) worldwide. The symptoms appear shortly after birth, a few patients have extrahepatic developmental anomalies, and some have ductal plate malformation (DPMs), altogether suggesting that developmental deregulation underlies BA. Yet the developmental theory of BA is still controversial especially with possible disease heterogeneity. We aim to test whether the developmental deregulation causes non-syndromic BA. Liver DNAs of 22 BA patients were screened for mutations in developmental genes by whole exome sequencing and the liver histopathology was analysed. Immunostaining was performed on 4 biopsies taken at the initial Kasai operation (KO) and18 at LT. Biliary proliferation that is typical of BA was reported at KO for the 18 patients, yet at LT, ductopenia occurred in 9 patients, 4 carrying ≥1 damaging mutations in *JAG1-NOTCH2* associated with Alagille disease. The remaining 9 patients showed signs of secondary biliary cirrhosis with profound biliary proliferation at LT with 4 carrying mutations in cystic biliary disease causal genes but no mutations in *JAG1-NOTCH2*. Nonetheless, no DPM was detected in the 22 livers either at Kasai or LT, leaving the effect of the developmental mutations on the pathogenic stage of BA elusive, despite the link with the BA pathological progress after KO. Further, the mutation burden of developmental genes indeed is heavy in the healthy population (N=616). The burden test showed that the IL4R pathway but not developmental gene/pathways are associated with BA (FDR *q*<0.05). We then explored if there was any connection between the developmental genes and the BA-associated genes without disease or biological hypothesis, for which we retrieved 103 genes through a genome-wide gene-based SNP association test (181 cases vs 431 controls). We examined the connectivity between the 103 candidates tagged by SNPs and the developmental genes (N=8, along with 184 genes with CMC *p*<0.05 in Exome screening). The SNP-tagged genes and the mutant genes were connected (*p*=0.031) in the interactome, while both are enriched with proinflammatory pathways. Moreover, their network fits into a core/periphery structure where immunity modules dominate the core and developmental genes fall at the periphery. This suggests that developmental genes may modify the BA manifestation but the occurrence of the disease is predominantly driven by immunity deregulation.

1323F

Characterization of *ELMO1* as a target for kidney disease using genetic and gene expression data. *D.M. Waterworth[1], L. Li[2], J. Yao[3], E. Hu[4], M. O'Donoghue[5], H. White[6], L. Wallentin[7], D. Rajpal[3].* 1) Genetics, GlaxoSmithKline, King of Prussia, PA; 2) Genomic Medicine Group, PAREXEL, Durham, NC; 3) Computational Biology, GlaxoSmithKline, King of Prussia, PA; 4) Heart Failure Discovery Performance unit, GlaxoSmithKline, King of Prussia, PA; 5) TIMI study group, Cardiovascular Division, Brigham and Women's Hospital, Boston, MA; 6) Green Lane Cardiovascular Service, Auckland City Hospital and University of Auckland, Auckland, New Zealand; 7) Department of Medical Sciences, Cardiology & Uppsala Clinical Research Center, Uppsala University, Uppsala, Sweden.

ELMO1 (engulfment and cell motility 1) encodes a member of the engulfment and cell motility protein family. These proteins interact with dedicator of cytokinesis proteins to promote phagocytosis and cell migration. The *ELMO1* gene locus has been associated with diabetic nephropathy in the GoKinD analysis but was not robustly replicated in the Genetics of Nephropathy (GENIE) consortium. Mouse studies have demonstrated that high Elmo1 expression aggravates and low Elmo1 expression prevents diabetic nephropathy. It has been hypothesized that *ELMO1* may have a role in the advanced stages of diabetic nephropathy, perhaps contributing to renal function decline, rather than its initiation. In order to see if we could obtain further evidence on the relationship between *ELMO1* and renal function as well as failure, we investigated CKD status and incident serious renal failure events (n=293) in two large cardiovascular outcome trials (STABILITY and SOLID-TIMI 52, total n=21310). These trials had a high proportion of diabetics (37.8 and 34.6% respectively) and CKD II-IV (73 and 61% respectively). No marked associations with baseline eGFR or CKD criteria were observed after bonferroni correction for the number of variants within the gene, but an association with incident renal events was observed with a low frequency variant rs73689696 (MAF 0.02) OR 2.9 (1.9-4.4), p=7.4e-7. This association was directionally consistent across both trials and each arm of the trial (IP vs placebo) and remained significant after bonferroni correction adjusting for variants analyzed in the gene (p=7.22e-5). Similar to GoKinD, the associated region is at the 3' end of the *ELMO1* gene, but rs73689696 is not in high LD with the reported variants. The renal events in these trials were predominantly acute renal events. Additionally, investigation of multiple human renal gene expression studies suggested that *ELMO1* gene expression is dys-regulated in the glomeruli of hypertensive nephropathy and IgA nephropathy as well as in the tubuli of minimal change disease, which causes nephrotic syndrome. The combined evidence suggests that ELMO1 is a promising target for a range of kidney diseases, but in particular for more advanced diabetic nephropathies and acute renal events in coronary heart disease patients.

1324W

Rare anti-Müllerian hormone (*AMH*) variants with functional impact *in vitro* **identified in women with polycystic ovary syndrome.** *L.K. Gorsic[1], G. Kosova[1], B. Werstein[1], R. Sisk[1], R.S. Legro[4], M.G. Hayes[1,2,3], J.M. Teixeira[5], A. Dunaif[1], M. Urbanek[1,2].* 1) Division of Endocrinology, Metabolism, and Molecular Medicine, Department of Medicine, Northwestern University Feinberg School of Medicine, Chicago, IL; 2) Center for Genetic Medicine, Northwestern University Feinberg School of Medicine, Chicago, IL; 3) Department of Anthropology, Northwestern University, Evanston, IL; 4) Department of Obstetrics and Gynecology, Penn State College of Medicine, Hershey, PA; 5) Department of Obstetrics, Gynecology and Reproductive Biology, College of Human Medicine, Michigan State University, Grand Rapids, MI.

Polycystic ovary syndrome (PCOS) is a common endocrine condition characterized by disordered gonadotropin secretion, increased androgen production and polycystic ovarian morphology (PCO). It is the leading cause of anovulatory infertility. As with other complex traits, common disease-susceptibility variants account for a small percentage of PCOS heritability. We performed whole genome sequencing in 57 PCOS cases and 12 reproductively normal control women to test the hypothesis that rare variants contribute to this deficit in heritability. Implementing a candidate gene approach, we detected likely to be deleterious variants in *AMH*, which encodes anti-Müllerian hormone (AMH), a key regulator of follicular recruitment and development and is secreted by granulosa cells of preantral and small antral follicles. Since circulating AMH levels correlate with antral follicle counts, AMH has been proposed to be a marker for follicle number. PCO is characterized by an increase in ovarian follicles and consistent with this, circulating AMH levels are typically elevated in PCOS. However, AMH also inhibits androgen production in the theca cells of the ovary. Given its biological relevance to PCOS, we performed targeted re-sequencing of the *AMH* gene in an additional 644 PCOS women and 153 reproductively normal women of comparable age. We identified 24 rare (MAF<0.01) variants within *AMH* dispersed across all five exons. All women were heterozygous for the variants. Four variants occurred in PCOS and control women, two variants occurred solely in control women and 18 variants were specific to women with PCOS. Fifteen of the 18 PCOS-specific variants were singletons (found in one subject), while three variants occurred in multiple affected women (V12G in 6; T99S in 2; P352S in 3). One woman with PCOS had two missense variants, R194H and A385V, mapping to the same copy of the gene. Dual luciferase reporter assays assessed the impact of AMH variants on AMH signaling. Seventeen of the 18 PCOS-specific variants showed significantly reduced AMH signaling. No variants observed in control women had impaired signaling activity. In this comprehensive genetic screen of the *AMH* gene, we demonstrate that a subset of women with PCOS have functional *AMH* variants. This study is the first to identify and functionally validate rare genetic variants associated with a common PCOS phenotype and suggests a previously unrecognized mechanism for AMH's role in PCOS: decreased AMH bioactivity.

1325T

Treatment of hepatitis C with interferon may lead to reduced risk of liver fibrosis via downregulation of *MERTK* by allele-specific binding of IRF1. *C. Wadelius, G. Pan, H. Nord, E. Wallen Arzt, M. Cavalli.* Immunology, Genetics and Pathology, Uppsala University, Uppsala, Sweden.

Background: Hepatitis C virus infection can result in the development of liver fibrosis and may eventually progress into cirrhosis and hepatocellular carcinoma. Genome-wide association studies of reduced risk of fibrosis have shown association to rs4374383 and 72 SNPs in high LD but the functional variant has not been detected. **Methods and results:** We utilized a bioinformatics approach to identify a non-coding regulatory variant, rs6726639, with genome-wide significant differential transcription factor binding between the alleles which could likely be the driver of the association, as it is in high LD with rs4374383. ChIP-seq showed significantly more reads to the A than the C allele consistent with a stronger band for the A allele in electrophoresis mobility shift assay (EMSA). In luciferase assays the A allele showed significantly lower signal indicating that a repressor may bind. The A allele of rs4374383 is on the same haplotype as the A allele of rs6726639 and is associated to reduced risk of liver fibrosis. Interferon alpha (INFA) is used to treat hepatitis C to prevent fibrosis and it up-regulates interferon regulatory factor 1 (*IRF1*). Motif analysis showed that binding sites for the IRF family overlaps rs6726639 and that this variant could disrupt the binding of IRF1. EMSA supershift experiments with an antibody against IRF1 showed decreased binding at this site. **Conclusions:** Treatment of hepatitis C with INFA results in increased IRF1 levels and our data suggest that this leads to an allele-specific down-regulation of *MERTK* mediated by allelic down-regulation of the regulatory element containing the functional rs6726639. This variant also shows the hallmarks for being the driver of the GWAS for reduced risk of liver fibrosis at *MERTK*.

1326F

Association of polymorphisms Glu298Asp and 4b/a of *eNOS* gene with renal function parameters in Mexican patients with Fabry disease. *A. Marín-Medina[1,2], J.J. Gómez-Ramos[3], G. Rodríguez-Pinto[1], L.E. Figuera-Villanueva[1,2].* 1) Genetica , Centro de Investigación Biomedica de Occidente (CIBO) IMSS , Guadalajara , Jalisco, Mexico; 2) Doctorado en Genetica Humana-CUCS Universidad de Guadalajara; 3) Departamento de Urgencias, HGZ 89 IMSS Guadalajara, Jalisco,México.

Fabry disease (FD) is an X-linked inherited lysosomal disease that courses with renal failure in an important percentage of the affected individuals. On the other hand, *eNOS* gene encodes to the endothelial nitric oxide synthase that plays an important role in glomerular hemodynamics. This gene has 2 main polymorphisms (Glu298Asp and the 4b/a) that have been studied in many diseases including those with cardiovascular and renal alterations. Considering the lack of information, we investigated if there was association of these genetic variants with renal function parameters in Mexican patients with FD and renal impairment. We included 15 patients with FD and renal alterations and associated these *eNOS* polymorphisms with the renal function parameters (urea, creatinine and glomerular filtration rate or GFR) taken from the clinical records at the first visit to the nephrology service. The alleles Asp298 and 4a of *eNOS* gene were significantly associated with increased levels of urea, creatinine and decreased GFR in the patients included that behaved in a co-dominant fashion. Our results coincide with other reports showing an association of these polymorphisms with kidney disease and others involved in the the nitric oxide pathway and suggest that these variants affect the severity of nephropathy in patients with FD.

Whole genome sequencing in severe chronic obstructive pulmonary disease. *M.H. Cho[1], D. Prokopenko[3], H. Fier[3], D. Qiao[1], C. Lange[4], T.H. Beaty[2], J.D. Crapo[5], E.K. Silverman[1], COPDGene Investigators, NHLBI TOPMed Investigators.* 1) BWH, Boston, MA; 2) Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 3) University of Bonn, Bonn; 4) Harvard School of Public Health, Boston, MA; 5) National Jewish Health, Denver, CO.

Background: Genome-wide association studies have identified common variants associated with chronic obstructive pulmonary disease (COPD). Rare variants can also increase COPD susceptibility. Whole-genome sequencing (WGS) offers several advantages over exome sequencing, including improvements in calling of coding regions and interrogation of impactful variants in non-coding regions. We hypothesize that WGS in subjects with severe COPD and smoking controls with preserved pulmonary function will allow us to identify novel genetic determinants for COPD. Methods: As part of the NHLBI Trans☐Omics for Precision Medicine (TOPMed) program, we submitted DNA samples for sequencing from 600 severely affected white and 330 African-American COPD cases with a mean forced expiratory volume in 1 second (FEV_1) of 32% and 35% predicted, respectively. Current and ex-smoker controls (500 white and 570 AA) had FEV_1 > 85%. Samples were sequenced at > 30x coverage using PCR-free libraries, with centralized mapping and variant calling by the University of Michigan Informatics Research Core. We adjusted for population substructure using the Jaccard method and grouped variants using a region-based approach. We performed preliminary single-variant and gene-based analysis both genome-wide and in candidate regions. Results: We performed an initial analysis in 689 subjects. In this small sample size, we identified 15q25 ($p = 9 \times 10^{-6}$) in whites and *THSD4* ($p = 2 \times 10^{-5}$) in African-Americans among the top SNPs in genome-wide single variant analyses. In a region-based assessment, top results included the 15q25 region ($p = 4 \times 10^{-7}$). Conclusions: Whole-genome sequencing can identify large numbers of potentially functional and deleterious variants, and will serve as an important resource for identifying causal variants at known and novel loci for COPD. Future plans include association tests in the larger sample for affection status and for secondary phenotypes including imaging and transcriptomics data. Funding: This work was supported by NHLBI R01 HL084323, P01 HL083069, P01 HL105339 and R01 HL089856 (E.K.S.); R01 HL113264 (M.H.C. and E.K.S.), and R01 HL089897 (J.D.C.). The COPDGene study (NCT00608764) is also supported by the COPD Foundation through contributions made to an Industry Advisory Board comprised of AstraZeneca, Boehringer Ingelheim, Novartis, Pfizer, GlaxoSmithKline, Siemens and Sunovion.

Background: Chronic obstructive pulmonary disease (COPD) is the third leading cause of death worldwide. Surfactant protein D (SPD) is lung-specific protein that is involved in the innate immune response and clearance of pathogens. SPD can be detected in peripheral blood and serum/plasma concentrations have been shown to negatively correlate with lung function and health status in COPD. We hypothesized that SPD serum protein and lung mRNA levels are under genetic control in COPD subjects. **Methods**: The Lung Health Study (LHS) is a longitudinal multicenter study of mild-to-moderate COPD subjects, who were followed over 11 years. In year 5, SPD serum levels were measured in 4,061 individuals who also had whole genome genotypes. A genome-wide association study (GWAS) for SPD levels was undertaken using 1000 genome imputed genotypes, assuming an additive genetic model, and adjusting for age, sex, BMI, and genetic principal components. The SPD-associated single nucleotide polymorphisms (SNPs) were tested for lung expression quantitative trait loci (eQTLs) in the lung eQTL study (n=1,111) and additionally tested for association with lung function in LHS subjects and in a number of large publically available lung function GWAS data sets including the UKBiLEVE study (n=15,000) and the SpiroMeta consortium (n=38,000). **Results**: There were 4 loci associated with SPD levels. The strongest association was on chr10 near the SPD encoding gene *SFTPD* (P=1.1E-81) and SNPs in this locus were lung eQTLs for *SFTPD* and interestingly for two additional genes; annexin A11 (*ANXA11*) and tetraspanin 14 (*TSPAN14*). The second SPD locus included the major histocompatibility complex region on chr6 (P=9.33E-55). The third included SNPs spanning the ATPase secretory pathway Ca2+ transporting 2 (*ATP2C2*) gene region on chr16 (P= 1.52E-16) and were also lung eQTLs for *ATP2C2*. The fourth locus included SNPs which reside in, and are lung eQTLs for the complement component 4 binding protein alpha (*C4BPA*) gene on chr1 (P= 3.75E-09). The sentinel SNPs on chr 1, 6, and 10 loci showed association (P<0.05) with lung function in LHS and in publically available lung function GWAS data from the UKBiLEVE study and the SpiroMeta consortium. **Conclusion**: Integrating genome-wide protein and mRNA genetic determinants of SPD and lung function phenotypes provided significant insights into SPD biology and supported the role of SPD in the pathogenesis of COPD. SPD represents a promising biomarker for COPD.

1329F

Novel genetic variants for cartilage thickness and hip osteoarthritis.

Osteoarthritis is one of the most frequent and disabling diseases of the elderly. Only few genetic variants have been identified for osteoarthritis, which is partly due to large phenotype heterogeneity. To reduce heterogeneity, we here examined cartilage thickness, one of the structural components of joint health. We conducted a genome-wide association study of minimal joint space width (mJSW), a proxy for cartilage thickness, in a discovery set of 13,013 participants from five different cohorts and replication in 8,227 individuals from seven independent cohorts. We identified five genome-wide significant (GWS, P≤5·0×10⁻⁸) SNPs annotated to four distinct loci. In addition, we found two additional loci that were significantly replicated, but results of combined meta-analysis fell just below the genome wide significance threshold. The four novel associated genetic loci were located in/near *TGFA* (rs2862851), *PIK3R1* (rs10471753), *SLBP/FGFR3* (rs2236995), and *TREH/DDX6* (rs496547), while the other two (*DOT1L* and *SUPT3H/RUNX2*) were previously identified. A systematic prioritization for underlying causal genes was performed using diverse lines of evidence. Exome sequencing data (n=2,050 individuals) indicated that there were no rare exonic variants that could explain the identified associations. In addition, *TGFA, FGFR3* and *PIK3R1* were differentially expressed in OA cartilage lesions versus non-lesioned cartilage in the same individuals. In conclusion, we identified four novel loci (*TGFA, PIK3R1, FGFR3 and TREH*) and confirmed two loci known to be associated with cartilage thickness. The identified associations were not caused by rare exonic variants. This is the first report linking *TGFA* to human OA, which may serve as a new target for future therapies.

1330W

Mutation of the planar cell polarity gene *VANGL1* **in adolescent idiopathic scoliosis.** *L.A. Larsen[1], M.R. Andersen[1], M. Farooq[1], K. Koefoed[1], K.W. Kjaer[1], A. Simony[2], S.T. Christensen[3].* 1) Department of Cellular and Molecular Medicine, University of Copenhagen, Copenhagen, Denmark; 2) Center for Spine Surgery & Research Middelfart, Region of Southern Denmark, Denmark; 3) Department of Biology, University of Copenhagen, Denmark.

Adolescent idiopathic scoliosis (AIS) is a spinal deformity which occurs in 1-3% of the population. The cause of AIS is often unknown, but genetic factors are important in the etiology. We performed mutation screening in 157 unrelated patients with moderate to severe AIS and identified two rare missense mutations in *VANGL1*, encoding a receptor involved in WNT/planar cell polarity (PCP) signaling. The mutations, p.I136N and p.F440V, are predicted to be damaging and to affect evolutionary conserved amino acid residues of VANGL1. Functional analysis in Madin-Darby Canine Kidney cells showed that both mutations abolish the normal translocation of VANGL1 to the cell membrane. Our data suggest a possible involvement of *VANGL1* in the aetiology of AIS and further analysis of the role of WNT/PCP signalling in AIS is warranted.

1331T

The rare mutations of *MYH3* **gene is an important etiology of congenital scoliosis.** *W. Chen[1,2], Y. Zuo[2], J. Liu[3], Z. Liu[2], S. Liu[2], G. Qiu[2,4], N. Wu[2,4,5], Z. Wu[1,4,6].* 1) Chinese Academy of Medical Sciences and Peking Union Medical College, Beijing, Beijing, China; 2) Department of Orthopaedic Surgery, Peking Union Medical College Hospital, Peking Union Medical College and Chinese Academy of Medical Sciences, Beijing 100730, China; 3) Breast Surgical Oncology, Cancer Hospital of Chinese Academy of Medical Sciences, Beijing 100021, China; 4) Beijing Key Laboratory for Genetic Research of Skeletal; 5) Medical Research Center of Orthopaedics, Chinese Academy of Medical Sciences, Beijing China; 6) Department of Central Laboratory, Peking Union Medical College Hospital, Peking Union Medical College and Chinese Academy of Medical Sciences, Beijing 100730, China.

Introduction: Congenital scoliosis (CS) is a rare and severe congenital disease with an estimated prevalence of 0.5 to 1 in 1000 live births. It is defined as a lateral curvature of the spine exceeding 10 degrees caused by congenital vertebral malformation (CVM). Etiology of CS is very complex. Previously, we have elucidated the genetic basis of a significant portion of sporadic CS by a model of compound inheritance (Wu, et al 2015 NEJM 372: 341-350). *MYH3* encodes muscle embryonic myosin heavy chain, which is associated with Distal Arthrogryposis (DA) type 2A, type 2B and type 8. In DA type 8, *MYH3* mutations were reported to be associated with vertebral fusion. In this study, we report that the mutations of *MYH3* gene may contribute to the genetic etiology for CS. **Methods:** We enrolled patients diagnosed as CS in Peking Union Medical College Hospital (PUMCH) between October 2010 and November 2015. The CS diagnosis were confirmed by radiological imaging. The patients with known syndromes were excluded. We performed whole exome sequencing (WES) in 6 trios with additional 316 patients target sequenced by an in silicon designed target panel. **Results:** We identified one de novo *MYH3* mutation (c.841G>A,p.E281K) in one patient by WES. This variant did not exist in ExAC, 1000 Genome and ESP6500 database. The prediction of Polyphen2 and SIFT were probably damaging or deleterious,respectively (the Polyphen2 score is 1, the SIFT score is 0,the GERP score is 5.11 and the CADD score is 26). Notably, the patient presents as CS, unsegmentation in Thoracic vertebrae and distal arthrogryposis. Furthermore, we identified 6 patients with *MYH3* missense mutations (c.265G>A,p.E89K; c.1400A>C,p.E467A; c.1802C>T,p.P601L; c.3449G>A,p.R1150Q; c.3526C>T,p.R1176C; c.5134G>A,p.E1712K) in 316 patients highly conserved domain (6/316, 1.9%). **Conclusion**: Up to our knowledge, our findings indicated that *MYH3* might affect vertebral development. Our data showed that about 2% CS patients carried highly pathogenic *MYH3* mutations,firstly indicating *MYH3* might be another important gene causing CS.

1332F

RNA expression elucidates roles of osteoporosis candidate genes in skeletal fragility. *E. Quillen[1], T.L. Bredbenner[2], J.P. Glenn[1], V. Mattern[1], A.E. Nichols[2], D.E. Moravits[2], L.M. Havill[3], L.A. Cox[1], D.P. Nicolella[2].* 1) Department of Genetics, Texas Biomedical Research Institute, San Antonio, TX; 2) Musculoskeletal Biomechanics, Southwest Research Institute, San Antonio, TX; 3) Southwest National Primate Research Center, San Antonio, TX.

Skeletal fragility is a major risk factor for osteoporotic fracture but is incompletely indexed by the most common clinical indicator, bone mineral density. The structural integrity of bone is a complex phenotype with many contributing genetic, environmental, and lifestyle factors. Using the baboon as a naturally occurring model of osteoporosis (OP), we identify 31 differentially expressed transcripts associated with bone fragility traits and biomarkers in 100 adult animals (50 female) with a wide age range. No animals were sacrificed for this study; all died naturally or were euthanized for other reasons. Both femurs were scanned by microCT, digitally reconstructed, and total variation reduced into a statistical shape model (SSM). Fracture strength was determined in a non-habitual loading direction equivalent to a side-ways fall. Cortical bone from the femur mid shaft was mechanically tested to determine tensile material properties. Osteopontin (OPN) concentrations were measured in the serum. Total RNA was extracted from white blood cells collected at necropsy and mRNA libraries generated using the KAPA Stranded mRNA-Seq kit for sequencing on the HiSeq2500. Reads were aligned to the *Papio anubis* reference genome using the STAR aligner and normalized to total read counts per sample. Read counts were scaled across samples and adjusted for age and sex effects. For 909 transcripts derived from known OP candidate genes selected from the HuGE Navigator, normalized counts were assessed for association with bone health traits using a variance component model in SOLAR. After Bonferroni correction, 31 were associated with one or more structural traits, mechanical strength, or biomarkers. Thirteen transcripts were associated with overall femur size while 7 were associated with OPN including *GPNMB* which regulates bone turnover in a mouse model. Matrix metalloproteinase *MMP1* and insulin-regulating *PCSK1* were associated with SSM factors. *TTC23*, a locational candidate gene from previous OP meta-analyses, was associated with tensile strength. *CYP27B1*, a contributor to age-related decline in bone mass in a rat model, was associated with bone strength in the fall simulation. These findings illuminate potential mechanisms for previously identified genetic variants while clarifying the role of these genes in the complex interactions contributing to bone fragility. This work was funded by NIH/NIAMS R01 AR060341-03 and the William & Ella Owens Medical Research Foundation.

1333W

Genome-wide association study of DNA methylation identifies a novel locus associated with bone mineral density. *J.A. Morris[1], P.-C. Tsai[2], Y.-H. Hsu[3], R. Joehanes[3], J. Zheng[4], K. Trajanoska[5], M. Soerensen[6], V. Forgetta[1], M. Frost[6], K. Christensen[6], L. Christiansen[6], F. Rivadeneira[5], T.D. Spector[2], J.H. Tobias[4], D.M. Evans[4], D.P. Kiel[3], J.B. Richards[1,2], J.T. Bell[2].* 1) Department of Human Genetics, Lady Davis Institute, McGill University, Montreal, Quebec, Canada; 2) Department of Twin Research & Genetic Epidemiology, King's College London, London, UK; 3) Institute for Aging Research, Hebrew SeniorLife, Department of Medicine, BIDMC, & Harvard Medical School, Boston, Massachusetts, USA; 4) MRC Integrative Epidemiology Unit, University of Bristol, Bristol, UK; 5) Departments of Internal Medicine and Epidemiology, Erasmus Medical Center, Rotterdam, Netherlands; 6) The Danish Twin Registry, Institute of Public Health, Endocrine Research Unit, KMEB, University of Southern Denmark, Odense, Denmark.

Purpose Osteoporosis is a common, complex disease characterized by increased bone fragility, often resulting in fracture. Bone mineral density (BMD) is measured to diagnose osteoporosis and estimate fracture risk. Genetic and environmental determinants of osteoporosis risk may converge through the epigenome, providing a tool to better understand osteoporosis pathophysiology. As the epigenetics of BMD have been largely unexplored in humans, we undertook an epigenome wide association study (EWAS) of BMD. **Methods** We undertook an international, large-scale BMD EWAS using the Illumina Infinium HumanMethylation450 array to measure site-specific DNA methylation across four cohorts in up to 4,827 individuals of European descent. Using these data, we aimed to identify differentially methylated probes (DMPs) associated with dual energy X-ray absorptiometry derived femoral neck and lumbar spine BMD. DNA methylation was measured in whole-blood tissue as epigenetic status is partially shared across tissues, immune cells may influence BMD, and some bone cells arise from monocyte-macrophage precursors. We performed sex-combined and stratified analyses, controlling for age, weight, smoking status, sex (for combined analyses), estimated white blood cell proportions, and random effects for relatedness and batch effects. We defined statistical significance of DMPs as being associated with BMD at a 5% false-discovery rate (FDR). **Results** We identified one DMP significantly associated with femoral neck BMD in females-only ($P = 7.9x10^{-11}$; $N = 3,444$) and pooled ($P = 3.0x10^{-8}$; $N = 4,827$) analyses. The DMP maps to the liver carboxylesterase 1 (*CES1*) gene 5' UTR. This association postulates a novel locus for bone biology as no genetic associations with BMD and *CES1* have been reported to date. The association is not mediated by genetic variation mapping to the DMP, as the association remains significant after conditional analyses on SNPs at the locus. **Conclusion** Undertaking the most comprehensive genome-wide analysis to-date for the role of whole-blood methylation on BMD variation, we identified a novel epigenetic locus for bone biology mapping to *CES1*. Further follow-up experiments to understand the function of DNA methylation and *CES1* with respect to BMD are underway. Interrogation of the function of this region will help to understand how environmental and genetic effects converge upon the epigenome to regulate BMD.

1334T

Clubfoot-associated *FSTL5* implicates the FSTL5/YAP axis in embryonic limb development. *J. Rios[1,2,3,4], A. Khanshour[1], L. Fraga[5], A. Diamond[6], V. De Mello[5], J. Kozlitina[2], M. Wilson[6], J. Hecht[7], B. Richards[8], M. Dobbs[9], H. Wackerhage[5], N. Vargesson[5], C. Gurnett[10].* 1) Research Department, Texas Scottish Rite Hospital for Children, Dallas, TX; 2) McDermott Center for Human Growth and Development, University of Texas Southwestern Medical Center, Dallas, TX; 3) Department of Pediatrics, University of Texas Southwestern Medical Center, Dallas, TX; 4) Department of Orthopaedic Surgery, University of Texas Southwestern Medical Center, Dallas, TX; 5) School of Medical Sciences, Institute of Medical Sciences, University of Aberdeen, Aberdeen, Scotland, United Kingdom; 6) Department of Anatomy, University of Otago, Dunedin, New Zealand; 7) McGovern Medical School, University of Texas Health, Houston, TX; 8) Department of Orthopaedic Surgery, Texas Scottish Rite Hospital for Children, Dallas, TX; 9) Department of Orthopaedic Surgery, School of Medicine, Washington University, St Louis, MO; 10) Department of Neurology, School of Medicine, Washington University, St Louis, MO.

Congenital clubfoot, or talipes equinovarus (TEV), is a common structural birth defect occurring twice as frequently in males than females. TEV presents with bilateral or unilateral involvement at similar frequencies and is associated with maternal smoking during pregnancy. TEV may develop secondary to other musculoskeletal disease (syndromic TEV) or as an isolated idiopathic TEV (iTEV). The transcription factors *PITX1* and *TBX4* were previously implicated in TEV and are known to regulate embryonic limb specification and development, though pathogenic variants occur rarely in TEV patients and neither has been associated with TEV in population studies. We performed a genome-wide association study (GWAS) following imputation of 81.2 million variants in 399 non-Hispanic white (NHW) iTEV patients and 7,820 NHW controls. After quality control filtering, a total 8.6 million variants were included in the association analysis. GWAS analysis identified a significantly associated locus (rs76973778, P_{GWAS}=1.92×10^{-8}, OR=0.348) within intron 3 of the *FSTL5* gene, encoding follistatin-like 5. A highly correlated SNP (rs76811724, r^2=0.96, P_{GWAS}=2.06×10^{-7}) was tested for replication in an independent cohort of 335 and 2,738 NHW cases and controls, respectively. Following replication, the association of rs76811724 improved to $P_{COMBINED}$=2.99×10^{-9}. Though largely uncharacterized, the FSTL5 protein is similar to follistatin-like 1, an antagonist of bone morphogenetic protein that is required for proper hindlimb skeletal development in mice. Expression profiling of developing embryonic limb buds showed *Fstl5* expression increased throughout the time points investigated in both bat (CS15-17) and chicken (S15-30) embryos as well as mouse (E12-13.5), albeit at lower levels. *Fstl5* expression was detected in the distal segments of developing embryonic chick wings by whole-mount *in situ* hybridization, suggesting *Fstl5* may be expressed later in limb development and may regulate distal limb formation. FSTL5 was recently shown to negatively regulate *YAP1* and may also regulate expression of *VCAN*, which encodes versican, a regulator of TGF-beta signaling known to be required for proper joint development in the distal hind limbs of both mouse and chicken embryos. Using genome-wide association analysis, we identified the *FSTL5* gene as the first locus associated with iTEV, suggesting a role for the FSTL5/YAP/Hippo axis in regulating later stages of embryonic limb development.

1335F

Association of 3q13.32 variants with hip trochanter and intertrochanter bone mineral density identified by a genome-wide association study. *L. Zhang[1,2], Z.G. Xie[3], W.Z. Hu[1,2], L.B. Li[3], S. Ran[4], Y. Lin[4], R. Hai[5], H. Shen[6], Q. Tian[6], Y.H. Zhang[2,7], S.F. Lei[1,2], C.J. Papasian[8], H.W. Deng[6], Y.F. Pei[2,7].* 1) Center for Genetic Epidemiology and Genomics, School of Public Health, Soochow University, Suzhou, Jiangsu, China; 2) Jiangsu Key Laboratory of Preventive and Translational Medicine for Geriatric Diseases, Soochow University, Suzhou, Jiangsu, China; 3) The Second Affiliated Hospital of Soochow University, Suzhou, Jiangsu, China; 4) Center of System Biomedical Sciences, University of Shanghai for Science and Technology, Shanghai, P. Hip trochanter (TRO) and intertrochanter (INT) sub-regions have important clinical relevance to subtrochanteric and intertrochanteric fractures, but have rarely been studied by genome-wide association studies (GWASs). Aiming to identify genomic loci associated with BMD variation at TRO and INT regions, we performed a GWAS utilizing the Framingham heart study (FHS, *N*=6,912) as discovery sample, and utilized the Women's health initiative (WHI) African-American sub-sample (*N*=845), WHI Hispanic sub-sample (*N*=446), and Omaha osteoporosis study (*N*=963), for replication. Combining the evidence from both the discovery and the replication samples, we identified one novel locus around the associated variations at chromosomal region 3q13.32 (*rs1949542*, discovery p=6.16×10^{-8}, replication p=2.86×10^{-4} for INT-BMD; discovery p=1.35×10^{-7}, replication p=4.16×10^{-4} for TRO-BMD, closest gene *RP11-384F7.1*). We also replicated two loci at chromosomal regions 3p21 (*rs148725943*, discovery p=6.61x10^{-7}, replication p=5.22×10^{-4} for TRO-BMD, closest gene *CTNNB1*) and 8q24 (*rs7839059*, discovery p=2.28×10^{-7}, replication p=1.55×10^{-3} for TRO-BMD, closest gene *TNFRSF11B*) that were reported previously. We demonstrated that the effects at both 3q13.32 and 3p21 were specific to the TRO, but not to the femoral neck and spine. In contrast, the effect at 8q24 was common to all the sites. Our findings provide useful insights that enhance our understanding of bone development, osteoporosis, and fracture pathogenesis.

1336W

A genome-wide association study identifies novel genetic loci for pediatric atopic dermatitis in European and African American populations. *B. Almoguera[1], L. Vazquez[1], J. Connolly[1], A. Cederquist[1], E. Ryan[1], M. Khan[1], F. Mentch[1], P.L. Peissig[2], J.G. Linneman[2], M. Brilliant[2], P. Sleiman[1], H. Hakonarson[1].* 1) Center for Applied Genomics, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Marshfield Clinic Research Foundation, Marshfield, Wisconsin, USA.

   Introduction: Atopic dermatitis (AD) is a common chronic inflammatory skin disease with a major genetic component. To date, 31 genetic loci have been identified through GWAS but despite AD being more prevalent in African American populations, this group has been under-represented in these studies. Here we present a GWAS with the largest African American pediatric population studied to date where we have identified a variant in chromosome 1 significantly associated with AD. **Methods**: Cases and controls were defined by a phenotyping algorithm that mines electronic medical record (EMR) data for diagnostic (i.e. ICD9 codes) and medication information. The algorithm was run and validated internally at the Center for Applied Genomics (CAG), with external validation at an independent site from the electronic Medical Records and Genomics network (eMERGE). After imputation of non-observed genotypes with SHAPEIT and IMPUTE2, a GWAS was performed in European and African American populations separately using SNPtest, including sex and 10 principal components as covariates, followed by meta-analysis with METAL. **Results**: Validation of the phenotyping algorithm yielded positive predictive values of 92%-96%. A total of 9,075 subjects were included in the analysis: 4,014 African American (1,415 cases) and 5,061 individuals of European ancestry (231 cases). Meta-analysis of the GWAS results identified rs6665826 in locus 1q24.3 reaching genome-wide significance ($p=2.40 \times 10^{-8}$). This variant is located 159kb downstream of *TNFSF18*, which encodes the member 18 of the tumor necrosis factor superfamily, and has a *cis*-regulatory effect over *FASLG* (Fas ligand) in whole blood. The region is a known risk factor for Crohn's disease. Two additional loci with suggestive significance were found: variant rs7540799 ($p=1.14 \times 10^{-7}$) in the gene *RORC* (RAR-related orphan receptor C) also in chromosome 1, associated with intestinal bowel disease (IBD) and rs79790432 in chromosome 4 ($p=1.82 \times 10^{-7}$), upstream the member 1 RasGEF domain family gene (*RASGEF1B*) and expressed in skin. **Conclusion**: We have identified a novel loci for AD in children of European and African American ancestry with intriguing function and previously associated with IBD, which is consistent with the known genetic overlap of this condition with other inflammatory and autoimmune diseases. Replication of these results in an independent sample is currently in progress.

1337T

A genome-wide analysis of severe cutaneous adverse drug reactions to anti-epileptic drugs. *M. McCormack[1], G. Wright[2], U. Amstutz[3], N. Shear[4], A. Gamberdella[5], G. Sills[6], Z.    Anti-epileptic drugs (AEDs) are widely used as a treatment for epilepsy. However, they commonly cause cutaneous adverse drug reactions (cADRs) ranging from mild rash to potentially fatal hypersensitivity syndrome (HSS) and Stevens-Johnson syndrome/toxic epidermal necrolysis (SJS/TEN) that have an annual incidence of 0.4 to 1.2 individuals per million. Alleles in the major histocompatibility locus, *HLA-A*31:01* and *HLA-B*15:02*, and the cytochrome P450 allele, *CYP2C9*3*, have diagnostic value in predicting cADR risk in various ethnic backgrounds, yet these markers do not have complete prognostic sensitivity and specificity, and risk factors in patients experiencing cADRs but not carrying these markers remain elusive. In order to address this need, we have collected detailed point-of-care phenotypic and genomic information for epilepsy patients via two large consortiums across Europe and North America, providing a framework to study these cADRs. To date, we have assembled 80 cases of severe cADRs (n=41 HSS and n=39 SJS/TEN) associated with carbamazepine, oxcarbazepine, lamotrigine and phenytoin and 198 matched drug-tolerant controls of European descent. In addition, we have collected a further 18 cases of other ancestral backgrounds. We are currently performing a genome-wide assessment of genetic variation employing both high throughput genotyping arrays and exome sequencing. These approaches will enable us to analyse our cohort for association of severe cADRs with common and rare variation. Preliminary analyses show replication of the *HLA-A*31:01*/carbamazepine and *CYP2C9*3*/phenytoin cADR associations, while the *HLA-B*15:02* allele was not observed in our European patients, which is in line with previous studies. In conclusion, the present study represents one of the largest collections of severe cADRs caused by AEDs in European ancestral patients assembled to date. Identification of genomic markers for AED-induced severe cADRs will facilitate more personalized prescribing and is expected to reduce the overall rates of AED discontinuation due to ADRs as well as improve the safety of anticonvulsant therapies. .

1338F

Pleiotropic effects of noncoding variants near *EFEMP1*, *WT1*, *ADAMTS6*, **and** *EBF2* **on the risk of abdominal hernias support an etiological role for collagen and elastin homeostasis in hernia susceptibility.** *E. Jorgenson[1], N. Makki[2,3], K.K. Thai[1], D.C. Chen[4], W. Eckalbar[2,3], A. Avins[1], N. Ahituv[2,3].* 1) Division of Research, Kaiser Permanente, Oakland, CA; 2) Department of Bio-engineering and Therapeutic Sciences, University of California San Francisco, San Francisco, CA 94158, USA; 3) Institute for Human Genetics, University of California San Francisco, San Francisco, CA, 94158, USA; 4) Lichtenstein Amid Hernia Clinic, David Geffen School of Medicine at the University of California Los Angeles, Los Angeles, CA 90095, USA.

Abdominal hernias are some of the most frequently diagnosed conditions in clinical practice, with more than twenty million hernia repair surgeries performed annually around the world. While family studies suggest that genetic factors play an important role in hernia susceptibility, studies assessing specific genetic risk factors have been limited. Because the risks associated with hernias, specifically, bowel incarceration with a substantial risk of mortality, must be balanced against the risks associated with their treatment, which include chronic pain (6%) and hernia recurrence (10%), there is a clear need for a better understanding of hernia etiology and improved treatment options. We conducted the first large-scale genetic study of hernia risk, identifying noncoding variants at four novel genetic loci underlying the risk of inguinal hernia—the most common type of hernia. We showed that four genes in these loci (EFEMP1, WT1, EBF2, and ADAMTS6) are expressed in mouse connective tissue. We investigated whether risk SNPs in these loci were associated with other abdominal hernia subtypes, specifically, umbilical, femoral, and ventral hernias. We observed significant associations between the EFEMP1 and WT1 loci and each of these subtypes, including a genome-wide significant association between EFEMP1 and ventral hernia (p = 7.9*10-10). Pathway analysis suggested that WT1 and EFEMP1 might influence connective tissue maintenance/homeostasis through their action on extracellular matrix enzymes, including matrix metalloproteinases that degrade collagen and elastin fibers. These findings indicate that these loci affect the risk of hernias across anatomical sites and suggest their mechanism of action may underlie hernia susceptibility more generally.

1339W

Association between single nucleotide polymorphisms of *BMP5* **gene and risk of knee osteoarthritis.** *A. Sharma, R.N. Srivastava, S.R. Srivastava, S. Raj.* orthopaedic surgery, king george medical university, Lucknow, Uttar Pradesh, India, India.

Background: Osteoarthritis (OA) is a chronic degenerative disorder probably affected by both genetics and environmental causes. Bone morphogenetic proteins (BMPs) are bone-derived factors that can induce new bone formation. Previous study identified single nucleotide Polymorphisms (SNP□s) that altered transcriptional activity of the BMP5 promoter, which implies that these polymorphism of BMP5 gene is involved in OA susceptibility. In this case control study, we investigated the correlation of rs1470527 and rs9382564 SNP of BMP5 gene with susceptibility to knee OA. Methods: A total of 499 cases that confirmed radiographic knee OA and 458 age and sex matched healthy controls were enrolled. Venous blood samples were obtained from all cases as well as controls for genetic analysis. Restriction fragment length polymorphism was performed for SNP analysis. Results: The genotype distribution for rs1470527and rs9382564 SNP was significantly different between the cases and controls (P<0.0001). Within both the SNPs of BMP5 gene, genotype CT and TT was found to be significantly (p<0.0001) associated with knee OA as compared with the CC genotype. In addition when alleles were compared, T allele of both the studied SNP was observed to be significantly associated with knee OA (P<0.0001). Further in relation with clinical symptom of OA, we observed signification association of TT genotype with both visual analogue scale (VAS) (p<0.0001) and WOMAC (Western Ontario and McMaster Universities) score (p<0.05). Conclusion: Our results indicate significant association of rs1470527 and rs9382564 polymorphism of BMP5 gene with knee OA.

Two novel hidradenitis suppurativa risk loci identified by genome-wide association study. *M. Liu, J. Degner, A. Grundstad, H. Teixeira, D. Williams, W. Davis, J. Waring.* Abbvie Inc, North Chicago, IL.

   Hidradenitis suppurativa (HS, also known as acne inversa) is an autosomal chronic inflammatory inherited skin disease affecting approximately 1% of the population. Genes involved in HS susceptibility have yet to be determined. A total of 359 DNA samples from HS subjects enrolled in Pioneer I and II (NCT01468207 and NCT01468233) were combined with 188 healthy controls in order to conduct a case/control GWAS of HS risk. Genotyping was performed using the Illumina HumanOmniExpressExome v1.2B bead-chip and imputation made to the 1KG Phase III reference panel using BEAGLE 4.1, resulting in approximately 31.6 million candidate SNPs for association. We identified two genome-wide significant (p<5x10^{-8}) regions in Chromosomes 4 and 13. The assoiated LD block in Chr13 covers *SLC25A15* and some intergenic space near *ELF1*. Variants in the region were previously reported to associate with other autoimmune diseases such as Crohn's and Systemic Lupus Erythematosus; for these other diseases, *ELF1* was proposed as the causal gene because of its involvement in T-cell specific gene regulation, including regulation of *CD4*. However, public eQTL databases revealed that the putative SNPs associated with HS are significant eQTLs with *WBP4* in skin tissue and with *SLC25A15* in muscles. Interestingly, *SLC25A15* is a key enzyme that catalyzes the urea cycle for transporting ornithine which has been shown to enhance wound healing. Furthermore, an assessment of several studies in psoriasis showed that *SLC25A15* is more elevated in lesion tissue than non-lesional tissue in psoriasis patients. Potential casual variants in the associated Chr4 LD-block include *PPEF2, ASAHL* and *CXCL9/10/11,* with the later all being chemokines important in psoriasis disease etiology and whose levels in serum has been shown to increase during wound healing. Moreover, *CXCL9/10* expression is 3 to 4 fold greater in skin samples from lesions as compared to normal individuals or from non-lesion tissue in HS patients. *PPEF2* is involved in epidermal barrier function while *ASAHL* inhibitors have been proposed as therapeutic agents in the treatment of inflammatory disease such as allergic dermatitis and psoriasis. Ongoing functional assays will help us to dissect the causal pathway by which these variants lead to differences in HS susceptibility. * Liu M and Degner JF contributed equally to this work.

1341F

Lack of predictive deep phenotyping variables in *PIK3CA* mosaicism. *S. Polubothu[1and2], R. Knox[3], L. Al-Olabi[1], V. Parker[3], R. Semple[3], V. Kinsler[1and2].* 1) Genetics and Genomic Medicine, UCL Institute of Child Health, London, United Kingdom; 2) Paediatric Dermatology, Great Ormond St Hospital for Children, London; 3) WT-MRC Institute of Metabolic Science, Addenbrooke's Hospital, Cambridge, United Kingdom.

   PIK3CA Related Overgrowth Spectrum (PROS) is an umbrella term describing the known and emerging clinical entities associated with post-zygotic *PIK3CA* mutations. More recently *PIK3CA* mutations have been described in venous malformations without overgrowth. Many individuals present with overlapping features of syndromes previously thought to be clinically distinct. Accurate phenotypic and genotypic description of the clinical spectrum is necessary to improve our understanding of the condition, and to direct individuals with *PIK3CA* mutations to international trials of MTOR inhibitors. We undertook targeted next generation sequencing of 60 known overgrowth genes on tissue samples from a cohort of 85 children with a diagnosis of vascular malformation and/or overgrowth, on whom genotyping results are so far available for 43 (all will be available by the time of the ASHG 2016). Sequencing had a sensitivity of 1% for fresh and 5% for paraffin-embedded samples, using an average read depth of 1000X. Multiple logistic regression was used to model *PIK3CA* mutation status on the basis of deep phenotyping, including clinical, radiological, histopathological, haematological and outcome variables. Median age at presentation was 1.2 years, median follow up 7.0 years. 42% of patients had overgrowth of body and/or limb, 7% had macrocephaly, 57% had a visible superficial component to the vascular malformation, 11% had epidermal naevi, 49% had abnormal clotting parameters, 95% had positive pS6 (MTOR) immunohistochemistry, 59% required surgery and 41% sclerotherapy for pain or overgrowth. *PIK3CA* mutations were detected in affected tissue of 17/43 (41%), and absent from blood. The mutant allele frequency was 1.2-28%. No phenotypic variables were statistically predictive of *PIK3CA* mosaicism. Our findings confirm the broad phenotypic spectrum reported with post-zygotic mutations in *PIK3CA*. Thus far we have not identified any phenotypic predictors of genotype, although a larger group is required to stratify by affected protein domain. Currently we will continue to offer sensitive genotyping to this whole phenotypic group to best direct the choice of novel targeted therapeutic strategies.

1342W

Rare variant analysis of human neurodegenerative disorders guided by high-throughput yeast screens for alpha-synuclein toxicity. *D. Zielinski[1], V. Khurana[2], J. Sandoe[2], S. Lindquist[2], Y. Erlich[1].* 1) New York Genome Center, New York, NY; 2) Whitehead Institute for Biomedical Research, Cambridge, MA.

Rare risk variants pose a major challenge for association studies of complex human conditions. Hypothesis free searches require an overwhelming number of individuals to reach the statistical power needed to associate these variants. We took a radically different approach for the search of rare variants in neurodegenerative diseases. In our previous studies, we established an alpha-synuclein yeast model that recapitulates the molecular pathologies of Parkinson's disease. Using this model, we conducted high-throughput screens to search for modifiers of alpha-synuclein toxicity in yeast. We conducted an exploratory sequencing study targeting the human homologs of these genes as well as known Parkinson's risk genes in more than 500 familial and sporadic synucleinopathy patients. Despite the small number of samples, the relatively small set of 430 genes allowed us to concentrate the statistical power on more likely targets. As a control, we compared the amount of rare variants to the ExAC resource and a cohort of aged individuals with no CNS pathology. This process generated nearly 300 variants that passed an FDR of 5%. After the exploratory stage, we rescreened the same exact variants in a yeast model and patient-derive neurons to obtain an orthogonal validation of their pathogenicity. We envision that our cross-species approaches will continue to yield important insights for complex diseases with evolutionarily conserved biological mechanisms, and perhaps help fulfill therapeutic promises in the post-genomics era.

1343T

Analysis of whole-genome-sequence in an extended pedigree with autism: Identification of a candidate gene, with replication. *N. Chapman[1], R. Bernier[2], D. Bilder[3], T. Darlington[3], J. Morgan[3], H. Coon[3], E. Wijsman[3].* 1) Medical Genetics, University of Washington, Seattle, WA; 2) Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA; 3) Psychiatry, University of Utah, Salt Lake City, UT.

Autism is a complex disorder, with high heterogeneity that inhibits replication. Under heterogeneity, large multiplex families, while rare, are a powerful tool for discovery of susceptibility genes. We report the discovery in a large family of an excellent candidate gene for autism, with replication in a 2nd family. We carried out gene-discovery in Family A (47 individuals, 5 generations). Dense SNP data and whole exome sequence were available on 44 and 5 individuals, respectively. Linkage analysis identified a 2.1Mb region of interest on chr 22. Of 11 affected individuals, 8 share a haplotype in this region. There are also 11 unaffected individuals carrying the risk haplotype (RH), including 3 female siblings of affecteds. The only rare exome variant on the RH is synonymous and unlikely to be a risk allele (Hum Hered 74:153, 2012). We also obtained whole genome sequence (WGS) on two trios in Family A where the RH was transmitted to an affected child. We filtered for variants that were transmitted from non-founder parents to the affected child, with a frequency of ≤1% in the 1000 Genomes Project Europeans. 3 of the resulting 16 variants are rare (0.1% frequency) and are close to or intronic to the same gene, which is an excellent candidate for autism. For replication, we examined WGS on 88 individuals (57 affecteds and 31 unaffected siblings) in 13 large families with autism. Dense SNP panels were available for these and many family members. After quality filtering, we found that 10 of the 16 rare variants on the RH were represented in the replication sample. 5 of these could be rejected as autism risk variants, either because they appeared solely in unaffected individuals, or because they did not segregate with autism. The remaining 5 replicated variants include the same 3 implicated in Family A. In the replication set all 5 appear together in an affected male and his unaffected sister, who has epilepsy and symptoms of ADHD. Analysis of SNP data in these individuals and 6 additional nuclear family members showed that the 5 variants are transmitted from the grandfather to the father and then to all 4 children, as an intact haplotype. The grandfather has an inflated score on the Social Responsiveness Scale, a measure of autistic social impairment. A rare haplotype with variants in a novel autism candidate gene segregates with autism in 2 large multiplex families. Details of the variants and the gene will be shared at the meeting.

1344F

Induced pluripotent stem cell models of autism spectrum disorder associated with early brain overgrowth. *C. Fu[1], H. Belinson[3], S.P. Smieszek[2], L.A.D. Bury[1], M.X. Zhang[1], J.I. Haines[2], A. Wynshaw Boris[1].* 1) Genetics and Genomics, Case western reserve university, Cleveland, OH; 2) Epidemiology and Biostatistics, Case western reserve university, Cleveland, OH; 3) Department of Pediatrics, School of Medicine, University of California San Francisco.

Autism Spectrum Disorder (ASD) is a highly heterogeneous neurodevelopmental disorder, characterized by deficits in social interaction, verbal communication and repetitive behavior. The molecular mechanisms for ASD are poorly understood. We have been investigating the hypothesis that a subset of patients (~25-30%) with ASD display early brain overgrowth. Our lab has recently produced two relevant models that we believe model important aspects of early brain overgrowth in ASD. First, we produced mouse models deficient for *Dvl1* and *Dvl3* (*Dvl1-/-3+/-* mutant) that display adult social behavior abnormalities associated with transient embryonic brain enlargement during deep layer cortical formation (Belinson et al. 2016). Second, we generated human induced pluripotent stem cell (iPSC) models by reprogramming fibroblasts obtained from 8 ASD individuals with early brain overgrowth and 5 non-ASD controls with normal brain size. Neuronal progenitor cells (NPCs) derived from ASD iPSC lines displayed enhanced proliferation compared to control NPCs (Marchetto, Belinson et al. 2016). In both models, these aberrant ASD phenotypes were caused by down-regulation of Beta-catenin activity and its direct target BRN2. Additionally, treatment of GSK3β inhibitor to both mice embryo and human NPCs can rescue the cellular and behavioral phenotype (Belinson et al. 2016, Marchetto, Belinson et al. 2016). To investigate the primary and secondary targets of Beta-catenin and BRN2, we are performing ChIPSeq using antibodies for Beta-catenin and BRN2 for each of human NPC lines, as well as NPCs from wild-type and *Dvl1-/-3+/-* mutant mice strain, in both GSK3β inhibitor treated and untreated condition. Significant RNASeq and ChIPSeq results are used as input for Gene Ontology and pathway analysis. Initial results of RNASeq and ChIPSeq for BRN2 for 1 ASD NPC line and 1 control line in both GSK3β inhibitor treated and untreated condition demonstrated that 20 RNAs displayed differential expression levels and differential BRN2 binding (and corrected by GSK3β inhibitor treatment). These 20 genes were participants in 13 significant pathways, including the Wnt signaling pathway, cell cycle and synaptic vesicle cycle. We are currently performing similar analyses on the other ASD and control lines. Taken together, the current results suggest our approach is promising for uncovering molecular mechanisms for brain overgrowth and ASD.

Rare mutations contribute significantly to autism spectrum disorder (ASD) and the importance of large, rare *de novo* copy number variants (CNV) and *de novo* protein disrupting single nucleotide variants (SNV) is well established in simplex families in the Simons Simplex Collection (SSC) with no close relatives with ASD. The SSC families are likely to be enriched for sporadic ASD, potentially overemphasizing the importance of *de novo* variation. We analyzed 1464 families from the Autism Genetic Resource Exchange (AGRE) to assess the impact of inherited and *de novo* CNVs on ASD risk in a primarily multiplex cohort. The overall burden of rare, large CNVs is higher in ASD cases compared to their unaffected siblings (OR 1.7, p 0.01) in AGRE. However, the rate of large, rare *de novo* CNVs is not significantly associated with ASD in AGRE and is significantly lower in AGRE cases compared to cases in the SSC (p 0.01). We examined CNVs overlapping previously established ASD associated genes and risk-CNVs in AGRE. A significant overall CNV burden was discovered in cases compared to unaffected siblings, although no individual gene was associated with ASD. We also assessed 49 CNVs that were observed in previously identified ASD risk loci, comprising 24 inherited, 19 *de novo*, and 6 CNVs of unknown inheritance. In 21 (71%) of 30 families harboring a previously identified ASD CNV, such as 15q11.2-13.1 duplication, at least one additional affected sibling did not share the risk CNV with their other affected sibling(s), although 5/21 families had inherited risk CNVs. We conclude that the genetic risk in multiplex families is complex, multifactorial and clearly differs from SSC families, warranting the collection of larger multiplex ASD cohorts. Finally, we find evidence for a novel *de novo* CNV locus at 2q24 that includes the genes *NR4A2* and *GPD2*, of which, former is a highly constrained gene and the latter harbors several likely deleterious variants in the general population. There are no *NR4A2* overlapping CNVs in any non-ASD cohorts, including the DGV, and siblings form AGRE and SSC (p = 0.02). We found in total seven individuals with 2q24.1 deletion: 2 in AGRE, and 4 in DECIPHER and 1 in ClinGen clinical databases. Patients with a deletion in 2q24 share distinct clinical phenotypes, such as ASD, developmental delay and delay in language development, which implies a novel form of syndromic ASD. .

1346T

Genetic determinants of treatment outcome and social impairments in autism spectrum disorder. *K. Tammimies[1,2], V. Nicolaou[1], S. Stamouli[1], N. Choque Olsson[2], S. Berggren[1,2], S. Bölte[1,2].* 1) Center of Neurodevelopmental Disorders (KIND), Pediatric Neuropsychiatry Unit, Department of Women's and Children's Health, Karolinska Institutet , Stockholm , Sweden; 2) Child and Adolescent Psychiatry Stockholm, Center for Psychiatry Research, Stockholm County Council, Stockholm, Sweden.

Deficits in social communication and interaction are core symptoms in autism spectrum disorder (ASD). ASD is currently incurable, but behavioral and other interventions, such as social skills group training (SSGT), can be used to prevent worse outcomes and comorbidity. However, an individual's response to these treatments can be highly variable and the specific factors influencing the outcome are mostly unknown. Limited information exists as to whether rare genetic variants, such as large copy number variants (CNVs), can be used to predict changes in social impairments in ASD and treatment outcome. This study aims to investigate the genetic predictors associated with treatment outcome of SSGT and analyze genetic profiles connected with distinct longitudinal changes in social impairments. For this, a cohort of 302 ASD individuals with common comorbid conditions such as attention-deficit hyperactivity disorder and IQ >70 from the randomized control trial (RCT) for SSGT KONTAKT (clinicaltrials.gov Identifier: NCT01854346) was used. The primary outcome measure used was the change in the parent rated social responsiveness scale (SRS) scores from pre- to post-treatment and after three month follow-up. We are now conducting high resolution genomic analyses in this cohort including CNV profiling using the Affymetrix Cytoscan HD® platform and whole exome/genome sequencing. First, we have assessed whether the presence of large rare CNVs (>500 kb) affected the change in SRS during the training period using linear regression model. Our preliminary results revealed that large rare CNVs were associated with worse outcome following SSGT (β= -14.6, p=0.02) explaining 10% of the variation in the treatment outcome among the participants. The majority of these CNVs were well-known risk loci for neurodevelopmental disorders. For example, we identified a participant with 7q11.23 duplication syndrome, in which social anxiety is known characteristic, whose social impairments increased significantly during the training. We are now expanding these analyses to include the standard care group, selecting individuals for sequencing based on their SRS profile and performing pathway enrichment analyses from the genomic findings. The results from this study can pave the way to understand how genetic information can be used to understand the social impairment profiles in ASD and better tailor the limited resources in treatments for affected individuals.

1347F

***PLXNA3* variant rs5945430 is associated with severe clinical course in male multiple sclerosis patients from Kuwait.** *M. Hatem[1], M. Qureshi[1], R. Alroughani[2,3], F. Al-Mulla[4], R. Al-temaimi[5].* 1) 7th year Medical student , Faculty of Medicine , Kuwait University; 2) Division of Neurology, Department of Medicine, Amiri Hospital, Kuwait; 3) Neurology Clinic, Department of Medicine, Dasman Diabetes Institute, Kuwait; 4) Molecular Pathology Unit, Department of Pathology, Faculty of Medicine, Kuwait University; 5) Human Genetics Unit, Department of Pathology, Faculty of Medicine, Kuwait University.

ABSTRACT: Statement of Purpose: Multiple Sclerosis (MS) is an inflammatory autoimmune demyelinating disease affecting the central nervous system. MS prevalence and clinical course are significantly affected by gender. MS clinical course has been shown to be more aggressive in MS males. Our objective was to identify the genetic factors influencing this phenomenon. **Methods Used:** Eight male and 19 female Kuwaiti MS patients were recruited at Dasman Diabetes institute's neurology clinic. Patient selection was based on having a high MS severity score (MSSS >5). DNA was extracted from blood using Qiagen DNA mini kit. Exome sequencing was performed on an Illumina HiSeq2000 platform using TruSeq v4 chemistry with target coverage of 50X. Patient exome sequences were analyzed using Tute Genomic s application. An additional 62 males and 120 female MS patients were genotyped to confirm exome analysis finding using Taqman genotyping assay for *PLXNA3* variant rs5945430. **Summary of Results:** Female MS exomes were compared to male MS exomes and a genetic variant was discovered in *PLXNA3* gene on chromosome X resulting in a non-synonymous amino acid change (c.2589C>G, p.D863E, rs5945430) (p=3.6300e-5). Male MS patients hemizygous for allele G had significantly higher MS severity scores (MSSS) and increased expanded disability status scale (EDSS) when compared to allele C male MS patients (p=0.005, p=0.02; respectively). Allele G associated with an aggressive MS clinical course in male MS patients (p=0.01; Relative risk (RR) 2.5; 95%CI: 1.07-5.8). No significant association was found for homozygous GG females and MS clinical variables. Our results suggest that a genetic variant in *PLXNA3* (p.D863E), a protein involved in axon path-finding; is associated with MS aggressive clinical course specifically in male patients. We propose *PLXNA3* as a novel sex influenced predictive marker for male MS patients' clinical course.   Keywords from list: Autoimmune disorder (8), Brain/nervous system (14), Exome sequencing (59), Neurodegeneration (127),.

The pharmacogenomics of serious adverse drug reactions associated with disease-modifying therapies for multiple sclerosis: Work in progress. *K. Kowalec[1], E. Kingwell[1], R. Carruthers[1], A. Traboulsee[1], G.E.B. Wright[1], B.I. Drögemöller[1], F. Aminkeng[1], S. Bernatsky[2], C.J.D. Ross[1], B.C. Carleton[1], H. Tremlett[1].* 1) University of British Columbia, Vancouver, British Columbia, Canada; 2) McGill University, Montréal, Québec, Canada.

   Background: Multiple sclerosis (MS) is a chronic degenerative disease of the central nervous system. Ten different disease-modifying therapies (DMT) have become available over the past two decades for the treatment of relapsing MS. Some recently licensed include fingolimod, dimethyl fumarate (DMF), teriflunomide and alemtuzumab and are associated with an increased risk of numerous adverse drug reactions (ADRs). DMF and fingolimod have been associated with progressive multifocal leukoencephalopathy (a serious brain infection); individuals exposed to teriflunomide experience an increased risk of hepatotoxicity, with alemtuzumab increasing the risk for autoimmune thyroiditis and immune-mediated thrombocytopenia. These serious ADRs are currently unpredictable using current clinical and demographic information. **Statement of purpose**: To identify genomic variation associated with the occurrence of serious ADRs in MS, with the ultimate goal of preventing these reactions by either avoiding therapies in specific patients with a high risk of drug-induced harm or by critically informing complex treatment discussions between health care providers and patients. **Study design:** This case-control study will recruit from specialist MS clinics across Canada. Cases are defined as MS patients who have experienced a serious ADR as follows: DMF-associated lymphopenia; DMF-, teriflunomide- or fingolimod-associated hepatotoxicity; or alemtuzumab-associated autoimmune thyroiditis or immune thrombocytopenia. Controls are MS patients who have been exposed to the relevant DMT for an equivalent period of time (e.g. +/- 1 year), with no biochemical/clinical evidence of the ADR and will be matched to cases based on follow-up time. Patient's saliva-derived DNA will be genotyped on a genome–wide panel of genes (1.7M SNPs) involved in drug biotransformation and those associated with DMT ADRs (if any) to identify variants associated with ADR susceptibility. Data will be analyzed using logistic regression to compare genotype frequencies between cases and controls with adjustment for relevant clinical factors and statistical significance set at the Bonferroni-corrected alpha level. **Status**: Recruitment will begin in June 2016, with a total of 200 patients to be enrolled for the first ADR (DMF-lymphopenia). **Conclusion**: Few published studies have attempted to use pharmacogenomic methods to predict and prevent ADRs to MS DMTs. We will present this innovative study as a work in progress.

1349T

Analysis of sporadic inclusion body myositis using high density arrays for immune related genes confirms the human leukocyte antigen as the most associated region and suggests a role for chemokine receptor 5. *J.A. Lamb[1], S. Rothwell[2], R.G. Cooper[3], I.E. Lundberg[4], P.K. Gregersen[5], M.K. Herbert[6,7], G.J.M. Pruijn[6], J. Bowes[8], M.G. Hanna[9], P.M. Machado[9,10], J.B. Lilleker[8,11], M.F. Chinoy[8], MYOGEN Inclusion Body Myositis Investigators.* 1) Centre for Integrated Genomic Medical Research, University of Manchester, Manchester, United Kingdom; 2) Centre for Musculoskeletal Research, University of Manchester, Manchester, UK; 3) MRC/ARUK Institute of Ageing and Chronic Disease, University of Liverpool, Liverpool, UK; 4) Rheumatology Unit, Department of Medicine, Karolinska University Hospital, Karolinska Institutet, Stockholm, SE; 5) Center for Genomics & Human Genetics, Feinstein Institute for Medical Research, Manhasset, NY, US; 6) Department of Biomolecular Chemistry, Institute for Molecules and Materials, Radboud University Nijmegen, NL; 7) Department of Haematology/Oncology, Beth Israel Deaconess Medical Center (BIDMC), Boston, MA, US; 8) National Institute of Health Research Manchester Musculoskeletal Biomedical Research Unit, Central Manchester University Hospitals NHS Foundation Trust, University of Manchester, UK; 9) MRC Centre for Neuromuscular Diseases, University College London, London, UK; 10) Centre for Rheumatology Research, University College London, London, UK; 11) Greater Manchester Neurosciences Unit, Salford Royal NHS Foundation Trust, Salford, UK; 12) Department of Biochemistry and Molecular Medicine, University of California Davis, Davis, CA, US.

   Objective: Sporadic inclusion body myositis (IBM) is characterised by a combination of inflammatory and degenerative changes affecting muscle. While the primary cause of IBM is unknown, genetic factors may influence disease susceptibility. We have conducted the largest genetic association study to date in IBM, investigating immune-related genes using the Immunochip.Methods: 252 Caucasian IBM cases fulfilling Griggs/ENMC/MRC inclusion criteria were recruited from 11 countries through the Myositis Genetics Consortium (MYOGEN), and compared with 1,008 ethnically matched controls. Classical HLA alleles and amino acids were imputed using SNP2HLA. Linear regression analyses were used to investigate the relationships between HLA alleles and age of onset of IBM.Results: The results confirmed the HLA as the most strongly associated region (p=3.58x10[-33]) in IBM. Three non-HLA regions reached suggestive significance, including chr3(p21.21), an established risk locus for autoimmune disease, where a frameshift mutation in CCR5 is thought to be the causal variant. HLA imputation identified three independent associations with HLA-DRB1 alleles, although the strongest association was with amino acid positions 26 and 11 of the HLA-DRB1 molecule. No association with anti-cN-1A positive status was found independent of HLA-DRB1*03:01. There was no association of HLA genotypes with age of onset of IBM.Interpretation: This is the largest, most comprehensive genetic association study to date in IBM. The data confirm that the HLA is the most strongly associated region and identifies novel amino acid associations that may explain the risk in this locus. A novel suggestive association within the chr3(p21.21) locus suggests a role for CCR5.

1350F

Causal networks of Alzheimer's disease on a large RNA-seq dataset. *N.D. Beckmann[1], M. Wang[1], R. Chang[1], V. Haroutunian[2], B. Zhang[1], E.E. Schadt[1].* 1) Genetics and Genomics, Icahn School of Medicine at Mount Sinai, New York, NY; 2) Psychiatry and Neuroscience, Icahn School of Medicine at Mount Sinai, New York, NY.

   Alzheimer's Disease (AD) is the leading cause of dementia worldwide, with more than 28 million cases globally, and this number projected to double in the next 20 years. AD is characterized by progressive loss of cognitive function, affecting ones ability to think, reason and remember. The hallmarks of AD are senile plaques in the brain, composed of accumulated Amyloid Beta and neu-rofibrillary tangles (hyperphosphorylated Tau protein). While several genetic components of AD have already been identified and many biological pathways associated to the disease, the lack of causal genes, pathways/networks, and mechanisms of the disease continue to elude the scientific community.   Here, we study a large group of post-mortem samples (n>300) with the complete range of neuropathologies (from controls to definite AD) across 4 brain regions from the AMP-AD consortium. Using whole exome sequencing (WES) for each sample and RNA-seq from each brain region, we defined a set of differen-tially expressed and differentially connected (between cases and controls) genes that were enriched in coexpression subnetworks (modules) that were associated with AD. These modules were then assigned, when possible, to specific brain-associated cell types. We then constructed probabilistic causal network models of the genes in these modules for cases and controls across the 4 brain regions. These networks organize the genetic, expression, and clinical data of this large dataset in ways that enable us to identify important key drivers of these regulatory networks. We demonstrate that the key driver genes we identify and their surrounding sub-networks provide novel insights into the mechanisms underlying AD risk and pathogenesis.

1351W

Whole genome sequencing in an Amish Parkinson Disease pedigree reveals large allele frequency differences between noncoding variants in individuals with PD versus those successfully aged. *K. Nuytemans[1,2], L. Maldonado[1,2], K. John-Williams[1,2], A. Mehta[1,2], G.W. Beecham[1,2], E.R. Martin[1,2], J.L. Haines[3], W.K. Scott[1,2], J.M. Vance[1,2].* 1) Hussman Institute for Human Genomics, University of Miami, Miami, FL; 2) Miami Udall Center, University of Miami, Miami, FL; 3) Case Western Reserve, Cleveland, OH.

   Previous genetic analyses in a large multi-case family with Parkinson Disease (PD) in the Amish community in Ohio and Indiana has supported a complex nature of the disease in this isolated group. However, as a population isolate, it should have an enrichment of rare variants (RV) that contribute to PD. We focused our analysis on a 0.5 MB region on chromosome 5 that we have shown previously to have the strongest evidence of sharing between PD cases in this family. This region also overlaps with a linkage peak previously reported in non-Amish families [Scott et al 2001]. After whole exome sequenc-ing in 32 cases failed to identify obvious rare coding variant(s) responsible for PD in this region, we sequenced the whole genome of 28 affected individuals from 10 branches of the family, as well as 21 successfully aged (SA; lacking significant cognitive or physical impariment, >80yo) Amish individuals from the same community. A total of 1880 noncoding variants were identified in the chr5 region, of which 181 variants were shared between cases in branches identified to contribute to the chr5 signal in the genetic analyses. Twenty-two of those variants were identified as having potential functional effect by several algorithms (RegulomeDB, CADDv1.3, GWAVA, VistaEnhancer, transcription factor binding sites (TFBS)) though only two of the variants showed evidence in more than one (both CADD and TFBS). Alternatively, 50 variants have an allele frequency of <10% in the SA individuals, 18 of which are also rare in the 1000 genomes dataset (<5%). All but one of the 50 show an allele frequency difference of at least 8-10% between affected and SA individuals. One noncoding variant (rs338950) has a CADD>15, overlaps a potential transcription factor binding site and has a 10% allele frequency difference in affected (~18%) versus SA individuals (~7%). This variant is intergenic, located ~23kb from the closest gene *FGF1*, which has been shown to prevent the death of dopamine neurons in animal models of PD. Contrary to our whole exome analysis, our initial genome data analysis has identified many potential noncoding risk variants, lying in the chromosome 5 region in our large Amish PD family. Current experiments are underway to assess the potential impact of these variants in PD.

1352T

Potential involvement of *DYSF* in Amyotrophic Lateral Sclerosis. *A. Orr-Urtreger[1,2], O. Goldstein[1], O. Nayshool[1], B. Nefussy[3], Z. Gan-Or[4], G.A. Rouleau[4], M. Gana-Weisz[1], V.E. Drory[3,2].* 1) Genetic Institute, Tel Aviv Sourasky Medical Center, Tel Aviv, Tel Aviv, Israel; 2) Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel; 3) Neuromuscular Service, Department of Neurology, Tel Aviv Sourasky Medical Center, 6 Weizmann Street, Tel Aviv 64239, Israel; 4) Department of Neurology and Neurosurgery, McGill University, Montreal, Quebec, H3A 0G4 Canada; Department of Human Genetics, McGill University, Montreal, Quebec, H3A 0G4 Canada; Montreal Neurological Institute, McGill University, Montreal, Quebec, H3A 0G4.

   Amyotrophic lateral sclerosis (ALS) is a devastating neurodegenerative disease affecting 2-3 per 100,000 people per year worldwide. The disease features a wide phenotypic and genetic heterogeneity. The age at disease onset (AAO), the site of disease onset (bulbar, limb), the rate of progression, the disease manifestations and other characteristics, vary significantly. A large number of recently identified causative mutations in more than 20 genes accounts for the genetic heterogeneity of ALS. The various protein functions of these genes suggest multiple pathological pathways. Among the major pathways are proteosomal and autophagy pathways, RNA processing, and axonal dysfunction. We aimed to detect rare genetic variants underlying familial and sporadic ALS that are involved in both recessive and dominant modes of inheritance. Whole-exome-sequencing of Ashkenazi Jewish patients affected with ALS was carried out. A trio-analysis of a patient, which was diagnosed at the age of 21 years old, and her parents was performed. A homozygous *DYSF* variant was detected and subsequently further genotyped on 325 Ashkenazi Jewish patients with ALS and 970 ethnically matched controls .A mutation in *DYSF* was identified in a homozygous state in the ALS patient that changes a conserved amino acid at position 128 from glycine to glutamic acid (c.383G>A; p.G128E). Two additional ALS patients homozygous to the mutation were identified, accounting for about 1% of all Ashkenazi Jewish ALS patients. No homozygotes were observed in controls. Under recessive mode of inheritance these results show a significant association to ALS (p=0.009, χ2 test). The frequency of the mutated allele in the Ashkenazi controls is 0.056. The observed *DYSF* variant is associated with ALS in a homozygous state. For our knowledge, this is the first time that this myopathic gene is demonstrated to have a potential role in ALS. Its relatively high frequency in controls may suggest a model of age-dependent incomplete penetrance for homozygotes, or a risk factor. Further studies in large groups of patients and controls from other ethnicities are necessary to evaluate the role of *DYSF* in ALS pathogenesis.

1353F

Association of *SLC24A4* coding variants with the risk of posterior cortical atrophy. *M.M. Carrasquillo[1], I. Barber[2], S.M. Reeder[1], J. Siuda[1], M.L. Kachadoorian[1], J.D. Burgess[1], A. N'songo[1], S.J. Lincoln[1], T. Nguyen[1], K.G. Malphrus[1], L. Ma[1], G.D. Bisceglio[1], M. Allen[1], M.E. Murray[1], Q. ul Ain Khan[3], S.G. Younkin[1], D.W. Dickson[1], B.F. Boeve[4], N.R. Graff-Radford[3], R.C. Petersen[4], K. Morgan[2], N. Ertekin-Taner[1,3].* 1) Department of Neuroscience, Mayo Clinic Florida, Jacksonville, FL 32224, USA; 2) Human Genetics Group, University of Nottingham, Nottingham, UK NG7 2UH; 3) Department of Neurology, Mayo Clinic Florida, Jacksonville, FL 32224, USA; 4) Department of Neurology, Mayo Clinic Minnesota, Rochester, MN 55905, USA.

   Posterior cortical atrophy (PCA) is usually associated with Alzheimer's disease (AD) pathology. It is characterized by progressive visual impairment, relatively preserved memory and language in the early stages of the disease, and AD pathology predominantly in posterior brain regions. A recent PCA genome-wide association study (GWAS) identified study-wide significant associations at three loci not previously associated with AD, and only nominal significance was found at three of the twenty AD GWAS loci replicated in the International Genomics of Alzheimer's Project (IGAP) meta-analysis. In the present study we set out to evaluate if coding variants at the 20 AD-risk loci present in the NeuroX array, and not evaluated in the PCA GWAS study, may modify PCA risk. Gene-based analysis in our NeuroX cohort consisting of 124 PCA cases and 171 non-demented elderly controls identified significant association at the *SLC24A4* locus (p=2.5x10[-4]). Testing single variants for association with PCA risk (124 PCA cases vs. 3,557 non-demented elderly controls) demonstrated significant association with a rare variant not previously implicated in AD, *SCLC24A4*-rs62623445 (p.S362N), and conditional analyses suggest that the effect of this coding variant is independent from that detected with the AD GWAS intronic SNP *SCLC24A4*-rs10498633. In this first systematic evaluation of coding variants at AD-risk loci in a PCA cohort, we report a rare coding variant in *SCLC24A4* that associates with PCA risk, as well as significant association with *SCLC24A4* at the gene level. Thus, the results of this study provide support for further studies of the influence of *SLC24A4* in PCA-risk.

1354W

Apolipoprotein E and Alzheimer disease risk in a Puerto Rican Alzheimer disease data set. *B. Feliciano[1], K.L. Hamilton-Nelson[2], L.D. Adams[2], P.L. Whitehead[2], N.K. Hofmann[2], H.N. Cukier[2,3], A. Chinea[4], H. Acosta[5], N.I. Feliciano[6], J.L. Haines[7], J.L. McCauley[2,8], R.M. Carney[2], J.M. Vance[2,3,8], M. Cuccaro[2,8], G.W. Beecham[2,8], M.A. Pericak-Vance[2,3,8].* 1) PRADI, SJB School of Medicine, Caguas, PR; 2) John P. Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL; 3) Department of Neurology, University of Miami Miller School of Medicine, Miami, FL; 4) San Juan MS Center Guaynabo, PR; 5) Centro Caribeño para el Estudio de la Memoria y Cognición, San Juan, PR; 6) Psychiatry, PRADI and Veterans Administration Hospital de San Juan, PR; 7) Institute for Computational Biology, Case Western Reserve University School of Medicine, Cleveland, OH; 8) Department of Human Genetics, University of Miami Miller School of Medicine, Miami, FL.

   BACKGROUND: There are over 5 million individuals of Puerto Rican (PR) origin, making up over 1.5% of the US population and representing the 2nd largest Hispanic/Latino population in the continental US. The number of Alzheimer disease (AD) cases on the island of PR is estimated at 65,000. Genetic studies have been limited to a few rare families with early onset AD (PSEN mutations). The PR population is highly admixed, with average ancestry values of 64% European, 21% African, and 15% Native American, but individual ancestries are highly variable. The strong association between Apolipoprotein E 4 (*APOE4)* and AD has been confirmed world-wide but there is variability in the effect size in Hispanics and data suggesting that both African Americans and Hispanics have an increase incidence of AD regardless of *APOE* genotype. The purpose of the present study was to directly assess the effect of *APOE4* in a PR AD data set.   **ANALYSIS AND RESULTS:** To date we have ascertained 74 unrelated individuals into the PR AD Initiative (PRADI) study including 44 AD cases and 30 cognitively intact controls. Seventy five percent of the cases are female, and 63% of controls are female. The mean age at exam for the cases is 76.8 ± 9.0, while the mean age at exam for control individuals is 69.9 ± 7.7. The APOE e4 allele frequency in the cases is 22.7%, while the *APOE4* frequency in the controls is 21.7%. Logistic regression was performed to determine whether there was an association between affection status and *APOE* genotype, adjusting for age at exam and gender. The association between *APOE4* dose and affection status was not significant (OR=1.10, beta=0.091, se=0.45, p-value=0.84). However, given the current sample size an Odds Ratio of 2.55 would be needed to achieve 80% power. We do note that the three *APOE4* homozygotes all had AD.   **CONCLUSIONS:** Our data support the hypothesis that *APOE4* does not strongly contribute to risk in PR AD. These findings are interesting given a previous report suggesting that among PR non-demented nonagenarians the *APOE4* allele is associated with better cognition (Carrion-Baralt et al., 2009). GWAS genotyping is underway to examine local ancestry at the *APOE* locus as well as global ancestry in the PRADI data set as well as additional sampling and expansion of the PRADI data set.

A genome-wide study of structural variants in patients with epilepsy. *S.L. Girard[1,2,3], J. Monlong[2], C. Meloche[3], M. Cadieux-Dion[3], M. Gravel[3], S. Dobrzeniecka[3], D. Spiegelman[4], A. Dionne-Laporte[4], C. Boelman[5], G.A. Rouleau[4], J. Michaud[6], R.G. Lafreniere[3], B. Minassian[5], G. Bourque[2], P. Cossette[4].* 1) Université du Québec à Chicoutimi, Chicoutimi, Canada; 2) Genome Center, McGill University, Montréal, Canada; 3) Centre de Recherche du CHUM, Montréal, Canada; 4) Montreal Neurological Institute, Montréal, Canada; 5) Sick Kids Hospital, Toronto, Canada; 6) CHU Ste-Justine, Montréal, Canada.

   Background: Epilepsy is a complex neurological disorder that is characterized by abnormal excessive or synchronous neuronal activity in the brain. Although a small portion of the disorder can be explained by fully penetrant genetic mutations, a large fraction of the genetic heritability remains unknown to this day. The Canadian Epilepsy Network (CENet) is a Genome Canada funded initiative to bring epilepsy into the personalized medicine era. Methodology: A specific aim of this project was to evaluate the implication of structural variants (SVs) in the genetic mechanism of the disease. To do so, we performed whole genome sequencing on 200 patients suffering from various types of epilepsy, including generalized, partial and photosensitive epilepsy. We used PopSV, a detection algorithm developed by some members of our group to identify small and large structural variants in the genome of epilepsy patients. In order to evaluate the frequency of the identified SVs, we had access to more than 300 whole genome sequences from healthy individuals. Results: Out of the most promising SVs identified, a significant portion encompassed genes already linked to epilepsy thus showing the great importance of SVs in the genetic mechanism of the disease. We also found that on average, epilepsy patients carry more exon-disrupting SVs than healthy individuals. More specifically, we were able to identify structural variants in many genes previously known to harbour single nucleotide variants linked to epilepsy (*LGI1*, *CHD2*, *DEPDC5*) as well as larger chromosomal events (15q11.2 and 15q11.3). We also identified several new genes harbouring recurrent deleterious structural variants. These genes represent excellent new candidates to better explain the genetic etiology of epilepsy.

1356F

Benign familial neonatal seizures to early onset epileptic encephalopathy: What's mosaicism got to do with it? *A. Guerin, C. Kiss, A. Rusnak, J. MacKenzie.* Divison of Medical Genetics, Department of Pediatrics, Kingston General Hospital, Kingston, Ontario, Canada.

   Benign familial neonatal seizures is an autosomal dominant epilepsy syndrome that self resolves with favorable development. Up to 70% of families have a mutation in either *KCNQ2* or *KCNQ3*. However, it is recognized that the same mutations in *KCNQ2* also cause early onset epileptic encephalopathy, a severe, refractory form of epilepsy associated with significant developmental disability.   We present a patient who was born at term with refectory epilepsy developing at four days of life. Pregnancy was complicated by intrauterine growth restriction and neonatal 'hiccups'. EEG confirmed epileptiform activity and the patient had several medication trials. Family history was significant for benign neonatal seizures in the patient's mother, which self-resolved by the age of one year with no sequelae. On examination, the child was non-dysmorphic, with axial and appendicular hypotonia. Investigations including infection screening, microarray and biochemical analysis were negative. MRI brain revealed white matter abnormalities, consistent with micro-hemorrhages. An epilepsy gene panel revealed an undescribed heterozygous mutation in *KCNQ2* (c.790 T>A). The mutation is predicted to be pathogenic as it affects a conserved region essential for protein structure and function. This mutation with the clinical picture, fits a diagnosis of early onset epileptic encephalopathy. Parental testing revealed the mutation was maternally inherited, but present at much lower levels, suggesting somatic mosaicism. This may explain the history of benign neonatal seizures, in the context of a variable phenotype. The patient is currently two years old with well controlled epilepsy and developmental disability.   Our severe presentation of the patient with a more attenuated presentation in her mother, in the context of parental mosaicism, poses additional questions about the genotype–phenotype relationship of *KCNQ2, particularly with this mutation.* It could be proposed that mutations in *KCNQ2* have either a threshold effect, where a yet undetermined proportion of cells with the mutation must be present in order to have a phenotype, or that another gene is modifying the phenotype in our patient. Additionally, timing of expression may play a role, as benign epilepsy was present in our patient's mother and perhaps neonatal neurons are more susceptible and require a lower level of mutation to manifest as epilepsy. .

1357W

Genome-wide association scans of the brain's white matter microstructure reveals a pleiotropic relation with cardiovascular disease – Results from the ENIGMA- diffusion tensor imaging consortium. *N. Jahanshad, The Enhancing Neuro Imaging Genetics through Meta Analysis (ENIGMA) Consortium and DTI Working Group.* Neurology, University of Southern California, Marina del Rey, CA.

   Diffusion-weighted MRI (dMRI) reveals the brain's microstructure and connectivity using advanced metrics beyond those obtainable with standard anatomical MRI; dMRI offers insight into the properties of neural pathways, including axonal packing, myelination, and fiber connection patterns in the brain. Large-scale population studies of diffusion tensor imaging (DTI) are now underway, analyzing brain scans from many clinical and research dMRI protocols, to understand factors that affect white matter microstructure. One of the most common measures from DTI - fractional anisotropy (FA) - is a biomarker for numerous neuropsychiatric disorders, and is highly heritable in populations around the world. We present results from GWAS meta-analyses of FA derived from brain scans of over 10,000 individuals. Diffusion brain scans were analyzed using harmonized processing and quality-control protocols (http://enigma.ini.usc.edu/protocols/dti-protocols/). Several brain regions of interest are extracted from the protocols, of which 21 were found to be reliable and heritable across sites and protocols. These ROIs (including whole-brain average FA) were used for the GWAS; all ROI measures are bilaterally averaged across the left and right hemispheres. The genotypic data from each cohort were quality-controlled and imputed to the 1000 Genomes reference panel. All cohorts computed ancestry multi-dimensional ancestry scores with harmonized protocols. GWASs were conducted on all 21 ROIs. Corrections for sex, age (linear and quadratic effects) and their interactions were included. An additional covariate was included in the analysis for sites with patients and healthy controls. Patients included individuals with ADHD, Alzheimer's disease, bipolar disorder, Parkinson's disease and schizophrenia. The discovery sample included CEU individuals scanned at over 30 sites around the world. Results of the GWAS meta-analyses reveal an association between the FA in the anterior corona radiata and a locus in the *BCHE* gene, previously found to have strong influences over cardiovascular and metabolic risk factors. We report these results and present findings for many historically "candidate" SNPs for psychiatric disorders previously reported to affect FA in single-site studies. We relate findings to known biological and developmental processes affecting brain connectivity, and report the genetic covariation with other brain traits, as well as neuropsychiatric and cognitive phenotypes.

1358T

Mapping the effects of common variants within the human cortex: Results from the ENIGMA consortium GWAS meta-analyses of cortical thickness and surface area. *S.E. Medland, The Enhancing Neuro Imaging Genetics through Meta-Analysis (ENIGMA) Consortium.* Psychiatric Genetics, Queensland Institute of Medical Research, Brisbane, Australia.

At the individual level, there is substantial variation in cortical thickness and surface area which has been implicated in a wide range of psychiatric and neurological traits. Thinning of the cortical starts in childhood and continues across the lifespan, whereas cortical surface area expands until about 12 years, remains relatively stable through middle age and then decreases. While cortical thickness and surface area are both strongly heritable, the two processes are genetically independent and there is little known about the loci influencing these morphological characteristics. Here we present results from GWAS meta-analyses of the thickness and surface area of cortical regions of interest derived from magnetic resonance imaging (MRI) scans from over 15,000 individuals.   Across cohorts, structural T1-weighted MRI brain scans were analysed locally using harmonized analysis and quality-control protocols (http://enigma.ini.usc.edu/protocols). All cortical parcellations were performed with the freely available and validated segmentation software. Cortical thickness and surface area were calculated for 68 (34 left and 34 right) cortical gray matter regions were visually inspected and statistically evaluated for outliers. The genotypic data from each cohort were quality-control and imputed to the 1000 genome reference panel and all cohorts computed ancestry multi-dimensional scores following harmonized protocols.   To improve measurement accuracy, the cortical measurements were averaged across the hemispheres resulting in the average thickness and surface area of 34 regions. We also analyzed two summary measures, average cortical thickness across regions and total surface area, resulting in a total of 70 cortical phenotypes. Corrections for sex, age (linear and quadratic effects) and their interactions were included in all GWAS analyses. For the regional measures corrections for the corresponding summary measures were also included in the GWAS to account for the omnibus effects of brain size.   The GWAS meta analyses presented provide an overview of the loci influencing univariate region level thickness and surface area. We also present the results of the multivariate analyses which focus on identifying patterns of genetic variation across regions. We relate these to known biological and developmental processes, examine the conservation of these loci and characterize the genetic covariation with psychiatric, neurological and cognitive phenotypes.

1359F

Genetics of trigeminal neuralgia: Insight from 15 families and whole exome sequencing. *S.J. Mosca[1], Z.H. Kiss[2], A.M. Innes[1,3].* 1) Department of Medical Genetics, University of Calgary, Calgary, Alberta, Canada; 2) Department of Clinical Neuroscience, Hotchkiss Brain Institute, University of Calgary, Calgary, Alberta, Canada; 3) Alberta Children's Hospital Research Institute, Calgary, Alberta, Canada.

Trigeminal neuralgia (TN) (OMIM 190400) is a rare neuropathic pain condition typically characterized by intense unilateral paroxysmal attacks in the trigeminal nerve distribution, with an incidence of about 5 per 100,000 person-years. TN, which has also been called the "suicide disease", has been described as the worst pain known to man. The pathophysiology is thought to be related to neurovascular compression and demyelination of the nerve root entry zone. Treatment of TN includes anticonvulsant medications and surgeries that either relieve compression of the trigeminal nerve or deafferent the nerve. An enhanced understanding of the underlying disease mechanisms could inform future therapeutic considerations.   Evidence for an underlying genetic component includes a small number of reported pedigrees, with a familial form of TN accounting for about 1-2% of cases. The previous reports of familial TN have demonstrated that segregation of the disease is consistent with autosomal dominant inheritance with reduced penetrance. In addition, there is a co-occurrence of TN in certain Mendelian disorders, specifically Charcot-Marie-Tooth disease (CMT), a disorder of impaired myelination. Further evidence of dysmyelination in TN comes from the known association with multiple sclerosis (MS), as about 1-2% of MS patients develop TN.   Identifying genes predisposing to TN using conventional genetic techniques has been limited due to age-related reduced penetrance and typically small numbers of living affected individuals, but cohort analysis using whole-exome sequencing (WES) provides a new avenue of inquiry. Here we report our experience with a cohort of patients with familial TN, ascertained from a single academic neurosurgical practice. We have reviewed 15 affected individuals with a positive family history of TN. In three of these families at least some affected individuals had MS, but in most families MS was not present. Families had two to four affected individuals and were generally all consistent with autosomal dominant inheritance with reduced (and age-dependent) penetrance. 10 families presented for further genetic assessment, and interrogation of 3 common CMT-causing genes (PMP22, MPZ, GJB1) was negative in all families. We proceeded to WES on a proportion of cases (8 individuals from 5 families). Preliminary approaches and results from the data analysis will be discussed.

1360W

Searching for the missing genetic component of amyotrophic lateral sclerosis using a candidate gene approach. *E.P. McCann[1], K.L. Williams[1], J.A. Fifita[1], I.S. Tarr[1], Q. Zhao[2], D.B. Rowe[1], N. Wray[2], G.A. Nicoloson[1,3], I.P. Blair[1].* 1) Department of Biomedical Sciences, Faculty of Medicine and Health Sciences, Macquarie University, Sydney, New South Wales, Australia; 2) Centre for Neurogenetics and Statistical Genomics, Queensland Brain Institute, Unviersity of Queensland; 3) ANZAC Research Institute, University of Sydney, Concord Hospital, Sydney, New South Wales, Australia.

   Amyotrophic lateral sclerosis (ALS, also known as Lou Gehrig's disease) is a debilitating and ultimately fatal neurodegenerative disease. Roughly 10% of cases are hereditary (familial ALS), while the remainder occur sporadically. The only known causes of ALS are gene mutations, with over twenty genes implicated to date. Gene mutations have driven the discovery of much functional knowledge underlying ALS. However, known mutations account for just two thirds of familial ALS and 11% of sporadic ALS. Thus, there is a pressing need to uncover the remaining proportion of the genetic causes underlying ALS. Classic gene discovery efforts in large ALS families have identified most known currently known ALS genes. The remaining ALS families are generally small and often exhibit incomplete penetrance of disease, complicating ALS gene discovery. Thus, we propose a candidate gene approach for identifying the remaining ALS mutations. Custom bioinformatics pipelines using the R interface have been developed to parse patient exome sequence data for shared variants in families or candidate genes, followed by Fisher's Exact testing for associations with ALS. Identified variants are then prioritised using a combination of the following: absence from control databases, gene function, predicted functional consequence, amino acid conservation, natural variation and variation tolerance of the gene, and presence in replication cohorts. We first investigated candidates proposed based on genome wide association data (n=4 genes), transgeneic mouse models (n=1 gene) or functional evidence (n=1 gene). This provided strong evidence implicating one of these genes in ALS. Further, shared variant analysis using exome data from eight ALS families comprised of multiple affected individuals identified between 26 and 112 candidate ALS mutations in each family. By applying this prioritisation approach to the first family, we have reduced the number of potential causal variants from 26 to 8 high priority and 2 medium priority variants. Identification of causal ALS mutations using this approach will enhance our understanding of ALS pathogenesis and inspire follow up studies investigating mutant effects on protein structure and function. Such discoveries are also imperative for providing patients and families the opportunity for diagnostic testing, which may be vital for future personalised therapeutics, as well as predictive testing or pre-implantation embryonic screening.

1361T

Phenotypic variability of *de novo* **mutations in** *ASXL3. S. Walker[1], R.K.C. Yuen[1], B. Thiruvahindrapuram[1], T. Woo[1], M. Woodbury-Smith[2], R. Dad[3], P. Szatmari[4], B.A. Minassian[3], S.W. Scherer[1].* 1) The Centre for Applied Genomics, Genetics and Genome Biology, Hospital for Sick Children, Toronto, Ontario, Canada; 2) Department of Psychiatry & Behavioural Neurosciences, Faculty of Health Sciences, McMaster University, Hamilton, Ontario, Canada; 3) Division of Neurology, Genetics and Genome Biology, The Hospital for Sick Children, University of Toronto, Ontario, Canada; 4) Centre for Addiction and Mental Health, The Hospital for Sick Children, University of Toronto, Toronto, Canada.

   Bainbridge Ropers syndrome is an autosomal dominant disorder characterized by growth retardation, psychomotor delay, feeding difficulties and dysmorphology. The syndrome presents with an overlapping but distinct phenotype to Bohring-Opitz syndrome, which is caused by *de novo* mutations in *ASXL1*. Brainbridge-Ropers syndrome has been attributed to mutations in *ASXL3*, with all mutations resulting in premature truncation of the protein and arising *de novo* in affected cases. *ASXL3* (Additional sex combs-like 3) is a human homologue of the Drosophila gene asx and is involved in chromatin modification and transcription regulation. To date, 10 cases with *de novo* loss of function mutations in *ASXL3* have been published with a further 10 cases being described in DECIPHER. In 2014, *de novo* truncating mutations were also identified from exome sequencing in Autism Spectrum Disorder (ASD) cohorts. All but one of the mutations found are in exon 11 or 12, but are located throughout the protein since these two exons encode 83% of the coding sequence. Nearly all cases have developmental delay and language difficulties but there is variable presentation of additional symptoms, including motor-delay and hypotonia, ASD, intellectual disability and microcephaly. Here we present two new cases with *de novo* loss of function variants in *ASXL3* with differing phenotypes. Case one is a 15 year-old boy diagnosed with intellectual disability (ID). His phenotype is also characterized by delayed language development, microcephaly, short stature and craniofacial dysmorphology. He also presents with myoclonus and psychomotor slowing in the absence of any history of hypotonia. Through exome sequencing, a *de novo* frameshifting substitution was detected in exon 11 which results in premature termination at amino acid 445 (p.Ser439Argfs*7). Case two is a 9 year-old boy diagnosed with ASD, ID and comorbid ADHD. He also has a history of language delay and gross motor vulnerabilities. Through whole genome sequencing of the child and his parents, a *de novo* single base substitution was detected in exon 12 that results in the introduction of a premature stop codon at amino acid 1636 (p.Gln1636*). These two, along with other published cases, indicate that there is significant phenotypic variability arising from *de novo* truncating mutations in *ASXL3* and further assessment, including searching for other genetic contributors in these individuals, is necessary to correlate genotypes with phenotypes observed.

1362F

Identification of genes predisposing to syringomyelia associated with Chiari malformation I. *F. Ancot[1,2], P. Lemay[1,2], S.P. Knowler[3], G. Rouleau[4], C. Rusbridge[3], Z. Kibar[1,2].* 1) Sainte Justine Hospital Research Center, Montréal, Canada; 2) University of Montréal, Canada; 3) School of Veterinary Medicine and University of Surrey, Surrey, UK; 4) Montréal Neurological Institute and McGill University.

Chiari I malformation (CMI) is a common congenital abnormality of the craniovertebral junction (CVJ) affecting 1 in 1280. It is characterized by a descent of the cerebellar tonsils into the foramen magnum, often in association with a fluid filled cavity within the spinal cord called syringomyelia (SM). The exact pathogenesis of SM associated with CMI remains largely unknown. SM has emerged as one of the most common spinal cord diseases affecting toy breed dogs and as in humans it is mostly associated with Chiari-like malformation (CM). CM is ubiquitous in the Cavalier King Charles spaniels (CKCS) however not all dogs develop SM. To better understand the pathogenesis of SM/CM and attempt to predict its risk, there is a necessity to identify its genetic cause(s) in order to reduce or eliminate this condition in the numerous affected breeds. SM/CM has a complex inheritance. To investigate the genetics of SM/CM, we adopted a quantitative trait locus (QTL) approach where a total of 27 cranial measurements were taken in 65 CKCS dogs (including 33 SM unaffected) and were subjected to a whole-genome association study using the Illumina CanineHD beadchip array. Significant associations were identified in 2 candidate genomic regions of 0.8Mb on CFA26 and of 0.9Mb on CFA22.We have re-sequenced these 2 candidate regions using the SeqCap developer EZ and relaxed baits designed by Roche Nimblegen custom group and refined a significantly associated haplotype of 0,4 Mb on CFA26. Further bioinformatics and functional validation of associated variants residing in this haplotype is currently underway. Our study will help better understand the molecular pathogenic mechanisms underlying SM/CM and provides an entry point for identification of genes predisposing to SM/CMI in humans.

1363W

Polygenic overlap between amyotrophic lateral sclerosis and schizophrenia. *R.L. McLaughlin[1,2], D. Schijven[3,4], W. van Rheenen[3], K.R. van Eijk[3], M. O'Brien[1], R. Kahn[4], R.A. Ophoff[4,5,6], A. Goris[7,8], D.G. Bradley[1], A. Al-Chalabi[9], L.H. van den Berg[3], J.J. Luykx[3,4,10], O. Hardiman[2], J.H. Veldink[3], Project MinE GWAS Consortium, Schizophrenia Working Group of the Psychiatric Genomics Consortium.* 1) Smurfit Institute of Genetics, Trinity College Dublin, Dublin, Ireland; 2) Academic Unit of Neurology, Trinity Biomedical Sciences Institute, Dublin, Ireland; 3) Department of Neurology and Neurosurgery, Brain Center Rudolf Magnus, University Medical Center Utrecht, Utrecht, The Netherlands; 4) Department of Psychiatry, Brain Center Rudolf Magnus, University Medical Center Utrecht, Utrecht, The Netherlands; 5) Department of Human Genetics, David Geffen School of Medicine, University of California, Los Angeles, CA, USA; 6) Center for Neurobehavioral Genetics, Semel Institute for Neuroscience and Human Behavior, University of California, Los Angeles, CA, USA; 7) KU Leuven - University of Leuven, Department of Neurosciences, Experimental Neurology and Leuven Research Institute for Neuroscience and Disease (LIND), B-3000 Leuven, Belgium; 8) VIB, Vesalius Research Center, Laboratory of Neurobiology, B-3000 Leuven, Belgium; 9) Maurice Wohl Clinical Neuroscience Institute, King's College London, Department of Basic and Clinical Neuroscience, London, United Kingdom; 10) Department of Psychiatry, Hospital Network Antwerp (ZNA) Stuivenberg and Sint Erasmus, Antwerp, Belgium.

Amyotrophic lateral sclerosis (ALS) is a complex neurodegenerative disease characterized by rapid-onset loss of upper and lower motor neurones, resulting in progressive paralysis and death from respiratory failure, typically within 3-5 years of symptom onset. Schizophrenia is a neuropsychiatric disease with positive symptoms, negative symptoms and impairment over a broad range of cognitive abilities. We have recently shown that schizophrenia occurs with a higher frequency than expected in the pedigrees of ALS patients, suggesting an aetiological relationship between both diseases. Substantial SNP-based heritabilities and variance explained by polygenic risk scores (PRS) indicate polygenic components to both diseases. Using linkage disequilibrium score regression with summary statistics for GWAS of ALS and schizophrenia comprising over 100,000 unique individuals, we estimated the genetic correlation between ALS and schizophrenia derived from these polygenic components to be 14.3% (95% confidence interval 7.05-21.6; p = 1×10[-4]). We supported this estimate with analysis of schizophrenia PRS in a target of ALS cases without shared and related individuals in the schizophrenia dataset. Up to 0.12% of the variance in ALS was explained by PRS calculated on schizophrenia-associated alleles (p = 8.4×10[-7]). We leveraged the apparent pleiotropic relationship between ALS and schizophrenia to identify five potential novel ALS-associated genomic loci at conditional false discovery rate < 0.01. Diagnostic misclassification in the schizophrenia cohort did not contribute significantly to our observations (BUHMBOX p = 0.94) and we estimated that 4.86% (2.47-7.13%) of ALS cases would need to be misdiagnosed as schizophrenia in order to observe our genetic correlation estimate under a true genetic correlation of 0%. Our results indicate that the lifetime risk for comorbid ALS and schizophrenia increases from 1 in 40,000 to 1 in 34,336, which would require an incident cohort of 16,488 ALS patients to observe epidemiologically. Our findings suggest shared underlying biology between ALS and schizophrenia which will direct novel approaches in research and therapeutic development.

1364T

Use of NINDS Repository DNA samples in genomic studies available through dbGaP: A source of enhanced-annotation of biospecimens publicly available for neurological disorders research. *C.A. Pérez[1], S. Heil[1], J. Santana[1], A. Amberson[1], A. Green[1], R. Zhang[2].* 1) NINDS Repository, Coriell Institute for Medical Research, Camden, NJ; 2) NIH-NINDS, Bethesda, MD.

The burden of neurological disorders is a serious health concern and presents a massive challenge to healthcare systems globally. Studies aimed at identifying such pathogenic mechanisms will accelerate discovery of disease-specific genetic markers, the development of tools for monitoring disease onset and progression, and the implementation of therapies. The National Institute of Neurological Disorders and Stroke (NINDS) Repository is a public resource established to provide a centralized and open resource of DNA and lymphoblastoid cell lines with their corresponding de-identified clinical and phenotypic data. NINDS Repository samples cover a diverse population of neurological patients and neurologically normal controls. Since its establishment, biomaterials from more than 44,000 individuals with cerebrovascular diseases, Parkinsonism, motor neuron diseases, epilepsy, Tourette syndrome, Dystonia, and neurologically-normal controls have been submitted to the repository and more than 34,500 unique samples have been successfully banked in the NINDS Repository and are available via its online catalog (http://catalog.coriell.org/1/NINDS). To aid high-throughput gene discovery, the NINDS Repository offers disease- and neurologically-normal control panels of genomic DNA samples in 96-well plate formats as well as custom plate design services. As a result, since its inception back in 2002, more than 6,500 samples from the NINDS Repository have been used in GWAS, SNP, CNV, or sequencing studies and the results of such studies has been deposited in dbGaP, a NIH/NLM-sponsored repository for restricted-access data from studies investigating the interaction of genotype and phenotype. dbGaP, the Database of Genotypes and Phenotypes is available online (http://www.ncbi.nlm.nih.gov/gap). The NINDS Repository regularly monitors new dbGaP studies to identify those that include genomic information about NINDS Repository samples. In addition, a faceted-search tool in the Coriell Biorepositories online catalog allows users to filter samples of interest to identify those with additional genomic characterization data in dbGaP. This cross-referencing of the NINDS repository and dbGaP databases allows NINDS Repository users to access additional characterization data for thousands of biospecimens and complements the available samples and their associated clinical data.

1365F

Identification and characterization of multiple sclerosis associated loci in the continental Italian population. *M. Sorosina[1], N. Barizzone[2,3], F. Clarelli[1], S. Anand[4], S. Lupoli[5], F. Esposito[1,6], E. Mangano[4], R. Bordoni[4], V. Martinelli[6], G. Comi[6], M. Leone[2], D. Cusi[5], N.A. Patsopoulos[7,8,9,10], P. De Jager[7,8,9,10], G. De Bellis[4], S. D'Alfonso[2,3], F. Multiple sclerosis (MS) is a complex disorder characterized by myelin damage and neurodegeneration. Until now 103 susceptibility genetic loci have been identified though genome-wide association studies (GWAS), however they involved samples from several different countries that could have a different genetic and environmental predisposition. The aim of the present project was to identify and characterise the most associated regions in the Italian continental population following a multi-step approach. We started from two cohorts of Italian continental MS patients and healthy controls (HC): ITA$_{GWAS}$ (750 MS, 1291 HC) with available imputed genome-wide genotypes and ITA$_{iChip}$ (977 MS, 1000 HC) with genotyping data in 184 immune regions. To boost the statistical power of the study, the top associated signals of association (p<0.005) in the two Italian cohorts were meta-analysed with an imputation-based meta-analysed cohort of 20,512 cases and 19,145 HC of European ancestry from US. A total of 16 loci of association were identified (p<5x10^{-7}), and then tested for genetic association in a third Italian cohort (903 MS, 884 HC). This replication phase confirmed the association of two loci on chromosome 17 and chromosome 3, already known to be associated with the disease. To better characterize them, we did a target sequencing study in an Italian cohort of 600 MS and 408 HC using a pooling approach and comparing high-risk MS patients and low-risk HC according to their genetic burden. In the locus on chromosome 17, sequencing data revealed the presence of 203 SNPs associated with disease (best signal: p= 1.11x10^{-23}). We tested, based on their availability, these 203 SNPs for the existence of cis-eQTL association using Braineac, Gtex Portal and SNPExpress databases. We found an association of several SNPs with the expression of *EFCAB13* in brain tissues, while in immunological tissues we observed that a different gene, *TBKBP1*, is also regulated, with an opposite direction compared to brain. A total of 12 signals were identified by sequencing analysis in the intergenic locus on chromosome 3 with no eQTL associations for any of those SNPs. Concluding, we confirmed that two loci on chromosome 17 and 3 are highly associated also in the Italian population, and we better characterised the origin of these signals using next-generation sequencing approach. Moreover, we observed tissue-dependent regulatory functions, opening questions on the role of *EFCAB13* and *TBKBP1* in MS.

1366W

Genetic contributions to motor learning and spindle density through sleep: Recall by genotype investigation of ZNF804A. *M. Taylor[1], U. Bartsch[1], C. Hellmich[1], C. Durant[2], L. Corbin[3], M. Jones[1], N. Timpson[3].* 1) School of Physiology and Pharmacology, Bristol University, Bristol, Bristol, United Kingdom; 2) Clinical Research and Imaging Centre, Bristol University, Bristol, Bristol, United Kingdom; 3) MRC Integrative Epidemiology Unit at Bristol University, Bristol, Bristol, United Kingdom.

rs1344706 in *ZNF804A* was among the first genetic variants associated with schizophrenia and since then a number of studies have examined the influence of rs1344706 on cognition, brain structure and physiology. We used a Recall by Genotype (RbG) design implemented in the Avon Longitudinal Study of Parents and Children to investigate impacts of rs1344706 on sleep architecture, neurophysiology and sleep-dependent memory consolidation in healthy young adult homozygotes CC (n=12) and AA (n=14). We used a combination of Actigraphy and sleep diaries (collected over two weeks) to assert sleep wake cycles. Participants were monitored using controlled sleep laboratory polysomnography (PSG) on two nights. A motor sequence task (MST) was used to probe sleep-dependent memory consolidation. We ran a detection algorithm to quantify non- rapid eye movement neurophysiology characteristics including sleep spindles, slow waves and delta rhythms. Measures were inverse rank transformed and linear regression was used to test for between group differences. Actigraphy revealed similar rest-activity cycles between groups. As expected, we found no evidence for differences in sleep architecture (such as sleep latency, total sleep time, or time spent in sleep stages) between groups. There was evidence that the AA group performed worse (mean rank change in number of correct sequences = -0.86 95% CI -1.64, 0.09, p=0.03) and had a slower reaction time (mean rank change of button press latency = 0.79 95% CI 0.002, 1.58, p=0.05) on the MST. We found weak evidence for reduced spindle density (mean rank change of number of spindles per minute = -0.62 95% CI -1.39, 0.14, p=0.10) and delta frequency (mean rank change in time between delta events = -0.70, 95% CI -1.45, 0.05, p=0.07) in AA carriers. The overall pattern of association signal results suggested a reduction in coordinated neural activity which was complemented by impaired performance in the MST testing. Although current evidence is weak, findings here (along with the overall consistency across multiple PSG phenotypes) suggest that rs1344706 is likely to be correlated with finely measured neurological phenotypes during sleep. This work not only highlights the utility of RbG as an efficient design for following up genetic association signals, but has allowed direct comparison of animal model results to human experiments and development of functional interpretation of established gene effects.

1367T

Copy number variation in mesial temporal lobe epilepsy. *T.K Araujo[1], F.R. Torres[1], R. Secolin[1], A. Donatti[1], M.K.M Alvim[2], C.S. Rocha[1], M.E Morita[2], C. Yasuda[2], B.S. Carvalho[3], F. Cendes[2], I.L. Cendes[1].* 1) Department of Medical Genetics , School of Medical Sciences, University of Campinas – UNICAMP , Campinas, SP, São Paulo, Brazil; 2) Department of Neurology; School of Medical SciencesUniversity of Campinas – UNICAMP , Campinas, SP, São Paulo, Brazil; 3) Department of Statistics, Institute of Mathematics, Statistics and Scientific Computing; University of Campinas – UNICAMP and Brazilian Institute of Neuroscience and Neurotechnology, Campinas, SP, BRAZIL.

Epilepsy is a common brain disorder characterized by recurring seizures. Mesial temporal lobe epilepsy (MTLE) is the most common form epilepsy in adults and it is frequently associated with medically refractory seizures. Most patients with MTLE do not present positive family history of the disease, which is believed to have a complex mode of inheritance. Copy number variations (CNV) have been identified in a wide-range of neurodevelopmental disorders, many of which are also associates with epilepsy. The objective of the present study was to investigate the distribution of CNVs in patients with MTLE. To date, we have studied a total 396 individuals, 198 patients with MTLE and 198 control subjects. CNVs were identified by array genomic hybridization (aGH) using the Affymetrix Genome-Wide Human SNP Array 6.0 (Affymetrix, Santa Clara, CA, USA). We considered only CNVs that were ≥ 100kb and that spanns 25 probes for deletion and 50 probes for duplications. We identified CNVs in several genomic hotspots, which were previously associated with different epilepsy syndromes including 1q21.1, 15q11.2, 15q13.3, 15q11–q13, 16p11.2, and 16p13.11. Furthermore, we identify many overlapping CNVs that are present in different patients (until 90 patients). The size of CNVs ranges between 245kb to 2840kb.We identified microdeletions and microduplications at the following chromosomal regions 1q21.2, 1p21.1, 2p11.2, 2q35, 3p12.2, 3q12.2, 3q26.1, 4q13.2, 5p15.33, 5p15.2, 5q13.2, 6p25.3, 7q35, 8p11.22, 8p23.1, 9p11.2, 9p12 p11.2, 9q13-q21.11, 10q11.21, 10q26.3, 11p11.12, 11q14.1, 12q14.2, 13q21.1, 14q11.2, 15q11.2, 15q11.1-q11.2, 15q13.2, 16p11.2, 17p13.3, 17q12, 17q2131, 19q13.31, 22q11.21 and 22q11.22. Although we are reporting here only preliminary findings and additional analysis are under way, we found evidence that CNVs may be an important genetic susceptibility factor involved in the pathogenesis of epilepsy syndromes with complex inheritance such as MTLE. Genetic overlap between epilepsy and schizophrenia, using GWAS summary statistics and raw genotypes. *S.S. Cherny[1,2,3], H. Gui[2], M. Li[1,2], P.C. Sham[1,2,3], L. Baum[1,2], P. Kwan[4,5].* 1) Psychiatry, Univ Hong Kong, Pokfulam, Hong Kong; 2) Centre for Genomic Sciences, University of Hong Kong; 3) State Key Laboratory of Brain and Cognitive Sciences, University of Hong Kong; 4) Department of Medicine & Therapeutics, Chinese University of Hong Kong; 5) Department of Neurology, Royal Melbourne Hospital, Australia.

   Epilepsy and schizophrenia both common disorders, and neurological and psychiatric illnesses, respectively. A patient suffering from epilepsy may have depression or other mental illnesses, and some forms of seizures may mimic the symptoms of psychosis. Better understanding of epilepsy may therefore provide insights on schizophrenia, and vice versa. However, genome-wide association studies (GWAS) of schizophrenia and epilepsy have identified no common genetic loci. In this study, summary statistics were obtained from both the Psychiatric Genomics Consortia (PGC) and International League Against Epilepsy (ILAE) Consortium on Complex Epilepsies meta-analyses of schizophrenia and epilepy. In addition, raw genotype data were employed from our own GWAS of schizophrenia and epilepsy on Chinese populations. To investigate the genetic relationship between the two disorders, we calculated the overall genetic correlation by LD-score regression analyses and polygenic risk scores (PRS) projected on each other. In addition, we searched for shared susceptibility genetic loci by cross-phenotype analyses on three different levels (SNPs, genes, and gene-sets). A non-significant very low genetic correlation (r=-0.01) was found between these two disorders. PRS on different *p*-values for one phenotype cannot predict the other one. Genetic sharing was only found for one SNP located at 2p16.1 locus. These negative findings may partially be due to low power of the epilepsy meta-analysis GWAS, which only explained 7% of phenotype variance. Nevertheless, this also suggests the comorbidity between these two brain diseases is less likely to be caused by genetic sharing than other confounding environmental risk factors.

1369W

Effect of CYP2C19 polymorphisms on stiripentol administration in cases of Dravet syndrome. *T. Kouga[1], H. Osaka[1], H. Shimbo[2], K. Takano[2], M. Iai[2], S. Yamashita[2], T. Yamagata[1], A. Ishii[3,4], S. Hirose[3,4], K. Yamakawa[5].* 1) Department of Pediatrics, Jichi Medical University, Tochigi, Japan; 2) Division of Neurology, Kanagawa Children's Medical Center, Yokohama, Japan; 3) Department of Pediatrics, School of Medicine, Fukuoka University, Fukuoka, Japan; 4) Central Research Institute for the Pathomechanisms of Epilepsy, Fukuoka University, Fukuoka, Japan; 5) Laboratory for Neurogenetics, RIKEN Brain Science Institute, Saitama, Japan.

   [;**Objective**];Dravet syndrome (DS) is an intractable epilepsy characterized by the recurring febrile and afebrile seizures in early childhood. Stiripentol (STP), an inhibitor of cytochrome P450, increases plasma concentrations of concomitant antiepileptic drugs and showed efficacy in DS. An increase in blood concentration of clobazam (CLB) and its major metabolite, norclobazam (N-CLB), had been attributed to the antiepileptic efficacy of STP. STP increases the N-CLB through attenuation of its hydroxylation by CYP2C19. The objective is to investigate STP administration in cases of DS by comparing CYP2C19 allelic polymorphisms with clinical effects of STP. [;**Method**];CYP2C19 polymorphism were examined in eleven cases of DS.CYP2C19 has two main allelic polymorphisms, CYP2C19*2 and CYP2C19*3, in addition to the wild genotype, CYP2C19*1. The *2 variant derives from a single-nucleotide polymorphism (G to A), and creates an exon aberrant splice site resulting in aberrant splicing and out of frame transcription. The *3 variant derives from a single-nucleotide polymorphism (G to A), resulting in a premature stop codon. Each polymorphism were examined with clinical characteristics of the cases; age at the study period, body weight, mean dose and plasma concentration of valproate acid (VPA)/CLB off and on STP, mean plasma concentration of N-CLB off and on STP, degree of seizure reduction, and adverse effects of STP. [;**Result**];There were 3 cases of DS with wild type (*1/*1), 6 with intermediate type (*1/*2, *1/*3), and 2 with poor type of CYP2C19 polymorphisms (*2/*2, *2/*3). The N-CLB concentration/CLB dose ratio and N-CLB/CLB concentration ratio off STP were significantly higher in poor metabolizers. Three of 8 cases showed no effectiveness of STP regardless of the N-CLB concentration increase, and 1 of 3 cases showed effectiveness of STP regardless of N-CLB concentration decrease. In total, six of 11 cases with DS had >50% reduction in seizure frequency without significant differences over the CYP2C19 polymorphisms. [;**Conclusion**];This study demonstrated an effect of CYP2C19 polymorphisms on STP administration in cases of DS. There were cases of seizure reduction regardless of N-CLB concentration decrease on STP, which indicates a significant anti-convulsant action of STP in itself. N-CLB concentration decrease on STP was observed in 2 cases with *3 allelic polymorphisms. STP may partially restore the enzyme activity of CYP2C19*3.

1370T

NTRK2 is associated with multidrug-resistant epilepsy in European and African American populations. *L. Vazquez[1], B. Almoguera[1], E. Robbins[2], D. Dlugos[2], J. Connolly[1], F. Mentch[1], R. Pellegrino[1], F. Mafra[1], J. Garifallou[1], L. Tian[1], S. Manzi[3], P. Sleiman[1], H. Hakonarson[1].* 1) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Department of Neurology, Children's Hospital of Philadelphia, Philadelphia, PA; 3) Department of Pharmacy, Boston Children's Hospital, Boston, MA.

   Introduction: Up to 40% of patients with epilepsy do not respond to currently available antiepileptic treatment options. Although genetic factors are likely to play a role in drug-resistant epilepsy (DRE), no strong gene candidate has emerged yet. Our aim was to investigate the genetic factors involved in multidrug-resistant epilepsy.   **Methods:** Identification of subjects with DRE and responders was done using an EMR based algorithm, which mines EMR data for pertinent diagnostic and medication information. The algorithm was implemented at the Children's Hospital of Philadelphia, revealing positive predictive values of 84.6% for responders and 83.3% for DRE. It was validated in a research cohort at Boston Children's Hospital with a positive predictive value of 100%. We used the PGRN sequencing platform of 82 genes to sequence a cohort of 97 DRE, 337 drug-responders and 866 non-epilepsy controls. The effect of genetic variants on DRE was assessed in European Americans (EA) and African Americans (AA) separately comparing DRE versus drug-responders and DRE versus non-epilepsy controls. Single variant analysis, gene-based analysis of rare functional variants and meta-analysis were performed with raremetalworker and raremetal, correcting for cryptic relatedness and population structure.   **Results:** No significant results were found in the DRE versus drug-responders analysis. However, in the analysis of DRE versus non-epilepsy controls, *NTRK2* was significantly associated with DRE in both the single variant as well as the gene-based analyses. A rare missense variant, rs76950094 (minor allele frequency –MAF- of 0.0016) was associated with DRE with a p-value=4.94×10^{-8} (p-value in EA=1.19×10^{-4}; p-value in AA=1.10×10^{-4}, with a cutoff for significance of 1.31×10^{-5} after correcting for multiple testing). In the gene-based analysis, seven functional variants with MAF<0.05 were associated with DRE (p-value=5.65×10^{-5}; with a cutoff for significance set as 1.87×10^{-4} after correcting for 276 genes).   **Conclusion:** *NTRK2* is involved in the development and maturation of the central and the peripheral nervous systems and has a role in neuronal excitability. The identification of variants in the *NTRK2* gene in association with DRE may contribute to a better understanding and improved therapeutic management of these patients in the future.

1371F

Whole exome sequencing implicates VLDLR as a risk factor for cerebral palsy. *J. Connolly[1], J. Li[1], F. Mentch[1], Y. Guo[1], D. Abrams[1], M. Oskui[2], M. Shevell[2], S. Lafleur[2], L. Tian[1,3], H. Hakonarson[1,3,4].* 1) Ctr Applied Genomics, Children's Hosp Philadelphia, Philadelphia, PA; 2) Department of Neurology, McGill University, Montreal, Canada; 3) Division of Human Genetics Dept. of Pediatrics, Perelman School of Medicine, Philadelphia, PA; 4) Dept. of Pulmonary Medicine, CHOP, Philadelphia, PA.

   Several recent studies have suggested a prominent role for genomic factors in susceptibility to cerebral palsy (CP). To address the genetic underpinnings of CP, we conducted a genome-wide association study (GWAS) on our cohort of 697 cases and >2,000 controls. While no single SNP reached genome-wide significance, several leading signals were notable as functional candidates, and were used to inform subsequent analyses. Next, we selected 65 patients for whole exome sequencing (WES). Exclusion criteria for cases were prematurity, complications of pregnancy, complications of labor, and co-morbidity with known Mendelian disorders. Results were compared against 688 internal controls, selected on the basis of stringent exclusion criteria including pre-/post-/peri-natal complications, and a wide range of neurological deficits. After quality control filtering, we analyzed subjects of European ancestry and African American subgroups separately. We conducted gene-wise tests on the CP phenotype, using 7 different algorithms implemented in software package EP-ACTS (Efficient and Parallelizable Association Container Toolbox) to compare cases *versus* controls. Then we performed meta-analysis of the two groups. The gene *VLDLR*, encoding for Very Low Density Lipoprotein Receptor, came out with P-value < 5×10^{-5} in 6 out of 7 tests in subgroup of European ancestry and in 2 tests in African Americans. In all instances, meta-analyses yielded a more significant P-value for each type of test. Mutations in this gene have been associated with cerebellar hypoplasia and disequilibrium syndrome, suggesting functional plausibility and valuable insight into possible etiology of CP.

Early-onset epilepsy: Diagnostic yield and treatment impact of whole-exome sequencing. *I. Guella[1], M.B. McKenzie[1], S.E. Buerki[2], E. Toyota[2], S. Adam[2], M. Van Allen[3], G. Sinclair[4], G. Horvath[4], C.D. Van Karnebeek[4], P. Eydoux[5], D. Evans[1], A. Datta[2], C. Boelman[2], L. Huh[2], A. Micholaus[2], B. Bjornson[2], T. Nelson[6], M. Connolly[2], M.K. Demos[2], M.J. Farrer[1].* 1) Centre for Applied Neurogenetics, Djavad Mowafaghian Centre, Dept of Medical Genetics, University of British Columbia, Vancouver, British Columbia, Canada; 2) Division of Neurology, Department of Pediatrics, University of British Columbia and BC Children's Hospital, Vancouver, BC, Canada; 3) Department of Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 4) Division of Biochemical Diseases, Department of Pediatrics, University of British Columbia and BC Children's Hospital, Vancouver, BC, Canada; 5) Department of Pathology and Laboratory Medicine, University of British Columbia and British Columbia Children's Hospital, Vancouver, BC, Canada; 6) Department of Pathology and Laboratory Medicine, Children's and Women's Health Center of British Columbia, Vancouver, BC, Canada.

Epilepsy is one of the most common neurological disorders and affected children are at increased risk of having developmental delay, autism and a psychiatric illness. Modern genomic technologies, such as targeted next generation sequencing and whole exome sequencing (WES), enable the identification of pathogenic variants in 10 – 78 % of selected patients with unexplained epilepsy. The clinical impact is significant and includes an earlier diagnosis of disorders with specific treatment implications. Exome trio intersections, of parents and children, may identify novel causes of disease. Here, we report results on 148 patients with early onset epilepsy (≤ 5 years), evaluating diagnostic yield, time to diagnosis and treatment impact. WES was performed in 109 retrospective (epilepsy > 6 months) and 39 prospective (epilepsy < 6 months) patients. Detailed clinical data was abstracted in a REDCap database. WES was performed using Ion Proton™ System within 2 weeks of receiving samples. Average coverage was >80x across all samples. Initial reporting was restricted to ~550 genes previously implicated in epilepsy. Putative causative mutations were validated by Sanger sequencing and by parental testing. In patients with no immediate genetic diagnosis we also performed proband-parent trio-based WES analyses. We established a genetic diagnosis in 23% of patients which included the identification of variants in 25 known epilepsy genes. A possible diagnosis was identified in an additional 11% of patients for whom supporting evidence is pending. Moreover, genetic diagnosis had potential treatment implications in 18 probands (12%) which resulted in anti-seizure medication changes and/or treatment with specific therapies. Time to genetic diagnosis from enrollment with genetic counselling averaged 46 days for the first 50 patients studied. The analysis of 22 family trios is currently ongoing and may further increase diagnostic yield. Clinical utility of WES in this epilepsy patient cohort was supported by a timely potential diagnoses in 34% of patients, with a higher yield in the prospective cohort compared to the retrospective cohort (44% vs 32%). The protocol accelerates triage in pediatric epilepsy, for patients and their families, and will likely improve patient care and potentially outcomes.

1373T

Whole exome sequencing approach for the identification of pain-related mutations in an Italian cohort of familial and early-onset patients affected by idiopathic peripheral neuropathy. *F. Martinelli Boneschi[1,7], A. Zauli[1], S. Santoro[1], M. Marchi[2], M. Sorosina[1], L. Grevendonk[1], D. Cazzato[2], R. Lombardi[2], C.G. Faber[3], M.M. Gerrits[4], R. Almomani[4], J.G.J. Hoeijmakers[3], I.S.J. Merkies[3], H. Fadavi[5], R. Malik[5], D. Ziegler[6], G. Boenhof[6], G. Comi[1,7], S.D. Dib-Hajj[8], S.G. Waxman[8], G. Lauria[2].* 1) Laboratory of Human Genetics of Neurological Disorders, San Raffaele Scientific Institute, Milan, IT; 2) Neuroalgology Unit, Neurological Institute Carlo Besta, Milan, IT; 3) Department of Neurology, Maastricht University Medical Center, Maastricht, NL; 4) Clinical Genetics, Maastricht University Medical Center, Maastricht, NL; 5) Centre for Endocrinology and Diabetes, University of Manchester and Central Manchester NHS Foundation Trust, Manchester, UK; 6) German Diabetes Center, Medical Faculty Heinrich Heine University, Düsseldorf, DE; 7) Department of Neurology, San Raffaele Scientific Institute, Milan, IT; 8) Department of Neurology, Yale University School of Medicine, New Haven, CT, USA.

Neuropathic pain is a frequent feature of peripheral neuropathy causing a significant impact on patients' quality of life and health care costs. The Consortium of 9 partners from 6 countries coordinated by IRCCS Neurological Institute Carlo Besta is engaged in the project for Probing the Role of Sodium Channels in Painful Neuropathies (the PROPANE STUDY). We propose to use a whole exome sequencing approach in a cohort of familial and early-onset painful neuropathic patients to identify rare variants causative of the disease, to achieve a stratification of patients at high-risk for neuropathic pain and to enhance our understanding of underlying mechanisms. Inclusion criteria were (i) families with ≥2 affected members or (ii) patients with an early-onset of disease (<40 years). Ten Italian families with a total of 29 patients and 11 healthy controls, as well as 36 early-onset Italian patients were recruited. DNA extracted from peripheral blood was enriched using the Agilent SureSelect Human All Exon QXT V5. Paired-end sequencing (2x101bp) was performed on Illumina Hiseq 2500 platform. Reads were trimmed and aligned with BWA using hg19 as reference genome. Variants were identified using GATK pipeline and annotated using SnpEff suite. We focused on variants according to their depth (<6), evolutionary conservation (GERP++RS>0), mutation frequency (<0.01 for MODERATE and <0.05 for HIGH impact variants), in silico predicted effect (Polyphen2 >0.15, SIFT <0.05, and MetaSVM >0) and segregating under a transmission model according to the pedigree in familial cases or shared among patients in the early-onset sporadic cohort. Until now we sequenced 23 subjects belonging to 8 families and 36 early-onset patients reaching a mean coverage of 90X. In two large families, characterized by an autosomal dominant transmission, a mean of 17.000 variants of HIGH and MODERATE impact were identified. Following a dominant transmission model, a total of 49 and 40 rare/novel variants with a putative functional role were identified respectively in the first and second family. Analyses on additional families and early-onset cases are ongoing at present time. The application of exome-sequencing in familial or atypical cases of painful neuropathy is effective in identifying causative genes, and can help to better understand the pathophysiology of the disease.

1374F

Exome sequencing identifies targets in ophthalmoplegic myasthenia gravis. *M. Nel[1], M. Jalali Sefid Dashti[2], S. Prince[3], J. Gamieldien[2], J.M. Heckmann[1].* 1) Department of Medicine, University of Cape Town, South Africa; 2) South African National Bioinformatics Institute, University of the Western Cape, South Africa; 3) Department of Human Biology, University of Cape Town, South Africa.

Background: We described a distinct ophthalmoplegic complication (OP-MG) in myasthenia gravis (MG) patients of African-genetic ancestry that remains treatment-resistant. A previous candidate approach identified 2 African-specific gene expression traits linked to OP-MG, decay accelerating factor (*DAF*) and transforming growth factor beta-1 (*TGFB1*). We speculate that OP-MG may result from a genetic network activated in extraocular muscles (EOMs) by autoimmune MG, in these and as yet unknown targets. Objective: To use the unbiased approach of whole exome sequencing (WES) in a selected cohort of juvenile-onset OP-MG vs control MG individuals to discover OP-MG susceptibility variants. Method: Next-generation sequencing (Agilent v5, Otogenetics, USA) of the coding and untranslated regions (UTRs) was performed on genomic DNA from 15 African ancestry individuals at 50x coverage (11 OP-MG vs 4 control MG). Read alignment and variant calling were carried out. Filtering strategies were employed to prioritize variants for Sanger sequencing in a replication sample (14 OP-MG, 46 control MG). Gene expression of top variants was assessed by qPCR in a phenotype-specific cell culture model. Results: We identified 356 potentially pathogenic variants (>60% in 3' UTRs) which were more common in OP-MG (MAF ≥0.27) compared to control MG (MAF ≤0.12). Two filtering strategies were then applied: unbiased prioritization of variants in genes transcribed in EOM according to strength of association with OP-MG (p ≤0.05), and functional filtering of variants related to biological relevance for known MG disease pathways. This approach identified 13 variants associating with OP-MG in the discovery set; the top candidate, a 3'UTR variant in *DDX17*, is implicated in myogenesis and was also shown to be associated with OP-MG in the replication set (OR 2.4, p=0.014). Consistent with the hypothesis that OP-MG is a polygenic problem (multiple genetic risk loci with small effect sizes), we found a weighted genetic risk score for candidate and unbiased variants positively correlated with OP-MG. Preliminary results show that our "muscle model" was informative in showing altered transcript levels in at least 2 of our gene candidates. Discussion: Exome sequencing in a well-characterized discovery set has identified several potentially pathogenic variants that associate with OP-MG. Preliminary results suggest novel gene variants involved in myogenesis may cross-talk with known MG-associated pathways.

1375W

Rapsyn N88K mutation is not a prevalent cause of Congenital Myasthenic Syndrome in Iranian patients. *S. Parvizi Omran[1], P. Karimzadeh[2,3], R. Parvizi Omran[4], M. Houshmand[5].* 1) Department of Biology, Damghan Branch, Islamic Azad University, Damghan, Iran; 2) Department of Pediatric Neurology, Shahid Beheshti University of Medical Sciences, Tehran, Iran; 3) Pediatric Neurology Research Center, Shahid Beheshti University of Medical Sciences, Tehran, Iran; 4) Department of Biology, Concordia University, West, Montreal, Canada; 5) Department of Human Genetics, National Institute of Genetic Engineering and Biotechnology, Tehran, Iran.

Congenital myasthenic syndromes (CMSs) are considered as a rare heterogeneous group of disorders that cause dysfunction of neuromuscular transmission. In CMSs impaired neural transmission have identified in pre-synaptic, synaptic and most frequently in post-synaptic stages. Mainly, post-synaptic CMSs are caused by deficiency or kinetic abnormalities of acetylcholine receptor (AChR). The major clinical signs of CMSs are hypotonia, episodic apnea, ptosis and fatigability that appear in early infancy or childhood. Mutations in *RAPSN* [MIM 601592] are the second most common cause of autosomal recessive post-synaptic CMSs. In the present study, were aimed at identifying mutations in *RAPSN* gene in 18 patients with confirmed post-synaptic CMSs. For the mutation screening, we used polymerase chain reaction (PCR) to amplify exon 2 of *RAPSN* gene, then direct DNA sequencing was used for mutation identification. All the patients were negative for mutations c.264C/A (p.Asn88Lys), c.271C/T (p.Arg91Cys), c.280G/A (p.Glu94Lys), c.490C/T (p.Arg164Cys), and c.493G/A (p.Val165Met) of *RAPSN* gene. We found a previously reported polymorphism c.193-15C/T (IVS1-15C/T) in a 4-year-old boy , while there is no relation between the known polymorphism to CMSs. Regarding to these findings, N88K is not a recurrent mutation in CMSs patients from Iran. It could be concluded that mutations spectrum of *RAPSN* gene in CMSs is population specific. Further studies that screen RAPSN gene full sequence for possible variations are warranted to more elucidate mutational basis of CMSs in Iran. **Keywords:** Congenital mysthenic syndrome; Rapsyn; Mutation N88K; Neuromuscular disease.

Whole exome sequencing of multiplex families with late onset Alzheimer's disease identifies rare coding variants in known candidates and novel genes. *S. Rolati[1], H.N. Cukier[1,2], B.W. Kunkle[1], K.L. Hamilton-Nelson[1], N.K. Hofmann[1], M.A. Kohli[1], P.L. Whitehead[1], J.M. Vance[1,3], M.L. Cuccaro[1,3], R.M. Carney[1,4], J.R. Gilbert[1,3], E.R. Martin[1,3], G.W. Beecham[1,3], J.L. Haines[5], M.A. Pericak-Vance[1,2,3].* 1) John P. Hussman Institute for Human Genomics, University of Miami, Miami, FL; 2) Department of Neurology, University of Miami, Miami, FL; 3) Dr. John T. Macdonald Foundation Department of Human Genetics, University of Miami, Miami, FL; 4) Mental Health and Behavioral Sciences Service, Miami Veterans Affairs, Miami, FL; 5) Department of Epidemiology & Biostatistics, Case Western Reserve University, Cleveland, OH.

Alzheimer's disease is a neurodegenerative disorder that can present with either an early (<65 years) or late (65+ years) age of onset. While greater than 25 loci have been associated with late onset Alzheimer's disease (LOAD), there is still a large number of genetic factors that have yet to be revealed. We performed whole exome sequencing (WES) on 28 multi-generational LOAD families to identify rare LOAD risk variants. The pedigrees chosen display a dominant inheritance pattern and have an average of eight Alzheimer affected subjects. Between 1-9 individuals were sequenced for each family. Variants were filtered for segregating, nonsynonymous, and loss-of-function rare variants (MAF <0.01). Variants were given a high priority if they were predicted to have a functional consequence as represented by a high CADD score (>15), fell within a family-specific or previously reported linkage peak, and by comparing results across families. Following WES, 10 families were identified to have variants of interest located in peak LOD regions (LOD=1.02-2.95). Examples include a family with a variant co-segregating in 11 AD individuals in *TTC3*, a regulator of Akt signaling (LOD=2.66, Cukier, et al, 2016), and a different family with 10 affected individuals carrying an alteration in *CD163L1*, a gene involved in immunity and endocytosis (LOD=2.95). Another segregating variant was identified in the tumor suppressor gene *CTNNA1*, which encodes a catenin protein involved in the cerebral cortex (LOD=2.36). We also discovered segregating variants in the reported LOAD gene *SORL1*. When comparing variants across families, genes with alterations identified in more than one family include *PLEKHG5*, a gene reported to be involved in Charcot-Marie-Tooth Disease as well as distal spinal muscular atrophy, and *THBS2*, which is involved in synaptogenesis in the central nervous system. In conclusion, WES of large LOAD pedigrees identified genes with rare variants co-segregating with disease, some of which were identified in more than one family. Given the known functions of some of these genes, they have the potential to be involved in AD risk.

1377F

Familial essential tremor candidate genes have been identified by whole exome sequencing study. *M. Sen[1,2], I.O. Tuncay[1,2], S. Yaylacı[2], O.E. Onat[3], C. Ulusoy[4], C. Akbostancı[4], O. Dogu[5], H. Topaloglu[6], T. Ozcelik[2,3], A.B. Tekinay[1,2].* 1) Neuroscience, Bilkent University, Ankara 06800, Turkey; 2) Institute of Materials Science and Nanotechnology, National Nanotechnology Research Center, Ankara 06800, Turkey; 3) Department of Molecular Biology and Genetics, Bilkent University, Ankara 06800, Turkey; 4) Department of Neurology, Faculty of Medicine, Ankara University, Ankara 06100, Turkey; 5) Department of Neurology, Faculty of Medicine, Mersin University, Mersin 33343, Turkey; 6) Pediatrics, Neurology Unit, Faculty of Medicine, Hacettepe University, Ankara 06100, Turkey.

Essential tremor (ET) is the most common inherited movement disorder and it is known to be generally transmitted as an autosomal dominant trait. Although the main cause of ET is not known, there is a consensus about the presence of etiologic heterogeneity and a strong genetic predisposition. Genetic mapping and candidate gene sequencing revealed that there are few susceptibility genes related with ET. Our approach is to search for rare, high-penetrance, and gene-disrupting mutations through whole exome sequencing of the ET subjects in the setting of familial cases. For identifying genes that cause ET, clinical evaluation and correct diagnosis for probands and their relatives were performed based on WHIGET and MDS criteria. For whole exome sequencing, at least two affected and one control individuals were selected in the same family. Read pairs were aligned to the reference human genome hg19 (GRCh37) using the Burrows-Wheeler Aligner (BWA). Removal of PCR duplicates, sorting and indexing were done using SAMtools v0.1.18. Local realignments around insertions or deletions (indels) were performed using the Genome Analysis Toolkit (GATK v.3.1-1). Finally, whole exome sequencing data was analyzed with annotation tools. For segregation analysis, Sanger sequencing was carried out with selected candidate genes primers. We are searching for candidate genes which segregated with disease for different families. Variants that included any variation that was predicted to alter gene expression or protein function have been prioritized. Candidate alleles have also been selected predicted as damaging with in silico analysis tools. Identification of the causal mutations that are correlated with the ET phenotype will provide invaluable insights into underlying mechanism of the disease and will potentially open new avenues for treatment.

1378W

Whole exome sequencing approach in a cohort of multiplex Italian families with multiple sclerosis. *A. Zauli[1], C. Guaschino[1,2], E. Mascia[1], F. Esposito[1,2], M. Sorosina[1], A.M. Osiceanu[1], S. Peroni[1], S. Santoro[1], D. Biancolini[3], D. Lazarevic[3], S. Bonfiglio[3], D. Cittaro[3], V. Martinelli[2], G. Meola[4], S. D'Alfonso[5,6], G. Comi[1,2], F. Martinelli Boneschi[1,2].* 1) Laboratory of Human Genetics of Neurological Disorders, San Raffaele Scientific Institute, Milan, IT; 2) Department of Neurology, San Raffaele Scientific Institute, Milan, IT; 3) Center for Translational Genomics and BioInformatics, San Raffaele Hospital, Milan, IT; 4) Department of Neurology, San Donato Hospital, San Donato Milanese, IT; 5) Interdisciplinary Research Center of Autoimmune Diseases (IRCAD), University of Eastern Piedmont, Novara, IT; 6) Department of Health Sciences, University of Eastern Piedmont, Novara, IT.

While the role of common genetic variants is established from whole-genome association studies (GWAS) in Multiple Sclerosis (MS), pointing to the existence of more than 100 non-HLA genetic loci, the heritability of the disease is still poorly captured, suggesting the existence of rare variants implicated in the susceptibility to the disease. The aim of the study is to identify rare variants involved in the predisposition of MS by analyzing multiplex families using whole exome sequencing approach. 12 Italian families with at least two affected relatives (1 with 5, 4 with 4, 6 with 3, and 1 with 2 affected) have been recruited as part of a large multicentric Italian study. DNA extracted from peripheral blood was enriched using the Agilent SureSelect Human All Exon QXT V5. Paired-end sequencing (2x101bp) was performed on Illumina Hiseq2500 platform. Reads were trimmed and aligned with BWA using hg19 as reference genome. Variants were identified using GATK pipeline and annotated using SnpEff suite. We focused on variants according to their depth (<6), evolutionary conservation (GERP++RS>2), mutation frequency in the general population (MAF<0.05), in silico predicted effect (Polyphen2 >0.15, SIFT <0.05, and MetaSVM >0), and segregating under a transmission model according to the pedigree. WES was performed in 37 relatives with a general coverage >70X in all individuals. Around 40.000 functional variants were found in affected relatives, of which 16.000 with frequency <5%. We focused on variants shared among families, as well as variants which segregate across families. We also looked at variants which fall in MS-associated genetic loci, as well as genes known to be implicated in MS-like diseases (mithocondrial lysosomal and peroxisomal disorders, leukoencephalopathies and neurometabolic diseases). These preliminary data represent a potential pool of rare functional variants implicated in MS pathophysiology that should be further analyzed in larger datasets of familial and sporadic cases.

Genome-wide linkage analysis in Dutch families identifies novel candidate genes for Alzheimer's disease. *S. Ahmad[1], N. Amin[1], E. Blue[2], S.J. van der Lee[1], A.Q. Nato[2], H. Sohi[2], B. Wang[5], E. Boerwinkle[3], A.L. DeStefano[4], E. Wijsman[2,6], C.M.V. Duijn[1], Alzheimer's disease sequencing project (ADSP).* 1) Erasmus University Medical Center, Department of Epidemiology, Genetic Epidemiology Unit. PO Box 2040 3000CA Rotterdam , Netherlands; 2) Division of Medical Genetics, Department of Medicine, University of Washington, Seattle, WA 98195, USA; 3) Human Genetics Center, University of Texas Health Sciences Center at Houston, Houston, TX, 77030, USA; 4) The National Heart, Lung, and Blood Institute's Framingham Heart Study, Framingham MA, USA; 5) Department of Statistics, University of Washington, USA; 6) Department of Biostatistics and Genome Sciences, University of Washington, USA.

Purpose: Alzheimer's disease is one of the most heritable disorders in old age, and both rare as well as common variants are implicated. Whole genomes of 30 Alzheimer's disease (AD) patients from two large and complex multigenerational Dutch families were sequenced as a part of the ongoing Alzheimer's disease sequencing project (ADSP) to identify rare sequence variation that can have large effects on AD. To identify regions that might harbour rare variants, multipoint parametric and non-parametric linkage analyses were performed, with implicated regions evaluated for potential causal variants. **Methods**: We selected maximally informative heterozygous single nucleotide polymorphisms (SNPs) from an Illumina SNP microarray (370K) for linkage analysis. Affected-only linkage analysis was performed in MERLIN with 10,431 SNPs by splitting the 30 cases into six smaller sub-families. Findings were validated using Markov chain Monte Carlo (MCMC) in the two intact large families with analysis from 2734 uniformly-spaced, maximally informative SNPs in the genome scan. To identify the potential explanatory variants, we searched for sequence variation shared by the AD patients of the contributing families in the LOD-2 support interval of the linked regions. **Results**: Significant linkage evidence was observed for chromosome 5p14.3 (logarithm of odds (LOD) score MERLIN=3.29; MCMC=3.12). The LOD score was mainly determined by one family with 7 AD patients. The 7 cases shared at least 294 rare sequence variants (including 2 deleterious variants) within the LOD-2 interval. The region encompassing these variants is a highly conserved region and contains a cluster of Cadherin genes most notably *CDH12* and *CDH18*. *CDH* genes are highly expressed in the nervous system and are known to be involved in presenilin-mediated signaling. Furthermore, *CDH12* is predicted to be involved in the development of hippocampus and cerebellum and *CDH18* is predicted to be involved in memory. We validated the region using MCMC and extend the pedigree with 6 new patients. There is a 50 bp haplotype shared among subjects who drive the linkage sgnal in the extended pedigree. **Conclusions**: AD is linked to chromosome 5p14 in a large pedigree from the Netherlands, with 13-18 patients out of 30 contributing substantially to the evidence for linkage. Based on known and predicted function, the cadherin genes are the most likely candidate genes.

1380F

Whole genome sequencing analysis of a human with total insensitivity to capsaicin. *H. Kim[1], J. Park[2], J. Gill[1], S. Yun[3], A. Cashion[1], H. Na[2].* 1) SML, NINR/NIH, Bethesda, MD; 2) Dept. Physiology, Korea University, Seoul, Korea; 3) Yotta Biomed, Bethesda, MD.

Because the transient receptor potential V1 (TRPV1) is known to mediate chemical, thermal and pain stimuli, the capsaicin, the source of spicy taste in hot peppers and the agonist of TRPV1, has been suggested to affect multiple neuroscience behaviors. Various genetic variations in TRPV1 and other TRP channel encoding genes have been discovered, but it is not yet clear what genetic factors influence capsaicin sensitivity.We tested and sequenced a 51 year old female Korean subject who has a complete lack of sensitivity to capsaicin but hypersensitivity to allicin, along with her 55 year old sister control subject with normal to both capsaicin and allicin. Both subjects had normal responses to other sensory tests. Illumina Hiseq 2500 was used to sequence whole genome for both subjects. For analysis, base call quality was determined using FASTQC software. Alignment was performed on hg18 with BWA, version 0.7.10. Variation calling was performed using the haplotypecaller in GATK, version 3.4-46. ANNOVAR was used to annotate variants.We obtained 324 million reads for the patient, and 318 million reads for her normal sister in paired-end sequencing, which corresponds to ~ 32x coverage. We obtained 4.9 million and 4.8 million variants for the patient and her normal sister, respectively. We selected homozygous insertions/deletions, stop-gain/loss, missense, or splice-site mutation. Then, we filtered out her normal sister's variants and Korean common SNPs. We filtered out the variants further by requiring minor allele frequency less than 0.01 in 1000 Genome database. Finally, we obtained 57 genes, and performed pathway analysis with Ingenuity IPA. IPA revealed 3 associated network functions (cancer, molecular transport, drug metabolism) and 5 upstream regulators. These findings suggest an analytical tool to investigate whole genome sequencing data with small sample sizes. It will also lead to an increased understanding of how dynamic regulation of the genome is associated with capsaicin sensitivity and other neuroscience behaviors.

1381W

Deciphering the genetic basis of Hirschsprung disease by whole genome sequencing. *C. Tang[1,2], H.S. Gui[3], M.T. So[1], S.S. Cherny[3,4], P.C. Sham[3,4], M.M. Garcia-Barceló[1], P.K.H. Tam[1].* 1) Department of Surgery, LKS Faculty of Medicine, The University of Hong Kong, Pokfulam, Hong Kong; 2) Dr. Li Dak-Sum Research Centre, The University of Hong Kong - Karolinska Institutet Collaboration in Regenerative Medicine, The University of Hong Kong, Pokfulam, Hong Kong; 3) Genome Research Centre, The University of Hong Kong, Pokfulam, Hong Kong; 4) Department of Psychiatry, LKS Faculty of Medicine, The University of Hong Kong, Pokfulam, Hong Kong.

Hirschsprung disease (HSCR) is a congenital disorder characterized by the absence of enteric ganglia along the lower intestinal tract. The disease is caused by the failure in migration, differentiation and/or proliferation of the enteric neural crest cells to the hindgut, leading to colonic aganglionosis. The differential contributions of rare versus common variants as well as coding versus noncoding variants tend to vary in accordance with the length of aganglionosis. Short-segment HSCR (S-HSCR), accounting for ~80% of the patients, is believed to be genetically complex whereas the rarer subtype, long-segment HSCR (L-HSCR), could be attributed to damaging *de novo* or recessive mutation. To understand comprehensively the genetic basis across the disease spectrum, we carried out an integrative analysis by high coverage whole-genome sequencing (30-45X) of 443 Chinese S-HSCR, 11 L-HSCR of 10 families (9 trios and 1 quartet) and 493 controls of East Asian ethnicity, aiming to identify novel HSCR genes. Gene-based association analysis on rare variants of S-HSCR not only vindicated the causal roles of the two known genes—*RET* (SKAT-O P=6.8x10^{-6}) and *EDNRB* (CMC P=0.0055)—but also revealed higher burden of rare protein-altering variants in *PTGS2* and *BACE2* (P<0.001) in S-HSCR. Our data also show that *de novo* as well as inherited variants contribute to the development of enteric nervous system and thereby to HSCR. Recent progress of CNV analysis will also be presented.

1382T

Project MinE: Study design and pilot analyses of a large-scale whole genome sequencing study in amyotrophic lateral sclerosis. *W. van Rheenen, S.L Pulit, R.A.A. van der Spek, A.M. Dekker, B.M. Middelkoop, L.H. van den Berg, J.H. Veldink, Project MinE Sequencing Consortium.* Department of Neurology, Brain Center Rudolf Magnus, University Medical Center Utrecht, Utrecht, Netherlands.

Amyotrophic lateral sclerosis (ALS) is a fatal neurodegenerative disease affecting 1 in 400 people. We recently showed a disproportionate contribution from low-frequency variants in genetic susceptibility to ALS. We therefore have begun Project MinE, an international collaboration that seeks to whole-genome sequence 15,000 ALS patients and 7,500 controls. Here, we report on the design of Project MinE and pilot analyses including 1,264 ALS patients and 611 controls. We find an abundance of rare genetic variation (allele frequency < 0.1%), of which the vast majority is absent in public data sets. Principal component analysis reveals that strong geographical clustering of these variants even within The Netherlands. We further test the implications of poor geographical matching of cases and controls and investigate how externally sequenced controls, selected from the identical population as cases, can induce false positive associations and reduce power to discover true genetic signal. Finally, we present the project MinE variant server: a publicly available server to interrogate the genome for (rare) genetic variation observed in project MinE.

1383F

Investigating the genetic contribution to Amplified Musculoskeletal Pain Syndromes (AMPS) in pediatric populations. *M.V. Gonzalez[1,2], S.A. Gmuca[2], J. Tress[2], F.D. Mentch[1], R. Chiavacci[1], P. Sleiman[1], G.A. Barr[3], D.D. Sherry[2,4], H. Hakonarson[1,4].* 1) Center for Applied Genomics, The Children's Hospital of Philadelphia, Philadelphia, PA. 19104; 2) Amplified Pain Program, Division of Rheumatology, The Children's Hospital of Philadelphia, Philadelphia, PA. 19104; 3) Department of Anesthesiology and Critical Care Medicine, The Children's Hospital of Philadelphia, Philadelphia, PA. 19104; 4) Department of Pediatrics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA. 19104.

Chronic pain is one of the most costly conditions in modern western society. Pediatric chronic pain conditions have been estimated to account for more than 5.2 billion dollars annually. Many diagnostic terms are used, however, a common thread in these pain conditions is central and/or peripheral sensory amplification. Amplified musculoskeletal pain syndromes (AMPS) comprise a range of disorders that can present with a variety of signs and symptoms related to increasing pain over time, allodynia, and disproportional dysfunction. AMPS are most prevalent in adolescent females of European Caucasian (EC) descent (approx. 75%) and often significantly interfere with daily function and quality of life. Additionally, pediatric amplified musculoskeletal disorders differ significantly from those occurring in adults. The etiology and pathophysiological mechanisms of AMPS are currently unknown. Familial aggregation and candidate gene studies suggest a strong genetic component in the development of AMPS, but many of the genetic susceptibility factors remain unidentified. Genome-wide association studies (GWAS) facilitate impartial queries of common genetic variation, allowing identification of novel genetic contributions to the development of complex disorders. To our knowledge, this is the first report of a genome-wide investigation of AMPS in a large pediatric cohort. To this end, 952 male/female AMPS cases and 8,930 controls of African American and European Caucasian descent were selected for genotyping utilizing single nucleotide polymorphism (SNP) arrays. Logistic regression models were used to determine association between AMPS incidence and SNP genotype. Because European Caucasian females are predominantly affected with AMPS, these samples were separated from the total population and analyzed separately (359 cases, 4151 controls). The total AMPS and female EC analyses identified 6 and 15 genomic regions respectively. Many of these implicated genomic loci included genes influencing neurogenesis, neurotransmission, and regulation of the innate and adaptive immune response. Replication and validation of these results in an independent cohort of 629 AMPS cases is currently underway. The genes identified in these initial genome-wide investigations of AMPS deliver a number of possible functional candidates and may provide novel therapeutic targets for children suffering from neurologic pain disorders.

1384W

A common genetic basis between neurodevelopmental disorders of childhood. *F. Tsetsos[1], D. Koukousi[1], M. Mpampali[1], S.S. Padmanabhuni[1], J. Alexander[1], I. Karagiannidis[1], D. Mantzaris[1], M. Georgitsi[1,2], P. Drineas[3], P. Paschou[1].* 1) Molecular Biology and Genetics, Democritus University of Thrace, Alexandroupolis, Evros, Greece; 2) Laboratory of General Biology, Department of Medicine, Aristotle University of Thessaloniki, Thessaloniki, Greece; 3) Computer Science Department, Rensselaer Polytechnic Institute, Troy, Ny, USA.

Gilles de la Tourette Sydrome (TS) is a childhood onset neurodevelopmental disorder, characterized phenotypically by the presence of multiple motor and vocal tics. It is often accompanied by multiple neuropsychiatric comorbidities, with Attention Deficit/Hyperactivity Disorder (ADHD) and Autism Spectrum Disorders (ASD) among the most common. The extensive co-occurrence of the three disorders suggests a shared genetic background. A major step towards the elucidation of the genetic architecture of TS was performed by the first TS Genome-wide Association Study (GWAS) reporting 552 SNPs that were moderately associated with TS (p<1E-3) [Scharf et al, 2013]. The latest genome-wide attempts towards the identification of the genetic background of ADHD and ASD were described in the cross-disorder meta-analysis of the Psychiatric Genomics Consortium [Smoller et al. 2013]. In this study we examine the common genetic background of the three neuropsychiatric phenotypes, by meta-analyzing the 552 top hits in the TS GWAS with the results of the GWAS for ADHD and ASD that preceded the cross-disorder meta-analysis undertaken by the PGC. We identified 19 significant SNPs in the TS/ADHD meta-analysis, with the top four implicated genes being TBC1D7, GUCY1A3, RAP1GDS1 and CHST11. TBCD17 harbors the top scoring SNP, rs1866863 (p:3.23E-07), located in a regulatory region downstream of the gene, and the third best-scoring SNP, rs2458304 (p:2.54E-06), located within an intron of the gene. Both variants were in linkage disequilibrium with eQTL rs499818, indicating a role in the expression levels of the gene. TBC1D7 is the third subunit of the TSC1/TSC2 complex, with a Rheb-GAP activity. The top genes indicate a complex and intricate interplay between them, warranting further investigation into a possibly shared etiological mechanism for TS and ADHD. In the TS/ASD meta-analysis, we identified 10 significant SNPs, with the top two residing in the same region (rs8004624, p: 5.57E-06 and rs4898764, p:1.11E-05), in an LD-block that harbors the genes STYX, PSMC6 and GNPNAT1. Our study will also include the results of the EMTICS and TS-EUROTRAIN initiatives that will generate genome-wide genetic data from another 2600 European patients with TS. Our results provide some interesting insight into the common genetic mechanisms that underlie neurodevelopmental disorders, with the main theme of the TS/ADHD overlap being the structural and circulatory function of specific areas in the brain.

1385T

Integration of genetic, epigenetic, and transcriptional variation in the context of multiple disease phenotypes reveals diverse molecular signatures of Alzheimer's disease. *M. Kellis[1,2], Y. Park[1,2], Z. Zhang[1,2], M. Eaton[1,2], D. Bennett[3], P. De Jager[4].* 1) Computer Science and Artificial Intelligence Lab, Massachusetts Institute of Technology, Cambridge, MA; 2) Broad Institute of MIT and Harvard, Cambridge, MA; 3) Rush University, Chicago, IL; 4) Harvard Medical School, Brigham and Women's Hospital, Boston, MA.

Perhaps the greatest surprise of human genome-wide association studies (GWAS) is that 90% of disease-associated regions do not affect proteins directly, but instead lie in non-coding regions with putative gene-regulatory roles. This has increased the urgency of understanding the non-coding genome, as a key component of understanding human disease. To address this challenge, we generated maps of genomic control elements across 127 primary human tissues and cell types, and tissue-specific regulatory networks linking these elements to their target genes and their regulators. We have used these maps and circuits to understand how human genetic variation contributes to disease, providing an unbiased view of disease genetics and sometimes re-shaping our understanding of common disorders. For Alzheimer's Disease, we find evidence that genetic variants contributing to disease predisposition act primarily through immune processes, rather than neuronal processes. To gain insights on the intermediate phenotypes that lead to disease onset, we study epigenetic, transcriptional, and phenotypic information from risk and non-risk individuals using postmortem brain samples and longitudinal phenotypes in a cohort of aging. We find that methylation differences are highly correlated with Alzheimer's disease diagnosis, and lead to significantly higher classification power than genetic information alone. The genomic regions that show the highest correlation with Alzheimer's disease status are significantly enriched for genetic variants associated with Alzheimer's disease, including large numbers of loci that do not reach genome-wide significance, indicating the potential to identify new disease loci. We find that the genomic regions showing methylation differences associated with Alzheimer's disease can be partitioned according to the subset of phenotypes that they are associated with, including neuritic plaques, neurofibrilary tangles, and cognitive decline. These subsets are enriched in diverse functional categories based on the gene ontology classifications of nearby genes, indicating diverse functions in adherens, signaling, and immune functions. They are also enriched in enhancer and promoter regions active in distinct groups of cell types and differentiation stages, including embryonic stem cells, immune cells, and fetal and adult brain cells. These results indicate that epigenetic profiling can help partition complex trait associations into diverse intermediate phenotypes.

1386F

Identification and functional characterisation of a novel regulatory variant in monoamine oxidase-A (*MAO-A)* **gene in Parkinson's disease.** *S. Kumar[1], B.K. Thelma[1], K.A. Michealraj[1], U. Muthane[2].* 1) Dept of Genetics, Delhi University, New Delhi, India; 2) Parkinsons & Ageing Research foundation, Bangalore, India.

Parkinson's disease (PD) is a common progressive complex disorder of the elderly caused by the interaction of genes and environmental factors. Loss of dopaminergic neurons in *substantia nigra* results in dopamine (DA) depletion which results in motor symptoms associated with this disease. Oxidative stress is believed to be a key player in this neuronal loss. *Post mortem* reports of PD patients show higher levels of lipid peroxidation. Degradation of DA leads to formation of reactive oxygen species and thus DA metabolism may itself be a major contributor to oxidative stress. Consequently, DA metabolising genes such as *COMT, DBH, DDC* and *MAO* etc. are strong candidates in PD pathology as variants in these genes will affect the DA determined phenotypes. Inhibitors of such gene products are routinely used in PD treatment. Genetic variants in *COMT*, *MAO*, *DAT, NET,* and *5- HTT* genes from DA metabolism pathways have been documented to alter amines and their metabolic product levels. With this background, we attempted to establish genotype-phenotype correlations in two dopamine metabolising genes namely *MAO-A* and *MAO-B.* Enzymatic activity in the blood sera of same cohort was measured using Amplex Red Monoamine oxidase kit (Thermo Fisher Scientific, USA) and protein quantitation was done by by Elisa (MyBioSource, USA). Deep sequencing of exonic and regulatory regions of these two genes in 50 healthy individuals was carried by Dr. K. A. Michealraj using Ion torrent platform; A novel 5' UTR variant was identified in an individual with higher MAO-A quantity and activity. Interestingly, the same variant was also identified in a multi-generation family with late onset of PD. The proband in the family had increased sleep disturbance and hypotension in later stages which is in accordance with the reported effects of higher MAO-A enzyme levels. To establish the genotype-phenotype correlation of this novel regulatory variant, wild type and variant alleles with native MAO-A promotor were cloned in the luciferase expression vector. Results from ongoing expression assays in human cell line SH-SY5Y expressing MAO-A together with test of association of this variant in an independent PD case-control cohort will be presented.

1387W

Whole genome sequencing and rare variant discovery in the ASPIRE autism spectrum disorder cohort. *B. Callaghan[1,2], P. Tan[1,2], S. Rogic[1,2], K. Calli[3], Y. Qiao[4], M. Jacobson[1,2], M. Belmadani[1,2], N. Holmes[1,2], C. Yu[5], Y. Li[5], Y. Li[5], F. Kurtzke[3], A. Yu[3], M. Hudson[6,7], A. Dionne-Laporte[8,9], S. Girard[10], P. Liang[11], E. Rajcan Separovic[4], X. Liu[6,7], G. Rouleau[8,9], P. Pavlidis[1,2], S. Lewis[3].* 1) Michael Smith Laboratories, UBC, Vancouver, BC; 2) Department of Psychiatry, UBC, Vancouver, BC; 3) Department of Medical Genetics, UBC, Vancouver, BC; 4) Department of Pathology and Laboratory Medicine, UBC, Vancouver, BC; 5) BGI Tech Solutions; 6) Queen's Genomics Lab at Ongwanada, Ongwanada Resource Center, Kingston, ON; 7) Department of Psychiatry, Queen's University, Kingston, ON; 8) Montreal Neurological Institute, Montréal, QC; 9) Department of Neurology and Neurosurgery, McGill University, Montréal, QC; 10) Department of Human Genetics, McGill University, Montréal, QC; 11) Department of Biological Sciences, Brock University, St. Catharines, ON.

We characterized rare genetic variation in a cohort of 119 individuals with autism spectrum disorder (ASD) using whole genome sequencing. The cases were drawn from the ASPIRE (Autism SPectrum Interdisciplinary REsearch) British Columbia cohort. Individuals in this cohort have been diagnosed with ASD (DSM-IV; ADOS-G/ADI-R) and underwent a detailed standardized phenotyping protocol including morphometrics. We obtained whole genome sequences (Illumina paired-end 100 base pair reads, average depth 30x) for each subject. Variants were called using the Genome Analysis Toolkit (GATK) against the human reference genome, and filtered for quality and rarity in population data. To prioritize variants further, we relied on a combination of existing and in-house bioinformatics tools incorporating both gene-level metrics (genic intolerance to mutation, functional effect prediction) and variant level metrics (population frequency, predicted damage). Our efforts included recurating variants reported in the ASD literature, totalling 4768 variants from 28 publications. We have made the resulting database available as MARVdb (www.chibi.ubc.ca/marvdb). To collaboratively analyze variants we also applied our general interactive assessment tool, ASPIREdb (aspiredb.chibi.ubc.ca). In total 97 high-priority candidate variants were identified, affecting 66 subjects. All of these variants were heterozygous and all but one were autosomal. Of these, 31 were predicted loss-of-function mutations, 3 affecting genes previously associated with ASD and 3 affecting genes associated with other neurodevelopmental disorders. A total of 66 candidate MS mutations were prioritised as potentially pathogenic, including 12 affecting literature-associated ASD genes, and 8 affecting genes associated with other neurodevelopmental disorders. High priority variants are being subjected to trio resequencing to assess inheritance. Using this approach we have thus far identified a novel de novo splice site variant in *SCN2A*, predicted to result in a loss of function, in an individual with severe autism and intellectual disability. This finding adds to the evidence that mutations in this gene can be associated with autism without comorbid seizure disorders.

1388T

Novel gene discovery in familial amyotrophic lateral sclerosis. *J.A. Fifita, K.L. Williams, S. Yang, K. Zhang, G.A. Nicholson, D.B. Rowe, I.P. Blair.* Faculty of Medicine and Health Sciences, Macquarie University, Sydney, New South WaFaculty of Medicine and Health Sciences, Macquarie University, Sydney, NSW Australia, Australia.

   Amyotrophic lateral sclerosis (ALS), also known as Lou Gehrig's disease, is a fatal neurodegenerative disease that is caused by the progressive death of motor neurons. Ten percent of cases are familial (FALS), with the remaining 90% considered sporadic (SALS). To date, the only known causes of ALS are gene mutations. Mutations in ALS genes, including *SOD1, TARDBP, C9ORF72,* and *CCNF* account for approximately 60% FALS and 10% of SALS. We aim to identify remaining ALS genes and mutations. Gene discovery strategies utliize exome sequence data from Australian familial ALS cases. We have completed whole exome capture and sequencing of probands from 74 ALS families, as well as ten individuals from three multigenerational ALS families negative for all known ALS genes. Custom bioinformatics analysis of these families has identified candidate gene mutations in genes not previously linked to ALS. A custom *in silico* prioritisation pipeline was designed to predict pathogenicity of all candidates and prioritize for functional studies. To predict pathogenicity the pipeline includes standard use of multiple protein prediction software and analysis of conservation data. In addition to genic tolerance information, large control datasets are used to determine the natural variation of each gene. To predict a link between potentially pathogenic variants and ALS, protein expression, function and interacting partners are compared to what is known of ALS pathobiology. This pipeline has prioritized candidate variants. All candidates from Family One have undergone functional studies to examine potential pathogenicity *in vitro* using neuronal cell lines. These analyses begin with a general toxicity assay to determine pathogenicity. To determine causality, specific aspects of ALS-linked pathology were investigated, with results reflecting the *in silico* predictions. The pathogenic basis of ALS remains poorly understood. The identification of novel ALS genes increases our knowledge of disease biology, adds to diagnostic regimes, and provides tools for the development of cell and animal models and long-term therapeutic discovery.

1389F

Short sequence variations (SSVs) may explain multiplicity of *SOD1*-**SNP mutations in Amyotrophic Lateral Sclerosis.** *A.D. Roses[1,2], P.A. Akkari[2], M.W. Lutz[1], D.K. Burns[2], R. Saul[3], T. Siddique[4].* 1) Neurology, Duke University School of Medicine, Chapel Hill, NC; 2) Shiraz Pharmaceuticals, Inc., Chapel Hill, NC; 3) Polymorphic DNA Technologies, Inc, Alameda, CA; 4) Neurology, Northwestern University School of Medicine, Chicago, Il.

   There are multiple SNPs assigned as specific "mutations" for each of several amyotrophic lateral sclerosis [ALS] genes. More than 150 separate SNP variants within SOD1 have been proposed as familial ALS-*SOD1* "mutations" to date. We initially screened short structural variants [SSVs] located near SOD1 in familial and sporadic ALS patients [fALS and sALS], and observed an association between rs71714698 18T allele and ALS patients. This initial survey was performed with 159 fALS and sALS cases and 33 age matched controls. Additional SOD1, TARBDP and C9ORF72 cases and controls were added to this cohort: 205 ALS cases consisting of 147 SOD1 cases with 32 different SOD1 mutations, 11 C9ORF72, 15 TARDBP familial ALS patients, 32 sporadic ALS cases, and 459 controls and genotyped in a follow-up study. The addition of cases and controls strengthened the initial association between rs71714698 18T allele and ALS. Patients who carried at least one rs71714698 18T allele included; 29 SOD1 cases (28 A4V, 1 G100K); 3 ALS cases formerly scored as sporadic, 1 TARDBP N325B case and 2 C9ORF72 fALS cases compared to controls (p=1*10^{-12}, Likelihood Ratio test). 27 out of 31 ALS cases who carry the rs71714698 18T allele were positive for the common A4V mutation. Examination of the A4V and G100K ALS missense mutations reveals that they are 11327bp and 3790kb upstream from rs71714698 respectively. We then examined duration and age of onset for rs71714698 in ALS cases and observed that 18T was associated with the shortest duration until death of a patient when compared to 17T or 16T [p< 0.0054]. We hypothesize that the varying length of rs71714698 polyT may affect transcription similarly in those SOD1 SNPs clustered on 18T-carrying phylogenetic clade branches. SOD1 is flanked by POLR2A binding sites (https://genome.ucsc.edu) which may extend the length of the SSV affects to include many uncommon SNPs sharing the phylogenetic clustered clades carrying 18T, appearing as separate SNP "mutations." The common causative variant may be 18T for each uncommon SNP recognized as a "SOD1 mutation" that is cis-linked to 18T. This is analogous to the rs10524523 TOMM40-Long polyT in Alzheimer's disease clades. In-vitro confirmation of the functional effect of rs71714698 18T could therefore provide a rational for a pathogenetic mechanism and a strategy to select targets for drug discovery and pharmacogenetic-assisted drug development.

1390W

Next-generation sequencing of Alzheimer's and Parkinson's Disease genes in neuropathologically confirmed DLB, PDD and AD cases. *D. Tsuang[1], I. Mata[2], J. Leverenz[3], D. Bennett[4], J. Background: Next-generation sequencing (NGS) has been useful in gene discovery for complex genetic disorders. We sought to use a comprehensive NGS-based panel to identify pathogenic variants in a large sample of autopsied subjects with dementia. Lewy body dementias (LBD) encompasses a spectrum of clinicopathologic entities that include Parkinson disease dementia (PDD), and dementia with Lewy bodies (DLB), which are differentiated from one another based on occurrence of parkinsonism relative to dementia. Neuropathologic changes include classic histologic inclusions of Lewy bodies, but whether these disorders share genetic risk factors remain unclear. Methods: All 314 subjects were diagnosed with dementia and classified as having neuropathologically-confirmed Alzheimer's disease (AD; n=71), Lewy body dementia with concomitant AD (LBD-AD; n=109), pure dementia with Lewy bodies (pDLB; n=78), and Parkinson's disease dementia (PDD; n=56). For each individual, we screened the entire coding region of 27 causative genes for AD, PD, and other dementing neurodegenerative disorders as follows: sample libraries were constructed and enriched for the genes of interest using xGEN custom probes. Using Illumina technology, >100X mean sequence coverage was generated for each sample; the resulting sequences were aligned to the human genome reference (hg19) using the Burrows-Wheeler Aligner and variants identified with the Genome Analysis Took Kit. We excluded those variants that did not meet standard quality values, those with >1% minor allele frequency in Exome Aggregation Consortium (ExAC) database and those classified as low impact by SnpEff prediction tools. Results: Twenty-five potentially pathogenic variant changes were identified, including 5 high-impact changes (e.g., stop-gained, frameshift mutations) and 20 moderate-impact changes (e.g., missense mutations, inframe deletions). All five of the high-impact variants were either previously reported but with very low frequencies in the ExAC database (< 0.0001) and/or were not found in ClinVar. These five high-impact novel variants were found in PDD (n=2) and LBD-AD (n=2) and pDLB (n=1) cases. Conclusions: Using a custom genetic sequencing panel, we identified potentially pathogenic variant changes in ~9 percent (23 out of 243) of our subjects with LBD. Our findings suggest that NGS methods are likely to uncover meaningful genetic changes and should be incorporated in future studies of LBD.

Association of genetic factors increasing serum glutamine metabolite levels with risk for migraine and depression. *D.R. Nyholt, IHGC and ENGAGE consortia.* Institute of Health and Biomedical Innovation (IHBI), Queensland University of Technology (QUT), Brisbane, QLD, Australia.

Migraine and major depressive disorder (MDD) are two frequent complex disorders, each affecting around 10–20% of the global population. Twin and family studies indicate moderate heritabilities ranging from 30 to 50% and point to the presence of shared genetic components underlying the two conditions. In 2013, the International Headache Genetics Consortium (IHGC) published results of a genome-wide association (GWA) meta-analysis of 23285 migraine cases and 95425 controls. This study of 1.8 million single nucleotide polymorphisms (SNPs) identified 12 loci robustly associated with migraine susceptibility ($P < 5×10^{-8}$).[1] In contrast, the 2013 Psychiatric Genomics Consortium (PGC) MDD GWA mega-analysis of 1.2 million SNPs in 9240 cases and 9519 controls failed to robustly identify any MDD risk loci.[2] While more recently, the ENGAGE (European Network for Genetic and Genomic Epidemiology) Consortium performed a large GWA meta-analysis of 131 serum metabolites in human blood (measured via mass spectrometry at Biocrates Life Sciences AG). This study of 2.6 million SNPs in 7478 individuals of European descent, found 4068 genome- and metabolome-wide significant associations, involving 59 independent SNPs and 85 metabolites ($P < 1.09×10^{-9}$).[3] To identify biological processes and pathways involved with migraine and depression aetiology, we tested for an association between genetic factors influencing the 131 ENGAGE serum metabolites and genetic risk factors for migraine and depression. Analysis of ~24000 independent SNPs with the most significant association *P*-values in the IHGC migraine GWA and PGC MDD GWA, found genetic factors for increased Glutamine metabolite levels were significantly correlated with genetic risk for both migraine and MDD. Our results strongly support previous suggestions that alterations in the glutaminergic system play a key role in migraine and MDD pathogenesis. References: 1. Anttila et al. LCM coupled with single-cell gene expression assay: Isolating neurons from archive frozen brains for functional genomic studies of neuro-degenerative diseases. *L. Tagliafierro[1,2], K. Bonawitz[1,2], O.C. Glenn[1,2], O. Chiba-Falek[1,2].* 1) Neurology, Duke University Medical Center, Durham, NC; 2) Center for Genomic and Computational Biology, Duke University Medical Center, Durham, NC.

Changes in gene expression in brain tissues from neurodegenerative disease patients compared to healthy controls have been reported. However, the majority of these studies used brain tissue homogenates that represent multiple cell-types. Gene expression profiles in a specific population of cells is more informative than studying the whole tissue, particularly in the brain, where different pathologies affect a specific subset of cells. Due to the difficulty to obtain homogenous cell populations, gene expression in specific cell-types (neurons, glial-types) has been understudied. Thus the specific cell-type responsible for the observed alteration in expression levels remained largely elusive. To leverage the archive resources of frozen human brains and address these key gaps in knowledge, we developed and calibrated a method to quantify cell-type specific – neuronal, astrocytes, microglial – expression profiles of neurodegenerative disease-risk genes. Archive human frozen brain tissues were used to prepare slides for rapid immunostaining. The immunoreactive-cells were isolated by Laser Capture Microdissection (LCM). We optimized the technique to preserve the RNA integrity, so that the RNA was suitable for downstream analyses. Following RNA extraction, the gene expression was determined digitally using nCounter Single Cell Gene Expression Assay (NanoString). The enrichment for a particular cell-type was determined by the expression of cell-specific markers. Comparisons of mRNA levels between brains from patients affected by neurodegenerative diseases, including Alzheimer's (AD) and Parkinson's (PD), and normal controls, revealed trends of differential expression profiles for several genes implicated in these pathologies. Noteworthy, *APOE-* and *TOMM40*-mRNAs were higher in neurons from Mild Cognitive Impairment (MCI) due to AD compared to neurons from normal brains, while the neuronal *SORL1*-mRNA levels were lower in MCI. *SNCA*-mRNA levels showed elevated levels in PD neurons. These results were consistent with our previous findings using brain tissues homogenates from AD and PD vs. control, and suggested that the alterations in expression of these genes occur in neurons. Experiments to identify *cis*-variants that contribute to the neuronal-regulation of these genes are underway. In conclusion, we suggest that neuronal-regulation of expression of disease critical genes may have a causative role in the etiology of neurodegenerative diseases of the aging brain.

HIV-related neurocognitive impairment is related to polymorphisms in *CCR2* and *CD163* in the absence of cocaine and opiate dependency. *M.M. Jacobs[1], D. Byrd[1,2], S. Morgello[1,3,4].* 1) Neurology, Icahn School of Medicine at Mount Sinai, New York, NY; 2) Psychiatry, Icahn School of Medicine at Mount Sinai, New York, NY; 3) Neuroscience, Icahn School of Medicine at Mount Sinai, New York, NY; 4) Pathology, Icahn School of Medicine at Mount Sinai, New York, NY.

Despite the widespread use of efficacious antiretroviral therapies, HIV-associated neurocognitive disorder (HAND) remains highly prevalent, and its dissociation from HIV replication makes it imperative to understand non-viral factors related to its neuropathogenesis. Chronic immune activation has been implicated, but the role of genetics has not been explored. Using an advanced-staged multi-ethnic HIV-positive population (n=276), we examined 230 polymorphisms within 55 genes proposed to play a role in both immune dysregulation and cognition. We examined these polymorphisms for associations with neuropsychological performance in global and cognitive domain T-scores (Motor, Processing Speed, Verbal Fluency, Learning, Memory, Executive Functioning, Working Memory) while controlling for opiate and cocaine dependency using linear regression analysis. While significant associations were observed in nearly every domain across both populations for multiple polymorphisms, one of the most significant effects in Caucasian subjects was observed in the Motor domain with the *CCR2* V64I polymorphism (rs1799864), such that nonsubstance users carrying the mutation had poorer motor performance while substance users with the mutation had better motor performance (p=0.004). When we examined levels of *CCR2* mRNA expression in peripheral blood mononuclear cells, we observed that nonsubstance users with the mutation had decreased expression of *CCR2* as compared to those without the mutation; such differences were not seen in drug users. For African- American subjects, the most significant effects were observed for several *CD163* polymorphisms in multiple domains (Global, Processing Speed, Verbal Fluency, and Working Memory). In African-Americans, nonsubstance users carrying *CD163* mutations had poorer performance, as compared to substance using individuals, who had better performance across multiple domains. Gene expression studies for *CD163* are ongoing, as are replication of these results with additional samples (n=500) from the National NeuroAIDS Tissue Consortium. These results suggest that substance use changes that neurobiological relationship of cognitive impairment to inflammatory processes, and should be factored into genetic studies of HAND.

Pathogenic *SORL1* mutations in Alzheimer's disease. *M. Cuccaro[1], R. Carney[2], Y. Zhang[4], C. Bohm[4], B. Kunkle[1], B. Vardarajan[3], P. Whitehead[1], H. Cukier[1], R. Mayeux[3], P. St. George-Hyslop[5], M. Pericak-Vance[1].* 1) University of Miami Miller School of Medicine, Miami, FL; 2) Bruce W. Carter VA Medical Center, Miami, Florida; 3) College of Physicians and Surgeons, Columbia University, New York, New York; 4) University of Toronto, Toronto, Ontario, M5T 2S8, Canada; 5) University of Cambridge, Cambridge, CB2 0XY, United Kingdom.

The *sortilin-related receptor LDLR class A repeats containing* (*SORL1*) gene has been implicated in both early and late onset Alzheimer's disease (AD). Located on chromosome 11q23.2-q24.2, *SORL1* plays a key role in differential sorting of the amyloid precursor protein (APP) and regulation of amyloid-β (Aβ) production. We describe clinical and molecular findings among individuals with AD and *SORL1* mutations. *SORL1* changes were identified by whole exome sequencing in 50 early onset AD families which contained at least one case with AD onset less than 60 years of age. The clinical consequences associated with SORL1 mutations were characterized based on clinical reviews of medical records. Functional studies were completed to evaluate (Aβ) production and APP trafficking associated with SORL1 mutations. Constructs were generated using human SORL1-MYC pcDNA3.1. Site directed mutagenesis was used to insert the T588I and T2134IM mutations verified by sequencing, and either the wild type or mutant constructs transfected into HEK293 cells expressing the Swedish APP mutant (APPsw). Cell culture and transfection followed previously described standard protocols. Aβ, Western blot, and co-immunoprecipitation assays were performed. A novel *SORL1* T588I change was identified in four individuals with AD from one EOAD family, two of whom also presented with Parkinsonian features. A second EOAD family was found to carry the T2134 alteration in three of four AD cases; one case with the T2134M variant was identified postmortem to have Lewy bodies. In a third family, two individuals, one with AD and one with MCI, were found to carry a p.Cys1431fs mutation in *SORL1*. Functional studies demonstrate that the variants weaken the interaction of *SORL1* with full-length APP, resulting in altered levels of Aβ and interfering with APP trafficking. Finally, a review of unrelated cases from a previously published study of *SORL1* mutations in late onset AD (Vardarajan 2015) identified four individuals with either *SORL1* A528T or T947M alterations who also presented with Parkinsonian features. The findings from this study support an important role for *SORL1* mutations in AD pathogenesis by way of altering Aβ levels and interfering with APP trafficking. In addition, the results point to a potential association of *SORL1* in the manifestation of Parkinsonian features among individuals with AD, expanding the phenotypic spectrum of *SORL1* mutations.

The evolving genetic risk landscape of sporadic amyotrophic lateral sclerosis. *J.M. Downie[1], S.B. Gibson[2], K.P. Figueroa[2], M.B. Bromberg[2], S.M. Pulst[2], L.B. Jorde[1].* 1) Department of Human Genetics, University of Utah School of Medicine, 15 North 2030 East Room 5100, Salt Lake City, UT 84112; 2) Department of Neurology, University of Utah School of Medicine, 175 North Medical Drive East, Salt Lake City, UT 84132.

Amyotrophic lateral sclerosis (ALS) is a disease in which the upper and lower motor neurons progressively degenerate, leading to paralysis and death. Understanding the genetic landscape of ALS is important in determining the pathogenic mechanisms of ALS and in the development of better clinical care. 90% of ALS cases occur sporadically (SALS) with no family history of the disease. It is known that genetic factors play a role in the pathogenesis of SALS; more than 33 genes have been associated with ALS. However, there is disagreement regarding the percentage of SALS cases that are caused by mutations in these genes, with estimates ranging between 11% and 28%. These calculations have been derived by determining the proportion of SALS cases that have a rare, protein-altering variant in a set of ALS genes. However, a large proportion of nonsynonymous variants are not deleterious. Thus, a shortcoming of these studies is that variant pathogenicity is not considered. To improve the understanding of ALS risk factors, we performed whole-exome sequencing of 96 SALS patients. BWA and GATK were used to perform read mapping and variant calling. Pathogenic repeat expansions of *ATXN2* and *C9orf72* were detected using PCR-based assays. Principal components analysis and *ADMIXTURE* identified 87 high-quality European SALS samples, which were used for analysis. Variants from these individuals were annotated by SnpEff to determine which ones produced nonsynonymous or splice-site gene changes. These variants were also annotated by dbNSFP v2.9, which contains allele frequency information and predictions of variant pathogenicity from 11 different variant prediction methods. Exome-sequencing data from 324 healthy adults from the Simons Simplex Collection (SSC) underwent the same process. An odds ratio comparing the proportion of SALS cases with a rare (<0.001 ExAC European MAF) and deleterious variant or pathogenic repeat expansion in at least 1 of 33 ALS-associated genes compared to SSC controls was calculated for each prediction method. 7 of these methods showed a significant excess of genetic burden in ALS genes compared to SSC controls indicating they are making accurate predictions. From these 7 methods, the average proportion of SALS cases with an identifiable genetic variant likely responsible for disease was 16.5%. This estimate, which incorporates both variant deleteriousness and frequency, is likely more accurate than previous estimates based on only variant frequency.

1396W

NOX genes - Genetic markers for severity of multiple sclerosis? *A. Gyllenberg[1], L.M. Olsson[2], B. Acharjee[1], M. Khademi[1], H. Lund[1], R. Parsa[1], F. Piehl[1], L. Alfredsson[3,4], J. Hillert[5], R. Holmdahl[2], T. Olsson[1], I. Kockum[1].* 1) Neuroimmunology Unit, Dep. of Clinical Neuroscience, Karolinska Institutet, Centre for Molecular Medicine, Karolinska University Hospital (Solna), S-171 76 Stockholm, Sweden; 2) Division of Medical Inflammation Research, Dep. of Medical Biochemistry and Biophysics, Karolinska Institutet, S-171 77 Stockholm, Sweden; 3) Cardiovascular Epidemiology, Inst. of Environmental Medicine, Karolinska Institutet, S-171 77 Stockholm, Sweden; 4) Stockholm Center for Public Health, Stockholm County Council, Stockholm, Sweden; 5) The Multiple Sclerosis Research group, Dep. of Clinical Neuroscience, Karolinska Institutet, Centre for Molecular Medicine, Karolinska University Hospital (Solna), S-171 76 Stockholm, Sweden.

Statement of purpose: The focus in this project is to analyze how NADPH oxidases (NOX enzymes), essential for the formation of reactive oxygen species (ROS), govern neuroinflammation in Multiple Sclerosis (MS [MIM 126200]). We aim to identify severity variables and investigate genetic association between NOX related genes and MS progress in relation to NOX enzyme activity. Methods used; Using genotypes from a custom made Illumina chip from 7701 MS patients and 6637 healthy controls, we analyzed 1733 Single Nucleotide Polymorphisms (SNPs) in 34 NOX-related genes and for 4 MS-associated biomarkers measured in cerebrospinal fluid (CSF). We also performed qPCR measuring the mRNA levels of gene-expression in CSF samples. Oxidative burst in peripheral blood mononuclear cells (PBMC) was measured in 156 patients with MS or other neurological disease (OND). In the analysis, we compared both MS patients and healthy controls, but also used variables developed to estimate severity or progress of disease. Summary of results; 29 SNP markers in high linkage disequilibrium in the cytochrome b-245 beta chain (*CYBB*) gene on chromosome Xp21.1, coding for a subunit of the enzyme complex NADPH oxidase, where analyzed. We found association to patients with both high MS severity scores (MSSS) and second line treatment compared to individuals with low scores (quartiles) and first line treatment (p=0.003 OR (CI):1.4 (1.1-1.7)) and with strength of burst (Mean Fluorescent Intensity, MFI) in stimulated monocytes (Beta: -0.12, p=0.01) for twenty of these markers. The associated allele correlates with lower burst and also, *CYBB* mRNA is expressed at a lower level in CSF samples from MS patients compared to OND patients. We also identified the same alleles in the *CYBB* gene to be associated with increased levels of neurofilament light (NFL) in CSF, a biomarker for neuronal damage. This association was only among MS patients and not in controls. Taken together, decreased activity of *CYBB* seem to associate with more severe MS. Our results provide preliminary evidence for the involvement of the NOX related gene *CYBB* in severity and progress of MS disease, possibly through the mechanisms of oxidative burst. Importantly, these results do not reach formal criteria for genome wide significance and need confirmation in independent cohorts. We acknowledge the International Multiple Sclerosis Genetics Consortium (IMSGC) for the genotyping. This specific project have support from EU fp7, Neurinox.

1397T

A method for the identification of variants in Alzheimer's disease candidate genes and transcripts using hybridization capture combined with long-read sequencing. *S. Kujawa[1], J. Ekholm[1], M. Jarosz[2], K. Giorda[2].* 1) Pacific Biosciences, Menlo Park, CA; 2) Integrated DNA Technologies, Coralville, IA.

Alzheimer's disease (AD) is a devastating neurodegenerative disease that is genetically complex. Although great progress has been made in identifying fully penetrant mutations in genes such as *APP*, *PSEN1* and *PSEN2* that cause early-onset AD, these still represent a very small percentage of AD cases. Large-scale, genome-wide association studies (GWAS) have identified at least 20 additional genetic risk loci for the more common form of late-onset AD. However, the identified SNPs are typically not the actual risk variants, but are in linkage disequilibrium with the presumed causative variant (Van Cauwenberghe C, et al., The genetic landscape of Alzheimer disease: clinical implications and perspectives. *Genet Med* 2015;18:421-430).Long-read sequencing together with hybrid-capture targeting technologies provides a powerful combination to target candidate genes/transcripts of interest. Shearing the genomic DNA to ~5 kb fragments and then capturing with probes that span the whole gene(s) of interest can provide uniform coverage across the entire region, identifying variants and allowing for phasing into two haplotypes. Furthermore, capturing full-length cDNA from the same sample using the same capture probes can also provide an understanding of isoforms that are generated and allow them to be assigned to their corresponding haplotype.Here we present a method for capturing genomic DNA and cDNA from an AD sample using a panel of probes targeting approximately 20 late-onset AD candidate genes which includes *CLU, ABCA7, CD33, TREM2, TOMM40, PSEN2, APH1* and *BIN1*. By combining xGen® Lockdown® probes with SMRT® Sequencing, we provide completely sequenced candidate genes as well as their corresponding transcripts. In addition, we are also able to evaluate structural variants that due to their size, repetitive nature, or low sequence complexity have been un-sequenceable using short-read technologies.

1398F

Association of CpG-related SNPs (CGSs) with Alzheimer disease. *Y. Ma[1], K.L. Lunetta[1], G. Jun[1,2], J. Chung[1], R. Koester[3], C.C. White[4,5,6], P.L. De Jager[4,5,6], A.C. Naj[7], B.W. Kunkle[8], R. Mayeux[9], J.L. Haines[10], M.A. Pericak-Vance[8], G.D. Schellenberg[7], L.A. Farrer[1], the Alzheimer's Disease Genetics Consortium.* 1) Boston University, Boston, Massachusetts, USA; 2) Andover Production Creation Innovation System (A-PCIS), Eisai Inc., Andover, MA, USA; 3) Medical and Population Genetics Program, Broad Institute, Cambridge, MA, USA; 4) Program in Translational NeuroPsychiatric Genomics, Institute for the Neurosciences, Departments of Neurology and Psychiatry, Brigham and Women's Hospital, Boston, Massachusetts, USA; 5) Harvard Medical School, Boston, Massachusetts, USA; 6) Program in Medical and Population Genetics, Broad Institute, Cambridge, Massachusetts, USA; 7) University of Pennsylvania, Philadelphia, Pennsylvania, USA; 8) University of Miami, Miami, Florida, USA; 9) Columbia University, New York, New York, USA; 10) Case Western Reserve University, Cleveland, Ohio, USA.

There is growing evidence of epigenetic influences on Alzheimer disease (AD) risk, but little is known about associations with CpG-related single nucleotide polymorphisms (CGSs) that govern site-specific methylation. We conducted an AD GWAS focused specifically on CGS using 24 cohorts containing 11,956 AD cases and 12,252 controls assembled by the Alzheimer's Disease Genetics Consortium. We used a sliding-window approach with a window size of 1 kb and a sliding interval of 500 bp to capture the potential regional effects of methylation. After filtering out those CGSs with imputation quality ≤ 0.4 and with genotype information in ≤ 12 cohorts, we obtained 2,288,371 windows containing at least 2 CGSs per window. We identified genome-wide significant (GWS, $P<5\times10^{-8}$) associations with windows spanning 932 kb in the *APOE* region; in *BIN1* (best window: chr2:127,847,001-127,848,000, $P=1.3\times10^{-13}$); the intergenic region between *LRFN2* and *UNC5CL* (best window, chr6:40,825,501-40,826,501, $P=1.2\times10^{-8}$); *TREM2* (best window, chr6:41,128,501-41,129,500, $P=1.7\times10^{-8}$); *MS4A6A* (best window, chr11:59,923,001-59,924,000, $P=2.7\times10^{-10}$); *MS4A4A* (best window: chr11:60,030,001-60,031,000, $P=4.8\times10^{-11}$); and *PICALM* (best window: chr11:85,759,501-85,760,500, $P=6.3\times10^{-9}$). Associations in 13 of the 15 GWS windows were no longer significant in analyses that controlled for non-CGSs in these windows, suggesting a unique role of CGSs in AD. We investigated the functional relevance of these findings by evaluating the association of CGSs in the best window of each significant locus with methylation levels of CpG sites reported to be related with neurofibrillary tangle counts in brains of 708 random subjects from the Religious Order Study and the Memory and Aging Project. The combined effect of CGSs in the best window of *BIN1* is associated with methylation level of cg22883290 ($P=1.4\times10^{-3}$), and that in the best windows of *MS4A6A* ($P=3.9\times10^{-3}$) and *PICALM* ($P=0.02$) are associated with methylation level of cg04585722. Methylation data were unavailable to evaluate these associations for top windows in chromosome 6. Our study suggests that DNA methylation has an important role in pathways leading to AD.

1399W

Genome-wide significant associations with AD and variants in *UGT2B28*, *AXIN2*, *SYCE1*, *BCAT1*, *FAM13A*, **and** *DQ594761*: **The Alzheimer's Disease Sequencing Project Dominican families.** *A. Parrado[1], L. Henehan[2], Q. Li[3], P. Peeters[4], G. Rajagapol[1], K. Bachman[1].* 1) Discovery Sciences, Janssen Pharmceutical R&D, Spring House, PA, USA; 2) Trinity Prep High School, Winter Park, FL, USA; 3) Janssen Pharmaceutical, Titusville, NJ, USA; 4) Janssen Pharmaceutical, Beerse, Belgium.

Introduction: To identify novel genetic variants contributing to increased risk or protection against developing Alzheimer's disease (AD) among Caribbean Hispanic and Caucasian families. **Methods:** We preformed family-based association tests (FBAT) to identify an over or under-transmission of alleles among affected offspring that deviate from the expected distribution, derived using Mendel's law of segregation, using the Alzheimer's Disease Sequencing Project (ADSP – discovery phase) whole-genome sequence (WGS) cohort consisting of 84 highly informative multiplex families. We studied the WGS data of 362 AD diagnosed patients and 68 unaffected relatives, the largest proportion (n=67) of families self-reported from Dominican Hispanic ancestry (the first of the six consent groups from the ADSP Study). **Results:** We identified six variants located in the intronic or promoter region of six genes (*UGT2B28, AXIN2, SYCE1, BCAT1, FAM13A* and *DQ594761*) that achieved a genome-wide level of statistical significant association (FBAT $P < 5\times10^{-8}$) with Alzheimer's disease diagnosis. Additionally, we identified six variants in or near six genes (*POU6F1, NRG3, SLITRK1, SMIM15, AC092684.1,* and *RP11-986E7.2*) with a suggestive level of statistical significant association (FBAT $P < 1\times10^{-6}$) with AD diagnosis. **Conclusions:** Interestingly, *UGT2B28, SLITRK1, AXIN2, BCAT1,* and *NRG3* are expressed in the brain (i.e. hippocampus, glial cells, and ganglion), furthermore, *NRG3* and *SLITRK1* have been associated with neurological diseases (Schizophrenia and Tourette's, respectively). *Axin2* plays an important role in the Wnt/Hedgehog/Notch signaling pathway, in concert with *PSEN1* and *PSEN2.* Neuregulin 3 *(NRG3)* is involved in the nuclear signaling pathway through *ErbB4* with *PSEN2.* Noteworthy, similar to *APP* and *PICALM, SLITRK1* (SLIT And NTRK-Like Family, Member 1) plays a role in Axonogenesis.

1400T

Identification of amyotrophic lateral sclerosis loci using distantly related relatives in large pedigrees. *K.L. Russell[1], J.M. Downie[1], S.B. Gibson[2], K.P. Figueroa[2], M.B. Bromberg[2], S.M. Pulst[2], L.B. Jorde[1].* 1) Department of Human Genetics, University of Utah School of Medicine, Salt Lake City, UT 84112; 2) Department of Neurology, University of Utah School of Medicine, Salt Lake City, UT 84132.

Amyotrophic lateral sclerosis (ALS) is a fatal disease that causes both upper and lower motor neurons to progressively degenerate, culminating in paralysis and respiratory failure. Approximately 68% of familial ALS cases (i.e., those in which a first- or second-degree relative is affected) have an identifiable mutation in one of more than 30 ALS-causing genes. Among non-familial ALS cases, about 16% have a mutation in one of these genes. The purpose of this study is to identify ALS genetic risk loci by performing whole-genome sequencing and shared genomic segment analysis between pairs of ALS patients who are considered to be non-familial but are distantly related and may share disease-causing variants. The Utah Population Database (UPDB) was used to identify 35 ALS patients who were distantly related to at least one other ALS patient. UPDB identified 30 pairwise relationships among these 35 patients, which range from 6-14 degrees of relationship (median = 10). Whole-genome sequencing was performed on these 35 ALS patients to an average coverage of 60X. BWA and GATK (v3.3) were used to perform read alignment and variant calling. Genomic segments that were on average 589 kb in size and were shared between the ALS patients were identified in a pairwise manner using IBDseq. To validate our approach, we determined whether these shared genomic segments contained any of 33 genes known to be associated with ALS pathogenesis (*ANG, ATXN2, CHCHD10, CHMP2B, C9orf72, DAO, DCTN1, ELP3, ERBB4, EWSR1, FIG4, FUS, GLE1, GRN, HNRNPA1, HNRNPA2B1, MATR3, NEFH, NEK1, OPTN, PFN1, SETX, SOD1, SPAST, SQSTM1, SS18L1, TAF15, TARDBP, TBK1, TUBA4A, UBQLN2, VAPB, VCP*). Four pairs of samples shared a genomic segment that contained *SOD1, CHCHD10, CHMP2B,* or *DCTN1*. Next, we sought to determine if any nonsynonymous variants could be identified in these genes. Ensembl's Variant Effect Predictor tool was used to identify variants that result in protein coding sequence changes. A single shared nonsynonymous variant in *CHCHD10* (rs9153) was identified. The encoded protein is located in the intermembrane space of mitochondria and is hypothesized to be involved in cristae structure maintenance. These results suggest that shared genomic segment analysis may be helpful in identifying both known and novel ALS risk loci. Future efforts will be made to identify specific variants in these shared genomic segments that may be responsible for ALS pathogenesis.

Rescue of locomotion defect in Drosophila model of spastin hereditary spastic paraplegia. *F.V. Bolduc[1,2,3], C. Rosenfelt[1], J.A. Parker[4], P. Drapeau[4], G.A. Rouleau[5].* 1) Dept Pediatrics, Univ Alberta, Edmonton, Alberta, Canada; 2) Neuroscience and Mental Health Institute, University of Alberta; 3) Dept Medical Genetics, Univ Alberta, Edmonton, Alberta, Canada; 4) CRCHUM and Department of Neuroscience, Université de Montréal, Montréal, Québec, Canada; 5) Montreal Neurological Institute and Hospital, McGill University, Montreal, Quebec, Canada.

Background. Hereditary spastic paraplegia (HSP) is associated with progressive locomotion defects in human. Several causative genes have been identified but there remain no clinical treatment available. *SPASTIN* is the most common gene mutated in autosomal dominant HSP. We recently identified a role for oxidative stress in *SPASTIN* homologues mutants using various model organisms. Furthermore, we were able to show that pharmacological treatments aimed at reducing oxidative stress (methylene blue, n-acetylcysteine and phenazine). In all three models, improvement in locomotion was observed. Furthermore, cellular markers of oxidative stress were reduced closer to control level. Here we tested another potential treatment for HSP not tested in the Drosophila model: guanabenz. Methods. Transgenic Drosophila expressing spastin RNAi with the pan neuronal driver ELAV were used. Groups of 20 flies are used for each trial. Flies are incubated for 21 hours at 22C before being inserted into a glass cylinder for the assay. Flies are then tapped at the bottom of the cylinder and allowed to climb. The percentage of flies climbing above the 190mL line is recorded every 10 seconds for 2 minutes. For drug treatment, flies were transferred to drug/vehicle 24 hours prior to testing. Statistical analysis is performed using Tukey test to compare each group (untreated and treated for each genotype). Results. We observed a significant improvement (P=0.0091) in the percentage of ELAV-spas RNAi flies climbing above the target line after treatment with 300uM guanabenz. Conclusions. HSP is a devastating disorder associated with progressive loss of mobility and spasticity that remains without treatment. These results combined with our previously published data provide strong pre-clinical support for the use of antioxidants in HSP.

1402W

Genetic variants in the *SNCA* and alpha-synuclein immunostaining in the gastric and colonic mucosa in Parkinson's disease. *S. Chung[1], K. Lohmann[2], J. Kim[3], H. Ryu[1], F. Hinrichs[2], H. Lee[4], K. Kim[1], J. Lee[4], K. Jung[4], M. Kim[5], Y. Kim[1], S. Yun[6], J. Lee[7], S. Hong[8], S. Myung[4], C. Klein[2].* 1) Department of Neurology, Asan Medical Center, Seoul; 2) Institute of Neurogenetics, University of Luebeck, Luebeck; 3) Department of Neurology, Metro hospital, Anyang; 4) Department of Gastroenterology, Asan Medical Center, Seoul; 5) Health Screening and Promotion Center, Asan Medical Center, Seoul; 6) Division of Biostatistics, Center for Medical Research and Information, Asan Medical Center, Seoul; 7) Asan Institute for Life Sciences, Asan Medical Center, Seoul; 8) Department of Pathology, Asan Medical Center, Seoul.

Background: Alpha-synuclein (a-Syn) deposition in the enteric nervous system (ENS) has been reported in patients with Parkinson's disease (PD). However, enteric α-Syn has also been reported in healthy individuals. The determining factors for the a-Syn deposition in the gastric and colonic mucosa of human are unclear. **Objectives:** We aimed to investigate the association between genetic variants in the *SNCA* and a-Syn immunostaining in the ENS in PD patients and controls. **Methods:** Study subjects consisted of 38 patients with PD and 53 controls. The a-Syn immunohistochemistry was performed for gastric and colonic mucosal tissues that was obtained by endoscopic gastroduodenoscopy and colonoscopy. The *SNCA* SNP rs11931074 and REP1 variants were genotyped in all subjects. **Results:** The positivity of a-Syn immunostaining was not different between PD patients (31.6% for stomach and 10.4% for colon) and controls (33.3% for stomach and 18.5% for colon). In comparisons between subjects with positive a-Syn immunostaining and those without, *SNCA* SNP rs11931074 (G allele) were significantly associated with positive a-Syn immunostaining for the stomach and colon mucosa in analyses for PD patients only (OR = 5.96, 95% CI = 1.70 – 20.97, P = 0.005, additive model) and in analyses for all subjects (PD patients + controls) (OR = 1.98, 95% CI = 1.02 – 3.82, P = 0.043, additive model). The longer *SNCA* REP1 alleles are associated with positive a-Syn immunostaining for the stomach and colon in all subjects (PD patients + controls) (OR = 4.16; 95% CI = 1.27 – 13.67; P = 0.019). **Conclusion:** Genetic variants in the *SNCA* may have an effect on a-Syn deposition in the gastric and colonic mucosa in PD patients as well as in healthy individuals.

1403T

***NUBPL* mutations link Parkinson's disease and other movement disorders to recessive Complex I deficiency.** *P.S. Eis[1], B. Schüle[2], S. Kim[2], J.W. Langston[2], V.E. Kimonis[3], E. Hatchwell[1].* 1) Population Diagnostics, Inc., Melville, NY; 2) The Parkinson's Institute and Clinical Center, Sunnyvale, CA; 3) Division of Genetics and Metabolism, Department of Pediatrics, University of California, Irvine, Children's Hospital of Orange County, Orange, CA.

Complex I Deficiency (CID) is an autosomal recessive disorder caused by homozygous or compound heterozygous mutations in one of at least 23 nuclear-encoded genes, which include Complex I (CI) subunits and assembly factors (MIM 252010). Parkinson's Disease (PD) pathology in many patients includes deficiency in CI activity (first reported in 1989). In a genome-wide PD gene discovery study, we performed array comparative genomic hybridization (aCGH) on a PD cohort of 468 patients to identify copy number variants (CNVs) impacting genes potentially causative of PD. This genome-wide screen led to the identification of one patient with a large, complex chromosomal rearrangement that was an apparent loss of function mutation impacting CI assembly factor *NUBPL* (nucleotide binding protein-like), an Fe-S protein. Mutations in *NUBPL* (MIM 613621) were identified as a cause of CID in 2010, and intriguingly, the first patient was reported to have a CNV identical to that found in our PD patient on one allele, and a splicing mutation (c.815-27T>C) on the other allele. Given the strong biology linking CI activity and PD, we sequenced *NUBPL* in the PD cohort (n=477) and found three novel SNVs that may be causing or contributing to PD. We also observed three patients that are heterozygous for the splicing mutation (c.815-27T>C). Subsequent identification of two new patients with *NUBPL* CID revealed a family history, in older relatives, of PD, essential tremor (ET), or restless legs syndrome (RLS), which further supports the role of this CI assembly factor in late-onset movement disorders. Analogous to mutations in *GBA* (MIM 606463) linking autosomal recessive Gaucher disease to an increased risk of PD in *GBA* mutation carriers, we hypothesize that heterozygous *NUBPL* mutation carriers have an increased risk for late-onset movement disorders that include PD, ET, and RLS.

1404F

Assessing the contribution of common polygenic risk and rare variation in 1,975 migraine families from Finland. *P. Gormley[1,2,7], M.I. Kurki[1-3,7], A. Mitchell[4], M. Hiekkala[5], P. Häppölä[3], D. Lal[1,2], I. Surakka[3], P. Palta[3], G. Srivastava[4], M. Kaunisto[3], J. Rämö[1-3], E. Hämäläinen[3], M.J. Daly[1,2], S. Ripatti[3], M. Kallela[6], H. Runz[4], B.M. Neale[1,2], M. Wessman[3,5], A. Palotie[1-3].* 1) Massachusetts General Hospital, Harvard Medical School, Boston, MA; 2) Broad Institute of Harvard and MIT, Cambridge, MA; 3) Institute for Molecular Medicine Finland (FIMM), University of Helsinki, Helsinki, Finland; 4) Department of Genetics & Pharmacogenomics, Merck Research Laboratories, Merck and Co., Inc., Boston, MA; 5) Folkhälsan Institute of Genetics, Folkhälsan Research Center, Helsinki, Finland; 6) Helsinki University Central Hospital, Helsinki, Finland; 7) These authors contributed equally.

Migraine is a complex neurological disease affecting almost one billion people worldwide (PMID:26063472). It is known to aggregate in families and twin studies have established a strong genetic component (PMID:25985137). Disease presentation ranges from the rare (and severe) hemiplegic migraine (HM) to the more common forms; migraine with aura (MA) and migraine without aura (MO). Likewise, the spectrum of genetic variation conferring risk ranges from three Mendelian gene variants known for HM (*CACNA1A, ATP1A2,* and *SCN1A*) to the 38 common variant loci identified by genome-wide association studies (Gormley et al., *Nat. Genet.*, In press). We investigate the contribution of common polygenic and rare variation to migraine in 1,975 families from Finland, including 563 HM, 2,649 MA, 2,622 MO, and 2,813 unaffected members. It is the largest collection of migraine families to our knowledge. We genotyped 8,992 family members on either the Illumina Core-Exome or PsychArray. We compared the within-family imputation accuracy by three approaches; 1) a Finnish reference panel of 1,941 individuals whole-genome sequenced (WGS) at low coverage (4.6x); 2) a joint Finnish + 1000 Genomes panel (2,504 individuals at 7.4x WGS + 65.7x exome); and 3) a family-based imputation using high coverage (30x) WGS from 631 members of the same families. Both population panels accurately imputed allele frequencies down to 0.1% and while sensitivity was 4% higher for the joint panel, the Finnish-specific panel introduced only a fraction (27.5%) of the false positives imputed by the joint panel. In the family-based approach, imputation was accurate for individuals with two sequenced parents and one sibling (95–99% of true variants were imputed with 0.2% discordance). However, much lower accuracy was observed for those more distantly related to sequenced individuals (e.g. with two sequenced grandparents only 30% of variants were imputed with 10% discordance). To assess the relative contribution of common polygenic and rare variation, we calculated polygenic risk scores (PRS) for each individual using effect sizes from a recent migraine GWAS (*N*=375,000). We identified 442 families (22.4%) with a median PRS in the highest quartile of the PRS distribution (i.e. migraine risk was mostly polygenic) and 383 families (19.4%) in the lowest quartile where rare variation likely contributes more. Future work will assess rare variants aggregating in these low PRS families by association and linkage analyses.

1405W

Whole-exome sequencing identifies *FIG4* as a risk gene for ALS in a central European cohort. *A. Osmanovic[1], I. Rangnau[1], A. Kosfeld[1], J.H. Martens[1], S. Abdulla[2], C. Janssen[2], B. Auber[1], P. Raab[3], M. Preller[4], S. Petri[2], R.G. Weber[1].* 1) Hannover Medical School, Department of Human Genetics, Hannover, Germany; 2) Hannover Medical School, Department of Neurology, Hannover, Germany; 3) Hannover Medical School, Department of Neuroradiology, Hannover, Germany; 4) Hannover Medical School, Institute for Biophysical Chemistry and Center for Structural Systems Biology, German Electron Synchrotron (DESY), Hamburg, Germany.

We aimed to identify the genetic cause of the devastating neurodegenerative disease amyotrophic lateral sclerosis (ALS) in a German family with two affected individuals, and to assess the prevalence of mutations in the identified risk gene, *FIG4*, in a central European ALS cohort. Therefore, whole-exome sequencing (WES) and an overlapping data analysis strategy were performed in an ALS family with autosomal dominant inheritance and incomplete penetrance. Additionally, 200 central European ALS patients were analyzed using whole-exome or targeted sequencing. All patients were subjected to clinical, electrophysiological, and neuroradiological characterization to explore genotype-phenotype relationships. WES analysis of the ALS family identified the rare heterozygous frameshift mutation *FIG4*,c.759delG;p.(F254Sfs*8) predicted to delete the catalytic domain and active center from the encoded phosphoinositide 5-phosphatase with a key role in endosomal vesicle trafficking. Additionally, novel or rare heterozygous *FIG4* missense mutations predicted to be deleterious were detected in five sporadic ALS patients revealing an overall *FIG4* mutation frequency of 3% in our cohort. Four of six variants identified were previously associated with ALS or the motor and sensory neuropathy Charcot-Marie-Tooth disease type 4J (CMT4J), while two variants were novel. In *FIG4* mutation carriers, disease duration was longer and upper motor neuron predominance was significantly more frequent compared to ALS patients without *FIG4* mutation. In summary, our study confirms *FIG4* as an ALS risk gene in a central European cohort, adds new variants to the mutational spectrum, links ALS to CMT4J on a genetic level, and describes a distinctive ALS phenotype for *FIG4* mutation carriers.

1406T

Targeted high-throughput screening of olivocerebellar motor circuitry genes in essential tremor. *J-F. Schmouth[1], C. Leblond[2], G. Houle[2], S. Beatrice-Laurent[1], C. Bourrassa[1], C. Vilarino-Guell[3], A. Rajput[4], P. Dion[1], G. Rouleau[1].* 1) Neurology and Neurosurgery, McGill University, Montreal, Quebec, Canada; 2) Human Genetics, McGill University, Montréal, Quebec, Canada; 3) Medical Genetics, University of British Columbia, Vancouver, British-Columbia, Canada; 4) University of Saskatchewan, Saskatoon, Saskatchewan, Canada.

   Background: Essential Tremor (ET) is a prevalent neurological disorder of unknown etiology that is characterized by the presence of action tremors occurring during voluntary motion. The worldwide prevalence of ET is 0.9% in the general population and 4.6% in individuals ≥65 years old. Twin studies are suggesting that genetic risk factors likely contribute to the pathology. To date, no gene was reproducibly reported to cause ET across unrelated cohorts which is likely due to the genetic heterogeneity of the disorder. Mounting evidence currently suggests dysfunctions affecting the olivocerebellar motor circuitry as the primary source of tremors; with the inferior olive, Purkinje cells and deep cerebellar nuclei being the main affected brain regions. **Hypothesis:** Genes that are phylogenetically conserved for their expressions in the olivocerebellar circuitry are susceptible to present genetic variations that would be ET risk factors. **Methods:** A preliminary list of 11 candidate genes that were selected based on their high level of expression in the olivocerebellar circuitry in both human and mouse has been generated. The 11 genes from this list, which noticeably appear to encode several proteins involved in calcium and glutamate signaling pathways, will be screened for the presence of genetic variations in a cohort of cases and controls. Calcium related genes are plausible candidates since previous evidence supports calcium dependent pathways to play a role in the generation of neuronal oscillations, resonance and pacemaker activities. Glutamate signaling related genes are also good candidates since NMDAR agonists are known to alleviate harmaline induced tremors. The mutation screen was done using a Molecular Inversion Probes (MIPs) capture methodology. For this particular project, a total of 991 MIPs were designed to screen 269 cases and 288 matching control individuals. The primary focus of our genetic analysis will be on the identification of nonsense and missense mutations. Further examination will use a statistical burden method that will collapses all the rare variants located in the different candidate genes into a single value, which is then tested for association with the phenotype. **Outcome:** The list of 11 candidates contains genes functionally related to three defined pathways. Hence, if proven true, this approach has not only the potential in identifying novel ET risk factors but could also link this pathology to a particular signaling pathway.

1407F

Linkage analysis on the 20 consanguineous singleton families with multiple system atrophy. *T. Yasuda, T. Matsukawa, H. Ishiura, J. Mitsui, S. Tsuji.* Neurology, The University of Tokyo, Bunkyo-ku, Tokyo, Japan.

   Background & Purpose: Although MSA is mostly a sporadic disease, mutations in *COQ2* with an autosomal recessive inheritance was associated with MSA in rare familial cases. Assuming there may be other causative genes with autosomal recessive inheritance, we focused on patients with MSA born to consanguineous parents. We conducted a parametric linkage analysis with an autosomal recessive inheritance model. **Methods:** We analyzed 20 Japanese MSA patients born to consanguineous parents. The consanguineous parents were all first cousins. We calculated the multipoint parametric LOD scores based on SNP typing. Unaffected siblings of the MSA patients, if available, were also included in the analysis. We used Genome-Wide Human SNP Array 6.0 (Affymetrix) for SNP typing. LOD scores were calculated using SNP HiTLink and Allegro 2.0 under an autosomal recessive model (disease allele frequency of 10^{-3} and a penetrance of 1.0). **Result:** In these 20 families, the onset ages ranged from 35 to 69 years old, including 11 female and 9 male cases. These cases included 14 MSA-C, 4 MSA-P and 2 unclassifiable cases. In these cases, one MSA-C patient carried a homozygous V393A mutation in *COQ2*. Cumulative multipoint parametric LOD scores did not reveal loci with positive LOD scores, suggesting genetic heterogeneity. There were multiple loci giving positive HLOD scores exceeding 1.0. **Conclusion:** Presence of homozygous V393A in one patient further supports our previous findings that *COQ2* variants are associated with MSA. Further detailed linkage analyses are required to dissect genetic loci involved in MSA. In particular, detailed linkage analyses of the MSA patients born to consanguineous parents should facilitate the search for genes involved in MSA.

1408W

Genome wide association study of cisplatin-induced peripheral neuropathy (CIPN) in testicular cancer survivors. *O. El-Charif[1], H.E. Wheeler[2], B. Mapes[1], T. Mushiroda[3], M. Kubo[3], E. Gamazon[4], D.R. Feldman[5], R.J. Hamilton[6], D.J. Vaughn[7], C.J. Beard[8], C. Fung[9], S.D. Fossa[10], C. Albany[11], N.J. Cox[4], L.H. Einhorn[11], L.B. Travis[11], M.E. Dolan[1].* 1) Medicine, Univ Chicago, Chicago, IL; 2) Departments of Biology and Computer Science, Loyola University, Chicago, IL; 3) RIKEN Center for Integrative Medical Science, Yokohama, Japan; 4) Division of Genetic Medicine, Vanderbilt University, Nashville, TN; 5) Department of Medical Oncology, Memorial Sloan-Kettering Cancer Center, Memorial Sloan-Kettering, New York, NY; 6) Department of Surgical Oncology, Princess Margaret Cancer Centre, Princess Margaret Cancer Centre, Toronto, ON; 7) Department of Medicine University of Pennsylvania, Philadelphia, PA; 8) Department of Radiation Oncology, Dana-Farber Cancer Institute, Boston, MA; 9) J.P. Wilmot Cancer Institute, University of Rochester Medical Center University of Rochester Medical Center, Rochester, NY; 10) Department of Oncology, Oslo University Hospital, Radiumhospital, Oslo Norway; 11) Department of Medical Oncology Indiana University, Indianapolis, IN.

Chemotherapy-induced peripheral neuropathy, one of the most common and potentially permanent side effects of modern chemotherapy, can adversely affect survivors' quality of life due to the lack of treatment that can effectively prevent or mitigate it. Although cisplatin-based therapy is curative for testicular cancer, this drug is associated with multiple long-term serious toxicities, including peripheral neuropathy. We performed a genome-wide analysis of neuropathy in a cohort of 847 testicular cancer survivors using EORTC-CIPN20, a validated patient-reported questionnaire. Median age at diagnosis was 30 ± 9 (SD) years and median cumulative dose was 400 mg/m². The most clinically relevant symptoms (tingling, numbness and pain) were common (55% having any). The subscale from these items indicated excellent internal consistency (Cronbach $\alpha = 0.88$) and was subsequently used to model CIPN. Patients were placed into 3 severity groups: 45% none, 39% a little, and 16% quite a bit/very much. 5.1 million SNPs passed quality control in 680 genetically European individuals; SNP dosages and covariates including age, dose and 10 genetic principal components were regressed on this phenotype using an additive ordinal model. SNPs within several genes involved in cytochrome C-dependent apoptosis, neural excitability, intracellular trafficking, and vascularization were identified ($p < 5 \times 10^{-5}$). Chip heritability analysis revealed that CIPN likely has a polygenic architecture ($h^2 = 0.70 \pm 0.49$, $P = 0.049$). An eQTL for *GSTT1*, a gene known to play a role in cisplatin detoxification was also identified ($p = 1.8 \times 10^{-5}$). We performed permutation-resampling analysis to identify enrichment of candidate genes involved in cisplatin metabolism, i.e., Mendelian Charcot-Marie-Tooth (CMT) genes, and SNPs associated with preclinical cellular sensitivity to cisplatin. Enrichment of CMT genes was significant across a range of p-values (0.005-0.05, $\alpha = 0.10$) and implicated the gene *FGD4*, previously identified in a GWAS of paclitaxel-induced neuropathy. Further studies will focus on replication of findings in an independent cohort and functional validation of the implicated pathways.

1409T

The genetics of levodopa-induced dyskinesia in Parkinson's disease. *O.V. Sazonova, I. Hallgrímsdóttir, J. Shelton, P. Cannon. Research, 23andMe, Mountain View, CA.*

Parkinson's disease (PD) is a progressive movement disorder that afflicts approximately one percent of the population. PD is caused in part by the progressive destruction of dopamine-producing neurons of the substantia nigra, precipitating the onset of a wide range of symptoms. Levodopa, a compound converted into dopamine in the brain, is the most effective therapy for treating the stiffness, tremors, spasms, and poor muscle control of PD. However, the majority of patients using levodopa-containing therapies go on to develop levodopa-induced dyskinesia (LID), a disorder of involuntary, jerky movements. Many discontinue the therapy or reduce drug dosage due to LID severity, all to the detriment of managing their PD symptoms. Recent candidate gene studies have demonstrated a genetic predisposition for LID involving a number of genes that play a role in neurotransmission. 23andMe has a large research database of genetic and phenotypic information collected from individuals diagnosed with PD, with over 12,200 genotyped individuals who have consented to research. We hypothesized that there are genetic markers of LID that can be discovered through genotyping and self-reported dyskinesia among individuals on levodopa therapies. To test this hypothesis, we developed a new survey to define binary and quantitative phenotypes for individuals who have altered or discontinued their levodopa regimens due to dyskinesia symptoms. By capturing timelines of PD onset, the start of levodopa treatment, the start of LID, and the disruption of treatment due to LID, the data enabled genome-wide association studies (GWAS) of LID onset and severity. We present these results along with their comparison to previous candidate gene studies, thereby deepening our understanding of the role of genetic variation in levodopa-induced dyskinesia. Leveraging the unique resources of 23andMe's PD cohort, the present study is the first genome-wide investigation of side effects associated with levodopa therapy. Our findings offer important insight into the complex mechanisms of this disorder, and lay the groundwork for developing new therapies to reduce LID and for personalizing PD treatment based on patient genotype.

1410F

Impaired mitochondrial function and dynamics in the pathogenesis of FXTAS. *M.I. Alvarez-Mora[1], L. Rodriguez-Revenga[1], I. Madrigal[1], M. Guitart-Mampel[2], G. Garrabou[2], M. Milà[1].* 1) Biochemistry and Molecular Genetics, Hospital Clinic and CIBERER, Barcelona, Spain; 2) Muscle Research and Mitochondrial Function Laboratory, CELLEX, Faculty of Medicine-University of Barcelona, Internal Medicine Department, Hospital Clinic and CIBERER, Barcelona, Spain.

Mitochondrial involvement plays an important role in neurodegenerative diseases. At least one-third of adult carriers of a *FMR1* premutation (55-200 CGG repeats) are at risk of presenting an adult-onset neurodegenerative disorder known as fragile X-associated tremor/ataxia syndrome (FXTAS). In an attempt to provide new insights into the mechanisms involved in the pathogenesis of FXTAS, we characterized mitochondrial function and dynamics by the assessment of oxidative respiratory chain function, mitochondrial content, oxidative stress levels and mitochondrial network complexity. Regarding mitochondrial function we found that mitochondrial respiratory capacity is compromised in skin fibroblasts whereas in blood no differences were observed between the FXTAS and control groups. Furthermore, fibroblasts from FXTAS patients presented altered mitochondrial architecture, with more circular and less interconnected mitochondria being observed. Mitochondrial function and dynamics deregulation, characteristic of neurological disorders, are present in FXTAS patients. These features might be limiting temporal and spatial bioenergetics cells supply and thus contributing to disease pathogenesis.

1411W

Generation of disease-specific autopsy-confirmed iPSCs lines from post-mortem isolated peripheral blood mononuclear cells. *A. Ali[1], K. Belle[1,2], F. Shabazz[2], K. Nuytemans[2], D. Davis[3], J. Young[1,2], W. Scott[1,2], D. Mash[3,4], J. Vance[1,2], D. Dykxhoorn[1,2].* 1) University of Miami, Miami, FL., Select a Country; 2) John P. Hussman Institute for Human Genomics,; 3) Department of Neurology; 4) Department of Molecular and Cellular Pharmacology,.

Understanding the molecular mechanisms that underlie neurodegenerative disorders has been hampered by a lack of readily available model systems that replicate the complexity of the human disease. Recent advances in stem cell technology have facilitated the derivation of patient-specific stem cells from a variety of differentiated cell types. Induced pluripotent stem cells (iPSCs) are an attractive disease model since they can be grown and differentiated to produce large numbers of disease-relevant cell types. However, most iPSC lines are derived in advance of, and without the benefit of, neuropathological confirmation of the donor – the gold standard for many disease classifications and measurement of disease severity. While others have reported the generation of autopsy-confirmed iPSC lines from patient explants, these methods require outgrowth of cadaver tissue, which require additional time and is often only successful ~50% of the time. Here we report the rapid generation of autopsy-confirmed iPSC lines from peripheral blood mononuclear cells (PBMCs) drawn postmortem. Since this approach doesn't require the propagation of previously frozen cadaver tissue, iPSC can be rapidly and efficiently produced from patients with autopsy-confirmed pathology. These matched iPSC-derived patient-specific neurons and postmortem brain tissue will support studies of specific mechanisms that drive the pathogenesis of neurodegenerative diseases.

1412T

BLM DNA helicase protects against (CAG)•(CTG) repeat instability.

M.H.M. Schmidt[1,2], G.B. Panigrahi[1], S. Lanni[1], M. Kekis[3], T. Ezzy[1,4], S. Sample[5], C.E. Pearson[1,2]. 1) Genetics & Genome Biology, The Hospital for Sick Children, Toronto, Canada; 2) Molecular Genetics, The University of Toronto, Toronto, Canada; 3) Cytogenetics & Molecular Genetics, Emory University, Atlanta, GA; 4) Molecular Biology & Biotechnology, University of Toronto at Scarborough, Toronto, Canada; 5) Michael G. DeGroote School of Medicine, McMaster University, Hamilton, Canada.

Trinucleotide repeat expansions are associated with 43 neuromuscular and neurodegenerative disorders. Ongoing repeat expansions drive disease progression, and are caused by aberrant DNA repair. The Bloom (BLM) protein regulates sister chromatid exchange with it's DNA unwinding (helicase) and DNA annealing activities, critical during DNA replication and DNA repair. BLM's branch migration activity at three- and four-way DNA junctions suggests a possible role for BLM in unwinding unusual DNA structures such as slipped-DNAs, which we have previously shown to arise at expanded (CAG)•(CTG) repeat tracts of the myotonic dystrophy locus in patient tissues. Here we examined the replication products of (CAG)•(CTG) repeat tracts in the presence or absence of BLM. In the absence of BLM, we detect the formation of slipped-DNA structures that are indicative of repeat instability (expansions and contraction events). These structures formed only when (CTG) was used as the lagging strand template for DNA replication, where repeats tended to contract. Inclusion of functional BLM eliminated the accumulation of slipped-DNAs. Point mutations that inactivate the DNA unwinding helicase or DNA annealing domains of BLM revealed that the helicase domain was necessary to avoid slipped-DNA formation. Further, we show that BLM helicase activity, but not BLM annealing activity, is required for *in vitro* repair of DNA containing a single (CTG) repeat unit slip-out. The BLM helicase activity is not required for the repair of a longer slip-out of 20 repeats, suggesting that BLM protects against small changes of repeat lengths. Together, these results support a new model through which disease-associate trinucleotide repeat are protected from contractions by the BLM helicase.

1413F

Repetitive and restrictive behaviors associate with the prohibitin gene in autism.

R. Cantor-Chiu[1], L. Navarro[1], D. Geschwind[2], J. Lowe[2]. 1) Dept Human Gen, UCLA Sch Med, Los Angeles, CA; 2) Dept Neurology, UCLA Sch Med, Los Angeles, CA.

Autism Spectrum Disorders (ASDs) are behaviorally defined phenotypes that manifest prior to age 3 as deficits in communication skills and social interactions, including restricted and repetitive behaviors (RRBs). A salient conclusion of current genetic studies is that ASDs are polygenic and genetically complex, with as many as 1,000 predisposing genes. We hypothesized that focusing analyses on RRBs, a feature of ASDs, might reduce genetic heterogeneity and complexity. We mined Caucasian GWAS data from two of the largest ASD family cohorts. RRBs were measured in the Autism Genetics Resource Exchange (AGRE) and the Autism Genome Project (AGP) families using the Autism Diagnostic Inventory –Revised (ADIR), an interview administered to the parents of potential ASD cases. In the full AGRE sample, seven of twelve RRBs measured were significantly familial. The seven RRBs were tested for association, genome-wide, in the 1592 ASD affected children from 846 AGRE families and the 1108 ASD affected children from 1092 AGP families that were genotyped. Imputation resulted in 5,755,879 AGRE and 3,972,813 AGP SNPs for association analyses with the seven RRBs. GWAS were conducted using the EMMAX software to account for family structure. A stringent p-value, correcting for testing multiple traits, was employed (p<7.1E-9). Replication was set at p<0.01. In the AGP sample, significant association (p<6.8E-9) was seen with rs2898883 within an intron of the Prohibitin (PHB) gene at 17p21 for the RRB described as the repetitive use of objects or interest in parts of objects. Association was seen with multiple independent PHB SNPs for the same trait in the AGRE sample (p<0.01). Remarkably, 17p21 previously showed linkage and its replication in earlier analyses of ASD in the AGRE sample. PHB, a regulatory gene for cell growth that inhibits DNA synthesis, has not previously been associated with ASD. These analyses identify a novel risk gene for a behavior used to define ASD and support the hypothesis that reducing phenotypic complexity can enhance the power to identify novel risk genes for complex traits.

1414W

De novo loss of function mutations in *KMT2A* is a risk factor for autism spectrum disorder and other neurodevelopmental phenotypes. *A. Chan[1,2], M. Uddin[1], R. Yuen[1], T. Higginbotham[1], M. Zarrei[1], S. Walker[1], S.W. Scherer[1,2,3].* 1) The Centre for Applied Genomics and Program in Genetics and Genome Biology, The Hospital for Sick Children, Toronto, On, Canada; 2) Department of Molecular Genetics, University of Toronto, Toronto, On, Canada; 3) McLaughlin Centre, University of Toronto, Toronto, On, Canada.

De novo loss of function (LoF) mutations in *KMT2A* have been associated with Wiedemann-Steiner Syndrome (WSS), which is characterized by hypertrichosis cubiti, dysmorphic facial features, short stature, developmental delay, and intellectual disability. Recently, whole-exome sequencing studies have found de novo LoF mutations in some individuals with neurodevelopmental disorders (NDDs), including autism spectrum disorder (ASD). *KMT2A* encodes a histone methyltransferase that is required for neurogenesis, early development and hematopoiesis. Here, we present the clinical and genomic characterization of two unrelated individuals with ASD, who possess de novo frameshift mutations in *KMT2A* identified by whole-genome sequencing. By performing a meta-analysis on WSS cohorts (n=16), ASD (n=5615) and other NDD cohorts (n=1797), and control trios (n=2169), we found that 0.32% (24/7412 cases) of individuals with NDDs have de novo LoF mutations in *KMT2A*, while no de novo LoF mutations were found in controls. These mutations are significantly enriched in individuals with NDDs compared to unaffected control trios (p=0.0021), which collectively indicate that these mutations are highly penetrant for NDDs and NDD-associated conditions. Collectively, de novo LoF mutations were found in eight individuals with ASD, suggesting that *KMT2A* is a novel ASD risk gene. De novo LoF mutations in *KMT2A* were also present in individuals with other NDD phenotypes, such as developmental delay and intellectual disability. This finding supports the notion that *KMT2A* mutations possess a shared genetic risk affecting common genes and pathways for different NDDs. The genetic and clinical findings in this study establish a role of *KMT2A* in ASD and neurodevelopmental disorders, which will aid clinical interpretation of *KMT2A* mutations. These findings also contribute to the accumulating evidence of the role of chromatin-associated genes in ASD and other NDDs.

1415T

Properties of pathogenic *de novo* missense mutations guide discovery of new neurodevelopmental disease risk genes. *M. Geisheker[1], B. Coe[1], T. Wang[2], H. Stessman[1], T. Turner[1], E. Eichler[1,3].* 1) University of Washington School of Medicine, Seattle, WA; 2) The State Key Laboratory of Medical Genetics, School of Life Sciences, Central South University, Changsha, Hunan, China; 3) Howard Hughes Medical Institute, Seattle, WA.

De novo missense mutations contribute to more cases of autism spectrum disorders than likely gene-disruptive mutations but they have been understudied because an estimated 87% of them are incidental based on studies of simplex autism. We created a database from 23 published studies of genetically-overlapping neurodevelopmental disorders (NDDs) and compared the properties of 6,451 de novo missense mutations in 9,267 cases with 1,514 in 2,243 controls. We find a significantly elevated rate of de novo missense mutations in cases. De novo missense mutations in cases are predicted to be more deleterious as their distribution shows a significant skew towards higher CADD scores (P = 3.364×10^{-6}, Wilcoxon rank-sum test). Further, the likelihood ratio for a mutation increases with CADD scores, reaching 1.5 at a CADD score of 29. Out of 4,620 genes with de novo missense mutations in cases, 1,126 (24.3%) bear mutations in two or more unrelated individuals. In 10,000 down-sampling permutations matching the number of de novo missense mutations in cases with the number in controls, the average number of genes hit recurrently in cases was greater than that seen in controls; significance was reached at three or more mutations per gene (simulated P = 0.002). Thirty-four genes had significantly more de novo missense mutations in cases than expected, and 12 of them have already been implicated as NDD risk genes. Strikingly, 28 amino acid positions in 25 genes were hit by two or more rare de novo missense mutations with a CADD score over 20 in unrelated cases; this was not observed in controls. Targeted sequencing of these recurrently mutated amino acids and other clusters of mutations in 9,126 additional cases and 2,599 controls identified 54 more mutations in cases and 5 in controls. Eleven of these mutations map to nine of the 23 targeted amino acids; four establish two new sites of recurrence. Some of these newly found mutations establish significance in genes associated with NDDs, such as *CLCN4* and *ALG13*, and genes critical for neuronal function, such as *GRIA1*. Preliminary phenotypic and functional data suggest syndromic effects of some of these recurrent mutations and strengthen their association with disease. Our analysis reveals that clustered, recurrent and severe de novo mutations provide a useful method to identify new causal genes, expanding our understanding of the pathology of NDDs.

1416F

Noncoding autism spectrum disorder risk variants identified by whole genome sequencing in extended multiplex families. *J.R. Gilbert[1,2], A.J. Griswold[1], H.N. Cukier[1], D. Van Booven[1], P.L. Whitehead[1], N.K. Hofmann[1], E.R. Martin[1,2], M.L. Cuccaro[1,2], J.P. Hussman[3], M.A Pericak-Vance[1,2].* 1) John P. Hussman Institute for Human Genomics, University of Miami, Miami Miller School of Medicine, Miami, FL; 2) John T. Macdonald Foundation Department of Human Genetics, University of Miami, Miller School Medicine, Miami, FL; 3) Hussman Institute for Autism, Baltimore, MD.

Autism spectrum disorder (ASD) is a neurodevelopmental condition with a strong, but heterogeneous, genetic etiology with more than 100 genes and genetic loci implicated. Recent massively parallel sequencing efforts in ASD have focused on whole exome (WES) or whole genome sequencing (WGS) in cohorts of simplex trios and the identification of *de novo* loss of function coding variants. While these are strong risk factors for ASD, we hypothesize that there are other factors contributing to the underlying genetic risk including poorly covered coding regions, functional and regulatory variants in the 98% of the genome that is noncoding, and unidentified genomic structural variation. To identify such factors, our study applied WGS to extended, multiplex families with at least one pair of cousins with ASD. We performed WGS on two or more ASD individuals across six families (15 total) where compelling candidate coding variants had not been identified by WES (Cukier HN, 2014). We sequenced each genome to 40X and analyzed with a GATK best practice pipeline and structural variants (SVs) called with the SWAN algorithm. Annotations were applied with ANNOVAR including functional predictions for noncoding variants (GWAVA, CADD, FATHMM-MKL, and Eigen). Because each genome contained more than ~4 million single nucleotide variants and indels and more than 100 SVs, we refined our regions of interest by calculating identity by descent (IBD) with existing genotyping data and filtering IBD alterations for each family. Variants were prioritized by 1) sharing in all ASD individuals per family, 2) low frequency in the population (<1%), and 3) functionality based on computational predictions. Among coding variants poorly covered by previous WES, a family carried a rare missense mutation in the neurogenesis growth factor *GDF11* and another family a frameshift in the first exon of the axonal development gene *SLAIN1*. Furthermore, WGS identified noncoding variants including two in the promoter of the ASD candidate gene *CNTN4* in one family and two upstream of potassium channel *KCTD1* in a different family. Rare SVs in single families were identified including one disrupting the promoter of the neurodevelopmental *WWOX* gene and another deleting an exon of the lincRNA *FIRRE* involved in chromosomal organization. By studying these unique pedigrees, we establish that WGS in extended families can be used to identify ASD risk alterations beyond *de novo* protein coding variants.

1417W

Increased burden of deleterious variants in essential genes in autism spectrum disorder. *X. Ji[1,2], R. Kember[2], C. Brown[2], M. Bucan[2,3].* 1) Genomics and Computational Biology Program, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 2) Department of Genetics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 3) Department of Psychiatry, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA.

Autism spectrum disorder (ASD) is a heterogeneous, highly heritable neurodevelopmental syndrome characterized by impaired social interaction, communication and repetitive behavior. The highly polygenic nature of ASD suggests that the analysis of the full spectrum of sequence variants, including those with small effects, will be necessary for deeper understanding of disrupted neuronal function. Human orthologs of genes with an essential role in pre- and postnatal development in the mouse ("essential genes") are enriched for human disease genes and under strong purifying selection relative to human orthologs of mouse genes with known non-lethal phenotype ("non-essential genes"). This intolerance to deleterious mutations, coupled with commonly observed haploinsufficiency of essential genes (EGs), suggests a possible cumulative effect of a large number of small-effect variants in essential genes on a disease phenotype such as ASD. We hypothesized that a cumulative effect of deleterious variants in EGs, within the same pathway or across pathways, may underlie impaired brain development and individual's ASD risk. To test this hypothesis, we identified the most comprehensive list of 3,915 EGs established to date by combining human orthologs of EGs in the mouse and genes that are essential for viability in human cell lines. We assessed the cumulative contribution of EGs to ASD risk by combined analysis of genomic and phenotypic data in ASD families and transcriptomic data in developing human brain. We found that EGs were enriched in the recently identified high-confidence ASD-associated genes. By examining the *de novo* and inherited variations from 1,781 ASD families from the Simons Simplex Collection, we demonstrated a higher burden of damaging mutations in EGs in ASD probands compared to their non-ASD siblings. In addition, we found that deleterious variants in EGs contribute to decreased social skills in males. Furthermore, the co-expression analysis of EGs in the developing brain identified three clusters of EGs implicated in ASD. Finally, we suggested 29 EGs as strong candidates for further investigation in their role in ASD. Overall, we provide multiple lines of evidence for a strong contribution of EGs to ASD risk. Our findings show that large-scale studies of gene function in model organisms provide a powerful approach for prioritization of genes and pathogenic variants identified by sequencing studies of human disease.

Deciphering the non-coding regulatory landscape in autism spectrum disorders. *J. Li[1], J. Zhou[1], Z. Ma[1], M. Shi[1], D. Phanstiel[1], R. Yuen[5], D. Merico[5], G. Li[1], H. Wang[3], M. Deurloo[3], Q. Li[3], B. Zhou[2], Y. Cheng[1], J. Hallmayer[2], A. Urban[2], Z. Feng[3], S. Scherer[5], M. Pletcher[4], M. Snyder[1].* 1) Genetics, Stanford University, Stanford, CA; 2) Department of Psychiatry & Behavioral Sciences, Stanford University School of Medicine, Stanford, CA 94304, USA; 3) Department of Physiology, Collaborative Program in Neuroscience, University of Toronto, Ontario M5S 1A8, Canada; 4) Genomic Discovery, Autism Speaks Inc., 1 East 33rd Street, New York, NY 10016; 5) The Centre for Applied Genomics (TCAG), Program in Genetics and Genome Biology, The Hospital for Sick Children, Toronto, Ontario, Canada M5G 0A4.

For decades, technical and cost hurdles have prevented the systematic investigation of non-coding sequences in complex human diseases, and thus our knowledge about autism spectrum disorders (ASD) has been primarily obtained from analysis of protein-coding sequences. We have combined the analysis of whole genome sequencing with global studies of regulatory sequences of human cortical neurons to reveal the regulatory architecture of ASD. Analysis of de novo mutations from whole genome sequencing of 261 autism families revealed the physical proximity of ASD de novo mutations specifically to the cortical expression quantitative loci (eQTLs) of synaptic genes. We performed ATAC-Seq, ChIP-Seq, RNA-Seq and Hi-C experiments on human cortical neurons, which for the first time provided a paranormal view of the regulatory landscape in these cells. We found that ASD de novo mutations preferentially affect regulatory elements, and the associated genes are shared targets of two ASD syndromic factors, CHD8 and PTEN. Analyzing 15 chromatin states across 127 human tissue/cell types revealed a significant enrichment of ASD de novo mutations in active transcription start sites and the perturbed genes implicated in neuron functions; this distribution enabled us to develop a machine-learning algorithm to assess potential ASD risk for a given individual. Taken together, our study for the first time revealed the regulatory landscape in human neurons, demonstrated the importance of the non-coding genome in ASD and provides a general framework for analyzing regulatory mutations for other complex human diseases.

1419F

CDH4 and TSNAX-DISC1 moderate a novel quantitative autism phenotype. *S. Luzi[1], L. Gomez[1], H.N. Cukier[1], S. Slifer[1], P.L. Whitehead[1], J.R. Gilbert[1,2], J.L. Haines[3], J.P. Hussman[4], E.R. Martin[1,2], M.L. Cuccaro[1,2], M.A. Pericak-Vance[1,2].* 1) Human Genomics, University of Miami - Miller School of Medicine (HIHG), Miami, FL; 2) Dr. John T. Macdonald Department of Human Genetics, University of Miami, Miami, FL; 3) Department of Epidemiology and Biostatistics, Institute for Computational Biology, Case Western Reserve University School of Medicine, Cleveland, Ohio, USA; 4) Hussman Institute for Autism, Baltimore, MD, USA.

Autism spectrum disorder (ASD) is highly prevalent and has a complex genetic architecture. The ASD phenotype is multi-dimensional and variable, consisting of core social-communicative and behavioral features which vary considerably among individuals. Changes in diagnostic criteria have contributed to an increased prevalence of ASD as well as phenotypic heterogeneity. We aim to identify a narrower ASD phenotype based on core ASD features and to find genes associated with this phenotype.We hypothesize that genetic variants modify the ASD phenotype and lead to an increased number of core autism features. We developed a Quantitative Autism Score (QAS) using items from the ADI-R which consistently discriminate ASD from non-ASD, occur early in development and remain stable throughout changing diagnostic criteria. Our initial discovery sample consisted of 1118 individuals with ASD, 268 ascertained at the Hussman Institute for Human Genomics (HIHG) and 850 from the Simons Simplex Collection (SSC).We targeted 689 genes (Griswold, 2015) and conducted a SKAT-O gene-based test using the QAS as a continuous trait. Results showed the *CDH4* and *LGR5* genes to be significant, adjusting for number of genes tested (p-values=9.20E-06 and 3.59E-05, respectively).To follow up these results, a meta-analysis was run on whole exome sequencing (WES) data available for the HIHG sample (N=253) and the SSC sample (N=1130). Again, results showed *CDH4* to be among the top nominally significant genes (p-value=0.0002). The *TSNAX-DISC1* gene was also nominally significant with a p-value of 0.0003.No genes were significant when we compared ASD cases to controls in a binary SKAT-O analysis.The QAS is a novel trait whose application in the current study narrowed the clinical phenotype to individuals with core features of ASD as a strategy for gene discovery. Refining the ASD phenotype using the QAS allowed for identification of two potential risk genes.*CDH4* is a neuronal cell adhesion molecule which plays a role in neuronal outgrowth and has been previously associated with ASD. *TSNAX-DISC1* is a transcription between the neighboring TSNAX and DISC1 whose alterations in gene processing have been associated with psychiatric disorders like Schizophrenia.These genes are associated with a greater presence of core ASD features, which can be an indicator of ASD severity.This novel approach is the first step towards dissecting a polygenic and multi-dimensional condition to clarify its underlying biology.

1420W

Identification of candidate genes for IQ discrepancy in extended families with autism using whole exome sequencing data: An update. *A.Q. Nato[1], N.H. Chapman[1], H.K. Sohi[1], B. Wang[2], H.D. Nguyen[1], J.M. Viskochil[3], H. Coon[3], E.M. Wijsman[1,4,5].* 1) Division of Medical Genetics, Department of Medicine, University of Washington, Seattle, WA, USA; 2) Department of Statistics, University of Washington, Seattle, WA, USA; 3) Department of Psychiatry, University of Utah, Salt Lake City, UT, USA; 4) Department of Biostatistics, University of Washington, Seattle, WA, USA; 5) Department of Genome Sciences, University of Washington, Seattle, WA, USA.

Performance IQ (PIQ) is typically greater than verbal IQ (VIQ) in individuals with autism spectrum disorders (ASD). The strongest evidence of linkage on chromosomes (chr) 10p12 and 17 was previously implicated in a linkage analysis of IQ discrepancy (PIQ-VIQ) in University of Washington (UW) nuclear families [Hum Genet 2011:129,59-70]. We also reported a region of interest (ROI) on chr 15 from variance component (VC) linkage analysis of 4 large multi-generational families (457 individuals) from Utah (UT1), where 195 individuals were typed for ~750K SNPs, and 110 have IQ data. In the Utah (UT) data, we defined IQ discrepancy (PIQ-VIQ) using Wechsler block design or DAS pattern construction subtests (BD) to represent PIQ, and Wechsler vocabulary or DAS naming vocabulary and word definition subtests (VOC) to represent VIQ. Here, we analyzed 12 trimmed UT families (1,064 individuals), ranging from 23 to 153 individuals, where 520 individuals were typed for ~750K SNPs and 387 individuals have IQ data. UT1 is a subset of UT. Our current VC linkage analysis of IQ discrepancy (BD-VOC) in UT showed evidence of linkage on chr 1q, 9q, 10p, and 22q. The previous linkage signal on chr 15 decreased, however, we now have a linkage peak (lod=1.46) that partially overlaps the strongest evidence in UW PIQ-VIQ on chr 10p. The ROI on chr 10 spans ~22 cM. We obtained whole exome sequencing (WES) data of 86 individuals in 7 of the 12 UT families (782 individuals), and identified 16,560 variants on chr 10, where 1,383 are within this ROI. Within each family, we selected single nucleotide variants (SNVs) which have ≥2 copies, resulting in 160 SNVs (range: 19-114) after excluding indels. We further selected nonsynonymous SNVs (using SeattleSeq 138 annotation) that have minor allele frequency <0.05 (from 1000 Genomes European genotype data). This filtration step resulted in 23 nonsynonymous SNVs (range: 0-9 per family) in 13 genes (range: 1-7 per family), where 6 SNVs and 5 genes with nonsynonymous SNVs are observed in 2-4 families. 3 of these SNVs are predicted by PolyPhen to be possibly- or probably-damaging. We performed file manipulation through PBAP and genotype imputation for the remaining 696 individuals using GIGI. The dosages of both observed and imputed data are used as a measure of gene burden, which we use as a covariate in VC linkage analyses in SOLAR, to identify genes that *as covariates* decrease linkage signals.

1421T

Affected sib-pair analysis to identify risk variants for autism endophenotypes. *M. Pirooznia[1], T. Niranjan[2], F. Goes[1], D. Avramopoulos[1,2], J. Potash[3], P. Zandi[1], T. Wang[2].* 1) Psychiatry, Johns Hopkins University, Baltimore, MD; 2) Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 3) Psychiatry, University of Iowa.

Case-control and family-based studies have implicated many autism risk genes by identifying shared common variants of small effects, higher mutation load for rare variants of large effects, and recurrent and/or *de novo* variants in affected probands. Identification of genetic factors contributing to specific autism endophenotypes remains a big challenge. In certain multiplex families, affected sibs manifest significant difference in severity of one or more endophenotypes. Since sibs often grow up together during infancy and early childhood, familial contributions are reduced as a confounding factor for differences in severity of phenotype. Because sibs share a large fraction of their genome, we speculate that genetic contributions to differences in phenotypic severity likely reside in the fraction of their unshared genome. We developed a novel strategy using affected male sibs with extreme difference in severity to identify risk alleles for autism. We sequenced the exons of synaptome genes (n=1,886) in 274 pairs of affected male sibs from multiplex families. These sib-pairs were selected based on their extreme differences in severity of one or more endophenotypes. We first compared the cumulative burden of rare (MAF≤1%) and presumably functional variants from synaptome and pathway-specific genes between sibs with severe versus mild social deficits as determined by ADI-R social interaction scores and found no difference (*p*=0.96). We next identified subsets of affected sibs either with large (SOCT_CS≥10; n=92 pairs) or small (SOCT_CS≤4; n=108 pairs) differences in severity of social deficits as determined by cumulative ADI-R social interaction scores. We reason that sib pairs with large differences in severity harbor a higher load of variants contributing to social deficits as compared to sib pairs with small differences. Preliminary studies on the cumulative mutation loads in synaptome genes identified a significant difference in variant loads between the cohorts with large versus small differences in severity (large difference cohort: 705.1±16.2; small difference cohort, 668.3±9.0; *p*=0.025). Genetic and functional studies on selected variants potentially contributing to social deficits in autism are ongoing. Exploring variants in affected sibs with significant differences in severity of individual endophenotypes may be a valuable approach for identification of autism risk genes.

1422F

Dysregulation of translation processes: A persistent signal in the diagnostic prediction of autism in toddlers from community pediatric practices. *T. Pramparo[1], K. Pierce[1], C. Carter Barnes[1], L. Lopez[1], S. Nalabolu[1], Z. Guo[2], J. Li[2], N. Lewis[3], P. Yu[2], E. Courchesne[1].* 1) UC San Diego, Autism Center of Excellence, Department of Neuroscience, University of California San Diego School of Medicine, La Jolla; 2) Texas A&M University, Department of Electrical and Computer Engineering & TEES-AgriLife Center for Bioinformatics and Genomic Systems Engineering (CBGSE); 3) Pediatrics, University of California San Diego School of Medicine, La Jolla.

Recent efforts have provided evidence that accessible tissues, such as peripheral blood, may carry genetic signatures or biomarkers useful to predict infants and toddlers with Autism Spectrum Disorder (ASD) recruited from community practices (Pramparo et al., 2015). These findings hold the promise to be validated and further developed into a clinical test for ASD that can be used as a population screening in 1 year olds. However, a major obstacle in the study of genetic signatures of ASD is the identification of reproducible signals surviving the intrinsic large heterogeneity of the disorder as well as the presence of confounding variables. To continue our effort in the identification of early biomarkers of ASD, we sought to identify genetic signatures of ASD in blood at young ages using RNA sequencing data from a largely new pediatric sample. Our first goal was to validate at the functional level the previously reported gene expression signature which displayed gene enrichment for translation and immune functions and high specificity and sensitivity in diagnostic classification of ASD. Recruitment of participants was done in general pediatric clinics and community settings following criteria of the 1-Year Well-Baby Check-Up Approach. Diagnostic judgment followed DSM-V and Autism Diagnostic Observation Schedule criteria for autism. ASD male infants and toddlers (age range, 1-4 years) were compared with age- and gender-matched typically developing control subjects. Preliminary results displayed >4,200 differentially expressed genes between ASD and controls (q<0.05) that clustered into 22 modules of co-expressed genes. Permuted AUC-modeling (10,000 iterations) followed by logistic regression with cross-validation analysis of these 22 modules displayed a mono-modal distribution in accuracy with mean around 87%. Specificity and sensitivity distributions were instead bi-modal suggesting the presence of two genetically distinct subgroups of ASD subjects, and mean values ranged from 80 to 90%. Finally, pathway enrichment analysis, using one of the best-performing models included 1970 differentially co-expressed genes and displayed a strong significant enrichment in translation processes. These preliminary RNA-seq findings point to the previously identified genetic signature of ASD using a largely independent set of subjects, and strongly suggest that altered translation in ASD may be a persistent signal in blood useful for early diagnostic identification.

1423W

Integrating expression quantitative brain loci in autism spectrum disorder genome-wide association analyses. *C. Shu[1,2], C. Ladd-Acosta[2,3], K. Benke[1,2], A. Jaffe[4], J.L. Daniels[5], C.J. Newschaffer[6], A.M. Reynolds[7], D.E. Schendel[8], L.A. Schieve[9], M.D. Fallin[1,2].* 1) Department of Mental Health, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 2) Wendy Klag Center for Autism and Developmental Disabilities, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 3) Department of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 4) Lieber Institute for Brain Development, Baltimore, MD; 5) University of North Carolina, Chapel Hill, NC; 6) A.J. Drexel Autism Institute, Philadelphia, PA; 7) Pediatrics, University of Colorado Denver, Aurora, CO; 8) Aarhus University, Aarhus, Denmark; 9) National Center on Birth Defects and Developmental Disabilities, Centers for Disease Control and Prevention, Atlanta, GA.

Background: Autism Spectrum Disorder (ASD) is highly heritable and evidence showed genetic variation plays a major role in this variability. However, genome-wide association studies (GWAS) thus far have had limited success. Genetics studies of other psychiatric disorders have shown enrichment for brain expression quantitative trait loci (eQTLs). Limiting genome-wide single nucleotide polymorphism (SNP) analyses to subsets known to be brain eQTLs (denoted "eSNPs"), can reduce the search space allowing important association signals to separate from signals simply due to millions of tests performed. **Objectives:** To perform genome-scale SNP association analyses for ASD, limited to SNPs known to be brain eSNPs or known to be located in genes expressed in early neural development and subsets defined by expression in specific brain regions. **Methods:** Brain eSNPs were obtained from 6 published brain eQTLs studies on 11 different brain tissue types. GWAS was performed on all SNPs, subsets of brain eSNPs, and brain tissue specific eSNPs after LD-based SNP pruning, using SNPs data from the Study to Explore Early Development (SEED) from 584 ASD cases and 725 non-ASD controls drawn from the general population. Comparisons were made by examining the patterns of QQ plots. **Results:** A total of 288,675 brain eSNPs were obtained after LD pruning, along with brain tissue specific eSNPs in cerebellum(3,027), frontal cortex(1,450), hippocampus(764), inferior olivary nucleus(659), occipital cortex(695), pons(440), putamen(425), substantia nigra(359), temporal cortex(1,420), thalamus(636), and intralobular white matter(1,034). GWAS based on brain eQTLs revealed SNPs that separated from expectation in QQ plots, while no separation was observed in the overall GWAS analysis of SEED data. The QQ patterns were also differential by subset in analyses based on eSNPs for specific brain tissues, where only QQ plots of temporal cortex eSNP subsets showed clear positive separation from expectation, and only QQ plots of cerebellum and frontal cortex showed suggestive separation with no apparent deflation and inflation. **Conclusions:** The findings reported here are consistent with literature on the key brain regions involved in ASD etiology, namely cerebellum, frontal cortex and temporal cortex. Subsetting GWAS analysis to brain eSNPs can provide further insight on the ASD common variant signals.

1424T

Exome sequencing of "pure" sporadic cases of autism identifies rare potentially causative mutations. *C.P. Sjaarda[1,2], A.J.M. McNaughton[1,2], C. Henry[1,2], L. Santavy[1,2], M.L. Hudson[1,2], M. Ayub[1,2], A. Guerin[3], X. Liu[1,2].* 1) Department of Psychiatry, Queen's University, Kingston, ON, Canada; 2) Queen's Genomics Lab at Ongwanada Resource Centre, Kingston, Ontario, Canada; 3) Department of Pediatrics, Queen's University, Kingston, ON, Canada.

   Autism Spectrum Disorder (ASD: MIM 209850) is a complex neurodevelopmental disorder affecting 1 in 64 children. Although genetic factors contribute to an estimated >90% of ASD cases and over 100 autism susceptibility genes have been described, only 20-25% of cases have a defined genetic cause. This study reports the analysis of the whole exome sequencing for 21 families with relatively "pure" sporadic cases of ASD based on the hypothesis that *de novo* damaging mutations are most likely the cause for these cases. These 21 families were selected from our database of >1300 families by examination of comprehensive family histories. Families with ASD in the extended family or neurodevelopmental and/or psychiatric disorder in the immediate family were excluded from the study. This rigorous selection process warrants that detected variants are true *de novo* variants. Analysis of exome sequencing data identified 349 rare, *de novo* variants in 289 genes, of which 37 variants in 35 genes have predicted high impact on gene function. Based on a literature search into the function of the genes containing these variants, 8 genes having a role in brain function or immune response were selected for further analysis. PCR and Sanger sequencing confirmed the presence of the SNP in 7 of the 8 variants (87.5%). *In silico* analysis using MutationTaster, MutationAssessor, Polyphen2, HumVar, FATHMM and SIFT showed that each of the 7 variants cause deleterious effects on the function of their respective gene products. This study identifies several *de novo* variants (*APEX1, EMP2, OR6C70, GAD1, TRIM60, XRCC6, ZC3HC1*) that may contribute to the genetic load underlying the development of ASD.

   From the initial descriptions in 1943, autism spectrum disorder (ASD) has emerged as a common form of neurobehavioral disability that affects as many as 1/68 children born in the United States. Despite recent advances, the specific etiology of the majority of cases of ASD is unknown, although numerous genetic/genomic variants and alterations of diverse cellular functions have been reported. The current diagnostic protocol is limited to developmental screening and comprehensive behavioral evaluation that is complex and often difficult to administer to small children. Currently, there are no validated laboratory diagnostic tests or biomarkers for ASD that establish the clinical diagnosis, permit early diagnosis of ASD, or provide efficient screening of individuals with behavioral features suggestive of ASD. To address this, we have investigated whether the metabolomics approach might yield results which could simultaneously lead to a blood-based screening or diagnostic test and to treatment options. We performed nontargeted metabolic profiling, analyzing over 650 plasma metabolites, representing over 70 biochemical pathways, in two large cohorts of patients and controls (discovery cohort: 100 ASD, 32 controls; validation cohort: 83 ASD, 76 controls). The analysis revealed that the plasma metabolome is influenced by both disease status and age, with the effect being more prominent in younger age group (2-10 years of age). We identified more than 25 plasma metabolites that can discriminate children with ASD, as young as 2 years, from children that are developing typically. Furthermore, a quantitative analysis of 18 key discriminant metabolites in 127 ASD and 83 control plasma samples shows that various subsets of these metabolites could be used to detect the ASD samples with a sensitivity and specificity of greater than 85 percent. The metabolites associated with ASD represent several key biochemical pathways representing inflammation and immune dysregulation, increased oxidative stress, and mitochondrial dysfunction. The findings provide new insight by providing the basis for a first-generation blood-based quantitative screening test that can have immediate benefits by identifying individuals with ASD, even at 2 years of age, and thus adding to a better understanding of ASD and improving patient care.

Autism and obesity: Assessing the prevalence of antipsychotic-induced weight gain SNPs. *Z. Talebizadeh, A. Shah, H. Dai.* Children's Mercy Hosp, Kansas City, MO.

The existing challenge in the reproducibility of genetic findings for autism is, in part, due to its extensive level of heterogeneity. Initiatives such as the Autism Genetic Resource Exchange (AGRE) and Simons Simplex Collection (SSC) provide invaluable resources to the research community by collecting phenotypic data and ongoing generation of massive genetic data from subjects with autism. We designed a study to re-analyze already existing genetic data generated from autistic subjects from AGRE and SSC to address an important and previously unanswered question.   The objective of this project is to better understand the relationship between autism and obesity. It is not clear if obesity is co-occurring with autism or is related to antipsychotic-induced weight gain (AIWG). Weight gain is one of the main side-effects of the commonly used antipsychotics. Since the majority of patients with autism take antipsychotics, a *general assumption* is that the observed elevated rate of obesity in autism (i.e., 40%) is caused by AIWG. Our hypothesis is that the prevalence of known AIWG associated SNPs in obese and non-obese autistic subjects is comparable; thus, AIWG cannot be the only reason for the observed higher rate of obesity. To test this hypothesis, we will re-analyze already existing data (from AGRE and SSC families) by comparing the prevalence of AIWG associated SNPs in obese and non-obese autistic subjects. We will apply equivalence tests on genotyping data to test the presence of equality instead of differences between the two study groups (obese and non-obese). Weight/Height data has been obtained from the AGRE and SSC databases and BMI has been calculated for autistic subjects. We have compiled data on more than 100 AIWG SNPs, which cover all the reported SNPs, so far, and we refer to this list as our Master List in this study. We correlated the SNPs in our Master List with the dbSNP database, a public-domain archive for genetic polymorphisms to collect more detail information, including physical mapping, population data, and microarray platforms. We utilized several tools to obtain Tag SNPs: SNAP, TagSNP, and Tagger. We also searched for LD status of our Master list SNPs.   We downloaded AGRE and SSC genotyping data (combined Affymetrix and Illumina platforms). We are examining this genotyping list for the presence of the AIWG Master List SNPs and identified Tag SNPs. Final data including statistical analyses will be presented at the meeting.

Whole-genome sequencing provides additional insight into the genetic architecture of autism. *T.N. Turner[1], B.P. Coe[1], B.J. Nelson[1], M.C. Zody[2], F. Hormozdiari[3], Z.N. Kronenberg[1], S.A. McClymont[4], P.W. Hook[4], K. Hoekzema[1], M.H. Duyzend[1], A. Raja[1,5], C. Baker[1], R. Bernier[6], A.S. McCallion[4], R.B. Darnell[2,7], E.E. Eichler[1,5].* 1) Department of Genome Sciences, University of Washington, Seattle, WA; 2) New York Genome Center, New York, NY; 3) Department of Biochemistry and Molecular Medicine, Davis, CA; 4) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 5) Howard Hughes Medical Institute, University of Washington, Seattle, WA; 6) Department of Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA; 7) Howard Hughes Medical Institute, Rockefeller University, New York, NY.

We performed deep (30-fold) Illumina whole-genome sequencing (WGS) on 2,160 genomes from 540 simplex autism families negative for *de novo* likely gene-disruptive (LGD) mutation or large (>100 kbp) copy number variants (CNVs). Using a hybrid cloud / local compute analysis workflow, we processed all genomes in one month. We applied two SNV/indel and four CNV callers to generate a sensitive variant call set of 59 million SNVs/indels and 193 thousand unique CNVs. Extensive, orthogonal experimental validation was undertaken to determine the inheritance status of high-impact variants. WGS analysis recovered ~25% more *de novo*, exonic SNVs/indels and ~85% more gene-disrupting CNVs than previously discovered by whole-exome sequencing (WES) analysis of the same samples. This included *de novo* LGD events in *PCM1*, *MED12L*, and *VARS* and gene-breaking *de novo* CNVs in *APOBEC3D*, *APOBEC3F*, *CHD2*, *DDX43*, *DMD*, *FANCA*, *LINC01347*, *LNPEP*, *MIR3129*, *MUC19*, *PCDHB17*, *PCDHB6*, *TAF1B*, and *ZNF462*. We observed a significant enrichment (p=0.01) of *de novo* missense mutations in children with autism when compared to their unaffected siblings for autism risk genes with known dosage sensitivity. This included proband-specific events in *UBE3C*, *PTEN*, *SUV420H1*, *CREBBP*, *LAMC3*, *GABRB3*, *SYNGAP1*, *NR3C2*, *SRCAP*, *TRIP12*, *UNC45B*, *SCN2A*, *POGZ*, and *TRIO*. We report a modest enrichment (p=0.04) of *de novo* and private disruptive mutations for putative regulatory elements for dosage-sensitive autism genes. We define these as fetal central nervous system (CNS) DNase I hypersensitive sites mapping within 50 kbp of the start and end of the candidate gene transcript. Functional testing of the regions affected by these events confirms that the CNVs enrich in enhancers within the central nervous system. Overall, WGS provides additional insight into the genetic etiology of autism by significantly increasing the yield of gene-disrupting mutations and providing access to noncoding portions of the genome which when deleted adversely affect dosage of autism-risk genes during development.

1428F

Uncovering obsessive-compulsive disorder risk genes in a paediatric cohort by high-resolution analysis of copy number variation. *M. Zarrei[1], M.J. Gazzellone[1], C.L. Burton[2], S. Walker[1], M.     Obsessive-compulsive disorder (OCD) is a highly heterogeneous neuropsychiatric condition, thought to have a significant genetic component. When onset occurs in childhood, affected individuals typically experience a more severe manifestation, which can worsen in adulthood. Since neuropsychiatric conditions are associated with copy number variations (CNVs), we considered their potential role in the etiology of OCD. We genotyped 307 unrelated paediatric probands with idiopathic OCD (including 174 that were part of complete parent-child trios) and compared their genotypes with those of 3,861 population controls, in order to identify rare CNVs (<0.5% frequency) of at least 15 kb in size that might contribute to OCD. We uncovered *de novo* CNVs in 4/174 probands (2.3%). Our case cohort was significantly enriched for CNVs in genes that encode targets of the fragile X mental retardation protein ($p=1.85×10^{-03}$), similar to previous findings in autism and schizophrenia. These results identified deletions or duplications of exons in genes involved in neuronal migration (*ASTN2*), synapse formation (*NLGN1* and *PTPRD*), and postsynaptic scaffolding (*DLGAP1* and *DLGAP2*), which may be relevant to the pathogenesis of OCD. Four cases had CNVs involving known genomic disorder loci (1q21.1-21.2, 15q11.2-q13.1, 16p13.11, and 5p11-p12 and 17p12 in the same individual). Further, we identified *BTBD9* as a plausible new candidate gene for OCD. We also sequenced exomes of ten "CNV positive" trios and identified in one an additional clinically relevant mutation: a 13 bp deletion in *DRD4*.

1429W

Polygenic risk score and their clinical traits correlations in schizophrenia: From the first episode of psychosis to chronic patients. *S.I. Belangero[1], M.L. Santoro[1], V.K. Ota[1], S. Jong[2], C. Noto[1], E.S. Gouvea[1,3], P.N. Moretti[1], L.M. Spíndola[1], G. Xavier[1], F. Talarico[1], A. Gadelha[1], Q. Cordeiro[3], R. Bressan[1], G. Breen[2].* 1) Morphology and Genetics, Federal University of Sao Paulo, Sao Paulo, Brazil; 2) Institute of Psychiatry, King's College of London, London, UK; 3) Department of Psychiatry, Santa Casa de Misericórdia, São Paulo, Brazil.

    Background: Schizophrenia (SCZ) is a complex disease, with great influence of the environment but yet a disease with considerable heritability. The polygenic Risk Score (PRS) is an important tool that access the multiple genetic variations and their low effect sizes. Aim: In this study, we aimed to (1) confirm if PRS was able to differentiate cases and controls in two brazilian cohorts of SCZ patients; (2) verify if PRS is correlated to clinical variables of severity and of response to antipsychotics during: first episode of psychosis (FEP) stage, eight weeks after Risperidone treatment and in a chronic schizophrenia patients cohort. Methods: We performed the clinical assessment (SCID, PANSS, CGI and GAF) of 60 antipsychotic naïve patients in their FEP and after eight weeks of Risperidone tratment, 175 chronic schizophrenia patients and 297 healthy controls. After blood collection and DNA isolation, the samples were genotyped using the PsychArray Chips or Omni Express chips. We performed the imputation using the http://imputationserver.sanger.ac.uk and PRSice software to generate the scores and to evaluate the best p-threshold for the PRS in our sample. We used the last available data from PGC2 SCZ as a training sample. Results and discussion: we verified that the PRS works for the Brazilian population but with a moderate explained variance (0.15) and with a best p-threshold lower than that found in PGC (0.05). Furthermore, we found that GAF, CGI, PANSS exc and PANSS Dis are all positively correlated to PRS during the FEP but not after eight weeks of Risperidone treatment or to the chronic schizophrenia cohort. Recently, a study suggested that individuals with higher PRS for schizophrenia are more likely to discontinue longitudinal studies or do not respond questionaries, and thus, they are likely underrepresented in cohort studies. Curiously, we found that those FEP that did not return for the follow-up have even higher symptoms than that who did the follow-up. In the next studies we hope to genotype these individuals and confirm if they have even higher PRS scores. .

Replicative analysis of SNPs, associated with schizophrenia and its cognitive endophenotypes, in Kazakh patients with schizophrenia. *A. Bocharova[1], A. Marusin[1], K. Saduakasova[2], G. Svyatova[3], G. Berezina[3], V. Stepanov[1,4].* 1) Research Institute of Medical Genetics SB RAMS, Tomsk, Russian Federation; 2) Kazakh National Medical University, Almaty, Kazakhstan; 3) Republican Scientific Centre for Obstetrics, Gynecology and Perinatology, Almaty, Kazakhstan; 4) Tomsk State University, Tomsk, Russian Federation.

   Introduction. Schizophrenia is the most common psychotic disease, with a global prevalence of less than 1%. Patients with schizophrenia commonly experience debilitating social and occupational impairments. Symptom onset is generally between late adolescence and the mid-30s. Schizophrenia is associated with marked executive function disturbances, working memory impairment and thought disorder. These cognitive endophenotypes are frequently found in family and twin studies in clinically unaffected family members. Schizophrenia affects all ethnicities, but a large number of studies for schizophrenia have been conducted mainly in the Caucasoid population. However, it is desirable to research similar studies in different ethnic groups to reaffirm the status of the association identified. The aim of this study was to analyze associations of 45 SNPs reported in GWAS in Kazakh patients with schizophrenia and its cognitive endophenotypes. **Subjects and methods.** 102 patients with schizophrenia and 190 healthy controls, matched to the patients by age, gender, and ethnicity were included in study. 15 SNPs were genotyped by real-time PCR using TaqMan-assay (Applied Biosystems) and 30 SNPs were genotyped by MALDI-TOF mass-spectrometry using MassARRAY Analyzer 4 (Sequenom). Allele-specific ORs and associated p-values were calculated. **Results.** We found 5 significant associations of SNPs with schizophrenia in Kazakh patients: rs2312147 at *VRK2* gene (OR=0.58, p=0.008), rs2247572 at *KCNB2* gene (OR=0.65, p=0.03), rs2252521 at *CPVL* gene (OR=1.46, p=0.037), rs138880 at *BRD1* gene (OR=0.55, p=0.03), and rs6859 at *PVRL2* gene (OR=0.65, p=0.03). **Conclusions.** These genetic markers were previously reported in GWAS associated with cognitive endophenotypes (rs2247572 in *KCNB2* gene, rs2252521 in *CPVL* gene), schizophrenia (rs2312147 in *VRK2* gene, rs138880 in *BRD1* gene) and Alzheimer's disease (rs6859 in *PVRL2* gene).Genetic markers of *VRK2, KCNB2, CPVL, BRD1* and *PVRL2* are associated with schizophrenia but their role in pathogenesis of the disease is not clear. Our findings also demonstrate that genetic variability in schizophrenia, Alzheimer's disease and cognitive endophenotype has overlapping genetic background. This work was supported by the Russian Science Foundation (project # 16-14-00020).

1431F

Genetic risk for schizophrenia associates with living in cities. *L. Colodro Conde[1], B. Couvy Duchesne[1], G. Zhu[1], A. Meyer Lindenberg[2], M. Rietschel[2], S. Medland[1], J. Whitfield[1], N. Martin[1].* 1) QIMR Berghofer Medical Research Institute, Brisbane, Australia; 2) Central Institute of Mental Health, Mannheim, Germany.

   Background. Urbanization is positively associated with prevalence of schizophrenia and to explain this it has been proposed that the stress of city life may increase the risk of this disease. On the other hand, genetic factors have been shown to have a higher impact on the country v.s city living as people grow older (>40y), while the impact of family background decreases. Our aim was to test the hypothesis that adults with higher genetic risk for schizophrenia are more likely to move to and live in urbanized and populated areas than those with lower risk. **Methods.** Our sample was comprised of 15,253 participants in 7,019 families (63.4% women) over 40 years old (M = 54.43, SD = 10.86) living in Australia. The participants reported their postcode as part of the protocols of several studies on health and wellbeing conducted from QIMR. Participants were genotyped genome-wide and imputed to 1000G v.3. We used three measures of urbanicity; (i) subjects' postcodes were categorized into urban, suburban or rural zones; we also computed (ii) distance to the closest city centre and (iii) the population density of the postcode district. Polygenic risk scores (PRS) for schizophrenia based on summary statistics from the Psychiatric Genomics Consortium (PGC-2) were computed with PLINK 1.90 (version 3) for eight different P-value thresholds. We used linear mixed models to predict the three urbanicity measures from the schizophrenia PRS, controlling for age, sex, genetic principal components, GWAS chip and genetic relationship matrix. Predictions were calculated using GCTA (Genome-wide Complex Trait Analysis, version 1.22). **Results.** Genetic risk for schizophrenia was associated with the place where the participants lived in the expected direction, with increased effects as the risk scores included more SNPs. P-values for PRS at thresholds <0.05 were $7.20*10^{-5}$, $4.75*10^{-2}$ and $9.78*10^{-6}$, for zone, city distance and population density respectively while for threshold P<1 they were correspondingly $4.75*10^{-7}$, $1.2*10^{-3}$ and $1.19*10^{-6}$. **Discussion.** Our results suggest that people with a higher genetic risk for schizophrenia may prefer to live in more urban and populated areas. This study proposes that greater genetic predisposition to schizophrenia is at least one mechanism explaining why this illness is more prevalent in city environments.

1432W

Molecular subtypes of schizophrenia show negative symptom elevation and earlier age of onset: Application of subtyping methods accounting for population stratification and sex to the Wellcome Trust Schizophrenia Case-Control sample. *A.R. Docherty[1,2], D.E. Adkins[1,2], B.P. Reilly[1], A. Corvin[3], A.C. Edwards[1], K.S. Kendler[1], A.H. Fanous[1], S.A. Bacanu[1].* 1) Virginia Commonwealth University, Richmond, VA; 2) University of Utah School of Medicine, Salt Lake City, UT; 3) Trinity College, Dublin, Ireland.

   Background: Identifying genetic subtypes of schizophrenia (SZ) could reduce genetic heterogeneity prior to quantitative phenotypic profiling. Thus far, genetic subtyping analyses of SZ have been largely unsuccessful, mainly due to using all markers in the genome and not controlling for critical covariates such as population stratification and sex. The authors developed, tested, and present here methods to identify putative genetic subtypes of SZ. **Methods:** We used the implicated human biological pathways from the Psychiatric Genomics Consortium (PGC2) SZ GWAS to calculate pathway-based risk scores in the Wellcome Trust case-control sample. Two algorithms, both accounting for population stratification and sex, were considered feasible: a preferred method used model-based clustering in R, and an alternative that used model-based recursive partitioning which constructs its trees using only cuts which are statistically significant after adjusting for multiple testing. **Results:** While hierarchical clustering consistently resulted in only one genetic subtype, recursive partitioning resulted in 4 genetic subtypes with sufficient sample sizes. After testing these methods on a PGC subsample of SZ cases and controls, we then examined symptom dimensions (negative and positive) and age of onset in cases in order to differentiate the genetic subtypes phenotypically. Preliminary results show that individuals in one of the genetic subtypes have significantly elevated negative symptoms. Individuals in another have significantly earlier age of onset of psychosis. Because of its size, the large PGC2 sample provides optimal data for application of the genetic subtyping methods; thus, forthcoming analyses will apply these methods to the largest phenotyped SZ sample to date. **Conclusions:** Previous applications focused on classification algorithms of whole, high dimensional genotypic data, and neglected to account for critical covariates. The application of significance-based recursive partitioning methods to PGC2 biological pathway-based polygenic risk scores, to model genetic subtypes in GWAS, could significantly aid in studying the biological mechanisms of SZ risk. These analyses highlight the power of a careful, stepwise genetic subtyping framework, that is both computationally feasible and accounts for covariates, to provide potential avenues for early prediction and prevention of psychosis.

1433T

Genes influence human sexual partnering behavior. *L.A Farrer[1], R. Sherva[1], R. Koesterer[1], L. Almasy[2], H. Zhao[3], H.R. Kranzler[4], J. Gelernter[5].* 1) Biomedical Genetics, Boston Univ Sch Med, Boston, MA; 2) Texas Biomedical Research Institute, San Antonio, TX; 3) Yale University School of Public Health, New Haven, CT; 4) Department of Psychiatry, Perelman School of Medicine, University of Pennsylvania, PA; 5) Departments of Psychiatry, Genetics and Neuroscience, Yale University School of Medicine, New Haven, CT.

   Human sexual partnering is a complex behavior that is influenced by both environmental and biological factors. We investigated the genetic basis of this behavior using a GWAS approach in a sample of 7,311 African- and European-American (AA and EA) subjects ascertained for genetic studies of substance use disorders who were interviewed using the Semi-Structured Assessment for Drug Dependence and Alcoholism (SSADDA). Association of the log-transformed response to the SSADDA item "How many sexual partners have you had in your life?" was tested with SNP genotypes imputed to the most current 1000 Genomes reference panel. Analyses were conducted separately in AAs and EAs and also within males and females. Models included covariates for age and principal components of ancestry. Results across groups were combined by meta-analysis. We identified genome-wide significant (GWS) SNPs with *RAD18* (rs141996649, p=2.45x10^{-9}) and *PDSS2* (rs11964253, p=2.56x10^{-8}) in AA females, and *AGBL2* (rs28537909, p=3.24x10^{-9}) in AA males and females. The functional relevance of these genes to sexual partnering behavior is not clear. *RAD18* is involved in post-replicative DNA repair; *PDSS2* is an enzyme that synthesizes the prenyl side-chain of coenzyme Q; and *AGBL2* encodes a glutamate decarboxylase that catalyzes the deglutamylation of polyglutamylated proteins. We observed sub-GWS signals in several biologically interesting genes, including two genes in EA males and females including *OPCML* (rs73604550, 7.9x10^{-8}) which plays an accessory role in opioid receptor function and *CES1* (rs4122231, p=3.57x10^{-7}) which is involved in hydrolysis or transesterification of xenobiotics including cocaine and heroin; and *DLG2* in AA males and females (rs76371861, p=8.77x10^{-7}) which is required for the perception of chronic pain mediated by NMDA receptor signaling. These results suggest a shared genetic liability for substance use and sexual partnering behaviors. We also observed sub-GWS signals in genes involved in hormonal pathways and fertility including *KCNMA1* in EA and AA females (rs72805525, p=1.70x10^{-7}), which is a voltage gated K+ ion channel expressed in brain and smooth muscle and regulated by estrogen, and *NKAIN3* in EA males and females (rs1455569, p=2.59x10^{-7}), which encodes a molecule that interacts with Na/K transporting ATPase (sodium pump). The sodium pump has a role in aspects of steroidogenesis that are crucial for male fertility and reproduction. Replication efforts are underway.

1434F

Mouse brain transcriptome of innate and stress-induced anxiety-like behavior. *I. Hovatta[1], K. Trontti[1], J. Väänänen[1], B. Paranko[1], D. Greco[2]. 1) Department of Biosciences, University of Helsinki, Helsinki, Finland; 2) Institute of Biotechnology, University of Helsinki, Helsinki, Finland.*

Anxiety disorders are complex diseases with largely unknown etiology. Both behavioral and physiological responses to anxiety-provoking situations are evolutionarily conserved and therefore, mouse models allow investigation of both innate and stress-induced anxiety in a controlled environment and genetically homogeneous background. We have taken a cross-species approach to identify genes that regulate anxiety-like behavior using inbred mouse strains. We carried out RNAseq and miRNAseq of frontal cortex and hippocampus, two brain regions central in the regulation of anxiety, in two different mouse models of anxiety: 1) a panel of six inbred mouse strains (DBA/2J, A/J, 129S1/SvImJ, C3H/HeJ, C57BL/6J, and FVB/NJ) that differ in their innate anxiety; and 2) a psychosocial stress-induced anxiety (chronic social defeat stress) in two inbred strains (C57BL/6 and DBA/2). In the innate model, we correlated the gene expression levels with the levels of anxiety-like behavior (measured by the open field and light dark box tests) across the strains to identify genes and gene networks that putatively regulate anxiety. In the hippocampus, the differentially expressed genes were enriched in the vesicle mediated transport, mitotic nuclear division, and lipid metabolism Gene Ontology categories. In the frontal cortex, we observed enrichment in the cell division, vesicle mediated transport, and lipid metabolism categories. We are currently carrying out similar analysis with the psychosocial stress model. These two datasets offer an excellent setup to investigate whether the same biological processes are involved in the regulation of innate anxiety and stress-induced anxiety, i.e. if individuals who are innately more anxious are also more susceptible to stress-induced anxiety and whether these two different types of behaviors are regulated by the same molecular mechanisms. Our long-term aim is to determine whether the pathways identified using mouse models are involved in the etiology of human anxiety disorders.

1435W

***BDNF* methylation and stress response in a clinical population with major depressive disorder.** *C. Lattig[1], V.A. Villamizar[1], A. Gaviria[1], J.D. Angel[2], C. Cañizares[2], E. Ferro[3], A. Arenas[4], Y. Gomez[2]. 1) Dept Biological Sciences, Univ de los Andes, Bogota, Colombia; 2) Dept Psychology, Univ de los Andes, Bogota, Colombia; 3) El Instituto Colombiano del Sistema Nervioso, Clinica Montserrat. Bogota, Colombia; 4) Hermanas Hospitalarias Clínica La Inmaculada. Bogota, Colombia.*

Major Depressive Disorder (MDD [MIM: 608516]) is a multifactorial disease that affects morbidity, mortality and quality of life. It has a reported heritability of approximately 35-40%, indicating an important genetic component. Brain-Derived Neurotrophic Factor Gene (BDNF) Val66Met (rs6265) variant has a well-established role in neuronal plasticity and decreased levels have been observed in individuals with MDD. Additionally, early childhood adversity and stressful life events are recognized environmental risk factors for MDD. Previous studies present evidence that support the idea that vulnerability to environmental stress is mediated by the rs6265 variant. On the other hand, changes in methylation patterns in exon IV of BDNF are emerging as a possible explanation for how stress events can disrupt BDNF expression. However, there is still some controversy on the topic, mainly because most of these studies have been carried out in non-clinical populations. Here we present a case-control study using a clinical population from two psychiatric clinics and matched controls. Informed consent of the study was provided by all individuals. This study was approved by the ethics committee of all the participant institutions. Early stress events where assessed in the clinical questionnaire, the stressful live events questionnaire was applied to evaluate number and response to adverse events. The rs6265 variant was genotyped using real time PCR with Taqman probes from Applied Biosystems 7500/7500. Methylation patterns in exon IV of BDNF were assessed by bisulfite treatment using the EZ-96 DNA Methylation kit (Zymo research) followed by Sanger sequencing and subsequent quantification of methylation percentage at each CpG region. We did not find any association or gene x environment interaction between the rs6265 variant and MDD, however when analyzing methylation patterns we did find an association among percentage of methylation and MDD (p=0.001). We also found association in methylation patterns among controls that had experienced early adverse events (p=0.005), however this association was not observed in cases. Our results suggest that initial alteration of BDNF expression resulting from higher levels of methylation as observed in individuals who experienced early life events, may not necessarily predispose an individual to develop MDD supporting the idea that depression vulnerability and stress response can be mediated by different factors.

1436T

Alcoholism, schizophrenia and Alzheimer's disease susceptibility genes associations with cognitive and mental traits in Russian population. *A.V. Marusin[1], A.N. Kornetov[2], M.G. Swarovskaya[1], K.V. Vagaitseva[1], E.S. Pavlenyuk[2], V.A. Stepanov[1].* 1) Scientific Research Institute of Medical Genetics of Russian Academy of Science, Tomsk, Tomsk area, Russian Federation, 634050; 2) Siberian State Medical University, Tomsk, Tomsk area, Russian Federation, 634050.

    Objectives There is abundant evidence, that personality traits are substantially influenced by the genes. All the genes that determine the intellectual abilities, especially traits of thought and behavior have not been identified yet. The aim of this study was to analyze associations of 12 SNPs polymorphisms involved in the development of severe mental disorders - alcoholism, schizophrenia and Alzheimer's disease with cognitive and mental traits. **Methods** Associations of personality, temperament and character quantitative traits determined by Cattell's (The Sixteen Personality Factor Questionnaire (16PF)), Leonhard's, Spielberger-Khanin's, and Eysenck's (IQ) tests were analyzed with 12 gene polymorphisms. DNA samples from 150 students were genotyped using TaqMan® SNP Genotyping Assays (Applied Biosystems) under condition recommended by the manufacturer. **Results** Paired combinations of *GABRA2 - PICALM*, *PICALM - ADCY3*, *CLU - CBX7* and *CLU - ADCY3* polymorphisms in interallelic nonrandom associations was detected. This may reflect the adaptive nature of natural selection, it is directed on maintaining behavioral homeostasis in the population. A number of statistically significant associations of genetic variation were found: *CLU* with perfectionism (Q3) of 16PF and the exaltation of the Leonhard's tests, *PICALM* with tension (Q4) of 16PF and the imbalance of Leonhard's tests, *DISC1* with vigilance (L) of 16PF, and exaltation, cyclothymia of Leonhard's tests, *ZNF804A* with imbalance by Leonhard's test, *SLC6A4* with reasoning (B) of 16PF test, *ADCY3* with self-reliance (Q2) and extraversion (F2) of 16PF test, *MIR9-2* emotional stability (C), liveliness (C), social boldness (H), extraversion (F2) of 16PF, and dysthymia, hyperthymia of Leonhard's tests, with the personal anxiety of Spielberger-Khanin's test, *CBX7* with vigilance (L), and warmth (A) of 16PF test, *SLC6A3* with IQ by Eysenck's test. For the polymorphism rs13219354, *GAB2*, and *GABRA2* relationship to the the intelligence, temperament and character traits were not found. **Conclusion** Perhaps data of 12 SNPs associations with personal characteristics may be applied for the treatment of severe mental disorders. This work was supported by the Russian Science Foundation (project # 16-14-00020).

Genome-wide association study of major depressive disorder in European Americans and African Americans. *L. Wen[1], Y. Yao[1], W. Cui[1], T.J. Payne[2], J.Z. Ma[3], M.D. Li[1,4].* 1) State Key Laboratory for Diagnosis and Treatment of Infectious Diseases, Zhejiang Universityj, Hangzhou, China; 2) Department of Otolaryngology and Communicative Sciences, University of Mississippi Medical Center, Jackson, MS; 3) Department of Public Health Sciences, University of Virginia, Charlottesville, VA; 4) Institute of NeuroImmune Pharmacology, Seton Hall University, South Orange, NJ.

    Major depressive disorder (MDD) is a common complex mental illness, which is one of leading causes of preventable deaths and disabilities throughout the world. To date, genome-wide association study (GWAS) for MDD and its related phenotypes has not yielded consistent results. In this study, we conducted a GWAS for the Center for Epidemiological Studies Depression (CES-D) score, a widely used questionnaire for measuring MDD, in European American (EA) and African American (AA) populations, with age, sex, ancestry-informative principal component scores, and smoking status as covariates. Considering there is no evidence for the presence of heterogeneity between the AA and EA samples, we analyzed the two populations together, giving a sample size of 4,817. Our results revealed a genome-wide significant association between a nonsynonymous SNP rs61753730 in *FZD6* (frizzled class receptor 6; a negative regulator of the canonical Wnt/beta-catenin signaling cascade) that gives rise to a glutamine-to-glutamate substitution and CES-D score ($P = 8.46 \times 10^{-9}$). Such a significant finding has received independent support from molecular study using an animal model where knockdown of *FZD6* expression led to a depressive effect. Because there were a few SNPs included in the Illumina Infinium HumanExome BeadChip for *FZD6*, we performed imputation analysis for the gene with IMPUTE2 using 1000 Genomes as references and then conducted a gene-based association study using SNP-set Kernel Association Test (SKAT) in the pooled samples, which revealed a significant association of *FZD6* with the CES-D score ($P < 0.01$). Additional gene-by-gene interaction analysis using a generalized multifactor dimensionality reduction (GMDR) algorithm showed a significant interaction between *FZD6* and *CREB3L1* ($P = 0.0016$) and between *FZD6* and *CREB3L4* ($P = 0.002$). Finally, we showed that tobacco smoking plays a significant role in the association of *FZD6* with depression, in that significant association of the gene with the CES-D score was detected only in smokers. This study shows that *FZD6* is a plausible candidate gene for MDD, and further study with a large sample is warranted.

Whole-exome sequencing in bipolar disorder identifies rare variants associated with Parkinson disease and other neuropsychiatric diseases. *X. Jia[1,3], M. Kvale[2,3], L. Shen[4], P.Y. Kwok[2,3], C. Schaefer[4], N. Risch[2,3,4].* 1) Department of Neurology, University of California San Francisco, San Francisco, CA; 2) Department of Epidemiology and Biostatistics, University of California San Francisco, San Francisco, CA; 3) Institute for Human Genetics, University of California San Francisco, San Francisco, CA; 4) Kaiser Permanente Northern California Division of Research, Oakland, CA.

We performed whole-exome sequencing in 483 individuals with bipolar disorder (BD) from the Multi-ethnic Study of Bipolar Disorder and 483 ancestry-matched controls from the Kaiser Permanente Research Program on Genes Environment and Health (RPGEH) using the NimbleGen SeqCap EZ system. Of the 5.8 million called genomic positions, we extracted 1,013,033 positions within the capture target interval with calls made at ≥ 10X coverage. We validated exome sequencing genotypes in 104,719 overlapping SNPs genotyped using the Affymetrix Axiom system, which contained 675,000 to 891,000 SNP markers on four ancestry-specific arrays (non-Hispanic white, African-American, Latino, and Asian). Genotype concordance ranged from 98.1% to 99.3% across the four arrays. Among 966 individuals, we identified a total of 842 rare (minor allele frequency < 0.5%) nonsynonymous exonic and splice-site variants that were predicted to be pathogenic or likely pathogenic by ACMG Guideline classification. Of 290 genes containing a pathogenic or likely pathogenic variant in more than one individual, none reached statistical significance for association with bipolar disorder. However, analysis of top 5% associated genes revealed an enrichment of pathogenic variants in genes previously implicated in bipolar disorder or other neuropsychiatric conditions. *LRRK2*, previously associated with mood disorders in patients with Parkinson Disease, contained exonic mutations in 6 cases and 1 control (OR = 6.1, *p* = 0.13). Mutations in *GBA*, the lysosomal enzyme deficient in Gaucher's disease associated with Parkinson Disease in heterozygotes, was found in 8 cases and 3 controls (OR = 2.7, *p* = 0.22). *ATP7B*, a copper-transporting ATPase implicated in Wilson Disease, contained variants found in 7 cases and 2 controls (OR = 3.5, *p* = 0.18). *DPYD*, a risk locus for schizophrenia, contained variants found in 7 cases and 2 controls (OR = 3.5, *p* = 0.18). These findings suggest a possible pre-morbid link between bipolar disorder and Parkinson disease, as previously observed in *LRRK2*. Additional studies are needed to further investigate the role of rare variants in co-morbid risk for bipolar disorder and other neuropsychiatric conditions.

The first case of a child with a Joubert Syndrome with obsessive compulsive disorder. *Y. Cengiz[1], M.C. Ergoren[2,4], B. Kaymakamzade[3].* 1) Child and Adolescent Pyshchiatry, School of Medicine, East University, Nicosia, Cyprus; 2) Department of Medical Biology, School of Medicine, East University, Nicosia, Cyprus; 3) Department of Neurology, School of Medicine, East University, Nicosia, Cyprus; 4) Experimental Health Sciences Research Centre,School of Medicine, East University, Nicosia, Cyprus.

Joubert syndrome (JS) is a rare autosomal recessive disorder with partial or complete agenesis of cerebellar vermis. This syndrome is identified mainly by the presence of molar tooth sign in magnetic resonance imaging of the brain since it has a varied phenotypic presentation. Obsessive-compulsive disorder (OCD) is a neuropsychiatric disorder, commonly having an early age of onset, and is characterized by the presence of obsessions (unwanted, intrusive thoughts) and compulsions (repetitive behaviors) that can become incapacitating. Here in, we report a 16 year-old male patient with JS who shows the symptoms of OCD. He was admitted to the neurology department with the chief complaint of inbalance and abnormal eye movements since his birth. He had also delayed motor and cognitive milestones. His mother described neonatal episodic hyperpnea and hypotonia for the early childhood period. On neurological examination he had oculomotor apraxia and truncal ataxia. The brain MRI revealed typical molar-tooth sign. The patient presented to child and adolescent psychiatry department, two years duration of illness characterized by repetitive questions, extreme anxiety and anger when non-answered questions by his mother and worrying about getting sick. Neuropsychological testing performed after clinical interview using the Wechsler Intelligence Scale for Children, revised edition, he demonstrated moderate intellectual disability overall. There is increasing understanding that the interconnectivity between association neocortex, limbic cortex and the cerebellar hemispheres may play a key role in the processing of multimodal information. In turn, disruption of this circuitry may play a role in neuropsychiatric disease. There are many studies that show relation between Joubert syndrome and autistic spectrum disorders suggesting a link between abnormalities of the cerebellar vermis and autism. To the best of our knowledge, this is the first case of Joubert syndrome with OCD. Recent morphological studies demonstrate a potential important role of cerebellum in OCD. Studies focusing on psychiatric symptoms in JS are necessary for clarifying their relation.

1440F

Whole genome sequencing in a multigenerational family with a specific deficit in semantic cognition. *A.K. Tilot[1], K.S. Kucera[1], J. Briscoe[2], D. Skuse[3], S.E. Fisher[1,4].* 1) Language and Genetics, Max Planck Institute for Psycholinguistics, Nijmegen, Gelderland, Netherlands; 2) School of Experimental Psychology, University of Bristol, Bristol, United Kingdom; 3) Behavioural and Brain Sciences, Institute of Child Health, University College London, London, United Kingdom; 4) Donders Institute for Brain, Cognition and Behaviour, Radboud University, Nijmegen, Gelderland, Netherlands.

Semantic cognition refers to our ability to connect words with meanings, and make use of those relationships in language. In the JR family, a specific deficit in semantic cognition manifests as difficulty recalling verbally presented information and frequent struggles with the tip-of-the-tongue phenomenon. Intensive phenotyping of this family previously revealed deficits in memory for stories, word learning, listening comprehension and using conceptual knowledge to match words across lists. This constellation of phenotypes was remarkably consistent across affected family members, and the pedigree suggested a dominant and highly penetrant inheritance pattern.   Our goal in this study was to identify a potential genetic explanation for the phenotype, following MRI findings that suggested structural abnormalities in the anterior temporal cortex, an area associated with semantic cognition. For this work, we adopted a monogenic model which assumed that any causative mutations would be rare and follow a dominant inheritance pattern. Initial genotyping of 15 family members (seven affected) identified several suggestive regions of linkage, but none that exceeded the LOD>3 threshold for significance. We next applied whole genome sequencing (WGS) to five samples (three affected). We integrated WGS-based structural variant calls from three programs with copy number variation in the remaining samples, and did not find evidence for a causative structural variant in the family. Filtering smaller variants identified in the WGS data by their inheritance pattern and minor allele frequency (< 0.001) yielded 467 rare variants for further analysis.   To aid variant prioritization, we compared three methods for assessing deleteriousness (Variant Effect Predictor, CADD, and Eigen) and constructed a list of 12 variants categorized as likely deleterious by at least one program. Interestingly, there was only modest correspondence between the three methods, with only four variants considered strongly deleterious by more than one program. Half of the variants were outside of coding regions, and none were linked to related cognitive deficits. These results suggest that this unique neurological phenotype may stem from genetic alterations outside of those currently associated with cognitive phenotypes. Further work will determine if any of the variants in noncoding regions are tied to genes implicated in other cognitive deficits through regulatory networks.

1441W

Gene-environmental interactions between genetic variants in antiviral response genes and prenatal maternal infections in schizophrenia. *V.M. Rajagopal[1], L. Reinert[1], S.R. Palludan[1], J. Grove[1], P.F.R. Nielsen[2], R. Yolken[3], D.M. Hougaard[4], M. Nordentoft[5], T. Werge[6], A. Børglum[1], P.B. Mortensen[2], D. Demontis[1].* 1) Department of Biomedicine, Aarhus University, Aarhus, Denmark; 2) National Centre for Register-based Research, Aarhus University, Aarhus, Denmark; 3) Stanley Division of Developmental Stanley Division of Developmental Neurovirology, The Johns Hopkins University School of Medicine, Baltimore, MD; 4) Statens Serum Institut, Copenhagen S; 5) Mental Health Centre Copenhagen, Capital Region of Denmark; 6) Mental Health Center Sct. Hans, Capital Region of Denmark.

Background: Several epidemiological studies have found that prenatal maternal infections with herpes simplex virus 1 and 2 (HSV1 and HSV2) and cytomegalovirus (CMV) increase the risk for schizophrenia in the offspring. Multiple mechanisms have been postulated explaining the biological plausibility behind these associations. One among them is activation of the innate immune system leading to release of inflammatory mediators disrupting the neurodevelopment in the embryo. We studied the gene environment interactions between single nucleotide polymorphisms located in the genes (*TLR3, TMEM173, MV21D1, IFNB1, IFI16, TBK1, IRF3* and *IRF7*) involved in innate immune response and prenatal maternal infections with viruses: HSV1, 2 and CMV in schizophrenia. Also, we studied the imputed expression levels of those genes with respect to schizophrenia and maternal infection status. **Methods**: Totally 1806 samples comprising 908 cases (ICD-10: F20) and 898 healthy controls were identified from the Danish Psychiatric Central register. The DNA was isolated from the dried blood spot of the participants stored in the Danish Newborn Screening Biobank. Maternal infection status was established for HSV1, 2 and CMV viruses by measuring the IgG antibodies from the dried blood spot. Genotyping was done using the exome core chip from Illumina. SNPs located within and around 5kb up/downstream of the genes of interest were extracted and analyzed for interaction between maternal infection and offspring genotype using logistic regression. The expression levels of the genes in various brain tissues were imputed using PrediXcan software and compared between the samples with mothers with and without infections among cases and controls. **Results**: We found nominally significant interactions of variants in the analyzed genes of the offspring with maternal infections: *IFI16* with HSV1, *TLR3* with HSV2, and *TMEM173*, *IRF7* and *TBK* with CMV. Also, we found significant differences in the imputed expression patterns of *TLR3*, *IFNB1*, *IRF7*, *MB21D1*, *TBK1*, *TMEM173* and *IFI16* in the brain between the groups. **Conclusion**: In summary, we found indications that the offspring risk of schizophrenia could be influenced by genetic variations in the genes involved in innate immune response interacting with the presence of viral infections (HSV1, 2 and CMV) in the mother during pregnancy. Additionally our results indicate that such interactions could be due to differential expression of the studied genes in the brain.

1442T

Leveraging polygenic risk scores to discover novel biomarkers of disease in a large biobank setting. *L. Davis[1], J. Dennis[1], D. Hucks[1], G. Chen[2].* 1) Division of Genetic Medicine, Vanderbilt University Medical Center, Nashville, TN; 2) Department of Biostatistics, Vanderbilt University Medical Center, Nashville, TN.

For polygenic traits, genetic risk is distributed throughout the genome and therefore individual single nucleotide polymorphisms (SNPs) explain a very small proportion of trait heritability. Though individually small, the aggregate effects of common SNPs are substantial and can be measured in the form of polygenic risk scores (PRS) defined as the sum of the number of risk alleles weighted by the effect size of each risk allele based on a discovery GWAS. PRS are often used to estimate genetic correlation between complex traits. It follows that quantitative measures (i.e., biomarkers) of a given disease state may also be correlated with the PRS for that disease or disorder. GWAS summary statistics are available for many phenotypes for which there are no reliable biomarkers, such as neuropsychiatric traits. The Vanderbilt University Medical Center Biobank (BioVU) includes genetic data and routinely collected clinical laboratory measurements on over 20,000 people. Lab measures such as complete blood count (CBC) and lipid panels, among many others ($N_{labs} > 200$), can be mined for novel biomarkers of disease through PRS analyses. In a proof of principal experiment, we calculated PRS for triglycerides (PRS_{trigs}) (based on the Global Lipids Genetics Consortium meta-analysis results) in each individual in BioVU genotyped on the Omni-Quad platform (N = 3,422). The best fit PRS_{trigs} (i.e., weighted sum of 3,307 independent triglyceride associated SNPs with p<0.01) accounted for a significant proportion of the variance in mean triglyceride levels ($R^2 = 0.034$; $p = 4.2 \times 10^{-27}$) while adjusting for sex, age, and ancestry. These results provide evidence that PRS derived from GWAS can account for a significant proportion of variance in routinely collected laboratory measurements across a cohort-like hospital population. We will report on our ongoing project to create a panel of PRS representing all complex traits for which GWAS have been performed, for each individual in BioVU with existing genetic data. Associations between PRS of complex traits and available laboratory measurements in BioVU will be presented as will pitfalls and lessons learned during analysis. The application of PRS to laboratory measures collected in a biobank setting provides a unique opportunity to identify biomarkers for notoriously elusive phenotypes such as neuropsychiatric traits, and may substantially improve diagnostics, early interventions, and therapeutics for many diseases and disorders.

1443F

Polygenic risk scores reveal patterns of assortative mating and anticipation in a large severely affected pedigree. *S. de Jong[1], M.J.A. Diniz[2,3], A.C.S. Rodrigues[2,3], A. Gadelha[2], M.L. Santoro[4], V.K. Ota[4], C.S. Noto[4], C. Curtis[1,5], H. Patel[1,5], L. Hall[6], P.F. O'Reilly[1], S.I. Belangero[2,5], R. Bressan[2], G. Breen[1,5].* 1) MRC Social Genetic and Developmental Psychiatry Centre, Institute of Psychiatry Psychology and Neuroscience, King's College London, London, United Kingdom; 2) Department of Psychiatry, Universidade Federal de São Paulo (UNIFESP/EPM), São Paulo, Brazil; 3) Pax Clinica Psiquiatrica, Rodovia Br153, Santa Luzia - Aparecida de Goiânia/GO CEP: 74922-810; 4) Department of Morphology and Genetics, Universidade Federal de São Paulo (UNIFESP/EPM), São Paulo, Brazil; 5) National Institute of Health Research Biomedical Research Centre for Mental Health, Maudsley Hospital and Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom; 6) Institute of Genetic Medicine, International Centre for Life , Newcastle University, Newcastle upon Tyne, United Kingdom.

The aim of this study is to examine the role that common genetic variation confers on disease risk in a severely affected pedigree that would have traditionally been viewed through the prism of monogenic inheritance only. To achieve this we exploit both a large pedigree (n~300) with high prevalence of mood disorders (30% of family members is affected with major depressive disorder (MDD) or bipolar disorder (BP)) and the recently popular polygenic risk score (PRS) approach. Illumina Psych chip data is available for 243 family members of which 78 individuals are affected with mood disorders (including 36 BP and 38 MDD patients) and 59 unrelated healthy Brazilian controls. Using psychiatric PRS derived from recent large GWAS mega analysis efforts in psychiatric disorders like schizophrenia (SCZ), BP and MDD, we examine patterns of assortative mating and anticipation in the family. First, we examine common variant effect on risk via an association between PRS and case/control status in the pedigree. Next we investigate an increase in PRS value across the generations, seemingly driven by the transmission of elevated PRS to offspring from 11 affected married-in individuals (vs 35 unaffected married-in individuals). This suggests that PRS contributions from married-in individuals, caused by assortative mating on phenotype, may increase risk for psychiatric disorders beyond that conferred by rare variation transmitted from within the family. A joint analysis of both rare and common variation may be the most powerful way to understand the familial genetics of mood and psychiatric disorders.

1444W

Transcriptomic signatures of schizophrenia revealed by dopamine perturbation of lymphoblastoid cell lines. *P.V. Gejman[1,2], J. Duan[1,2], A.R. Sanders[1,2], E. Drigalenko[3], H.H.H. Göring[4].* 1) Ctr Psychiatric Genetics, University of Chicago School of Medicine, Chicago, IL; 2) NorthShore University Health System, Evanston, IL; 3) Department of Genetics, Texas Biomedical Research Institute, San Antonio, TX; 4) South Texas Diabetes and Obesity Institute, University of Texas Rio Grande Valley School of Medicine, San Antonio, TX.

We performed a dopamine perturbation on lymphoblastoid cell lines from 515 schizophrenia cases and 692 controls and studied the resultant RNA-seq profiles. Dopamine had widespread effects on expression profiles, though these effects were likely not mediated through dopamine receptors. Upon stimulation, of the reliably expressed genes, 3,756 (19%) had expression changes >1 SD at FDR<5%. Of those genes, 539 showed differential response in schizophrenia cases and controls. Pathway analyses uncovered that the set of differentially expressed genes were enriched for two factors: (1) brain expression, and (2) immune and/or apoptotic mechanism involvement. The latter observation is consistent with schizophrenia GWAS findings whose most significant locus is the extended major histocompatibility complex region, which contains numerous genes with fundamental roles in immune response.

1445T

Integrative genomic analysis reveals casual role of genes and networks involved in nicotine consumption using both human and animal data. *P. Huang[1], T. Nesil[2], S. Wang[2], Z. Yang[1], M.D. Li[1,2].* 1) State Key Laboratory for Diagnosis and Treatment of Infectious Diseases, The First Affiliated Hospital, Zhejiang University School of Medicine, Hangzhou, China; 2) Institute of NeuroImmune Pharmacology, Seton Hall University, South Orange, NJ USA.

Family and twin studies have revealed a moderate-to-high heritability of nicotine dependence (ND), a primary factor maintaining continuous tobacco smoking. However, the molecular mechanisms underlying ND are still largely unknown. In this study, we used the RNA deep-sequencing approach to determine the hippocampus transcriptome profiles of two lines of rats with 9.3-fold difference in nicotine consumption. We detected 1,275 differentially expressed (DE) genes and 1,512 DE transcripts encoded by 1452 genes. Functional enrichment analyses revealed significant overrepresentation of Gene Ontology categories involved in regulating synaptic transmission, plasticity, and the pathways implicated in ND such as calcium signaling, long-term potentiation, and glutamatergic and dopaminergic synapse signaling. Further, weighted gene co-expression network analysis (WGCNA) identified 18 modules whose overall expression profiles were significantly associated with nicotine intake. Follow-up integration analysis using three human GWAS datasets confirmed an important role for a gene module (GM12), where significant enrichment was detected for included genes by containing at least one nominally significantly associated SNP with ND. The GM12 module contained a number of genes known to be important in nicotine addiction, such as *Chrna4*, *Gabrb2*, *Grin3a*, *Grin2d*, and *Slc17a6*. Functional characterization of GM12 revealed their alliances with nicotine addiction, neurotransmitter receptor binding, and gated channel activity. In sum, we provide convergent evidence for the potential casual roles of large-scale gene expression alterations and coordinated differential expression of one ND-associated sub-network in nicotine intake in rats. Given the high similarities between nicotine intake in rats and smoking in humans, our findings provide new insights into the molecular mechanisms underlying nicotine addiction, although further replication and investigation are needed.

1446F

Genetic and phenotypic heterogeneity of mood disorders in a large multigenerational pedigree. *R.L. Kember[1], L. Hou[2], X. Ji[1], L.H. Andersen[3], L.N. Estrella[3], F.J. McMahon[2], C.D. Brown[1], M. Bucan[1].* 1) Department of Genetics, Philadelphia, PA; 2) Human Genetics Branch, National Institute of Mental Health Intramural Research Program, National Institutes of Health, Bethesda, MD; 3) Lancaster General Health/Penn Medicine, University of Pennsylvania Health System, Lancaster, PA.

Bipolar disorder (BD) is a mental disorder characterized by alternating periods of depression and mania. Individuals with BD have higher levels of early mortality than the general population, and a substantial proportion of this may be linked to increased risk for co-morbid diseases. Medical co-morbidity may be a consequence of either chromosomal proximity of a BD-risk gene to a gene underlying non-psychiatric phenotype, or the pleiotropic effect of a risk-allele on both mental illness and other phenotypes. In order to identify the molecular events that underlie BD and related medical co-morbidities, we performed whole genome sequence (WGS) and RNA sequence analysis of lymphoblastoid cell lines from an extended multigenerational Old Order Amish pedigree (400 family members) segregating BD and related disorders. We mapped disease causing variants at known Mendelian loci and performed genomic profiling using polygenic risk scores for several complex diseases, allowing us to genetically 'diagnose' all family members. In addition to known Mendelian mutations, we identified 167 high confidence loss-of-function (LoF) mutations in disease genes. Each individual has on average 31 LoF variants in disease genes with five disease genes predicted to be completely inactivated. Variants in five of these genes (*TMCO1, TPO, SPG21, IDH2, COL18A1*) lead to differential expression between individuals with and without the LoF variant. To explore the contribution of disease genes to BD we performed gene-based and variant-based association tests for BD, and found that Mendelian disease genes are enriched in the top results from both tests. We identified disease causing variants in cardiovascular genes which are found at a higher frequency in individuals with BD compared to unaffected individuals, including a variant in *APOB* associated with hypercholesterolemia. Finally, we examined the region containing the top BD associated linkage peak, and identified a cluster of damaging mutations in human disease genes. In particular, one of the haplotypes associated with BD contains multiple damaging variants in disease genes. Taken together, our results indicate that medical co-morbidity between complex diseases and Mendelian disorders arises as a combination of chromosomal proximity of disease causing variants and pleiotropy of disease genes.

1447W

A second update on susceptibility genes for nicotine dependence identified by genome-wide linkage, candidate gene association, genome-wide association, and targeted sequencing approaches. *M. Li[1,2], J. Yang[1,2], T. Payne[3], J. Ma[4].* 1) Institute of Neuroimmune Pharmacology, Seton Hall University, South Orange, NJ; 2) State Key Laboratory for Diagnosis and Treatment of Infectious Diseases, Zhejiang University, Hangzhou, China; 3) Department of Otolaryngology and Communicative Sciences, University of Mississippi Medical Center, Jackson, MS; 4) Department of Public Health Sciences, University of Virginia, Charlottesville, VA.

Tobacco smoking is a severe health hazard worldwide, as nearly one-third of the global adult population smokes tobacco products, and these have been associated with numerous serious health problems. This high prevalence of tobacco use highlights the importance of studying the genetic determinants of nicotine dependence (ND). To identify genetic factors for ND, various approaches have been used, including genome-wide linkage, candidate gene-based association, genome-wide association (GWAS), and targeted sequencing analysis. In this study, we systematically analysed the findings from all the abovementioned approaches according to rigorous selection criteria for each included study such as sample size, statistical significance, and independent replication. Our analysis revealed 14 regions nominated by genome-wide linkage analysis and 34 significantly associated loci in 43 genes by candidate gene-based association. The GWAS and meta-GWAS revealed 11 genome-wide significant loci; however, only the loci on chromosomes 8, 15, and 19 have received independent replication. Although it is still in early stages, limited targeted sequencing studies using next-generation techniques have implicated 18 variants in the aetiology of ND. Together, we identified 14 linkage regions and 47 unique loci in 60 genes involved in the development of ND, which forms our current understanding of the susceptibility map for ND. Because almost all of these loci and genes have received replication by independent approaches in different samples, they should be considered high priorities for future functional study of ND.

1448T

Contribution of common genetic variation to risk for severe developmental disorders. *M. Niemi, J. Barrett, The Deciphering Developmental Disorders Study.* Wellcome Trust Sanger Institute, Hinxton, United Kingdom.

Rare and common variants in the genome both contribute substantially to human disease, but these have typically been studied separately from each other. Rare disease variants often have severely deleterious effects on an individual, whereas common variants tend to have relatively small individual effects but can collectively substantially influence a person's disease risk. Recent studies have now conclusively implicated both rare and common variation in common neurodevelopmental conditions, such as autism and schizophrenia.   The Deciphering Developmental Disorders (DDD) study has recruited >13,500 children with severe developmental disorders without a genetic diagnosis from clinical genetics departments around the UK. We are primarily using exome sequencing of the children and their parents to search for rare or *de novo* variants of strong effect, because these individuals are presumed to have Mendelian genetic disorders. Here, we test whether these children also have a higher burden of common variants associated with other neurodevelopmental traits by analysing GWAS data in 2,268 DDD cases and 9,275 healthy controls of European ancestry. We calculated polygenic risk scores (PRS) for a range of diseases from published GWAS summary statistics. For nearly all diseases, we saw no difference between DDD cases and controls (Kolmogorov-Smirnov test) p>0.05, which illustrated that our cases and controls were generally well matched. However, our DDD cases had a significantly higher burden of schizophrenia polygenic risk compared to controls (p=0.0028). Previous evidence of genetic overlap among neurodevelopmental disorders suggests that this PRS might serve as a proxy for neurodevelopment, and is well powered due to the large sample size of the underlying schizophrenia GWAS. These data suggest there is a polygenic component to developmental disorders at least in a subset of patients, and that there may be shared common genetic architecture among a range of neurodevelopmental disorders.

1449F

***MC1R* gene variation and fear related to dental care: Evidence of fear of pain as mediator.** *C.L. Randall[1,2], D.W. McNeil[1,2,3], J.R. Shaffer[2,4], R.J. Crout[2,5], R.J. Weyant[2,6], M.L. Marazita[2,4,7,8,9,10].* 1) Department of Psychology, Eberly College of Arts and Sciences, West Virginia University, Morgantown, WV; 2) Department of Dental Practice and Rural Health, School of Dentistry, West Virginia University, Morgantown, WV; 3) Center for Oral Health Research in Appalachia; 4) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 5) Department of Periodontics, School of Dentistry, West Virginia University, Morgantown, WV; 6) Department of Dental Public Health, School of Dental Medicine, University of Pittsburgh, Pittsburgh, PA; 7) Center for Craniofacial and Dental Genetics, University of Pittsburgh, Pittsburgh, PA; 8) Department of Oral Biology, School of Dental Medicine, University of Pittsburgh, Pittsburgh, PA; 9) Department of Psychiatry, School of Medicine, University of Pittsburgh, Pittsburgh, PA; 10) Department of Clinical and Translational Science, University of Pittsburgh, Pittsburgh, PA.

Anecdotal evidence in medicine and dentistry has long suggested that individuals with red hair are hypersensitive to pain and more likely to be anxious or fearful. Consistent with this persistent clinical lore, recent investigations have confirmed that variation in the melanocortin-1 receptor (*MC1R* [MIM 155555]) gene, which has approximately 97% prevalence in red-haired and approximately 33% prevalence in dark-haired Caucasians, is associated with general acute pain sensitivity, dental pain sensitivity, and fears related to dental care. The study objective was to clarify genetic influences in the etiology of dental care-related fear, which is ubiquitous and, at high levels, impacts dental treatment-seeking behavior and oral and systemic health. Specifically, the present study aimed to: (1) replicate the finding that *MC1R* variation and dental care-related fear are associated, (2) determine for the first time whether *MC1R* variation is associated with general fear of pain, and (3) determine whether fear of pain plays an intermediary role in the association between *MC1R* variant status and dental care-related fear. Participants were 817 Caucasian adults (62.5% female, *M* age = 34.7 years, *SD* = 8.7) taking part in a larger, cross-sectional project that identified determinants of oral diseases at the community-, family-, and individual levels (Center for Oral Health Research in Appalachia, cohort 1; COHRA1). Six SNPs on *MC1R* (rs1805006, rs11547464, rs1805007, rs1110400, rs1805008, rs1805009) were genotyped for participants who also completed self-report measures of dental care-related fear and fear of pain. Variation at one or more *MC1R* SNPs predicted higher levels of dental care-related fear and fear of pain. Importantly, fear of pain fully mediated the relation between *MC1R* variant status and dental care-related fear, B = 1.60, 95% CI [0.281, 3.056]. *MC1R* variation may influence orofacial/dental pain and, in turn, predispose individuals to develop fears about pain. Such pain-related concerns may contribute to the genesis of fears about dental treatment. This study provides support for genetic influences in the etiologies of fear of pain and dental care-related fear, and offers directions for future research that could identify biomarkers of dental pain sensitivity, fear of pain, and dental care-related fear. Investigating the prevalence of treatable genetic disorders with neuropsychiatric symptoms in schizophrenia and bipolar populations. *V. Sriretnakumar[1,2], K. Mittal[1], R. Harripaul[3,4], J. Kennedy[1,3,5], J. So[1,2,5,6].* 1) Neuropsychiatry Genetics, Center for Addiction and Mental Health (CAMH), Toronto, Ontario, Canada; 2) Laboratory Medicine and Pathobiology (LMP), Faculty of Medicine, University of Toronto, Toronto, Ontario, Canada; 3) Institute of Medical Science (IMS), Faculty of Medicine, University of Toronto, Ontario, Canada; 4) Molecular Neuropsychiatry and Development Laboratory, Centre for Addiction and Mental Health (CAMH), Toronto, Ontario, Canada; 5) Department of Psychiatry, University of Toronto, Toronto, Ontario, Canada; 6) The Fred A. Litwin Family Centre in Genetic Medicine, University Health Network and Mount Sinai Hospital, Toronto, Ontario, Canada.

   Background: Many rare genetic syndromes are known to phenotypically manifest with psychiatric symptoms that can be indistinguishable from primary psychiatric disorders. While the majority of ongoing psychiatric genetic research has been dedicated to the identification and characterization of genes involved in primary psychiatric disorders, little research has been done to determine the extent to which rare genetic variants contribute to the overall psychiatric disease load. Within schizophrenia and bipolar populations, we are conducting the first study of its kind to determine the prevalence of four treatable genetic syndromes (Niemann Pick disease type C (NPC), Wilson disease, acute intermittent porphyria (AIP), and homocystinuria (HOM)) manifesting as primary psychiatric disorders. **Methods:** We are screening 1323 schizophrenia and 1200 bipolar disorder samples, along with 980 sex- and age-matched healthy controls, all with available DNA and extensive phenotype data. We are using a matrix-type pooled targeted deep sequencing of the genes *NPC1, NPC2, ATP7B, HMBS,* and *CBS* to screen for the 4 genetic diseases. Pathogenic variants within the targeted genes will be identified using an in-house analytic pipeline with quality control, variant discovery designed specifically for identifying variants in the matrix pooled targeted sequencing approach, and functionality prediction programs to determine variant pathogenicity. Sanger sequencing will be used to validate identified mutations and decrease false positive calls. **Results:** 1024 schizophrenia samples have been sequenced (average read depth = 468X per sample, average read length=190bp, 98.8% sequencing accuracy). uSequencing of an additional 1024 schizophrenia and bipolar samples, as well as, variant analysis of the already sequenced samples is currently underway. We hypothesize that a significant sub-population of patients with psychiatric disorders have underlying rare genetic conditions. **Conclusions:** Screening for treatable genetic diseases, such as NPC, WD, AIP and HOM, within schizophrenia and bipolar samples could provide a possible explanation for severe treatment resistance and treating the genetic condition can effectively "cure" patients of their otherwise difficult-to-treat psychiatric symptoms. Ultimately, this proof-of-principle study will lead to the development of molecular diagnostic tools for detection of underlying genetic disorders in psychiatric patients and will allow for precision medicine.

Novel genetic variants in X-linked genes identified in children with apraxia of speech. *C.M. Stein[1,2], E.R. Chan[1,3], B. Truitt[1], H. Voss-Hoynes[1], L. Freebairn[5], J. Tag[5], J. Vick[5], H.G. Taylor[6], B.A. Lewis[5], S.K. Iyengar[1,4].* 1) Department of Epidemiology & Biostatistics, Case Western Reserve University, Cleveland, OH; 2) Center for Proteomics & Bioinformatics, Case Western Reserve University, Cleveland, OH; 3) Institute for Computational Biology, Case Western Reserve University, Cleveland, OH; 4) Department of Genetics & Genome Sciences, Case Western Reserve University, Cleveland, OH; 5) Department of Psychological Sciences, Case Western Reserve University, Cleveland, OH; 6) Department of Pediatrics, Case Western Reserve University, Cleveland, OH.

   Childhood apraxia of speech (CAS) is a severe communication disorder that affects 1-2/1000 children in which the precision and consistency of movements underlying speech are impaired in the absence of known neuromuscular deficits. We have found that cases of CAS are predominantly sporadic in families, that is, only one child diagnosed with CAS per nuclear pedigree. Thus, we hypothesized that such a rare and severe disorder could be caused by novel genetic variants, so we conducted whole genome sequencing of 21 cases of CAS and 21 unaffected family members from 21 CAS families. Whole genome sequencing was performed using DNA isolated from blood using PCR-Free sample preparation with Illumina HiSeq X™ Ten v2 chemistry run to 30X Mean Coverage. Reads were aligned to hg19 and variants called using the GATK pipeline. Initial filtering for exonic variants without rs numbers in dbSNP only present in CAS cases and not in unaffected siblings led to 105 novel variants occurring in 79 unique genes. Of these 12 were highly deleterious and non-synonymous and occurred in brain/neural pathways or morphological development, thus having potential relevance to CAS. Five of these genes, *FLNA, RAI2, HUWE1, PLXNB3,* and *VCX3B*, are X-linked, which may explain the sex ratio distortion seen in CAS and other communication disorders. Deficits in *FLNA* have been associated with syndromes manifested by hearing loss and problems in development of the palate. Similarly, deficits in *RAI2* have been associated with syndromes manifested by visual impairment, intellectual deficit, and psychomotor delay. *HUWE1* has been associated with mental retardation and intellectual disability. *PLXNB3* plays a role in axon guidance and cell migration, and has been associated with verbal performance. *VCX3B* has also been associated with intellectual disability and psychomotor delay. Multiple novel variants also occurred in *PCDHA10*, a protocadherin involved in cell-cell connections in the brain. Unexpectedly, there were no known or novel variants in CAS cases in *FOXP2*, a gene previously identified for dyspraxia of speech and presumed to be the most common genetic cause of CAS. Our findings illustrate the genetic heterogeneity underlying CAS, reflecting its phenotypic complexity, thus posing challenges for clinical diagnosis and classification. Furthermore, these findings broaden our knowledge of the genetic basis of human speech development.

ADHD, IQ, and inherited deletions in Canadian children with 22q11.2 deletion syndrome. *E. Chow[1,2], T. Leung[2], D. Young[2], A. Rideout[3], S. Dyack[3,4].* 1) Clinical Gen Service, Ctr Addiction & Mental Hlth, Toronto, ON, Canada; 2) University of Toronto, ON, Canada; 3) IWK Health Centre, Halifax, NS, Canada; 4) Dalhousie University, Halifax, NS, Canada.

Background: Attention Deficit Hyperactivity Disorder (ADHD) is common in children with 22q11.2 deletion syndrome (22q11DS), with reported prevalence rates between 31% to 55%. ADHD may be more common in the general population in individuals with intellectual disability. We aim to examine the prevalence of ADHD in a group of Canadian children with 22q11DS and to report on their IQ, medication usage and outcomes on follow-up. Methods: 41 children with 22q11DS (19M, 22F) and between 8 to 12 years old (mean=10.1 years, SD =1.8 years) were recruited from Canadian medical genetic clinics in Toronto and Halifax. All subjects have had FISH or microarray studies confirming a microdeletion in the 22q11.2 region. The 22q11.2 deletion was known to be inherited in 10 of these subjects. All subjects were interviewed with a parent using K-SADS-PL to assess for DSM-IV ADHD. They also had their IQ assessed using WISC-III/IV. Subjects diagnosed with ADHD were re-assessed approximately 5 years later. Results: The baseline prevalence of ADHD in this cohort was 31.7% (n=13). The mean full-scale IQ (FSIQ) for the whole group was 67.2 (SD=11.7). Average FSIQ for subjects with ADHD was non-significantly lower than that for subjects without ADHD. Subjects with inherited deletions were more likely to have ADHD than the rest of the group (46.2% vs 14.3%, p=0.049), although their mean FSIQ did not differ significantly. The most common ADHD subtype was the combined type (n=8, 61.5%). In 6 of the 13 subjects (46.2%), ADHD was a new diagnosis, made during this research assessment. Subjects previously diagnosed with ADHD were treated with stimulants (n=5), risperidone (n=2), atomoxetine (n=1), and no medications (n=1) at time of initial assessment. Ten of the 13 subjects with ADHD at initial assessment were reassessed at an average of 5.1 years later. ADHD Not Otherwise Specified was the most common type (n=4, 40%) at reassessment. Only 4 out of 10 subjects were on medications (all stimulants) at reassessment. Reasons for not accepting medications included side effects (n=2), medication felt not to be needed (n=2), psychosis (n=1) and parental refusal (n=1). Conclusions: ADHD is common in 22q11DS in Canada, but it is not always diagnosed in a timely fashion nor treated with medications. Medical geneticists can assist in prompt identification and management of ADHD in 22q11DS by having a higher index of suspicion, especially in children with inherited deletions.

Finding causal variants in the GWAS-implicated *MIR137* locus for schizophrenia. *J. Szatkiewicz[1], X. Zheng[1], S. Williams[1], K. Sakamoto[1], N. Ancalade[1], P. Giusti-Rodríguez[1], M. de Ussel[1], A. Collins[1], Y. Li[1], P. Sullivan[1,2].* 1) University of North Carolina , Chapel Hill, NC; 2) Karolinska Institutet, Stockholm, Sweden.

Schizophrenia (SCZ) is a common and devastating neuropsychiatric illness. Finding causal variants is essential for understanding SCZ etiology. The largest GWAS to date successfully identified common risk variants in 108 loci, but the identification of causal variants remains elusive. One of the strongest association loci spans *MIR137*, a microRNA gene important for neuronal function. We conducted a set of fine-mapping experiments to identify both novel and known variants that are the best candidates for functionally affecting MIR137 or other genes in the same locus, and thereby most likely contributing to SCZ risk. Our discovery sample included 280 SCZ cases and 280 controls from the Swedish Schizophrenia Study (S3). First, we deeply sequenced the 750kb LD region surrounding *MIR137* in the discovery sample to generate high-quality variant calls for SNPs, Indels, and CNVs. Using the same discovery sample, we also genotyped a known variable number tandem repeat (VNTR), 6bp upstream of the pre-*MIR137* gene. We integrated SNPs, Indels, CNVs, and VNTR to construct phased reference haplotypes. Next, we imputed the reference haplotypes into the full S3 sample, carried out experimental validation of the imputed data, performed association testing using imputed dosages, and conducted functional annotation using public databases and our own functional data on the region. Our resequencing identified 3061 novel SNPs not present in the 1000 Genomes database. Association testing based on SNPs identified two refined associations beyond the original GWAS in gene *DPYD* (rs61787785, rs75641275) and *MIR137* (rs1198577, rs10875125), both reported previously. Association testing based on VNTR suggests that this variant is unlikely to alter SCZ risk. Our deep resequencing data, imputation reference, and VNTR imputation method are useful resources for the community.

1454T

Refining the association between *de novo* **copy number variation and ASD risk.** *E.M. Wigdor[1,2], J.A. Kosmicki[1,2,3], D.J. Weiner[1,2], K.E. Samocha[1,2,4], S.J. Sanders[5], M.J. Daly[1,2], E.B. Robinson[1,2].* 1) Stanley Center for Psychiatric Research, Broad Institute of MIT and Harvard, Cambridge, MA; 2) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA; 3) Program in Bioinformatics and Integrative Genomics, Harvard University, Cambridge, MA; 4) Program in Genetics and Genomics, Biological and Biomedical Sciences, Harvard Medical School, Boston, MA; 5) University of California, San Francisco, San Francisco, CA.

De novo copy number variants (dnCNVs) are significantly associated with risk for autism spectrum disorders (ASDs; Sanders et al., 2015). The purpose of this study was to identify and interpret subgroups of dnCNVs, particularly de novo deletions, which are responsible for the majority of this association. Using data from the Simons Simplex Collection (SSC), we found that deletions including a gene intolerant of heterozygous loss of function variation (from here: constrained genes; Lek et al., bioRxiv 2015) are seen more than 4 times as frequently in ASD cases compared to controls (Carrier Ratio (CR)=4.12, p=5.20e-07). After accounting for the presence of a constrained gene, deletion size and case status are no longer associated (p=0.72). Large (>500kb) deletions lacking a constrained gene are similarly overrepresented in cases compared to controls (CR=6.50, p=0.05), but are rare as most (>80%) large deletions include a constrained gene. These two categories form our strong acting deletions group (total CR=4.3, p= 9.13e-08) and can be found in approximately 2.6% of ASD cases and 0.6% of controls. The remaining deletions (not in one of these two categories) can be found in 1.9% of cases and 1.5% of controls. These show no association with ASD risk (CR=1.22, p=0.43). The associations are not meaningfully different in models controlling for sex or parental age. Highly damaging de novo variants associated with ASD risk are consistently more common in ASD cases with low IQ. We see a strong association between ASD proband IQ and rate of de novo deletions in the strong acting category (p=0.002), but no association between proband IQ and the rate of remaining de novo deletions (p=0.53). As previously shown with de novo protein truncating variants (Kosmicki et al., biorRxiv 2016), strongly contributing de novo deletions are overrepresented in female ASD cases (p<0.05). This is not true for the remaining de novo deletions. In contrast to the deletion findings, we do not see evidence that constrained genes are any more associated with ASD risk when duplicated than other genes (p=0.92). This finding suggests that duplication of highly constrained genes is generally well tolerated. These analyses suggest that risk conferred by de novo deletions primarily reflects the loss of function of a constrained gene. This finding will improve interpretation and functional follow up studies of risk-conferring copy number variants.

1455F

Genome wide interaction between SNPs and global methylation in conferring risk for suicide in schizophrenia. *V. De Luca, A. Bani Fatemi, R. Raymond, J. Nobrega.* CAMH, Toronto, Canada.

Background: Suicide attempt in schizophrenia is an important clinical issue. We performed a genome-wide association study to identify genetic markers, which increase the risk for suicide attempt in schizophrenia. **Methods:** Suicide attempt lifetime was assessed in 433 schizophrenia patients and defined by the means of the Columbia Suicide Severity Rating Scale and the Beck Scale for Suicidal Ideation. Genotype distribution of 1,205,383 single nucleotide polymorphisms (SNPs) in patients with suicide attempt lifetime was compared to that in patients without any suicide attempt lifetime. The same SNPs were analyzed in interaction with global DNA methylation in white blood cells. **Results:** None of the variants reached genome-wide significance, the best marker in the main genetic model was the SNP rs12895203 (p=0.00001) and the top SNP interacting with global methylation was the marker rs7897059 (p=0.00005). The odd-ratio of the top SNP in the main-genetic effect model was 3.91 and in the gene-methylation interaction model was 1.13. We also found an interesting locus effect on chromosome 15 in controlling the global methylation variation. **Conclusions:** Although our data need to be interpreted carefully owing to the small numbers in this cohort, they suggest that a combination of genetic markers and global DNA methylation might be used to identify patients at risk for suicide attempt.

1456W

De novo germline and nodular heterotopia-associated postzygotic mutations of STXBP1 in an epilepsy patient successfully treated with resective surgery. *M. Uddin[1,2], C. Boelman[3], M. Woodbury-Smith[4], A. Chan[1,2], L. Brunga[2], S. Lamoureux[1,2], D. Stavropoulos[5], J. Drake[6], C. Hahn[7], C. Hawkins[8], A. Shlien[2], B. Minassian[2,6], S.W. Scherer[1,2,9,10].* 1) Genetics and Genome Biology, The Hospital for Sick Children, Toronto, The Centre for Applied Genomics, The Hospital for Sick Children, Toronto, Ontario, CanadaOntario, Canada; 2) Genetics and Genome Biology, The Hospital for Sick Children, Toronto, Ontario, Canada; 3) Division of Neurology, BC Children's Hospital, Vancouver, BC, Canada; 4) Department of Psychiatry and Behavioral Neurosciences, McMaster University, Hamilton, Ontario, Canada; 5) Genome Diagnostics, Pediatric Laboratory Medicine, The Hospital for Sick Children, Toronto, Ontario, Canada; 6) Division of Neurosurgery, The Hospital for Sick Children, Toronto, Ontario, Canada; 7) Division of Neurology, The Hospital for Sick Children, Toronto, Ontario, Canada; 8) Division of Pathology, The Hospital for Sick Children, Toronto, Ontario, Canada; 9) Department of Molecular Genetics, University of Toronto, Toronto, Ontario, Canada; 10) McLaughlin Centre, University of Toronto, Toronto, Ontario, Canada.

Syntaxin-binding protein 1 (STXBP1) mutations have been reported across a spectrum of neurodevelopmental disorders, including Otahara syndrome and other epileptic encephalopathies. In order to delineate the phenotypic complexity of cases, it is necessary to analyze the STXBP1 mutation with consideration for the sequence context. Here, we report the first case of a successfully treated epilepsy surgery patient with a heterozygous STXBP1 germline mutation that was mosaic within a surgically resected area populated with dysplastic cells. Patients undergoing resective epilepsy surgery for refractory focal epilepsy that was associated with suspected cortical dysplasia were recruited prospectively for genetic study. For the current patient, a targeted sequencing approach was applied to identify rare pathogenic mutations. DNA from peripheral blood was collected from the nuclear family. DNA was also collected from resected left lateral temporal cortex tissue with dysplastic neurons. We applied droplet digital PCR (ddPCR) technology to validate the copy number variation (CNVs). We have identified a *de novo* 4.9Kb deletion impacting exon 3-4 of the STXBP1 gene in a 6-year old proband (male) diagnosed with refractory focal-onset epilepsy with initial infantile spasms, global developmental disorder, autism spectrum disorder and MRI imaging suspicious for focal cortical dysplasia type 1 in the left anterior temporal cortex. The patient underwent left anterior temporal lesionectomy including mesial structures. Surgical pathology demonstrated nodular heterotopias in the superior temporal gyrus and deep temporal white matter with collections of cells with small round nuclei and clear cytoplasm. Hippocampus, para-hippocampal gyrus and lateral temporal cortex were normal. The ddPCR result revealed heterozygous state of the deletion in blood, whereas, evidence of the mosaic presence of heterozygous and homozygous deletions was observed within the dysplastic tissue cell population of the proband. The patient has been seizure free since surgery. We report a novel *de novo* mutation within STXBP1 in a patient with a complex neurodevelopmental phenotype and focal epilepsy with areas of dysplastic neurons. This is the first case of STXBP1 showing formation of mosaic copy number variations within dysplastic brain cells. These findings suggest a role for STXBP1 in malformations of cortical development and a role for epilepsy surgery in the management of STXBP1-associated epilepsy.

1457T

TROVE2 alleles are linked to aversive memory: A whole exome sequencing study in phenotypic extremes. *A. Heck[1,2], A. Milnik[1,2], V. Vukojevic[1,3], J. Petrovska[1], T. Egli[1], J. Singer[4], P. Escobar[5], T. Sengstag[5], D. Coynel[6], V. Freytag[1], P. Demougin[3], E. Loos[6], F. Hartmann[1], N. Schicktanz[6], C. Vogler[1,2], C. Beisel[7], N. Beerenwinkel[4], D. de Quervain[2,3], A. Papassotiropoulos[1,2,3].* 1) University of Basel, Department of Psychology, Division of Molecular Neuroscience, Basel, Switzerland; 2) University of Basel, Psychiatric University Clinics, Basel, Switzerland; 3) University of Basel, Department Biozentrum, Life Sciences Training Facility, Basel, Switzerland; 4) ETH Zurich, Department of Biosystems .Science and Engineering, Basel, Switzerland; 5) University of Basel, sciCORE Center for Scientific Computing, Basel, Switzerland; 6) University of Basel, Department of Psychology, Division of Cognitive Neuroscience, Basel, Switzerland; 7) ETH Zurich, Quantitive Genomics Facility, Basel, Switzerland.

Over the last decade, whole exome sequencing (WES) has become a standard approach for the identification of rare variants implicated in monogenetic disease. However, also for complex traits, WES gained popularity in the last years[1,2]. By sequencing only individuals at the extreme ends of an empiric phenotypic distribution, WES offers a cost-effective still statistically powerful method, based on the assumption that rare alleles are enriched in the extreme end of the distribution. We followed this approach and sequenced 94 individuals with extremes in aversive memory performance. WES was performed using the SureSelectXT Human All Exon V5+UTR kit (Agilent) on an Illumina HiSeq 2500 machine. After alignment (BWA) and de-dupping (Picard), further preprocessing was done with GATK. The mean sample coverage was 111X, with 94% of the target regions having a coverage equal or greater than 30X. Aversive memory was initially tested in 2'739 healthy young individuals with European background with a picture-based memory test. After matching for sex, age, smoking and genetic background, 47 pairs (i.e. 47 high and 47 low performers) were sequenced. We performed burden tests with PlinkSeq and restricted our analysis to variants showing a minor allele frequency < 0.125 in the population of phenotypic extremes. We identified one Bonferroni-corrected association between *TROVE2* and aversive memory performance (p=2.0E-6). One SNP, rs72740218, drives the association, with 10 minor allele carriers in the high-performer group versus 2 minor-allele carriers in the low-performer group. This association could be validated in an independent sample (n=2'590). In an fMRI study in a subsample of probands (n=1'258) the minor allele of SNP rs727403218 was positively correlated with brain activation in the frontal cortex (t=5.4, P_{FWE}=0.0015) during the encoding of aversive pictures. Next, we analyzed the public available data of the BRAINEAC project. In these data, SNP rs727403218 SNP was associated with expression of *TROVE2* transcript 2372955 in post-mortem frontal cortex (p=0.005). By combining WES with an extreme phenotype approach, we provide first evidence that *TROVE2* plays a role in aversive memory performance. The allelic architecture of complex traits is likely to be underlined by multiple common and rare variants. Large-scale consortia GWAS meta-analyses have successfully been applied in the search for common variants affecting the risk of developing psychiatric disorders, in particular schizophrenia. However, these studies are designed to examining only "the common variant" proportion of the genomic landscape, while next-generation-sequencing allows direct examination of both common and rare alleles. Schizophrenia is one of the most disabling mental disorders. It has a lifetime prevalence of around 1 % and a heritability estimated as high as 80%. Although around one third of the heritability can be attributed to common variants, it is likely that rare variants also contribute substantially to the etiology. A collaboration between iPSYCH (The Lundbeck Initiative for Integrative Psychiatric Research, Denmark) and the Broad Institute, Boston, has been established to perform large scale exome sequencing of major psychiatric disorders, including schizophrenia. The DNA is extracted from blood samples existing in the Danish Neonatal Screening Biobank, which has collected dried blood spots (DBS) for every child born in Denmark since 1981. The samples available (totaling more than 2.2 million) can be matched to a wide range of phenotypic information available in Danish registries, thus empowering the analysis of genetic data with a wealth of data from medical history as well as social and cultural environment. We present here an analysis of a large collection of schizophrenia individuals recruited in clinical centers (1,686) and from DBS samples (3,545): a total of 5,231 cases and 7,258 controls from Denmark. We follow-up in a similarly sized sample from Sweden; a related Scandinavian population. The combined analysis represents the largest exome sequencing study in schizophrenia to date. In a preliminary data freeze consisting of 3,200 exomes, we have found evidence suggesting a higher per-person rate of ultra-rare loss-of-function variants located in constrained genes among schizophrenia cases compared to controls. Likewise in the full data set, particular focus is devoted to the analysis of the polygenic burden of rare and ultra-rare variation. The results from burden and enrichment analysis, as well as ranking of mutational load, will be discussed in the larger perspective of findings from GWAS, and other exome analyses in schizophrenia.

1459W

The use and abuse of alcohol and nicotine has a significant impact on public health. Twin and family studies show that these behaviors have a significant genetic component. Genetic association studies have discovered common variants associated with alcohol and nicotine. The exome chip portion of the GWAS & Sequencing Consortium of Alcohol and Nicotine Use (GSCAN) was formed to examine the association between rare nonsynonymous variants and alcohol and nicotine use, by aggregating and meta-analyzing studies using exome sequencing or genotyping arrays with substantial rare exonic content. Recently, we have added the UK Biobank cohort. The UK Biobank has collected genetic and phenotypic data from 500,000 volunteers in the United Kingdom. 92% of the sample was genotyped on a custom platform, the UK Biobank Axiom array, which contains 111,162 rare nonsynonymous variants and 280,838 additional rare variants. The remainder were genotyped on the UK BiLEVE array which has a high degree of marker overlap with the Axiom array. Genetic data from 150,000 individuals is currently available with the remainder expected by the end of 2016. We performed extensive quality control and phenotype standardization, followed by rare variant association analyses, separately in the BiLEVE and Axiom subsamples, for five phenotypes: smoking initiation (total N=112,811), cigarettes per day (total N=40,882), age of initation of smoking (total N=41,634), pack years (total N=40,624), and drinks per week (total N=90,213). Genome-wide significant rare variant associations were found in the classic *CYP2A6* locus for cigarettes per day and in the alcohol metabolism genes *ADH1B* and *ADH1C*. A meta-analysis was then performed between BiLEVE and Axiom. Although these data are not available at this time, results will be presented from a meta-analysis of the UK Biobank sample with the other samples in the GSCAN exome chip consortium, adding approximately 100,000 individuals to our analysis and including both single variant and gene based tests.

1460T

Conduct disorder GWAS and extension to corticolimbic function. *C.E. Carey[1], N. Vakkalagadda[1], A. Agrawal[2], E. Drabant Conley[3], A.R. Hariri[4], E.C. Nelson[2], R. Bogdan[1].* 1) Psychological and Brain Sciences, Washington University in St. Louis, St. Louis, MO; 2) Psychiatry, Washington University School of Medicine, St. Louis, MO; 3) 23andMe, Mountain View, CA; 4) Psychology and Neuroscience, Duke University, Durham, NC.

Conduct disorder (CD), a heritable childhood psychiatric illness characterized by high levels of aggression and rule-violating behavior, is a strong predictor of violence in adulthood. However, little is known about the individual genetic variants conferring risk for CD, or the neural mechanisms that might mediate associations between genetic risk and antisocial behavior. To examine this, we performed a genomewide association of retrospectively reported CD in the Comorbidity and Trauma Study (n_{cases} = 680, $n_{controls}$ = 995), which yielded one genomewide significant hit: rs12536973 in an intergenic region on chromosome 7. We then probed the effects of this genetic risk on Self Report of Psychopathy Short Form (SRP-SF) scores and corticolimbic function during an emotional face-matching task among 404 non-Hispanic Caucasian young adult participants in the Duke Neurogenetics Study. rs12536973 genotype was associated with the SRP-SF Lifestyle subscale, but not with corticolimbic function. Genomewide polygenic risk scores predicted greater SRP-SF Antisocial scores, as well as decreased insula reactivity to emotional faces. These results provide insight into the neurogenetic underpinnings of CD and antisocial behavior and may, in the future, help to inspire interventions to prevent children with CD from committing violent acts as adults.

1461F

Genome-wide association study of the traits defining the three-factor model of post-traumatic stress disorder symptomology reveals novel risk variants. *R. Sherva[1], H.R. Kranzler[2], R.H. Pietrzak[3,8], L.A. Farrer[1,4,5,6,7], J. Gelernter[8,9,10,11].* 1) Biomedical Genetics Department, Boston University School of Medicine, Boston, MA; 2) Department of Psychiatry, Perelman School of Medicine of the University of Pennsylvania and VISN 4 MIRECC, Philadelphia VAMC, Philadelphia, PA; 3) Translational Psychiatric Epidemiology Laboratory, Clinical Neurosciences Division, U.S. Department of Veterans Affairs National Center for PTSD, New Haven, CT; 4) Department of Neurology, Boston University School of Medicine, Boston, MA; 5) Department of Ophthalmology, Boston University School of Medicine, Boston, MA; 6) Department of Biostatistics, Boston University School of Public Health, Boston, MA; 7) Department of Epidemiology, Boston University School of Public Health, Boston, MA; 8) Department of Psychiatry, Yale University School of Medicine, New Haven, CT; 9) VA Cooperative Studies Program Coordinating Center, West Haven, CT; 10) VA CT Healthcare Center, West Haven, CT; 11) Department of Neurobiology, Yale School of Medicine, New Haven, CT.

Posttraumatic stress disorder (PTSD) is a potentially serious psychiatric disorder that can develop after a traumatic event. Individuals vary in their susceptibility to PTSD following similar exposures, and in addition to demographic factors and other environmental risk factors, approximately 40% of the variability in risk is attributable to genetic risk factors. Several genome-wide association studies have been performed using PTSD diagnosis as a trait. The results have been mixed and inconsistently replicated. We performed a GWAS for each of three major domains of DSM-IV PTSD symptoms: 1) re-experiencing the event (defined as the sum of the number of symptoms related to experiencing intrusive thoughts, nightmares, flashbacks, and reactivity to reminders of the trauma); 2) avoidance and emotional numbing (the sum of symptoms of avoidance of stimuli associated with the trauma and anhedonia); and 3) hyperarousal (the sum of symptoms associated with anger, hypervigilance, exaggerated startle response, and sleep disruption). The sample included 2,561 trauma-exposed African Americans and European Americans recruited for studies of addiction, including 1,198 with DSM-IV PTSD diagnoses. We identified 3 novel regions with genome-wide significant SNP associations for the re-experiencing score, one for avoidance/numbing, and 7 for hyperarousal. The SNPs associated with re-experiencing symptoms were located in an overlapping pseudogene and antisense transcript (*RN7SKP83* and *AC105053.3*, respectively, p=4.78×10^{-8}), cilia and flagella associated protein 77 (*CFAP77*, p=3.67×10^{-8}), and an intergenic region between an antisense transcript and pancreatic ribonuclease *(RP11-219E7.1* and *RNASE1*, respectively, p=4.56×10^{-8}). The SNPs associated with avoidance/numbing symptoms were located between two processed pseudogenes (*RP11-550A9.1* and *RP11-448K10.1*, p=2.69×10^{-8}). The SNPs associated with hyperarousal include variants in *RP5-952N6.1*, *DNAJC13*, *ANXA3*, *GDPD4*, and *USP3*; between *snoU13* and *CTD-2037L6.2*; and a missense variant in *ZNF217*. Two of the signals are significant after correcting for testing three outcomes (*USP3*, p=9.16×10^{-9} and *ZNF217*, p=1.49×10^{-11}). These findings require replication but illustrate: 1) the utility of PTSD symptom cluster scores for genetic analysis; 2) hyperarousal symptoms may have the strongest genetic influence; and 3) genetic risk factors for PTSD symptomology may be a combination of coding and regulatory variants in poorly understood pathways.

1462W

Genetic influences on normative and problematic alcohol use in a population-based sample of college students. *B.T. Webb[1,2], A.E. Edwards[1,2], A.R Woolen[4], J.E. Salvatore[1,5], F. Aliev[6,7], B.P. Riley[1,2,3], C. Sun[1,2], V.S. Williamson[1], J.N. Kitchens[1], K. Pedersen[2], A. Adkins[5,8], M.E. Cooke[1], J.E. Savage[1], Z. Neale[5], S.B. Cho[6], D.M. Dick[3,5,6,7], K.S. Kendler[1,2].* 1) Virginia Institute for Psychiatric and Behavioral Genetics, Virginia Commonwealth University, Richmond, VA, US; 2) Department of Psychiatry, Virginia Commonwealth University, Richmond, VA, US; 3) Department of Human and Molecular Genetics, Virginia Commonwealth University, Richmond, VA, US; 4) Center for Biomarker Research and Precision Medicine, Virginia Commonwealth University, Richmond, VA, US; 5) Department of Psychology, Virginia Commonwealth University, Richmond, VA, US; 6) Department of African-American Studies, Virginia Commonwealth University, Richmond, VA, US; 7) Faculty of Business, Karabuk University, Turkey; 8) College Behavioral and Emotional Health Institute, Virginia Commonwealth University, Richmond, VA, US.

Background: Genetic factors impact alcohol use behaviors and these factors may become increasingly evident during emerging adulthood. Examination of the effects of individual variants as well as aggregate genetic variation can clarify mechanisms underlying risk. Methods: We conducted genome-wide association studies (GWAS) in an ethnically diverse sample of college students for three quantitative outcomes including typical monthly alcohol consumption, alcohol problems, and maximum number of drinks in 24 hours. While these outcomes are moderately heritable in older adults, their heritability is known to change with age. Therefore, heritability based on common genetic variants (h^2_{SNP}) was assessed for this age group. We also evaluated whether risk variants in aggregate were associated with alcohol use outcomes in an independent sample. Results: Two genome-wide significant markers were observed: rs11201929 in *GRID1* for maximum drinks in 24 hours, with supportive evidence across all ancestry groups; and rs73317305 in *SAMD12* (alcohol problems), tested only in the African ancestry group. The h^2_{SNP} estimate was 0.19 (SE=0.11) for consumption, and was non-significant for other outcomes. Genome-wide polygenic scores were significantly associated with alcohol outcomes in an independent sample. Conclusions: These results robustly identify genetic risk for alcohol use outcomes at the variant level and in aggregate. We confirm prior evidence that genetic variation in *GRID1* impacts alcohol use, and identify novel loci of interest for multiple alcohol outcomes in emerging adults. These findings indicate that genetic variation influencing normative and problematic alcohol use is, to some extent, convergent across ancestry groups, and is relevant though modest during emerging adulthood. Studying college populations represents a promising avenue by which to obtain large, diverse samples for gene identification.

1463T

Anorexia nervosa genetic risk score. *Z. Yilmaz[1], S.C. Zerwas[1], L.M. Thornton[1], J. Euesden[2], L.E. Duncan[3], N. Micali[4], L. Huckins[4], J.H. Baker[1], M.A. Munn-Chernoff[1], J.J. Crowley[5], PGC Anorexia Nervosa Working Group[6], E. Zeggini[7], P.F. Sullivan[1,5,8], G. Breen[9], C.M. Bulik[1,8,10].* 1) Department of Psychiatry, University of North Carolina, Chapel Hill, NC; 2) Social Genetic & Developmental Psychiatry, King's College London, London, United Kingdom; 3) Department of Psychiatry, Stanford University, Palo Alto, CA; 4) Department of Psychiatry, Icahn School of Medicine at Mount Sinai, New York, NY; 5) Department of Genetics, University of North Carolina, Chapel Hill, NC; 6) Psychiatric Genomics Consortium; 7) Wellcome Trust Sanger Institute, Hinxton, United Kingdom; 8) Department of Medical Epidemiology and Biostatistics, Karolinska Institutet, Stockholm, Sweden; 9) Institute of Psychiatry, King's College London, London, United Kingdom; 10) Department of Nutrition, University of North Carolina, Chapel Hill, NC.

Anorexia nervosa (AN) is a serious eating disorder which is heritable (~50-60%) and has the highest mortality rate of any psychiatric disorder. As genetic research on AN progresses, investigating the effects of a genetic risk score (GRS)—calculated as the weighted sum of common genetic risk variants per individual—on developmental and clinical characteristics is a logical next step. Thus, we calculated GRS in a discovery dataset of 2,464 female AN cases and 7,355 female controls from the Genetic Consortium for Anorexia Nervosa (GCAN)/Wellcome Trust Case Control Consortium 3 (WTCCC3). The resulting AN GRS was then applied to a target dataset of 1,031 AN cases from the Price Foundation/Children's Hospital study and 3,627 pediatric controls recruited by Children's Hospital of Philadelphia. GRS was calculated using PRSice (http://prsice.info), with case-control significant principal components as covariates. The best-fit p-value threshold was determined to be 0.1384, and the AN GRS set at this threshold included 30,005 SNPs. The GRS model fit (Nagelkerke's R^2) from a logistic regression of AN case/control status was significant (p = 2.9 x 10^{-8}), and individuals with AN GRS in the highest decile had a significantly higher risk of AN compared to the individuals with AN GRS in the lowest decile (OR=2.1; 95% CI 1.6, 2.9). These results provide evidence for polygenicity in the etiology of AN and suggest that AN GRS has the potential to be an important tool in the development of multi-factorial risk prediction models in the future. However, larger samples with greater statistical power are required to increase the utility of AN GRS in contributing to the prediction of risk or illness course. As the Anorexia Nervosa Working Group of the Psychiatric Genomics Consortium adds a significant number of genotyped samples over the next two years (~20,000), AN GRS will become more robust and its utility will increase.

1464F

Postmortem transcriptomic profiling of three psychiatric disorders reveals widespread dysregulation of cell-type associated transcripts and novel disease-related transcription changes. *B.N. Lasseigne[1], K.M. Bowling[1], R.C. Ramaker[1,2], M.H. Hagenauer[3], N.S. Davis[1], J. Gertz[1], P.M. Cartagena[4], D.M. Walsh[4], M.P. Vawter[4], A.F. Schatzberg[5], J.D. Barchas[6], S.J. Watson[3], B.G. Bunney[4], H. Akil[3], W.E. Bunney[4], J.Z. Li[7], S.J. Cooper[1], R.M. Myers[1]. 1) HudsonAlpha Institute for Biotechnology, Huntsville, AL; 2) Department of Genetics, The University of Alabama at Birmingham, Birmingham, AL; 3) Mental Health Research Institute, University of Michigan, Ann Arbor, MI; 4) Department of Psychiatry and Human Behavior, College of Medicine, University of California, Irvine, Irvine, Ca; 5) Department of Psychiatry, Stanford University School of Medicine, Stanford, CA; 6) Psychiatry, Weill Cornell Medical College, New York, NY; 7) Department of Human Genetics, University of Michigan, Ann Arbor, MI.*

Psychiatric disorders are multigenic diseases with complex etiology contributing significantly to human morbidity and mortality. We compared molecular signatures across brain regions and disorders in the transcriptomes of postmortem human brain samples (Pritzker Neuropsychiatric Disorders Research Consortium). RNA sequencing was performed on tissue from the anterior cingulate cortex, dorsolateral prefrontal cortex, and nucleus accumbens from three groups of 24 patients each diagnosed with schizophrenia, bipolar disorder, or major depressive disorder, and from 24 control subjects. We validated 129 gene expression changes (FDR<0.05) with an independent cohort provided by the Stanley Neuropathology Consortium Integrative Database Array Collection. The most significant disease differences were observed in the anterior cingulate cortex of schizophrenia samples compared to controls and biochemical consequences of gene expression changes were assessed with untargeted metabolomic profiling. We also detected significant heterogeneity within schizophrenia and bipolar disorder samples with a subset of patients exhibiting gene expression profiles significantly different from both the larger subset of schizophrenia and bipolar disorder patients and from the major depressive disorder and control cohorts. We find no evidence this disease heterogeneity is linked to any known clinical phenotypes or technical variables, however virtual microdissection reveals high correlation with transcripts previously identified as specific to astrocyte- (p-value = 6.90x10-04) and endothelial-specific expression (p-value = 4.99x10-07), but depleted of neuron-specific expression (p-value = 3.77x10-09). We identify *NPAS4*, *IGKC*, and *IGHG1* as a refined list of putative cell-type independent transcripts associated with psychiatric disease. Chromatin immunopreciptation with massively parallel DNA sequencing of NPAS4 in human neuronal cell lines demonstrates enriched binding near GWAS-implicated psychiatric disorder associated genes (p-value = 6.66x10-16). Furthermore, knockdown of *NPAS4* resulted in reduced expression of a subset of those genes (*ABCB9*, *CHRNA3*, and *NDUFA6*), indicating cis-regulation by NPAS4. Here we provide a set of high confidence, independently validated genes differentially expressed between schizophrenia and control patients and propose a refined list of putative cell-type independent transcripts that may particularly warrant further investigation.

1465W

CNV deletions may affect schizophrenia risks through lncRNA genes that regulate protein-coding genes. *C. Liu[1,2], Q. Meng[2], K. Wang[2], Y. Xia[2], C. Jiao[2], C. Chen[2]. 1) Dept Psychiatry, Univ Illinois, Chicago, Chicago, IL., USA; 2) The State Key Laboratory of Medical Genetics, Central South University, Changsha, Hunan, China.*

Schizophrenia is a complex psychiatric disorder with strong genetic background. Studies demonstrated that rare copy number variations (CNVs) contribute to the risk of schizophrenia. However, the exact mechanisms remain unclear. More attention has been put to protein-coding genes residing in those CNVs. In this study, we explored the potential roles of long non-coding RNAs (lncRNAs) inside CNV deletions (CNV-lncRNAs) in schizophrenia risk. We retrieved lncRNAs mapped to the CNV deletion regions known to increase risks of developing schizophrenia. Seven such regions were repeatedly reported by large case-control studies, including 1q21.1, 3q29, 15q11.2, 15q13.3, 17p12, 17q12, and 22q11.2. We carried out weighted gene co-expression network analysis (WGCNA) using RNA-seq data from Genotype-Tissue Expression (GTEx) and BrainSpan projects to look for coexpression modules that harbor CNV-lncRNAs. We identified one male reproduction-related module in male individuals, one neuronal functions-related module both in male and female individuals. Protein-coding genes inside the neuronal functions enriched modules involved several ion channel activities including calcium and potassium channel activities, which were known to be related to schizophrenia. Pathway analysis of these two modules further suggested that CNV-lncRNAs involved in the olfactory transduction, neuroactive ligand-receptor and calcium signaling pathways. The CNV-lncRNA co-expression patterns were preserved through the different development and aging time points, and across different tissue types of human body. Our results suggest that lncRNAs inside those rare CNVs may play significant temporal and spatial roles in regulating other protein-coding genes, and subsequently contribute to schizophrenia risk. Future studies of those CNVs should pay more attention to the regulatory cascades instead of the few protein-coding genes inside them to fully appreciate the impact of those CNVs.

1466T

Exploring association of the mitochondrial genome with antipsychotic-induced weight gain. *K. Mittal[1,2], V. Goncalves[1,2], A.K. Tiwari[1,2], D.J. Mueller[1,2], M.P. Vawter[3], J.L. Kennedy[1,2].* 1) Campbell Family Mental Health Research Institute, Centre for Addiction and Mental Health, Toronto, Ontario, Canada; 2) Department of Psychiatry, University of Toronto, ON, Canada; 3) Functional Genomics Laboratory, Department of Psychiatry and Human Behavior, University of California, Irvine, CA, USA.

Schizophrenia (SCZ) is a complex disorder characterized by psychosis with a lifetime prevalence of 0.4-1.0 %, and is ranked among top 10 causes of disability among people in developed countries. Antipsychotic medication treatment of schizophrenia often results in excessive weight gain, which can then lead to diabetes and cardiovascular diseases. Mitochondria play a vital role in brain metabolism since they are the main source of aerobic energy for cellular functioning. There is increasing evidence that antipsychotics such as clozapine and olanzapine modulate mitochondrial function, for example, by inhibiting activity of the oxidative phosphorylation pathway and altering its physiology. This study assessed the role of mitochondrial DNA (mtDNA) variants in conferring risk for Anti-Psychotic Induced Weight Gain (AIWG) in Schizophrenia patients. We analyzed 101 individuals from the Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE). Only individuals of European ancestry were used for association analysis. The mitochondrial genome was sequenced in these samples and association analysis was conducted to assess 161 common variants and 502 rare variants. We analyzed coding region (577-16023 bp) as well as the control region (16024-576 bp) SNPs. The sequencing protocol was validated to work reliably on mtDNA, capturing all types of variation present in the mitochondrial genome, including common SNPs, small insertions/deletions, and heteroplasmy. The sequencing coverage was $\geq$500x average with >98% confidence in variant calling. Association between each common mitochondrial SNP and AIWG was tested using linear regression assuming an additive model and using treatment duration as covariate. We found nominal significance (p<0.05) for six mitochondrial SNPs, one in CO1 gene, one in ND3, and four in the mtDNA control region with anti-psychotic induced weight gain. The significance did not change after inclusion in the model of treatment duration as a covariate. The rare variants were analyzed using the SKAT protocol. No significant association with rare SNPs was detected. To our knowledge, this is the first study to address the role of mtDNA in anti-psychotic induced weight gain. Analysis in a larger sample is required and will allow a better understanding of the role of mitochondria in anti-psychotic induced weight gain.

1467F

Increased mitochondrial content in schizophrenia and functional implications. *L. Olde Loohuis[1], A. Ori[1], T. Wu[1], R. Kahn[2], R. Ophoff[1,3].* 1) Center for Neurobehavioral Genetics, University California Los Angeles, Los Angeles, CA; 2) 2)Department of Psychiatry, Rudolf Magnus Institute of Neuroscience, University Medical Centre Utrecht, The Netherlands; 3) 3)Department of Human Genetics, David Geffen School of Medicine, University of California Los Angeles, California, USA.

Changes in the amount of mitochondrial DNA (mtDNA) have been linked to stress and inflammation, and increased levels of mtDNA have, among others, been reported in patients with major depressive disorder. While mitochondrial dysfunction has been suggested to play a role in the pathophysiology of schizophrenia, it is unknown whether patients also have increased mtDNA content. Here, we aim to test this hypothesis, and relate mtDNA content to transcriptome-wide expression patterns. Using whole exome sequencing (WES) data from whole blood of 96 cases and 96 matched controls, we quantify relative mtDNA content using the ratio of reads mapping to the mitochondrial reference genome and autosomal reads. In addition, we quantify mtDNA content in a (partially overlapping) sample of 96 cases and 96 controls using multiplex RT-qPCR. We observe a highly robust and significant increase in mtDNA content in cases (42% increase, P=5.7e-09, t-test on residuals). This difference is independent of age and gender and not due to technical artifacts. Using RT-qPCR, we measure a similar increase (P=1.8e-15), and observe a strong correlation between the two measurements in the overlapping sample of mainly controls (r2=0.43, P=2.5e7, n=48 controls, 7 cases), thus both validating and replicating this result. mtDNA content does not correlate with cell-type proportions as estimated from methylation data (n=52). Preliminary gene expression analysis using RNA sequencing (RNAseq) of the discovery sample shows that mtDNA levels do not correlate with increased expression of the any gene on the mitochondrial genome. However, expression of several autosomal genes is associated with mtDNA content, including MTND1P23 (β=0.06, P=3.3e-39) and IGLV7-43 (β=0.05, P=4.1e-12). We are the first to show blood-derived increased levels of mtDNA in schizophrenia, and are able to relate this finding to gene expression differences using RNAseq. The strong correlation between the two quantification methods (based on WES and RT-qPCR) highlights the value of WES to study mtDNA content across groups. The absence of a direct link between mitochondrial expression and mtDNA content is surprising, and may point to decreased functioning of the mitochondria. While we continue to explore the functional underpinnings of mtDNA content at the transcription level, to gain insight in the relation between mtDNA content and disease, we also study connections with genetic risk, disease severity and medication use.

1468W

Identifying functionally relevant mental health hotspots and polymorphisms in African Americans. *C. Cross[1], L. Jackson[2], M. Shestov[3].* 1) Anatomy Dept, College of Medicine, Howard University, Washington DC; 2) National Human Genome Center, College of Medicine, Washington DC; 3) Biomedical Engineering, Sciences and Health System, Drexel University, Philadelphia, PA.

   BACKGROUND: African Americans are 20 percent more likely to report serious psychological distress than European Americans. Recent work by our group suggests that genes sitting at the intersection of addiction and mental health form genomic hotspots that are functionally cohesive with drugable targets. This lead us to question how the mental health genes underlying schizophrenia, bipolar disorder, post-traumatic stress disorder, and depression form functional hotspots in the genome, whether they have unique allele frequencies in African ancestry populations, and whether those hotspots had drugable targets.   **METHODS:** Mental health associated gene sets were obtained from NCBI Gene and were projected onto gene ontology categories and cellular pathways to draw a bioinformatics portrayal of mental health disorders. Single nucleotide polymorphism datasets (HapMap, Human Genome Diversity Panel) were used identify sequence variants that were significantly different in African Americans from other populations. Finally we annotated the drug binding sites lying in each hotspot to predict the effects of these drugs on human populations.   **RESULTS:** Mapping addiction genes onto human genome resulted in eight gene clusters, with at least 20 mental health genes (Range: 21-46 genes/ hotspot) in a 4Mb distance along DNA. Hotspot genes were involved in neurological transmission, responses to organic substances, and cell-cell signaling. Analysis of hotspot drug binding sites show that mental health has a treatment overlaps with the functional annotations   **CONCLUSION:** This approach identified 10 key putative variants for mental health in individuals of African Ancestry, found functionally cohesive hotspots. Drugable targets annotation suggest that treatment could be better targeted (*in progress*).

1469T

Cascade TF-miRNA-mRNA regulations identified by co-expression network modules in brains of patients with schizophrenia and bipolar disorder. *C. Chen[1], L. Cheng[2], P. Gunaratne[3], C. Zhang[4], Q. Meng[1], Y. Xia[1], J. Badner[5], E. Gershon[6], C. Liu[1,2], The PsychENCODE Consortium.* 1) State Key Laboratory of Medical Genetics, Central South University, Changsha, Hunan, China; 2) Psychiatry Department, University of Illinois at Chicago, Chicago, IL, USA; 3) Biology and Biochemistry Department, University of Houston, Houston, TX, USA; 4) Center for Research Informatics, The University of Chicago, Chicago, IL, USA; 5) Department of Psychiatry, Rush University Medical Center, Chicago, IL, USA; 6) Department of Psychiatry and Behavioral Neuroscience, The University of Chicago, Chicago, IL, USA.

   Schizophrenia and bipolar disorder are complex mental disorders, with risks contributed by multiple genes. Recently, genome-wide systemic approaches have been used to reveal the associations of hundreds of SNPs with those disorders. Disregulation of gene expression has been implied, but little is known about such regulation systems in the human brain. By integrating gene expression data of mRNA and microRNA (miRNA) obtained from the same brain collection of 51 cases and 24 controls using the weighted gene co-expression network analysis (WGCNA), we built mRNA-miRNA co-expression networks and detected modules differentially expressed between controls and patients of schizophrenia and bipolar disorder. In the disorder-associated modules, we identified the potential regulators, including transcription factors (TFs) and miRNAs, and their co-expressed protein-coding genes. In silico predicted binding relationships were used to validate the putative regulations suggested by co-expression patterns. Using SNP genotype data, we resolved some causal relationships among the regulators and their targets. We further validated the predicted regulations using RNA interference knockdown experimentally. We identified a module differentially expressed between cases and controls. This module contained five miRNAs and 501 mRNA genes. Six TFs also served as hub genes in these modules. The co-expression-suggested regulatory relationships were consistent with the binding relationships predicted by databases. Focusing on those regulations containing TFs and miRNAs, we resolved a regulation cascade from SNP variants (rs16853832) to TF (POU2F1) to miRNA (hsa-mir-320e) to target genes (NR2E1) and ultimately, to disease risks. This study showed that we can utilize multi-dimensional data to construct co-expression networks, which were enriched for regulatory relationships. Causal relationships can be resolved among SNPs, regulatory molecules and their downstream target genes through data integration. Novel genes and their corresponding regulations underlying the disease risks could be revealed.

1470F

Association of norepinephrine transporter gene (*SLC6A2*) variant with remission to venlafaxine in older adults with depression. *V. Marshe[1,2], M. Maciukiewicz[2], S. Rej[3], A.K. Arun K. Tiwari[2,4], E. Sibille[2,5], D. Blumberger[2,4], J. Karp[6,7], J.L. Kennedy[1,2,4], E.J. Lenze[8], B.H. Mulsant[1,2,4], C.F. Reynolds, III[6], D.J. Müller[1,2,4].* 1) Institute of Medical Science, Faculty of Medicine, University of Toronto, Toronto, Ontario, Canada; 2) Campbell Family Mental Health Institute, Centre for Addiction and Mental Health, Toronto, Ontario, Canada; 3) Department of Psychiatry, McGill University, Montreal, QC, Canada; 4) Department of Psychiatry, Faculty of Medicine, University of Toronto, Toronto, Ontario, Canada; 5) Department of Pharmacology, University of Toronto, Toronto, Ontario, Canada; 6) Department of Psychiatry, University of Pittsburgh, Pittsburgh, PA, USA; 7) Geriatric Research Education and Clinical Center, VA Pittsburgh Health System, Pittsburgh, PA, USA; 8) Healthy Mind Lab, Department of Psychiatry, Washington University, St. Louis, MO, USA.

   Background: Finding predictive biomarkers for antidepressant treatment response is imperative in the geriatric population to optimize response and minimize side effects. We investigated the putatively functional variant rs2242446/T-182C of the norepinephrine transporter (*SLC6A2*, *NET*) and 5-HTTLPR of the serotonin transporter (*SLC6A4*, *SERT*) in association with remission to the dual serotonin-norepinephrine reuptake inhibitor, venlafaxine. As an exploratory analysis, we also investigated 20 variants of other serotonergic system genes (*HTR1A*, *HTR2A*, *HTR1B*, *TPH1* and *TPH2*). **Methods:** Our sample comprised of 350 participants (≥60 years) assessing efficacy of venlafaxine treatment using a randomised, double-blind, placebo-controlled design. Participants diagnosed with major depression (MADRS≥15) were prospectively assessed for approximately 12 weeks. Associations with remission status (MADRS≤10) were conducted using multivariate binary logistic regression. We conducted mixed-models analysis for response trajectories as well as investigated time-to remission using Kaplan-Meier survival and log rank (Mantel-Cox) analyses. **Results:** The *NET* variant rs2242446, but not the *SERT* 5-HTTLPR, was significantly associated with remission after adjusting for covariates and correcting for number of tests (OR=1.68, *95% C.I.* [1.15, 2.45], p=0.007). Individuals with the C/C genotype (73.1% remitters) were more likely to remit than those with either the C/T (51.5%) or T/T genotypes (48.3%). Mixed-models analysis also revealed a significant difference in response trajectories across eight time-points (χ^2=10.47, p=0.005). Individuals with the C/C genotype reached remission faster (M=8.13±4.63 weeks) than those with the C/T (M=9.98±3.90 weeks) or T/T (M=10.25±4.34 weeks) genotypes (Mantel Cox, χ^2=7.88, p=0.019). **Conclusion:** Our findings suggest that *NET* rs2242446/T-182C mediates response to venlafaxine in late-life depression.

1471W

Association of *HTR1B* genetic polymorphisms with alcohol dependence, using the Alcohol Use Disorders Identification Test (AUDIT). *J. Kim[1], I. Choi[2], H. Shin[1,3].* 1) Research Institute for Basic Science, Sogang University, Seoul, Seoul, South Korea; 2) Department of Neuropsychiatry, Hallym University Kangnam Sacred Heart Hospital, Seoul, South Korea; 3) Department of Life Science, Sogang University, Seoul, South Korea.

   Several studies have suggested *5-hydroxytryptamine (serotonin) receptor 1B* (*HTR1B*) as a risk gene for alcohol use disorders. In addition, the serotonergic pathway has been considered as a modulator that plays an important role in numerous neuropsychiatric disorders including alcohol and drug dependence. To investigate the association between *HTR1B* genetic polymorphisms and alcohol dependence based on The Alcohol Use Disorders Identification Test (AUDIT) as a reliable and widely used screening scale, we genotyped a total of 7 common single nucleotide polymorphisms (SNPs) in 459 alcoholic patients and 455 nonalcoholic controls. Although *HTR1B* polymorphisms showed nominal associations with alcohol dependence based on DSM-IV in the case–control study, further linear regression analyses based on the AUDIT scores showed relatively significant associations between *HTR1B* polymorphisms and haplotype with alcohol dependence (minimum *P* = 0.006). Despite the needs for replications in other populations and further functional evaluations, our replication study suggests that *HTR1B* polymorphisms might be associated with alcohol dependence.

Integrating gene expression, GWAS, and eQTL results in schizophrenia.
C. Armoskus, V. Spitsyna, T. Souaiaia, C. Walker, J. Nguyen, A. Camarena, J. Herstein, K. Wang, J.A. Knowles, O.V. Evgrafov. Zilkha Neurogenetic Institute, USC, Los Angeles, CA.

   Genome-Wide Association Studies (GWAS) on schizophrenia (SCZ) have been successful in identifying over 100 regions containing variants believed to be associated with the disorder. However, given that most of the variants identified are non-coding and many loci are in intergenic regions, the mechanism connecting genomic variation to disease risk is not immediately clear. One hypothesis is that genetic differences result in differences in gene expression that then increase or decrease risk of developing SCZ. To identify such expression Quantitative Trait Loci (eQTLs) we collected gene expression data from cultured neural progenitor cells derived from olfactory neuroepithelium (CNON) from 91 patients with SCZ as well as 99 controls by RNA-Seq. Genotype data was also gathered on the patients. Comparison of CNON gene expression data to that provided by the GTEx project confirmed that CNON cultures show the closest matches to brain tissue, of the various tissues examined, and comparison to Brainspan data shows the cells are most similar to fetal brain, rather than child/adult brain tissue. Using identified eQTLs, we looked for cases where a GWAS risk variant is connected to a gene differentially expressed in SZ (DE).   SHAPEIT and Impute2 were used to impute genotyping against the 1000G reference panel. Associations between genetic variants and DESeq2-normalized gene expression were analyzed by Matrix-EQTL, which identified 4,847 cis-eQTLs (max 1 Mb between gene and variant) matching 1,224 genes, as well as 4,316 trans-eQTLs matching 1,064 genes. In total 11% of genes expressed in these samples had at least 1 eQTL identified for them. Of the 1,224 genes with cis-eQTLs, 6 had SNVs that showed significant association in the PGC SCZ GWAS, including *AS3MT*, *ITIH4*, and *SRR*, which have previous reports implicating them in SCZ pathology. 14 genes out of 121 found to be differentially expressed between SCZ and control (DE) were found to have associated eQTLs. The most significant eQTL SNV for a DE gene in the GWAS results was rs62227018 regulating *EFCAB6* which has a p-value of 0.005 for association with SCZ. Using GTEx eQTL data, we can find connections of greater significance. For example, *PRSS16* was found to be and to be connected by cis-eQTL to a nearby indel (rs201260192; raw p = 2.6e-11) which shows significant association with SCZ (raw p = 4.2e-10). In conclusion, using eQTL data allows us to bridge the gap between variants identified by GWAS and the effected genes.

1473F

Whole genome sequencing of multiply-affected schizophrenia and bipolar disorder families from the Azores and Madeira. *T.B. Bigdeli[1], S.A. Bacanu[1], K.S. Benke[2], B.S. Maher[2], J.A. Knowles[3], S. McCarroll[4], M. Pato[5], C.N. Pato[5], A.H. Fanous[6].* 1) Virginia Inst Psychiatric & Behavioral Gen, VCU, Richmond, VA; 2) Dept of Mental Health, Johns Hopkins University, Baltimore, MD; 3) Keck School of Medicine, University of Southern California, Los Angeles, CA; 4) Department of Genetics, Harvard Medical School, Cambridge, MA; 5) Department of Psychiatry, SUNY Downstate Medical Center, Brooklyn, New York; 6) Mental Health Service Line, Washington VA Medical Center.

   Schizophrenia (SZ) and bipolar disorder (BP) are debilitating neuropsychiatric disorders, each affecting 0.5-1% of the world's population, and for which a shared polygenic liability has been demonstrated. Here, we consider recent progress in an ongoing, whole genome sequencing (WGS) study of multiply affected SZ and BP families from the Portuguese archipelagos of the Azores and Madeira. Using the Illumina HiSeq2000 platform, we obtained deep, WGS data (~30X) for 51 SCZ and 39 BP cases, and 72 unaffected relatives from 40 families; an additional 16 relatives meeting criteria for some other psychiatric diagnosis (e.g., major depression or alcoholism) and 7 of unknown phenotype; and 30 unrelated ethnically-matched controls.   Using a basic prioritization strategy for filtering putatively functional SNPs and INDELs, based on population frequency and sharing between affected relatives, we identified a disruptive INDEL in *SERPINA1* carried by affected members of 10 families, and a disruptive INDEL in *PCDHGA9* shared between all affected relatives in a pedigree which contributed substantially to a published linkage finding at 5q31-34. Individual burden scores of rare disruptive variants are markedly greater among affected subjects (*P*= 0.00076), as well as their unaffected relatives (*P*=.00034), recapitulating the pattern of results observed for common polygenic risk scores constructed from PGC2 results, for which the comparisons of affected and unaffected relatives to controls were also significant (*P*=0.01 and *P*=0.02, respectively). Next, we compared lists of genes carrying family-specific variants shared among affected relatives to curated, etiologically relevant gene-sets. Following correction for multiple tests, we observed a significant overlap of genes carrying disruptive or non-synonymous variants in the PIC with genes enriched for *de novo* non-synonymous variants (*P*=5.9E-5), associated SCZ GWAS intervals (*P*=3.48E-4), and human post-synaptic density genes (*P*=9.14E-4)**.** Genes with disruptive or non-synonymous variants also exhibited significant overlap with *de novo* findings for autism and intellectual disability, autism PPI networks, and FMRP targets. Ongoing analyses include prioritization of variants leveraged by observed population structure of these geographically isolated island populations, and attempted replication of prioritized variants an independent sample of 220 SZ cases and 185 controls from the Genomic Psychiatry Cohort (GPC).

1474W

Targeted sequencing of *FKBP5* in suicide attempters with bipolar disorder. *M. Breen[1], E. Monson[1], S. Gaynor[1], K. de Klerk[1], M. Parsons[1], T. Braun[2,3], A. DeLuca[2], P. Zandi[4], J. Potash[1], V. Willour[1].* 1) Dept. of Psychiatry, University of Iowa, Iowa City, IA; 2) Dept. of Ophthalmology and Visual Sciences, University of Iowa Carver College of Medicine, Iowa City, IA; 3) Dept. of Biomedical Engineering, University of Iowa College of Engineering, Iowa City, IA; 4) Dept. of Mental Health, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD.

Background: FK506 Binding Protein 5 (FKBP5) is a critical component of the Hypothalamic-Pituitary-Adrenal (HPA) axis, a system which regulates our response to stress. FKBP5 forms part of a complex of chaperones, which inhibits binding of cortisol and glucocorticoid receptor translocation to the nucleus. Variations in both the HPA axis and *FKBP5* have been associated with suicidal behavior. **Methods:** We developed a systematic, targeted sequencing approach to investigate both coding and regulatory regions in or near *FKBP5* in 476 bipolar disorder (BP) suicide attempters and 473 BP non-attempters. This allowed us to cover more functional areas of *FKBP5* and therefore interrogate the gene more fully than our previous genome-wide association study could. Following stringent quality control checks, we performed single variant, gene burden and haplotype tests on the resulting 481 common and rare variants. Secondary analyses were performed to investigate whether sex-specific variations in *FKBP5* increased the risk of attempted suicide. **Results:** One variant, rs141713011, remained statistically significant following correction for multiple testing (P-value=7.5 x 10^{-4}, Corrected P-value=0.038, Odds Ratio=6.65). The minor allele for this variant was present in 1.7% of attempters and 0.2% of non-attempters. Three female-specific and four male-specific variants of nominal significance were also identified (P<0.05). The gene burden and haplotype association tests did not produce any significant results (P≤0.05). **Conclusions:** This comprehensive study of common and rare variants in *FKBP5* is the first to employ a novel sequencing approach that focused on both regulatory and coding regions in relation to attempted suicide. One rare variant, residing in an intron and the 3' untranslated region of multiple *FKBP5* transcripts, remained significant following permutation testing. Further investigation is required in larger sample sets to fully elucidate its association with suicidal behavior.

Genetic architecture of mental disorders: A family study based on national register data. *A. Buil[1], C. Fan[2], D. Helenius[1], A. Rosengreen[1], W. Thompson[1], Y. Wang[1,3], C.B. Pedersen[4], P.B. Mortensen[4], T. Werge[1], IP-SYCH-BROAD Researchers.* 1) Mental Health Centre Sct. Hans, Roskilde, Denmark; 2) University of San Diego, California, US; 3) NORMENT, institute of clinical medicine, University of Oslo, Norway; 4) National Centre for Register-based Research, Aarhus University, Denmark.

Recent efforts have been made to describe the genetic architecture of different mental disorders and the overlap of genetic effects affecting several disorders at the same time. However, these results are based on SNP chip data that only capture common genetic effects. Classical quantitative genetics methods applied to family related samples give estimates of heritability, genetic correlation and individual breeding values using only the family relationships among individuals. This approach informs on a larger part of the underlying heritability than SNP based studies. In this work we use classical quantitative genetic methods to describe the genetic architecture of mental disorders in the Danish population and compare these results with the SNP-based counterparts commonly used nowadays. The iPSYCH project consists in 80000 Danish individuals born between 1981 and 2005. 30000 individuals were sampled randomly from the population (~2% of subjects born in the period) while the remaining 50,000 subjects have a diagnosis of schizophrenia, bipolar disorder, attention deficit disorder, major depression or autism (100% of diseased subjects born in the period). All 80,000 subjects have been genotyped on the PsychChip. We retrieved information from the national civil and health registers on all first degree relatives, including familiar relationships and diagnosis, expanding the sample to 500000 individuals. Variance components (VC) models allow the estimation of disease heritability of diseases as well as genetic correlation between diseases. Cox linear mixed models allow the estimation of heritability taking into account the age of onset of the disease and produces breeding values (genetic load related to the disease) for each individual. Here we present genealogy-based estimates of heritability for the five major mental disorders and compare them with current SNP-based estimates of heritability in the same population. We also calculate genealogy-based pairwise estimates of genetic correlations and compare them to their SNP-based counterparts. Finally, we will estimate individual breeding values for each disease and we will compare them with the polygenic risk scores obtained from SNP data and the burden of putative high-risk variants identified through SNP and sequence based analyses. In summary, we show the utility of classical quantitative genetics methods applied to national based register data to describe the genetic architecture of mental disorders.

1476F

Multiple rare mutations of postsynaptic protein genes associated with schizophrenia. *M. Cheng, S. Hsu, H. Tsai, S. Tsai.* Department of Psychiatry, Yuli Branch, Taipei Veterans General Hospital, Hualien County, Taiwan.

Schizophrenia is a chronic debilitating mental disorder with a high genetic component in its etiology. Mounting studies have shown that schizophrenia is a neurobiological disorder with aberrant synaptic connectivity and synaptogenesis. Gene involved in the formation and functional integrity of synapse can be considered as the candidate gene of schizophrenia. We resequenced the exon regions of 18 genes encoding the synaptic proteins that belong to DLGAP, NRXN, NLGN, SHANK, and HOMER family in 50 schizophrenia patients using targeted-sequencing method for searching potential genetic variants related to schizophrenia. We identified 23 missense mutations from schizophrenic patients. Bioinformatic analysis showed some of these mutations were damaging or pathological to the protein function. Of note, we detected one putative damaging missense mutation, p.R309Q, of the *NLGN2* gene in one patient but not in 549 controls. This patient-specific mutant significantly reduced the reporter gene activity compared with NLGN2 wild-type, which is in line with our previous findings (Hum Mol Genet 2011 Aug 1;20(15):3042-51), supporting that rare missense mutations of the *NLGN2* gene are associated with schizophrenia. In addition, we found four missense mutations of SHANK genes in schizophrenia patients, including SHANK1:p.2074C, SHANK2:p.R443H, SHANK3:p.P209A, and SHANK3:p.T1236I. These missense mutations were not identified in 526 controls. Taken together, multiple rare missense variants of the gene encoding postsynaptic protein contribute to the pathogenesis of schizophrenia in some patients, but gene functional assays are needed to verify their relevance to the pathogenesis of schizophrenia.

1477W

A pilot study for association of tryptophan metabolome and major depressive disorder in Taiwan. *L. Chuang[1], Y. Chung[2], P. Kuo[2].* 1) Department of Nursing, Cardinal Tien Junior College of Healthcare & Management, I-LAN, Taiwan; 2) Department of Public Health & Institute of Epidemiology and Preventive Medicine, College of Public Health, National Taiwan University, Taipei, Taiwan.

Objectives: Major depressive disorder (MDD) is one the most common psychiatric disease. Serious emotional disturbance, insomnia and suicide attempt of these patients then cause serious problems at work and social life. Many studies have indicated the significant association between MDD episode and interaction of life stress and serotonin transportation. Serotonin is metabolized from tryptophan. Tryptophan has two major metabolic pathways, serotonin and kynurenine pathway. The regulation of restriction enzyme for tryptophan metabolism may influence the balance between amount of serotonin and kynurenine in the blood. Recent studies indicated cytokine interferon-γ of inflammation can regulate the restriction enzyme of tryptophan metabolism. The present study explored the possible interaction between inflammation cytokine, tryptophan metabolome, and Taiwan MDD. **Methods:** We used one-to-one conditional case-control study design. We recruited 38 patients of MDD and 38 subjects for healthy control group, and gender and age gap that within 5 years were matched between case and control subjects. Enzyme-linked immunosorbent assay was used to detect the amount of serotonin in the serum. The amount of tryptophan metabolome was detected by liquid chromatography-mass spectrometry. **Results:** After adjusted the frozen period of serum sample, subjects cannot detect serotonin in the peripheral blood were associated with an increased risk of the MDD showing odds ratios (ORs) with 95% confidence intervals (CI) of 8.9 (2.3-46.8) (p-value=0.0036). Compared with participant who can detect serotonin and low kynurenine expression, our data shown non-detectable serotonin and high kynurenine expression plus non-detectable serotonin had increased risks of the MDD showing multivariate ORs (95% CIs) of 18.6 (2.74-384.3)(p-value=0.0011) and 21.5 (2.4-511.1) (p-value=0.0159), respectively. Experimental validation is underway for the individual genotype of rs2430561 in gene interferon-γ to evaluate the possible hypothesis of regulation for restriction enzyme of tryptophan metabolism. **Conclusion:** The expression of tryptophan metabolome has significant association for MDD in Taiwanese population. .

Contribution of rare copy number variants to the development of autism spectrum disorder in high-risk siblings. *L. D'Abate[1,2], S. Walker[1], R.K.C. Yuen[1], K. Tammimies[1,3], M.J. Gazzellone[1,2], B. Thiruvahindrapuram[1], J. Howe[1], J. Brian[4], S. Bryson[5], K. Dobkins[6], R. Landa[7], D. Messinger[8], S. Ozonoff[9], I. Smith[5], W. Stone[10], S. Warren[11], G. Young[9], L. Zwaigenbaum[12], S.W. Scherer[1,2], Infant Siblings Consortium.* 1) Hospital for Sick Children, Toronto, Ontario, Canada; 2) Department of Molecular Genetics and McLaughlin Centre, University of Toronto, Toronto, Ontario, Canada; 3) Center of Neurodevelopmental Disorders (KIND), Department of Women's and Children's Health, Karolinska Institutet, Stockholm, Sweden; 4) Autism Research Centre, Bloorview Research Institute, Toronto, Ontario, Canada; 5) IWK Health Centre, Dalhousie University, Halifax, Nova Scotia, Canada; 6) Department of Psychology, UC San Diego, La Jolla, California, USA; 7) Hugo Moser Research Institute, Kennedy Krieger Institute, Baltimore, Maryland, USA; 8) Department of Psychology, University of Miami, Coral Gables, Florida, USA; 9) MIND Institute, UC Davis, Davis, California, USA; 10) Autism Centre, University of Washington, Seattle, Washington, USA; 11) Vanderbilt Kennedy Center Treatment and Research Institute for Autism Spectrum Disorders, Vanderbilt Kennedy Centre, Nashville, Tennessee, USA; 12) Autism Research Centre, University of Alberta, Edmonton, Alberta, Canada.

   Background: Studies conducted on trios and quartet families have implicated rare *de novo* and inherited copy number variants (CNVs) in the complex etiology of Autism Spectrum Disorder (ASD), however no study to date has investigated whether genetic testing in young children can inform of ASD status prior to the typical age of onset of symptoms. Here, we correlated our genetic findings with longitudinal clinical data available on infant siblings registered with the Infant Siblings Consortium, allowing us to assess the predictive value of early genetic testing. **Methods:** A total of 441 individuals (190 probands, 84 siblings with ASD, 167 unaffected siblings) from 199 families (126 SPX, 73 MPX) were genotyped on the high-resolution Affymetrix CytoScan HD platform, with high-confidence rare CNVs (<0.1% of control population) being ascertained. All infant siblings were clinically assessed periodically and given an ASD diagnosis, if appropriate, at 3 yrs. of age. **Results:** Of 199 families analyzed, we observed *de novo* CNV rates of 5.3% in affected individuals and 3.5% in unaffected siblings. Two of the non-ASD siblings harbouring *de novo* CNVs displayed a broader autism phenotype (BAP). Presumed pathogenic rare CNVs were found in 15/199 families (7.5%). In 7 of these families, the index case and one or more siblings carried the presumed pathogenic CNV; in 6 of these cases the carrier individual either had ASD (4) or had a subclinical form of ASD (2). One such example was a maternally-inherited 90 Kb deletion of the third exon of *PTCHD1-AS* in a male proband and male sibling. Another notable genetic finding was a 200 KB deletion spanning the 5'-end of *NRXN1* in a male proband and non-ASD female sibling. Close examination of the latter sibling's phenotype revealed global developmental delay and BAP. There were also 4 additional families in which CNV data would have been informative for early diagnosis. **Conclusions:** Our results suggest CNVs may serve as early biological markers for ASD, information particularly relevant when there is a family history.

1479F

Co-localization of eQTL and GWAS signatures in schizophrenia. *A. Dobbyn[1,4], L.M. Huckins[1], S.K. Sieberts[6], B. Devlin[5], P. Roussos[1,2,3], C. Giambartolomei[1], P. Sklar[1,2,3,4], E.A. Stahl[1,2], CommonMind Consortium.* 1) Division of Psychiatric Genomics, Department of Psychiatry, Icahn School of Medicine at Mount Sinai, New York, NY 10029; 2) Institute for Genomics and Multiscale Biology, Department of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY 10029; 3) Friedman Brain Institute, Icahn School of Medicine at Mount Sinai, New York, NY 10029; 4) Department of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY, 10029; 5) Department of Psychiatry, University of Pittsburgh, 3811 O'Hara Street, Pittsburgh, Pennsylvania 15213; 6) Systems Biology, Sage Bionetworks, 1100 Fairview Ave N, Seattle, WA, 98109, USA.

   INTRODUCTION: GWA studies have identified numerous Schizophrenia (SCZ) associated loci. However, the utility of GWAS for SCZ and other complex, polygenic disorders has been limited by a lack of mechanistic hypotheses linking associated variants to risk. Expression quantitative trait loci (eQTLs), variants that are associated with changes in gene expression, represent the best known example of a putative functional role for genetic associations. Using summary statistics from the latest SCZ GWAS and eQTLs from DLPFC, we characterized the overlap between GWAS loci and eQTL association signals, for primary (most significant) and secondary (significant after conditioning on the primary) eQTLs. Co-localization of secondary but not primary eQTLs with GWAS signal is consistent with regulation of expression underlying genetic risk in cell types, developmental time points, or stimulation conditions that are only partly represented by available eQTL data. METHODS: We ran MatrixEQTL on genotype and RNA-seq data from CommonMind Consortium post-mortem DLPFC samples (467 EA cases and controls) to identify primary and secondary (conditional) cis-eQTLs (FDR <=0.05). We tabulated the number of primary and secondary eQTLs falling within 108 PGC SCZ GWAS (36,989/113,075 cases/controls) loci defined as r^2 >=0.6 LD-range, resulting in 158 genes with overlapping eQTLS. For each of these genes, we ran a set of conditional analyses to determine the association signal of each conditional cis-eQTL in isolation. We assessed concordance between SCZ GWAS and eQTL signals by (1) COLOC (PMID: 24830394), and (2) inspection of SCZ GWAS versus eQTL p-values. RESULTS: The stepwise forward selection analysis identified ~29,000 primary and/or secondary eQTLs in ~13,000 genes, with a mean of 2.24 eQTLs per gene. COLOC results show 42/158 genes to have a maximum posterior probability for one common causal GWAS association/eQTL: 37/42 of these genes correspond to the primary eQTL and 5/42 (including DOC2A, IREB2, and NEK1) to secondary. Manual inspection of plots supports these findings. CONCLUSIONS: There is evidence for overlap between GWAS association and eQTL signature in 42/158 SCZ-associated genes. The relationship between eQTL and GWAS signature in the remaining 116/158 genes is unclear; for these loci, eQTLs do not appear to explain the regional GWAS signal.

1480W

Investigating the genetic relationship between Alzheimer's disease and cancer using GWAS summary statistics. *Y. Feng[1], J. Cormick[3], K. Cho[3,5], J. Driver[3,4,5], L. Liang[1,2], IGAP consortium, GAME-ON consortium.* 1) Department of Epidemiology, Harvard T.H. Chan School of Public Health, Boston, MA; 2) Department of Biostatistics, Harvard T.H. Chan School of Public Health, Boston, MA; 3) Massachusetts Veterans Epidemiology Resource and Information Center, Boston VA Medical Center; 4) Geriatric Research Education and Clinical Center and Boston VA Medical Center, Boston, MA; 5) Division of Aging, Brigham and Women's Hospital, Boston, MA.

Epidemiological cohort studies and transcriptomic meta-analysis suggest an unusual inverse association between Alzheimer's disease (AD) and cancers. We adopted a genome-wide approach, examining the genetic correlation between AD and a variety of cancer types using GWAS summary statistics from studies with a sample size of up to 20,000-30,000 individuals and >5 million SNPs imputed from the 1000 Genomes European reference panel. Our main results, estimated by cross-trait LD Score regression, showed an overall positive genetic correlation between AD and any of the five cancers combined (colon, breast, prostate, ovarian, and lung; r_g = 0.17, P = 0.04); specifically, we found a significant positive genome-wide relationship of AD with breast cancer (ER-negative and overall; r_g = 0.21 and 0.18, minP = 0.03) and with lung cancer (adenocarcinoma, squamous cell carcinoma and overall; r_g = 0.31, 0.38 and 0.30, minP = 0.01) while a negative genetic correlation of AD with prostate cancer (aggressive and overall; r_g = -0.07 and -0.09, minP = 0.20). This indicated that the two diseases share some genetic variants involved in biological processes that modulate disease risk in the same or opposite direction. Potential cross-phenotype associations were detected between AD and breast, prostate, or lung cancer at specific SNPs, also pointing to common genetic pathways shared by the two traits. Partitioning genetic covariance between AD and each cancer type into functional categories via stratified LD Score regression showed a mixture of positive and negative signals, with stronger signals appearing at enhancers, histone marks (H3K4me1 and H3K4me3), and DNase hypersensitivity sites (DHSs), suggesting that these functional elements may contribute more to the co-heritability between the two diseases than others across the genome. Gene expression data in the most relevant tissues is needed for comprehensive investigation of patterns of shared disease mechanisms and connecting the association observed at the genetic level to that at the phenotypic level. Our study is the first to our knowledge that examines the genetic overlap between AD and specific cancer types using large-scale GWAS meta-analysis results where no individual genotype data is required. We anticipate that our findings will be incorporated into future functional studies that can provide insight into the development of novel therapies for both AD and cancer.

1481T

Transcriptome sequencing in post-mortem brain samples implicates a role for the complement system in schizophrenia. *L. Feuk[1,2], E. Lindholm Carlström[1,2], J. Halvardson[1,2], M. Etemadikhah[1], J. Brännström[1], G. Rajkowska[3], C.A. Stockmeier[3], B. Nilsson[1], P.U. Magnusson[1].* 1) Dept. of Immunology, Genetics and Pathology, Uppsala University, Uppsala, Sweden; 2) Science for Life Laboratory, Uppsala, Sweden; 3) University of Mississippi Medical Center, Jackson, MS, USA.

Transcriptome sequencing is a robust and powerful method to estimate gene expression changes. Here we present findings from transcriptome sequencing in post mortem brain tissue in a cohort of 65 schizophrenia patients and 43 age and sex matched control samples. This represents a sample size twice as large as previously published brain tissue analyses in schizophrenia. Fresh frozen tissue samples were obtained from frontal cortex (Brodmann area 8 and 9) and inferior frontal gyrus. Each sample was cryo-sectioned twice, and then sequenced in duplicate using independent libraries. Expression analysis yielded 42 significant differentially expressed genes between the patient and control groups (adjusted p-value < 0.05). The set of differentially expressed genes showed a general enrichment of immune system genes, with a striking up-regulation of several genes in the complement system in patients. Clustering based on differentially expressed genes yielded three clear clusters, with one cluster containing >80% patients. This group of samples all showed strong complement system activation. Several previous studies point to an important role for the classical complement cascade in neuron differentiation and synaptic pruning. While we do find significant differential expression for the recently published C4 gene (adj. p-value=0.003), we find equal or more highly significant expression differences for several additional complement genes, including C1R, CFB and C7. The overexpression of complement factors in patients was validated with qrtPCR. Using immunohistochemistry we also show that complement factor differences can be detected at the level of the protein in brain sections. Taken together our findings support an important role for C4, but in addition implicate activation of many other genes in the complement cascade as a crucial pathway in schizophrenia pathology.

1482F

Targeted sequencing and functional assessment of the 2p25 region in attempted suicide. *S.C. Gaynor[1], M.E. Breen[1], E.T. Monson[1], K. de Klerk[1], M. Parsons[1], A.P. DeLuca[2], T.E. Scheetz[2,3], P.P. Zandi[4], J.B. Potash[1], V.L. Willour[1].* 1) Department of Psychiatry, University of Iowa Carver College of Medicine, Iowa City, IA; 2) Department of Ophthalmology and Visual Sciences, University of Iowa Carver College of Medicine, Iowa City, IA; 3) Department of Biomedical Engineering, University of Iowa College of Engineering, Iowa City, IA; 4) Department of Mental Health, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD.

Suicidal behavior is a complex phenotype with an estimated heritability of 30-50%. This heritability partly depends on the presence of a comorbid psychiatric disorder. However, there is thought to be an independent heritable factor that is specific to suicide. We previously conducted a genome-wide association study (GWAS) of the attempted suicide phenotype with the goal of identifying this independent factor (Willour et al., 2012). This GWAS implicated common variation in 2p25, a 350kb region encompassing four genes (*FAM110C, SH3YL1, ACP1, FAM150B*). In the current study, we have performed a targeted next-generation sequencing assessment of the entire 2p25 region in an effort to identify both common and rare variation that may contribute to the risk for suicidal behavior. We assessed 476 bipolar subjects with a history of attempted suicide (224 males and 252 females) and 473 bipolar subjects with no history of an attempt (222 males and 251 females). Our top gene-level finding from this study was *FAM150B* (p = 0.022), but this result did not remain significant following correction for multiple testing. Our top individual-variant result was rs300799, an intergenic variant between *FAM110C* and *SH3YL1*. This variant was significantly associated with the attempted suicide phenotype in males, with the minor allele present in 22.3% of attempters and 12.3% of non-attempters (p = 4.8×10^{-5}, corrected p = 0.035, odds ratio = 2.13). Nearly all of our top variants localized to an 80kb linkage disequilibrium block within 2p25. As part of the current study, we are also performing a functional assessment of this 80kb region using the CRISPR-Cas genome-editing system to look for the presence of regulatory elements affecting gene expression or cellular morphology. This study provides further support for a potential role of the 2p25 region in the attempted suicide phenotype.

1483W

Polygenic risk score reveals a genetic relationship between SCZ and OCD. *W. Guo[1], C. Mathews[2], E.M. Derks[3], D.Y. Yu[4], D. Schijven[5], J.J. Luykx[5], J. Scharf[6,7,8], S.E. Stewart[9], J. Samuels[10], J.A. Knowles[11], G. Nestadt[10], Y.Y. It is known that obsessive-compulsive disorder (OCD) and schizophrenia (SCZ) are both highly heritable neurodevelopmental disorders and seem to have notable levels of overlap on the psychopathological level. OCD is fairly common in SCZ, having approximately 13.6% prevalence. In this study, we sought to explore the genetic relationship within and across the two disorders by conducting a standard polygenic score approach. Polygenic score is defined as the sum of multiple single-nucleotide polymorphism alleles associated with the trait for an individual, and the sum is typically weighted by effect sizes estimated from a genome-wide association study. In this study, we use the summary statistics obtained from the PGC-GWAS analysis to predict OCD susceptibility. The first OCD (OCGAS) dataset includes 2,064 individuals in nuclear families. The second OCD (IOEU) dataset includes 3,859 unrelated individuals. The SCZ dataset include 36,989 cases and 113,075 controls. Together, the analyses conducted identified a statistically significant polygenic component of SCZ, predicting approximately 1% of the phenotypic variance in two independent OCD datasets. Our results suggested the presence of polygenic sharing between SCZ and OCD. Yet would like to note that we made the assumption that all genetic markers have effects that are included in the polygenic scores. The merits and limitations of using polygenic score analyses for the predication of psychiatric diseases need further evaluations. .

A comprehensive survey of protein truncating variants in schizophrenia. *H. Huang[1,2], M. Rivas[1,2], G. Genovese[2], T. Singh[3], D. Howrigan[1,2], F.K. Satterstrom[1,2], S.A. McCarroll[2,4], B.M. Neale[1,2], M.J. Daly[1,2].* 1) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA, USA; 2) Broad Institute of MIT and Harvard, Cambridge, MA, USA; 3) Sanger Institute, Hinton, UK; 4) Department of Genetics, Harvard Medical School, Boston, MA, USA.

Schizophrenia is a severe and disabling psychiatric disorder affecting one percent of the general population, with the overall cost of care in the U.S. exceeding $60 billion per year. There have been limited breakthroughs in the past 60 years in developing new treatments for schizophrenia, partially due to limited understanding of how the disease develops. It has been recognized that schizophrenia has a strong hereditary component, with a broad-sense heritability of up to 81%, indicating that genetics can be extremely helpful in providing new insights and advancing our knowledge of the mechanism of disease. Studies on common variants associated with schizophrenia have been successful with more than 100 susceptible loci identified to date. It is also important to find disease-associated rare variants, especially those that are functionally critical, as they generally have a large effect and are more easily translated into models of the disease mechanism. In addition, independent findings in common and rare variants have been shown to converge at a broad functional level, including genes encoding calcium channels or involved in glutamatergic neurotransmission and synaptic plasticity. Here we report a comprehensive survey of protein truncating variants (PTVs), a class of highly deleterious variants, in schizophrenia by combining large-scale exome-sequencing datasets. We aggregated 9,672 cases and 19,017 controls from various sources including the UK10K, Swedish, Finland, Ashkenazi Jewish and Taiwan datasets. After QC, we kept 64,938 PTVs that were not observed in the Exome Aggregation Consortium 'nopsych' subset (release 0.3, 45,376 samples excluding psychiatric cohorts). For each gene, we counted the numbers of PTVs in cases and controls, respectively, and tested for association using Fisher's exact test. Initial analysis identified several genes with suggestive associations with schizophrenia. As additional cohorts are added to this study, we expect the power will be improved such that some genes may reach genome-wide significance. All results, including the number of PTVs in cases and controls per cohort, are presented in an interactive browser for search and visualization. In addition to PTVs, we included all exonic variants sequenced in this study and their meta-analysis odds ratio and *P*-value.

Variants in mitochondrial metabolic enzymes are associated with major depressive disorder in the Japanese population. *D.D. Ikeda[1], K. Okuda[2], S. Nagasaka[3], T. Ono[1], M. Masuda[3], T. Fujiwara[3], H. Haretsugu[1], K. Hattori[4], H. Kunugi[4].* 1) Biomedical Technology Research Center, Otsuka pharmaceutical Co., Ltd., Tokushima, Japan; 2) Department of Clinical Research and Development, Otsuka Pharmaceutical Co.,Ltd., Osaka, Japan; 3) Clinical Pharmacology, Headquarters of Clinical Development, Otsuka pharmaceutical Co., Ltd., Osaka, Japan; 4) Department of Mental Disorder Research, National Institute of Neuroscience, National Center of Neurology and Psychiatry (NCNP), Tokyo, Japan.

Major depressive disorder (MDD) is a complex and chronic disease with a partly genetic etiology. Although a number of genome-wide association studies (GWASs) mainly in European large cohorts have been conducted so far, there were few replicated variants which achieved the genome-wide significance. Here we report a MDD-GWAS in the Japanese small population, which includes 103 cases and 3,229 healthy controls consisting partly of the JPDSC (the Japan PGx Data Science Consortium) database. After whole-genome imputation utilizing the 1000 genomes reference data, we gained over seven million high-quality (Rsq > 0.7) SNPs. We found that multiple candidate SNPs were identified in the two gene regions, *ME3* and *DHTKD1* ($p < 10^{-6}$). Several SNPs of them in the *ME3* gene region exceeded the genome-wide significance ($p < 5 \times 10^{-8}$). Notably, both the two genes encode metabolic enzymes localized in mitochondria. Furthermore, cis-eQTL analyses based on GTEx database (V6) revealed that four strongly disease-associated SNPs in the *ME3* gene region were also associated with the corresponding gene expressions in brain caudate ($p < 0.05$). These findings imply that metabolic imbalances in caudatal mitochondria could contribute to the disease state of MDD under specific genetic backgrounds or circumstances.

1486W

Mutations in *CADPS* identified in patients with bipolar disorder affect protein function and animal behavior. *S. Jamain[1,2,3], J. Sitbon[1,2,3], C. Kappeler[1,2,3], A. Nicolas[1,2,3], D. Nestvogel[4], A. Henrion[1,2,3], B. Etain[1,2,3,5], M. Leboyer[1,2,3,5], J.S. Rhee[4].* 1) Psychiatrie Translationnelle, INSERM U955, Créteil, France; 2) Université Paris Est, Faculté de Médecine, Créteil, France; 3) Fondation FondaMental, Créteil, France; 4) Department of Molecular Neurobiology, Max Planck Institute of Experimental Medicine, Göttingen, Germany; 5) AP-HP, Hôpital H. Mondor – A. Chenevier, Pôle de Psychiatrie, Créteil, France.

   With a prevalence of 1% in general population, bipolar disorder is one of the most severe and common psychiatric disorders. Many studies suggest a preponderant role for genetic factors in bipolar disorder, mainly in early-onset form of the disease. However molecular mechanisms underlying this disorder remain unclear. We identified missense variations and one deletion in a gene encoding the calcium-dependent activator protein for secretion (*CADPS*) in patients with early-onset bipolar disorder. CADPS is an essential regulator of synaptic and large dense core vesicles exocytosis in mammalian neurons and neuroendocrine cells, respectively. Moreover, CADPS promotes vesicular catecholamine uptake and storage mediated by vesicular monoamine transporters. In this study, we showed a higher mutation frequency in patients with early-onset bipolar disorder than in unaffected controls. In cellular models, the CADPS functions were affected by the mutations identified in patients. Some mutations resulted in a decreased expression level of the protein. Others impaired the ability of CADPS to promote the vesicular monoamine uptake *in vitro*. At last, some mutations affected the ability of CADPS to increase the calcium-dependent neurotransmitter release in PC12 cells. Behavioral studies of mutant mice for *Cadps* exhibited modification in anxiety-related behaviors as well as in forced swim test and tail suspension test, suggesting an altered sensitivity for these animals to mild acute stress, as compared to wild-type littermates. Altogether, our results suggest that impairment in CADPS functions may affect the behavior of mutant subjects. Such mutations may thus increase the vulnerability to early-onset bipolar disorders in humans.

Integrative analysis of *de novo* mutations and common variants in schizophrenia. *P. Jia[1], Z. Zhao[1,2].* 1) School of Biomedical Informatics, The University of Texas Health Science Center at Houston, Houston, TX; 2) Human Genetics Center, School of Public Health, The University of Texas Health Science Center at Houston, Houston, TX.

   Recent studies of schizophrenia (SCZ) have increasingly supported that genetic components susceptible to SCZ involve a wide spectrum of risk factors, including common variants (CVs), rare variants, and de novo mutations (DNMs) with effect sizes ranging from small to large. However, few overlapping genes were found both impacted by CVs associated with SCZ and by extremely rare DNMs occurred in only SCZ probands. Considering that it is unlikely these two types of variants work independently in unrelated biological processes and lead to the same disease phenotype, we hypothesized that they could congregate on common biological pathways and processes to cause SCZ. To this end, we referred to these variants as network-attacking variants and set to distinguish their interaction perturbations in networks by studying their residing genes. We mapped genes with DNMs (DNMgenes) and genes with CVs (CVgenes) onto the human protein-protein interaction (PPI) network as well as its sub-networks derived by spatial and temporal expression profiles in brain. Our results showed DNMgenes had a pattern of node attacking, where DNMs lead to node removal from the network and destroyed all the interactions of the DNMgenes. In contrast, CVgenes appeared to have a pattern of edge rewire, where some, but not all, of their interactions were impacted, likely due to dysregulated expression by CVs with regulatory roles. Both patterns were replicated in spatiotemporal sub-networks of brain development, especially in the frontal cortex and sub-cortical regions in fetal developmental stage. In addition, DNMgenes and CVgenes were found to be more accessible to each other than to control genes, indicating they were likely involved in common biological processes. We then developed a network-assisted method to link DNMgenes and CVgenes in frontal cortex during the fetal brain developmental stage and built a SCZ-specific module that was enriched with both categories of genes. We found the resultant SCZ-specific module featured with major groups of genes functional in immune, chromosome modification, and neuronal pathways, which were in line with previous studies on the largest GWAS of SCZ. Strikingly, both DNMgenes and CVgenes contributed to these functional pathways, suggesting a core set of common pathways and networks underlying SCZ. In summary, we conducted a systematic investigation of common variants and de novo mutations and revealed their linking roles underlying SCZ.

1488F

No evidence that the most studied candidate genes for schizophrenia are more relevant to schizophrenia than random sets of genes. *E.C. Johnson[1,2], W.E. Melroy-Greif[3], R. Border[1,2], C. de Leeuw[4], M.A. Ehringer[2,5], M.C. Keller[1,2].* 1) Department of Psychology and Neuroscience, University of Colorado at Boulder, Boulder, CO; 2) Institute for Behavioral Genetics, University of Colorado at Boulder, Boulder, CO; 3) Department of Molecular and Cellular Neuroscience, The Scripps Research Institute, La Jolla, CA; 4) Department of Neurosciences-CNCR, VU University Amsterdam, Amsterdam, Netherlands; 5) Department of Integrative Physiology, University of Colorado at Boulder, Boulder, CO.

A recent analysis of 25 historical candidate gene polymorphisms for schizophrenia found no clear evidence that these polymorphisms were associated at levels above chance in the largest GWAS study conducted to date. However, this study focused on specific polymorphisms, leaving open the question of whether the classic schizophrenia candidate genes themselves, and not just the most studied polymorphisms, are more enriched for lower GWAS p-values than random genes. To answer this question, we used a gene set analysis to examine whether there is evidence that these 25 previously studied candidate genes have stronger associations with schizophrenia than would be expected by chance. Based on our findings, there is no evidence that these classic candidate genes are any more associated with schizophrenia than sets of randomly chosen genes. Candidate gene research continues to be conducted on other phenotypes, but the candidate gene literature from schizophrenia should serve as a cautionary tale. Our results suggest that hypothesis-driven candidate genes need to be validated by GWAS data before further scientific effort is devoted to them.

1489W

Sex-specific characterization of the genetic architecture of obsessive-compulsive disorder. *E.A. Khramtsova[1,2], R. Heldman[3], D. Yu[4], E.M. Derks[5], B.E. Stranger[1,2], L.K. Davis[6] on behalf of the OCD PGC Workgroup.* 1) Department of Medicine, Section of Genetic Medicine, The University of Chicago, Chicago, IL; 2) Institute for Genomics and Systems Biology, The University of Chicago, Chicago, IL; 3) University of California, Berkeley, California; 4) Psychiatric and Neurodevelopmental Genetics Unit, Center for Human Genetics Research, Department of Psychiatry, Harvard Medical School, Massachusetts General Hospital, Boston, Massachusetts, United States of America; 5) Department of Psychiatry, Academic Medical Center, University of Amsterdam, Amsterdam, The Netherlands; 6) Vanderbilt Genetics Institute, Department of Medicine, Division of Genetic Medicine, Vanderbilt University, Nashville, TN.

Although sexually dimorphic human phenotypes and disease characteristics are widespread, the etiology of those differences remains poorly understood. Such dichotomy is exemplified by higher prevalence of many autoimmune diseases in females and many of the neurodevelopmental phenotypes in males. These differences are often attributed to varying sex-hormones or to the sex chromosomes. Recent genetic studies have implicated a contribution to sex-biased phenotypes from autosomal genetic variation, subsequently motivating the characterization of the sex-specific genetic architecture of complex traits. Obsessive-compulsive disorder (OCD) demonstrates a sex-biased age of onset, with males displaying earlier age of onset peaking in adolescence and females displaying a later age of onset peaking in adulthood, suggesting a possible difference in genetic architecture between the sexes. We sought to characterize the sex-specific genetic architecture of OCD by first performing a sex-stratified genome-wide association meta-analysis on over 10,000 samples available through the OCD-PGC (N_{female} = 6030; N_{male} = 4130). We did not identify any genome-wide significant genetic associations for either sex. Next, we performed a sex-stratified estimation of narrow-sense heritability (h^2) using LD score regression method, and found that the heritability of OCD in males (h^2 = 0.15, SE = 0.08) is lower than in females (h^2 = 0.24, SE = 0.08). Based on the genetic correlation between the sexes (rg = 1.0, SE = 0.49, p=0.03), we find that this difference does not reflect variable genetic mechanisms, but may suggest a difference in liability thresholds between the sexes. Additionally, we report results from ongoing analyses including the contribution of sex-biased expression quantitative trait loci to OCD, global analysis of heterogeneity (I^2) between the sexes, and an assessment of the polygenic contribution of the X chromosome. Finally, to further characterize the genetic correlation between OCD and common sex-biased comorbidities (such as Tourette syndrome and attention deficit and hyperactivity disorder), we provide results of a polygenic risk score analysis performed on our sex-stratified sample. In addition, we provide an analytic pipeline and share pitfalls and best practices for sex-specific genetic analyses. Our analysis provides insight into the sex-specific polygenic architecture of OCD.

1490T

Whole genome sequencing analysis of a large pedigree with psychiatric disorders. *J. Lihm[1], P. Thomson[2], S. McCarthy[1], K.L. Evans[2], N.M. Ryan[2], M. Kramer[1], E. Ghiban[1], J.K. Millar[2], A. McIntosh[2], D. Blackwood[2], D. Porteous[2], W.R. McCombie[1].* 1) Stanley Institute for Cognitive Genomics, Cold Spring Harbor Laboratory, New York, USA; 2) University of Edinburgh, Edinburgh, UK.

The study of complex diseases in an extended pedigree design has several advantages. Family based design avoids population stratification and reduces genetic heterogeneity, narrowing the search for rare and novel variants that segregate with a phenotype. However, there are a number of challenges in collecting and analyzing the data, particularly when the pedigree is large and multigenerational. Here we will present a comprehensive analysis pipeline that addresses measures of data quality control for pedigrees, and detects and prioritizes various types of variants including single nucleotide variants, small InDels, copy number variations, and structural variations. We constructed the pipeline with published and in-house software tools such as GATK, Scalpel, LUMPY, and ANNOVAR. The analysis pipeline was applied to a multigenerational pedigree where major mental illness segregates with a balanced translocation t(1;11), between chromosomes 1 and 11. Forty-nine samples were available for whole genome sequencing (20 carriers, 29 non-carriers of the translocation). We implemented quality measures from sequencing and variant calling, gender confirmation, and measures to confirm pairwise relations as marked in the pedigree. Next, for a fast and straightforward scan of SNVs and CNVs, we prioritized possible risk variants by odds ratios and allele frequency. Genome-wide analysis identified rare and novel SNVs in chromosome 1 with high odds ratios that segregate with the translocation located within 8.4Mb of the translocation breakpoint in chromosome 1. Around the t(1;11) breakpoint on chromosome 11, we identified relatively common (MAF≤0.08) intronic and intergenic SNVs within 3Mb of the breakpoint and relatively rare (MAF 0.02) single copy deletion in a TENM4 intron within 11Mb of the breakpoint, all of which segregate with the translocation. We would like to extend this approach to small InDels and structural vairations, incorporating annotations for functional class including the study of the transmission pattern of common and rare variants with different penetrance values. We will use the pipeline to study the effect of shared variants in the affected members and their interaction with the DISC1 pathway.

Genetic variation and DNA methylation of *SKA2* in obsessive-compulsive disorder. *A.J. Lisoway[1,2], C.C. Zai[1,3], G. Zai[1,2,3,4], A. Nair[2,5], S. Ebrahimi[2,5], A.K. Tiwari[1,3], V. Labrie[2,3,5], A. Petronis[2,3,5], Z.A. Kaminsky[6], J.L. Kennedy[1,2,3], M.A. Richter[1,2,3,4].* 1) Neurogenetics Section, Campbell Family Mental Health Research Institute, Centre for Addiction and Mental Health, Toronto, ON; 2) Institute of Medical Science, University of Toronto, Toronto, ON; 3) Department of Psychiatry, University of Toronto, Toronto, ON; 4) Frederick W. Thompson Anxiety Disorders Centre, Sunnybrook Health Sciences Centre, Toronto, ON; 5) Krembil Family Epigenetics Laboratory, Campbell Family Mental Health Research Institute, Centre for Addiction and Mental Health, Toronto, ON; 6) Department of Psychiatry and Behavioral Sciences, Johns Hopkins University, Baltimore, MD.

Background: Obsessive-Compulsive Disorder (OCD) has a strong genetic component, is highly comorbid with Major Depressive Disorder (MDD), and is often triggered by environmental stress. Epigenetic modifications are thought to play a significant role in complex psychiatric disorders and may impact the relationship between genes and the environment via the hypothalamic-pituitary-adrenal (HPA) axis. The *SKA2* gene interacts with the glucocorticoid receptor, is implicated in mediating HPA axis function, but has yet to be examined in OCD. We hypothesized that genetic and epigenetic variation in *SKA2* may play a role in OCD disease risk and symptom severity. **Methods:** A sample of n=64 OCD patients, divided equally by presence/absence of comorbid MDD, and age and gender matched, were selected. Yale-Brown Obsessive-Compulsive Scale (Y-BOCS) score was used to measure disease severity. Genotyping for the *SKA2* rs7208505 marker was performed using the Taqman allele specific assay method and DNA methylation levels were quantified using bisulfite pyrosequencing. Methylation percentage was corrected for genotype using previously established methods. Genotypes for rs7208505 were compared to controls of European ancestry (n=365; 1000 Genomes Project Consortium) using Pearson's chi-squared test. The relationship among the rs7208505 variant, methylation corrected, symptom severity, and MDD status was modeled using linear regression. **Results:** The *SKA2* rs7208505 genotype distributions significantly differed between OCD patients and controls (χ^2=8.66, p=0.013). Genotypes were associated with symptom severity (p=0.011), in that patients with the CC genotype had lower Y-BOCS scores than the CT/TT genotypes. While OCD patients diagnosed with MDD had more severe Y-BOCS scores (p=0.023), neither genetic nor epigenetic variation of rs7208505 was associated with comorbid MDD status. Methylation corrected for genotype was not significant in the regression model (p>0.05). **Conclusions:** These results provide some evidence that *SKA2* genetic variation may be associated with OCD risk and symptom severity. Methylation corrected for genotype was not associated with OCD symptom severity; however, patients with TT and CT genotypes had more severe Y-BOCS scores than the CC genotype carriers. Further work will include replication in larger samples and interrogating additional genetic and epigenetic variations in *SKA2*.

1492W

Objective ranking of neurocognitive endophenotypes for schizophrenia in the Western Australian Family Study of Schizophrenia (WAFSS) using measures of heritability and genetic correlation. *N.S. McCarthy[1], M.L. Clark[2], E.E.M Knowles[3], G. Cadby[1], D. Glahn[3], J. Blangero[4], M. Dragović[2], P.E. Melton[1], E.K. Moses[1], J.C. Badcock[2], A. Jablensky[2].* 1) Centre for the Genetic Origins of Health and Disease, Faculty of Health Sciences, Curtin University and Faculty of Medicine, Dentistry & Health Sciences, University of Western Australia; 2) Centre for Clinical Research in Neuropsychiatry, School of Psychiatry and Clinical Neurosciences, University of Western Australia; 3) Department of Psychiatry, Yale University School of Medicine; 4) South Texas Diabetes and Obesity Institute, The University of Texas Rio Grande Valley.

Schizophrenia (SZ) is a clinically heterogeneous disorder with multifactorial causes including a significant genetic contribution. Identifying endophenotypes of SZ will reduce heterogeneity and improve power for disease gene discovery. *Glahn et al* (2012) have described the *Endophenotype Ranking Value (ERV)* using family-based observations to assess heritability of the endophenotype and its genetic correlation with disease liability. W*e used the ERV to rank neurocognitive measures (candidate endophenotypes of SZ) in the Western Australian Family Study of Schizophrenia (WAFSS) and tested them for association with the Polygenic Risk Score for SZ.* Our cohort comprised 157 families (n=657, including 161 SZ cases). We tested cognitive measures across 6 domains: *General cognitive ability* (National Adult Reading Test, NART & Shipley Institute of Living Scale, SILS IQ); *verbal learning and memory* (Rey Auditory Verbal Learning Test, RAVLT); *sustained attention* (Continuous Performance Task, degraded stimulus, CPT-DS and identical pairs, CPT-IP); *personality factors* (Schizotypal Personality Questionnaire, SPQ & Temperament and Character Inventory, TCI); *speed of information processing* (inspection time, IT); *executive function* (Controlled Word Association Task, COWAT); plus two composite measures, cognitively deficit (CD) and cognitively spared (CS) (Hallmayer et al, 2005). Heritability (h_{CP}) and genetic correlation with SZ (ρ_g) was calculated for each measure in SOLAR and used to calculate ERV=$| \sqrt{h_{SZ}}\sqrt{h_{CP}}\rho_g |$ (h_{SZ} = heritability of SZ). PRS was calculated for each individual using genotypes at 102,636 SNPs (Psychiatric Genomics Consortium). The IQ measures were the most heritable; h^2= 0.56 (SILS) and 0.68 (NART) ($P<10^{-16}$). Genetic correlation was high (>0.5) for most traits. The highest ERVs were for SILS (0.67) and NART (0.55) IQ, RAVLT immediate (0.58) and delayed (0.54), and the CPT-IP (0.51). For all traits there was a trend towards increased neurocognitive deficit with increasing Polygenic Risk Score – especially for CPT-IP (P0.008) and SPQ (P0.02). Overall, measures of *general cognitive ability, verbal learning and memory and sustained attention* are the most promising neurocognitive endophenotypes for SZ among those tested here. Genetic analysis of these endophenotypes may identify latent variants previously missed due to the heterogeneity of the neurobiological disorders subsumed under the clinical diagnosis of SZ.

1493T

Genome-wide association studies and polygenic score analyses of suicide attempt in mood disorders. *N. Mullins[1], R.A. Power[1], A. McQuillin[2], E. Stahl[3], D. Mehta[4], C.M. Lewis[1,5], Major Depressive Disorder and Bipolar Disorder Working Groups of the Psychiatric Genomics Consortium.* 1) MRC Social, Genetic and Developmental Psychiatry Centre, Institute of Psychiatry, Psychology and Neuroscience,, King's College London, United Kingdom; 2) Molecular Psychiatry Laboratory, Division of Psychiatry, University College London, United Kingdom; 3) Department of Psychiatry, Mount Sinai School of Medicine, New York, USA; 4) Queensland Brain Institute, The University of Queensland, Brisbane, Australia; 5) Department of Medical and Molecular Genetics, King's College London, Guy's Hospital, London, United Kingdom.

Background: Suicide is a global public health problem and the 10th leading cause of death in the U.S. Over 90% of suicide attempters or victims have a psychiatric diagnosis, particularly bipolar disorder (BPD) and major depressive disorder (MDD). However, twin and family studies have recognized a genetic component to suicidal behavior, which is independent of psychiatric disorders. Genome-wide association studies (GWAS) to date have failed to identify replicable genetic associations with suicide attempt. These studies have indicated that suicide attempt is a polygenic trait, arising from the combined effect of many risk alleles, each with small effect sizes. Here, we conduct GWAS and polygenic score analyses on suicide attempt using the largest available cohorts of patients with mood disorders, in the Psychiatric Genomics Consortium. **Methods:** Samples comprise 1075 suicide attempters and 7081 non-attempters with MDD and 2021 suicide attempters and 3253 non-attempters with BPD, as well as 18215 healthy controls from initial PGC1 studies. Two GWAS were performed in the MDD and BPD cohorts: a within-case analysis of suicide attempter cases vs. non-attempter cases and an analysis of suicide attempter cases vs. healthy controls. To further explore the genetic architecture of suicide attempt, polygenic risk scoring was used to test whether suicide attempt in MDD and BPD have a shared genetic etiology. **Results:** A genome-wide significant association was found on chromosome 14 comparing suicide attempters with MDD vs. healthy controls (rs8013144, P=8.60x10^{-11}, OR=2.2). No significant associations were found in the BPD sample or in meta-analysis of the cohorts. Polygenic risk scores for suicide attempt in BPD were associated with suicide attempt in MDD, indicating genetic overlap between suicide attempt in the mood disorders (P=0.01). We are currently incorporating new PGC2 data which will increase this sample size to over 4500 suicide attempters, 15500 non-attempters and 50000 controls. **Discussion:** This GWAS on suicide attempt is the largest to date. Polygenic risk scoring is a useful approach to investigating the genetics of a complex trait and should further our understanding of the genetic architecture of suicidality and its relationship with psychiatric disorders.

1494F

Integrated analysis of multiple types of rare variants to infer risk genes for schizophrenia. *T. Nguyen[1], D. Ruderfer[1,2], M. Fromer[1,5], P. Sklar[1,2], S. Purcell[1,2], X. He[3], P. Sullivan[4], E. Stahl[1,2].* 1) Division of Psychiatric Genomics, Department of Psychiatry, Icahn School of Medicine at Mount Sinai, New York, New York 10029, USA; 2) Institute for Genomics and Multiscale Biology, Icahn School of Medicine at Mount Sinai, New York, New York 10029, USA; 3) Department of Human Genetics, University of Chicago, Chicago, IL 60637, USA; 4) Departments of Genetics and Psychiatry, University of North Carolina, Chapel Hill, North Carolina 27599-7264, USA; 5) Verily Life Sciences.

Integrating rare variation from family and case/control studies has successfully implicated specific genes contributing to risk of autism spectrum disorder (ASD). In schizophrenia, however, while sets of genes have been implicated through study of rare variation, very few individual risk genes have been identified. Here, we apply hierarchical Bayesian modeling of rare variation in schizophrenia and infer the proportion of risk genes and distribution of risk variant effect sizes across multiple variant annotation categories. Briefly, we employed the same model used previously in ASD studies. To simplify the complexity of the model, an approximation for the case-control model is used in which case variants are conditional on total counts. All classes of de novo and case-control variants are used jointly to infer genetic parameters using Markov Chain Monte Carlo. We applied this method to 1,024 trios and 4,954 cases/6,239 controls. We defined four variant annotation categories: disruptive (nonsense, frameshift, essential splice site mutations) and missense damaging *de novos* (predicting damaging by seven algorithms), and disruptive and missense damaging case/control singletons. We estimated that 8.4% of 19,441 genes are risk genes (95% credible interval 3.5-16%), with mean effect sizes (95% CIs) of 14.21 (5.04- 25.65) for disruptive *de novos*, 1.99 (1-3.99) for missense damaging *de novos*, 1.79 (1-2.94) for disruptive case/control singletons, and 1.56 (1-2.46) for missense damaging case/control singletons. Our analysis identified only three genes with FDR<0.1: SETD1A, TAF13 (both with FDR<0.05) and RB1CC1. We further analyzed the top 100 genes, with FDR<=0.496, for enrichment in several candidate gene sets. Significant results are observed in gene sets previously implicated in schizophrenia (including in a subset of these data): targets of the fragile X mental retardation protein genes (FMRP), the RNA binding proteins genes (Rbfox2/13), missense constrained genes, genes with ASD *de novo* mutations (all sets p < 7.8x10[-4]), and synaptic genes (p = 1.3x10[-3]). Overall, our results replicate previous studies for known gene sets as well as the SETD1A gene, indicating the robustness of the approach. We anticipate this approach will improve our power to detect schizophrenia risk genes as more data are included.

1495W

An in-depth characterization of common and rare coding variants in schizophrenia risk loci using targeted sequencing. *N. Norgren[1], J. Kang[1], M. Lam[2], J. Foo[1], E. Shyong Tai[3], J. Lee[2], J. Liu[1].* 1) Genome Institute of Singapore, Singapore; 2) Institute of Mental Health, Singapore; 3) Saw Swee Hock School of Public Health, National University of Singapore, Singapore.

Genome-wide association studies (GWAS) have revealed more and more loci associated with schizophrenia, the largest and most recent study being from the Schizophrenia Working Group of the Psychiatric Genomics Consortium (PGC) study. They reported 108 loci, some previously implicated in the disease, and some novel, as associated with SCZ exceeding genome-wide significance. Our purpose with this study is to characterize the variant burden in the Asian schizophrenia population, and identify rare variants in genes increasing disease risk. For achieving this we apply multiplex targeted sequencing using Molecular Inversion Probes (MIPs), of 375 genes within the reported GWAS loci from the PGC study, to deep sequence the Singapore-Chinese schizophrenia cohort. 1585 cases and 2202 controls were sequenced to an average depth of 159 and 124X respectively. 12,205 variants passed quality controls, of which 58% were singletons. Single variant analysis revealed a nonsynonymous SNP on chr12, rs36121382, displaying a suggestive level of significance. Meta analysis with an additional 153 cases and 1900 controls increased the significance to P = 2.38e-05, OR = 1.23. This variant is much more frequent in the Asian population (maf = 0.3) than in the European (maf = 0.05). Rs36121382 is a nonsynonymous variant causing an amino acid change in the MPHOSPH9 gene, and also overlaps with an H3K27Ac mark, which are commonly found near regulatory sites. The rs36121382 variant might induce a dysregulation of the expression of MPHOSPH9 by altering its regulatory regions Burden tests were used to assess the burden of rare variants in cases for each gene. Some of the genes that displayed an increased burden (P < 0.05) are: AMBRA1, regulator of autophagy and nervous system development, DRD2, the D2 subtype of the dopamine receptor, and PCDHA6, a gene that may be involved in establishment and maintenance of specific neuronal connections in the brain. However, none of these genes could withstand Bonferroni correction, probably due to the relatively small sample size. Further sequencing on larger sample sizes are needed to confirm these associations. In conclusion, we found a nonsynonymous variant on chr12 associated with schizophrenia, which could potentially alter MPHOSPH9 expression. Further we discovered nominally significant genes involved in regulation of the nervous system with a higher burden of rare variants in cases.

Polygenic risk score associated with chronotype is associated with sleep problems and obesity in Chinese women from the CONVERGE study of major depressive disorder. *R.E. Peterson[1], T.B. Bigdeli[1], M. Lind[1], S.A. Bacanu[1], J. Flint[2], K.S. Kendler[1], CONVERGE Consortium.* 1) Virginia Institute for Psychiatric and Behavioral Genetics, Virginia Commonwealth University, Richmond, VA; 2) Center for Neurobehavioral Genetics, Semel Institute for Neuroscience and Human Behavior, University of California Los Angeles, Los Angeles, CA.

Our innate, individual partiality for mornings or evenings, known as chronotype, is determined by circadian rhythms, and has relevant implications for numerous health-related outcomes. For example, chronotype has been associated with sleep problems, psychiatric disorders, and obesity. Twin and family studies indicate a partial genetic basis of chronotype, with estimates of heritability ranging from 12 to 42%. Recently, meta-analysis of two genome-wide association studies (GWAS) of European descent from 23andMe and UK Biobank yielded 15 genome-wide significant single-nucleotide polymorphisms (SNPs) associated with chronotype, including 7 loci near known circadian genes. The authors also reported phenotypic associations between chronotype and depression, body mass index (BMI), and educational attainment. Here, we sought to investigate the relationship between chronotype-associated loci and major depressive disorder (MD) in the CONVERGE (**C**hina, **O**xford a**n**d **V**CU **E**xperimental **R**esearch on **G**enetic **E**pidemiology) study of 5278 Han Chinese women with recurrent MD and 5,196 screened controls. Our strategy consisted of (1) constructing polygenic risk scores (PRS) from the 23andMe and UKBiobank meta-analysis of chronotype; (2) testing for associations between chronotype-PRS and MD, MD subtypes, MD symptoms (including sleep problems), BMI, and educational attainment; and (3) testing for enrichment of chronotype-associated genes in MD. Of the 15 reported GWAS loci for chronotype, only 1 was associated with MD in CONVERGE (rs3972456 in *FAM185A*, p=0.007). However, several top SNPs from the meta-analysis were associated with sleep problems among MD cases (i.e; rs12995069 in *VSNL1,* p=0.0001; rs2749951 in *BANF2,* p=0.002). A chronotype-PRS constructed from 456 SNPs (p<10-4 in meta-analysis) was not associated with MD but showed a nominal association in the expected direction with the melancholic MD subtype (p=0.020). Within MD cases, this PRS was nominally positively associated with trouble sleeping during MD episodes (p=0.034) but not with early-waking or "sleeping too much". The PRS was not associated with BMI but was nominally positively associated with obesity (p=0.042), which is consistent with the UKBiobank analysis. No association was found between chronotype-PRS and educational attainment. Preliminary results suggest a genetic link between chronotype-associated loci and MD subtypes--adding support for the role of circadian rhythmicity in psychological health.

1497F

NCAM1 interactions pathway association with depressive symptoms and their DTI correlates in healthy individuals: A gene set-based approach. *J. Petrovska[1], D. Coynel[2], M. Fastenrath[2], A. Milnik[1,4], B. Auschra[1], T. Egli[1], L. Gschwind[1], F. Hartmann[1], E. Loos[2], K. Spalek[1], C. Vogler[1], D.F. de Quervain[2,4], A. Papassotiropoulos[1,3,4], A. Heck[1,4].* 1) University of Basel, Department of Psychology, Division of Molecular Neuroscience, Basel, Switzerland; 2) University of Basel, Department of Psychology, Division of Cognitive Neuroscience, Basel, Switzerland; 3) University of Basel, Department Biozentrum, Life Sciences Training Facility, Basel, Switzerland; 4) University of Basel, Psychiatric University Clinics, Basel, Switzerland.

Depressive symptoms exist on a continuum, the far end of which is found in depressive disorders. Therefore, utilizing the continuous spectrum of depressive symptoms may contribute to the investigation of the biological underpinnings of depression. Gene set enrichment analysis (GSEA) is a potent tool for identifying gene sets underlying complex traits, and is used in the present study to dissect the genetic background of depression scores and their brain-level structural correlates in two large samples of healthy young individuals. Robust enrichment was identified for two gene sets: NCAM1 Interactions and Collagen Formation, in association with depression scores. Depression scores were also associated with fractional anisotropy (FA) decrease within the forceps minor and the left (temporal) superior longitudinal fasciculus. The mean FA value for depression score-associated voxels within each of these tracts was used as a phenotype in a post-hoc GSEA. The NCAM1 Interactions gene set was significantly enriched across all tracts. By associating the NCAM1 Interactions gene set with depression scores and their imaging correlates in healthy participants, the current study suggests its relevance for depression, when operationalized as a continuous phenotype in a nonclinical population.

Investigation of *SHANK3* in schizophrenia suggests the variant G1011V as a rare risk factor shared with autism spectrum disorder. *G. Rappold[1,2], A. de Sena Cortabitarte[1], F. Degenhardt[3], J. Strohmaier[4], M. Lang[4], B. Weiss[1], R. Roeth[1], I. Giegling[5], S. Heilmann-Heimbach[3], A. Hofmann[3], D. Rujescu[5], C. Fischer[6], M. Rietschel[4,7], M. Nöthen[3,8], S. Berkel[1].* 1) Human Molecular Genetics, Institute for Human Genetics, Heidelberg, Germany; 2) Interdisciplinary Center for Neurosciences (IZN), University of Heidelberg, Germany; 3) Department of Genomics, Life & Brain Center, University of Bonn, Bonn, Germany; 4) Department of Genetic Epidemiology in Psychiatry, Central Institute of Mental Health Mannheim, Medical Faculty Mannheim, University of Heidelberg, Germany; 5) Klinik für Psychiatrie, Psychotherapie und Psychosomatik, Universitätsklinikum Halle (Saale),Halle, Germany; 6) Institute of Human Genetics, University of Heidelberg, Heidelberg, Germany; 7) Department of Psychiatry, University of Bonn, Bonn, Germany; 8) Institute of Human Genetics, University of Bonn, Bonn, Germany.

The postsynaptic scaffolding protein SHANK3 is essential for the normal function of glutamatergic synapses in the brain. Emerging evidence suggests that impaired plasticity of glutamatergic synapses is partly responsible for the pathology of schizophrenia (SCZ). To investigate whether variants in the *SHANK3* gene contribute to the etiology of SCZ, we sequenced *SHANK3* in 500 affected individuals (cohort C1). In total, we identified 48 variants and compared them to European controls from the 1000 Genomes Project and the Exome Variant Server. The five most promising variants were followed up in an independent cohort (C2) comprising 993 SCZ patients and 932 German controls. We could not find an association for three of these variants (rs140201628, rs1557620 and rs61729471). Two rare variants with predicted functional relevance were identified in further SCZ individuals: c.3032G>T (p. G1011V) and c.*27C>T. The 3´UTR variant was found in one additional SCZ individual and the G1011V variant was identified in two additional SCZ individuals from cohort C2. The G1011V variant was the most interesting variant in our study; together with previous studies this variant has been identified in 4 out of 1524 SCZ patients and in 4 out of 2147 individuals with autism spectrum disorder (ASD), but not in 2468 European Sanger-sequenced controls. Therefore, we conclude that this variant may be a risk factor for both disorders. A comparison of deleterious *SHANK3* mutations comprising frameshift, nonsense, missense and splice variants between ASD and SCZ individuals revealed a higher frequency in individuals with ASD compared to SCZ.

1499T

Genetic mapping of mental disorder in the Greenlandic population. *A. Rosengreen[1], Y. Wang[1,3], C.B. Pedersen[2], P.B. Mortensen[2], J. Grauholm[4], D. Houggard[4], T. Hansen[5], I. Molkte[6], A. Albretchsen[6], T. Werge[1], W. Thomsom[1], A. Buil[1], IPSYCH-BROAD Researchers.* 1) Mental Health Centre Sct. Hans, Roskilde, Denmark; 2) National Centre for Register-based Research, Aarhus University, Aarhus, Denmark; 3) NORMENT, institute of clinical medicine, University of Oslo Norway; 4) Statens Serum Institut, Copenhagen, Denmark; 5) The Novo Nordisk Foundation Center for Basic Metabolic Research, Copenhagen University, Denmark; 6) The Bioinformatics Centre at Copenhagen University, Demark.

Identifying the etiology and pathology of mental disorders is one of the more challenging problems in modern biomedical sciences. Even that some of them, like schizophrenia, bipolar disorder or autism have high heritabilities (>=70) little is known about the underlying genetic causes of these diseases. The inhabitants of Greenland constitute an isolated and admixed population with a unique genetic history that resulted in a unique allele frequency distribution that enhances the power to map genes related to complex diseases. Recent studies in type II diabetes found genome-wide significant results in a Greenlandic sample with only 223 cases and about 2000 controls. We hypothesize that we can find similar results for mental disorder traits and aim to find genes related to mental disorders in the Greenlandic population. We use a sample of 1708 individuals born in Greenland or with at least one parent born in Greenland. 905 of them have at least one diagnose for schizophrenia, bipolar disorder, autism, attention deficit disorder or depression and the rest are healthy controls. All subjects have been genotyped on the PsychChip. We use two complementary approaches to identify genetic loci related to disease: 1) Genome-wide ancestry-specific association-mapping that takes population admixture as well as family relationships into account. 2) Genomic segments Identical by Descent (IBD) were identified using BEAGLE and EMI and linear mixed models to test the association of genomic loci with mental diseases. Preliminary analysis GWAS analysis of 1213 samples shows a significant hit on chromosome 5 for autism spectrum disorder. Preliminary IBD analysis of 595 samples shows a suggestive signal for mood disorders in chromosome 3. In summary, the isolated population of Greenland improves the power to map genetic loci related to mental disorders. .

Identification of rare variants conferring risk for psychiatric disorders by whole exome sequencing of dried bloodspots. *F.K. Satterstrom[1,2], F. Lescai[3,4,5], C.R. Stevens[1], J.B. Maller[1,2], D.M. Hougaard[3,6], T.M. Werge[3,7,8], B.M. Neale[1,2,9], A.D. Børglum[3,4,5], M.J. Daly[1,2,9], iPSYCH-Broad Consortium.* 1) Stanley Center for Psychiatric Research and Program in Medical and Population Genetics, Broad Institute of Harvard and MIT, Cambridge, MA, USA; 2) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA, USA; 3) iPSYCH, The Lundbeck Foundation Initiative for Integrative Psychiatric Research, Aarhus, Denmark; 4) Department of Biomedicine, Aarhus University, Aarhus, Denmark; 5) iSEQ, Centre for Integrative Sequencing, Aarhus University, Aarhus, Denmark; 6) Center for Neonatal Screening, Department for Congenital Disorders, Statens Serum Institut, Copenhagen, Denmark; 7) Mental Health Centre Sct. Hans, Institute for Biological Psychiatry, Capital Region of Denmark, Roskilde, Denmark; 8) Department of Clinical Medicine, University of Copenhagen, Copenhagen, Denmark; 9) Department of Medicine, Harvard Medical School, Boston, MA, USA.

To uncover rare genetic variants conferring risk for psychiatric disorders, the iPSYCH-Broad Consortium has begun a large-scale exome sequencing effort, drawing upon a wealth of existing biological and phenotypic data in Denmark. The Danish Neonatal Screening Biobank has stored dried neonatal blood samples for virtually every child born in the country since 1981, and methods have been developed by Denmark's Statens Serum Institut to recover sufficient DNA for high-throughput DNA sequencing from these samples. Using phenotypes from the Danish Psychiatric Central Registry, our consortium seeks to obtain whole exome sequences from the archived bloodspots of individuals who have been diagnosed with psychiatric disorders. Previous comparisons of sequences obtained from archived bloodspots with sequences obtained from fresh samples of whole blood (presented at this meeting last year) have demonstrated high quality (e.g. 99.9% concordance of heterozygote calls between the two sample sources), leading us to pursue a much larger study.　We present results from the combined analysis of approximately 20,000 bloodspot-derived exome sequences, including over 5,000 autism cases and 6,000 controls, as well as over 3,500 ADHD cases, 3,500 schizophrenia cases, and 1,000 bipolar cases. In a preliminary data freeze consisting of 8,000 exomes, we have identified significantly higher per-person rates of deleterious rare variants (not present in the Exome Aggregation Consortium database and causing truncation, frameshift, or essential splice site loss in proteins which have been identified as intolerant of loss-of-function mutation) in autism and ADHD compared to controls. As a further positive control, the genes with the most rare loss-of-function variants observed in autism cases include known autism- and intellectual disability-associated genes identified in *de novo* mutation studies, such as *SCN2A*, *SYNGAP1*, and *SHANK3*. While the presence of these variants in our data is likely due to *de novo* mutation, the scale of our data enables identification of new genes not previously flagged by *de novo* mutation analysis. Specifically, genes with lower penetrance, and therefore lower selective pressure, likely present with excesses of loss-of-function variants that will be inherited rather than *de novo*; for such variants, a very large sample size, such as that brought by this project, will be necessary to identify them as risk factors for psychiatric disorder.

1501W

GWAS of longitudinally collected brain MRI data in ADHD enriched samples. *T. Schwantes-An[1], E. Székely[2], C.M. Justice[1], R. Muetzel[3], P.R. Jansen[3], H. Tiemeier[3], T.J.H. White[3], P. Shaw[2], A.F. Wilson[1].* 1) Genometrics Section, Computational and Statistical Genomics Branch, National Human Genome Research Institute, Baltimore, MD; 2) Neurobehavioral Clinical Research Section, Social and Behavioral Research Branch, National Human Genome Research Institute, Bethesda, MD; 3) The Generation R Study Group, Erasmus University Medical Center, Rotterdam, the Netherlands.

In vivo magnetic resonance imaging (MRI) of the developing child has tied the course of childhood psychopathology to the trajectories of structural brain development. Several groups have associated attention-deficit/hyperactivity disorder (ADHD) with atypical neuroanatomical growth trajectories of the cerebral cortex, cerebellum and striatum. Using repeated MRI measures of brain volume from two independent cohorts, we performed a genome wide association study (GWAS) of brain growth during childhood and adolescence. We focused on six key regions of the brain: cerebellum, cerebral cortex, left and right lateral prefrontal cortex, basal ganglia and cortical white matter. The GWAS was conducted on 458 individuals, of whom 119 had a diagnosis of ADHD, using EMMAX (Efficient Mixed-Model Association eXpedited) to control for population stratification and sample relatedness. In the second stage, an independent cohort of 260 individuals also with an *in vivo* brain growth phenotype was tested with EMMAX. Meta-analysis was then performed with the rMETA package in R, focusing on the 288,218 SNPs that were genotyped in both cohorts. No significant associations were found after Bonferroni correction (2.89×10^{-08}). However, there were 141 suggestive hits at a critical value of 1×10^{-05} across the six brain compartment measures. The most significant association was between rs1424450 (chr7:134,209,317), an intergenic variant, and white matter with a p-value of 3.06×10^{-08}. Rs7089041 (chr10:125,003,630) showed suggestive associations with left (p-value = 5.26×10^{-06}) and right (9.46×10^{-05}) prefrontal cortex and cerebral (2.74×10^{-05}) cortex traits, and is located near GPR26, a gene reported to be expressed in mouse cerebral cortex. Overall, we report 141 suggestive associations between SNPs and brain growth in a sample enriched for behavioral problems characteristic of ADHD. The lack of significance at the Bonferroni level is likely due to the small sample size, a reflection of the scarcity of longitudinal MRI measures. Further work in prioritizing the nominally associated variants and implicated biological pathways is in progress. Additionally, we will explore the genetic overlap between our brain growth phenotypes and the diagnosis of ADHD using polygenic risk score analysis.

1502T

Schizophrenia polygenic burden is significantly associated with cognitive performance in nonpsychotic individuals. *R. Shafee[1,3], P. Nanda[4], N. Tandon[5,6], J. Padmanabhan[5,7], N. Alliey-Rodriguez[8], E. Gershon[8], B. Clementz[9], G. Pearlson[10], C. Tamminga[11], M. Keshavan[2,6], S. McCarroll[1,3].* 1) Genetics, Harvard Medical School, Boston, MA; 2) Psychiatry, Harvard Medical School, Boston, MA; 3) Stanley Center, Broad Institute of MIT and Harvard, Cambridge, MA; 4) Neurological Surgery, Columbia University Medical Center, New York, NY; 5) Psychiatry, Beth Israel Deaconess medical Center, Boston, MA; 6) Baylor College of Medicine, Houston, TX; 7) McLean Hospital, Belmont, MA; 8) Psychiatry and Human Genetics, University of Chicago, Chicago, IL; 9) Psychology, University of Georgia, Athens, GA; 10) Psychiatry, Yale University School of Medicine, New Haven, CT; 11) Psychiatry, UT Southwestern Medical School, Dallas, TX.

   Psychiatric disorders such as schizophrenia are frequently accompanied by cognitive deficits. Probands as well as their unaffected relatives show decreased functioning in many cognitive domains. The Brief Assessment of Cognition in Schizophrenia (BACS) is a cognitive battery designed to capture the deficits that are seen frequently in schizophrenia. We used data from the Bipolar-Schizophrenia Network for Intermediate Phenotypes (BSNIP) consortium to investigate the effect of the polygenic burden of schizophrenia common variants (PRS_SZ) on BACS performance as well as on Wide Range Achievement Test (WRAT, often used as a proxy for premorbid IQ) in two groups: psychotic probands (N = 314) and nonpsychotic individuals consisting of healthy controls and non-psychotic relatives (N = 438). Our BACS score consisted of six components: verbal memory, verbal fluency, digit sequencing, digit symbol coding, token motor task and Tower of London. We found that PRS_SZ is significantly negatively correlated with digit sequencing (DS) and digit symbol (DSC) coding scores in the nonpsychotic group (combined r = -0.21, $p<10^{-4}$) but not in the psychotic group (p>0.05). PRS_SZ showed no significant correlation with WRAT in either group. Additionally, the correlation between BACS and PRS_SZ in the nonpsychotic group remained unchanged after regressing out WRAT. We noted that while DS and DSC BACS scores differed significantly between the psychotic and nonpsychotic groups ($p<10^{-10}$), WRAT was only nominally different (p~0.05 after controlling for years of education). Additionally, a polygenic score for educational attainment showed significant positive correlation with WRAT ($p<10^{-3}$) but not with BACS (p>0.05). Together these results indicate that in our sample schizophrenia polygenic burden captures the variability in cognitive functions affected in schizophrenia much better than the variability in overall intelligence. The absence of significant correlation between PRS_SZ and BACS components in the probands could be due to the effects of medication or due to disease pathology altering these cognitive functions in a way that could not be captured by genetic predisposition to schizophrenia. .

1503F

Schizophrenia patients have an increased burden of rare disruptive variants in genes shared with neurodevelopmental disorders. *T. Singh[1], J.T.R. Walters[2], M. Johnstone[3], E. Rees[2], J. Suvisaari[4], M. Torniainen[4], D. Curtis[5], A.M. McInstosh[3], D. Blackwood[3], G.K. Kirov[2], A. Palotie[6], M.C. O'Donovan[2], M.J. Owen[2], J.C. Barrett[1] on behalf of the UK10K consortium.* 1) Department of Human Genetics, Wellcome Trust Sanger Institute, Hinxton, Cambridgeshire, UK; 2) MRC Centre for Neuropsychiatric Genetics & Genomics, Cardiff University, Cardiff, UK; 3) Division of Psychiatry, The University of Edinburgh, Royal Edinburgh Hospital, Edinburgh, UK; 4) National Institute for Health and Welfare (THL), Helsinki, Finland; 5) University College London (UCL) Genetics Institute, London, UK; 6) The Broad Institute of MIT and Harvard, Cambridge, USA.

   Substantial progress has been made using whole-exome sequencing to identify genes in which damaging rare variation or *de novo* mutations confer very high risk for autism, intellectual disability, and severe developmental disorders. Indeed, these studies, which have largely been conducted independently, have revealed that many of the same genes are disrupted in patients with a wide range of diagnoses and presentations. In a recent meta-analysis of schizophrenia exomes, we identified at genome-wide significance the first such gene (*SETD1A*) for which loss of function (LoF) variants confer substantial risk for schizophrenia, an adult onset neuropsychiatric disorder where the genetic connections to autism and developmental disorders are less clear. Intriguingly, LoF variants in the same gene were also found to confer risk for severe developmental disorders.   Here, we describe a series of analyses based on large-scale genetic datasets that further explores the potential overlap of genetic risk between schizophrenia and broader developmental disorders. We jointly analyzed data from 1,077 schizophrenia trios, 4,264 case and 9,343 control exomes, and array-based CNV calls from 6,882 cases and 11,255 controls. We first show that schizophrenia individuals carry a higher burden of rare damaging variants in a subset of 3,230 genes with near-complete depletion of truncating variants ($P < 1x10^{-14}$). Rare variant enrichment analyses in 1,776 gene sets demonstrate that this burden is most strongly enriched in known autism risk genes ($P = 1.6x10^{-5}$), genes diagnostic of severe developmental disorders ($P = 3.5x10^{-5}$), and the autism-implicated sets of promoter targets of *CHD8* ($P = 5.7x10^{-7}$), and splice targets of *RBFOX* ($P = 3.3x10^{-4}$). Furthermore, in a subset of 119 schizophrenia patients with learning disability, we show this burden is even stronger than in the general schizophrenia population ($P = 7.3x10^{-5}$), mirroring previous results comparing low and high IQ autism probands. Notably, a general enrichment of rare variants still exists in the larger schizophrenia population, including in patients without cognitive impairment. Combined, our results demonstrate that schizophrenia risk loci of large effect implicate a common set of genes shared with broader neurodevelopmental disorders, further supporting a neurodevelopmental etiology to the pathogenesis of schizophrenia.

1504W

Induced pluripotent stem cells as a tool to analyze the molecular effects of the 15q13.3 microdeletion. *S. Zhang, C. Purmann, J. Hallmayer, A. Urban.* Department of Psychiatry and Behavioral Sciences, Stanford University, Palo Alto, CA.

The 1.5 Mb microdeletion on human chromosome 15q13.3 is strongly associated with a number of neurodevelopmental symptoms, including developmental disability, seizures, speech problems, schizophrenia and autism spectrum disorder. However, there are at least eight genes affected by the microdeletion, and quite possibly in a manner specific to tissue and developmental time point, and novel approaches are needed to analyze the deletion's effects on the molecular and cellular level. Using the Sendai virus approach, we have created a cohort of induced pluripotent stem cells (iPSCs), from fibroblasts from three patients with the 15q13.3 deletion, and from matching controls. The iPSCs' genomes have been characterized with digital droplet PCR and whole-genome sequencing. The cell lines were characterized by staining for the pluripotency markers Nanog, Tra-1-60, and SSEA-4. RNA-Seq analysis of gene expression patterns was carried out for both the fibroblast and iPSC stage and showed mostly decreased gene expression levels, in a cell type specific manner, for the genes within the deletion boundaries, as well as genome wide effects on the transcriptome. Furthermore, we induced the iPSCs into a neuronal cell type (induced Neurons, iNs), using the protocol described in Zhang et al 2013. In summary, we have created a cohort of iPSCs from patients with the 15q13.3 microdeletion, the lines are well characterized on the genome level and on the level of gene expression patterns, and they show distinct potential to differentiate into a neuronal cellular phenotype. We expect this cohort to be a useful tool in the analysis of the molecular effects to the 15q13.3 microdeletion.

1505T

Genome-wide association study of post-cannabis dependence anxiety. *H. Zhou[1], H.R. Kranzler[2,3], R. Sherva[4], B.Z. Yang[1], J.L. Montalvo-Ortiz[1], L. Farrer[4,5,6,7,8], H. Zhao[9,10], J. Cannabis use disorder and anxiety disorders often co-occur. Cannabis use is associated with new onset of panic disorder and can worsen anxiety symptoms. Thus, anxiety can be viewed as an adverse consequence of cannabis abuse. We examined genetic factors influencing cannabis-associated anxiety disorder onset by comparing cannabis dependence (CaD) subjects with anxiety onset after CaD onset (case group) to all other CaD subjects (i.e., those whose onset of anxiety disorder was before that of CaD or who had no anxiety disorder (control group)). Subjects were recruited from 2000 to 2013 as part of the Yale-Penn study and were interviewed using the Semi-Structured Assessment for Drug Dependence and Alcoholism (SSADDA), with CaD diagnosed according to DSM-IV criteria. Anxiety disorder onset was defined as the earliest time of diagnosis of any one of the following anxiety disorders: generalized anxiety disorder, panic disorder, agoraphobia and social phobia. Subjects included 1,185 CaD African Americans (AAs) and 1,249 CaD European Americans (EAs) in two datasets. The first dataset comprised 61 AA cases, 806 AA controls, 90 EA cases and 662 EA controls, which were genotyped using the Illumina HumanOmni1-Quad array (~890,000 SNPs). The second dataset comprised 21 AA cases, 297 AA controls, 64 EA cases and 433 EA controls, which were genotyped using the Illumina HumanCore Exome array (~500,000 SNPs). Additional genotypes were imputed with the 1000 Genomes Project panel. We conducted genome-wide association studies (GWAS) and meta-analysis in each population. A short deletion, rs201796339, was significantly associated with anxiety onset after CaD in EAs ($P = 2.09 \times 10^{-8}$ in dataset 1, $P = 2.83 \times 10^{-3}$ in dataset 2, and $P = 4.37 \times 10^{-10}$ for meta-analysis). This variant is ~60kb downstream of *NUDT12* (nudix hydrolase 12), which is sparsely annotated and has been demonstrated to play a role in NAD metabolism. This study provides insight into the genetics of anxiety disorder onset in the context of CaD.

1506F

Genetic polymorphisms and serum concentrations of adiponectin and resistin in anorexia nervosa and healthy controls. *K. Ziora-Jakutowicz[1], J.G. Zimowski[1], F. Rybakowski[2], M. Bednarska-Makaruk[1], J. Zaremba[1], M. Pawelec[1], D. Narowska[1], K. Ziora[3].* 1) Department of Genetics, Institute of Psychiatry and Neurology, Warsaw, Poland; 2) Department of Child and Adolescent Psychiatry, Institute of Psychiatry and Neurology, Warsaw, Poland; 3) Department of Paediatrics, School of Medicine with the Division of Dentistry in Zabrze, SUM in Katowice, Poland.

   Introduction- Anorexia nervosa (AN) is a heritable disorder characterized by low body weight and disturbances of appetite. A possible role of adipokines in the regulation of body mass has been proposed. Polymorphisms in genes encoding adiponectin and resistin in AN have not been frequently assessed. **Aims of the study-**1. To assess the frequency of selected polymorphisms in adiponectin gene: *ADP*c.45 T>G and *ADP* c.276G>T and in resistin gene: *RETN*c.62 G>A and *RETN*c.-180C>G in AN patients and healthy controls (HC); 2. To assess the correlation between specific polymorphisms with adiponectin and resistin plasma levels. **Material and methods-** We examined 67 AN girls (aged 11-18) and 38 controls (aged 11-18). Analyses of polymorphisms in adiponectin (*ADP*) and resistin (*RETN*) genes were performed using RFLP method, after the DNA was isolated from frozen samples of peripheral blood. Adiponectin and resistin serum levels were examined with the use of commercial kits for ELISA [Bio-Vendor, LLC (USA)]. **Results-** We observed a statistically significant differences in allele frequency in polymorphic sites *ADP* c.276 and *RETN*c.-180 between AN patients and HC. In AN subjects, TT genotype in polymorphism *ADP* c.276 was significantly more frequent than in HC (p=0.005; contingence index C=0.31). Also, GG genotype of *RETN*c.-180 in AN patients was significantly more frequent, than in HC (p<0.0001; C=0.47), in whom CC alleles were predominant. In *ADP*c.45 polymorphic site, TT alleles were the most frequent in AN (93.8%), as well as in HC (78.9%). Alleles TG in this site were more frequent in HC (21.1%) than in AN (6.2%), but this difference was not statistically significant (p=0.051; C=0.19). In *RETN* c.62 alleles distribution of GA and GG did not differ significantly in both groups (p=0.591; C=0.05). The most frequently observed genotype was GG in both AN (86.57%) and HC (92.11%). The mean adiponectin serum level in AN (43.8 ± 5.3 µg/ml) was significantly higher than in control group (6.52 ± 1,3 µg/ml; p< 0.0001). The mean resistin serum level in AN (2.75 ± 0.60 ng/ml) was significantly lower than in control group (9.15 ± 1.38 ng/ml).There were no statistically significant relationships between mean adiponectin and resistin serum levels and allele frequency in polymorphisms *ADP*c.276 and *RETN*c.-180 in neither group. **Conclusion-** Differences in genotype frequencies of *ADP*c.276 and *RETN*c.-180 suggest a need for studies on a larger cohort.

1507W

Comprehensive genomic characterization of long non-coding rnas of amygdala tissues in schizophrenia. *Z. Wei[1], T. Tian[1], X. Chang[2], Y. Liu[2], P. Sleiman[2,3], H. Hakonarson[2,3].* 1) New Jersey Institute of Technology, Newark, NJ; 2) The Children's Hospital of Philadelphia, Philadelphia, PA; 3) The Perelman School of Medicine University of Pennsylvania, Philadelphia, PA.

   Schizophrenia is a chronic and severe mental disorder with which people will exhibit abnormal social behavior and/or fail to differentiate real from unreal. The amygdala brain region has been implicated in the pathophysiology of schizophrenia through emotion processing. Long noncoding RNAs (lncRNAs) have gained widespread attention in recent years as a potentially new and crucial layer of biological regulation. lncRNAs of all kinds have been implicated in a range of developmental processes and diseases, but very few, if any, studies have investigated long Non-coding RNAs (lncRNAs) in the amygdala of schizophrenia. To delineate genome-wide lncRNA expression, we curated 22 schizophrenia patients and 24 non-psychiatric controls through deep RNA-sequencing (over 100 M reads on average per sample). We applied *ab initio* assembly methodology to this data set, and identified a consensus transcriptome of 839 novel lncRNAs of high quality after stringent QC. Gene Set Enrichment Analysis (GSEA) of these novel lncRNAs reveal that many pathways relevant to neuron development are significantly down-regulated in schizophrenia patients vs controls. These findings may shed light on unraveling the molecular mechanism of schizophrenia.

Investigation of gene dosage sensitivity in 22q11.2 deletion syndrome.
A. Salaka, H. Moss, M. Niarchou, S. Chawner, M. Van Den Bree, M.J. Owen, N.M. Williams. MRC Centre for Neuropsychiatric Genetics& Genomics, Cardiff University, Cardiff, United Kingdom.

Individuals with chromosome 22q11.2 deletion syndrome (22q11.2DS) have an increased risk of developing a diverse spectrum of behavioural and psychiatric outcomes. However, there is a lack of understanding of the mechanisms explaining how such a degree of pleiotropy could arise from a relatively homogenous microdeletion on chromosome 22q11.2. As 22q11.2DS patients carry the same deletion it is most likely that haploinsufficiency of dosage sensitive genes spanning the deleted region influence the pathogenesis of the resulting psychiatric phenotypes. It is expected that deletion of 22q11.2 will have an impact on the level of gene expression of deleted genes which could be reduced by 50%. Consequently, reduction in the expression of these genes would change their biological function. We set out to identify dosage sensitive genes by differential gene expression analysis of the 22q11.2 deletion region and genome-wide in 22q11.2 deletion group and a normal control group. As not all genes are dosage sensitive the identification of genes that are differentially expressed between 22q11.2 deletion carriers and non-deleted controls will highlight those whose expression are influenced by the deletion. The expression of genes away from the CNV boundaries can be directly influenced the deletion. This phenomenon is called a 'position effect' which was investigated by performing genome-wide gene expression analysis to assess the expression of genes located outside 22q11.2. For gene expression analysis RNA samples of 22q11.2DS cases (n=33) and controls (n=36) were analysed by Illumina HumanHT-12 v4 Expression BeadChip which targets 47,231 probes. Samples and probes were subjected to quality control assessments. Differential gene expression analysis was applied by fitting a linear model and defining a contrast comparing cases to controls using Limma package on R. The result of differential gene expression analysis shows ~35% of genes located within the 3MB 22q11.2 region are significantly differentially expressed between 22q11.2 deletion cases and controls (FDR<0.05). There is a minor *in CIS* position effect of 22q11.2 deletion on nearby genes. However, the deletion has a negligible effect genome-wide, with only 2.2% of genes being significantly differentially expressed with FDR<0.05. As these studies have used RNA samples which were extracted from peripheral blood, future studies will be required to establish how they reflect gene expression in the human brain.

1509F

Childhood maltreatment and major depressive disorder: Indirect mediating effect of gene expression. *L. Spindola[1,2,3,4], P. Pan[2,3,4], P. Moretti[1,2,3,4], V. Ota[1,2,3,4], M. Santoro[1,2,3,4], H. Cogo-Moreira[2,3,4], A. Gadelha[2,3,4], G. Salum[3,8], G. Manfro[3,8], J. Mari[2,3,4], H. Brentani[3,5], R. Grassi-Oliveira[3,6,7], E. Brietzke[2,3,4], E. Miguel[3,5], L. Rohde[3,8], J. Sato[3,9], R. Bressan[2,3,4], S. Belangero[1,2,3,4].* 1) Genetics Division, Department of Morphology and Genetics, Universidade Federal de São Paulo (UNIFESP), São Paulo, Brazil; 2) LiNC - Interdisciplinary Laboratory of Clinical Neurosciences, UNIFESP, São Paulo, Brazil; 3) National Institute of Developmental Psychiatry for Children and Adolescents (INPD), Brazil; 4) Department of Psychiatry, UNIFESP, São Paulo, Brazil; 5) Department & Institute of Psychiatry, Faculdade de Medicina da Universidade de São Paulo (FMUSP), São Paulo, Brazil; 6) Post-Graduation Program in Psychology, Pontifícia Universidade Católica do Rio Grande do Sul (PUCRS), Porto Alegre, Brazil; 7) Developmental Cognitive Neuroscience Lab (DCNL), Pontifícia Universidade Católica do Rio Grande do Sul (PUCRS), Porto Alegre, Brazil; 8) Department of Psychiatry, Hospital de Clínicas de Porto Alegre, Universidade Federal do Rio Grande do Sul, Porto Alegre (UFRGS), Brazil; 9) Center of Mathematics, Computation and Cognition, Universidade Federal do ABC, Santo André, Brazil.

Investigating major depressive disorder (MDD) in childhood and adolescence can help reveal the relative contributions of genetic and environmental factors to MDD, since early stages of disease have less influence of illness exposure. Thus, we investigated the mRNA expression of 12 genes related to the hypothalamic–pituitary–adrenal (HPA) axis, inflammation, neurodevelopment and neurotransmission in the blood of children and adolescents with MDD and tested whether a history of childhood maltreatment (CM) affects MDD through gene expression. Whole-blood mRNA levels of 12 genes were compared among 20 children and adolescents with MDD diagnosis (MDD group), 49 participants without MDD diagnosis but with high levels of depressive symptoms (DS group), and 61 healthy controls (HC group). The differentially expressed genes were inserted in a mediation model in which CM, MDD, and gene expression were, respectively, the independent variable, outcome, and intermediary variable. *NR3C1*, *TNF*, *TNFR1* and *IL1B* were expressed at significantly lower levels in the MDD group than in the other groups. CM history did not exert a significant direct effect on MDD. However, an indirect effect of the aggregate expression of the 4 genes mediated the relationship between CM and MDD. In the largest study investigating gene expression in children with MDD, we demonstrated that *NR3C1*, *TNF*, *TNFR1* and *IL1B* expression levels are related to MDD and conjunctly mediate the effect of CM history on the risk of developing MDD. This supports a role of glucocorticoids and inflammation as potential effectors of environmental stress in MDD.

1510W

Genetic modifiers in patients with autism and Williams-Beuren syndrome. *M. Codina-Solà[1,2,3], D. Pérez-García[1,2,3], R. Flores[1,2,3], G. Palacios-Verdú[1,2,3], L. Pérez-Jurado[1,2,3], I. Cuscó[1,2,3].* 1) Centro de Investigación Biomédica en Red de Enfermedades Raras (CIBERER), Barcelona, Spain; 2) Departament de Ciències Experimentals i de la Salut, Universitat Pompeu Fabra, Barcelona, Spain; 3) Institut Hospital del Mar d'Investigacions Mèdiques (IMIM), Barcelona, Spain.

The hallmark of the neurobehavioral phenotype of Williams-Beuren syndrome (WBS) is increased sociability and relatively preserved language skills, often described as the opposite to Autism Spectrum Disorders (ASD). However, the prevalence of ASD among WBS individuals is 12%, approximately 10 fold higher than in the general population. To look for phenotypic modifying factors, we have performed an unbiased study of genetic variants in individuals with WBS and co-occurring ASD. The study was conducted on eight individuals with WBS (4 males and 4 females) and a confirmed diagnosis of ASD by the Autism Diagnostic Interview-Revised (ADI-R). We first performed a detailed characterization of the deletion at the molecular level in order to find cis-acting modifiers. In addition we looked for genome-wide variants, both rare and common, using exome sequencing. The detailed study of the 7q11.23 region showed that patients did not differ in deletion breakpoints, but in seven of eight the deletion had originated in the paternal allele. In addition, we found an overrepresented rare SNP (rs12539160) in the remaining hemizygous allele in two individuals, which was previously associated to ASD by Genome-Wide Association studies. Our genome-wide analysis found large Copy Number Variants (CNVs), but identified several loss of function (LoF) mutations in ASD candidate genes and brain-expressed genes with a high probability of LoF intolerance. Some of these loci, such as *AGAP1* or *EPHB1*, are transcriptionally dysregulated in WBS. In addition, females carried a higher burden of rare deleterious variants in candidate genes compared to males (p=0.03). The increased frequency of paternal deletions in our cohort suggests a role of imprinting mechanisms that along with trans-acting factors in the remaining allele, such as ASD susceptibility loci, could influence the neurobehavioral profile. Our results also point towards a role for deleterious variants in functionally constrained brain expressed genes, that could act as second-hit modifying factors in an epistatic manner. Finally, the higher load of deleterious variants in ASD candidate genes in females reinforces the female protective effect for a more severe phenotype in a disorder of full penetrance.

1511T

Meta-analysis of 4,500 ASD exomes reveals novel genes and connections to developmental disorders. *L. He, J.C. Barrett, The DDD Study.* Wellcome Trust Sanger Institute, Cambridge, United Kingdom.

Authors: Liu He, Jeffrey C. Barrett, the DDD Study Recent research based on whole-exome sequencing has established a prominent role of *de novo* mutations in the etiology of sporadic autism spectrum disorders (ASD). However the rarity of *de novo* mutations, especially those expected to cause loss-of-function (LoF) through protein truncation, as well as the number of possible affected genes, require very large sample sizes to reliably identify risk genes. Here, using aggregated data from ~4500 published families affected by ASD, we re-examine the pathogenic contribution of *de novo* LoF mutations. By applying a stringent exome-wide significance cutoff, 15 genes were classified as ASD genes, among which 11 have been previously reported with high confidence and four more —*ANKRD11, ASXL3, MED13L, FOXP1* — though previously implicated in ASD by other means, have now also been confirmed based on a statistically significant enrichment of *de novo* LoF mutations in cases. Through comparison with recent published research from the DDD project focusing on *de novo* mutations in ~4300 families affected by severe developmental disorders (DD), 12 of these 15 genes were also associated with DD, which points to the converging genetics of *de novo* damaging variants and their substantial contribution to neurodevelopmental risk. In general, highly damaging *de novo* variants confer risk for a broad spectrum of neurodevelopmental and neuropsychiatric disorders, including ASD, SCZ, and DD. Intriguingly, in addition to the general overlap, we further find a significant (p= 0.001804) ~2-fold enrichment of *de novo* LoF mutations in ASD genes in DD probands also diagnosed with ASD, compared to the rest of DD probands. These findings support the repeatedly observed convergence of the biology and etiology between neurodevelopmental disorders and also illustrates the existence of potentially distinctive genetic architecture specific to different disorders, namely ASD & DD. .

1512F

Targeted deep sequencing reveals significant enrichment of putatively damaging rare variants in reading and language genes. *A.K. Adams[1], D.T. Truong[2], M.M.C. DeMille[2], B.F. Pennington[3], S.D. Smith[4], R.K. Olson[5], J.R. Gruen[1,2].* 1) Department of Genetics, Yale University, New Haven, CT; 2) Department of Pediatrics, Yale University, New Haven, CT; 3) Department of Psychology, University of Denver, Denver, CO; 4) Department of Pediatrics, University of Nebraska at Omaha, Omaha, NE; 5) Department of Psychology, University of Colorado at Boulder, Boulder, CO.

Reading disability (RD; dyslexia) is a common disorder with prevalence estimates ranging from 5% to 17%. Individuals with RD fall behind their peers by middle school in terms of reading performance, and remain impaired. Without intervention, affected individuals have lower SES and poorer educational outcomes over the course of their lives. Twin and family studies have demonstrated moderate to high heritability values of 0.4-0.8 for RD. Given the strong genetic component, a genetic screen could be used to identify children at risk, allowing them to receive intervention early, when it is most effective. Understanding the full genetic landscape of RD has proved troublesome, with known associations not accounting for a large portion of the heritability. This is at least partly due to a lack of large population or case-control cohorts limiting the ability to identify common variants through GWAS, and a paucity of resequencing reports of genes previously associated with reading and language to identify rare variants of high putative effect. Utilizing a targeted sequencing approach, 11 curated loci for reading and language performance were selected for deep sequencing from 96 RD cases. Cases were selected from the Colorado Learning Disability Research Center collections based on poor performance on a well-studied composite metric derived from the Peabody Individual Achievement Test. Loci of interest were isolated and sequenced. Resulting sequence was aligned to human reference genome hg19, and observed variants were scored for putative effect using SIFT and Polyphen-2. Two genes, *CCDC136* and *FLNC*, both encoded on 7q32, had 17 missense variants in 192 case chromosomes, showing a high disproportional enrichment of rare (MAF <0.05), and putatively damaging (Polyphen-2 score > 0.8) coding variants relative to the 23 other genes that were sequenced. Comparing these results to 503 individuals of European ancestry from the 1000 Genomes Project unselected for reading performance, revealed a nearly 2-fold enrichment of identified variants (2-tailed Fisher's Exact P= 0.0392) in these two genes. Other regions demonstrating disproportional enrichment of rare variants of high effect included the *DCDC2-KIAA0319* locus, within which the gene *FAM65B* (12 variants) was prominent. Taken together, RD follows the same pattern of other complex disorders, with enrichment of rare variants of high putative effect in reading and language genes.

Consanguinity negatively affects scholastic success. *N. Ghiasvand[1,2], H. Gholamhoseini[3], F. Rashidi[4], E. Samarbafzadeh[4], A. Solgi[1], R. Ghiasvand[5], F. Yaghoubi[1], M. Zabihi[1], S. BaniArdalan[1], M. Motejali[1], Z. Jahani[1], M. Sinclair[2], K. Szostak[6], N. Maghsoudi[4], A. Zali[1].* 1) Functional Neurosurgery Research Center, Shahid Beheshti University of Medical Sciences, Tehran, Iran; 2) Biology Department, Grand Valley State University, Allendale, Michigan, USA; 3) Radiology Department, Modares Hospital, Shahid Beheshti University of Medical Sciences, Tehran, Iran; 4) Neuroscience Research Institute, Shahid Beheshti University of Medical Sciences, Tehran, Iran; 5) Department of Biostatistics, Faculty of Medicine, University of Oslo, Oslo, Norway; 6) Biomedical Sciences Department, Grand Valley State University, Allendale, Michigan, USA.

BACKGROUND: The association between consanguinity and simple autosomal recessive traits has long been established. However, some recent studies indicate a possible association between a number of complex traits and consanguinity. To investigate this controversial issue with regard to education educability we studied the relationship between consanguinity and scholastic success. METHOD: In Iran, higher education of children is of high priority for families, and annually more than a million competitors compete in the nation-wide university entrance exam for less than 100,000 seats. For this study the average coefficients of inbreeding (α) for four student groups with normal IQ, and also for their parents were calculated and compared. The four student groups included: 1) Struggling students who appeared to be incapable of obtaining a high school diploma. 2) Students who could successfully finish high school. 3) Students enrolled in a 4-year B.Sc. program in a top public university in Tehran. 4) Medical and engineering students who ranked among the top 400 in the nation-wide competition. For this study students were recruited after giving informed consent and obtaining internal review board approval. RESULTS: The coefficients of inbreeding for these groups were significantly different from each other; smaller values for those with greater scholastic success. Compared to their parents, the coefficients of inbreeding for groups 1 and 4 were significantly larger and smaller, respectively. The coefficients of inbreeding for groups 2 and 3 were not significantly different from those for their parents. CONCLUSION: Apparently, consanguinity results in inbreeding depression for scholastic success, suggesting that the genes involved with this complex trait act in a directional dominance - not in an additive model that has long been postulated for such traits. Based on this finding, countries with high prevalence of consanguinity may increase their national IQ and also their people's scholastic achievement by educating the public about the undesirable consequences of consanguineous marriages. .

Compound effects of copy number variants del 1q21.2 and dup 17q12.
A. Goldberg[1], C.K. Stein[2], R. Auerbach[3], L. Pellegrino[1], M. Byler[1], R.R. Lebel[1].
1) Center for Development, Behavior and Genetics, Dept Pediatrics, SUNY Upstate Medical University, Syracuse, NY; 2) Cytogenetics Laboratory, Dept Pathology, SUNY Upstate Medical University, Syracuse, NY; 3) Binghamton, NY.

A 4 year old female presented with the constellation of poor growth, developmental delay, dysgraphia, coordination disorder, language disorder, chronic cough, hoarse voice, myopia, and ADHD. She had been the product of a non-consanguineous union, born at 39 weeks of gestation by vaginal route to a 32 year old primigravid Caucasian woman whose pregnancy was uncomplicated. Paternal age was 35 at that time. The family history was notable for learning disabilities in both parents, and the mother is short of stature. Physical examination for the patient was notable for short stature, thin habitus, microcephaly, crowded dentition, hoarse voice, fifth finger clinodactyly, joint laxity, low pedal arches, and hypopigmented rings of spots on the irides (reminiscent of Brushfield spots). Microarray analysis revealed two clinically significant copy number variants (CNV), a 2.4 MB deletion of 1q21.2 and a 1.9 MB duplication of 17q12. Microarray analysis for the parents was declined under their insurance plan, but fluorescent in situ hybridization (FISH) analysis showed the CNVs to be of maternal (1q21.2) and paternal (17q12) origin. To our knowledge, there are no previous reports of this combination of anomalies, and the constellation of features is inconsistent with any existing identified syndrome. Girirajan et al (2012) found that patients with more than one copy-number variant often have more dramatic presentations than what would be expected with either of the copy-number variants alone. This appears to be the case for our patient as she manifests a more adverse phenotype than is found in either of her parents.

1515F

Complex form of mental retardation identified by next generation sequencing. *D. Panahi Zadeh.* Social Insurance, Ahvaz, Iran.

We found a nonsense change at c.486C>G, p.Tyr162* of the FAM126A gene that is to date unreported and regarding prediction programs is likely-pathogenic. This gene is also reported to the cause Leukodystrophy, hypomyelinating, 5 characterized by weakness and wasting of the lower limbs, scoliosis, progressive, developmental delay (apparent after the first year of life), delayed motor development, mental retardation, mild to moderate, cerebellar signs, abnormal folding of the myelin sheath, peripheral neuropathy with variable severity. Affected son is homozygous for detected change. His parents, and his healthy brother and sister are heterozygous. .

1516W

6q26 and 16p12.2 heterozygous deletions support oligogenic model for autism spectrum disorder. *C.C.V. da Silva-Camargo[1], J. Rosenfeld[2], S. Raskin[1,3], V.S. Sotomaior[1].* 1) Group for Advanced Molecular Investigation (NIMA), Graduate Program in Health Sciences, School of Medicine, Pontifícia Universidade Católica do Paraná, Curitiba, Brazil; 2) Signature Genomics, PerkinElmer, Inc., Spokane, Washington, USA; 3) GENETIKA – Centro de Aconselhamento e Laboratorio de Genetica, Curitiba, Paraná, Brazil.

The development of autism spectrum disorder (ASD) is related to multiple factors in particular the genetics ones. With the highest heritability observed for commons neuropsychiatric disorder, ASD is caused frequently by copy number variations (CNVs). Studies of the genetic basis of this disorder have identified a large number of candidate mutations and genes, supporting an oligogenic model for the development of this disease. Through microarray-based comparative genomic hybridization (aCGH) we detected two microdeletions (in 6q26 and 16p12.2) in a 10-year-old autistic female with developmental and speech delay, seizures, difficulty with coordination and literacy, repetitive thoughts and movements and tendency to social isolation. The 6q26 deletion is entirely within the *PARK2* gene, which encodes the protein parkin that has important roles in mitochondrial homeostasis and degradation of damaged proteins and has been associated with development of ASD as well as other neurodegenerative diseases. The recurrent 16p12.2 deletion encompassing *OTOA*, *METTL9* and *IGSF6* genes, microdeletions in this region has been previously reported in individuals with autistic features, and was proposed to contribute to the development of ASD when other factors are present. We propose that these two deletions are contributing synergistically to the patient's phenotype, consistent with the proposed oligogenic model of ASD where multiple genetic factors interact to lead to autistic features.

1517T

Mouse models of mitochondrial dysfunction display autism endophenotypes. *T. Yardeni, M. Patel, M. McManus, D.G. Murdock, D.C. Wallace.* Center for Mitochondrial and Epigenomic Medicine, Children's Hospital of Philadelphia, Philadelphia, PA.

Autism spectrum disorder (ASD) is characterized by impaired social interaction and communication, repetitive behavior, and restricted interests. Numerous studies have reported mild mitochondrial defects in ASD patients, including reduced mitochondrial enzyme levels and respiration in muscle, brain autopsies, and lymphoblastoid cell lines. It has been concluded, based on a meta-analysis, that children with ASD have a spectrum of differing severities of mitochondrial dysfunction. In addition, ASD has a strong male bias (4:1) which is inconsistent with Mendelian expectations but is characteristic of milder mtDNA diseases such as Leber Hereditary Optic Neuropathy (LHON). Based on the above facts, we have hypothesized that partial mitochondrial defects in mice due to nuclear DNA (nDNA), mitochondrial DNA (mtDNA), or environmental insults could result in autistic behavioral phenotypes. To test this hypothesis, we exposed our unique mouse models of mitochondrial dysfunction to a battery of behavioral tests that can reveal ASD endophenotypes. Our results on three month old mice harboring the mtDNA *ND6* nt 13997G>A P25L mutation with or without a null mutation in the nDNA nicotinamide nucleotide transhydrogenase gene *(Nnt)* revealed autism endophenotypes. These included repetitive activity (displayed as increased marble burying) and decrease in social interaction monitored by three-chamber social approach test. These results show for the first time that mutations that cause partial mitochondrial dysfunction are sufficient in themselves to cause autism-associated phenotypes. Since mitochondrial function requires one to two thousand nDNA genes plus hundreds of copies of the mtDNA, inactivation of one allele of a nDNA bioenergetic gene, functionally different mtDNA lineages, mildly deleterious mtDNA mutations, and/or mitochondrial toxins could all contribute to the complex etiology of autism.

1518F

Lack of association between *COL1A1* **polymorphisms and otosclerosis in Mexican patients.** *M.L. Arenas-Sordo[1], L. Casas-Avila[1], M. Valdes-Flores[1], G. Cordero-Olmos[2], C.E. Urquijo-Torres[1], L. Hernandez-Hernandez[3].* 1) Genetics, Instituto Nacional de Rehabilitacion, Mexico City, Mexico City, Mexico; 2) Othorinolaringology; 3) Audiology.

   Introduction. Otosclerosis is an illness that affects the optic capsule, caused by changes in bone metabolism. It is one of the most common causes of conductive hearing loss in adults and tends to be progressive in nature. It is the cause of 5–9% of the cases with hearing loss and of 18–22% of conductive hearing loss. From a genetic point of view, otosclerosis is usually considered as a multifactorial disease. Despite many studies over the time, a lot of etiological factors and theories have been suggested but the process of development of the otosclerosis remains unclear. *COL1A1* was the first gene to be associated with otosclerosis. This gene shared clinical and histopathological findings between otosclerosis and osteogenesis imperfect and is also related with osteoporosis. Some studies have demonstrated there are association between some polymorphisms and otosclerosis: rs2857396, rs16970089, rs113237935, rs9898186, rs 1800012, rs 2586498, rs2586488, rs1061237 (Americans), rs86498 y rs1061237 (Spanish), rs16970089, rs11327935, rs9898186, rs1800012, rs2586498, rs2857396, rs2586488, rs1061237 (Germans), rs16970089, rs11327935, rs9898186, rs1800012, rs2586498, rs2075555, rs2141279, rs2857396, rs2075559 (Belgium), and many others. The aim of this study was to determine if there is association between otosclerosis and the polymorphisms rs1107946, rs2586498, rs2141279 and rs1800012 of *COL1A1*. **Methods**.A case-control study was done with 90 cases and 135 controls. All patients and controls have complete medical records and audiological studies: otoscopy, audiometry, and signed the informant consent. The molecular study was done with RT-PCR **Results**: The 56% of the patients have family history of otosclerosis. From the 90 patients 70% were female and 30% male and in the controls 76% and 24% respectively. The mean age was 47.63 ± 9.8 years (23-65) in cases and 41.27 ± 12.05 years (24-75) in controls. The disease was bilateral in 82 cases (91%) and unilateral in 8 (9%), more frequent left side involved. The disease started before 40 years of age in 85% of the cases and the evolution mean time of evolution was 14.12 ± 9.7 years. None of the polymorphisms showed association with otosclerosis in Mexican patients. **Conclusions.** We did not found any association. This could be because we are different from other populations and/or the sample size was not big enough. Also one polymorphism (rs214179) was not in Hardy Weinberg equilibrium.

1519W

The first GWAS for tinnitus indicates a very low heritability for this trait. *E. Fransen[1,2], A. Gilles[3], P. Van de Heyning[3], G. Van Camp[1].* 1) Center for Medical Genetics, University of Antwerp, Antwerp, Belgium; 2) StatUa Center for Statistics, University of Antwerp, Antwerp, Belgium; 3) ENT department, Antwerp University Hospital, Edegem, Belgium.

   Tinnitus, the perception of an auditory phantom sound in the form of ringing, buzzing, roaring or hissing in the absence of an external sound source, is perceived by approximately 15% of the population of which 2.5% experiences a severely bothersome tinnitus. The cause of tinnitus may be otologic (hearing loss, noise trauma, Ménière's disease, acoustic neurinoma, ototoxic medications or substances), neurologic (multiple sclerosis, head injury), metabolic (thyroid disorder, hyperlipidemia, vitamin B12 deficiency) or psychogenic (depression, anxiety, fibromyalgia). However, despite thorough clinical examination, tinnitus etiology often remains unclear. We performed a genome-wide association study on 916 independent individuals, of whom 18% reported episodes of tinnitus lasting for longer than 5 minutes. After imputation and quality checking, we tested the association between the tinnitus phenotype and 4,000,000 SNPs using PLINK (v1.07) assuming an additive model. None of the SNPs reached the threshold for genome-wide significance ($p < 5E-8$). The most significant SNPs, which are situated outside coding genes, reach a p-value of 3.4E-7. Using the Genetic Analysis of Complex Traits (GACT) software, we estimated the percentage of the variance explained by all SNPs in the GWAS. This showed a very low heritability of tinnitus (3.2%).

1520T

Linkage analysis of hearing loss severity identifies a potential modulator of *TMTC2*, a novel dominant mutation for familial sensorineural hearing loss. *J. Kent[1], C. Erbe[2], W.-M. Kwok[3], H. Guillen Ahlers[1], C.L. Runge[2], M. Olivier[1].* 1) Dept Genetics, Tx Biomed Res Inst, San Antonio, TX; 2) Dept Otolaryngology & Communication Sciences, Medical College of Wisconsin, Milwaukee, WI; 3) Dept Anesthesiology, Medical College of Wisconsin, Milwaukee, WI.

Familial sensorineural hearing loss (SNHL) is a complex of inherited pathologies of cochlear structure or the auditory nerve. While many SNHL genes have been identified, the full spectrum of genetic risk is not known. In a six-generation family of Northern European descent (N=46), we have recently identified a SNP, rs35725509, in *TMTC2* (chr12q21) as a novel autosomal dominant mutation sufficient to cause early-onset, moderate to severe SNHL in this family, and have confirmed association of this variant with SNHL in the general population. However, two branches of the family (first and second cousins in generation IV and their offspring) exhibit variation in severity and rate of progression of SNHL, suggesting the possibility of genetic modifier(s) segregating in the family. Using a subset of family members (N=36) with audiographic data and/or confirmed normal hearing, heritability of affection status was 1.0 (p=1e-07) using a probit model in SOLAR. We performed two-point genome-wide linkage scans in SOLAR using a panel of 79,163 Affymetrix SNP genotypes. We replicated our original primary linkage (LOD=2.9) of SNHL affection status to chr12q21, and this QTL accounted for all of the heritability for SNHL status. However, for a severity measure, audiographic threshold pure tone average (PTA, dB), heritability was 0.67+/-0.38 (p=0.03) and the peak linkage was at 5q13.2-q13.3 (LOD=9.3). The significance of the chr5q13 QTL as a potential modifier of SNHL severity needs further study. This locus has been reported as an autosomal recessive QTL for SNHL in a Qatari family. Genes in our linkage region of potential relevance include *MAP1B*, which encodes a microtubule-associated protein required for neurogenesis, and *S100Z*, which encodes a calcium binding protein. S100 family proteins are known to modulate calcium and potassium ion channels. TMTC2 is associated with the endoplasmic reticulum calcium uptake pump SERCA2B (ATP2A2), also on chr12. Other genes at chr5q13 may be relevant to the function of the TMTC2/SERCA2B complex, and normal auditory function.

Whole exome sequencing (WES) analysis in a Caucasian family with keratoconus. *Y. Bykhovskaya[1], E.L. Crowgey[2], Y. Liu[3], X. Li[4], Y.S. Rabinowitz[1].* 1) Cedars-Sinai Medical Center, Los Angeles, CA; 2) Nemours Alfred I. Dupont Hospital for Children, Wilmington, DE; 3) The Medical College of Georgia, Georgia Regents University, Augusta, GA; 4) Institute for Translational Genomics and Population Sciences, Biomedical Research Institute, Harbor-UCLA Medical Center, Los Angeles CA.

Genome-wide linkage analysis in a large four generation Caucasian pedigree with non-syndromic keratoconus mapped the responsible gene to a novel 8.2 MB genomic region located at 5q14.3-q21.1 with LOD of 3.53 which was further narrowed down to 5MB (96 Mb-100 Mb) using high density SNP panel with LOD of 2.49. We also identified SNPs associated with the trait under dominant model with p values ranging from 0.05 to 0.004. To identify keratoconus susceptibility variant (s), we performed whole exome sequencing in nine family members representing three family trios. After appropriate level of quality of the sequenced reads was confirmed by fastqc, a platform independent NGS quality tool, sequences were aligned to the human reference genome hg19 using bwa-mem (version 0.7.4). Following GATK best practices, Bam files were processed using Picard Tools (version 1.67) and GATK Haplotyper (version 3.4-0) for SNP and small indel detection under the default parameters. Variant call file (VCF version 4.1) was then annotated with SnpEff (Version 3.3a). In total, more than 500K variants were identified. No variants so far have been identified in top candidate gene in the region *CAST* which was implicated in genetic susceptibility to keratoconus in independent family and case-control panels. However, we have identified a combination of one common and one rare variant in the adjacent functionally related genes also located in the linkage region as a potential cause of keratoconus in this family. We are also performing comprehensive analysis of all sequencing data using multiple bioinformatic tools including variant prioritization using biological evidence and family segregation analysis using Phevor and CNV analysis using Conifer (version 0.2.2). We are also performing linkage analysis of all WES variants to identify additional evidence of linkage on chromosome 5 and/or other genomic regions. Identification of the variant(s) causing non-syndromic keratoconus in this family will provide significant new information on the genetic susceptibility to this ocular disease with complex genetic inheritance.

1522W

Identification of loci associated with response to intraocular pressure treatments in the Genetic Epidemiology Research on Adult Health and Aging cohort. *H. Choquet[1], K.K. Thai[1], R. Melles[2], E. Jorgenson[1]. 1) Kaiser Permanente, Division of Research, Oakland, CA; 2) Kaiser Permanente, Department of Ophthalmology, Redwood City, CA.*

Purpose: Elevated intraocular pressure (IOP) is the most important modifiable risk factor for glaucoma, a common eye condition which can lead to vision loss. Topical IOP lowering medications are used to control elevated IOP levels, however, there is variability among patients in response to these treatments, suggesting the influence of modifying factors. Here, we examine whether genetic factors may explain some of the variability in treatment response. **Methods:** We conducted a genome-wide association study (GWAS) of response to IOP lowering medications in the Kaiser Permanente Genetic Epidemiology Research in Adult Health and Aging (GERA) cohort. As part of standard care, subjects had IOP measurements and were treated with IOP lowering medications for elevated IOP. We identified 4,037 patients of European ancestry with prescriptions for alpha-adrenergic agonists, beta-blockers, carbonic anhydrase inhibitors, Cosopt, and prostaglandin analogs. We selected IOP measurements in subjects' right eyes pre-treatment (up to 60 days prior to first prescription) and post-treatment (up to 120 days after). Response to IOP treatment was defined as the difference in IOP between the two measurements and as the percentage change in IOP measurement. Over 6.6 million genetic markers were imputed with $r^2>0.8$ and minor allele frequency > 0.05 using the 1000 Genomes reference panel. We first examined association between genetic markers and response to treatment, in the five treatment groups separately, using linear regression. A meta-analysis was then conducted by combining all the treatment groups. **Results:** We identified 12 loci that reached a suggestive level of association ($p<10^{-6}$) in individual treatment group analyses. No SNP associations reached genome-wide significance. By combining the five treatments in a meta-analysis, we observed a suggestive association ($p=4.12*10^{-7}$) between rs4876582 on chromosome 8 and response to IOP treatment. **Conclusions:** While we did not identify a genome-wide significant association with response to IOP treatment, we would expect 5 suggestive loci and we observed 12. Our results are consistent with a role for genetic factors underlying some of the variability among patients with elevated IOP. Despite this being the largest study to date of the genetics of IOP treatment response, additional analyses are needed to further refine these findings. Nonetheless, this is an important first step toward the pharmacogenetics of IOP treatment response.

1523T

Age-related macular degeneration patients carrying rare variants in the *CFH* and *CFI* genes have a reduced ability to degrade C3b. *M.J. Geerlings[1], M. Kremlitzka[2], B. Bakker[1], S.C. Nilsson[2], N.T. Saksens[1], Y.T. Lechanteur[1], M. Pauper[1], J. Corominas[1], S. Fauser[3], C.B. Hoyng[1], A.M. Blom[2], E.K. de Jong[1], A.I. den Hollander[1,4]. 1) Department of Ophthalmology, Donders Institute for Brain, Cognition and Behaviour, Radboud University Medical Center, Nijmegen, the Netherlands; 2) Division of Medical protein chemistry, Department of Translational Medicine, Lund University, Malmö, Sweden; 3) Department of Ophthalmology, University Hospital of Cologne, Cologne, Germany; 4) Department of Human Genetics, Donders Institute for Brain, Cognition and Behaviour, Radboud University Medical Center, Nijmegen, the Netherlands.*

BACKGROUND Tight regulation of the complement system is needed to protect the cells of our body from tissue damage. In age-related macular degeneration (AMD) the complement system is highly burdened by genetic variation. Rare variants in complement factor H (*CFH*), complement factor I (*CFI*), component 9 (*C9*) and component 3 (*C3*) have been described to play an important role in AMD pathogenesis. It has been postulated that patients carrying these variations may have higher complement activation levels than AMD patients in general, but this has not yet been experimentally proven. Therefore, we aimed to determine the effect of rare genetic variants on levels of complement components in serum. In addition, we compared the activity of the complement system in rare variant carriers compared to non-carriers to evaluate if carriers are more likely to benefit from complement inhibiting therapy. **METHODS** Whole exome sequencing data of 22 severely affected AMD families was filtered for rare variants in complement genes *CFH*, *CFI*, *C9*, and *C3*. In addition, 3200 individuals from the European Genetic Database (EUGENDA) were genotyped using KASP Genotyping System (LGC). Serum samples were obtained from carriers of identified rare variants (n=177) and a non-carrier control set (n=157). The concentrations of Factor H, Factor I, C9 and C3 in serum samples were measured by ELISA. Additionally, serum samples were incubated with C3b-AFG47 and separated on 10% SDS-PAGE. The ability to degrade C3b was calculated as the ratio between the α'chain and the 43-kDa product. **RESULTS** Novel and previously described rare variants were predominantly found in cases and contributed to an increased risk to develop AMD (OR 2.1; p<0.001). *CFI* carriers (Gly119Arg; Leu131Arg) showed decreased factor I serum levels. Carriers of the *C9* Pro167Ser variant had increased C9 serum levels compared to non-carriers. Factor H and C3 serum levels did not differ between carriers and non-carriers. Carriers of rare variants in *CFH* (Ser193Leu; Arg175Gln) and *CFI* (Gly119Arg; Pro553Ser; Leu131Arg) genes had a reduced ability to degrade C3b compared to non-carriers. Additionally, we detected a correlation between both FH and FI levels with the ability to degrade C3b in non-carriers individuals (R^2 0.35 and R^2 0.31, respectively; p<0.001). **CONCLUSION** Carriers of rare variants in *CFH* and *CFI* have higher levels of complement activation and may benefit more from complement inhibiting therapy than AMD patients in general.

1524F

A cumulative genetic risk score is associated with younger age of diagnosis in primary open angle glaucoma. *J. Wiggs[1], R. Guo[1], J.N. Cooke Bailey[2], R.P. Igo, Jr.[2], J.L. Haines[2], L.R. Pasquale[1], NEIGHBORHOOD consortium.* 1) Dept Ophthalmology, Harvard Med Sch, MEEI, Boston, MA; 2) Dept of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, Ohio.

   Purpose: To determine if dosage of 12 primary open-angle glaucoma (POAG) genetic risk variants are associated with glaucoma features related to disease severity: age of diagnosis, disease severity based on visual field mean defect (MD) , and need for glaucoma filtration surgery. **Design:** Retrospective observational study with case-control and case-only components **Participants:** 976 POAG cases and 1140 controls from the Glaucoma Genes and Environment Study (GLAUGEN) and 1971 cases and 2347 controls from the National Eye Institute Glaucoma Human Genetics Collaboration (NEIGHBOR). **Methods:** We aligned the variant associated with increasing risk of POAG for 12 SNPs known to be associated with POAG in our case control sets. In case only analyses we formulated a weighted genetic risk score (GRS) from this panel and assessed the association with glaucoma features of interest. Multivariable results from cohort specific analyses were combined with meta-analytical techniques. **Main outcome measures:** Age of disease onset, Mean deviation (MD) on visual field testing (Humphrey) and need for incisional glaucoma surgery. **Results:** In case control analyses 10 of 12 SNPs had at least nominal association with POAG (p<0.05) and the GRS was strongly associated with POAG (P=5.1E-71). In case only analysis, the GRS ranged from 7 to 21 (maximum score was 24). In multivariable analysis, each unit higher in GRS was associated with a 0.26 year earlier age at diagnosis (95% confidence interval: -043, -0.08; p=0.005). These results were most significantly driven by GAS7 rs9897123 (beta = -0.72; 95% CI: -1.27, -0.17; p=0.01), FOXC1 rs2745572 (beta = -0.67; 95% CI: -1.29, -0.04; p=0.036) and CDKN2B-AS1 rs4977756 (beta = -0.69; 95% CI: -1.28, -0.10; p=0.021). Individuals with >19 risk alleles had an average age of diagnosis 4 years earlier than those with <9 risk alleles. The GRS was not related to maximum MD from the eye with more functional loss (beta = -0.019; 95% CI: -0.15, 0.11; p=0.77); nor was it associated with the need for filtration surgery in GLAUGEN where this information was available (OR=1.02; 95% CI: 0.93, 1.11; p=0.71). **Conclusion**: A higher dose of POAG risk alleles was associated with an earlier age of glaucoma diagnosis. On average, POAG patients with the highest GRS had 4.0 year earlier diagnosis of disease. Discovery of more POAG loci is needed to fully predict glaucoma features from genetic data. Funded by NIH/NEI R01EY022305.

1525W

Family-based rare variant association study of familial myopia in Amish and Ashkenazi Jewish families. *D. Lewis[1], C.L. Simpson[1,2], A.M. Musolf[1], L. Portas[1], F. Murgia[1], D. Stambolian[3], J.E. Bailey-Wilson[1].* 1) Computational and Statistical Genomics Branch, National Human Genome Research Institute, National Institutes of Health, Baltimore Maryland, United States; 2) University of Tennessee Health Sciences Center, Memphis, Tennessee, United States; 3) Ophthalmology, Perelman School of Medicine, University of Pennsylvania, Philadelphia, Pennsylvania, United States.

   Myopia is the largest cause of uncorrected visual impairments globally and constitutes a major public health problem that is dramatically increasing in many populations. Its complex multifactorial component is governed by both genetic and environmental factors that promote its development. Genome-wide association studies (GWAS) and linkage studies have identified multiple loci influencing the risk of developing myopia but, few causal variants have been identified. Compared to common variants, rare variants are more likely to be mutations of recent origin and therefore more likely to be population specific. Therefore, because of population history and differences in linkage disequilibrium (LD) patterns, it can potentially lead to spurious associations. The case-parent trio design has an advantage of dealing with confounding due to population structure by employing a family-based association test such as the transmission disequilibrium test (TDT). We have performed family based association analysis examining common and rare variants using the family-based association test (FBAT) software package on 37 Amish and 63 Ashkenazi Jewish families with strong family history of myopia from the Penn Family Study using genotypes from the Illumina HumanExome v1.1 array plus 24,263 custom SNPs. Individuals in the families were defined as myopic if their average refractive error was <= -1 Diopter (D) and were considered unaffected if their average refractive error was > 0.0 D; others were coded as having an unknown phenotype. More stringent rules were used to code children as unaffected since children's eyes become more myopic fairly rapidly during childhood and adolescence. Noteworthy are two variants (rs135 and rs136) for Amish families and one variant (rs6972578) for Ashkenazi Jewish families, all in the same gene (OSBPL3) that were suggestively associated (*p* < 1.4 x10[-4]) with common myopia under a significant linkage peak previously detected in a set of African American families from the Penn Family Study. To follow-up this observation of association of different variants in the same gene in two different samples, we are using rare-variant (RV) association analysis in the TDT framework to perform gene-based tests with the rare variants in these exome chip data. The RV-TDT framework can control for both admixture and substructure and thus avoid spurious associations. This method has the potential to improve our power to detect causal genetic variants.

***RRAGC* is associated with age-related macular degeneration (AMD) progression rate from intermediate to advanced AMD, implicating mTORC1 signaling in AMD pathogenesis.** *P.J. Persad[1], R.J. Sardell[1], S.S. Pan[1], P. Whitehead[1], L.D. Adams[1], R.A. Laux[2], J.A. Fortun[3], M.A. Brantley Jr.[4], J.L. Kovach[3], S.G. Schwartz[3], A. Agarwal[4], J.L. Haines[2], M.A. Pericak-Vance[1], W.K. Scott[1].* 1) John P. Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami , FL; 2) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH; 3) Bascom Palmer Eye Institute, University of Miami Miller School of Medicine, Miami, FL; 4) Ophthalmology and Visual Sciences, Vanderbilt University Medical Center, Nashville, TN.

Age-related macular degeneration (AMD) is a complex disease for which 52 risk variants across 34 loci have been identified. However, only some of these loci (*CFH, ARMS2, C2/CFB, C3, LIPC, ABCA1, COL8A1,* and *RAD51B*) have been associated with progression rate to advanced AMD. Identifying genes influencing progression could provide novel targets for therapeutics aimed at slowing disease pathogenesis and preserving visual acuity. Genome-wide association studies to identify novel loci influencing progression from intermediate to advanced AMD are lacking. Therefore, to identify progression loci, we examined a dataset of 397 European-descended subjects (606 eyes with intermediate AMD at baseline of which 178 eyes progressed) with at least two examinations and a mean follow-up time of 2.5 years (range 0.05-13). The mean age at baseline was 76.5 years, and 58% of subjects were female. Genome-wide genotyping was performed using the Illumina HumanCoreExome array and the dataset was imputed to 6.3 million variants (with imputation quality (R^2)>0.3 and minor allele frequency$\geq$0.05) using IMPUTE2 and the 1000 Genomes Project Phase I reference panel. Cox proportional hazards regression models were used to assess association between time to progression in each eye from intermediate AMD (extensive intermediate-size drusen or any large drusen) to advanced AMD (geographic atrophy and/or choroidal neovascularization) and imputed SNP dosage (with non-progressors censored at the time of last examination). Models included the top two principal components from population stratification analyses, sex, and age at baseline, and accounted for correlation between an individual's eyes. Thirteen SNPs in the *RRAGC* gene had genome-wide significant main effects [minimum p-value (rs188028731)=1.15×10^{-9}, hazard ratio (HR)=3.12, 95% CI=2.16-4.51]. These SNPs were associated with a shorter time to progression. Two other intergenic regions on chromosomes 3 and 12 produced genome-wide significant results. The 52 known AMD risk variants were not nominally statistically significant (p<0.01). *RRAGC* regulates mTORC1 signaling. This pathway influences neovascularization in AMD and is under consideration as a target for drug development. Thus, identification of *RRAGC* as a new progression locus may facilitate development of strategies for slowing progression rate from intermediate AMD to advanced AMD, slowing vision loss, and improving management of the disease in patients.

Genetic screening of the homozygous p.V37I variant in *GJB2* may facilitate early detection of postnatal childhood hearing loss. *T. Yang, Y. Chen, H. Wu.* Dept of Otolaryngology - Head And Neck Surgery, Xinhua Hospital, Shanghai, Shanghai, China.

Purpose: Widespread genetic screening of the homozygous p.V37I variant in *GJB2* may provide a new strategy for early detection of the postnatal childhood hearing loss. The effectiveness of this strategy, however, has not been evaluated in practice. Our study aimed to identify children with postnatal childhood hearing loss due to the homozygous p.V37I variant in a large Chinese Han cohort. **Methods:** Children with homozygous p.V37I were identified from 28378 Chinese Han children born in 2006 by high resolution melting analysis. Their hearing status was evaluated and compared with that of 200 randomly selected wild-type children at the age of eight. Postnatal childhood hearing loss was diagnosed with reviewing the newborn hearing screening result. **Results:** The homozygous p.V37I variant was detected in 126 (0.44%) of the 28378 children. Among them, 18 (14%) had sensorineural mild-to-moderate hearing loss at the age of eight including 8 (6.3%) with postnatal childhood hearing loss who passed their newborn hearing screening at birth. The homozygous p.V37I variant was associated with an increased risk of postnatal childhood hearing loss (RR, 27.1; 95% CI, 1.6-465.2; *P*=0.023). Most (7/8) children with postnatal hearing loss did not have any risk-indicating features listed in the Position Statement 2007 from the Joint Committee on Infant Hearing. **Conclusion:** Widespread newborn screening for the homozygous p.V37I variant in *GJB2* may reveal the genetic predisposition to congenital and postnatal childhood hearing loss in 0.44% of Chinese Han general population. With continued monitoring of the children's hearing, early detection of the postnatal childhood hearing loss can be achieved in approximately 6.3% of this specific susceptible group.

1528W

Genome-wide association study of Fuchs endothelial corneal dystrophy in a Japanese population. *M. Nakano[1], H. Adachi[1], Y. Tokuda[1], H. Nakagawa[2], Y. Ikeda[2], M. Ueno[2], C. Sotozono[2], S. Kinoshita[2,3], K. Tashiro[1].* 1) Dept Genomic Med Sci, Kyoto Prefectural Univ Med, Kyoto, Japan; 2) Dept Ophthal, Kyoto Prefectural Univ Med, Kyoto, Japan; 3) Dept Front Med Sci & Tech Ophthal, Kyoto Prefectural Univ Med, Kyoto, Japan.

Fuchs endothelial corneal dystrophy (FECD, MIM: 136800) is an inherited, progressive and degenerative disease affecting the corneal endothelium. In United States, FECD is regarded as a common disease - ~5% of the population over 40 years old suffer from the disease, whereas the prevalence of FECD is considered to be rarer in Japanese. In Caucasian, an intronic variant (rs613872) in the transcription factor 4 (*TCF4*) has been identified by a genome-wide association study (GWAS) as a significant risk factor of late-onset FECD. Furthermore, the expansion of CTG trinucleotide repeat in the third intron of *TCF4* was found to be associated with FECD patients in Caucasian. We also revealed that the CTG repeat in *TCF4* was significantly expanded in Japanese FECD patients compared to the controls, although the frequency of patients possessing expanded repeats was less than the Caucasian patients. These results suggested that additional undiscovered variants should be involved in the pathogenesis of FECD in Japanese. In this study, we therefore performed a GWAS in an attempt to identify novel susceptible variants in Japanese FECD patients. We earnestly recruited the patients together with the controls with informed consent from Sep. 2010 through Aug. 2015 at the University Hospital of Kyoto Prefectural University of Medicine and the Baptist Eye Clinic in Kyoto. Genomic DNA from the subjects was genotyped on illumina Infinium HumanCoreExome BeadChip with 538,448 variants according to the manufacturer's protocol. After removing samples and variants failed to pass the quality controls, the genotype data derived from 55 FECD patients and 445 controls were applied to a GWAS analyzing 278,032 autosomal variants. The association analyses were performed by PLINK and R software. As the results, we were not able to obtain any significant variants within 1 Mb of the *TCF4* locus. Especially, rs613872 in *TCF4* turned out to be monomorphic in our population, which was supported by the Japanese data based on NCBI dbSNP. By contrast, we succeeded in obtaining some suggestive loci other than *TCF4* locus, which seemed to be associated with the Japanese FECD patients. In particular, a genome-wide significant variant ($P < 5.0 \times 10^{-8}$) was identified at 6q15, and we are currently performing the replication analysis to confirm the result. Overall, these findings would provide the foundation for future studies to reveal the mechanism determining the FECD pathogenesis in different populations.

1529T

Genome-wide association study using the Japonica array for cold medicine-related Stevens-Johnson syndrome with severe ocular complications. *M. Ueta[1,2], H. Sawai[2], R. Shingaki[3], Y. Kawai[4], C. Sotozono[5], K. Kogima[4], M. Nagasaki[4], S. Kinoshita[1], K. Tokunaga[2].* 1) Department of Frontier Medical Science and Technology for Ophthalmology, Kyoto Prefectural University of Medicine, Kyoto, Japan; 2) Department of Human Genetics, Graduate School of Medicine, University of Tokyo, Tokyo, Japan; 3) Life Science Business Department, Healthcare Medical Business Promotion Division, Toshiba Corporation Healthcare Company, Tokyo, Japan; 4) Department of Integrative Genomics, Tohoku Medical Megabank Organization, Tohoku University, Sendai, Japan; 5) Department of Ophthalmology, Kyoto Prefectural University of Medicine, Kyoto, Japan.

A genome-wide association study (GWAS) for cold medicine-related Stevens-Johnson syndrome (CM-SJS) with severe ocular complications (SOC) was performed in a Japanese population. A recently developed ethnicity-specific array with genome-wide imputation that was based on the whole-genome sequences of 1,070 unrelated Japanese individuals was used. For GWAS, we used samples from 117 Japanese individuals with CM-SJS/TEN with SOC and 691 healthy Japanese volunteers and for validation, we included additional 21 Japanese CM-SJS/TEN with SOC patients and additional 192 healthy Japanese volunteers . Validation analysis with additional samples identified two new susceptibility loci on chromosomes 15 and 16. Moreover, interactive effects between the previously identified risk allele, *HLA-A*02:06*, and the newly detected risk variants were observed. This study confirmed the usefulness of GWAS using the ethnicity-specific array and genome-wide imputation based on large-scale whole-genome sequences. Our findings contribute to the understanding of genetic predisposition to CM-SJS with SOC.

1530F

Exploring the heritability of age-related macular degeneration endophe-notypes in the Ohio Amish. *N.A. Restrepo[1], E.S. Yeunjoo[1], R.J. Sardell[2], M.G. Nittala[3], L.D. Adams[2], R. Laux[1], D. Fuzzell[3], L. Reinhart-Mercer[2], L. Caywood[2], D. Dana[3], W.K. Scott[2], S.R. Sadda[2], D. Stambolian[4], M.A. Peri-cak-Vance[2], J.L. Haines[1].* 1) Epidemiology & Biostatistics, Case Western Reserve University, Cleveland, OH; 2) Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL; 3) Ophthalmology, Doheny Eye Institute, Los Angeles, CA; 4) Departments of Ophthalmology and Genetics, University of Pennsylvania, Philadelphia, PA.

Studies of the impact of vision impairment and blindness are rapidly accruing, resulting in a clearer picture of how vision loss will burden future economies and quality of life for global citizens. Genetics plays an integral role in the risk and onset of vision impairment and disease. Determining the genetic component to disease risk is the first step to studies of the genetic architecture of vision health. Heritability studies not only define the extent to which genetics influences interindividual variation of a phenotype, but also provide insight into environmental factors driving disease. Currently, 60% of the heritability of age-related macular degeneration (AMD) can be attributed to known common and rare genetic variants. The remaining unexplained heritability may partly reflect challenges defining the complex phenotype; the current classification system uses broad-scale grades that may not adequately represent the underlying biological basis of the disease. We hypothesized that parsing the AMD phenotype into heritable sub-phenotypes, each with a distinct genetic basis, will improve prediction of risk and increase our understanding of the genetic architecture of AMD. We sampled 228 related individuals from Amish families with early/intermediate AMD cases in Ohio. Individuals underwent detailed ophthalmologic exams including Ocular Coherence Tomography imaging to quantify retinal features, fundus imaging, and intraocular pressure. The Amish provide an excellent opportunity to analyze the heritability of complex traits given large nuclear families and relatively homogeneous environmental and genetic backgrounds. Utilizing a modified Twin study design under the ACE model, we calculated the additive genetic heritability for IOP as $h^2=0.88$ (0.84-0.93) and the unique environment at 11.7%. Estimates of CDR put additive heritability at $h^2=0.76$ (0.68-0.85) and unique environment at 14.2%. This study is the first reported estimate of the heritability of IOP and CDR in an Amish population, highlighting heritable, quantitative ocular traits that are both measurable in all individuals. Heritability estimates for IOP and CDR appear inflated compared to published estimates in other populations (0.29-0.74 and 0.56-0.78, respectively). This may be due to a highly shared environment which can inflate estimates. Additionally, heritability estimates are population specific and our results may simply reflect a population with low environmental burden for disease risk.

The highly variable response to anti-vascular endothelial growth factor (VEGF) drugs in neovascular age-related macular degeneration (nvAMD) patients is, in part, due to genetic predisposition. Several studies have implicated variants in genes associated with AMD and VEGF signaling, however, the results have been inconsistent. As a consequence, the nature of this genetic component needs to be further investigated. We sought to identify new variants influencing response to anti-VEGF therapy in nvAMD using candidate gene and genome-wide approaches. Response was defined as the change in best corrected visual acuity (VA) after the loading dose of three monthly ranibizumab or bevacizumab injections. In our candidate gene approach, we interrogated the role of four single nucleotide polymorphisms (SNPs) located in neuropilin-1 (*NRP1*), a co-receptor for VEGFA. The study cohort consisted of 377 nvAMD patients treated with ranibizumab. Patients carrying the GA or AA genotypes of SNP rs2070296 performed significantly worse than individuals carrying the GG genotype. A cumulative effect of rs2070296 in the *NRP1* gene and rs4576072 located in the *KDR* gene, previously associated with treatment response, was observed. Patients carrying two or more risk alleles performed significantly worse than patients carrying zero or one risk allele. In our hypothesis-free approach, 678 patients of European descent treated with ranibizumab or bevacizumab at five different clinics were genotyped using a custom-modified HumanCoreExome array (Illumina). After imputation and quality control procedures, 6,089,769 variants with a minor allele frequency ≥5% were assessed for association with treatment response per cohort. Linear regression analysis was conducted adjusting for baseline VA, age at first injection and the first two principal components, and the results were combined in a meta-analysis. Five suggestive association signals with a p-value <10-5 were identified. Replication of the top SNPs in a cohort of 900 European descent nvAMD patients is in progress and will be presented. A combined analysis of the discovery and replication cohorts may reveal novel genes influencing nvAMD treatment response. The cumulative effect of the variants identified in this project may be used in prediction models for treatment response to anti-VEGF injections, which in the future may help tailor medical care to individual needs.

Transcriptome profiling of human keratoconus corneas through RNA sequencing identifies collagen synthesis disruption and downregulation of core elements of TGF-β, Hippo, and Wnt pathways. *J.A. Karolak[1,2], M. Kabza[1,3], M. Rydzanicz[4], M.W. Szczesniak[3], D.M. Nowak[1,2], B. Ginter-Matuszewska[1,2], P. Polakowski[5], R. Ploski[4], J.P. Szaflik[5], M. Gajecka[1,2].* 1) Department of Genetics and Pharmaceutical Microbiology, Poznan University of Medical Sciences, Poznan, Poland; 2) Institute of Human Genetics, Polish Academy of Sciences, Poznan, Poland; 3) Department of Bioinformatics, Institute of Molecular Biology and Biotechnology, Adam Mickiewicz University in Poznan, Poznan, Poland; 4) Department of Medical Genetics, Medical University of Warsaw, Warsaw, Poland; 5) Department of Ophthalmology, Medical University of Warsaw, Warsaw, Poland.

Keratoconus (KTCN, OMIM 148300) is a degenerative eye disorder characterized by progressive stromal thinning, resulting in a conical shape of the cornea. Structural changes in the corneal layers cause optical aberrations, leading to a loss of visual function. To understand better the factors contributing to KTCN we performed comprehensive transcriptome profiling of human KTCN corneas for the first time using an RNA-Seq approach. 25 KTCN and 25 non-KTCN corneas were enrolled in this study. After RNA extraction, total RNA libraries were prepared and sequenced. The discovery RNA-Seq analysis (in eight KTCN and eight non-KTCN corneas) was conducted first, after which the replication RNA-Seq experiment was performed on a second set of samples (17 KTCN and 17 non-KTCN corneas). Over 82% of the genes and almost 75% of the transcripts detected as differentially expressed in KTCN and non-KTCN corneas were confirmed in the replication study using another set of samples. We used these differentially expressed genes to generate a network of KTCN-deregulated genes. We found an extensive disruption of collagen synthesis and maturation pathways, as well as downregulation of the core elements of the TGF-β, Hippo, and Wnt signaling pathways influencing corneal organization. This first comprehensive transcriptome profiling of human KTCN corneas points further to a complex etiology of KTCN. Supported by National Science Centre in Poland, Grant 2012/05/E/NZ5/02127.

Genetic analyses of Chinese patients with congenital cataract. *C. Hao, X. Chen.* Beijing Children's Hospital, Capital Medical University, Beijing, China.

Purpose: Cataract is the leading cause of poor vision and blindness in children. Children with congenital cataract failed to be early diagnosed and treated would led to permanent amblyopia. Pre-symptomatic gene diagnosis is critical to congenital cataracts treatment. Methods: The patients' ophthalmic performance and clinical data were recorded in detail. Genomic DNAs were extracted from the blood samples of 10 clinically diagnosed congenital cataract patients and 100 unaffected subjects. Genomic DNA of the probands were investigated using a Next-Generation Sequencing panel which included 40 cataract related genes. All candidate mutations were verified using Sanger sequencing. To exclude the previously unidentified alleles from polymorphisms, samples from 100 unaffected controls were sequenced for the same regions of variations. Possible functional impact of the mutations were predicted by the online software PolyPhen-2 and SIFT. The secondary structures and hydrophobic properties of the mutant amino acid were analyzed by Protscale software. Results: In all 10 patients, 6 unrelated pedigrees involved with autosomal dominant congenital cataracts was identified. Four cases had no apparent pathologic mutations in any of the genes studied. Three missense mutations in GJA8(Connexin50) have been found, including two novel mutation c.A188G(p.N63S) and c.C761T(p.S254F), and a known mutation c.C565T(p.P189S) which was previously found in a Danish family but firstly identified in Chinese pedigree. Other two novel missense mutations were also found in CRYGD c.C107T(p.A36V) and MIP c.T701C(p.L234P); one nonsense mutation was found in CRYGC c.G393A(p.W131Stop). Conclusions: This information will be useful for gene diagnosis and genetic counseling of congenital cataract in China.

1534W

Association between primary open-angle glaucoma and genetic variants associated with intraocular pressure. *F. Mabuchi[1], N. Mabuchi[1], Y. Sakurada[1], S. Yoneyama[1], K. Kashiwagi[1], Z. Yamagata[2], H. Iijima[1].* 1) Dept Ophthalmology, Univ Yamanashi, Chuo, Yamanashi, Japan; 2) Dept Health Sciences, Univ Yamanashi, Chuo, Yamanashi, Japan.

Purpose: To assess the association between primary open-angle glaucoma (POAG), including normal tension glaucoma (NTG) and high tension glaucoma (HTG), and the genetic variants associated with intraocular pressure (IOP). **Methods:** Two hundred and twenty five Japanese patients with NTG, 214 patients with HTG, and 181 control subjects without glaucoma were analyzed for 6 genetic variants associated with IOP; rs1052990 (near gene: *CAV2*), rs11656696 (*GAS7*), rs7081455 (*PLXDC2*), rs59072263 (*GLCCI1/ICA1*), rs2472493 (*ABCA1*), and rs58073046 (*ARHGEF12*). The total number of risk alleles for IOP elevation of these genetic variants was calculated for each participant and compared between the control subjects and patients with NTG or HTG. The risk (odds ratio) of POAG for each genetic variant was calculated using logistic regression model and the product of the odds ratios of these genetic variants was compared between the control subjects and patients with NTG or HTG. **Results:** The total number of risk alleles in patients with NTG (6.42 ± 1.46, mean ± standard deviation) and HTG (6.44 ± 1.62) were significantly more (P = 0.021, analysis of variance; P = 0.016 and P = 0.014 respectively, Bonferroni post hoc test) than that (6.06 ± 1.47) observed in the control subjects. Similarly, the product of the odds ratios in patients with NTG (2.51 ± 1.01) and HTG (2.53 ± 1.10) were also significantly larger (P = 0.0020, analysis of variance; P = 0.0022 and P = 0.0017 respectively, Bonferroni post hoc test) than that (2.21 ± 0.81) observed in the control subjects. **Conclusion:** These data support that POAG is a polygenic disorder by additive effects of multiple genetic variants associated with IOP.

1535T

Shared genetics between age-related macular degeneration (AMD) and complex diseases/traits suggest common pathways of AMD with cardiovascular and auto-immune diseases. *B. Weber[1], F. Grassmann[1], C. Kiel[1], M. Gorski[2], K. Stark[2], I. Heid[2], International AMD Genomics Consortium.* 1) Inst Human Gen, Univ Regensburg, Regensburg, Germany; 2) Department of Genetic Epidemiology, Univ Regensburg, Regensburg, Germany.

Purpose: Age-related macular degeneration (AMD) is the leading cause of vision loss with strong environmental and genetic components influencing disease development. With regard to the latter, the International AMD Genomics consortium (IAMDGC) recently reported the association of 52 genetic variants at 34 loci with AMD risk. To evaluate an overlap with the genetic risk of other complex diseases/traits, we calculated their genetic risk scores and assessed their association with AMD. Methods: First, we catalogued previously published, genome-wide significant variations for 62 complex diseases/traits and extracted a single variation per independent locus. Next, we calculated a genetic risk score for each trait/disease by calculating the weighted sum of risk alleles for all late stage AMD cases and controls. We then compared the genetic risk scores between late stage AMD cases and controls to identify significant overlaps between AMD risk and the risk for other diseases/traits. Results: The association of the genetic risk scores was evaluated with AMD risk and significant results were found for 17 of the complex diseases/traits (FDR < 0.01). By restricting the analysis to 1,824 variants initially used to compute the genetic risk scores, we identified 28 novel AMD risk variants representing 20 novel AMD-associated loci so far not recognized by AMD genome-wide association studies. Genes in the novel loci reinforce previous findings which strongly implicate the complement system in AMD pathogenesis. Conclusion: Our findings highlight the fact that unrelated pathologies share correlated genetic risk profiles with AMD and thus may point to common disease pathways.

1536F

Loss of function variants in a new gene increase risk for primary congenital glaucoma with variable expressivity. *T.L. Young[1], S. Tompson[1], B. Thompson[2,3], D. Berner[4], O. Siggs[5], V. Limviphuvadh[6], K. Whisenhunt[1], J. Wiggs[7], J. Craig[5], S. Quaggin[2,3], F. Pasutto[4], International Primary Congenital Glaucoma Genetics Consortium.* 1) Ophthalmology and Visual Sciences, University of Wisconsin, Madison, WI; 2) .Feinberg Cardiovascular Research Institute, Northwestern University Feinberg School of Medicine, Chicago, IL, USA; 3) Division of Nephrology/Hypertension, Northwestern University Feinberg School of Medicine, Chicago, IL, USA; 4) Institute of Human Genetics, Friedrich-Alexander-Universität Erlangen-Nürnberg, Germany; 5) Department of Ophthalmology, Flinders University, Adelaide, Australia; 6) Bioinformatics Institute, Agency for Science, Technology and Research (A*STAR), Singapore; 7) Department of Ophthalmology, Massachusetts Eye and Ear Infirmary, Harvard Medical School, Boston, MA, USA.

   Purpose: Primary congenital glaucoma (PCG) accounts for 5% of childhood blindness, and results from defects in the aqueous outflow system of the eye leading to high intraocular pressure (IOP), globe expansion and optic neuropathy. *CYP1B1* mutations are responsible for ~30-50% of cases, with some reports suggesting involvement of *LTBP2*, *FOXC1* and *MYOC* gene variants. We aimed to identify novel candidate genes for PCG using exome sequencing in unsolved families. **Methods**: An international multi-center cohort of 189 PCG families was assembled, all of which were Sanger sequenced and mutation negative for the 4 known genes. Exome sequencing was performed on 105 families using various platforms. Common and unrelated variants present in the ExAC public database and 119 internal control exomes, respectively, were filtered out. Sanger sequencing was used to validate candidate disease gene variants and identify further variants in 84 additional PCG families and 787 families with later-onset glaucoma (JOAG/POAG). Using a mouse line containing a doxycycline-inducible knock-out allele, animals lacking a functional allele were generated to model the human genotype. **Results**: Heterozygosity for 1 rare missense and 2 novel nonsense variants in the Angiopoietin-1 gene, *ANGPT1*, was identified in 3 of 189 unrelated PCG families. Heterozygosity for an additional novel nonsense and 2 novel missense variants was also identified in 3 of 787 families with JOAG/POAG. The 3 missense variants were located at evolutionarily well-conserved residues, but were predicted to be relatively tolerated by *in silico* tools. However, the 3 nonsense changes likely represented true loss-of-function (LoF) alleles. Remarkably, the ExAC database contains only a single heterozygous LoF variant in *ANGPT1* from more than 121,000 'normal' alleles, indicating LoF variation is not tolerated for this gene. Although mice hemizygous for *Angpt1* from embryonic day 13.5 did not shown any overt phenotype, conditionally homozygous knock-out mice did show a significantly raised IOP. **Conclusions**: For the first time, we have implicated mutations in *ANGPT1* as a risk factor for PCG and later-onset forms of glaucoma. Our data suggest the requirement for vigilant glaucoma screening in relatives of patients that carry an *ANGPT1* mutation, as they may develop glaucoma in later years.

1537W

Common medical comorbidities have no impact on cognitive or behavioral outcome in children with 22q11.2 deletion syndrome: The deletion trumps all! *D.M. McDonald-McGinn[1,2], T.B. Crowley[1], M. Unolt[1,3], K. Grand[1], D.E. McGinn[1], E. Moss[1], L. Katz[1,2], E. Goldmuntz[1,2], R. Sharkus[1], J.W. Gaynor[1,2], B.S. Emanuel[1,2], E.H. Zackai[1,2].* 1) Dept Clinical Genetics, Children's Hosp Philadelphia, Philadelphia, PA; 2) Perelman School of Medicine of the University of Pennsylvania; 3) La Sapienza University Policlinico Umberto I Rome.

   Background: Congenital heart disease (CHD) is one of the most common features (75%) associated with 22q11.2 deletion syndrome (22q). Neurodevelopmental dysfunction is the most frequent adverse outcome of CHD. Hypocalcemia too is common in 22q (50%) reportedly affecting long-term developmental outcome. Mean Full Scale IQ (MFSIQ) scores in children with 22q fall in the borderline range (70-79) and several behavioral differences are observed including ADHD, anxiety and ASD. Knowledge of medical associations with potential to alter cognitive outcomes/behavioral phenotypes is useful in providing anticipatory care and counseling for both families and caregivers. **Methods:** We retrospectively reviewed our records on 1321 patients with 22q for the presence and severity of CHD, hypocalcemia, a behavioral diagnosis of ADHD/anxiety/ASD and IQ scores. **Results:** 1102/1321 patients (83% of the total cohort) had a complete cardiology evaluation, of whom 366 (33%) had an age appropriate Wechsler neuropsychological evaluation yielding a FSIQ score. Likewise, 265/852 (31%) patients had both calcium data and a FSIQ score on record. Medical comorbidities and presence or absence of ADHD/anxiety/ASD were then compared with FSIQ scores in these groups. MFSIQ for patients with CHD (75.86; n=207) was not statistically different from those without CHD (76.86; n=159). We then stratified our patients with 22q and CHD two dimensionally (anatomically, physiologically) and found no significant difference in FSIQ in those patients with a simple, moderate or complex CHD as compared to those with no CHD or a CHD that was considered insignificant, e.g. VSD closing spontaneously. Similarly, FSIQ scores for those with a history of hypocalcemia (77.09; n=146) was not significantly different from those with no hypocalcemia (77.27; n=119). Furthermore, FSIQ scores for those patients with CHD and hypocalcemia (77.94; n=95) was no different than for those with no CHD nor hypocalcemia (77.88; n=59). Finally, neither presence nor absence of CHD/hypocalcemia affected behavioral outcomes nor did behavioral differences impact FSIQ. **Conclusion:** Common medical comorbidities have no impact on cognitive or behavioral outcomes in children with 22q including those with complex CHDs requiring surgical intervention in early infancy. This data may reflect the benefit of early diagnosis and optimal remediation or the intractable effect of haploinsufficiency of 22q11.2 trumping all other effects on neurocognition.

1538T

Genetics of microtia: Discovery of new genes using exome sequencing. *D.V. Luquetti[1,2], A.E. Timms[2], P.M. Hurtado[3], G.L. Porras[4], P. Ayala[5], E.E. Turner[1,2], J. Rosin[2], H.M. Pachajoa[6], T.C. Cox[1,2], I.M. Zarante[5].* 1) Craniofacial Division, Department of Pediatrics, University of Washington, Seattle, WA, USA; 2) Seattle Children's Research Institute, Seattle, WA, USA; 3) Pontificia Universidad Javeriana, Cali, Colombia; 4) Clinica Comfamiliar Risaralda, Pereira, Colombia; 5) Pontificia Universidad Javeriana, Bogota, Colombia; 6) Universidad ICESI, Cali; Colombia.

Microtia is a congenital malformation of the external ear ranging from mild structural abnormalities to complete absence of the ear. As with most birth defects Microtia can be syndromic or non-syndromic. The prevalence of non-syndormic microtia varies widely, in the US it is estimated to be between 1 and 2 per 10,000 births, whereas in Colombia is between 4 and 5 per 10,000 births. We have enrolled 85 patients with non-syndromic microtia from four sites in Colombia following a standardized protocol including physical exam, questionnaire on maternal risk factors and family history, 2D photographs and biological sample collection. We submitted DNA from 25 of these patients and their parents for whole exome sequencing (WES). Here, we present data from the WES on these 25 patients; sequencing results from additional 11 trios are pending and will be added to the presentation at the meeting. Our patient population consists of; 76% males, 21% with bilateral microtia and 70% with unilateral right microtia, 85% presented ear canal atresia, 35% had preauricular tags and 8% had a cleft palate. Abdominal ultrasound was performed in 65% of patients with no significant abnormalities found. When analyzing sequence variation, we found a range of 0-3 *de novo*, 0-5 homozygous and 0-14 compound heterozygotes variants per individual. We did not find recurrence of the same variants or genes. For the 30 *de novo* variants found, 16 seem likely causative based on protein prediction of deleterious effect (Polyphen2>0.85), CADD Phred (>15), sequence conservation in evolution (GERP>3.0), population frequency (<0.0001). Of those, 10 are expressed in branchial arch 2 (BA II-embryonic origin of the external ear) during ear development in the mice. We are currently performing in situ hybridizations to confirm the expression of those genes in BAII and confirm spatial representation. None of the genes found in the *de novo* analysis have been previously related to microtia, the data though suggests that these newly discovered genes are involved in the genetic susceptibility to microtia. For example, EPHA4 and NDST2, two of the genes with pathogenic mutations, directly interact with FGFs and FGFRs; FGF3 and 10 and FGFR2 and 3 are already known to cause syndromic microtia. Our future studies include gene expression in the developing human ear and functional studies of the variants in mice models.

1539F

Microduplication at *GRHL3* gene in an individual with non syndromic cleft lip and palate. *L.A. Ribeiro-Bicudo, M.S. Maranhão, J.T. Arruda, N.A. Bergamo, F. Almas.* Genetics, Federal University of Goias, Goiania, Brazil.

Nonsyndromic cleft lip with or without cleft palate (NSCL/P) is the most common orofacial birth defect with a wide range prevalence among different populations. Although the exact environmental and genetic risk factors associated with NSCL/P remains unclear, the understanding of the genetic mechanisms involved in this malformation are evolving. Syndromic CL/P is mainly caused by Mendelian disorders such as Van der Woude Syndrome (VWS). VWS, first been described in 1954, is an autosomal dominant developmental disorder in which CL/P is a representative hallmark .Previous linkage analysis identified 1q32-q41 and 1p34 as VWS loci. IRF6, located in VWS1 locus 1q32-q41, was identified as a causative gene that can explain ~70% of VWS cases. Given the similar phenotype between syndromic and nonsyndromic forms of CL/P, it is believed that causative genes identified in syndromic CL/P are promising candidate genes for NSCL/P as well. As such, identification of *IRF6* (Interferon Regulatory Factor 6) in VWS and NSCL/P is a typical example of the candidate gene approach. Recently, *GRHL3* (Grainyhead-like 3), located in VWS2 locus 1p34, was identified as a novel causative gene of VWS. As *IRF6*, *GRHL3* can be another example of candidate gene approach for NSCL/P. In the present work we search for microdeletions/duplications in *IRF6* and *GRHL3* genes, through MLPA analysis using the SALSA MLPA P304 kit, in 80 NSCL/P individuals. This study was approved by the institutional review board of the Institution, and written informed consent was obtained from the participants or their parents.MLPA results showed a duplication at exon 4 of *GRHL3* gene in a non syndromic CLP individual. MLPA results from parents did not show any variation. Mutations in *GRHL3* have been identified in VWS patients without *IRF6* mutations. Therefore, *GRHL3* was recognized as a novel causative gene of VWS and represents a promising candidate gene for NSCL/P as well. Although the association between *GRHL3* and NSCL/P remains unknown, recent report identified significant association between *GRHL*3 and NSCL/P susceptibility. This is the first report on a microduplication at *GRHL3* in a individual with NSCLP. Further analysis are necessary to clarify this finding. .

Gorlin-Goltz syndrome: Case report. *I. Briceño, J. Martinez, M. Sotelo, C. Montes, C. Martinez, A. Zarate, A. Saavedra, L. Arias.* medicine, Universidad de La Sabana, bogota, bogota, Colombia.

   Abstract The Gorlin-Goltz syndrome is a disease of embryonic development characterized by the appearance of multiple queratoquistics tumors, basal cell carcinomas, dimples palm and / or plantar, Vertebral, syndactyly, among others. Patients usually have high predisposition to cancer. The objective of this report is to present the case of a patient Operation Smile foundation with this peculiar condition. phenotypic characteristics found in relation to diagnostic characters for Gorlin-Goltz evaluated further evidence Comparative Genomic Hybridization in which no known mutations were detected, whereby genetic counseling performing molecular diagnostics he performed more robust techniques such as sequencing exome.

1541T

Clinical aspects associated with orofacial clefts in a Colombian population. *J. Martinez[1], I. Briceno[1], M. Sotelo[1], L. Arias[1], C. Montes[1], C. Martinez[1], A. Zarate[1], A. Saavedra[1], A. Montero[1], M. Zamora[1], A. Collins[2].* 1) Medicine, Universidad de La Sabana, Bogota, bogota, Colombia; 2) Genetics, University of Southampton, UK.

   Abstract Objectives: To present descriptive epidemiology of Orofacial Clefts and to determine the association of syndromic forms with antenatal high-risk conditions, preterm birth, and comorbidities among nested-series of cases. **Methods:** A study of nested-series of cases was conducted. Frequencies of cleft type, associated congenital anomalies, syndromic, non-syndromic and multiple malformation forms, and distribution of Orofacial Clefts according to sex and affected-side were determined. Odds ratios were calculated as measures of association between syndromic forms and antenatal high-risk conditions, preterm birth and comorbidities. A total of three hundred and eleven patients with Orofacial Clefts were assessed in a 12-month period. **Results:** The most frequent type of Orofacial Clefts was cleft lip and palate, this type of cleft was more frequent in males, whereas cleft palate occurred more often in females. The most common cases occurred as non-syndromic forms. Aarskog-Scott syndrome showed the highest frequency amongst syndromic forms. Hypertensive disorders in pregnancy, developmental dysplasia of the hip, central nervous diseases and respiratory failure showed significant statistical associations (p <0.05) with syndromic forms. **Conclusions:** These data provide an epidemiological reference of Orofacial Clefts in Colombia. Novel associations between syndromic forms and clinical variables are determined. In order to investigate causality relationships between these variables further studies must be carried out.

1542F

Causes of death associated with 22q11.2 deletion syndrome. *K. Coleman[1,5], L. Kobrynski[2], M. Oster[2,3], B. Pearce[4], J. Cubells[5,6,7], O. Ousley[6,7], C. Gunter[1,2,5].* 1) Marcus Autism Center, Children's Healthcare of Atlanta, 1920 Briarcliff Road NE, Atlanta, GA. 30329; 2) Emory University School of Medicine Department of Pediatrics, 2015 Uppergate Drive, Atlanta, Ga 30322; 3) Sibley Heart Center, 1405 Clifton Road NE, Atlanta, GA 30322; 4) Emory University Rollins School of Public Health, 1518 Clifton Road NE, Atlanta, Ga 30322; 5) Emory University School of Medicine Department of Human Genetics, 615 Michael Street, Suite 301, Atlanta, GA 30322; 6) Emory University School of Medicine, Department of Psychiatry, 12 Executive Park Dr, NE, 2nd Floor, Atlanta, GA 30329; 7) Emory Autism Center, 1551 Shoup Court, Atlanta, Georgia 30322.

Purpose: The purpose of this study is to describe the causes of death reported in patients with the 22q11.2 deletion syndrome (22qDS). This is a retrospective study of 715 patients from 1995 – March, 2016 maintained securely in the Southeast Regional Phenotypic 22q11DS (SERPh22) database by a consortium of researchers in Atlanta, Georgia. We cross-checked causes of death with two other 22qDS databases: the Sibley Heart Center and Emory Pediatric Immunology.Results: There were 53 deaths in the SERPh22 database; however, after cross-checking the other two databases, we could identify causes of death for an additional 5 patients. The total number of known deaths is 58 (8.1%) out of the 715 patients. These data are consistent with published reports on phenotype and known causes of morbidity/mortality in 22qDS patients. Of the deaths that occurred in patients younger than 18 years, 36% are due to cardiopulmonary arrest; 12.7% are due to sepsis or the flu; 3.6% are due to central apnea; 3.6% are due to intraventricular hemorrhages; and 9% are due to other causes (sudden death at home, oncology process with proliferation of cells in pulmonary artery, post-op complications from pacemaker insertion, withdrawal of treatment, and hospice treatment). As the majority of these data are collected from a pediatric healthcare system there are only 3 deaths known to have occurred in patients older than 18 years of age. Two patients had sudden deaths at home and 1 was an accidental death resulting from impulsive behavior.Conclusions: In this study, the main causes of death in 22qDS patients under 18 years is secondary to cardiopulmonary arrest with or without cardiac surgery, sepsis or infections, central apnea, and intraventricular hemorrhages. The low number of patients over 18 years is due to the population served by a pediatric healthcare system. Because this population includes deaths that occur outside of any healthcare facility, the 8.1% of deaths in this cohort is most likely an under-estimate. Future work will include cross-checking all 715 patients with the Georgia Vital Statistics/Death Registry.

1543W

Novel copy number variant (CNV) and neurodevelopmental profile (NDP) in boy with neurofibromatosis type 1 (NF1 [MIM 162200]). *C. Cappello[1], C. Keen[1], C. Samango-Sprouse[1,2,3].* 1) The Focus Foundation, Crofton, MD; 2) Department of Pediatrics, George Washington University, Washington, DC; 3) Department of Human and Molecular Genetics, Florida International University, Miami, FL.

Introduction: NF1 is an autosomal dominant neurogenetic disorder with a prevalence of 1:4650. It is either inherited or caused by a spontaneous mutation of chromosome 17q11.2 (MIM 613113). Physical manifestations include skinfold freckling, café-au-lait spots and neurofibromas. Cognitive dysfunction is common in NF1, specifically in executive function, attention, language, visual perception and learning. We present a 6-year-old male diagnosed with NF1 who also has a 58kb microdeletion on 3q24, affecting one copy of the *PLOD2* gene (MIM 609220). His NDP is complicated by global apraxia (GA), childhood apraxia of speech (CAS), autism spectrum disorder and sensory processing disorder. No previous literature reports NF1 patients with this microdeletion of 3q24 with CAS and GA. This case expands upon the genotypic and phenotypic profile of NF1 and CNV.**Statement of Purpose:** We investigated the NDP of a child with NF1 complicated by a novel CNV. We explored the impact and association of the CNV on this NDP compared to the common phenotypic profile of NF1.**Methods:** NDP was assessed using the Preschool Language Scale-5 (PLS-5), Wechsler Scales (WPPSI), Child Behavior Checklist (CBCL) and receptive vocabulary (ROWPVT-4), which probe cognitive, motor, language and behavioral domains.**Results:** Receptive vocabulary was within the low-average range (standard score=83). He had deficits in auditory and expressive comprehension (1st percentile) on the PLS-5, supporting expressive and receptive language disorder. Inability to imitate nonverbal movements, sounds, words or large motor movements demonstrated GA and CAS, especially since fluid reasoning on WPPSI-V (composite score=100) was an area of preservation. Sensory processing dysfunction impacted neurobehavioral outcomes, as the CBCL demonstrated deficits in executive dysfunction and social development common in NF1, CAS and GA.**Discussion:** This case presents a unique NDP for NF1. The GA and CAS are novel pieces in this phenotypic profile, which have not been described before in NF1. Further studies regarding the 3q24 microdeletion-NF1 interaction must be conducted to ascertain their link to GA, CAS and other neurodevelopmental sequelae. This report and other published findings suggest that atypical phenotypic presentation of NF1 may warrant further investigation of CNV to understand the complexity of the genotypic-phenotypic presentation.

1544T

Loss-of-function rare variants in *ARHGAP29* **contribute to the etiology of non-syndromic cleft lip and palate.** *A.C. Faria[1], C.P. Savastano[1], L.A. Brito[1], N. Seto-Salvia[2,3], E.    Background: Non-syndromic cleft lip with or without cleft palate (NSCL/P) represents one of the most common congenital human malformations, affecting about 1 in 700 liveborn children worldwide. Genome-Wide Association Studies (GWAS) have successfully detected common susceptibility alleles associated with NSCL/P, including SNVs at the 1p22 region, in which *ARHGAP29* has emerged as the best candidate gene. *ARHGAP29* re-sequencing studies in NSCL/P patients have identified rare variants, mostly missense, with uncertain involvement in the defect etiology. In this study, screening of *ARHGAP29* was conducted in 188 familial NSCL/P cases (173 families from Brazil and 15 families from the United Kingdom) and 1210 controls (609 from Brazil and 601 from United Kingdom). **Method:** Sequencing data from *ARHGAP29* was obtained from whole-exome sequencing in Illumina HiSeq2000, targeted gene sequencing in Illumina MiSeq and or Sanger sequencing in ABI3730 DNA Analyzer. Overall burden of *ARHGAP29* rare variants in patients and controls was tested using gene-based Sequence Kernel Association Test (SKAT). **Results:** We identified 10 rare variants in *ARHGAP29:* five missense, one inframe deletion, and four loss-of-function (LoF) variants. All missense changes already were described in public databases. Only one missense variant was predicted to be possibly pathogenic by *in silico* programs, but discarded after segregation analysis. The in-frame deletion was predicted to be non-pathogenic by *in silico* tools, so it was also not considered further. The four LoF variants, including three splice site and one stopgain variant, were all predicted to disrupt the protein based on *in silico* analysis. Segregation analysis of the LoF variants performed in two out of the four families were in accordance with an autosomal dominant pattern with incomplete penetrance (K=59%). Significant mutational burden of LoF (SKAT, P=0.0005), but not missense, variants were observed in cases compared to controls, suggesting that only LoF variants contribute to the etiology of NSCL/P. **Conclusion**: Our data demonstrate that rare LoF variants in *ARHGAP29* represent an important mechanism in the etiology of NSCL/P, occurring in 2.1% of familial cases. Genetic testing for this gene might be taken into consideration in genetic counseling of familial cases. Support: Fapesp/CEPID/CNPq/NHS Foundation/UCL/Illumina.

Novel association between rs1063588, an eQTL for *MRPL53* **(2p13)***,* **and nonsyndromic cleft lip with or without cleft palate.** *C. Masotti[1,2], L.A. Brito[1], A.C. Nica[3], D.Y. Sunaga[1], K.U. Ludwig[4], C. Malcher[1], .S.G. Ferreira[1], G.S Kobayashi[1], C.P. Savastano[1], M. Aguena[1], D. Meyer[1], T. Hünemeier[1], D.F. Bueno[2], N. Alonso[5], D. Franco[6], E. Mangold[4], E. Dermitzakis[3], M.R. Passos-Bueno[1].* 1) Department of Genetics, Institute of Biosciences, University of São Paulo, Sao Paulo, Brazil; 2) Hospital Sírio-Libanês, São Paulo, Brazil; 3) Department of Human Genetics and Development, University of Geneva, Switzerland; 4) Institute of Human Genetics, University of Bonn, Sigmund-Freud-Str.25,D-53127 Bonn, Germany; 5) Divison of Plastic Surgery, Medical School, University of São Paulo, São Paulo, Brazil; 6) Departamento de Cirurgia Plástica, Hospital Clementino Braga Filho, Faculdade de Medicina, Universidade Federal do Rio de Janeiro, Brazil.

   Nonsyndromic cleft lip with or without cleft palate (NSCL/P) is a prevalent complex disorder. Many susceptibility loci have been uncovered by genome-wide association studies (GWAS), most of which are low-effect variants falling within noncoding regions or gene deserts. In this regard, GWAS hits may be implicating regulatory regions, which can be active during craniofacial development. In this study, we investigated the association of expression quantitative trait loci (eQTLs) with NSCL/P, in order to directly examine regulatory variants. We firstly mapped eQTLs using mesenchymal stem cell culture samples derived from *orbicularis oris* muscle (OOMMSC) obtained from NSCL/P individuals. *Orbicular oris* muscle is a compromised tissue in NSCL/P patients, and easily collected during reconstructive surgery. By correlating genome-wide expression levels and genotypes, we mapped 119 *cis*-eQTLs related to 18 genes (P<0.0001; FDR=14%), and 31 were selected for further association analysis with 624 NSCL/P patients and 668 controls from Brazilian population. European, African and Amerincian ancestries were estimated for each individual using ancestry informative markers, in order to account for stratification bias. We found a novel association for the *MRPL53* gene best eQTL (rs1063588, P=0.0008). To investigate if a particular ethnic subgroup is driving this association, we stratified the analysis by individual ancestry, and found a stronger association signal for the subgroup enriched with Amerindian ancestry (264 patients x 165 controls with >20% of Amerindian genome: *P=0.008*, $OR_{het\_rs1063588}$ = 1.99 [1.09-3.64 95%CI], $OR_{hom\_rs1063588}$ = 2.77 [1.49-5.15]), compared to the non-Amerindian subgroup (*P*= 0.21; 356 patients x 510 controls with <20% of Amerindian genome), indicating that this locus may be a susceptibility factor in the Amerindian population. *MRPL53* (2p13) encodes a 39S protein subunit of mitochondrial ribosomes and interacts with cMYC, evidences suggesting that ribosome dysfunction may have an etiological impact on NSCL/P. The first genome-wide significant associations with the trait were shown in 2015 involving SNPs near the genes *EDAR* (2q13) and *SP5* (2q31), along with a suggestive signal at the 6q24 locus. We performed a meta-analysis of GWAS results from three ethnically distinct cohorts totaling 9155 individuals in an effort to uncover additional genetic signals contributing to variation in earlobe attachment and to investigate whether these signals are population-specific. Earlobe attachment data were available on US individuals of European ancestry (n=1791), a sample of admixed individuals from Latin America (n=4715) and a sample of Han Chinese individuals (n=2649). In each cohort, an ordinal tripartite phenotype definition was used to classify earlobes as free, partially attached, or attached. Results from a common set of 5,366,603 imputed SNPs were meta-analyzed using the inverse variance weighted method in METAL. We observed six genome-wide significant associations: rs3827760 (2q13;p=6.65E-10), rs6756973 (2q31;p=1.40E-28), rs12695694 (3q23;p=4.82E-13), rs58122955 (6q24;p=4.43E-14), rs7096127 (10p12.2;p=2.65E-08), and rs1950357 (14q13;p=4.86E-09). The previously associated signals near *EDAR* and *SP5* were each independently replicated in at least one additional cohort. The previously suggestive signal at 6q24 now reached genome-wide significance. Although there was statistical evidence of effect size heterogeneity at the 3q23 locus (driven primarily by the Chinese cohort), the direction of effect for each of the associated alleles was consistent among cohorts. The associated loci contained several genes involved in morphogenesis. To further investigate these regions, expression of genes in syntenic intervals around the GWAS peaks was investigated in second branchial arch tissue from wildtype E10.5 mouse embryos and two mutants with distinct pinna phenotypes. Of note, *Ranbp2* (2q13), *Vta1* (6q24), *Pax9* (14q13), and *Mipol1* (14q13) were highly expressed in wildtype tissue. *Sp5* and *Gad1*, both located at the 2q31 locus, were expressed at relatively low levels in wildtype embryos, but showed evidence of differential expression in the mutants. These findings shed light on the complex genetics underlying variation in ear morphology and highlight the role of several genes in craniofacial morphogenesis.

Menchaca, Guadalajara, Mexico; 3) CUCS, Universidad de Guadalajara, Guadalajara, Mexico.

Introduction. Non-syndromic cleft lip/palate (NSCLP) is a multifactorial congenital anomaly with an incidence of 1-3/1000 NB. A previous publication propose the association between NSCLP and polymorphysms G894T and A-922G of *NOS3* gene, related to angiogenesis and vascular disruption, although only in exposure of tobacco and lack of folate intake in the first trimester of pregnancy. **Objectives.** Determine if exist an association between the polymorphysm G894T and A-922G of *NOS3* gene and the exposure to vascular disruptor agents (VDA) as a risk factor for NSCLP in newborns in a school hospital from Guadalajara, Mexico. **Methods.** We studied 161 newborns (47 cases with NSCLP and 114 healthy controls) born in our school hospital during the period 2009 - 2014. DNA extraction form peripheral blood and genotyping by Sanger sequencing were performed previous informed consent. Exposure to VDA was determinate by standardized questionnarie to the mother in both groups. Multivariate analysis with binary logistic regression was performed to determinate the association. **Results.** Genotype frequencies for cases and controls respectively, were: a) *NOS3* A-922G: AA (wild-type) 30 (63.8%) vs 68 (59.6%); AG (heterozygous): 14 (29.8%) vs 41 (35.9%); GG (homozygous) 3 (6.4%) vs 5 (4.4%) and b) *NOS3* G894T: GG (wild-type): 31 (65.9%) vs 73 (64%); GT (heterozygous) 14 (29.8%) vs 35 (30%); TT (homozygous) 2 (4.2%) vs 6 (5.3%). These frequencies were in Hardy - Weinberg equilibrium in the control group, there were no differences stastistically significant, and not association. The multivariate analysis of exposure to VDA showed slightly association only with Coffee (OR= 2.01, CI 95%: 1.00 - 4.04). **Conclusion.** We do not found association between NSCLP and presence of polymorphisms studied, neither for the VDA previously reported. The association found between NSCLP and Coffee, suggest a relation Gene - Environment, but additional investigation is required.

Background: Nonsyndromic cleft lip with or without cleft palate (CL/P) and cleft palate only (CPO) are among the most common human birth defects caused by both genetic and environmental factors and/or their interactions. Genome wide association studies (GWAS) and meta-analyses of CL/P have been identified multiple genetic risk loci including *MAFB, VAX1, PAX7, FOXE1 and ABCA4*. Previous studies of the *DMD* gene also showed significant association with oral clefts that include cleft palate. **Methods:** We used 404 independent case-parent trios from three case groups: nonsyndromic cleft lip only (CLO; 104 case-parent trios), cleft lip and palate (CLP;135 case-parent trios) and cleft palate only (CPO;165 case-parent trios). Participants were genotyped by either TaqMan assays ® or Fluidigm ®. We genotyped 48 SNP markers, which were utilized and found statistically significnat in previous GWAS studies. Transmission disequilibrium tests were performed by the Family based Association Test and PLINK. This study was approved by institutional review boards and informed consents were obtained from the patients. **Results:** Statistically significant associations were observed with SNPs in genes *IRF6, FOXE1 and MAFB*. Regarding CL/P, TDT analysis showed associations with *IRF6* (rs2235371, *p*= 6.80E-06 and rs2013162 *p*= 0.03486) and *MAFB* (rs17820943, *p*= 0.002266, rs13041247 and rs11696257, *p*= 0.001862). Also *FOXE1* (rs894673 and rs3758249, *p*= 0.02) was slightly associated with CL/P. We could not confirm statistical significance between *VAX1* markers and the Vietnamese population that have previously shown an association in the Mongolian population. However, after Bonferroni correction of the above results, only *IRF6* showed significant association. **Conclusions:** Our study replicated previous GWAS findings in *48* markers from 22 genes for the Vietnamese population and identified that *IRF6* may contribute to a part of the cleft lip and/or cleft palate etiology. Our findings of this study also suggest that *MAFB* might be associated with CL/P, similar to our previous study of the Mongolian population. This work was supported by JSPS KAKENHI Grant Number JP24249092, JP26861757.

Genome-wide analyses reveal subtype-specific genetic effects in orofacial cleft birth defects. *E.J. Leslie[1], J.C. Carlson[2], J.R. Shaffer[2], A. Butali[3], C.J. Buxo[4], K. Christensen[5], F. Deleyiannis[6], J.T. Hecht[7], L. Moreno[3], I.M. Orioli[8], A.R. Vieira[2], G.L. Wehby[3], E. Feingold[2], S.M. Weinberg[1], J.C. Murray[3], T.H. Beaty[9], M.L. Marazita[1].* 1) Center for Craniofacial and Dental Genetics, University of Pittsburgh, Pittsburgh, PA; 2) University of Pittsburgh, Pittsburgh, PA; 3) University of Iowa, Iowa City, IA; 4) University of Puerto Rico, San Juan, Puerto Rico; 5) University of Southern Denmark, Odense, Denmark; 6) University of Colorado School of Medicine, Denver, CO; 7) University of Texas Health Science Center at Houston, Houston, TX; 8) ECLAMC (Latin American Collaborative Study of Congenital Malformations) at INAGEMP (National Institute of Population Medical Genetics), Rio de Janeiro, Brazil; 9) Johns Hopkins University, Baltimore, MD.

Complex diseases may include multiple subtypes manifesting similar physiological/anatomical features. While such subtypes are not often readily apparent from available clinical information for many complex diseases, orofacial clefts (OFCs) exhibit easily documented phenotypic heterogeneity, and thus are excellent models for studying phenotypic and genetic heterogeneity. OFCs are caused by incomplete fusion of the upper lip and/or palate, resulting in three major subtypes: cleft lip (CL), cleft palate (CP), and CL plus CP (CLP). Combined they represent the most common human craniofacial birth defects. Historically, CL and CLP were hypothesized to share an etiology, while CP was considered a distinct disorder. However, increasing evidence points to a mixture of independent and shared genetic risk factors across all OFC subtypes. We performed a genome-wide meta-analysis in 901 OFC cases, 1700 controls, and 3427 OFC trios from global populations. We considered 28 loci showing evidence of association with CL, CLP, and/or CP (p<1E-05), and compared estimated effect sizes and confidence intervals. Non-overlapping confidence intervals were considered evidence of differential effects between subtypes. We found eight loci where the effects could not be distinguished between CL, CLP, and CP, indicating these loci may be common to all orofacial clefts. Two loci showed evidence of association only with CLP; two were associated only with CP; while none appeared to be specific to CL. Sixteen loci had overlapping effects between CL and CLP, but not with CP. Among these, we found two loci contained several SNPs with differential effects between CL and CLP. At the *IRF6* locus, multiple SNPs showed larger estimated effects for CL than CLP. The top CL SNPs and the top CLP SNPs are not in linkage disequilibrium, suggesting these were independent signals. We confirmed this with reciprocal conditional analyses on the top hits within each subtype. However, each signal showed some evidence of association within the other subtype, suggesting these visible OFC subtypes are not genetically homogeneous. In conclusion, although multiple shared risk factors exist across subtypes, these do not follow traditional divisions of CL+CLP vs. CP. By identifying OFC subtype-specific signals, this study has facilitated delineation of genetically determined OFC subtypes which should allow us to examine more homogenous groups in future studies and to better understand mechanisms leading to OFCs.

1550T

Genome-wide interaction study implicates *VGLL2* **and alcohol exposure in orofacial clefting.** *J.C. Carlson[1], E.J. Leslie[1], J.R. Shaffer[1], K. Christensen[2], F. Deleyiannis[3], J.T. Hecht[4], L.M. Moreno Uribe[5], G.L. Wehby[5], E. Feingold[1], S.M. Weinberg[1], M.L. Marazita[1].* 1) University of Pittsburgh, Pittsburgh, PA; 2) University of Southern Denmark, Odense, Denmark; 3) University of Colorado School of Medicine, Denver, CO; 4) University of Texas Health Science Center at Houston, Houston, TX; 5) University of Iowa, Iowa City, IA.

Non-syndromic cleft lip with or without cleft palate (NSCL/P) is the most common craniofacial birth defect in humans, affecting approximately 1 in 700 births worldwide. NSCL/P has complex etiology including several known genes and environmental factors. However, known genetic risk variants only account for a small fraction of the heritability of NSCL/P. It is commonly suggested that gene-by-environment interactions (GxE) may help explain some of the missing heritability. We separately examined three prenatal exposures – alcohol, smoking, and vitamin use during the three months prior to conception through the end of the first trimester of pregnancy – in 242 NSCL/P cases and 351 controls of European descent from Denmark, Hungary, and the US. Joint tests of genetic and GxE effects were tested genome-wide (5,935,570 SNPs with MAF>0.10) using logistic regression assuming an additive genetic effect and adjusting for five principal components of ancestry. We further interrogated loci with suggestive results from the joint test (p<1E-05) by examining the GxE effects from the same model. Suggestive results (p<1E-05) for the joint test were observed in the 2q24.2 (alcohol), 4q28.3 (alcohol), 6q22.1 (alcohol), 7p14.1 (alcohol and smoking), 8p23.2 (vitamins use), 8q24.21 (alcohol and smoking), 12p13.31 (alcohol and smoking), and 20q13.2 (smoking) loci. From these regions, a GxE effect was seen for rs117083 in the 6q22.1 locus in the alcohol scan (p=9.54E-07, OR=3.86[2.25, 6.62]). This locus contains *VGLL2*, a gene required for craniofacial development in zebrafish. Interestingly, previous studies indicate that loss of vgll2 and alcohol exposure independently result in death of cranial neural crest cells supporting our observation that genetic variants at this locus and alcohol exposure interact to increase risk of orofacial clefting. R01DE016148, X01HG007485.

Genetic analysis of vascular malformations reveals both germline and somatic mutations. *W.L. Wooderchak-Donahue[1,2], J.H. Tu[3,4], R. Margraf[1], J. Le[1], P. Bayrak-Toydemir[1,2], J.M. Teng[3].* 1) ARUP Institute for Clinical and Experimental Pathology, Salt Lake City, UT; 2) Department of Pathology, University of Utah, Salt Lake City, UT; 3) Department of Dermatology, Stanford University, Stanford, CA; 4) Columbia University College of Physicians and Surgeons, New York, NY.

Vascular malformations are localized abnormal clusters of vessels that can affect capillaries, arteries, veins, lymphatics, or any combination of these. Somatic mutations in *PIK3CA* which codes for the catalytic subunit of phosphatidylinositol 3-kinase (PI3K) were recently identified as a major cause of lymphatic and venous malformations. We hypothesized that genetic factors in addition to mutations in *PIK3CA* account for the diverse clinical phenotypes and treatment responses observed. Here, we determined the prevalence of *PIK3CA* mutations and sought to identify additional germline and somatic variants in a cohort of pediatric patients with lymphatic, venous, or mixed venolymphatic malformations. DNA was extracted from formalin fixed paraffin embedded (FFPE) or fresh/frozen tissue and matched blood samples. A custom SureSelect next generation sequencing panel was used to target the coding regions of 451 genes implicated in vascular malformations and the PI3K/AKT/mTOR pathway. Samples were sequenced on a HiSeq2500 instrument using 2x100 paired-end reads. Sequences were aligned to the human genome reference sequence, and PCR duplicates were removed. Local realignment and variant calling were performed using GaTK, and FreeBayes was used to identify somatic variation down to 1%. Of the tissues evaluated, 7 of 11 (63.6%) had a somatic *PIK3CA* mutation ranging from 1-9% variant. Deleterious germline mutations were identified in two cases that did not have a *PIK3CA* mutation. One case with congenital systemic lymphangiectasia had two heterozygous *CCBE1* mutations causing Hennekam Syndrome, and another case with a venolymphatic malformation had two heterozygous *PIEZO1* variants causing a recently recognized lymphatic dysplasia syndrome. Additional novel germline and somatic variants from several genes whose products are upstream or downstream of PI3K in the mTOR pathway (*AKT1, TSC2, RPTOR, PIK3C2G,* and *MTOR*) were identified in cases that had a somatic *PIK3CA* mutation. This is the first report of the coexistence of germline mutations in the mTOR pathway with somatic *PIK3CA* mutations in patients with lymphatic and venolymphatic malformations. These results may provide new mechanistic insights as to how vascular anomalies develop and lead to better treatments. Our results highlight the genetic complexity of vascular anomalies and underscore the importance of genetic testing in these patients, as their mutation profile may influence differences in response to treatment.

1552W

Tetraploid-diploid mosaicism in a patient with pigmentary anomalies of hair and skin: A new dermatologic feature. *J. Schacht[1], E. Farnworth[1], J. Hogue[3], L. Rohena[1,2,4].* 1) Department of Pediatrics, San Antonio Military Medical Center, San Antonio, TX; 2) Department of Pediatrics, Division of Genetics, San Antonio Military Medical Center, San Antonio, TX; 3) Department of Pediatrics, Division of Medical Genetics, Madigan Army Medical Center, JBLM, Fort Lewis, WA; 4) Department of Pediatrics, University of Texas Health Science Center at San Antonio, San Antonio TX.

Tetraploid-diploid mosaicism in humans is exceedingly rare. Phenotypes are variable, but common features include dysmorphic facial features, growth retardation, developmental delays, and intellectual disability. Few cases report dermatologic findings with pigmentary changes. We present a 10 year old male with tetraploid-diploid mosaicism and coexistent hypopigmentation of his hair with hypo and hyperpigmentation of his skin. This case expands the current literature as we are not aware of previous documentation of this unique combination of pigmentary anomalies. Other significant clinical features affecting several organ systems in our patient include a horseshoe kidney with renal cysts on both moieties, bilateral cryptorchidism, pectus excavatum, 13 rib pairs, bilateral pes cavus, scoliosis, delayed gastric emptying, poor growth requiring g-tube placement, Dandy-Walker malformation, tethered cord, epilepsy, intellectual disability, sensorineural hearing loss, high myopia, lagopthalmos, persistent asthma, and hirsutism.

1553T

Psychosocial, behavioural, cognitive and molecular-cytogenetic aspects of Prader-Willi syndrome (PWS): An Egyptian study. *M. Shehab[1], H. Afifi[2], H. El-Bassyouni[3], E. Salah[4].* 1) Human Cytogenetics, National Research Centre, Cairo, Giza, Egypt; 2) Clinical Genetics; 3) Clinical Genetics; 4) Child Health.

Prader-Willi syndrome is a multifaceted complex genetic disorder that is not widely known in Egypt, and there is very evident lack of differentiation between children with PWS and those with other causes of IDandobesity. This study aimed to examine psychological and behavioral profile of a sample of children with different modes of inheritance. We screened all patients5-14yrs old who presented to CGDclinic, NRC, during5years for at least 3 of the following signs: obesity, hypotonia, delayed milestones and hypogonadism.Starting by105patients;we ended by45patients. They were23males and22femaleswith mean age of 8years.All patients were subjected to clinical examination , Pedigree analysis, Nutritional and Bone Mineral Density evaluation, Children WISC , Autism Rating Scale ,Behavior Checklist for ages4-18,Conners' Parent Rating Scale-Revised,Cytogenetic and FISH analysis. All patients presented with hypotonia and had8-12positive criteria. Positive family history was66.7%and positive consanguinity86.7%.Hypogonadism in82.3% (males showed micropenis, hypospadias and undescended testis; females had absent labia minora and clitoris). The majority of PWS patients53.3% had mild to moderate ID, borderline mentality 6.7%, mild ID20%, and severe ID 20%, mild autistic features6.6% and significant autism2.2%.FISH confirmed deletion in30 patients66.6%.No correlation between FISH results and the IQ. All patients presented with hyperphagia, Cognitive rigidity 86.6% and Inattention76.9%.No association between the prevalence of oppositional defiant,cognitive rigidity or psychosocial disorders and the degree of ID or hyperphagia.Oppositional personality trait was found to be positively related with FISH–ve patients. Conner's results confirmed the positive relation between hyperactivity, Anxiety disorder, Social problems and impulsivity subscale results and FISH–ve patients. ADHD severity index showed a significant +ve inclination towards the FISH–ve patients.DSM-IV Inattention score didn't show any stat. significant difference, DSM-IV Hyperactivity- Impulsivity score was related to the FISH –ve patients.The total score was suggesting a strong correlation of ADHD symptoms with the non deletion types of PWS. This study is a cross sectional study that focuses on a specific age range in PWSpatients, follow up studies assessing those patients till adulthood could result in different conclusions as the patients' psychological and behavioral profiles can vary markedly with age.

Neotenic Complex Syndrome: A rare condition characterized by neoteny and multiple congenital anomalies. *B.A. Peters[1,3], R.F. Walker[2], S. Ciotlos[1], Q. Mao[1], R. Chin[1], N. Barua[1], S. Drmanac[1], M.R. Agarwal[1], R.Y. Zhang[1], Z. Li[3], M. Wu[1], J.S. Liu[1], P. Carnevali[1], R. Drmanac[1].* 1) Department of Research, Complete Genomics, Inc., 2071 Stierlin Court, Mountain View, CA 94043; 2) Retired; 3) 3BGI-Shenzhen, Shenzhen 51803, China.

We describe a novel syndrome in six patients with extreme developmental delay and other congenital anomalies. The defining characteristic of this syndrome is neoteny, such that the patients appear to be much younger than there biological age. In each case there is no history of such phenotypes in the family suggesting either a *de novo* genetic or environmental cause. All are female with failure to thrive as demonstrated by height and weight well below the 5th percentile. The patients range in age from 3-23 yet none have developed an ability to communicate. Whole genome sequence (WGS) analysis of the patient, their parents, all unaffected siblings, and in some cases extended family members was performed on Complete Genomics' nanoarray platform for massively parallel sequencing to an average coverage of ~50X. The genomes of each patient and sibling were also analyzed to ~100X coverage using Complete Genomics' Long Fragment Read (LFR) technology to provide complete variant phasing information and additional mutation verification. The patients in this study all had normal karyotypes and were free of large structural amplifications and deletions as determined by aCGH and WGS read coverage analysis. We identified 45-135 *de novo* mutations (DNMs) in the genomes of the patients and 58-115 in their unaffected siblings. On average, we discovered ~1.2 coding DNMs per patient and ~1.4 per sibling, this difference was not found to be significant and suggests there is nothing unusual about the number of coding DNMs found in the patients. Two DNMs were found in genes previously found with DNMs in the patients of other severe developmental syndromes. In the remaining patients with DNMs in genes not associated with other syndromes, 80% were found in genes intolerant to variation compared with only 36% of the genes with DNMs in the siblings, lending support to some of these DNMs being potentially causative. Interestingly, the genes found to harbor DNMs in the patients were found to be involved in transcription regulation and chromatin modification; the functions of genes containing DNMs in the siblings were more broadly dispersed. Analysis of inherited variants in the patients and their unaffected siblings did not uncover any other potentially causative variants. In addition, there are no obvious environmental factors that could contribute to these patients' syndrome.

1555W

A rare missense mutation in *CHFR* is associated with IMAGe syndrome. *N. Paria[1], H. Hu[2], F. Payne[3], C. Logan[4], L. Bicknell[5], H. O'conner[6], R. Gray[6], R. Gupta[1], J. Huibregtse[6], R. Semple[7], A. Jackson[4], C. Huff[2], P. White[8], M. Zacharin[9], M. Hutchison[10], J. Rios[1,8,11,12].* 1) Sarah M. and Charles E. Seay Center for Musculoskeletal Research, Texas Scottish Rite Hospital for Children, Dallas, TX; 2) Department of Epidemiology, MD Anderson Cancer Center, Houston, TX; 3) The Wellcome Trust Sanger Institute, Cambridge, United Kingdom; 4) Institute for Genetics and Molecular Medicine, University of Edinburgh, Edinburgh, United Kingdom; 5) Department of Pathology, Dunedin School of Medicine, University of Otago, Dunedin, New Zealand; 6) Department of Molecular Biosciences, University of Texas at Austin, Austin, TX; 7) The University of Cambridge Metabolic Research Laboratories, Institute of Metabolic Science, Cambridge, UK; 8) Department of Pediatrics, University of Texas Southwestern Medical Center, Dallas, TX; 9) Division of Medicine, Royal Children's Hospital, Melbourne, Victoria, Australia; 10) Department of Pediatrics, Medical University of South Carolina, Charleston, South Carolina; 11) McDermott Center for Human Growth and Development, University of Texas Southwestern Medical Center, Dallas, TX; 12) Department of Orthopaedic Surgery, University of Texas Southwestern Medical Center, Dallas, TX.

IMAGe syndrome (MIM# 614732) is an extremely rare growth disorder presenting with severe dwarfism, adrenal insufficiency, skeletal dysplasia and genital anomalies. Previous studies identified mutations in the proliferating cell nuclear antigen (PCNA)-binding domain of CDKN1C, a negative regulator of cell proliferation. We performed whole-genome sequencing in four IMAGe patients from three families in whom no *CDKN1C* mutations were identified. pVAAST analysis identified a genome-wide significant association at a single locus harboring the *CHFR* (p=1x10[-7]) and *GOLGA3* (p=3x10[-7]) genes. Rare variants identified in each gene cosegregated on a 1.71 Mb haplotype shared among patients in all three families; however, genome-wide ERSA analysis confirmed no significant relatedness between samples to at least 9 generations. Both variants were screened in three additional unrelated individuals with IMAGe; two carried both variants while the third carried only the *CHFR* variant (CHFR[Q93R]), suggesting *CHFR* is associated with IMAGe syndrome. The CHFR[Q93R] variant is located at a highly conserved residue within the forkhead-associated (FHA) domain of the CHFR protein, an E3 ligase that functions as a cell-cycle checkpoint and regulator of cell proliferation. CHFR and the related RNF8 proteins are the only E3 ligases known to have both FHA and RING finger domains, and both have been shown to regulate poly- and monoubiquitination of PCNA, respectively. Cultured dermal fibroblasts from IMAGe patients displayed proliferation defects, including binucleated cells with disorganized actin, and failed to respond to growth factors in culture, consistent with altered cell cycle regulation. Transciptome profiling identified preferential expression of the mutant allele in patients compared to carrier parents. Furthermore, we screened for the CHFR[Q93R] variant among patients undergoing clinical whole-exome sequencing for whom no genetic diagnosis was identified. Among five patients carrying the CHFR[Q93R] allele, two adolescent/adult males and one infant female were identified with multiple features resembling IMAGe syndrome and a fourth infant female is described with multiple non-specific features (failure to thrive, global developmental delay, some growth abnormalities). Our results support *CHFR* as a new gene for IMAGe syndrome. We hypothesize that the CHFR[Q93R] allele is inherited with an as-yet unidentified trans-acting factor that may affect allele-specific expression. .

1556T

Sequencing the *GRHL3* coding region reveals the first common susceptibility variant and rare truncating mutations for nonsyndromic cleft palate. *A.C. Böhmer[1,2], E. Mangold[1], N. Ishorst[1,2], A. Hoebel[1,2], P. Gültepe[1,2], H. Schuenke[1,2], J. Klamt[1,2], A. Hofmann[1,2], L. Gölz[3], R. Raff[1], P. Tessmann[1,2], S. Nowak[1], H. Reutter[1,2,4], J. Stavusis[5], M. Ishida[6], R. Seselgyte[6], G.E. Moore[6], M.M. Nöthen[1,2], G. Borck[7], K.A. Aldhorae[8], B. Lace[5], P. Stanier[6], M. Knapp[9], K.U. Ludwig[1,2].* 1) Institute of Human Genetics, University of Bonn, Bonn, Germany; 2) Department of Genomics, Life and Brain Center, University of Bonn, Bonn, Germany; 3) Department of Orthodontics, University of Bonn, Bonn, Germany; 4) Department of Neonatology and Pediatric Intensive Care, Children's Hospital, University of Bonn, Bonn, Germany; 5) Medical Genetics and Mitochondrial Research Group, Latvian Biomedical Research and study Centre, Riga, Latvia; 6) Institute of Child Health, University College London, London, United Kingdom; 7) Institute of Human Genetics, Ulm University, Ulm, Germany; 8) Orthodontic Department, College of Dentistry, Thamar University, Thamar, Yemen; 9) Institute of Medical Biometry, Informatics and Epidemiology, University of Bonn, Bonn, Germany.

Orofacial clefts are common and occur either in isolation or as part of a syndrome. The two frequent forms are nonsyndromic cleft lip with or without cleft palate (nsCL/P) and nonsyndromic cleft palate only (nsCPO). Both are considered multifactorial with a strong genetic background, but with very limited overlap regarding the genetic etiology. The most common syndromic form of orofacial clefting is Van der Woude syndrome (VWS). Recently, ~5% of VWS patients were identified with mutations in the grainy head-like 3 (*GRHL3*) gene. VWS patients have either CL/P or CPO often accompanied with lower lip pits. As lip pits have an incomplete penetrance, VWS can sometimes mimic nonsyndromic clefting. To investigate *GRHL3* in nonsyndromic clefting, we sequenced its coding region in 576 Europeans with nsCL/P and 96 with nsCPO. Most strikingly, nsCPO-affected individuals had a higher minor allele frequency for rs41268753 (0.099) than control subjects (0.049; $P = 1.24 \times 10^{-2}$). This association was replicated in nsCPO/control cohorts from Latvia, Yemen, and the UK ($P_{combined} = 2.63 \times 10^{-5}$; $OR_{allelic} = 2.46$ [95% CI 1.6-3.7]) and reached genome-wide significance in combination with imputed data from a GWAS in nsCPO triads ($P = 2.73 \times 10^{-9}$). Notably, rs41268753 is not associated with nsCL/P ($P = 0.45$). Rs41268753 encodes the highly conserved missense variant p.Thr454Met (c.1361C>T) (GERP = 5.3), which numerous *in silico* prediction programs denote as deleterious. It has a CADD score of 29.6 and increases protein binding capacity *in silico*. Sequencing also revealed four novel truncating *GRHL3* mutations including two that were *de novo* in four families, where all nine individuals harboring mutations had nsCPO. This is important for genetic counseling: given that VWS is rare compared to nsCPO, our data suggest that dominant *GRHL3* mutations are more likely to cause nonsyndromic than syndromic CPO. Thus, with rare dominant mutations and a common risk variant in the coding region, we have identified an important contribution for *GRHL3* in nsCPO.

1557F

Strategies for selecting candidate genes for studying epistasis based on prior knowledge. *S. Ukraintseva, I. Zhbannikov, M. Duan, L. Arbeeva, K. Arbeev, A. Kulminski, I. Akushevich, A. Yashin.* Center for Population Health Aging, Duke University, Durham, NC.

Biological justification of candidate genes used in analyses of gene x gene interaction effects on aging phenotypes and longevity is critically important for obtaining meaningful results. We suggested several approaches to selecting candidate genes for analysis of epistasis, based on current biological knowledge about their functions and involvement in particular pathways, processes and health disorders. Then we selected SNPs in these genes and estimated the effect of pairwise epistasis on longevity and physiological aging-related phenotypes in four longitudinal human datasets (CHS, MESA, FHS, ARIC). Then we compared results of respective analyses, to see which approach lead to a more biologically plausible interpretation. Specifically, we tested the following sets of candidate genes: 1) Hub genes from aging/longevity related pathways that are known to be interacting; 2) Key regulatory genes involved in cell/tissue responses to damage, such as apoptosis, senescence, proliferation, autophagy, ECM clearing, and inflammation, regardless of their involvement in particular pathway; 3) Genes that are highly pleiotropic and influence risks of multiple diseases, according to information placed in NHGRI GWAS catalog; 4) Genes corresponding to pairs of SNPs that showed increase in LD with age in our data. Our analysis shows that candidate genes from groups (1) and (2) are more prone to significant epistatic interactions that influence aging and longevity than members of two other groups. These results support selection of candidate gene directly involved in aging related processes in cell and tissue for analyses of gene x gene interaction effects on phenotypes of physiological aging and longevity.

1558W

Largest ever GWAS of human lifespan. *P.K. Joshi[1], K. Fischer[2], T. Esko[2,3,4], J.F. Wilson[1,5], LifeGen.* 1) Centre for Global Health Research, Usher Institute for Population Health Sciences and Informatics, University of Edinburgh, Teviot Place, Edinburgh, EH8 9AG UK; 2) Estonian Genome Center, University of Tartu, Riia 23b, 51010, Tartu, Estonia; 3) Program in Medical and Population Genetics, Broad Institute, Cambridge Center 7, Cambridge, 02242, MA, USA; 4) Division of Endocrinology and Center for Basic and Translational Obesity Research, Boston Children's Hospital, Cambridge, 02141, MA; 5) MRC Human Genetics Unit, Institute of Genetics and Molecular Medicine, University of Edinburgh, Western General Hospital, Crewe Road, Edinburgh, EH4 2XU UK.

We shall present the results of a GWAS of ~1.4million parent lifespans: 1 million from UK Biobank and 400,000 from the other LifeGen Cohorts.   Lifespan is a trait of interest to everyone. Until recently GWAS have focussed on long-livedness as a binary trait, with *APOE* and perhaps *FOX03* being the only loci that have been robustly replicated (GWAS of longevity in CHARGE consortium confirms *APOE* and *FOXO3* candidacy, Broer *et al.* 2015 *J Gerontol A Biol Sci Med Sci.)*. Focussing on long-livedness has strengths and limitations: biologically it may focus on ageing rather than common disease, whilst statistically study of trait extremes should increase power, for a given sample size. On the other hand long-livedness may miss early life effects and subject recruitment may be difficult and, very importantly, requires specific recruitment of the aged, rather than permitting general population cohorts to take part. In a pilot study(with around one sixth of the present sample count), we recently developed a GWAS approach to lifespan that overcomes these difficulties and discovered two genome wide significant variants, both of which replicated – using parental lifespan information, coupled with Cox models (Joshi PK *et al.* Variants near CHRNA3/5 and APOE have age- and sex-related effects on human lifespan. *Nature Commun* 7, 11174, March 2016*).*   We shall present fresh results of the largest ever GWAMA of human lifespan and discuss the methodological extensions to cox modelling that made this tractable in large GWAS and appropriate to meta-analyse. .

1559T

Whole genome sequencing of a healthy aging cohort. *A. Torkamani[1], G.A. Erikson[1], D.L. Bodian[2], M. Rueda[1], B. Molparia[1], E.R. Scott[1], A.A. Scott-Van Zeeland[1], S.E. Topol[1], N.E. Wineinger[1], J.E. Niederhuber[2], E.J. Topol[1].* 1) Scripps Translational Science Institute, La Jolla, CA; 2) Inova Translational Medicine Institute, Falls Church, Virginia.

Studies of long-lived individuals have revealed few genetic mechanisms for protection against age-associated disease. This may be due to the fact that, in part, medical technology can promote longevity as a function of medical interventions per se. Yet, heritability estimates have demonstrated that longevity is in fact partially inherited, with a negligible genetic contribution to survival up to approximately 60 years of age, after which an increasing genetic component to survival is observed. Therefore, we pursued whole genome sequencing (WGS) of a related phenotype – healthy aging – to understand the genetics of disease-free aging without medical intervention. WGS was performed with the Complete Genomics platform on 511 healthy aging individuals were compared to 686 matched population controls.   In contrast with studies of exceptional longevity, we found that healthy aging is not associated with known longevity variants. We observe a significant depletion of *APOE*-ε4 alleles, which is associated with longevity but considered to be 'frailty' allele for late onset disease rather than a true longevity allele. Similarly, we observe a reduced overall genetic susceptibility to Alzheimer and coronary artery disease in healthy aging, as determined by genetic risk scores, but no reduced risk for type 2 diabetes, stroke, and common cancers. Additionally, we observe no association with a decreased rate of rare pathogenic variants for common Mendelian disorders (ACMG secondary findings genes, inherited cancer, nor familial dementia), potentially indicating the presence of disease-resistance factors. In keeping with this possibility, by performing a whole genome sequence based common variant genome-wide association study as well as a rare variant burden analysis; we identify suggestive common and rare variant genetic associations implying that protection against cognitive decline is a genetic component of healthy aging. Interestingly, the gene most enriched for rare variants in the health aging cohort is *COL25A1* – a neuron specific collagen that plays a critical role in regulating the buildup of Aβ fibrils.   These findings, based on a relatively small cohort, require independent replication. Overall, our results suggest healthy aging demonstrates characteristics similar to other complex polygenic phenotypes, and that healthy aging is a genetically overlapping but distinct phenotype from exceptional longevity that may be enriched with disease-protective genetic factors.

1560F

GWAS of frailty in older Caucasians and African Americans: The health and retirement study. *C. Wu, M.C. Odden, S.A. Ramsey, H. Bae.* Oregon State University, Corvallis, OR.

Background. Frailty is a clinical syndrome of decreased resilience to stressors, resulting from age-related declines in multiple organ systems. Frailty is common in older adults and is associated with death, disability, fractures, and falls. Heritability estimates of frailty ranged from 19% to 43%, suggesting genetic variation may play an important role in frailty. However, only a limited number of genes have been examined in candidate gene studies, with no consistent findings. No genome-wide association study (GWAS) has been published on frailty. **Methods.** We performed a GWAS to identify genetic variants of frailty in 4898 Caucasians and 650 African Americans (AAs) aged ≥65 years from the Health and Retirement Study (2006 and 2008 waves). Frailty was measured on a 0-5 scale counting the number of characteristics: low grip strength, slow gait speed, excessive weight loss (%), and low physical activity, defined based on the lowest quintile, and self-reported exhaustion. GWAS was conducted on ~1.65 million genotyped single nucleotide polymorphisms (SNPs) with minor allele frequency >5%. Race-stratified linear regression was conducted, adjusting for age, sex, and the top six eigenvectors derived from principal components analysis. The GWAS results were post-analyzed using the gene expression data from the Genotype-Tissue Expression project. **Results.** We found no genome-wide significant SNPs ($p < 5 \times 10^{-8}$), but 30 suggestive associations ($p < 5 \times 10^{-5}$) were present in Caucasians. Three SNPs, in strong linkage disequilibrium (LD), are located at *NTF3* gene, which is involved in the nervous system. One SNP was associated with the expression of *HDHD3* gene in 17 tissues, such as artery and muscle. Among AA, 2 SNPs, in strong LD, reached genome-wide significance, and 16 SNPs were suggestively related to frailty. The two genome-wide significant SNPs are located at *DYNC1I2* gene whose related pathways are involved in the immune system. One SNP that was suggestively associated with frailty in Caucasians was replicated in AAs ($p < 0.05$; consistent direction of estimate). However, strength and direction of many associations were different between Caucasians and AAs, suggesting there may be different genetic variants contributing to frailty by race. **Conclusions.** Many genetic variants may be associated with frailty. Caucasians and AAs may have different genetic architecture underlying frailty. Future GWAS using independent racially-diverse cohorts is needed to replicate these findings.

1561W

Somatic genetic variation in the brain during aging and in Alzheimer disease. *H.T. Helgadottir[1], P. Lundin[2], E. Wallén Arzt[1], L. Lilius[3,4], A-K. Lindström[3,4], C. Graff[3,4], M. Eriksson[1].* 1) Karolinska Institutet, Department of Biosciences and Nutrition, Center for Innovative Medicine, Huddinge, Sweden; 2) Science for Life Laboratory (SciLifeLab), Department of Biochemistry and Biophysics, Stockholm University, Stockholm, Sweden; 3) Karolinska Institutet, Department of NVS, Center for Alzheimer Research, Division for Neurogeriatrics, Huddinge, Sweden; 4) Deptartment of Geriatric Medicine, Karolinska University Hospital, Huddinge, Sweden.

Mutation accumulation in cells creates genetic mosaicism in a tissue. This accumulation may contribute to aging, and to neurodegenerative disease such as Alzheimer disease (AD; MIM 104300). Alzheimer disease is a neurological disorder that causes cognitive dysfunction and mainly affects elderly people. The neuropathological findings seen in the brain of AD patients can also be seen in older unaffected individuals, suggesting neurodegeneration has a more common effect on aging than previously thought. In this study, 2.85 Mb of the genome was sequenced with the average depth of 660x. Individuals with early-onset AD (n=4), late-onset AD (n=4), and age- and gender-matched non-dementia individuals (n=8) were included in the study. Blood and brain (temporal cortex) samples from each individual were sequenced with the aim of identifying low-degree somatic mutations that might contribute to aging. Variants were called according to the GATK Best Practices workflow, and the somatic callers, Varscan2 and MuTect1. Variants with minimum 100X depth in both tissues and minimum 5% alternate allele frequency were included in the study. To determine brain- or blood-specificity of each variant we applied the Fisher Exact test ($p < 0.05$) on observed reference and alternate reads from each tissue. When comparing the variant calls from the somatic callers, little overlap was observed, highlighting the complexity of detecting rare variants. Overall, fewer brain-specific variants were observed in late-onset AD patients compared to the early-onset AD. In non-dementia individuals, more variants were observed in older brains compared to the middle-aged brains. The amount of cells in the brain is expected to decrease during normal aging, and even more so in AD patients where cell loss is one of the hallmarks of the disease. Therefore, fewer mutations were expected to be seen in the brain of AD patients, as evidenced in our study. Several variants are recurrently mutated in different individuals, and clusters of mutations are seen within the same loci. Our results indicate different genetic variation in the brain and blood, and that AD has an effect on the genetic variation in the brain. .

1562T

Genome-wide association and pathway analysis of smoking cessation. *S. Kim[1], H. Kim[1], Y. Yun[1], Y. Chang[2], S. Ryu[2], H. Shin[3], H. Kim[1].* 1) Department of Biochemistry, School of Medicine, Ewha Womans University, Seoul, South Korea; 2) Center for Cohort Studies, Total Healthcare Center, Kangbuk Samsung Hospital, School of Medicine, Sungkyunkwan University, Seoul, South Korea; 3) Department of Family Medicine and Health Screening Center, Kangbuk Samsung Hospital, School of Medicine, Sungkyunkwan University, Seoul, South Korea.

The aim of this study was to investigate genetic variants and biological pathway associated with smoking cessation. The discovery samples included 679 subjects recruited from the Kangbuk Samsung Cohort Study which evaluated a wide range of health traits and diseases among Korean adults. The replication samples consisted of 3228 subjects selected from rural Ansung and urban Asan cohorts which are two community-based cohorts. SNP genotyping was conducted using Illumina or Affymetrix microarray chips. Quality control (QC) procedures were conducted to remove SNPs with missing genotyping rate > 5%, MAF > 0.05, HWE<10^{-6}. After QC, Genotyped data were imputed by IMPUTE2 using 1000 genome as a reference data. SNPs with an imputation quality score (R^2) greater than 0.8 and MAF>0.05 were used for the association analysis. Genome-wide association analysis (GWA) was performed using the logistic regression in Plink Ver. 1.90 to test the association of SNPs with smoking status as categorical variables. To identify biological pathways, GSEA with MAGENTA algorithm were conducted. GSEA p-value with threshold of 75 percentile cutoff. Pathway information was obtained from KEGG and REACTOME of the molecular signature database (MsigDB v4.0). In the discovery phase, the smallest P-valued was identified for a marker of rs6531222 located in chromosome 2, but it was not replicated. Although no SNPs were observed as associated with smoking cessation at genome-wide significance level, suggestive evidence of association was found in rs59476775 located near DUSP26 gene. In pathway analysis, Regulation of Insulin Secretion was top-ranked pathway in the discovery sample. Regulation of Insulin Secretion and MAPK Signaling Pathway were also found in the replication study. These findings contribute to our understanding of the genetic effects on smoking cessation and provide critical clues to biological mechanisms that influence them. [This research was supported by Korea Health Technology R&D Project through the Korea Health Industry Development Institute (KHIDI) funded by the Ministry of Health & Welfare (HI14C0072) and the National Research Foundation of Korea (NRF) funded by ICT & Future Planning (NRF-2014R1A2A2A04006291) and the Ministry of Education (NRF-2013R1A1A2062702).].

Genome-wide association study of male sexual orientation. *A.R. Sanders[1,2], G.W. Beecham[3], S. Guo[3], K. Dawood[4], G. Rieger[5], J.A. Badner[6], E.S. Gershon[2], R.S. Krishnappa[7], A.B. Kolundzija[8], J. Duan[1,2], P.V. Gejman[1,2], J.M. Bailey[9], E.R. Martin[3].* 1) Res Inst, NorthShore Univ HealthSystem, Evanston, IL; 2) Dept of Psychiatry and Behavioral Neuroscience, Univ of Chicago, Chicago, IL; 3) Dept of Human Genetics, Univ of Miami, Miami, FL; 4) Dept of Psychology, Pennsylvania State Univ, University Park, PA; 5) Dept of Psychology, Univ of Essex, Colchester, England, UK; 6) Dept of Psychiatry, Rush Univ Medical Center, Chicago, IL; 7) Dept of Psychiatry, Icahn School of Medicine at Mount Sinai, Elmhurst, NY; 8) Dept of Sociomedical Sciences, Mailman School of Public Health, Columbia Univ, New York, NY; 9) Dept of Psychology, Northwestern Univ, Evanston, IL.

Male sexual orientation is a scientifically and socially important trait shown by family and twin studies to be influenced by environmental and complex genetic factors. Genetic linkage studies have identified pericentromeric chromosome 8 and chromosome Xq28 as containing genetic variants contributing to its development, however, the linkage peaks are large and specific trait genes have not been identified. We conducted a genome-wide association study (GWAS) on a sample (N=2,381) including family data (i.e., GWAF) using Affymetrix single nucleotide polymorphism (SNP) arrays. Our analyzed European ancestry sample consisted of 1,273 sporadic (without family history data) samples (88 homosexual men and 1,185 heterosexual men) and 1,108 samples from families with homosexual brothers (1,022 homosexual men, 40 bisexual men, and 46 heterosexual men). After quality control, imputation, and analysis, we identified several SNPs with $p<10^{-5}$, including regions of multiple supporting SNPs on chromosomes 13, 14, and X. The genes nearest to these peaks have functions plausibly relevant to the development of sexual orientation. On chromosome 13, *SLITRK6* is a neurodevelopmental gene mostly expressed in the diencephalon, which contains a region previously reported as differing in size in men by sexual orientation. On chromosome 14, *TSHR* genetic variants in intron 1 could conceivably help explain past findings relating familial atypical thyroid function and male homosexuality. Furthermore, skewed X chromosome inactivation has been found in the thyroid condition, Graves' disease, as well as in mothers of homosexual men in other studies. On chromosome Xq25, *GRIA3* alterations in a mouse model resulted in unusual social behaviors in male-male interactions. On pericentromeric chromosome 8 within our previously reported linkage peak, we found nominal support for a SNP association reported in a previous scientific meeting (ASHG 2012). Although increasing evidence highlights genetic contributions to male sexual orientation, our current understanding of contributory loci is still limited, consistent with the complexity of the trait. Further increasing genetic knowledge about male sexual orientation should help advance our understanding of the biology of this important trait.

Methylenetetrahydrofolatereductase C677T polymorphism and the risk of Acute Myeloid Leukemia in Indian population: A case-control association study. *J.C. Silas[1,2], R. Reddy[3], S. Vishnupriya[4], V. Sugunakar[4], S. Rajender[3], K. Thangaraj[2].* 1) Taibah University, Madina, Saudi Arabia; 2) Centre for Cellular and Molecular Biology, Hyderabad, India; 3) Central Drug Research Institute, Lucknow, India; 4) Osmania University, Hyderabad, India.

Background: Methylenetetrahydrofolate reductase (MTHFR) enzyme is involved in folate metabolism and is crucial for maintaining DNA integrity in the cells**.** MTHFR gene polymorphisms have been previously associated with acute myeloid leukemia in many populations. The aim of this study is to evaluate the association of MTHFR C677T polymorphism with acute myeloid leukemia in Indian population. **Methods:** A total of 170 cases with acute myeloid leukemia and 243 age matched controls were tested for the C677T polymorphism using polymerase chain reaction followed by Sanger sequencing of the amplified product. **Result:** No significant association was found between MTHFR C677T Polymorphism and acute myeloid leukemia **Conclusion:** MTHFR C677Tpolymorphism is not strongly associated with acute myeloid leukemia in Indian population.

1565T

Haplotypes of vitamin D receptor gene: Both risky and protective for fibromiyalgia (FMS). *M. Akyol[1], A. Baklarlı[2], E. Tepeli[3], H. Balkarlı[1], S. Temel[4], V. Cobankara[4].* 1) Dept. of Medical Biology and Genetics, Akdeniz Universitiy, Antalya,Turkey; 2) Dept. Rhomotology-internal medicine, Antalya Training and research Hospital, Antalya,Turkey; 3) Dept. of Medical Genetics, Pamukkale Universitiy, Denizli,Turkey; 4) Dept. Rhomotology-internal medicine, Pamukkale Universitiy, Denizli,Turkey.

Background:Clinical observations suggest that vitaminD may influence fibromyalgia etiology. FMS and vitamin D deficiency share a similar symptom profile;the relationship between these conditions is unclear.VitaminD receptor is a crucial mediator of the symptoms of vitaminD deficiency.Thus, vitaminD receptor gene polymorphisms or haplotypes may contribute to vitaminD resistance.Objectives: This study evaluated the clinical relationship between FMS and vitaminD gene among Turkish FMS patients.Methods:73 patients with FMS were diagnosed according to the ACR 2010 criteria; the control group included 61 healthy unrelated volunteers.The rs2228570(Fok I), rs1544410(Bsm I), rs7975232(Apa I) and (rs731236.Taq I polymorphisms were examined using PCR-RFLPResults:In individual SNP analyses, none of the snps have been found to be associated with FMS(p values are 0.491, 0.477, 0.207, and 0.736 respectively). However, it has been detected that there is a strong association between haplotypes of VDR gene polymorphisms and FMS. As a result of this study, the effect of haplotypes is shown to be both risky and protective. P value of risk haplotypes ATC(rs2228570,rs1544410,rs7975232) is 0,015 (26,5%) and TTT is 0,0068 (12,8%).The p value of collected risk haplotypes (ATC, TTT) is 0,006 (39,3%) and (ATC, TGT, and TTT)0,000009 (58,7%).Frequent protective haplotype TTC is 0,0385 (6,8%).The p value of collected protective haplotypes (ATT, TCG, and TTC) is 0,008 (38%).Conclusions:The present study is the first study evaluating VDR gene in patients with FMS.Our results suggest that haplotypes in VDR are strongly associated with fibromyalgia expressing both risk and protective effect.Our findings may help guide future research needed to define the role of vitaminD in FMS.

Improving the resolution of GWAS in populations of African descent. *S. Chavan[1], M. Daya[1], N.M. Rafaels[1], H.R. Johnston[2], M. Boorgula[1], I. Ruczinski[3], T.H. Beaty[4], M. Taub[3], R.A. Mathias[4,5], K.C. Barnes[1], CAAPA consortium.* 1) Department of Medicine, University of Colorado, Denver, CO; 2) Department of Biostatistics and Bioinformatics, Emory University, Atlanta, GA; 3) Department of Biostatistics, Bloomberg School of Public Health, JHU, Baltimore, MD; 4) Department of Epidemiology, Bloomberg School of Public Health, JHU, Baltimore, MD; 5) Department of Medicine, Johns Hopkins University, Baltimore, MD.

The first genome-wide association study (GWAS) of asthma focused exclusively on African ancestry populations (464 + 471 African American cases and controls, and 299 + 355 African Caribbean cases and controls) identified an association between dipeptidyl peptidase 10 (*DPP10*) and clinical asthma (Mathias et al 2009). This gene was first identified as a candidate gene for asthma by positional cloning in 2003, with some evidence for association, but this evidence for association was not replicated across independent populations. We hypothesized that inadequate tagging of African ancestry genes by the commercial genotyping array used in the 2009 study (Illumina 650Y), combined with subtle differences in ancestry between populations, contributed to a failure to replicate associations for individual SNPs, even though gene-based evidence was seen. In addition, none of the HapMap imputed SNPs around the top SNP, rs1435879, were supportive, possibly due to inadequate representation of African ancestry in the imputation reference panel. As part of the Consortium on Asthma among African-ancestry Populations in the Americas (CAAPA), where whole genome sequence (WGS) data (30X coverage) was generated on 883 unrelated individuals of self-reported African ancestry from 15 North, Central, and South American and Caribbean populations (plus Yoruba-speaking individuals from Ibadan, Nigeria) the 'African Diaspora Power Chip' (ADPC) was developed. The ADPC is a genotyping array consisting of tagging SNPs useful in comprehensively identifying African specific genetic variation when combined with a commercially available GWAS chip. We genotyped a subset of subjects from the original Mathias et al. GWAS on the ADPC (678 cases and 723 controls), and imputed the combined GWAS and ADPC data sets against the CAAPA genomes, which provided a much better representation of African haplotypes compared to the current 1000 genomes reference panel. In this new imputed data set, rs1435879 was still the most significant association in the DPP10 region, but several intronic SNPs surrounding rs1435879 now supported the association signal. This finding highlights the importance of adequately tagging African ancestry variants, and using sufficient African ancestry representation for imputation reference panels, when doing genetic association studies in African ancestry populations.

1567W

Phenome-wide association study of *SULT1A1* copy number variation and correlation with estrogen metabolism. *J. Liu[1], R. Zhao[1], Z. Ye[2], A. Frey[3], N. Snyder[3], S. Hebbring[1].* 1) Center for Human Genetics, Marshfield Clinic Research Foundation, Marshfield, WI; 2) Biomedical Informatics Research Center, Marshfield Clinic Research Foundation, Marshfield, WI; 3) A.J. Drexel Autism Institute, Drexel University, Philadelphia, PA.

Human cytosolic sulfotransferase 1A1 (SULT1A1) is believed to be one of the most important SULT isoforms. This theory is driven by observations that SULT1A1 is widely expressed in multiple human tissues and enzyme experiments demonstrate SULT1A1 has a wide range of phenolic substrates. As such, SULT1A1 has been hypothesized to play a significant role in drug, hormone, and neurotransmitter metabolism, while also being involved in detoxification and carcinogenesis. Interestingly, *SULT1A1* is subject to common copy number variation (CNV) where the entire gene can be deleted and duplicated. To better understand the biological role of SULT1A1 in human health, we genotyped the CNV in 14,275 Marshfield Clinic patients linked to an extensive electronic health record (EHR) system. The majority of patients (64%) had 2 copies of *SULT1A1* whereas 36% had >2 copies (max 6 copies) and 11 patients (0.08%) were homozygous deleted. This is the first time individuals with 0 copies of *SULT1A1* have been identified. To determine if individuals with 0 copies is detrimental, we manually examined the clinical data from these patients and found no obvious shared health conditions. To further assess the importance of *SULT1A1* CNV, we conducted comprehensive phenome-wide association studies (PheWASs). PheWAS results using ICD9 coding and clinical text data provided evidence that *SULT1A1* CNV may play an important role in response to common allergens. The strongest association included the clinical documentation of "Nasacort" (p=6.2E-7), which is a medication commonly used to treat allergic rhinitis. This association passed a conservative Bonferroni correction. To further understand the potential biological involvement of SULT1A1 activity on hormone metabolism, most notably estrogen metabolism, we quantified estrogen metabolites in plasma from 100 patients with *SULT1A1* CNV genotype data. The patients were selected for extreme CNV variation and included 50 males between the ages 40-50 and 50 premenopausal women between ages 30-40. Results showed that *SULT1A1* CNV was positively correlated with estrone to estrone sulfate conjugate ratio (E1/E1S; p=0.03, r=0.32). With evidence demonstrating for the first time that *SULT1A1* CNV is associated with common allergies and may be involved in hormone metabolism according to ex vivo experiments, this study highlights the potential broad importance of SULT1A1 in a variety of biological processes that are important in human health.

1568T

SCN10A **gene variant in a case of sudden infant death syndrome.** *K. Leavitt[1], T. Goldwaser[1], S. Klugman[1], R. Marion[2], Y. Tang[3], T.V. McDonald[2].* 1) Division of Reproductive and Medical Genetics, Department of Obstetrics, Gynecology and Women's Health, Montefiore Medical Center, Bronx, NY; 2) Division of Genetic Medicine, Department of Pediatrics, Montefiore Medical Center, Bronx, NY; 3) Molecular Genetics Laboratory, Office of Chief Medical Examiner, New York, NY.

Background: Sudden infant death syndrome (SIDS), has an incidence of 38.7 deaths per 100,000 live births. The majority of cases appear to be multi-factorial, a combination of genetic susceptibility and environmental risk factors. Several single gene disorders have been recognized as causes of SIDS, such as mutations in one or more cardiac channel genes and fatty acid oxidation disorders. Case: 34 y/o G8P4032 who was referred to genetics because of a history of infant deaths at 2 months of age. The first one was a male from a different partner who died at 2 months of age in El Salvador in 1996. The second infant death was in October 2015, when her daughter of 2 months of age was found unresponsive on her crib. The patient has 2 healthy living children. The cause of death was preliminarily established as SIDS. Clinical course and diagnostic work-up: An autopsy was obtained through the Office of the Chief Medical Examiner of New York City, which included molecular testing of 95 cardiac arrhythmogenic genes, revealing a variant of uncertain significance, NP_006505.2: p.Leu867Phe in one allele in the SCN10A gene in the deceased child. The SCN10A gene encodes for the protein Nav1.8 of the voltage-gated sodium channel alpha subunit. In 2015, mutations in this gene have been reported in Brugada syndrome and atrial fibrillation, and are inherited in autosomal dominant pattern. However, other genetic and environmental factors influence disease expression and severity. Maternal testing was obtained and the results show that the mother does not carry that variant on the SCN10A gene, while testing on the father of both the deceased child and the current pregnancy is still pending. The patient declined amniocentesis. Plan: Given the possible association of an SCN10A variant, the cause of death of her previous child, and the unknown status of the father, the following were recommended: delivery at a tertiary hospital, continuous neonatal monitoring and electrocardiogram, presume the risk for Brugada syndrome and proceed accordingly. The patient was also cautioned to avoid high risk drugs, use crib monitoring for breathing and movement and consider umbilical cord blood sampling for targeted DNA sequencing for the SCN10A variant. Conclusion: The use of a molecular panel for cardiac arrhythmia genes has been included in the diagnostic work-up for SIDS in some states. This case is ongoing to determine the role of this SCN10A variant in this patient's multiple infant deaths.

1569F

Systematic evaluation of risk loci from candidate gene and genome-wide association studies of fatigue. *E.C. Corfield[1], S.M. Marshall-Gradisnik[2], N.G. Martin[3], D.R. Nyholt[1].* 1) Faculty of Health, Institute of Health and Biomedical Innovation, Queensland University of Technology, Brisbane, QLD, Australia; 2) National Centre for Neuroimmunology and Emerging Diseases, Menzies Health Institute Queensland, School of Medical Science, Griffith University, Southport, Australia; 3) QIMR Berghofer Medical Research Institute, Brisbane, Australia.

Chronic fatigue syndrome (CFS) is a complex, neurological disorder of unknown pathophysiology. However, the immune, endocrine, nervous, cardio-vascular, and digestive systems have been implicated. Additionally, classical twin studies have been utilised to estimate the heritability of CFS in females. The estimated contribution of additive genetic, common environmental, and unique environmental factors has been estimated at 51%, 12%, and 36%, respectively (Buchwald, et al., 2001). Limited studies have been conducted to investigate the underlying genetics of CFS, the majority of which involved very small sample sizes. The genetic contribution has been implicated through gene expression analyses, bioinformatic data mining approaches, candidate gene studies, and most recently genome-wide association (GWA) studies. However, replication studies are required to confirm these exploratory findings. Therefore, the present study aims to evaluate the findings from candidate gene and GWA studies. Additionally, the selected genes will be evaluated in a more general fatigue phenotype. Seventeen genes with nominal evidence for association were selected from published candidate gene studies while 323 genes plus 188 inter-genic SNPs were selected from published CFS GWA studies. SNPs within the study genes and 15 kb regions upstream and downstream (Pickerell, et al., 2010) were investigated in GWA data of 105 CFS cases and 71 controls. In addition, the selected genes were investigated in 307 fatigue cases and 745 controls. A kinship matrix was utilised to account for relatedness within the fatigue cohort, which was derived from a twin cohort. A Bonferroni-corrected significance threshold was calculated to assess the association of SNPs with CFS and fatigue. Although both GWA analyses contained relatively small sample sizes the CFS dataset contained over 2.5 times the number of cases compared to previously published CFS GWA studies. In addition to confirming association between previously implicated risk loci, results will be presented concerning the genetic similarity of CFS and more general fatigue.

Exome chip studies in allergic disease – Utilising multinomial logistic regression to uncover genetic associates of sensitisation disease phenotypes. *J.A. Curtin[1], A. Custovic[2], D.C. Belgrave[2], A. Simpson[1].* 1) University of Manchester, Manchester, United KingdomCentre for Respiratory Medicine and Allergy, Institute of Inflammation and Repair, University of Manchester, Manchester, Manchester, United Kingdom; 2) Department of Paediatrics, Imperial College London, London, UK.

   Background: Much of the heritability of complex traits (e.g. atopy, asthma) remains unexplained by genome wide association studies (GWAS), possibly due to poor phenotype definition. Conventionally, atopy is defined as the presence of a positive skin test or specific IgE to any allergen. We have proposed that this diagnostic label encompasses a number of different phenoypes. We applied machine learning approach to all available skin test and sIgE data collected from birth to age 8 years in the Manchester Asthma and Allergy Study (MAAS) to cluster children into different atopy classes (Simpson *et al.* AJRCCM 2010;181:1200-6); the majority of atopic children clustered into 4 distinct classes. We hypothesized that genetic associates of different phenotypes will be characteristic. **Methods:** We genotyped children from MAAS using the "Human Exome-12 v1.1 Beadchip", which resulted in 39714 SNPs after quality control and removing uninformative SNPs. We carried out a multinomial logistic regression likelihood test using the newml option in SNPT-EST (v2.5.2) on the sensitisation clusters where the null hypothesis is that are no differences between the different clusters. The four sensitisation classes were: "Multiple early" (122 cases), "Mite" (68 cases), "Grass" (34 cases); and "Persistent Sensitisation to a wide variety of allergens" (67 cases). The "No sensitisation" class (n=541) was the reference. We compared these results to those obtained from "Conventional atopy" (272 cases; 559 controls). **Results:** Using the additive model, we observed a trend association from the likelihood ratio test for 4 SNPs and differences between the 4 classes - 2 amino acid changing SNPs in *VWDE* (rs2192828 and rs848016 on 7p21; p=2.5E-06 and p=3.8E-05 respectively), 1 amino acid changing SNP in *OR52N4* (rs7394584 on 11p15; p=9E-05) and an intronic SNP in a gene with homology to mouse *Mir1192* (rs12446956 on 16q22 p=6E-05). In contrast we observed one intronic SNP in *WDR36* (rs10051830, 5q22; p=5.5E-05) was associated with conventional atopy. **Conclusions:** Atopy comprises multiple latent atopic vulnerabilities with different genetic risk factors. To date identifying the genetic associates of latent classes has been hampered by the multinomial nature of these phenotypes. Using a newly implemented multinomial logistic regression, we observed trend associations between different genetic regions precisely defined phenotypes of sensitisation.

1571T

Genome-wide association study identifies sex-specific genetic determinants of emphysema. *A. El Boueiz[1,2], M. Hardin[1,2], M.H. Cho[1,2], G.R. Washko[2], T.H. Beaty[3], J.D. Crapo[4], E.K. Silverman[1,2], B.J. Make[4], D.L. DeMeo[1,2] for the COPDGene Investigators.* 1) Channing Division of Network Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston; 2) Pulmonary and Critical Care Division, Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 3) Bloomberg School of Public Health, Johns Hopkins University, Baltimore, MD; 4) Division of Pulmonary Medicine, Department of Medicine, National Jewish Health, Denver, CO.

   Introduction: Chronic obstructive pulmonary disease (COPD) is the leading cause of chronic respiratory morbidity and mortality in the US. Despite the growing recognition that differences in COPD susceptibility and severity exist between male and female smokers, sex-specific determinants of COPD remain unknown. Emphysema, destruction of lung parenchyma, is commonly seen in smokers with COPD, and males and females with COPD demonstrate different percentages of radiographic emphysema at each stage of lung obstruction. The aim of this study was to identify sexually dimorphic genetic risk factors for emphysema. **Methods:** From the COPDGene cohort, we analyzed 4983 males and 4321 females with complete genotype and CT densitometry data. Genotyping was performed on the Illumina Omni Express platform with additional markers imputed using the 1000 Genomes Project. We conducted sex-stratified genetic association tests for radiographic emphysema using an additive model adjusting for age, body mass index, pack-years of smoking, current smoking, scanner type and genetic ancestry. Inverse normal transformation was applied to the phenotype to reduce the impact of deviation from normality. Separate analyses in non-Hispanic whites and African Americans were combined into a pooled analysis. **Results**: Stratification on the basis of sex reveals genome-wide significant genetic effects for markers in the 4q31 locus near *HHIP* in females but not in males (Effect size: 0.07±0.02, P: 3E-5 *(M)*; Effect size: 0.11±0.02, P: 1E-8 *(F)*). We did not detect any other genome-wide significant common SNP differences between men and women. However, three interesting top sub-threshold differential associations were found on chromosomes, 8p22 near *DLC1* (Effect size: -0.08±0.02, P: 8E-7 *(M)*; Effect size: -0.02±0.02, P: 0.23 *(F)*), 6q25 near *ESR1* (Effect size: -0.002±0.024, P:0.92 *(M)*; Effect size: -0.14±0.03, P: 4E-7 *(F)*) and 2p24 near *KCNK3* (Effect size: -0.02±0.02, P: 0.26 *(M);* Effect size: -0.12±0.02, P: 8E-7 *(F)*). **Conclusion:** There is mounting evidence of an important role for sex-differentiated effects in the architecture of complex traits such as COPD. This GWAS of quantitative emphysema in smokers identified potential risk loci with differential associations in males and females. These findings may help elucidate sexually-dimorphic mechanisms of the disease and inform sex-specific therapeutics and preventive strategies

1572F

Functional mutations in GRHL3 gene are associated with cleft palate in sub-Saharan Africa. *M.A. Eshete[1], W.L Adeyemo[2], L.J.J Gowans[3], P.A Mossey[4], T. Busch[5], O. James[2], E.A Augustine-Akpan[8], M.L Marazita[6], A.A Adeyemo[7], J.C Murray[5], A. Butali[8].* 1) Addis Ababa University, Addis Ababa, Select a Country; 2) University of Lagos, Nigeria; 3) Kwame Nkrumah University of Science and Technology, Ghana; 4) University of Dundee, UK; 5) Department of Pediatrics University of Iowa, USA; 6) Center for Craniofacial and Dental Genetics, Department of Oral Biology, University of Pittsburgh, U.S.A; 7) National Human Genomic Research Institute , Bethesda MD; 8) Department of Oral Pathology, Radiology and Medicine, University of Iowa, USA,.

Background/Objectives: Although progress has been made towards understanding the genetic etiology of cleft lip with or without cleft palate (CL/P), few significant findings have been reported for isolated cleft palate (CPO). The first gene with clear evidence of causality in CPO, Fas-associated factor-1 (*FAF1*), was reported by Ghassibe et al. (2011) . Recently*,* a common coding variant of *GRHL3* was shown to be associated with risk for non-syndromic CPO in Europeans (Leslie et al ., 2016). Mutations in this gene have also been reported in families with Van der Woude syndrome. The current study sequenced the *GRHL3* gene in cases with CPO from Africa. **Materials and methods:** We recruited participants from Ghana, Ethiopia and Nigeria. This cohort included case-parent trios, cases and other family members, as well as controls. Seventeen coding regions (exons) of *GRHL3* were amplified using Polymerase Chain Reaction (PCR). We sequenced exons of this gene in DNA from 134 non-syndromic and also the parent samples to identify *de novo* variants. Novel variants observed in cases were sequenced in 270 controls. **Results:** Six novel mutations were discovered (2 Ghanaian, 1 Ethiopian and 3 Nigerians,). The mutations were: missense (p.Pro166His, p.Asp410Gly and p.Arg603Lys), splice site (p.Ser428Arg), frameshift mutation (p.Gly65AlafsTer55) and nonsense mutation (p.Tyr559X). None of these mutations were seen in 270 controls and in any known exome and whole genome databases including the 1000 genomes database that has data from Africa. The p.Pro166His, p.Asp410Gly and p.Gly65AlafsTer55 segregate in the family and were seen in unaffected mothers. Mutations p.Ser428Arg, p.Arg603lys and p.Tyr559X were not seen in mothers and we could not ascertain de novo since father samples were unavailable. The p.Gly65AlafsTer55 and p.Tyr559X will lead to premature truncation of the protein. The p.Asp410Gly mutation damaged a sumoylation site. Serine and Threonine phosphorylation is also affected by the p.Ser428Arg mutation which damaged the CK1 phosphorylation site. Based on the amino acid properties and conservation of the wild type at position p.Asp410Gly and p.Ser428Arg in several species, these mutations were predicted to be probably damaging to the protein by Polyphen and SIFT. **Conclusions:** Our study provides evidence that, as in Caucasian populations, mutations in *GRHL3* may contribute to the risk of non-syndromic CPO in the African population.

1573W

Genetics of bilirubin serum levels and chronic obstructive pulmonary disease. *N. Fishbane[1], M. Obeidat[1], N.N. Hansel[2], N. Rafaels[3], R. Mathias[4], I. Ruczinski[5], T.H. Beaty[6], K.C. Barnes[3], P.D. Paré[1], D.D. Sin[1].* 1) Centre for Heart Lung Innovation, University of British Columbia, Vancouver, BC, Canada; 2) Pulmonary and Critical Care Medicine, School of Medicine, Johns Hopkins University, Baltimore, MD, USA; 3) Division of Biomedical Informatics and Personalized Medicine, Department of Medicine, University of Colorado School of Medicine, Anschutz Medical Campus, Aurora, CO, USA; 4) Division of Genetic Epidemiology, School of Medicine, Johns Hopkins University, Baltimore, MD, USA; 5) Department of Biostatistics, Bloomberg School of Public Health, Johns Hopkins University, Baltimore, MD, USA; 6) Department of Epidemiology, Bloomberg School of Public Health, Johns Hopkins University, Baltimore, MD, USA.

Background: Chronic obstructive pulmonary disease (COPD) is the third leading cause of death worldwide. The disease is characterized by increased oxidative stress. Bilirubin, a product of heme catabolism, has been shown to have antioxidant and anti-inflammatory properties. Serum levels of bilirubin correlate positively with lung function and high levels are associated with reduced incidence of COPD. We hypothesized that serum bilirubin levels are under genetic control in COPD subjects. **Methods**: The Lung Health Study (LHS) is a longitudinal multicenter study of mild-to-moderate COPD subjects, who were followed over 11 years. In year 5, bilirubin serum levels were measured in 4,101 individuals who also had whole genome genotypes. A genome-wide association study (GWAS) for bilirubin levels was undertaken using 1000 genome imputed genotypes, assuming an additive genetic model, and adjusting for age, sex, BMI, and genetic principal components. The top bilirubin-associated single nucleotide polymorphisms (SNPs) were tested for association with lung function in LHS subjects and in a number of large publically available lung function GWAS data sets including the UKBiLEVE study (n=15,000) and the SpiroMeta consortium (n=38,000). **Results**: One previously known locus was strongly associated with bilirubin levels on chromosome 2 in the UDP glucuronosyltransferase family 1 member A complex locus (UGT1A, P = 6.77E-135). The UGT1A genes are involved in the conjugation of bilirubin. Given this was the only genome-wide significant locus, a second GWAS was performed conditioning on the UGT1A locus. Three loci were borderline significant in this analysis: the previously identified solute carrier organic anion transporter family member 1B1 (*SLCO1B1*) gene region on chr12 (P= 1.44E-7), and two novel loci including *KIAA1217* gene on chr10 (P=5.8E-8) and an intergenic region on chr21 (P= 8.05E-08). The most significant SNP from the UGT1A locus was nominally associated with lung function in heavy smokers in the UKBiLEVE study (P = 0.039). **Conclusion**: The bilirubin GWAS in COPD subjects replicated previously identified loci and suggested two novel regions. Integrating bilirubin's genetic determinants with lung function suggests that bilirubin may contribute to the pathogenesis of COPD.

1574T

A genome-wide association study of vertical cup-disc ratio in Latinos. *X. Gao[1], D. Nannini[1], M. Torres[2], Y.I. Chen[3], K.D. Taylor[3], J.I. Rotter[3], R. Varma[2]. 1) Dept Ophthalmology & Visual Sci, Univ Illinois, Chicago, Chicago, IL; 2) USC Roski Eye Institute, Department of Ophthalmology, University of Southern California, Los Angeles, CA; 3) Institute for Translational Genomics and Population Sciences, Los Angeles Biomedical Research Institute and Department of Pediatrics and Medicine at Harbor-UCLA, Torrance, CA.*

Vertical cup-disc ratio (VCDR) is used as a clinical assessment measure to identify and monitor glaucomatous damage to the optic nerve. Previous genetic studies conducted in European and Asian populations have identified many loci associated with VCDR. The genetic factors in other ethnic populations, such as Latinos, influencing VCDR remain to be determined. Here, we describe the first genome-wide association study (GWAS) on VCDR in Latinos. We conducted this GWAS on VCDR using 4,537 Latinos who were genotyped using either the Illumina OmniExpress BeadChip (~730K markers) or the Illumina Hispanic/SOL BeadChip (~2.5 million markers). Study subjects were 40 years of age and older. Linear regression, adjusting for age, gender, and principal components of genetic ancestry, was conducted to assess the associations between single nucleotide polymorphisms (SNPs) and VCDR. We imputed SNPs from the 1000 Genomes Project to integrate additional SNPs not directly genotyped.We replicated two previously reported SNPs that reached GWAS significance, rs1900005 and rs7916697, in the *ATOH7-PBLD* region, as well as identified two suggestive associations in the *CDC7-TGFBR3* region on chromosome 1p22.1 and in the *ZNF770-DPH6* region on chromosome 15q14. We discovered a novel SNP, rs56238729 (P = 8.56E-11), in the *ATOH7-PBLD* region that is significantly associated with VCDR in Latinos. We replicated 10 previously reported regions, including *COL8A1, CDKN2BAS, BMP2,* and *CHEK2* (P < 2.17E-03). Our results discovered a novel SNP that is significantly associated with VCDR in Latinos and confirmed previously reported loci, providing further insight into the genetic architecture of VCDR.

1575F

Genetic and environmental factors influencing cardiovascular, anthropometric, and metabolic biomarker trait variation in sub-Saharan African populations. *M.E.B. Hansen[1], A. Ranciaro[1], S. Thompson[3], J. Hirbo[4], W. Beggs[1], M. Ibrahim[5], T. Nyambo[6], S. Omar[7], C. Wambebe[8], D. Meskel[9], G. Belay[9], M. Bilow[10], E. Eskin[10], C. Abnet[11], M. Yeager[11,12], S. Chanock[11], S.A. Tishkoff[1,2]. 1) Genetics Dept., University of Pennsylvania, Philadelphia, PA; 2) Biology Dept. University of Pennsylvania, Philadelphia, PA; 3) University College London, London, UK; 4) Vanderbilt University, Nashville, TN; 5) Dept. of Molecular Biology, Institute of Endemic Diseases, University of Khartoum, Khartoum, Sudan; 6) Dept. of Biochemistry, Muhimbili University of Health and Allied Sciences, Dares, Salaam, Tanzania; 7) Kenya Medical Research Institute, Center for Biotechnology Research and Development, Nairobi, Kenya; 8) International Biomedical Research in Africa, Abuja, Nigeria; 9) Dept. of Biology, Addis Ababa University, Addis Ababa, Ethiopia; 10) Depts. of Computer Science and Human Genetics, UCLA, Los Angeles, CA; 11) Division of Cancer Epidemiology and Genetics, National Cancer Institute, NIH, DHHS, Bethesda, MD; 12) Cancer Genomics Research Laboratory, NCI-DCEG, SAIC-Frederick Inc., Frederick, MD.*

The African continent is home to a diverse range of indigenous peoples that have adapted to a wide range of ecological environments and subsistence lifestyles. Many complex traits are expected to display variation between populations due to demographic history and/or natural selection to these diverse environments. In an effort to survey phenotypic variation in Africa and begin to understand the genetic and environmental factors that contribute to this variation, we measured 22 traits in a total cohort of ~4,900 individuals, with numbers per trait ranging from ~900 to 4,900 individuals. The cohort is comprised of agricultural, pastoral, and hunter-gatherer populations across eastern and western sub-Saharan Africa (Cameroon, Nigeria, Sudan, Ethiopia, Kenya, and Tanzania). The traits include anthropometric measurements (e.g. height, weight, waist circumference), cardiovascular measurements (e.g. systolic and diastolic blood pressure), and a panel of metabolic blood biomarkers (e.g. LDL, HDL, triglycerides, glucose, NEFA, C-peptide). We present the observed variation in these traits between sexes, across populations, and across dietary categories. We find significant differences between populations in both the mean trait values and the tails of the trait distributions. A subset of ~1,700 individuals were genotyped on the Illumina 1M-Duo or the Illumina 5M Omni SNP array. We performed genome-wide association tests using a linear mixed model approach on this subset, and analyzed the reproducibility of associations for loci identified in non-African cohorts. Several traits show strong ethnicity specific associations, including height and blood pressure. We estimated the trait heritability values and gene-by-diet/environment interactions, and discuss the degree to which genetic ancestry and subsistence practice impacts trait variation. This work underscores the need to include ethnically diverse populations in gene association studies and to develop better methodological approaches for leveraging association studies from small cohorts with diverse genetic and long-term dietary/environmental conditions.

1576W

The role of novel and low-frequency variants contributing to body fat distribution. *A. Justice[1], T. Karaderi[2], H. Highland[1], K. Young[1], M. Graff[3], P. Auer[3], V. Turcot[4], K. Lu[5], C. Body fat distribution, measured here as waist-to-hip ratio adjusted for BMI (WHR), is a heritable trait and a leading risk factor for cardiometabolic diseases. The majority of genetic studies focus on common, non-coding variants, but the genetic underpinnings of WHR may include rare and protein-coding variants with large effects. We aim to identify protein altering (coding/splicing), low-frequency variants (LFV) (MAF<5%), and genes influencing WHR using exome array data. First, we meta-analyzed study- specific single variant (SV) association results for ~240,000 variants from 344,369 individuals of European, African, Hispanic/Latino, South and East Asian ancestry. We conducted gene-based association tests using the sequence kernel association test (SKAT) method including up to 16,222 genes defined by LFVs predicted as damaging. Also, due to known gender differences in effects on WHR, we analyzed associations stratified by sex. We took the top 70 variants (P<2E-6) forward to validation and meta-analyses in an additional 132,177 European individuals. All tests assumed an additive model. For combined sexes, 47 (21 novel) coding/splicing variants reached array-wide significance (P<2E-7) in our meta-analysis, including six novel LFVs in *FGFR2*, *R3HDML*, *HIST1H1T*, *ACVR1C*, *RAPGEF3*, *PCNXL3*. Four additional variants were identified in the sex-specific analyses, including 2 novel LFV variants in *UGGT2* (men) and *ANGPTL4* (women). The largest effects were observed for LFV in *FGFR2* and *HIST1HIT* genes with 0.02 per allele change in WHR. Three genes identified in our SV analyses were also significantly associated in our gene-based results, including *RAPGEF3* for our total sample and *ACVR1C* and *ANGPTL4* in our women-only analysis (P<2.5E-6). Like known WHR genes, both *ANGPLT4* and *RAPGEF3* are involved in angiogenesis, a necessary pre-cursor for pre-adipocyte differentiation. Further, *ACVR1C* encodes ALK7, which is highly expressed in the brain, pancreas, and adipose tissues. Both ANGPLT4 and ALK7 may be involved in lipid homeostasis. We then performed a look up of our potential genes in adult *Drosophila* knockdowns to assess their role in the regulation of fat storage. We found significant increases in fat storage for two genes with common nonsynonymous variants associated with WHR, *PLXND1* and *DNAH10*. Our approach examining variants often missed by GWAS yielded specific novel genes that may impact adiposity, stressing the importance of targeting protein altering and LFV.

Genetic markers as risk or protection for mountain adaptation and disease. *S. Kohli[1,2], G. Mohammad[3], R. Kukreti[1,2], M.A.Q. Pasha[1,2].* 1) CSIR-Institute of Genomics and Integrative Biology, New Delhi, India; 2) Academy of Scientific and Innovative Research (AcSIR), New Delhi, India; 3) Department of Medicine, Sonam Norboo Memorial Hospital, Leh, Ladakh, Jammu, and Kashmir, India.

High-altitudes (HA) (1500–3500m), characterized by hypobaric hypoxic environment, are home to >140million people. The HA natives, over the generations, have undergone genetic remodelling to adapt in this extreme environment and hence exhibit distinct physiologic traits. However, in susceptible sojourners, hypobaric hypoxia stimulates oxidative stress triggering endothelial damage and vascular wall remodelling leading to high altitude pulmonary edema (HAPE). Hence, genetic analysis of HA natives and sojourners would offer a unique platform to understand the pattern of variations for mountain adaptation and diseases. We conducted a genome-wide study using Omni 1M beadchip, followed by replication using customized 1.1K chip, to identify differentiated variants, i.e., single nucleotide polymorphisms (SNPs) and copy number variations (CNVs) for adaptation and maladaptation in three well defined study groups namely HA natives, HAPE–controls and HAPE–patients, recruited through Sonam Norboo Memorial hospital, Leh (3500m), Ladakh, Jammu & Kashmir, India. Extensive statistical analysis and population stratification with HAPMAP and Indian genome variation populations identified variants, which were further validated for functionality by appropriate downstream experiments. Genetic analysis of HA natives revealed SNPs in *EPAS1* and *EGLN1*, and CNV in *LRRIQ1* and *SLC6A15* as most significant signals (P<1.00E−10); suggesting the regulation of vascular homeostasis and cellular oxygen sensing to direct adaptive cellular responses in natives. In HAPE, SNPs in *CHI3L1* and *DLC1* emerged as most significant signals (P≤8.30E−4); and at mRNA and protein level, CHI3L1, a promoter of vasodilation, was down-regulated by 1.83 and 1.58 folds (P≤0.0001), respectively, and DLC1, a GTPase-activating protein involved in cytoskeletal changes, was up-regulated by 2.30 and 1.44 folds (P≤0.005), respectively, suggesting the importance of pulmonary vasoconstriction and alveolar leakage in HAPE pathogenesis. Similarly, in HAPE, the most significant signals for CNVs emerged in region spanning *IKZF3* and *MEX3D* (P≤1.30E−05), the genes that directly or via BCL-2, are known to up-regulate HIF1α expression, the master transcriptional regulator of the adaptive response to hypoxia. To conclude, the present study identifies genes related to cellular and hypoxia signalling thereby regulating cellular response at HA.

1578F

A genome-wide association scan identifies multiple common genetic variants on *MECOM* and *SALL3* for human fingerprint patterns. *J. Li[1,2], H. Zhang[2], Y. Yang[2,3], J. Tan[2], Q. Peng[1,2], A. Ding[1,2], S. Wu[1,2], Y. Liu[1,2], S. Zheng[1], L. Jin[1,2,3], S. Wang[1,2].* 1) Chinese Academy of Sciences Key Laboratory of Computational Biology, Chinese Academy of Sciences-Max Planck Partner Institute for Computational Biology, Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, 320 Yue Yang Road, 200031 Sh; 2) State Key Laboratory of Genetic Engineering and Ministry of Education Key Laboratory of Contemporary Anthropology, Collaborative Innovation Center for Genetics and Development, School of Life Sciences, Fudan University, 200433 Shanghai, China; 3) Fudan-Taizhou Institute of Health Sciences, 1 Yaocheng Road, 225300 Taizhou, Jiangsu, China.

The fingerprint patterns are highly individualistic and have been utilized in methodological studies. They provide a permanent record of events during the first 4 months of foetal life. Here we report a genome-wide association study (GWAS) in 2,907 Han Chinese for patterns of fingerprint (arch, loop and whorl) on each digit. We find genome-wide significant association at two genomic regions (in 3q26 and 18q23) affecting patterns of fingerprint on multiple fingers. SNPs at 3q26 ($p=5.04\times10^{-12}$, $\beta=-0.097\pm0.014$) near *MECOM*, a complex locus of *MDS1* (myelodysplasia syndrome 1) and *EVI1* (Ecotropic virus integration site 1) are associated with patterns on six fingers (digit 2, 3 and 4 of both hands). The protein encoded by *MECOM* is a transcriptional regulator and oncoprotein that may be involved in hematopoiesis, apoptosis, cell differentiation and proliferation. *EVI1* also has the critical role in the development of forelimbs and fingers in humans. SNPs at 18q23 ($p=1.98\times10^{-12}$, $\beta=0.084\pm0.012$) near *SALL3* (Spalt-Like Transcription Factor 3), a key regulator of limb development at early stages, are associated with patterns on digit 5 of both hands. Previously reported variants in *ADAMTS9-AS2* at 3p14.1, associated with increased frequency of whorls in Caucasians, do not show any significance in our study (p=0.229). Our findings suggest that different genes may affect the formation of fingerprint patterns in different populations.

1579W

Genome-wide association study of 6,939 individuals identifies five novel loci and suggests that prenatal exposure to testosterone is not a major determinant of individual differences in 2D:4D finger ratio. *N.M. Warrington[1,2,3], G. Hemani[4,5], P.G. Hysi[6], M. Mangino[6], G. McMahon[4,5], M. Hickey[7], D. Wolke[8], G.W. Montgomery[9], M.J. Wright[9], D.A. Mackey[10], N.G. Martin[2], G. Davey Smith[4,5], C.E. Pennell[3], T.D. Spector[6], S.E. Medland[2], D.M. Evans[1,4,5].* 1) Diamantina Institute, University of Queensland, Brisbane, Queensland, Australia; 2) Queensland Institute of Medical Research, Brisbane, Queensland, Australia; 3) School of Women's and Infants' Health, The University of Western Australia, Perth, Western Australia, Australia; 4) MRC Integrative Epidemiology Unit, University of Bristol, Bristol, England; 5) School of Social and Community Medicine, University of Bristol, Bristol, England; 6) Department of Twin Research and Genetic Epidemiology, King's College London, London, England; 7) Department of Obstetrics and Gynaecology, University of Melbourne, Royal Women's Hospital, Victoria, Australia; 8) Department of Psychology and Health Sciences, University of Warwick, Coventry, England; 9) Queensland Brain Institute and Centre for Advanced Imaging, University of Queensland, Brisbane, Queensland, Australia; 10) Lions Eye Institute, Centre for Ophthalmology and Visual Science, The University of Western Australia, Perth, Western Australia, Australia.

It has long been hypothesized that during critical periods of development, including the prenatal period, sex steroids permanently alter the developing nervous system, which in turn influences behavior in later life. There is good evidence for the validity of this theory, referred to as the "Organizational Hypothesis", in experimental animals. However, it is difficult to test this hypothesis in humans as prenatal exposure to androgens is extremely difficult to measure. Based on several lines of indirect evidence, it has been hypothesized that the ratio of the length of the index finger to the length of the ring finger (2D:4D) is a marker of prenatal androgen exposure and could therefore be used as a retrospective non-invasive biomarker of testosterone exposure *in utero*. The 2D:4D ratio is sexually dimorphic; however, many studies of 2D:4D and sex related traits have involved small sample sizes and have been difficult to replicate, leading to substantial controversy over the utility and precise meaning of the measure. In the largest genome-wide association study of 2D:4D to date (N=6,939), we find little evidence to support the hypothesis that prenatal androgen exposure is a major driver of individual differences in 2D:4D. We show that the length of the CAG microsatellite in the androgen receptor gene, which influences sensitivity to testosterone, shows little evidence of association with 2D:4D. We also performed a genome-wide association study meta-analysis of 2D:4D and identified seven loci (five novel) that do not contain genes obviously related to testosterone. These seven loci explain 2.38% of the variance in the mean 2D:4D, which is equivalent to approximately half of the variance explained by sex. Furthermore, genetic variants associated with (adult) testosterone/sex hormone-binding globulin were not associated with 2D:4D. Together these findings suggest that 2D:4D is unlikely to represent a simple biomarker of prenatal androgen exposure and any effect of testosterone exposure on the measure may be small relative to the combined influence of other sources of variation. Accordingly, studies using 2D:4D as a biomarker for prenatal androgen exposure need to be cautious with respect to their broader interpretations relating to the Organizational Hypothesis.

1580T

Individuals at the tails of common phenotypes deviate from a polygenic mode of inheritance. *A.R. Wood, K.S. Ruth, R. Beaumont, J. Tyrrell, S.E. Jones, M.A. Tuke, H. Yaghootkar, R.M. Freathy, A. Murray, T.M. Frayling, M.N. Weedon. Genetics of Complex Traits, University of Exeter Medical School, Exeter, Devon, United Kingdom.*

Genome-wide association studies have shown that common genetic variants explain a large fraction of the heritability for many common diseases and quantitative traits. However, the relevance of common variants in individuals with extreme phenotypes is less understood. These individuals may carry a large number of common trait raising or lowering alleles, consistent with a polygenic model. Alternatively, they may deviate from this model due to monogenic or environmental factors. Using 120,000 British individuals from a single study, the UK Biobank, we aimed to determine whether participants at the extreme tails of several quantitative traits carried the number of common alleles expected under a polygenic model, and to identify individuals deviating from the polygenic model. Using published variants, we generated weighted allele scores (WAS) and tested the observed average WAS against the distribution of average WAS for a given percentile, derived from repeated simulations of the polygenic model. For all traits tested, the polygenic model was observed across the distribution until the extreme tails. For height, the shortest 1.5% of individuals carried fewer alleles associated with short stature than expected (P=5E-10), consistent with our previous work (Chan et al 2011). Inspection of ICD10 disease codes confirmed that some of these individuals had monogenic disorders of skeletal growth, including Turner's syndrome, spondyloepiphyseal dysplasia, and achondroplasia. For BMI, the thinnest 2% of individuals carried fewer BMI-lowering alleles than expected (P=6E-5). The most overweight 2% carried more BMI raising alleles than expected, although only in women (P=9E-5). This excess in the upper BMI tail remained after removing females self-reporting poor health, dieting, and regular exercise (P=4E-4). For menopause age and systolic blood pressure (SBP), we observed a significant excess and deficit of trait-raising alleles in the lower and upper tails, respectively. For menopause age, we observed deviation from a polygenic model in the youngest 2.5% (P=1E-6) and oldest 1.5% (P=5E-4). For SBP, we observed deviation in the lowest 1% (P=1E-3) and highest 0.5% (P=8E-3). We conclude that common genetic variants are associated with complex traits at the extremes as well as across the population, but additional factors consistent with either rare non-additive genetic or rare non-genetic factors become more prominent at the extremes.

Towards an innovative early prediction of pregnancy-related diseases with integrated analysis of daily life log records and multi-omics data. *T. Yamauchi[1], O. Daisuke[1], Y. Harada[2], R. Yamashita[2], T. Takai[2], S. Ogishima[2], N. Minegishi[2], O. Tanabe[2], S. Kuriyama[2], N. Fuse[2], N. Yaegashi[2], S. Hiyama[1], M. Nagasaki[2], J. Sugawara[2], Maternity-log Project Team. 1) Research Laboratories, NTT DOCOMO, INC., 3-6 Hikarino-oka, Yokosuka, Kanagawa, Japan; 2) Tohoku Medical Megabank Organization, Tohoku University, 2-1 Seiryo-machi, Aoba-ku, Sendai, Miyagi, Japan.*

A major issue in perinatal medicine is that personalized protocols for preventing various diseases related to pregnancy have not yet been established. Over two hundred thousand pregnant women each year are affected by pregnancy related disorders, including pregnancy induced hypertension, gestational diabetes, and premature deliveries in Japan. Those multifactorial diseases are caused by a complex interaction of genetic factors and acquired environmental factors such as lifestyle and living environment. To date, previous studies have been conducted to clarify pathogenesis of multifactorial diseases by using data on individual combinations of genomic analysis and changes in circulating factors, as well as subjective data on environmental factors collected through questionnaires. As described, environmental factors have been usually analyzed on the basis of questionnaires targeting an individual lifestyle, however, the accuracy, frequency, and currency of these data have been a major issue. To resolve these issues, we have designed a prospective cohort study "maternity-log study" for pregnant women. In this study, pregnant women are recruited in the first stage of pregnancy at routine obstetric visit in Tohoku University Hospital under satisfactory informed consent. Study participants upload daily information including morning sickness, abdominal pain, and uterine contractions, as well as physiological data such as body weight, blood pressure, heart rate, and body temperature. This study protocol obtained approval from the ethics review committee established by Tohoku University Graduate School of Medicine (ID 2014-1-704: application date 28 January 2015). To the best of our knowledge, this study will be the first to integrate multi-omics data of genome, transcriptome, proteome, metabolome, and metagenome, with objective data on environmental factors, including daily lifelog data of pregnant women. The present study is expected to elucidate the causal relationship between perinatal diseases and maternal lifestyle information, physiological changes, and multi-omics data and to establish methods for personalized early prediction of pregnancy related diseases. Precise protocol and expected results of this study will be discussed.

Genome-wide gene-environment interaction analysis for brain structure in healthy Korean women. *H. Kim[1], H. Kang[2], S. Kim[1], Y. Yun[1], Y. Chang[3], S. Ryu[3], D. Lee[2], H. Shin[4], H. Kim[1].* 1) Department of Biochemistry, School of Medicine, Ewha Womans University, Seoul, South Korea; 2) Department of Nuclear Medicine, Seoul National University College of Medicine, Seoul, South Korea; 3) Center for Cohort Studies, Total Healthcare Center, Kangbuk Samsung Hospital, School of Medicine, Sungkyunkwan University, Seoul, South Korea; 4) Department of Family Medicine and Health Screening Center, Kangbuk Samsung Hospital, School of Medicine, Sungkyunkwan University, Seoul, South Korea.

Neuroticism is known to be associated with the volume of different brain regions as well as emotion and health. Although recent genome-wide association studies have identified some novel loci for brain structure, few addressed genome-wide gene-environment interactions. To determine gene-personality interactions in brain volume, we found 11 different brain regions associated with neuroticism in 49 women scoring in the extremes of neuroticism (>90th and <10th percentile) and conducted genome-wide gene-environment interaction analyses for the brain regions. Based on analyses of 226,705 single nucleotide polymorphisms (SNPs) we found evidence for an interaction in which the associations between the genotype and brain volume depend on scores of neuroticism. The SNPs showed associations of the opposite direction with brain volume in low- and high-scored groups of neuroticism. Total 19 SNPs reached the genome-wide statistical significance (<2.21X10^{-7}). They included the interaction of neuroticism with *MIR548AB* for culmen, *PWRN1* and *SMOC2* for cingulate gyrus, *FBXO17*, *ZNF20* and *ZNF136* for inferior frontal gyrus, *METTL22* for inferior frontal gyrus, *RAPGEF3*, *VPS53* and *RPAP3* for middle frontal gyrus, *CTTNBP2NL* for middle occipital gyrus, *CTNNA2* for posterior cingulate, and *KCNK2* and *SASH1* for precentral gyrus. Most of these genes are known to be implicated in behavior and psychiatric disorders. We believe that our analysis is a pilot study that fist describes the gene-personality interaction in brain structure at genome-wide approaches. Our findings suggest that genes with effects on behavior and mental disorders may be involved in neuroticism-associated brain structure. [This research was supported by the National Research Foundation of Korea (NRF) funded by ICT & Future Planning (NRF-2014R1A2A2A04006291) and the Ministry of Education (NRF-2013R1A1A2062702), and Korea Health Technology R&D Project through the Korea Health Industry Development Institute (KHIDI) funded by the Ministry of Health & Welfare (HI14C0072).].

A new world of biobanking: CARTaGENE, an open-access resource for genomic epidemiology studies. *J. Tcherkezian, C. Boileau, S. Jacquemont, A.M. Nuyt.* CARTaGENE, CHU Sainte-Justine, Montréal, Québec, Canada.

Genome-based studies have provided powerful research tools for identifying genetic variants that contribute to chronic diseases. Recognition is growing, however, that chronic diseases are caused by a combination of an individual's genetic predisposition and their exposure to certain environmental risk factors. CARTaGENE was created to support the scientific community in identifying the determinants of chronic diseases of environmental and/or genetic origin. It was also created to accelerate the process of translational medicine through the identification of biomarkers for early diagnosis, disease treatment and prevention. CARTaGENE is conducting the largest prospective health study on men and women in Québec. Since 2007, the project has recruited 42 000 individuals, aged 40-69 years, representing six metropolitan regions of the province and collected detailed lifestyle, health and medical data on these individuals. The program also gathered detailed physical measurements, clinical and biochemical measures at baseline. Epigenomic, genotyping, and exome sequencing have been collected in subsets of CARTaGENE participants and have resulted in both preliminary data and high profile studies, while supporting over 40 research programs. Several of these projects offer unique opportunities for genomic epidemiology studies and some will be highlighted. These ongoing partnerships, our interoperability with other national biobanks, and our plan to develop other sectors of activity support our mission to provide meaningful high-quality data and biospecimens for years to come.

1584F

Comprehensive evaluation of disease- and trait-specific enrichment for eight functional elements among GWAS-identified variants. *C.A. Markunas, E.O. Johnson, D.B. Hancock.* RTI International, Research Triangle Park, NC, USA.

The majority of disease-associated variants identified from genome-wide association studies (GWAS) are present in functional elements. Studies of functional enrichment have focused on the NHGRI-EBI Catalog of published GWAS (GWAS Catalog) as a whole, or on a small number of functional elements across specific diseases. We sought to understand the relative importance of different functional elements across human diseases and traits, which may provide insight into biological mechanisms that disproportionately contribute to different diseases. We examined variability in functional enrichment of disease-associated variants (P≤5×10⁻⁸) in the GWAS catalog (v1.0.1) across 17 diseases/traits, including neurological and psychiatric disorders, cancers, autoimmune diseases, cardiovascular disease, metabolic disorders, eye disease, lung diseases and traits, viral diseases, drug response, and height. SNPs were annotated using HaploReg (v.4.1) for 8 functional elements: DNase I hypersensitivity sites, expression quantitative trait loci (eQTL), sequence conservation, enhancer marks (H3K4me1, H3K27ac), promoter marks (H3K9ac, H3K4me3), missense variants, sequence motifs, and protein binding sites. Functional enrichment analyses were conducted using logistic regression. Each disease/trait SNP set was compared to a set of 3,587 SNPs that were randomly drawn using SNPsnap, matching our collective set of GWAS SNPs (N=1,294) on allele frequency, gene density, distance to nearest gene, and linkage disequilibrium at a 3:1 ratio. After applying a conservative Bonferroni correction for 136 tests (p<0.0004), significant enrichment was observed for all functional annotations, except sequence motifs. The strongest enrichment signals were seen for missense variants (eye disease, OR [95% confidence interval] = 53.6 [21.1-136.4]), followed by eQTLs (autoimmune diseases, OR = 6.4 [4.9-8.2]). Significant differences in the relative enrichment of functional annotations were observed across disease categories (e.g. eQTL enrichment for autoimmune diseases OR = 6.4 [4.9-8.2] vs. cancer OR = 2.3 [1.7-3.0]) but were limited among diseases within categories. Understanding these commonalities and differences may help to generate hypotheses on common and distinctive mechanisms underlying variant-disease associations, guide the interpretation of GWAS results, and increase power to detect disease variants by further utilizing specific types of regulatory information.

1585W

***GPR161* variants identified in infants with neural tube defects.** *Y. Lei[1], E. Ross[2], G. Shaw[3], R. Finnell[1].* 1) University of Texas at Austin, Austin, TX; 2) Center for Neurogenetics, Brain and Mind Research Institute, Weill Cornell Medical College, New York, NY; 3) Department of Pediatrics, Division of Neonatology, Stanford University School of Medicine, Stanford, CA.

Neural tube defects (NTDs) result from failure of neural fold fusion along the length of the neural tube during early embryogenesis. These are among the most severe of any viable human malformations. The most frequent NTDs are spina bifida and anencephaly. The etiologies of NTDs are complex and include both genetic and environmental factors. Variants in over 400 genes have been identified in the mouse that result in NTD phenotypes. *GPR161*, which encodes a primary cilia protein, has recently been identified as a Tulp3/IFT-A-regulated GPCR. Homozygous *Gpr161* mutant mice are believed to have NTDs due to Shh signaling dysregulation. In a whole genome sequencing study of 125 spina bifida cases, we identified what was predicted to be loss of function variant (p.Pro18Ter) in 7 NTD cases, but the LOF variant was not observed in 158 matched nonmalformed controls. To validate the association between *GPR161* variants and NTDs, we resequenced a validation population of 384 spina bifida cases and 190 nonmalformed controls. Six rare missense variants were identified in 6 NTD cases (MAF<0.01), four of which did not appear in the non-malformed controls studied, or in dbSNP, EVS or ExAC (http://exac.broadinstitute.org). Of those four novel rare variants in NTD cases, two (p.Trp202Gly and p.Leu428Phe) were not found in any database and were predicted to be damaging by SIFT and/or PolyPhen analysis. A third probably damaging rare variant was found in an additional NTD case (MAF=0.003 in ExAC). Among 190 control, 6 of 7 rare *GPR161* variants identified had been previously reported in the EVS or ExAC databases, that were either synonymous or predicted to be benign by both SIFT and Poly-Phen. The frequency of rare (MAF<0.01) missense *GPR161* variants was significantly higher in NTDs (6/384) compared with ExAC data plus our own controls (472/60,898) (p<0.01). Our data indicate that damaging missense GPR161 variants could contribute to the etiology of spina bifida.

1586T

Ultra-rare disruptive mutations in highly constrained genes influence the cognitive and developmental spectrum in the general population.

Kathiresan[2,4], M.J. Daly[1,2], J. Flannick[2], P.F. Sullivan[3,9], A. Palotie[1,2,7], T. Esko[10], C. Hultman[3], B.M. Neale[1,2], MIgen Consortium, iPsych Consortium, AMP T2D Consortium, IBD Consortium, STARR cancer Consortium. 1) ATGU, Massachusetts General Hospital; Boston, MA, USA; 2) Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, MA, USA; 3) Department of Medical Epidemiology and Biostatistics, Karolinska Institutet, Stockholm, Sweden; 4) Center for Human Genetic Research and Cardiovascular Research Center, Massachusetts General Hospital, Boston, MA, USA; 5) Department of Biological Engineering, Massachusetts Institute of Technology, Cambridge, MA, USA; 6) Department of Genetics, Harvard Medical School, Boston, MA , USA; 7) Institute for Molecular Medicine Finland, FIMM, University of Helsinki, Helsinki, Finland; 8) National Centre for Register-based Research, Aarhus University, Aarhus, Denmark; 9) Departments of Genetics and Psychiatry, University of North Carolina, Chapel Hill, North Carolina, USA; 10) Estonian Genome Center, University of Tartu, Tartu, Estonia.

Large-scale sequencing studies allow to investigate the role of rare exonic variants in explaining observed phenotypic variation. We explored the impact of a subset of rare variants that we hypothesized would be more likely to drive phenotypic variation in the general population and differences in disease risk in case/control cohorts. Specifically, we considered only variants that were (1) singletons in the study and not observed in the Exome Aggregation Consortium, (2) in evolutionarily constrained genes and (3) predicted to modify the gene by either truncating the protein or causing non-sense mediated decay. These damaging ultra-rare variants in highly constrained genes (dURV-HCs) have been shown to be enriched in severe neurodevelopmental disorders, but the extent to which this class of rare variation explains the genetic risk for psychiatric disorders, and indeed a broader range of diseases and traits, is unknown. In this analysis, we included over 80,000 European individuals that were part of population-based studies or case-control studies of common diseases, and for which either whole-exome or whole-genome sequencing data was available. We investigated 16 diseases and 10 quantitative traits and observed enrichments of dURV-HC in neurodevelopmental and psychiatric disorders (including a previously unreported association with attention-deficit/hyperactivity disorder) and identified novel associations with HDL-cholesterol, height and years of education (YOE). For YOE specifically, an analysis of 18,329 individuals from four Northern European studies demonstrated that the presence of one or more dURV-HCs was associated with a decrease in YOE (2.7 fewer months for each additional mutation; $P=5\times10^{-7}$) and the effect was stronger in genes enriched for brain expression (6.1 fewer months, $P=6\times10^{-5}$). To place the effect of dURV-HCs into context, we also examined the impact of previously reported genetic influences on YOE, including a polygenic score from common variants, runs of homozygosity and a burden of rare pathogenic copy number variants. We found that the effect of dURV-HC interacted ($P=0.006$) with a common variant polygenic score for YOE and was more pronounced than the estimated effects of runs of homozygosity and pathogenic copy number variation. Our findings suggest that the impact of dURV-HCs is not confined to severe neurodevelopmental disorders, but that these variants influence the cognitive and developmental spectrum in the general population.

The TMM BirThree Cohort Study: World-first genome cohort study design of birth and three generation.

M. Ishikuro[1], H. Metoki[1,2], T. Obara[1,3], M. Kikuya[1], Y. Sato[1], M. Miyashita[1], C. Yamanaka[1], S. Mizuno[1], A. Hozawa[1], I. Tsuji[1], F. Nagami[1], S. Kure[1], N. Yaegashi[1], S. Kuriyama[1]. 1) Tohoku Medical Megabank Organization, Tohoku University, Sendai, Miyagi, Japan; 2) Tohoku Medical and Pharmaceutical University, Sendai, Miyagi, Japan; 3) Tohoku University Hospital, Sendai, Miyagi, Japan.

The Tohoku Medical Megabank Organization (ToMMo) was established by Tohoku University along with Iwate Medical University after the Great East Japan Earthquake to reconstruct the disaster area with introducing an advanced medical system. The mission of ToMMo is to identify health problems in the aftermath and to facilitate the solution with developing personalized health care and medicine. One of the projects to achieve its mission is "The Tohoku Medical Megabank Project Birth and Three-Generation Cohort Study (the TMM BirThree Cohort Study)". The TMM BirThree Cohort Study is a unique, large population based birth cohort study with genome analysis that recruits pregnant women and their babies as well as their family members, including relatives. The purpose of this cohort study is to identify health status of people in the aftermath of the disaster and transfer them to the medical facilities for receiving essential medical support, and to analyze the origin or causes of disease with their genomic information to establish personalized medicine in the disaster area. Recruitment of the BirThree Cohort Study was started in July, 2013 and would be continued until the end of March, 2017. The study collects blood or saliva, urine, questionnaires and medical or health records from all the participants, and additionally collect breast milk and cord blood from mothers and their babies. Extra physiological measurements are also obtained for participants who are interested in. All participants will be followed up at least every one year by questionnaires and medical or health records, furthermore, the study plans to provide a set of examination as same as baseline examination after five years. The number of the desirable participants is 70,000, and so far on May 18, 2016, 54,766 people excluding fetuses are involved in the study. There are varieties of pedigree types. At present, total of 3,551 trios with babies, 272 trios with siblings, and 1,931 quartet with babies and their siblings were participated. The number of pedigrees with whole three generations including grandparents, parents and babies has been reached 126 sets. Even more, there are 284 big families consists of more than 7 participants including relatives. Those varieties of pedigrees are enable us to elucidate the origin or causes of disease and contribute to build more quality-oriented care.

Genome wide association studies of transcriptomic endotypes of asthma. *J. Chu[1], X. Yan[1], J. Gomez[1], L. Cohn[1], B. Raby[2], G. Chupp[1].* 1) Section of Pulmonary, Critical Care, and Sleep Medicine and Department of Internal Medicine, Yale University School of Medicine, New Haven, CT; 2) The Channing Division of Network Medicine, Department of Medicine, Brigham and Women's Hospital, and Harvard Medical School, Boston, MA.

Background: Previously we have identified from gene expression in sputum and blood three transcriptomic endotypes of asthma (TEA) clusters with distinct clinical and physiological characteristics of asthma. These TEA clusters help explaining the pathophysiologic heterogeneity in asthma patients. This study aims to identify genetic variants associated with these TEA clusters. **Methods:** Genome wide association studies for the three TEA clusters were performed using SNP data from Yale Center for Asthma and Airway Diseases (YCAAD) cohort (asthmatic adult population, n=93) and Asthma BioRepository for Integrative Genomic Exploration (Asthma BRIDGE, asthmatic children population, n=728). The significant loci were furthered analyzed for associations with gene expression and clinical phenotypes. **Results:** We have identified 1 locus at genome-wide significance (FDR<0.05) at one cohort (rs1984564, LP-CAT3, previously linked to macrophages inflammatory response), along with many other loci that were below genome wide significant threshold and can be mapped to biologically plausible genes (eg. rs4525262, TRIM22, p=2.9E-05, previously linked to the airway epithelial response to viral infections). There were also 3 genes that map to genetic variants that were nominally significant (p<0.01) for both cohorts (OPRM1, MROH7, KBTBD12). LPCAT3, TRIM22 and OPRM1 loci were also significantly associated with many clinical phenotypes characterized by TEA clusters, including intubation, hospitalization, and atopy (p<1E-04). **Conclusion:** Our study identifies several genetic variants associated with TEA clusters that located in genes that may underlie key characteristics in the TEA clusters. These genes may be contributing to heterogeneity in asthma pathogenesis.

1589T

Tests of association for asthma among > 10,000 individuals of mixed African ancestry. *M. Daya[1], N.M. Rafaels[1], S. Chavan[1], M. Boorgula[1], H.R. Johnston[2], J.G. Wilson[3], L.K. Asthma is a complex disease with striking disparities between racial and ethnic groups, which may be partly attributable to genetic factors. The first asthma genome-wide association study (GWAS), revealing association between asthma and markers near the *ORMDL3* gene on chromosome 17q21 among European populations, has been widely replicated in several European, Asian and Hispanic cohorts. However, SNPs that significantly associated risk to asthma in these populations showed no evidence of association in several independent African ancestry cohorts, although SNPs elsewhere in the gene cluster were modestly associated, underscoring the challenges in replicating SNP-for-SNP findings from GWAS in European populations. One of the main goals of the Consortium on Asthma among African-ancestry Populations in the Americas (CAAPA) is to discover genes conferring risk to asthma in populations of African descent. In this study, we aimed to increase statistical power to detect genetic variants by performing a meta-analysis across CAAPA cohorts (using a total of 2,281 cases and 3,704 controls), genotyped on the African Diaspora Power Chip (ADPC) and imputed using the whole genome sequence reference panel from CAAPA itself. The ADPC is a SNP array consisting of tagging SNPs useful in comprehensively identifying African specific genetic variation when combined with a commercially available GWAS chip, and the 883 high coverage (~30X) CAAPA genomes provide a much better representation of African haplotypes compared to the standard 1000 Genomes panel. A large proportion of ADPC SNPs have been integrated into Illumina's Multi-Ethnic Genotyping Array (MEGA), and an additional 2000 cases and 2302 controls will be genotyped on this MEGA chip, which will further boost statistical power. We present our quality control, imputation and analysis pipeline, and showcase preliminary results on chromosome 17q21. Within CAAPA, the top 17q21 association signals were observed in a Puerto Rican cohort, consistent with previous reports, whereas signals in two of the African ancestry cohorts analyzed thus far were not suggestive of association. We show this can be explained by the relatively low European ancestry in our African ancestry cohorts compared to the Puerto Rican cohort, resulting in a decreased frequency of putative protective variants. In conclusion, we demonstrate the importance of considering specific ethnic background when conducting genetic association studies of asthma.

1590F

Genome-wide multivariate analyses of anthropometric traits in over 120,000 individuals. *A.W. Drong[1], T. Karaderi[1], P.K. Albers[1], R. Magi[2], A.P. Morris[1,3], C.M. Lindgren[1,4].* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 2) Estonian Genome Center, University of Tartu, Tartu 51010, Estonia; 3) Department of Biostatistics, University of Liverpool, Liverpool L69 3GL, UK; 4) Big Data Institute, University of Oxford, Oxford OX3 7BN, UK.

Recent studies suggested that adjusting for heritable covariates correlated with an outcome can introduce collider bias in genome-wide association studies (GWAS). Here, we apply multivariate models to examine the effect of correlation between phenotypes on the power to detect genetic associations in GWAS of anthropometric traits. We simulated 1,000 genotypes for 10,000 individuals, with effects for two traits (A/B) ranging from β=-0.03 to β=+0.03. Residual variation was then added allowing for non-genetic correlation of $\rho(A,B)$=0.5 or -0.5. The simulations results show good control of type I error rates at in a reverse regression multivariate model, while confirming a bias of $\rho(A,B)*\beta_B$ in β_A in traditional linear regression adjusted analyses. We filtered UK Biobank Interim I variants from European ancestry samples for minor allele frequency (MAF)>0.5% and info score>0.4, resulting in ~12M variants in up to 120,288 individuals. Height, weight, waist, hip, body mass index (BMI), waist-hip ratio (WHR), Body Fat% and Trunk Fat% were adjusted for the age, 15 principal components to adjust for population structure, assessment centre (batch effects) and array type. We fitted multivariate models using reverse regression and traditional univariate linear models for M1: height+weight+waist+hip; M2: M1+BMI+WHR; M3: BMI+WHR+BodyFat%+TrunkFat%. Of 49 previously-reported WHRadjBMI SNPs, we replicate 38 signals using M1 alone, with no improvement in adding BMI and WHR (M2). When selecting the best combination of variables by Bayesian Information Criterion (BIC) selection, the BMI+WHR model is enriched (19/49, P<1x10^{-9}). When adding the choice of BodyFat% and TrunkFat% (M3), for 11 out of these 19 SNPs, WHR+TrunkFat% is the best model for (P<3x10^{-9}), highlighting that these WHRadjBMI loci are indeed primarily associated with central adiposity For M1, we find 13 novel multi-trait associations at genome-wide significance (p<5x10-8), with strongest signals at loci near *LINC01214* (p=7.55x10^{-11}), *MCHR2-AS1* (p=4.83x10^{-10}), 9 loci for M2 (a subset of the 13 M1 loci)*;* and 11 for M3: *ADAMTS14* (p=1.89x10^{-11}), *DNM1P41* (p=6.52x10^{-10}) and *EEF1G* (p=5.76x10^{-10}). None of these signals were detected in our single-trait analyses in UK Biobank. In conclusion, we find that the 49 loci published by Shungin et al are unlikely to be false positives caused by collider bias. For future studies we recommend multivariate analyses as an alternative to adjusted analyses of multiple heritable traits.

1591W

The SHARE study: Meta-analysis of GWAS including 260,000 individuals identifies 40 new loci for allergic disease. *M. Ferreira[1], J. Esparza-Gordillo[2], A. Tillander[3], C. Tian[4], B. Brumpton[5], C. Almqvist[3], D. Hinds[4], D. Boomsma[6], G. Koppelman[7], L. Yi[3], G. Willemsen[6], V. Ullemar[3], P. Magnusson[3], H. Baurecht[8], I. Marenholz[2], J. Vonk[9], L. Paternoster[10], R. Karlsson[3], S. Grosche[3], S. Weidinger[8], Y.A. Lee[2] on behalf of the SHARE study.* 1) QIMR Berghofer Medical Research Institute, Brisbane, Australia; 2) Max Delbrück Center for Molecular Medicine, Berlin, Germany; 3) Karolinska Institute, Stockholm, Sweden; 4) 23andMe Inc, Mountain View, California, USA; 5) Norwegian University of Science and Technology, Trondheim, Norway; 6) VU University Amsterdam, Amsterdam, Netherlands; 7) University of Groningen, Groningen, Netherlands; 8) University of Kiel, Kiel, Germany; 9) University Medical Center Groningen, Groningen, Netherlands; 10) University of Bristol, England, UK.

Asthma, hay fever and eczema are common, highly polygenic allergic diseases that are thought to share ~50% of their genetic make-up. Despite this large genetic overlap, which translates into hundreds of shared genetic risk variants, almost all GWAS of allergic disease published to date have only considered one disease at a time. A consequence of this is that the control group for a given disease will include a large number of cases from a genetically-correlated disease, which considerably reduces power. Motivated by this limitation, we established the SHARE study to identify genetic risk variants shared between asthma, hay fever and eczema. In this study, we first used the LD-score regression approach to estimate the genetic correlation between the three diseases; estimates were consistent with those reported by twin and family studies: 0.45 between asthma and eczema (P=10^{-20}), 0.69 between asthma and hay fever (P=10^{-188}), and 0.55 between eczema and hay fever (P=10^{-60}). We then performed a GWAS in 13 studies with cases defined as individuals suffering from one or more of these three diseases, and controls as those who have never suffered from any allergic disease. GWAS results were available for 260,000 individuals of European descent. Meta-analysis of these results identified 166 independent (linkage disequilibrium [LD] r<0.1) variants located in 83 loci, of which 40 have not been previously implicated in allergic disease. For 21 of these novel loci, the sentinel SNP was in high LD (r>0.8) with one or more regulatory variants identified in eQTL studies conducted in 12 cell types/tissues relevant to asthma, thereby pointing to likely candidate genes underlying the association. We complemented this list of putative target genes by intersecting the location of risk SNPs with putative enhancers known to be involved in chromatin interactions with gene promoters. We also developed a novel gene-based test of association that focus on regulatory variants and identified additional risk genes missed by the single-SNP analysis. Collectively, our study provides the most comprehensive analysis of genetic risk variants for allergic disease reported to date, and demonstrates the improvement in power that can be obtained by considering information from all three allergic diseases in a GWAS.

1592T

A novel gene identified for alcohol drinking in more than 100K Europeans. *H. Gao[1], C. Liu[2,3,4], P. Song[5], S. Kliewer[5,6], D. Mangelsdorf[6], C.P. Müller[7], G. Schumann[8], E. Elliott[1], AlcGen and CHARGE+ consortia.* 1) Department of Epidemiology and Biostatistics, MRC-PHE Centre for Environment and Health, School of Public Health, Imperical College London, UK; 2) The Framingham Heart Study, Framingham, MA, USA; 3) The Population Sciences Branch, Division of Intramural Research, National Heart, Lung, and Blood Institute, Bethesda, MD, USA; 4) Boston University School of Public Health, Boston, MA, USA; 5) Department of Pharmacology and Howard Hughes Medical Institute, University of Texas Southwestern Medical Center, Dallas, TX, USA; 6) Department of Molecular Biology, University of Texas Southwestern Medical Center, Dallas, TX, USA; 7) Department of Psychiatry and Psychotherapy, Friedrich-Alexander-University Erlangen-Nuremberg, Erlangen, Germany; 8) Medical Research Council - Social, Genetic and Developmental Psychiatry Centre, Institute of Psychiatry, Psychology & Neuroscience, King's College London, UK.

Excessive alcohol consumption is a major public health problem worldwide. We conducted a genome-wide association meta-analysis and replication study among 105,898 individuals of European ancestry, and identify a novel locus associated with alcohol consumption calculated as log grams/day (SNP with smallest P=9.2x10^{-12}). We show genotype-dependent alcohol preference in this gene in brain-specific knock-out mice compared with controls. Our experiments in mice suggest that effect of alcohol is due to reinforcing behavior, not alleviation of anxiety. Whereas most previous studies investigating the mechanisms underlying alcohol drinking behavior have focused on investigations of brain functions alone, our results suggest the possibility of a coordinated action across two organ systems, liver and brain. The newly identified gene may play a part in the regulation of complex adaptive behaviors involving alcohol drinking.

1593F

GWAS of over 20,000 Generation Scotland: Scottish Family Health Study participants: Expansion of quantitative trait availability using linkage to electronic health records in Scotland. *C. Hayward, MRC QTL in Health and Disease group and Generation Scotland.* Human Geneics Unit, MRC Human Genetics Unit,IGMM, University of Edinburgh, Edinburgh, United Kingdom.

We are using a combination of genome-wide genotyping, sequencing and imputation in population cohorts with high kinship to search for quantitative trait loci (QTL) variants of clinical and biological relevance. The Generation Scotland Scottish Family Health Study (GS:SFHS) is a family-based cohort with biological samples, socio-demographic, clinical and genetic data from approximately 24,000 adult volunteers across Scotland (www.generationscotland.org). Although data collection was cross-sectional, GS:SFHS becomes a prospective cohort as a result of the ability to link to routine NHS electronic health record (EHR) data. GS:SFHS participants were analysed by genome-wide chip genotyping using the Illumina OMNI+exome chip. QC analyses were performed, data cleaned using quality scores and proportions typed, sample identity verified against recorded gender and pedigree, and data checked for unknown relationships based on estimated identity-by-descent. Genome-wide association studies (GWAS) were run on 20,032 individuals, correcting for family relationships using a polygenic kinship matrix and for population stratification using the first three principal components. Data was imputed to the Haplotype Reference Consortium dataset allowing accurate imputation of rare variants into all the genotyped samples. A number of separate programmes of activity are using this genetic data to investigate phenotypes relevant to pain, lung function, psychiatric disorders, cognition, cardiovascular and kidney disease. Here, we present GWAS of a range of biochemical traits obtained from data linkage to EHRs collected by the NHS in Scotland. Scotland has some of the best health service data in the world. Few other countries have information which combines high quality data, consistency, national coverage and the ability to link data to allow patient-based analysis and follow up. Proof of principle was achieved using serum uric acid measures on 2,238 participants after data cleaning, records dating from Oct 1988 to August 2015. A GWAS taking into account the sex of the participant and adjusting for age at the time of the test resulted in a top hit in the urate transporter SLC2A9 gene ($-\log_{10}$(p) value of 7.2 x 10^{-17}). The GWAS of uric acid, and other less studied laboratory measures, will be repeated using HRC-imputed data to investigate rarer variants and elucidate the genetic architecture of the traits.

1594W

A customized genotype array to investigate the genetic architecture of tuberculosis in Peru. *Y. Luo[1,2], L. Lecca[3], R. Calderon[3], C. Conteras[3], R. Yataco[3], Z.B. Zhang[5], J. Galea[3], B. Moody[8], M. Murray[3,4,5,6,7], S. Raychaudhuri[1,2].* 1) Division of Genetics and Rheumatology, Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 2) Program in Medical and Population Genetics, Broad Institute of Harvard and MIT, Cambridge, MA, USA; 3) Socios En Salud, Lima, Peru; 4) Partners In Health, Boston, MA, USA; 5) Division of Global Health Equity, Brigham and Women's Hospital, Boston, MA, USA; 6) Department of Global Health and Social Medicine, Harvard Medical School, Boston, MA, USA; 7) Department of Epidemiology, Harvard T.H. Chan School of Public Health, Boston, MA, USA; 8) Division of Rheumatology, Immunology and Allergy, Brigham and Women's Hospital, Harvard Medical School, Boston, MA, USA.

As a part of the Tuberculosis Research Unit program (TBRU) that aims to integrate basic and clinical research to study tuberculosis (TB) in countries where the disease is endemic, we are conducting the first TB genome-wide association study (GWAS) in a Latin American cohort in Lima, Peru consisting of 1,500 TB cases and 1,500 controls. While previous TB GWA studies have not always controlled for *Mycobacterium tuberculosis* (*Mtb*) infection status, here we will leverage a well-described cohort of cases and *Mtb* infected household contacts, thereby improving the power of the study to identify genetic variations associated with active TB. To optimize the capture of genetic variants in Peruvians, particularly those that might be missed from the current commercial genotype arrays which are often biased towards European populations, we designed a customized Affymetrix Axiom array based on whole-exome sequencing (WES) data from 116 Peruvian TB cases and 85 Peruvian individuals from the 1000 Genomes Phase 3 project whole-genome sequenced (WGS) at 7x. Our goal in conducting WES in 116 TB cases is to detect rare and low frequency coding variants that are population specific, and might also be predisposing to TB risk. The WGS data will also allow us to ascertain non-coding common variants, particularly those are specific to Peruvian populations only. Using available population genetics tools to infer demographic history both on a global scale and on an individual level, we demonstrate a unique heritage of our Peruvian samples. In total, the WES and WGS data identified 1.5 million variants that were not observed in any other populations included in 1000 Genomes. In particular, 156,162 variants with minor allele frequencies (MAF) ≥1% are private or show significant differences in allele frequencies compared to other populations included in the 1000 Genomes dataset. The customized array includes ~800K variants. After imputing using the 1000 Genomes Phase 3 reference panel, ~8 million high quality (info $r^2 \geq 0.4$) variants with MAF≥1% were detected. Compared to the Affymetrix UK Biobank array, this novel array improves the genome-wide coverage for common variants by 20%, and imputation quality by 35% with a mean imputation $r^2 = 0.901$. This highlights further the value of having a customized array that is tailored for the Peruvian population. The customized array is currently being manufactured and we expect to present the initial findings of the GWAS at the time of the meeting.

1595T

Comprehensive understanding of associations between HLA class II genes and chronic hepatitis B infection in Japanese individuals. *N. Nishida[1,2], J. Ohashi[3], S-S. Khor[2], M. Sugiyama[1], H. Sawai[2], K. Tokunaga[2], M. Mizokami[1].* 1) Research Center for Hepatitis and Immunology, National Center for Global Health and Medicine, Ichikawa, Chiba, Japan; 2) Department of Human Genetics, Graduate School of Medicine, The University of Tokyo, Bunkyo-ku, Tokyo, Japan; 3) Department of Biological Sciences, Graduate School of Science, The University of Tokyo, Tokyo, Japan.

Associations of variants located in the *HLA* class II region with chronic hepatitis B (CHB) infection have been identified in Asian populations. Moreover, previous reports revealed that polymorphisms within the *HLA-DP* and *HLA-DQ* loci were independently associated with CHB infection in the Japanese population. Here, *HLA* imputation method was applied to determine *HLA* alleles using genome-wide SNP typing data of 1,975 Japanese individuals (1,033 HBV patients and 942 healthy controls). Together with data of an additional 1,481 Japanese healthy controls, association tests of six *HLA* loci including *HLA-A*, *C*, *B*, *DRB1*, *DQB1*, and *DPB1*, were performed. To assess the association of each *HLA* allele or haplotype with CHB infection, Pearson's chi-square test was applied to a two-by-two contingency table based on the allele or haplotype frequencies. Although the strongest association was detected at a SNP located in the *HLA-DP* locus in a SNP-based GWAS using data from the 1,975 Japanese individuals, HLA genotyping-based analysis identified *DQB1ˑ06:01* as having the strongest association, showing a greater association with CHB susceptibility (OR = 1.76, P = 6.57×10^{-18}) than any one of five *HLA-DPB1* alleles that were previously reported as CHB susceptibility alleles. Moreover, *HLA* haplotype analysis showed that, among the five previously reported *HLA-DPB1* susceptibility and protective alleles, the association of two *DPB1* alleles (*DPB1ˑ09:01*, and *ˑ04:01*) had come from linkage disequilibrium (LD) with *HLA-DR-DQ* haplotypes, *DRB1ˑ15:02-DQB1ˑ06:01* and *DRB1ˑ13:02-DQB1ˑ06:04*, respectively. The present study showed that SNP-based GWAS does not necessarily detect the primary susceptibility locus in the *HLA* region due to the strong LD.

1596F

Association between *STOML2* and allergic diseases. *J.A. Revez[1,2], M.A.R. Ferreira[1].* 1) QIMR Berghofer Medical Research Institute, Brisbane, Australia; 2) School of Medicine, The University of Queensland, Brisbane, Australia.

A regulatory variant (rs7039317) in the Stomatin-like protein 2 (*STOML2*) gene was recently found to associate with asthma risk in two independent genome-wide association studies (GWAS). However, the evidence for association (combined $P = 2\times10^{-6}$; N = 48,154) was not genome-wide significant. Here, we studied this association in an additional independent GWAS (N=132,860) and examined the possible effect of this and other *STOML2* functional variants in asthma, hay fever and eczema – three allergic diseases that share a large fraction of their genetic make-up. rs7039317 had a significant association with allergic disease in the UK Biobank, with comparable effect sizes across asthma, hay fever and eczema. *STOML2* might represent a genetic risk factor shared between asthma, hay fever and eczema. This research has been conducted using the UK Biobank Resource.

1597W

Genetic ancestry and genome-wide associations with bronchopulmonary dysplasia in preterm infants treated with Inhaled Nitric Oxide (iNO). *D. Torgerson[1], S. Oh[1], R.L. Keller[2], S. Huntsman[1], D. Hu[1], C. Eng[1], D. Black[3], E.G. Burchard[1,4], P.L. Ballard[2], R.A. Ballard[2], the TOLSURF Study Group.* 1) Department of Medicine, University of California, San Francisco, San Francisco, CA; 2) Department of Pediatrics, University of California, San Francisco, San Francisco, CA; 3) Department of Epidemiology and Biostatistics, University of California, San Francisco, San Francisco, CA; 4) Department of Bioengineering and Therapeutic Sciences, University of California, San Francisco, San Francisco, CA.

Bronchopulmonary dysplasia (BPD) is a severe yet common disease in preterm infants. In the Trial of Late Surfactant (TOLSURF) study, in which all infants received iNO, those with maternal self-reported Black/African American race/ethnicity had increased survival without BPD at 36 weeks postmenstrual age as compared to Non-Hispanic White. However, when untreated no difference between racial/ethnic groups has been observed in prior studies, suggesting there may be population-specific genetic contributions to respiratory outcomes following iNO treatment. We performed ancestry analyses and a genome-wide association study for survival without BPD at 36 weeks postmenstrual age on 387 preterm infants from mothers of three racial/ethnic groups. Association testing using genome-wide SNP genotypes and local ancestry were performed within each racial/ethnic group using logistic regression, and combined in a meta-analysis. All analyses were adjusted for birth weight, gestational age, sex, multiple gestation, and global ancestry. Gene-based statistics were calculated using VEGAS, and pathway analyses performed using GREAT and IPA. Genomic African ancestry was associated with increased survival without BPD within infants of maternal self-reported Hispanic White race/ethnicity (OR=4.5, p=0.01), but not within infants of Black/African American race/ethnicity (OR=1.01, p=0.97). Admixture mapping found suggestive associations with local African ancestry at 18q21 and 10q22 and survival without BPD, and our top associated individual SNPs were within the intron of *NBL1* (meta-analysis $p=7.4\times10^{-7}$). Variants in NO pathway genes that differed in frequency between African Americans and non-Hispanic Whites were more likely to be associated with survival without BPD as compared to variants at similar frequencies ($p=1.6\times10^{-4}$), indicating a potential genetic contribution to differential response to iNO treatment between racial/ethnic groups. Furthermore, integration of genes upregulated in BPD lungs found a significant association with variation in *CCL18*. Pathway analyses implicated sets of genes that are transcriptionally regulated by histone methylation, and those involved in immune and inflammatory processes in response to infection and mechanical ventilation. Overall our results suggest that genetic variation contributes to individual differences in survival without BPD, and may contribute to racial/ethnic differences in respiratory outcomes following iNO treatment.

1598T

A genome-wide association study for gut microbiota populations. *Y. Yun[1], H. Kim[1], S. Kim[1], Y. Chang[2], S. Ryu[2], H. Shin[3], H. Kim[1].* 1) Department of Biochemistry, Ewha Medical Research Institute, School of Medicine, Ewha Womans University, Seoul, South Korea; 2) Center for Cohort Studies, Total Healthcare Center, Kangbuk Samsung Hospital, School of Medicine, Sungkyunkwan University, Seoul, South Korea; 3) Department of Family Medicine and Health Screening Center, Kangbuk Samsung Hospital, School of Medicine, Sungkyunkwan University, Seoul, South Korea.

The human gut microbiota has been studied extensively due to its vital functions that affect nutritional efficiency and overall health. However, it is still no clear how the host genome gives a selective pressure to build certain microbial populations. We analyzed the genome-wide association (GWA) to bacteria harboring in human intestine using GWA datasets in a cross-section of 873 adults (45.11±9.22 years of mean age, 535 male/338 female) having metagenomic microbial data from fecal samples. We selected two microbes existing in samples, 'Christensenellaceae' which is reported to be the most heritable especially in lean population and '*Akkermansia*' which is supposed to be a beneficial mucin-utilizing microbe in relation with host immunity. In the discovery phase, we identified variants of *AQP9* (aquaporin 9) that associated with Christensenellaceae colonization (P=1.29×10^{-7}). This gene encodes the protein that can facilitate the uptake of glycerol in hepatic tissue and also play a role in specialized leukocyte functions such as immunological responses and bactericidal activity. Although *Akkermansia* had no significant association with host gene, the pathway involved with beta subunit of IL-2 receptor was significantly associated with *Akkermansia* population (P<0.001, FDR=0.083). This subunit of receptor is essential for IL-2 signaling involved in T cell differentiation and proliferation, which activity is crucial to the regulation of the immune response. These findings will pave the way to understand the host genetic influences on gut microbial composition that codeveloped with the host from birth. Genes for good: Engaging the public in genetics research using social media. *A. Pandit[1], W. Li[1], E.M. Schmidt[1], G.J.M. Zajac[1], C.P. Clark[1], K. Brieger[1], L.G. Fritsche[1,2], J.R. Forster[1,2], G.R. Abecasis[1].* 1) Department of Biostatistics and Center for Statistical Genetics, University of Michigan, Ann Arbor, MI; 2) K.G. Jebsen Center for Genetic Epidemiology, Department of Public Health, NTNU, Norwegian University of Science and Technology, Trondheim, Norway.

Genes for Good is a new kind of genetic study which aims to engage 10,000s of individuals in genetic research through social media, with the goal of understanding the genetic basis of human health and disease. Participants sign up through a Facebook app and answer health-related questionnaires, including one-time health histories and longitudinal health tracking surveys that can be completed as often as once per day. After answering a minimum number of surveys, participants are eligible to request a spit kit and send in their saliva sample for genotyping. After processing, participants can access ancestry information through the app, compare the survey answers to aggregate summaries of other participants, and download their raw genetic information. We are developing new ways to visualize genetic results in order to provide participants with meaningful, interesting, and accessible insights into their own genomes.As of May 2016, >11,500 individuals from all 50 U.S. states have enrolled. Growth has steadily increased since the start of the study primarily through word of mouth, and being featured on local news and web articles has further increased participation. We observe a higher percentage of female participants (over 65% of our participants are female) and also a shortage of older participants (for example, 10% of participants are >61 years old versus 18% in the US Census).Preliminary analyses demonstrate that we can reproduce population-level associations between health traits (for example, replicating associations between diabetes and obesity or between smoking and cardiovascular disease) and also known genetic association signals (for traits ranging from skin color to obesity).Genes for Good is a collaborative study, and we encourage researchers to contact us about potential collaborations.

Pharmacogenomics of ritodrine as a tocolytic medication in preterm labor. *K. Lee[1], J. Park[2], Y. Kim[3], H. Hwang[4], H. Gwak[2].* 1) Chungbuk National University, Cheongju, South Korea; 2) Ewha Womans University, Seoul, South Korea; 3) Ewha Womans University School of Medicine, Seoul, Korea; 4) Konkuk University School of Medicine, Seoul, Korea.

Background Preterm labor is the leading cause of neonatal mortality and morbidity around the world. The beta-2 agonist ritodrine has been used as a tocolytic agent due to its mechanism to cause myometrial relaxation. The purpose of this study was to evaluate the association of genetic polymorphisms with therapeutic outcomes of ritodrine. Methods Forty-one single nucleotide polymorphisms of 10 genes were genotyped in 216 preterm labor patients: *ADRB2, PDE4D, PDE4B2, GRK5, GRK6, ARRB2, RGS2, RGS5, GNAS, and CACNA1C.* Baseline characteristics and blood samples of patients were collected for analyses. The primary endpoint was time to delivery (hours) or therapeutic failure defined by using alternative tocolytics. Results Among demographics of patients, gestational age at admission, modified Bishop score, and placental abnormality showed statistical significance with time to delivery or therapeutic failure in multivariate analysis. *ADRB2* rs1042719 (adjusted hazard ratio (AHR) 2.7, 95% CI 1.5–5.0), *PDE4D* rs983280 (AHR 2.1, 95% CI 1.2–3.7), *ADE4B2* rs2180335 (AHR 0.3, 95% CI 0.1-0.9), *RGS2* rs1152746 (AHR 0.1, 95 CI% 0.0-0.7), and *RGS5* rs4657251 (AHR 0.5, 95% CI 0.3-0.9) showed significant associations with time to delivery or therapeutic failure. Conclusion Our findings demonstrate the impact of mutations of pharmacodynamic genes of ritodrine on its pharmacologic response in preterm labor.

Genome-wide scans identify novel genetic variants on *SOX2*, *FOXD1* and *EDAR* influencing eyebrow thickness. *S. Wu[1], M. Zhang[1,2], J. Tan[2], Y. Yang[2,3], Q. Peng[1], J. Li[1], Y. Liu[1], H. Lou[1], D. Lu[1], Y. Gun[4], K. Adhikari[5], A. Ruiz-Linares[5], K. Tang[1,2], L. Jin[1,2], S. Xu[1,2,6], S. Wang[1,2].* 1) CAS-MPG Partner Institute for Computational Biology, Shanghai Institutes for Biological Sciences, University of Chinese Academy of Sciences, Shanghai, China; 2) State Key Laboratory of Genetic Engineering and Ministry of Education Key Laboratory of Contemporary Anthropology, Collaborative Innovation Center for Genetics and Development, School of Life Sciences, Fudan University, Shanghai 200438, China; 3) Fudan-Taizhou Institute of Health Sciences, Taizhou, Jiangsu 225300, China;; 4) Department of Biochemistry, Preclinical Medicine College, Xinjiang Medical University, Urumqi 830011, China; 5) Department of Genetics, Evolution and Environment, and UCL Genetics Institute, University College London, London WC1E 6BT, UK; 6) School of Life Science and Technology, ShanghaiTech University, Shanghai 200031, China;.

The eyebrow is an area of thick, delicate hairs above the eye that follows the shape of the lower margin of the brow ridges of some mammals. It was thought to plays a main function to prevent moisture, mostly sweat, rain and other debris, from falling down into the eye. It is also important to facial expression, human communication and face recognition. A recent genome-wide scan found common variants in the Forkhead Box L2 (*FOXL2*) gene that are associated with eyebrow thickness in Latin Americans, but different genes can be responsible for eyebrow thickness in other populations. We firstly performed a genome-wide scan for eyebrow thickness in 2,961 Han Chinese. Two novel loci were found to be significantly associated with thicker eyebrow: rs1345417 at 3q26.3 ($P=6.51\times10^{-10}$; $\beta=0.092\pm0.015$) near *SOX2*, a gene reported to specify hair follicle type and control hair growth; rs12651896 at 5q13.2 ($P=1.73\times10^{-8}$; $\beta=0.085\pm0.015$) near *FOXD1*, a gene that was enriched in dermal condensate cell. Then we validated the findings by performing a second genome-wide scan in 721 Uyghurs (rs1345417: $P=3.78\times10^{-4}$; $\beta=0.105\pm0.029$; rs12651896: $P=0.042$; $\beta=0.061\pm0.030$). Further, we found our findings can be replicated in published data of Latin Americans (rs1345417: $P=1.04\times10^{-7}$; $\beta=0.98\pm0.018$; rs12651896: $P=7.44\times10^{-6}$; $\beta=0.080\pm0.018$). However, the previously reported signal at *FOXL2* in the Latin Americans do not affect eyebrow thickness in Han Chinese ($P=0.730$) and Uyghur ($P=0.494$), suggesting distinctive mechanisms are affecting eyebrow thickness in different populations. Finally we performed a trans-ethnic meta-analysis with 2,961 Han Chinese, 721 Uyghurs, and 2,421 Latin Americans. One additional novel loci were found to be significantly with thicker eyebrow: rs1866188 at 2q12.3 ($P=4.96\times10^{-11}$; $\beta=0.099\pm0.025$) near *EDAR*, a gene that plays an important role in the development of ectodermal tissues such as the hair, teeth and other ectodermal derivatives. All of the above signals locate at regulatory region that exhibits distinct active enhancer signatures, suggesting an important way to affect the phenotype by regulating the expression of genes. These findings further expand our knowledge on the genetics of eyebrow thickness. .

Homocysteine and IgA nephropathy: A Mendelian randomization approach. *Y. Zhang[1], X. Zhou[1], B. Li[2], F. Yu[2], S. Shi[1], L. Liu[1], J. Lv[1], H. Zhang[1].* 1) renal department, peking university first hospital, Beijing, China; 2) School of International Trade and Economics, Central University of Finance and Economics, Beijing, China.

Objectives: Hyperhomocysteinemia (HHcy) occurs almost uniformly in patients with end stage renal disease (ESRD). IgA nephropathy (IgAN) is the most common form of immune related glomerulonephritis and cause of ESRD. However, whether the elevated plasma Hcy is related to IgAN is still unclear. Due to confounding factors, we used a novel analysis tool, namely 'Mendelian randomisation (MR) approach' for testing whether elevated plasma Hcy is causally related to IgAN. **Methods:** The study comprised 1686 patients with sporadic IgAN and 1442 healthy controls. Serum Hcy was measured and patients with minimal change disease (MCD) were enrolled as patient controls. For MR analysis, the missense variant rs1801133 in the gene *MTHFR* with the most consistent effect on plasma Hcy concentrations was selected as the instrument. It was genotyped by TaqMan allele discrimination assays and verified by Sanger sequencing. **Results:** Serum levels of Hcy were significantly elevated in patients with IgAN compared to those in MCD patients (medians: 18.32 umol/l vs 11.15 umol/l, $P = 1.26 \times 10^{-7}$) and healthy controls (medians: 18.32 umol/l vs 10.00 umol/l, $P = 1.96 \times 10^{-18}$). About 93.52% patients with IgAN showed elevated plasma levels of Hcy ($\geq$10umol/l, HHcy). And HHcy was associated with higher Scr levels ($P = 0.07$), lower estimated glomerular filtration rates (eGFRs) ($P = 6.38 \times 10^{-3}$), higher systolic blood pressures (SBPs) ($P = 0.01$) and diastolic blood pressures (DBPs) ($P = 0.07$), and a higher proportion of Oxford pathologic classification of tubular atrophy and interstitial fibrosis (T) ($P = 4.88 \times 10^{-3}$). In further, the risk allele of rs1801133-T was significantly associated with increased serum Hcy level ($P = 3.89 \times 10^{-4}$) and patients with the risk allele tended to have higher Scr levels ($P = 0.03$), higher SBPs ($P = 0.02$) and DBPs ($P=0.01$), and higher ratio of T lesion ($P = 0.01$). For long-term renal survival, patients with the risk allele of rs1801133-T were independently associated with kidney disease progression (log rank test $P = 0.04$). On instrumental variable analysis, genetically elevated Hcy resulted in effects of 0.76 ($P = 0.02$), 0.26 ($P = 0.01$), 0.20 ($P = 0.01$), and 0.011 ($P = 0.01$) for Scr, SBP, DBP, and T in IgAN. **Conclusions:** In a large cohort of IgAN patients, we tested the causality between Hcy and IgAN, which could be of great significance in predicting the pace of disease progression, developing targeted therapeutic strategies in preventing the progression of IgAN.

1603W

A genome-wide association study identifies *SIGLEC5* and the *DEF1A* locus as genetic risk factors of aggressive and chronic periodontitis. *M. Munz[1], G.M. Richter[1], Y. Jockel-Schneider[2], K. Periodontitis (PD) is a heritable common inflammatory disease with worldwide prevalence rates of 11% for the severe forms. It is the major cause of tooth loss in adults above 40 years and is characterized by destruction of the alveolar bone, resulting from the inflammatory process. To better understand the molecular mechanisms of PD, we performed a genome-wide association study in the worldwide largest sample of the severe early-onset phenotype aggressive periodontitis (AgP). A case-control sample (N=896 cases, N=7,090 controls) of German and Dutch descent was genotyped using OmniExpress BeadChips (Illumina). The genotypes were imputed (1000G Phase3 EUR haplotype reference), followed by a separate analysis of the German (GER) and Dutch (NL) samples (allelic model, adjusted for the covariates sex and smoking). Subsequently, a meta-analysis on the results of both samples was performed (random effects model) with subsequent filtering by p-value (p_{meta}GER, p_{NL}; $p_{meta}<10^{-5}$; p<0.05 for LD SNPs with $r^2 > 0.8$ [linkage disequilibrium] in both imputed and un-imputed data). 16 SNPs were selected for replication in a German case-control sample of the moderate but widespread phenotype chronic periodontitis. Variants at two loci, within the protein coding gene *SIGLEC5,* and at the annotated pseudogene *DEFA9P,* reached genome-wide significance in the pooled samples. Best associated were the GWAS lead SNPs rs4284742, intronic of *SIGLEC5* ($p_{meta}=3.83^{-8}$, odds ratio [OR]=0.75), and rs2738058, 4kb upstream *DEFA9P* (p=1.04^{-9}, OR=1.28). *In silico* functional analysis (Haploreg, GTEx) revealed expression quantitative trait loci effects of these SNPs on the genes *SIGLEC5* (p=7.7^{-14} in whole blood) and *DEFA4* (p=1.7^{-3} in blood), respectively. *SIGLEC5* inhibits the activation of several cell types including monocytes, macrophages and neutrophils. *DEFA9P* and *DEFA4* belong to the family of Defensins, which are abundant in the granules of neutrophils and the epithelia of mucosal surfaces such as the gingiva. They encode antimicrobial peptides and are involved in host defense. This study identifies, for the first time, shared risk loci of AgP and CP with genome-wide significance, and highlights the role of innate and adaptive immunity in the etiology of periodontitis.

Rare genomic anomalies at a number of known imprinted loci are associated with disorders of birth weight. However, to date, no common genetic variants have reported robust parent-of-origin associations with birth weight. We analysed 10,915 mother-child pairs and 583 parent-offspring trios from 7 studies to determine parental origin of alleles at 6.1M SNPs genome-wide (MAF >0.01; imputed to 1000 Genomes). We tested the associations between birth weight and (i) maternally-inherited alleles, (ii) paternally-inherited alleles and (iii) maternally- versus paternally-inherited alleles in heterozygotes. We highlight SNPs with associations $P<5\times10^{-8}$ in model (iii) AND $P<0.05$ in either (i) or (ii). For 59 loci identified in recent birth weight GWAS, we were able to include additional samples, resulting in a total N of 18,719 pairs/trios. To complement this approach, we tested for differences in birth weight variance between heterozygotes and homozygotes at 12.2M variants (MAF>0.01) in 103,619 unrelated individuals from 12 studies. Effect sizes on birth weight differed between maternally- and paternally-inherited alleles for SNPs at two loci (near *TENM4* and in *ARHGAP25*; model (iii) $P=3\times10^{-11}$ and $P=2\times10^{-8}$, respectively); for both SNPs only the maternally-inherited allele was associated with birth weight at $P<0.05$: 0.58 SD (95%CI: 0.27, 0.89 SD, $P=2\times10^{-4}$) change in birth weight per maternally-inherited allele near *TENM4* and 0.29 SD (95%CI: 0.08, 0.51 SD; $P=8\times10^{-3}$) in *ARHGAP25*. The paternally-inherited alleles showed no association with birth weight ($P>0.2$). One of the 59 known birth weight loci, *ANK1*, showed association in model (iii) after Bonferroni correction ($P=8\times10^{-4}$): 0.07 SD (95%CI: 0.04, 0.11 SD, $P=8\times10^{-5}$) change in birth weight per paternally-inherited allele; maternally-inherited $P=0.2$. Among unrelated individuals, no variant was associated with variance differences between heterozygotes and homozygotes at $P<5\times10^{-8}$, and there was no difference at either *TENM4* or *ARHGAP25* ($P>0.2$). However, there was some support for greater variance in heterozygotes than homozygotes at *ANK1* ($P=0.002$). Our initial analysis provides evidence of possible parent-of-origin effects on birth weight at 3 loci, but these require replication in further samples. The upcoming addition of further data, including GWAS in 11,000 parent-offspring trios, will greatly enhance our power to detect robust associations.

1605F

Parent-of-origin effect in asthma - GWAS meta-analysis in three Canadian cohorts. *A. Eslami[1], L. Akhabir[1], G. Ellis[1], A.B. Becker[2], A.L. Kozyrskyj[3], P.D. Paré[1], A.J. Sandford[1], C. Laprise[4], D. Daley[1].* 1) University of British Columbia, Vancouver, BC, Canada; 2) Department of Pediatrics and Child Health, Faculty of Medicine, University of Manitoba, Winnipeg, MB, Canada; 3) Department of Pediatrics, Faculty of Medicine and Dentistry, University of Alberta, Edmonton, AB, Canada; 4) Université du Québec à Chicoutimi, Saguenay, QC, Canada.

   Background: Asthma is a complex disease caused by a combination of genetic and environmental factors. Heritability is estimated to range between 0.48-0.79. To date, 44 significantly associated SNPs have been identified by 23 asthma genome-wide association studies (GWAS) (at $p<10^{-6}$). The consensus is that the main genetic effects of these common SNPs (with modest effects) do not fully explain the heritability of asthma. Genomic imprinting is a potential mechanism which may explain some of the 'missing heritability'. Imprinting is an epigenetic phenomenon where the expression of genes depends on their parental origin (parent-of-origin effect). Imprinting effects have been reported in the development of many complex diseases. **Hypothesis**: Imprinting is involved in the etiology of asthma. **Methods:** To identify candidate genomic regions for imprinting we used GWAS data from three family-based studies (two parents and one offspring). These studies are: 1) the Canadian Asthma Primary Prevention Study (CAPPS), a high-risk asthma birth cohort and, 2) the Study of Asthma Genes and Environment (SAGE), a population-based asthma birth cohort 3) the Saguenay-Lac-Saint-Jean Québec Familial Collection (SLSJ), a founder population of French-Canadians. We used a likelihood-based variant of the Transmission Disequilibrium Test. Parent-of-origin effects in SLSJ as well as the combined CAPPS and SAGE were performed by including parental sex as a modifier in the analysis. Meta-analysis was conducted using the results of SLSJ and the joint analysis of CAPPS and SAGE weighted by the number of informative transmissions for each study. **Results**: In SLSJ, 7 SNPs showed significant parent-of-origin effects with $p<10^{-5}$ (252 trios with asthmatic children). In the joint analysis of CAPPS and SAGE, 13 SNPs showed significant parent-of-origin effects with $p<10^{-5}$ (148 trios with asthmatic children). Notably, in the joint analysis of CAPPS and SAGE, we identified a parent-of-origin effect at a known imprinted gene, *CTNNA3*. This gene was previously identified in a GWAS study of occupational asthma. Of all significant results in those two analyses ($p<10^{-5}$), 12 out of 20 of the SNPs were in or near Long non-coding (lnc)RNA genes. LncRNAs are known to be involved in genomic imprinting and gene regulation. Meta-analysis resulted in two SNPs with significant parent-of-origin effects with $p<10^{-5}$ in the genes *SLC39A10* and *LNX2/POLR1D*. .

1606W

Cumulative impact of red blood cell polymorphisms in resistance and susceptibility to severe malaria. *G.M. Clarke[1], G. Band[1], C.M. Ndila[2], C.A.C. Spencer[1], K.A. Rockett[1,3], D.P. Kwiatkowski[1,3].* 1) Wellcome Trust Centre for Human, University of Oxford, Oxford, United Kingdom; 2) Department of Epidemiology and Demography, KEMRI-Wellcome Trust Research Programme, P.O. Box 230 Kilifi 80108, Kenya; 3) Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, Cambridge. CB10 1SA.

   Individually, polymorphisms in *HBB*, *ABO*, *ATP2B4*, *G6PD* and the glycophorin region have been reliably associated with protection from severe malaria due to *Plasmodium falciparum*. All are red blood cell (RBC) polymorphisms. Given the extensive changes in the host red cells brought about by invasion of the malaria parasite, it is natural to ask whether epistasis between these loci could be responsible for variation in malaria susceptibility. Here we assess interaction between combinations of these RBC loci in a case control study of 11,890 cases of severe malaria due to *Plasmodium falciparum* and 17,441 controls from 11 countries in Africa, Asia and Oceania. We find no evidence for any departure from independence of effects, indicating that protection accumulates cumulatively with each protective genotype carried. Cumulative genetic protective scores were calculated using unweighted and weighted approaches. We report on the predictive power of the genetic scores and show that as the genetic protective scores increase, the risk of severe malaria increases: individuals carrying protective genotypes at multiple loci have up to a 20-fold increase in protection compared to those carrying none. .

1607T

Variation in locus 5q31.1 confers resistance to *Mycobacterium tuberculosis* **infection in immunosuppressed individuals from hyper-endemic regions of East Africa.** *R.S. Sobota[1,2], C.M. Stein[3,4], N. Kodaman[1,2,3], S.A. Tishkoff[5], W.K. Scott[6], J.H. Moore[2,7], T. Lahey[2], W.H. Boom[3,4], C.F. von Reyn[2], S.M. Williams[2,3], G. Sirugo[8].* 1) Vanderbilt Genetics Institute, Vanderbilt University, Nashville, TN; 2) Geisel School of Medicine at Dartmouth, Hanover, NH; 3) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH; 4) Tuberculosis Research Unit, Case Western Reserve University, Cleveland, OH; 5) Department of Genetics, University of Pennsylvania, Philadelphia, PA; 6) John P. Hussman Institute for Human Genomics, University of Miami, Miami, FL; 7) Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA; 8) Centro di Ricerca, Ospedale San Pietro Fatebenefratelli, Rome, Italy.

One in three people in the world have been infected with *Mycobacterium tuberculosis* (MTB). Individuals immunosuppressed by HIV infection are more likely both to be infected with MTB and to develop subsequent clinical disease. We hypothesized that HIV-positive individuals who live in areas endemic for MTB but do not get infected are genetically resistant. We performed a genome-wide association study of tuberculin skin test positivity using 479 HIV-positive patients in two recently concluded prospective cohorts of tuberculosis from Tanzania and Uganda. In our screening, 244 tested positive for MTB infection either at enrollment or throughout the >8 year follow up, while 235 did not. We identified a genome-wide significant association between the dominant model of rs877356 and binary TST status in the combined cohort (OR = 0.2671, 95% CI 0.1696-0.4207, p = 1.22×10^{-8}). The variant lies in the 5q31.1 region, 57kb downstream from *IL9*. Two-locus analyses of association of variants near rs877356 showed that haplotype comprised of rs877356 and an *IL9* missense variant rs2069885 had the most significant association. *IL9* encodes for a cytokine produced by mast cells and T_H2 cells in inflammatory responses. It has been previously associated with bronchial hyperresponsiveness, a heightened bronchoconstriction and airway inflammation in response to external stimuli. Observational studies have reported decreased prevalence of MTB infection in people with chronic bronchial hyperresponsiveness, as seen in asthma. Our results identify a novel locus of MTB infection resistance, propose a possible link between airway inflammation and protection from MTB infection, and indicate that studying those who remain disease-free in the face of extensive exposure increases the power to detect associations in complex infectious disease.

1608F

Genome-wide association study of multivariate measures of human facial morphology. *M. Lee[1], E.J. Leslie[1], J.C. Carlson[2], E. Orlova[3], E. Feingold[3], M.L. Marazita[1], J.R. Shaffer[3], S.M. Weinberg[1].* 1) Department of Oral Biology, University of Pittsburgh, Pittsburgh, PA; 2) Department of Biostatistics, University of Pittsburgh, Pittsburgh, PA; 3) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA.

A small number of studies have reported genome-wide associations with quantitative aspects of normal human facial morphology. While these studies have each used different phenotyping approaches, significant associations have generally been restricted to univariate measures of facial morphology. Such measures capture only limited information about facial structure. In an effort to expand on previous efforts, we applied factor analysis to 276 measures (linear distances) covering the entire face. These distances were derived from 3D facial images of 2187 healthy White individuals of European ancestry and were adjusted by sex, age and body size. The samples were genotyped on the Illumina OmniExpress+Exome v1.2 array and imputed to the 1000 Genomes reference panel. Genome-wide association analyses were conducted on 23 extracted facial factors in PLINK adjusting for ancestry principal components. We observed a total of six genome-wide significant associations (p<5e-8) with different facial shape factors. Most notably, variants in *PARK2* (top SNP: rs9456748; 6q26) were associated with a factor defined by midfacial height (p=4.99e-8). Furthermore, variants in *FREM1* (top SNP: rs72713618; 9p22.3) were associated with a factor defined by height of the upper lip (p=2.02e-8). Mutations in *FREM1* have been associated with facial dysmorphology in humans and strong expression has been described in mouse embryos at the site of medial nasal process fusion. The role of *PARK2* in craniofacial development is currently unclear, but the gene is expressed in the epithelium of the nasal cavity in mice. These associations have not been reported previously. Our results provide further insight into the genetic underpinnings of normal-range variation in human facial morphology and suggest that multivariate data reduction methods may be useful for defining relevant facial phenotypes. .

Clinical, social and genomic factors associated with obesity at 12 months of age. *S. Hazrati[1], W. Wong[1], N. Prem[1], Y. Yui[1], K. Huddleston[1], S. Hourigan[1,2], J. Niederhuber[1].* 1) Inova Health System, Falls Church, VA; 2) Johns Hopkins University.

Purpose: To examine genomic, social and clinical predictors of obesity at 12 months of age Methods: Over 3000 families from various races or ethnicities have been recruited in prenatal stage, in the longitudinal study of genomics and child health, at Inova Translational Medicine Institute. 760 children had clinical and genomic data available at age 12 months. Whole genome sequencing was performed on blood. Weight for length at 12 months was calculated using WHO gender specific growth charts with the following definitions: overweight as greater or equal to 85th, obese as greater or equal to 95th, severely obese as greater or equal to 99th percentiles. A supervised genetic analysis was conducted using the SKAT for the association of rare variants (MAF less than or equal to 0.1) with obesity. Gene-set level p-values were computed for 363 obesity related genes from the human obesity gene map. Chi-square and paired t-test were used to test for association of clinical and social factors with obesity. Results: Of the 760 infants, 15% were overweight, 15% obese and 8% severely obese. Clinical or social factors significantly associated with being overweight, obese or severely obese at 12 months were ethnicity, maternal education, juice consumption and parental BMI (p -value less than 0.05). After adjusting for multiple testing with Bonferroni correction, only two genes were significant at the 0.1 level, namely, WT1 (P=0.0033) and CNR1 (P=0.090), for the severely obese group. Conclusion: Many genomic, clinical and social risk factors are associated with obesity. None of the genes were significant after Bonferroni correction for the overweight or obese groups. Clinical and socials factors that were significantly associated (p -value less than 0.05) with being overweight and obese in all 3 groups were Hispanic origin, lower maternal education and any juice consumption at 12 months.

Comparison of collection methods and whole genome amplification for pharmacogenetics. *J.S. Ang[1], H. Katzov-Eckert[1], M. Aloise[1], D. Dawes[1,2], A. Gonzalez-Suarez[1,3], A. Paterson[1,4,5], P. Stanley[1], R. Fraser[1,6], P. Cullis[1,6], M. Dawes[1,7].* 1) GenXys Health Care Systems, Vancouver, BC; 2) University of British Columbia Physical Therapy, Vancouver, BC; 3) University of British Columbia Department of Botany, Vancouver, BC; 4) University of British Columbia Faculty of Pharmaceutical Sciences, Vancouver, BC; 5) Clinicare Pharmacists Inc, Vancouver, BC; 6) University of British Columbia Personalized Medicine Initiative, Vancouver, BC; 7) University of British Columbia Family Practice, Vancouver, BC.

A simple, non-invasive sample collection method is key to the uptake and integration of pharmacogenetic testing by clinicians. We tested two different types of swabs as an alternative to saliva collection, which was used in the Implementation of Pharmacogenomics in Primary Care study. Swabs have the potential to be more cost effective and convenient for sample collection. Our goals were to compare the DNA yield and quality, to assess the feasibility of whole genome amplification (WGA) of low quantity DNA samples, and to evaluate sample performance on clinically relevant pharmacogenetic assays. One OraCollect DNA (OCR-100, DNA Genotek) and four PurFlock Ultra swabs (Puritan) were collected from thirty-one study volunteers. Genomic DNA (gDNA) was extracted using a bead-based extraction kit (Ambion, MagMAX, Applied Biosystems). To simulate postal delays, PurFlock swabs were extracted at two different time points: 3 days and 7 days after sample collection. A WGA step was added to the Puritan swabs extracted at day 3 using the REPLI-g kit (Qiagen). The DNA yield (mean±SD) and A260/280 (mean±SD) ratio was found to be 1.9±1.4µg and 1.85±0.39 for OraCollect DNA and 0.25±0.35µg and 1.72±0.78 for PurFlock swabs, respectively. Results indicated no significant differences in the yield and quality between PurFlock swabs extracted at two different time points. WGA resulted in a mean increase of 0.34 µg of initial DNA. SNP genotype call rate on the OpenArray for the WGA samples was low (21%) and only 45% of samples had copy number variant (CNV) confidence scores >95% for a TaqMan CNV assay. In comparison, samples obtained from OraCollect genotyped on the same platform had a genotyping call rate of 97% and CNV confidence scores of 100%. We conclude that WGA from gDNA extracted from buccal swabs is not suitable for genotyping on the OpenArray and may introduce bias for CNV assignment. The OraCollect DNA swab is a reliable source of genomic DNA that can be effectively used for pharmacogenetic testing.

Implementation of pharmacogenetics with clinical decision support in primary care. *H. Katzov-Eckert[1], M. Aloise[1], J.S. Ang[1], D. Dawes[1,2], A. Gonzalez-Suarez[1,3], G. Liknaitzky[1], A. Paterson[1,4,5], P. Stanley[1], R. Fraser[1,6], P. Cullis[1,6], M. Dawes[1,7].* 1) GenXys Health Care Systems, Vancouver, BC; 2) University of British Columbia Physical Therapy, Vancouver, BC; 3) University of British Columbia Department of Botany, Vancouver, BC; 4) University of British Columbia Faculty of Pharmaceutical Sciences, Vancouver, BC; 5) Clinicare Pharmacists Inc, Vancouver, BC; 6) University of British Columbia Personalized Medicine Initiative, Vancouver, BC,; 7) University of British Columbia Family Practice, Vancouver, BC.

Inappropriate prescribing increases patient morbidity and death due to adverse drug events. The inclusion of pharmacogenetics into primary care medication practices is one solution. We conducted a cohort study in six primary care settings, enrolling 191 adults with at least one of ten common diseases. To develop a pharmacogenetic test, evidence for genotype-guided medication dosing was compiled for drugs commonly prescribed by family physicians. Genetic variants that influence drug response were ranked according to clinical annotations from PharmGKB, Clinical Pharmacogenomics Implementation Consortium and FDA guidelines. Finally, a panel of genetic variants was selected and validated including *CYP2D6, CYP2C19, CYP2C9, VKORC1 SLC01B1, G6PD* and *HLA-B*58:01*. Saliva samples were collected and genomic DNA was isolated using a magnetic bead based extraction method (Ambion® MagMAX™, Applied Biosystems). Genotyping of SNPs and CNV was carried out by Openarray™ and TaqMan™ probe assays on the QuantStudio 12K Flex System (ThermoFisher Scientific). To provide personalized treatment options, annotated genotypes were integrated into a medication decision support system called TreatGx. Findings indicated that 96.8% of samples had at least one actionable genotype for medications included in TreatGx. Moreover, TreatGx facilitated the use of genetic information in the decision-making processes of health care professionals working in primary care. In conclusion, a decision support system that includes genetics can optimize personalized prescribing in primary care and may lead to a reduction in inappropriate prescribing.

1612W

The global spectrum of coding region pharmacogenomic diversity. *G. Wright[1], B. Carleton[2], M. Hayden[1], C. Ross[3].* 1) Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 2) Pediatrics, University of British Columbia, Vancouver, BC, Canada; 3) Faculty of Pharmaceutical Sciences, University of British Columbia, Vancouver, BC, Canada.

Background Inter-individual differences in response to medications are known to have a strong genetic component. By leveraging publically available genomic data, the spectrum of genetic variation in genes that influence either response to medications or adverse drug reactions can be investigated extensively. **Methods** Genes were selected based on relevance to pharmacogenomics according to the PharmGKB database and the literature. Genetic variants in these regions of interest were extracted from the 1000 Genomes Project data from 26 global populations (*n*=2504). Variants were then annotated using the Ensembl VEP and analysed in further detail utilising the program, VCFtools and the software environment, R. **Results** A total of 11902 genetic variants were found in the 58 genes that met inclusion criteria, with over 80% of the dataset comprising of rare variants. Seven genes were excluded due to accessibility to sequencing technologies and there was an overrepresentation of cytochrome *P450* genes found in segmental duplications (*P*=0.006). Pharmacogenomic variation tended to be most similar within continental populations and 16 gene regions contained a highly differentiated marker. Samples carried a median of five clinical variants with a high level of evidence and 36% of samples carried at least one loss of function (LOF) variant. LOF variants were found in 64% of the pharmacogenes, and *CYP3A5*, which influences tacrolimus dose, displayed the highest number of unique LOF variants. **Conclusion** These data demonstrate that current sequencing technologies can successfully identify large amounts of clinical pharmacogenomic variation. Since the relative frequency of deleterious variants is inversely correlated with allele frequency, future approaches need to consider this class of variation to fully understand the full spectrum of genetic diversity contributing to pharmacogenomic traits.

Introducing "SG10K": Cataloging genetic diversity and population structures in 10,000 South Asians. *C. Bellis[1], I.D. Irwan[1], C. Wang[2], W.W. Soon[3], A. Wilm[4], C.C. Shih[4], R.S. Foo[5,6], A.M. Richards[5], C.S. Lam[7], H.H. Ng[8], J. Liu[1].* 1) Human Genetics 2, Genome Institute of Singapore, Agency for Science, Technology and Research of Singapore, Singapore; 2) Computational and Systems Biology, Genome Institute of Singapore, Agency for Science, Technology and Research of Singapore, Singapore; 3) Next Generation Sequencing Platform, Genome Institute of Singapore, Agency for Science, Technology and Research of Singapore, Singapore; 4) Scientific and Research Computing, Genome Institute of Singapore, Agency for Science, Technology and Research of Singapore, Singapore; 5) Cardiovascular Research Institute, National University Health System, Singapore; 6) Human Genetics 3, Genome Institute of Singapore, Agency for Science, Technology and Research of Singapore, Singapore; 7) National Heart Centre Singapore, Singapore; 8) Gene Regulation Laboratory, Genome Institute of Singapore, Agency for Science, Technology and Research of Singapore, Singapore.

Genetic variation plays an important role in a variety of human diseases and quantitative traits. Due to different underlying genetic architecture and contrasting environmental exposures, many genetic findings have shown population-specific characteristics, highlighting the importance of population diversity in human genetic studies. The Singapore population consists of three major ethnic groups, Chinese, Malay, and Indian, which together represent >80% of the Asian population. To empower biomedical and human genetic studies in Asian populations, the SG10K project will perform 12-13× WGS of 10,000 Singaporeans. Coupled with powerful bioinformatics tools, our study design will enable high-quality genotype calling for a full frequency spectrum of genetic variants segregating in the population. Our main objectives are to (1) comprehensively characterize genetic variation in Singapore population; (2) create a WGS reference panel for accurate genotype imputation in Asian population; and (3) generate a large control dataset for WGS-based genetic association study of diseases. Our extensive calculations have provided substantial preliminary evidence allowing us to confidently proceed with our plan to survey our 10,000 samples at a depth of coverage between 12-13× in our WGS strategy. Because the phased variant calling will become more powerful with the increased sample size (via more accurate haplotype information), 10× WGS will allow us to characterize the full spectrum of germ-line genetic variants (except the private ones) in 10K individuals with the similar accuracy and sensitivity as 30× WGS. To achieve our goals, we will be employing the Illumina TruSeq Nano DNA Library Preparation Kit and sequencing study participants on the Illumina HiSeq 4000 instrument, in-house at GIS. However, this project is a fully national effort across multiple institutions; our collaborative partners include SingHealth Duke-NUS Institute of Precision Medicine, Singapore Eye Research Institute, Centre for Personalised and Precision Health, National University Health System and several Translational and Clinical Research Flagship Programmes (Heart failure, Parkinson disease). To date we have taken possession of the complete SG10K cohort and sequenced 576 samples. Upon completion, this study will provide valuable genetic information to facilitate clinical and pharmaceutical research in Singapore populations and will empower genetic studies of Singapore and Asian-centric diseases.

1614F

Genome-wide association study of sleep duration in the 14,000 Japanese general population. *T. Nishiyama[1,3], M. Nakatochi[2], A. Hosono[3], Y. Tamai[3], S. Suzuki[3], A. Hishida[4], K. Wakai[4], H. Tanaka[5], K. Matsuo[6], The Japan Multi-Institutional Collaborative Cohort Study.* 1) Department of Public Health, Aichi Medical University School of Medicine, Nagakute, Japan; 2) Center for Advanced Medicine and Clinical Research, Nagoya Univ. Hospital, Nagoya, Japan; 3) Dept. of Public Health, Nagoya City Univ. Graduate School of Medicine, Nagoya, Japan; 4) Dept. of Preventive Medicine, Nagoya Univ. Graduate School of Medicine, Nagoya, Japan; 5) Division of Epidemiology and Prevention, Aichi Cancer Center, Nagoya, Japan; 6) Division of Molecular Medicine, Aichi Cancer Center, Nagoya, Japan.

Usual sleep duration is heritable with heritability estimates being around 40%. Candidate gene association studies for sleep duration identified a number of potential loci, though the results were inconsistent. A GWAS of sleep duration have identified and replicated two SNPs near *PAX8* and *CBWD2* [Gottlieb DJ 2015], but in the other GWAS, any locus have neither reached genome-wide significance nor been replicated in independent samples presumably due to limitations in sample size. Therefore, we conducted a GWAS of sleep duration using data from the Japan Multi-Institutional Collaborative Cohort Study (J-MICC study). The J-MICC study is one of the largest population-based cohort studies in Japan [Wakai K 2011]. The participants were enrolled in 10 study areas throughout Japan except for the northern region. Phenotype information was obtained from self-administered questionnaires at study entry. The ethics committees of all participating institutions approved the protocol for the J-MICC study, and all participants provided written informed consent. Genotyping was performed with the Illumina Infinium OmniExpressExome-8 BeadChip. In total, 513,776 SNPs in 14,088 participants passed our quality control criteria (MAF ≥ 5%, HWE p-value ≥ 0.001 and call rate ≥ 95% for both individuals and markers). Single SNP association analysis of sleep duration as a quantitative trait was performed using PLINK, adjusted for age and gender. Population structure was also adjusted by the first principal component from principal components analysis. A gene-based association test was performed using the SKAT package in R. In the single SNP analysis, two SNPs (rs12229654 and rs2188380) were significantly associated with sleep duration with genome-wide level (p-value = 5.E-09 and 1.E-08, respectively). In the gene-based analysis, a gene, *PTPLAD2* was significantly associated with sleep duration after adjusting for multiple comparisons (p-value = 0.047 in Bonferroni method). The two associated SNPs are located 28kb apart from each other and display very strong linkage disequilibrium (r2 = 0 .94). These genes are located between two genes, *MYL2* and *CUX2* on chromosomes 12. These genes were not identified in the former GWAS of sleep duration and warrants further exploration.

The scope and mechanism of inbreeding depression in humans. *D.W. Clark[1], P.K. Joshi[1], I. Gandin[2], T. Esko[3,4,5], J.F. Wilson[1,6], ROHgen consortium.* 1) Centre for Global Health Research, University of Edinburgh, Edinburgh, Midlothian, United Kingdom; 2) Department of Medical Sciences, University of Trieste, Strada di Fiume 447 - Osp. di Cattinara, Trieste, 34149, Italy;; 3) Estonian Genome Center, University of Tartu, Riia 23b, 51010, Tartu, Estonia;; 4) Program in Medical and Population Genetics, Broad Institute, Cambridge Center 7, Cambridge, 02242, MA, USA;; 5) Division of Endocrinology and Center for Basic and Translational Obesity Research, Boston Children's Hospital, Cambridge, 02141, MA, USA;; 6) MRC Human Genetics Unit, Institute of Genetics and Molecular Medicine, University of Edinburgh, Western General Hospital, Crewe Road, Edinburgh, EH4 2XU, Scotland.

Homozygosity caused by consanguineous union has long been associated with an increased prevalence of rare Mendelian disorders. In contrast, the role of homozygosity in relation to quantitative traits and complex disease susceptibility is less well established. Recent work has shown that an increased burden of homozygous DNA segments (defined as the fraction of each genome in any Run of Homozygosity > 1.5 Mb, or F_{ROH}) is associated with reduced height and cognitive ability in diverse human populations. Here, we assess the scope of inbreeding depression in humans by analysing the effect of F_{ROH} on 41 quantitative traits of public health and evolutionary interest, in >500,000 individuals from >100 cohorts worldwide. Phenotypes studied include anthropometry, lipids, liver, lung and kidney function, cognition, glycaemia, fertility, inflammation, electrocardiography and haematology. We confirm the findings of previous work, and also show that increased F_{ROH} is associated with reduced values of several components of evolutionary fitness. The constancy of these effects across different levels of homozygosity and across diverse populations in which social confounding more plausibly engenders the opposite effect, strengthens the argument that F_{ROH} has a causal effect. In addition, we investigate the magnitude of inbreeding depression between men and women to explore whether sex-specific dominance may provide a mechanism, independent of the sex-chromosomes, by which males and females might adapt to different selective pressures. We investigate the mechanism of inbreeding depression by exploring different measures of homozygosity. Long homozygous segments arise from recent common ancestry and bring all variants, including rare causal variants, into a homozygous state. In contrast, shorter homozygous segments may arise from more ancient common ancestry and thus capture only the dominance effects of more common variants. Using multivariate linear models we show that F_{ROH} is more predictive of inbreeding depression than traditional estimates of inbreeding coefficient based on individual SNP homozygosity.

Analysis of expression quantitative trait loci in the human eye. *L.D. Orozco[1], J. Hackney[1], C. Cox[2], Y. Li[2], M. Jeanne[2], M. van Lookeren Campagne[2].* 1) Bioinformatics, Genentech, South San Francisco, CA; 2) Immunology, Genentech, South San Francisco, CA.

Age-related Macular Degeneration (AMD) is the leading cause of vision loss in the elderly. AMD affects over 10 million people in the US, and 20-25% of caucasians over 75 years of age. Risk factors of AMD include smoking, age, ethnicity, and genetics. In the most recent GWAS study, Fritsche and colleagues identified a total of 34 loci that account for 46% of the genetic variance, and observed a heritability of 44% for "wet" AMD, and 52% heritability for "dry" AMD. Anti-VEGF drugs such as *Lucentis* have revolutionized treatment for *neovascular* or "wet" AMD, but there are currently no available treatments for patients suffering from *geographic* or "dry" AMD. Risk variants identified through GWAS are a valuable source for new target identification, and eQTL studies allow for causal gene identification in complex traits. However, a focused eQTL study in the eye tissues affected by AMD has not been performed. In order to better understand the disease pathogenesis and prioritize candidate genes for AMD, we performed QTL analysis to identify tissue specific *cis*-eQTL. We profiled human eye donors for genotypes in 2 million SNPs, and expression patterns using RNAseq in macular and extra-macular retina and RPE/choroid. To identify eQTL, we filtered genes with normalized RPKM greater than 0.1 in at least 10 donors, and transformed expression levels using quantile normalization. The covariates in the model included 15 PEER factors estimated from the normalized expression, sex, age, and 3 genotyping eigen vectors. We selected SNPs with minor allele frequency greater than 10%, and missing frequency in less than 10% of individuals. Finally, we fit a linear regression model using the package MatrixEQTL, and called *cis*-eQTL based on 1 Mb distance from the gene. Overall, we followed the analysis pipeline used by the GTEx project. Here we describe, for the first time, eQTL in multiple tissues of the human eye. Our findings will aid our understanding of the biology behind AMD pathogenesis, and can be used to identify novel therapeutic targets and biomarkers.

1617F

Identifying genetic associations with variability in metabolic health and blood count laboratory values: Diving into the quantitative traits in an EHR. *S. Verma[1,2], A. Lucas[2], J. Leader[2], C. Bauer[2], R. Metpally[2], S. Krishnamurthy[2], F. Dewey[3], A. Lopez[3], J. Overton[3], J. Reid[3], G. Breitwieser[2], S. Pendergrass[2], M. Ritchie[2,4].* 1) The Huck Institute of Life Sciences, The Pennsylvania State University, University Park, PA; 2) Biomedical and Translational Informatics, Geisinger Health System, Danville, PA; 3) Regeneron Genetics Center, Tarrytown NY; 4) Biochemistry and Molecular Biology, The Pennsylvania State University, University Park, PA.

Metabolic and complete blood count (CBC) panels provide a comprehensive picture of health and disease in patients during routine clinical care. These blood panels are useful in diagnosis of many common, complex diseases, and can be used as quantitative traits to elucidate the genetics of disease. We extracted 25 clinical laboratory measures from the metabolic and CBC panels in ~40,000 patients from Geisinger Health System MyCodeâ Discov-EHR cohort to perform association studies of both common and rare variants associated with these traits. We identified 2,453 unique common loci (minor allele frequency >1%) above genome-wide significance (p-value < $5x10^{-8}$) that are associated with one or multiple traits. This analysis validated many known variants and revealed novel genes associated with variability among patients in these 25 phenotypes. For example, we replicate several known variants in the *UGT1A1* gene associated with bilirubin levels and also found many variants in genes *CASR*, *CCDC58*, *KPNA1*, *CSTA* associated with serum calcium levels. Our study also identified 22 associations with platelet counts where the odds ratio ranges from 172.19-11.22. These include some known associations (such as variants in *NF-E2* and *GP1BA*) as well as novel association such as variants in *PTPN11* and *ITPR3* that have not been identified by previous GWAS. We also explored pleiotropic associations from this study and identified variants in *ABO* and *GCKR* genes to be associated with multiple traits. Next, we explored the trait variability in patients based on the longitudinal data from the EHR, we tested patients with high and low variance for the 25 labs for association with ICD-9 based case/control diagnoses. Lastly, we performed gene-based rare variant collapsed analysis for all variants with minor allele frequency < 1% from whole exome sequencing data for same individuals. Rare variant binned SKAT-linear analysis also resulted in many known and novel associations. There were 235 results that pass bonferroni significance ($8.74x10^{-8}$) at alpha 0.05 (25 phenotypes and 22,874 genes tested). Among the top results is the association between rare variants in *HTR1F* and white-blood cell count (p-value $1.54x10^{-10}$). This study shows the utility of exploring clinical lab measures for association testing, identifying both common and rare variants related to trait variability among patients, and present a novel approach for exploring of associations between trait variability and disease diagnoses.

1618W

Genetic overlap between dizygotic twinning and BMI, height and smoking: Results from the Twinning GWAS Consortium. *H. Mbarek[1], M. Nivard[1], E.A. Ehli[2], G.E. Davies[2], D.I. Boomsma[1].* 1) Department of Biological Psychology, Netherlands Twin Register, Vrije Universiteit Amsterdam, Amsterdam, Netherlands; 2) Avera Institute for Human Genetics, Sioux Falls, SD 57108, USA.

Spontaneously becoming the mother of dizygotic twins (MoDZ) is a complex trait, which aggregates in families. MoDZ might index fertility and has distinct health implications for both the mother and the child. Recently we reported for the first time that sequence variation at the FSHB and SMAD3 loci increases the odds of MoDZ, based on three discovery cohorts from the Netherlands, Australia and Minnesota (USA). The findings were replicated in a large cohort from Iceland by deCODE (1).Our prior work on the role of body composition and smoking in DZ twinning (2) established that MoDZ is significantly associated with increasing height, an increased BMI, and smoking before the twin pregnancy. Here we used our meta-analysis results and the LD score regression method (3) to estimate genetic correlations between MoDZ and BMI, height and smoking. MoDZ shows positive genetic correlations with BMI, height and smoking (ever smoking and age at onset). All results are in the direction predicted by our prior work, however the correlations did not pass the significance threshold of 0.05 (corrected for multiple testing), likely due to low statistical power (our discovery sample included only ~2000 cases and 14,000 controls) and suggests that polygenic risk score analyses will give additional insights into the nature of these associations. 1. Mbarek, H., Steinberg, S., Nyholt, D.R., Gordon, S.D., Miller, M.B., McRae, A.F., Hottenga, J.J., Day, F.R., Willemsen, G., de Geus, E.J., et al. (2016). Identification of Common Genetic Variants Influencing Spontaneous Dizygotic Twinning and Female Fertility. Am J Hum Genet 98, 898-908. 2. 1619T

Genetic variants do not predict efficacy response with mepolizumab in severe asthma. *L. Condreay[1,2], M. Chiano[3], H. Ortega[2,4], N. Buchan[3], E. Harris[1,2], S.W. Yancey[2], S. Ghosh[5]. 1) PAREXEL International, Research Triangle Park, NC; 2) GSK, Research Triangle Park, NC, USA; 3) GSK, Stevenage, UK; 4) Genentech, South San Francisco, CA, USA; 5) GSK, King of Prussia, Pennsylvania, USA.*

Purpose: Treatment with mepolizumab, a humanized monoclonal antibody to interleukin-5, reduces the rate of asthma exacerbations and the requirement for systemic glucocorticoids while maintaining asthma control. Treatment benefit is guided by predictors of response such as blood eosinophil thresholds in patients with frequent exacerbations despite intensive anti-inflammatory and controller treatment. We investigated genetic variants that may predict efficacy response to mepolizumab treatment. **Methods:** Candidate genetic variant and an exploratory genome-wide association analyses (GWAS) were performed in 1053 patients with severe eosinophilic asthma treated with at least one dose of mepolizumab who provided consent for pharmacogenetic (PGx) research enrolled in phase 3 clinical studies, DREAM and MENSA. Evaluation of baseline factors indicated that PGx cohorts for DREAM (n=589) and MENSA (n=464) were representative of the intent-to-treat study populations (n=616 and 576, respectively). Analysis was post-hoc and included non-Hispanic white patients (n=820). A total of 105 genetic variants in 53 gene regions were selected for analysis based on prior history of association with relevant traits or pathways. Efficacy endpoints included: rate of clinically significant exacerbation (primary endpoint, tested by generalized linear regression), time to first exacerbation (tested with a Cox proportional hazards model), and change in exacerbation rate, change in eosinophil count, or change in IgE level (tested by linear regression). For the primary endpoint, candidate variant analysis had 80% power to identify exacerbation rate ratios of ≥ 1.6 (or ≥ 2.0 for GWAS) for common genetic variants with a minor allele frequency >20%. **Results:** No genetic variant was significantly associated with the primary endpoint, clinically significant exacerbation rate in candidate variant or GWAS analyses. The intronic variant, rs1021621, in *POU2F1* was significantly associated with time to first clinically significant exacerbation (p=2×10^{-5}) but the association was driven by DREAM data and not supported in additional sensitivity analyses by treatment regimen/dose. The available sample size had limited statistical power to detect small genetic effects from common variants or effects from rare variants using GWAS. **Conclusion:** No genetic effect on mepolizumab-treatment response was identified in this population with severe eosinophilic asthma. **Funding:** GSK (NCT01691859, NCT0169521).

1620F

Gene expression response to rhinovirus infection differs between Chronic Rhinosinusitis (CRS) Patients and non-CRS controls. *M. Soliai[1], A. Kato[3], J. Norton[3], A. Klinger[3], B. Tan[4], R. Kern[4], R. Schleimer[3], J. Pinto[2], C. Ober[1]. 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) Department of Surgery, University of Chicago, Chicago, IL; 3) Department of Surgery, Northwestern University Feinberg School of Medicine; 4) Department of Medicine, Northwestern University Feinberg School of Medicine.*

Chronic rhinosinusitis (CRS) is an inflammatory disorder of the nose and paranasal sinuses that affects upwards of 12% of the U.S. population. Microbes in the upper respiratory system can influence the development of CRS in individuals at risk for this disease, but little is known about inter-individual responses to infection. In this analysis, we interrogated genes that are differentially expressed in response to human rhinovirus (RV) infection in nasal uncinate tissue epithelial cells (UTEC) obtained from 47 cases with CRS with nasal polyps (CRSwNP) and 52 non-CRS controls. UTECs were cultured with RV or a vehicle control for 48 hours, followed by sequencing (Illumina RNA-Seq). Technical sources of variation were identified and adjusted by using principle components analysis and ComBat, respectively. A paired analysis of gene expression response to RV was conducted to identify different responses between cases and controls using limma, and including age, sex, and race as covariates. This was followed by Ingenuity Pathway Analysis (IPA) of the differentially expressed genes to identify multi-gene networks. Overall, 805 of the 11,341 genes that passed quality control were differentially expressed in response to RV in the cases, controls or combined sample (FDR 10% in each sample). 113 genes were responsive to RV in both CRS cases and controls, 428 were responsive to RV in the cases only, and 264 genes were responsive to RV in the controls only. Response genes unique to the controls, as well as response genes common to both cases and controls, are well known genes in viral response pathways, and are involved in networks associated with antimicrobial and inflammatory responses and infectious diseases (network score p-values < 10^{-40}). In contrast, response genes that were unique to the cases formed networks with functions associated with nucleic acid metabolism and small molecule biochemistry. Among these uniquely expressed genes in CRSwNP, *HDAC5* is a major gene hub in the top-scored network (p = 10^{-47}). Moreover, 10 response genes unique to CRSwNP cases are implicated in the cholesterol biosynthesis pathway (Fisher Exact Test, p-value = 6.14×10^{-11}), including *DHCR7*, *FDFT1*, and *HMGCR*. Overall, these data show different gene expression responses to RV between CRSwNP cases and non-CRS controls, and implicate different biological pathways in such responses, informing our understanding of underlying disease biology. Whole genome sequence analysis of a multi-ethnic population of children with asthma reveals novel pharmacogenetic associations. *M. White[1], A.C.Y. Mak[1], Z. Szpiech[1], D. Hu[1], M. Pino-Yanes[3], S. Huntsman[1], C. Eng[1], S. Oh[1], J. Galanter[1], D. Torgerson[1], M. Seibold[2], E. Ziv[1], N. Zaitlen[1], R. Hernandez[1], E.G. Burchard[1], New York Genome Center.* 1) Department of Medicine, University of California, San Francisco, San Francisco, CA; 2) Center for Genes, Environment, and Health, Department of Pediatrics, National Jewish Health, Denver, Colorado; 3) Research Unit, Hospital Universitario N.S. de Candelaria, Santa Cruz de Tenerife, Spain.

Asthma is a complex disease characterized by chronic inflammation of the airways, and is the most common chronic disease of childhood worldwide. Latinos and African Americans have the highest asthma morality and the lowest drug response to asthma therapies. Specifically, there are ethnic disparities to albuterol bronchodilator drug response (BDR) among children with asthma. Previous GWAS studies have failed to reveal common variants associated with BDR that account for the majority of the variation in BDR. We analyzed whole genome sequence (WGS) data to evaluate the impact of common variant effects on BDR in a multi-ethnic pediatric asthma study. We leveraged the increased statistical power obtained from performing an extreme phenotype study design to identify common variants associated with BDR. Our study consisted of 1500 children (500 Mexican, 500 Puerto Rican, 500 African American) sampled from the extremes of each group's BDR distribution. We performed association tests separately in each population and then performed a trans-ethnic meta-analysis across all populations to identify cosmopolitan effects. We identified one variant near *DNAH5* that reached genome-wide significance across populations (meta-analysis β= 0.44, p = 8.11 x 10⁻⁸), after correcting for the number of independent tests. This finding is of particular interest, as *DNAH5* has been associated with lung capacity in chronic obstructive pulmonary disease. To our knowledge, this is the first study to comprehensively investigate the effects of common variants in three admixed populations of children collected from the extremes of the bronchodilator drug response phenotypic distribution.

SNPs, linkage disequilibrium and transcriptional factor binding sites associated with chronic mountain sickness among Tibetan Chinese at the Qinghai-Tibetan Plateau. *N. Buroker[1], X-H. Ning[1,2], Z-N. Zhou[4], K. Li[3], W-J. Cen[3], X-F. Wu[4], W-Z. Zhu[5], C.R. Scott[1], S-H. Chen[1].* 1) Pediatrics, 356320, University of Washington, Seattle, WA; 2) Division of Cardiology, Seattle Children's Hospital. Institute. Foundation, Seattle, WA; 3) Lhasa People Hospital, Tibet; 4) Laboratory of Hypoxia Physiology, Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, China; 5) Center for Cardiolvascular Biology and Regenerative Medicine, University of Washington, Seattle, WA.

Chronic mountain sickness (CMS) or Monge's disease is estimated at 15% in Quechua Andeans and 1.2% in Tibetans living at the same high altitude greater than 3000 meters above sea level. A CMS Tibetan Chinese and a normal Tibetan group were compared. Eighteen simple nucleotide polymorphisms (SNPs) within 9 genes that have been associated with CMS were analyzed with respect to linkage disequilibrium (LD) between intra- and intergenic SNP alleles and alterations in transcriptional factor binding sites (TFBS). Included in the study was the angiotensin-converting enzyme (ACE) (rs4340), the angiotensinogen (*AGT*) (rs699) and the angotensin II type 1 receptor (*AGTR1*) (rs5186) SNPs from the renin-angiotension system (RAS) and a LDL apolipoprotein B (*APOB*) (rs693) SNP. The endothetal Per-Arnt-Sim (PAS) domain protein 1 (*EPAS1*) SNP and an egl nine homolog 1 (*EGLN1*) SNPS (rs480902) from the hypoxia-inducible factor (HIF) oxygen signaling pathway were included. SNPs analyzed in the vascular endothelial growth factor (VEGF*)* signaling pathway are the v-akt murine thymoma viral oncogene homolog 3 (*AKT3*) (rs4590656 and rs2291409), the endothelial cell nitric oxide synthase 3 (*eNOS3*) (rs1007311 and rs1799983) and the (*VEGFA*) (rs699947, rs34357231, rs79469752, rs13207351, rs28357093, rs1570360, rs2010963 and rs3025039). These SNP alleles alter the TFBS for transcriptional factor (TF) binding. Pair-wise LD was computed between SNPs. An increase in LD occurred in 40 pair-wise comparisons while a decrease was found in 55 pair-wise comparisons between the CMS and controls. Increases and decreases in LD pairs were found within and between signaling pathways and systems indicating the interaction of SNP alleles or potential TFBS from different areas of the genome. The most drastic change in TFBS occurs with ACE (I/D) SNP (rs4340) where the ACE-I allele generates 84 potential TFBS while the ACE-D allele generates only four binding sites. The alteration in TFBS generated by the 18 SNPs is discussed with respect to CMS.

Real-life prosocial attitudes in North America: A genome-wide association approach. *G. Primes, M. Fieder.* University of Vienna, Austria.

   In humans, prosocial behaviour is essential for social functioning. Twin studies suggest this distinct human trait to be partly hardwired. In the last decade research on the genetics of prosocial behaviour focused on neurotransmitters and neuropeptides, such as oxytocin, dopamine, and their respective pathways. Recent trends towards large scale medical studies targeting the genetic basis of complex diseases such as alzheimer's disease and schizophrenia pave the way for new directions also in behavioural genetics.Based on data from 10,713 participants of the American Health and Retirement Study we estimated heritability of helping behaviour – its total variance explained by 1.2 million single nucleotide polymorphisms – to be 11%. Two approaches of genetic association analyses identified *RS11697300*, an intergene variant on chromosome 20, as a candidate variant moderating this particular prosocial attitude. We assume that this so far undescribed area is worth further investigation in association with human prosocial behaviour.

1624W

Elucidating the complex relationship between pleiotropy and disease risk in the human genome. *K. Chesmore[1], J. Bartlett[2], S. Williams[2].* 1) Department of Genetics, Dartmouth College, Hanover NH; 2) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland OH.

   In recent years several studies have investigated pleiotropy in order to better understand the complex relationship among diverse human diseases. However, one facet of this relationship that has largely been unexplored is whether pleiotropic genes (those that associate with multiple disease phenotypes) have larger effects sizes than those that appear to only associate with a single disease. Taking advantage of the wealth of information gathered from the GWAS catalog, we explored this relationship using the number of disease phenotypes associated with each gene and the Odds Ratios of case/control studies as a measurement of effect size. We identified 10,153 genes that associate with 847 diseases and tested whether the number of diseases associates with a gene's effect size, using linear regression. Our results showed that genes associating with more disease phenotypes have significantly larger effect sizes (p = 2*10^-8). Additionally, we explored how the collection of more data through the years has helped to resolve this relationship. As more data was added to the GWAS catalog over the years we found evidence of more examples of pleiotropy for more genes (at present 46% of genes in the GWAS catalog are pleiotropic up from 10% in 2010). The shift of this distribution is resolving the relationship between pleiotropy and effect size, resulting in higher levels of correlations with more significant p-values. As more data is collected we expect this relationship to be resolve even further. Elucidating this relationship and the underlying mechanisms is crucial for understanding the potentially common between multiple diseases, and may allow for the development of predictive models of the molecular mechanisms that drive human diseases.

1625T

Polygenic load for neuroticism predicts chronic pain in the UK Biobank cohort. *M.E.S. Bailey[1], J. Ward[2], D.J. Smith[2], B.I. Nicholl[2], J.P. Pell[2].* 1) School of Life Sciences, CMVLS, University of Glasgow, Glasgow, United Kingdom; 2) Institute of Health and Wellbeing, CMVLS, University of Glasgow, Glasgow, United Kingdom.

Chronic pain affects up to 20% of adults in Europe and accounts for more disability in the developed world than any other condition. It is highly heterogeneous and influenced by a complex mixture of social, psychological and environmental exposures, yet its heritability is estimated at 20-40%, with a substantial genetic contribution. The basis for the known correlation between chronic pain and personality/psychological traits (e.g. neuroticism) is unclear. We have investigated the connection between chronic pain and neuroticism in the UK Biobank (UKB) population cohort using a polygenic risk score (PRS) approach. Data from a recent meta-GWAS of neuroticism (Smith et al., 2016), which included >90,000 individuals from UKB, were used to derive a series of PRSs with meta-GWAS-derived thresholds from $p<5x10^{-8}$ up to $p<0.5$. SNPs underwent full QC and were filtered after clumping for linkage disequilibrium. PRSs were calculated, using GWAS β weighting, for unrelated white European individuals in UKB that had not been included in the meta-GWAS. PRSs were ranked and divided into 13 quantiles, which was used as a quasi-quantitative variable in case/control logistic regression models in R. The main outcome tested was presence of chronic pain (>3 months in duration) at any of several pre-specified sites in the body (Case n=10,722). Controls (n=13,114) included only those reporting no pain >1 month in duration. Models were adjusted for 8 principal genetic components, age, sex, genotyping chip and data collection centre. Increasingly inclusive PRSs defining polygenic load for neuroticism were notable predictors for chronic pain (best $p=6.6x10^{-10}$) with a per-PRS level O.R. of 1.02. Number of pain sites was also predicted by neuroticism PRS, and individual sites predicted most strongly were back, neck, shoulder and head pain. Our findings support a biological basis for the known correlation between neuroticism and chronic pain. The polygenic load for neuroticism in the general population correlates with chronic pain prevalence and with number of pain sites reported. Mendelian Randomisation approaches may help distinguish whether this association is due to shared pleiotropic variants or to a causal influence of neuroticism-related psychology on propensity to experience or report pain. Further understanding of the biology of chronic pain will inform the development of new treatment approaches that help individuals maintain both good quality of life and economic productivity.

1626F

Discovery and replication of rare variant associations using a knowledge-driven PheWAS approach in eMERGE and Geisinger Health System. *A.O. Basile[1], A.M. Lucas[2], A. Verma[2], A.T. Frase[2], M. de Andrade[3], M.H. Brilliant[4], J.C. Denny[5], D.R. Velez Edwards[5], T. Edwards[5], M.M. He[4], S.J. Hebbring[5], B. Namjou-Khales[6], A. Lopez[7], J. Overton[7], J. Penn[7], J. Reid[7], L.J. Rasmussen-Torvik[8], O.J. Veatch[5], M.D. Ritchie[1,2].* 1) Department of Biochemistry and Molecular, The Pennsylvania State University, University Park, PA; 2) Department of Biomedical and Translational Informatics, Geisinger Health System, Danville, PA; 3) Division of Biomedical Statistics and Informatics, Mayo Clinic, Rochester, MN; 4) Center for Human Genetics, Marshfield Clinic Research Foundation, Marshfield, WI; 5) Vanderbilt Genetics Institute, Vanderbilt University Medical Center, Nashville,TN; 6) Center for Autoimmune Genomics and Etiology, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 7) Regeneron Genetics Center, Tarrytown, NY; 8) Department of Preventive Medicine, Northwestern University Feinberg School of Medicine, Chicago, IL.

Rare genetic variation has recently been implicated in various multifactorial conditions such as Alzheimer's disease and obesity. Elucidating the influence of rare variants has the potential to identify novel associations and expand our current understanding of the heritability of complex traits. As these variants are individually uncommon, standard approaches to association studies are statistically underpowered. We addressed this challenge by applying a knowledge-driven approach using BioBin to bin variants into biological features, thereby increasing the composite allele frequency. Herein, we applied Bio-Bin-SKAT (Bin-KAT) in a gene-based analysis to examine the influence of rare and low-frequency variants (MAF< 5%) in 8 phenotypes, asthma, benign prostatic hyperplasia, cataracts, diverticulosis, gastroesophageal reflux disease, hypertension, hypothyroidism and uterine fibroids, using two distinct EHR-linked biorepositories. Discovery analysis was performed in 7,000 subjects from the electronic Medical Records and Genomics (eMERGE) Network as part of the eMERGE-PGX study. Subjects were sequenced using PGRNseq, an 82 pharmacogene targeted sequencing platform. Case-control designation was determined by ICD-9 codes. All significant models from eMERGE (p< 0.05) were then tested in a replication set of approximately 39,000 individuals from the Geisinger Health System MyCode® Community Health Initiative sequenced at Regeneron Genetics Center as part of DiscovEHR. Associations in both datasets were evaluated using the SKAT implementation in BioBin, adjusting for sex, age, median BMI, and principal components. Our gene analysis, replicated 8 results with a p< 0.01, and 1 of these associations replicated with high significance (p< 10-4). The most significant replicating associations include rare variants in *CYP2C19* with asthma, *CRHR1* and *NR3C1* with uterine fibroids and *CES2* with diverticulosis. Notably, *CYP2C19* has previously been implicated in the development of asthma, as genetic variation is observed to affect the enzyme's ability to metabolize pollutants. We also applied Bin-KAT to 2 other biological feature analyses (pathway and SNPEff functional predictions) to provide further insight into the rare variant influence on these phenotypes. Our findings support a role for low-frequency variants in susceptibility to multiple complex phenotypes and demonstrate the utility of Bin-KAT for the biologically-inspired binning and effective analysis of rare variants.

1627W

Complex traits analysis with big data: A landscape of the effects of sample size, number of SNPs and the statistical model on prediction accuracy. *G. de los Campos[1,2], A. Grueneberg[1], H. Kim[1], A. Vazquez[1], S. Hsu[3].* 1) Epidemiology & Biostatistics, Michigan State University, East Lansing, MI; 2) Statistics & Probability, Michigan State University, East Lansing, MI; 3) Department of Physics, Michigan State University, East Lansing, MI.

The continued reduction of genotyping costs has lead to an increase in the availability of data sets comprising genotypes linked to phenotypes and disease outcomes. In the last decade GWAS studies have reported large number of variants associated with important human traits and diseases; however, our ability to use DNA information to predict phenotypes and health outcomes with complex genetic architecture remains limited. Prediction accuracy (PA) depends on the genetic architecture of the trait or disease being analyzed, the number of markers used (P) and how these were selected (S), the size (N) of the training (TRN) data set and the statistical method (M) used to estimate effects. Until recently, the investigation of how these factors interact in determining PA has been limited by the size of standard GWAS cohorts. Initiatives such as the UK Biobank and US Precision Medicine Initiative® will soon deliver very large biomedical datasets comprising genetic, clinical and phenotypic information; these resources will enable empirical research at a scale that was not previously possible. In this study we use data from the UK Biobank corresponding to unrelated individuals of Caucasian background to produce a landscape of PA in testing (TST) data as a function of N (from 5K to 80K records in TRN, K=thousand), P (from 0.5K to 50K SNPs, selected from GWAS done with TRN data), S (independent vs. linked markers) and M (shrinkage vs. variable selection methods) for anthropometric traits with complex genetic architecture. Using N=80K (20K) from model TRN (TST) and 50K SNPs we achieved levels of PA in TST data higher than what has been previously reported for the traits analyzed. The estimated response surface indicates that PA increases with P for all traits; however the increase in PA occurs at diminishing marginal rates; consequently, PA plateaus at a level that is largely determined by heritability and N. Our results also indicate that increasing N beyond 80K is likely to yield further gains in PA. Models that combine variable selection and shrinkage performed slightly better than shrinkage-only methods. We also find that the use of several markers per LD block increases PA relative to the use of 'independent' markers when P is large. We conclude that our ability to predict complex traits will continue to improve as more data becomes available; however, even with hundreds of thousands of records a sizable fraction of missing heritability will still remain.

1628T

Heritability enrichment of specifically expressed genes identifies disease-relevant tissues and cell types. *H.K. Finucane[1,2], Y.A. Reshef[1,3], A. Saunders[4], E. Macosko[4], K. Slowikowski[5], A. Byrnes[6,7], V. Anttila[4,7], S. Gazal[1], A. Gusev[1], G. Genovese[7], S. Pollack[1], J.R.B. Perry[8], S. Raychaudhuri[4], B. Neale[6,7], S. McCarroll[4], A.L. Price[1].* 1) Harvard T.H. Chan School of Public Health, Boston, MA; 2) Department of Mathematics, MIT, Cambridge, MA; 3) Department of Computer Science, Harvard University, Cambridge, MA; 4) Harvard Medical School, Boston, MA; 5) Bioinformatics and Integrative Genomics, Havard University, Cambridge, MA; 6) Massachusetts General Hospital, Boston, MA; 7) Broad Institute, Cambridge, MA; 8) MRC Epidemiology Unit, University of Cambridge School of Clinical Medicine, Cambridge, UK.

Genetics can provide an unbiased approach to discovering causal tissues and cell types for disease. Identifying these tissues is critical for developing ex vivo human systems to explore gene regulatory mechanisms that may be crucial to disease, and to follow up non-coding allelic function. Here, we analyze gene expression data from the GTEx Consortium and other sources, together with GWAS summary statistics for 52 diseases and traits with an average sample size of 83,751, to identify disease-relevant tissues and cell types. To accomplish this, we use stratified LD score regression to test whether disease heritability is enriched within 100kb of the top 10% of specifically expressed genes in a given tissue. We detected tissue-specific enrichments at FDR < 5% for 37 traits. We find that regions containing genes specifically expressed in arteries are enriched for heritability of migraine without aura, supporting a theory that migraine etiology has a vascular basis. Similarly, regions containing brain-specific genes are enriched for epilepsy heritability; this is particularly notable as there are only two genome-wide significant loci for this trait. For smoking behavior, we find the strongest heritability enrichment in regions containing genes that are specifically expressed in the nucleus accumbens, which is known to be important in addiction. Additionally, we find heritability enrichment for age at menarche in regions containing pituitary-specific and brain-specific genes; for schizophrenia, bipolar disorder, anorexia, Tourette syndrome, and major depressive disorder in brain-related regions; for rheumatoid arthritis and several other immunological traits in immune-related regions; for LDL and triglycerides in liver-related regions; and for waist-hip ratio in adipose-related regions, strengthening confidence in our method. We also applied this approach to single-cell expression data in two human and three mouse brains generated using Drop-seq. For schizophrenia, Tourette syndrome, smoking status, and other brain-related traits, we detected significant enrichments for neuronal cells relative to other brain cell types. Overall, our results suggest that gene expression data provides a valuable source of tissue-specific and cell-type-specific information for interpreting GWAS signals, and that a polygenic approach to detecting such enrichments can be more powerful than previous approaches based only on top SNPs.

1629F

Ygen: The first systematic assessment of the influence of human Y chromosome variation on a wide range of health-related traits. *I. Gandin[1], P.K. Joshi[2], T. Esko[3,4,5], J.F. Wilson[2,6], The Ygen consortium.* 1) Department of Medical Sciences, University of Trieste, Strada di Fiume 447 - Osp. di Cattinara, Trieste, 34149, Italy; 2) Centre for Global Health Research, Usher Institute for Population Health Sciences and Informatics, University of Edinburgh, Teviot Place, Edinburgh, EH8 9AG, Scotland; 3) Estonian Genome Center, University of Tartu, Riia 23b, 51010, Tartu, Estonia; 4) Program in Medical and Population Genetics, Broad Institute, Cambridge Center 7, Cambridge, 02242, MA, USA; 5) Division of Endocrinology and Center for Basic and Translational Obesity Research, Boston Children's Hospital, Cambridge, 02141, MA, USA; 6) MRC Human Genetics Unit, Institute of Genetics and Molecular Medicine, University of Edinburgh, Western General Hospital, Crewe Road, Edinburgh, EH4 2XU, Scotland.

Functions beyond sex determination and spermatogenesis have recently been suggested for the Y chromosome, however in terms of complex traits it remains the most poorly studied large block of DNA in the human genome. This is in large part due to the minimal representation of Y variants on genome-wide and custom SNP arrays, and further that these haploid data are routinely ignored in genome-wide association studies. The Ygen consortium leverages the inclusion of variants capturing the major branches of the Y chromosome gene genealogy into the widely genotyped exome chip, to perform the first systematic dissection of the influence of Y-linked variation on complex traits. Over 100 population-based and other cohort studies from 5 continental ancestries participate in Ygen, delivering the required statistical power with over 300,000 men. Genotypes at 68 markers, which represent ~4000 variants in perfect LD, are used to categorise men into 65 haplogroups, thus capturing the majority of global Y chromosome variability. 39 traits of public health and evolutionary interest are considered – including anthropometry, lipids, liver, lung and kidney function, cognition, glycaemia, fertility, inflammation, electrocardiography and haematology – and analysed in a single-SNP association analysis. We detail in high-resolution the spectrum of diverse haplogroup frequencies across the different cohorts. There are many challenges to the analysis of such strongly structured data, but initial meta-analyses suggest Y chromosome variants associate with adult height, the first evidence from large scale studies that the non-recombining region of the Y chromosome influences a complex trait. The yield per megabase of common "GWAS variants" on the Y chromosome appears to differ from that on the autosomes, suggesting the different selective exposures, effective population size and recombinational environments to the autosomes have influenced the function of Y DNA. .

Joint fine mapping of GWAS and eQTL detects target gene and relevant tissue. *F. Hormozdiari[1], A. Segre[2], M. van de Bunt[3,4], X. Li[2], J. Wha J Joo[1], M. Bilow[1], J. Sul[5,6], S. Sankararaman[1], B. Pasaniuc[7,8], E. Eskin[1,8].* 1) Department of Computer Science, University of California, Los Angeles, CA; 2) Cancer Program, The Broad Institute of Massachusetts Institute of Technology and Harvard University, Cambridge, MA; 3) Oxford Centre for Diabetes, Endocrinology & Metabolism, University of Oxford, Oxford, United Kingdom; 4) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 5) Department of Psychiatry and Biobehavioral Sciences, University of California, Los Angeles, CA; 6) Semel Center for Informatics and Personalized Genomics, University of California, Los Angeles, CA; 7) Department of Pathology and Laboratory Medicine, University of California, Los Angeles, CA; 8) Department of Human Genetics, University of California, Los Angeles, CA.

The vast majority of genome-wide association studies (GWAS) risk loci fall in non-coding regions of the genome. One possible hypothesis is that these GWAS risk loci alter the disease risk through their effect on gene expression in different tissues. In order to understand the mechanisms driving a GWAS risk locus, it is helpful to determine which gene is affected in specific tissue types. If the same variant responsible for a GWAS locus also affects gene expression, the relevant gene and tissue may play a role in the disease mechanism. Identifying whether or not the same variant is causal in both GWAS and eQTL studies is challenging due to the uncertainty induced by linkage disequilibrium (LD) and the fact that some loci harbor multiple causal variants. However, current methods that address this problem assume that each locus contains a single causal variant. In this paper, we present a new method, eCAVIAR, that is capable of accounting for LD while computing the quantity we refer to as the colocalization posterior probability (CLPP). The CLPP is the probability that the same variant is responsible for both the GWAS and eQTL signal. eCAVIAR has several key advantages. First, our method can account for more than one causal variant in any loci. Second, it can leverage summary statistics without accessing the individual genotype data. We use both simulated and real datasets to demonstrate the utility of our method. Utilizing data from the Genotype-Tissue Expression (GTEx) project, we demonstrate that computing CLPP can prioritize likely relevant tissues and target genes for a set of Glucose and Insulin-related traits loci.

1631T

Replication of genetic associations with height as a proof of concept for the Million Veteran Program (MVP) dataset. *H. Hunter-Zinck[1], Y. Shi[1], M. Li[1,5,11], N. Sun[2,6], J. Huang[1], C. Pan[3,7], J. Gelernter[2,10], P.S. Tsao[3,7], C.J. O'Donnell[1,9], E.R. Hauser[4,8], H. Zhao[2,6,10], T.L. Assimes[3,7], S. Pyarajan[1,9] for MVP Genomic Working Group.* 1) VA Boston Healthcare System, Boston, MA; 2) VA Connecticut Healthcare System, West Haven, CT; 3) VA Palo Alto Health Care System, Palo Alto, CA; 4) Durham VA Medical Center, Durham, NC; 5) University of Utah, Salt Lake City, UT; 6) Yale School of Public Health, New Haven, CT; 7) Stanford University School of Medicine, Stanford, CA; 8) Duke University, Durham, NC; 9) Harvard Medical School, Boston, MA; 10) Yale School of Medicine, New Haven, CT; 11) Johns Hopkins University, Baltimore, MD.

Height is a complex trait with polygenic architecture. Much effort has been spent to assemble large samples to better understand the genetic basis of this trait. We performed a genetic association analysis with height using approximately 110,000 samples of inferred European ancestry from the Million Veteran Program (MVP), from the U.S. Department of Veterans Affairs, to replicate previous associations and serve as a proof of concept for genome-wide association studies (GWAS) of other conditions using this dataset. We used data derived from the electronic health record of veteran participants, collected at the time of a clinical visit, for height and other covariates including sex and age. To assess replicability with the MVP dataset, we calculated the phenotypic variance explained by associated markers as well as the correlation in the direction of effect for previously associated markers in height meta-studies from Lango Allen, et al. in 2010 and Wood, et al. in 2014. Within the European ancestry cohort, we explain 8.1% of the variance in the height phenotype, a level comparable to previous studies. Using the overlap between markers on the MVP chip and markers analyzed in previous meta-studies, we replicate the direction of effect for 146 of 146 previously associated markers in the Lango Allen, et al. height GWAS and 135 of 136 markers associated in the Wood, et al. study. The Pearson correlation in effect sizes between the MVP study and the two previous analyses is 0.97 and 0.95 for the Lango Allen, et al. and Wood, et al. study, respectively. We also compared power and performance between self-reported and measured height to construct the phenotype as well as self-reported and inferred genetic ancestry to construct sample cohorts on which to conduct the GWAS. Finally, given the large numbers of individuals from other ancestry groups, we replicated associations found in the MVP cohort of European ancestry in a cohort of individuals admixed for European and African ancestry. The results strongly replicate previous genetic associations with height and serve as a demonstration of the utility of the MVP dataset for GWAS.

Background: As one of the preventive healthcare services, direct-to-consumer genetic tests are widely provided. Most of these tests are based on risk SNP markers from genome-wide association studies (GWAS) and genetic counseling of family histories are not usually provided. Although common diseases are frequently observed in family history, GWAS based genetic risks are tended to be weak. Thus the frequency and heritability of common diseases are need to be considered in interpretation. In this presentation, we will report the results of a clinical research about preventive healthcare program using GWAS based genetic test at Medical Hospital, Tokyo Medical and Dental University, Japan. **Methods:** 101 Japanese adults were recruited for this study subjects. Genome-wide SNP genotyping, family history questionnaire and health examination were performed. Then, we created reports about genetic risks of about 30 diseases and health examinations, in which congenital hereditary diseases are not included. All the reports were disclosed by physicians. Selections of genetic risk markers and creating a consultation guideline for high risk groups were discussed at the clinical advisory board meetings, where specialists from each clinical department are attended. **Results:** In relatively rare diseases such as ulcerative colitis, Graves' disease and gout, GWAS based genetic risks were significantly high in subjects with family histories compared to subjects without family histories (p-value < 0.05). On the other hand, in relatively common diseases such as hypertension and type 2 diabetes, GWAS based genetic risks were not significantly different by family histories. **Conclusion:** Subjects with family histories and high GWAS based genetic risks especially need follow-ups as high risk groups. For example, in Graves' disease, one of the subjects whose genetic risk was high commented that his results were acceptable with his family history and looked convinced. We expect those subjects keep motivated to change their behavior for prevention. Meanwhile, subjects with no family histories but high GWAS based genetic risks or subjects with abnormal results in health examination are also need follow-ups as high risk groups. These results suggest the combination of genetic risks, family histories and health examination results are the challenges of how to disclose genetic risks and also the potentials to better follow-up interventions.

1633W

Pleiotropy in complex diseases estimated from family health history collected in primary care. *R.A. Myers[1], L.A. Orlando[1], R.R. Wu[1,2,3], A.H. Buchanan[4], G.S. Ginsburg[1], E.R. Hauser[5,6].* 1) Center for Applied Genomics and Precision Medicine, Duke University School of Medicine, Durham, NC, USA; 2) Duke-National University of Singapore Medical School, Singapore; 3) National Heart Centre Singapore, Singapore; 4) Genomic Medicine Institute, Geisinger Health System, Danville, PA , USA; 5) Duke Molecular Physiology Institute, Duke University School of Medicine, Durham, NC, USA; 6) Cooperative Studies Program Epidemiology Center, Durham VAMC, Durham, NC, USA.

Complex diseases typically do not occur in isolation and are often accompanied by other conditions in individuals. Likewise, these sets of pleiotropic conditions may occur in families. The extent to which complex diseases are co-inherited and have shared genetic etiologies is informative in a number of applications such as patient disease-risk identification. PheWASs have been successful at identifying pleiotropic loci but do not quantify the extent to which pleiotropy exists in pairs or sets of complex diseases. We used family health histories (FHH) collected in primary care as a source of unascertained pedigrees to explore evidence for pleiotropy within families. We hypothesize that systematically collected, self-reported FHH can be used to quantify complex disease pleiotropy and describe the genetic relationships between complex diseases, thereby informing clinically relevant disease risk. MeTree® was used to collect FHH of 1608 patients for 48 different diseases. Patients averaged 25 relatives per family, 2.4 diseases for themselves, 1.3 for 1st degree relatives, and 0.6 diseases for 2nd degree relatives. We estimated heritability (h^2) using generalized linear mixed effect models and identified 39 diseases with h^2 >0, with values generally consistent with published h^2 estimates. We used logistic regression to estimate the odds ratio (OR) of a patient having disease A and a 1st, or 2nd degree relative having disease B, adjusted for age, sex, race, and family size, for all pairwise disease combinations. This measure of co-inheritance was positively correlated with h^2 for within-disease ORs (adj-r = 0.59, p = 0.0003). Genetically related sets of diseases were identified by using the ORs from disease-pairs with false discovery rate ≤ 5% to construct a network of diseases. The resulting network averaged 5.1 connections per disease and ranged from 0-13 connections per disease. There were several expected connections within physiologically related cancers, metabolic syndrome diseases, and autoimmune disorders (e.g. rheumatoid arthritis (RA), and lupus). The diseases with the largest number of connections were thyroid disease (13), RA (12), polyp count (11), and hypertension (11), suggesting the potential for novel pleiotropic relationships. Through analysis of unascertained FHH, we identify complex diseases with shared genetic etiologies that may help clinicians more comprehensively ascertain complex disease risk in families.

1634T

Steady-state gene expression explains 5-15% of heritability for many complex traits. *L.J. O'Connor[1,2], S. Gusev[1], X. Liu[1], H.K. Finucane[1,3], A.L. Price[1].* 1) Harvard University, CDepartment of Epidemiology, Harvard T.H. Chan School of Public Health, Boston, MAambridge, MA; 2) Program in Bioinformatics and Integrative Genomics, Harvard University, Cambridge, MA; 3) Department of Mathematics, Massachusetts Institute of Technology, Cambridge, MA.

Disease risk variants identified by GWAS are predominantly noncoding, suggesting that gene regulation plays an important role. eQTL studies in healthy individuals have often been used to link disease-associated variants with the genes they regulate, relying on the hypothesis that pathogenic patterns of gene expression include changes in steady-state expression levels. To test this hypothesis, we developed a method, GE co-score regression, to estimate the proportion of complex trait heritability explained by the cis-genetic component of assayed gene expression levels. This quantity measures the extent to which genetic effects on complex traits are mediated by cis-regulation of gene expression. Our method is based on the idea that, for a gene whose expression is associated with a phenotype, SNPs with similar effects on the expression of that gene will have similar phenotypic effects. Specifically, we regress products of trait z-scores, for pairs of SNPs in linkage equilibrium, on products of cis-eQTL z-scores. We verified that GE co-score regression produces unbiased estimates in simulations.We applied GE co-score regression to eQTL data in 42 tissues from the GTEx consortium (N=79-362) in conjunction with GWAS summary statistics for 24 complex traits (median N=70,000), estimating the proportion of heritability explained by the union of all tissues. Across traits, the median estimate was .10 (median s.e.=.05, median p=.02, aggregate p < 10^{-10}); for 18/24 traits, the estimate was between .05 and .15. There was little evidence of tissue specificity, consistent with high cis-genetic correlations across tissues. We also analyzed splicing QTL data in brain (N=452), which explained limited additional heritability (median 0.036, median s.e.=0.02, median p=.02, aggregate p< 10^{-10}). These results suggest that pathogenic expression profiles do include a steady state component but are primarily transient or context- and cell type-specific; more targeted eQTL study designs will be required before GWAS results can routinely be translated into biological insights using gene expression data.

1635F

Enrichment of regulatory variants in the PheWAS Catalog: An implication of phenome-wide association studies. *Z. Zhao[1,2], J. Zhao[1], F. Cheng[3,4], P. Jia[1].* 1) School of Biomedical Informatics, University of Texas Health Science Center at Houston, Houston, TX; 2) Human Genetics Center, School of Public Health, University of Texas Health Science Center at Houston, Houston, TX; 3) Center for Cancer Systems Biology, Dana-Farber Cancer Institute, Harvard Medical School, Boston, MA; 4) Center for Complex Networks Research, Northeastern University, Boston, MA.

   Genome-wide association study (GWAS) has evolved the primary approach to study the association of common genetic variants, typically in the form of single nucleotide polymorphisms (SNPs), with the complex diseases and traits during the last decade. So far, GWAS have identified thousands of SNP-trait associations, most of which are deposited in the GWAS Catalog. Recently, thank to the rapid accumulation of enriched phenotypic data from electronic medical records (EMRs), phenome-wide association studies (PheWAS) has become a feasible and a complementary approach to GWAS in order to detect genetic variants that are associated with multiple disease risks. A PheWAS Catalog that collected the large PheWAS dataset was made available by Denny *et al.* in 2013, which included 3,144 SNPs in the GWAS Catalog. These two catalogs allow us to investigate whether PheWAS variants are more likely to have functional impacts leading to develop multiple human diseases or traits. In this study, we used the functional annotation data, including transcription factor (TF) based motifs, promoters, enhancers, eQTLs from major databases such as FANTOM5, ENCODE, Roadmap and GTEx to curate the disease SNPs in PheWAS Catalog and GWAS Catalog. We found that the disease-associated loci in PheWAS Catalog were significantly enriched with functional SNPs. Based on these functional annotations, we constructed a comprehensive gene regulatory network using TF – Promoter/Enhancer – Target Gene (TF-PE-TG) interactions. Then, we investigated the trait-SNP associations in PheWAS Catalog at the tissue-specific regulatory circuit level. Our results indicated that using functional annotations could significantly improve the power of detecting novel associations in PheWAS Catalog. We found a number of novel associations in PheWAS Catalog that showed strong functional evidence even though they only had moderate significance in the original study. Our work enhanced the understanding of the associations in PheWAS Catalog in terms of their mechanisms on affecting multiple diseases and traits.

Rare copy number variants in over 100,000 subjects reveal novel disease and genomics element associations. *Y.R. Li[1,2,3], J.T. Glessner[1,4,5], B.P. Coe[6], J. Li[1], X. Chang[1], C. Kao[1], A. Cederquist[1], C. Kim[1], M. Khan[1], F. Mentch[1], M. Garris[1], D. Abrams[1], F.G. Otieno[1], P.A. Sleiman[1,2,7], E.E. Eichler[8], H. Hakonarson[1,2,7].* 1) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Department of Pediatrics, University of Pennsylvania Perelman School of Medicine, Philadelphia, PA, 19104, USA; 3) Medical Scientist Training Program, University of Pennsylvania Perelman School of Medicine, Philadelphia, PA, 19104, USA; 4) Psychiatric and Neurodevelopmental Genetics Unit, Molecular Neurogenetics Unit, Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA 02114, USA; 5) Department of Neurology, Massachusetts General Hospital and Harvard Medical School, Boston, MA 02114, USA; 6) Department of Genome Sciences, University of Washington School of Medicine, Seattle, Washington, 98195, USA; 7) Division of Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA, 19104, USA; 8) Department of Genome Sciences, University of Washington School of Medicine, Seattle, Washington; Howard Hughes Medical Institute, University of Washington School of Medicine, Seattle, Washington, 98195, USA.

   Copy number variations (CNVs) have a significant impact on the diversity of the human genome and loci bearing CNVs are known to affect gene function and are associated with common and rare human diseases. We report the 'CNV landscape' across the genome of 100,028 unrelated individuals of European ancestry, based on genome-wide SNP and CGH arrays. We observed over 1.7×10^6 CNVs, averaging a 650kb CNV burden/individual and mapping to 11,314 deletion, 5,625 duplication, and 2,746 homozygous-deletion (hd) CNV Regions (CNVRs). Most CNVRs are rare (freq<0.01) and recurrent (>98.5%), although 25% of hdCNVRs are private. Overall, 3.25% of identified CNVs are novel. Over 58% of CNVRs overlap at least one gene, and were enriched (P<1x10-4) for OMIM morbid genes (enrichment ratio 'ER'=2.94), GWAS loci (ER=1.52) and non-coding RNAs (ER=1.44). The CNVR-bearing loci were also strongly enriched (35.3%) for recombination hotspots (ER>10; P<1x10-4), underscoring a potential impact of natural selection in driving human genome diversity and CNV distribution. In contrast, rates of overlap with microsatellites and segmental duplications were the same as observed at random. The CNVRs identified associated with 4 major disease categories including autoimmune/ inflammatory (n=11,489), oncologic (n=9,105), congenital heart/metabolic (n=2,581), developmental delay (n= 29,085)/neurological (n=14,756) diseases. Of 131 significant disease-associated CNVRs (DA-CNVRs) identified, 18% overlap GWAS hits (ER=2.40 and 1.20, P<1x10-4); these include a novel deletion CNVRs associated with autoimmune disease mapping to chr7p15.3 (*ITGB8*), which encodes the cell surface glycoprotein beta-8 integrin ($P < 6.87 \times 10^{-19}$). Another deletion CNVR ($P < 6.53 \times 10^{-47}$) associated with neurological diseases maps to chr19p13.3 (*HCN2*), which encodes a hyperpolarization-activated, cyclic nucleotide-gated K+ channel expressed in the brain. Finally, we observed multiple DA-hdCNVRs, including an autoimmune disease-associated locus at chr2q34 interrupting the exonic region of *ERRB4*, a cell-surface receptor tyrosine kinase whose expression is attenuated in microglia of patients with relapsing-remitting MS. Our work encompassing the genome wide CNV landscape of >100K individuals underscore the value of large-scale, genome-wide CNV analysis and the need to consider variants common and rare CNVs as well as SNVs in understanding the genetic contribution to complex disease.

1637T

Integration of functional annotation with GWAS to build disease-specific pathogenic scores. *K. Burch[1], G. Kichaev[1], B. Pasaniuc[1,2,3].* 1) Bioinformatics IDP, University of California Los Angeles, Los Angeles, CA, USA; 2) Department of Pathology and Laboratory Medicine, David Geffen School of Medicine, University of California Los Angeles, Los Angeles, CA, USA; 3) Department of Human Genetics, David Geffen School of Medicine, University of California Los Angeles, Los Angeles, CA, USA.

Genome-wide association studies (GWAS) have provided invaluable insight into the genetic architecture of many complex traits, with recent works showing that functional elements of the genome are enriched with GWAS signals. The large compendium of functional annotations that describe regulatory features, conservation, and other sequence-based metrics can be used to construct integrative genetic models of disease architecture. CADD is one example of a variant scoring method that combines multiple, diverse annotations into a single score of deleteriousness (Kircher et al. 2014). However, current measures of functionality are calculated from information that is independent of GWAS data, and therefore cannot provide scores that are specific to a complex trait under investigation. Here, we describe a systematic, integrative analysis of 39 complex traits to produce disease-specific functionality scores. For each trait, we construct functional models by integrating GWAS summary data and functional annotations to deliver measures of pathogenicity readily interpreted as the prior probability that a SNP impacts the trait. We observe that pathogenicity indices correlate across related traits and find a number of regions in the genome that are enriched for pathogenic variants for many traits. We believe these scores will be useful for follow-up study design – particularly in the context of fine-mapping. We illustrate this by conducting integrative fine-mapping on over 2000 GWAS loci and observe that leveraging these disease-specific scores yields a marked reduction in the size of the 90% credible SNP set. Notably, we find hundreds of regions that have experimentally tractable credible set resolution of less than 10 SNPs that can serve as candidates for empirical validation in functional studies. In conclusion, we believe our atlas of disease-specific pathogenicity scores and fine-mapping credible SNPs will be a valuable resource for the genetics community.

1638F

Combination of promoter and coding region of *N-acetyltransferase 2* **(*NAT2*) have stronger effect in predicting anti-tuberculosis drug induced liver injury (DILI).** *R. Yuliwulandari[1,2], K. Prayuni[2], R.W. Susilowati[1], M. Muslikh[3].* 1) Faculty of Medicine, YARSI University, Indonesia, DKI Jakarta, Indonesia; 2) YARSI Research Institute, YARSI University, DKI Jakarta, Indonesia; 3) Faculty of Economic, YARSI University, DKI Jakarta, Indonesia.

Tuberculosis (TB), as one of global public health problems, needs to be treated and eradicated well. TB treatment needs a combination of several drugs, including isoniazid, and long term treatment, which can lead to severe side effect such as anti-tuberculosis drug induced-liver injury (AT-DILI). N-acetyltransferase 2 (NAT2) has been reported to have a role in isoniazid metabolism. NAT2 metabolic activity is classified into slow, intermediate and rapid acetylators. Our previous study reported that polymorphisms in the promoter of NAT2 may affect the NAT2 activity. Therefore, in the current study, we would like to examine the effect of the promoter polymorphisms in the susceptibility to develop AT-DILI, alone and in combination with the coding region haplotype. In total, 95 AT-DILI cases and 192 TB tolerant controls with Javanese, Sundanese and Betawi ethnics of Indonesia participated in this study. The DNA was extracted using Qiamp blood mini kit. The selected promoter SNPs was rs4646246 and was genotyped using Taqman assay (this SNP has been reported to affect NAT2 activity in the previous study). The result showed that rs4646246 has a significant association with AT-DILI (P=0,0001, odds ratio (OR)=2.27 (1.49-3.47)). As our previous study reported that among coding region haplotypes, only NAT2*6A showed significant association with AT-DILI (P=7.7 × 10[-4], OR=4.75 (1.8–12.55)), then we perform combined promoter and coding region haplotype analysis with focus on the combination between rs4646246 with NAT2*6A. We found that the combination of promoter and coding region of NAT2 showed stronger effect to the development of AT-DILI (P=0.0016, OR=5.02 (1.81-13.93)). This result is in accordance to the hypothesis in the previous reported study that there is an additional role of promoter of NAT2 in the prediction of AT-DILI. Therefore, we propose that screening of AT-DILI in TB patient before administering anti-tuberculosis drugs needs to be done, not only for the haplotype in the coding region, as commonly reported, but also include promoter region.

1639W

Prevalence of allelic heterogeneity in complex traits. *E. Eskin[1,4], F. Hormozdiari[1], A. Zhu[1], G. Kichaev[2], B. Pasaniuc[3,4], S. Shifman[5].* 1) Department of Computer Science, University of California, Los Angeles, California; 2) Bioinformatics IDP, University of California, Los Angeles; 3) Department of Pathology & Laboratory Medicine, University of California, Los Angeles; 4) Department of Human Genetics, University of California, Los Angeles, California; 5) Department of Genetics, The Life Sciences Institute, Edmond J. Safra Campus, The Hebrew University.

   Allelic heterogeneity (AH) is a phenomena where more than one variant in the same gene affects a phenotype. The Genotype-Tissue Expression project data provides an unprecedented opportunity to quantify the amount of allelic heterogeneity across tissues. The current approach for detecting the allelic heterogeneity is based on conditional analysis used in the context of fine-mapping. The conditional approach relies on an iterative selection of the most associated variants followed by re-computation of the statistical score for the remaining variants conditional on the already selected variants. The conditional process continues until statistical score for all the variants falls below a pre-defined significant threshold. As we show in our experiments, the conditional approach is sensitive to complex patterns of linkage disequilibrium and can often result in inaccurate predictions. In our work, we propose a novel probabilistic method to quantify allelic heterogeneity. Our method is an extension of our fine-mapping method, CAVIAR. The benefit for our method is that it provides a probability for different number of variants that affect the phenotype. Thus, we can assign probability to each gene which it harbors allelic heterogeneity and as a result we can have a confident level for our prediction of genes which harbors allelic heterogeneity. We assess the performance of our method using simulated and real datasets. Our simulation results show that our method has high confidence in detecting the allelic heterogeneity loci. In addition, we apply our method to GTEx datasets that consist of nine tissues, we observe multiple allelic heterogeneity loci in different tissues. We considered genes which are detected as allelic heterogeneity for both methods. We observe both tissue-specific and cross-tissue allelic heterogeneity. The software for our method is freely available for download at http://genetics.cs.ucla.edu/caviar/.

GWAS identifies two novel loci associated with daily consumption of spicy food in Chinese adults. *R.G. Walters[1], M.V. Holmes[1], W.X. Mei[1], Y. Guo[2], K. Lin[1], S. Rafiq[1], J. Lv[3], I.Y. Millwood[1], Z. Biang[2], L. Lee[2,3], Z. Chen[1] on behalf of the China Kadoorie Biobank Collaborative Group.* 1) Nuffield Department of Population Health, University of Oxford, Oxford, Oxon, United Kingdom; 2) Chinese Academy of Medical Sciences, Beijing, China; 3) School of Public Health, Peking University Health Science Center, Beijing, China.

   Background: A large cohort study in China recently showed that regular consumption of spicy food may have significant health benefits. However, the causal relevance of the observed associations is unclear. Capsaicin, the active component of chilli peppers, is responsible for a burning sensation following contact with mucous membranes. We hypothesised that genetic variation may affect sensing of or response to capsaicin (e.g. through changes in neural development or taste/olfactory receptor function/signalling), leading to a liking for or aversion to spicy foods. Such variation might enable the construction of a genetic score for use in Mendelian randomisation, to investigate whether spicy food consumption is causally protective against disease. **Methods:** The China Kadoorie Biobank is a prospective study of 512,000 adults recruited from 10 geographically diverse areas of China. At baseline, 30.1% of participants reported daily consumption of spicy food. We conducted genome-wide association analyses of the frequency of spicy food consumption, among 33,000 subjects genotyped using a custom Affymetrix Axiom® array. Additive per-allele effects were tested using linear regression against days-per-week of spicy food consumption, with sex and 10 principal components as covariates. To control for differences in local cuisine, the 10 regions were analysed separately and the results combined using fixed-effects meta-analysis with inverse-variance weighting. **Results**: Of the 517,443 autosomal markers passing quality control, two SNPs were close to genome-wide significance and reached array-wide significance ($P < 7 \times 10^{-8}$). One of these lies within the *PYGO1* gene, which has a potential role in the development of taste buds and papillae through its involvement in Wnt/β-catenin signalling. A further 18 independent SNPs were significant at a 5% false discovery rate. An unweighted gene score constructed from these 20 SNPs explained 0.4% of variance in the frequency of spicy food consumption (F-statistic=124). **Conclusions:** This first large GWAS of spicy food consumption has identified novel SNPs potentially impacting on food preference. Construction of a genetic score from these SNPs yields a strong instrument that will enable future Mendelian randomization analyses.

1641F

Functional properties of genomic region associated with multiple traits in genome-wide association studies. *Y.F. Wang, M. Guo, T.Y. Wang, Y. Zhang, J. Yang, Y.L. Lau, W. Yang.* Department of Paediatrics and Adolescent Medicine, LKS Faculty of Medicine, The University of Hong Kong, Pokfulam, Hong Kong.

More than 10,000 associations with over 600 human complex traits have been identified by genome-wide association studies (GWAS) in the past years. An interesting observation is that many genetic loci emerged as associated with multiple distinct traits. Although the pleiotropic phenomena have been examined on certain variants or genes, comprehensive characterization of these loci is still lacking. In this study, we collected a plethora of trait-associated variants from the National Human Genome Research Institute (NHGRI) Catalogue of Published Genome-wide Association Studies, and defined cross-phenotype (CP) loci as a region within which variants are associated with at least two phenotypes. We observed that nearly 25.36% of the GWAS loci are associated with multiple traits, accounting for 7.79% of human genome, suggesting a widespread existence of CP loci across the human genome. Besides, we showed that the functional markers such as DNase-I hypersensitive sites, transcription factor binding sites and histone modification regions are highly enriched in CP regions, much more so than single trait-associated loci or random genomic controls, suggesting that these loci may contain more functional elements and these elements may play a broader role in genetic regulation. Further study observed the variants within the CP loci are more likely to be eQTLs and are more likely to be located in early DNA replication regions, suggesting that distinct regulatory and functional elements may exist within these loci. Finally, through comparing the genetic overlapping between diseases, we have explored the shared and distinct mechanistic patterns and pathways among different diseases, which may have significant clinical implications and be informative on drug repositioning.

1642W

Identification of individuals by trait prediction from the genome. *C. Lippert[1], M.C. Maher[1], O. Arikan[1], E.Y. Kang[1], S. Lee[1], R. Sabatini[1], A. Harley[1], A. Bernal[1], P. Garst[1], V. Lavrenko[1], K. Yocum[1], T. Wong[1], S. Ramakrishnan[1], H. Tang[1], C. Xie[3], J. Piper[3], S. Brewerton[3], Y. Turpaz[2,3], A. Telenti[2], R.K. Roby[2,4], J.C. Venter[2,4], F.J. Och[1].* 1) Human Longevity, Inc., Mountain View, CA, USA; 2) Human Longevity, Inc., San Diego, CA, USA; 3) Human Longevity Singapore, Pte. Ltd., Singapore; 4) J. Craig Venter Institute, La Jolla, CA, USA.

Accurate prediction of human physical traits and demographic information from genomic data promises to revolutionize forensic genomics. To explore the capabilities of phenotype-based genomic identification, we applied whole-genome sequencing, detailed phenotyping, and statistical modeling to predict biometric traits in an ethnically diverse cohort of 1,061 participants. For a large fraction of traits, their complex genetic architecture limits predictive accuracy. However, we developed a novel framework to integrate these predictions for multiple phenotypes and re-identify a high percentage of held-out individuals in our cohort, as well as the first ten participants of the Personal Genome Project. We developed state-of-the-art predictive models for prediction of 3D facial structure and color, eye color, skin color, height, weight, BMI, age, and voice from genomic features. On this cohort, we achieved the following cross-validated fraction of variance in the trait explained by the predictive model (R^2): for face color R^2 of 0.74, for face depth R^2 of 0.30, for eye and skin color R^2 of 0.78-0.82 (for RGB), for age R^2 of 0.46, for height R^2 of 0.59 and weaker performance for the prediction of weight and BMI ($R^2=0.21$ and $R^2=0.12$, respectively). Next, we integrated each of the individual phenotypic prediction models to obtain a model for identification from genomic information. Given an individual's genomic sample, we sought to identify that individual out of a lineup of 10 individuals. We refer to this problem as *select at 10* (s_{10}). We found that for re-identification problem 3D face alone is highly informative, with a s_{10} value of 58%. We found that ethnicity was the second most informative feature, with a s_{10} performance of 50%. Voice had comparable performance to ethnicity, while age, height/weight/BMI, gender, and age all yielded s_{10} performance of around 20%. Finally, we integrated these variables to obtain s_{10} performance of 77%. The presented results have important implications for personal genomic privacy. We have shown that, by using our algorithms, it is possible to extract a genome from a database and identify the individual. If this is conducted for unethical purposes and for inappropriate uses, it compromises the identity of individuals who contributed their genomes. The scientific community is in need of dedicated programs to evaluate privacy in light of today's technological advances and ensure basic rights of all contributors.

1643T

Neurodevelopmental indications of increased vulnerability for executive dysfunction in boys with 47,XXY. *C. Samango-Sprouse[1,2], C. Keen[3], C. Cappello[3], T. Sadeghin[4], A. Gropman[5,6].* 1) Pediatrics, George Washington University, Washington, DC; 2) Molecular Genetics, Florida International University, Miami, FL; 3) The Focus Foundation, Davidsonville, MD; 4) Neurodevelopmental Diagnostic Center for Children, Crofton, MD; 5) Neurogenetics and Neurodevelopmental Pediatrics, Children's National Medical Center, Washington, DC; 6) Neurology, George Washington University, Washington, DC.

Introduction: Neuroimaging studies have found consistent neuroanatomical abnormalities in the frontal lobes of males with 47,XXY. Frontal lobes are critically pertinent to executive functions (EF), such as time management, planning, flexibility and rapidity of response. EF is an area of known dysfunction in 47,XXY, but neurodevelopmental indicators of vulnerability are less understood. Statement of Purpose: A small prospective pilot study was conducted to begin to characterize an algorithm of risk factors associated with greater vulnerability to impaired EF in males with 47,XXY. Methods: 15 boys with 47,XXY were referred for neurodevelopmental evaluations (median age=144mo.). Performances from the Comprehensive Trail Making Test (CTMT), visuomotor planning (VP) and motor planning (MP) of the Amsterdam Neuropsychological Tasks (ANT), Motor Coordination (MC) of the Beery-Buktenica Test of Visual Motor Integration, Fine Motor Control (FM) of the Bruininks-Oseretsky Test of Motor Proficiency, and Processing Speed Index (PSI) of the Weschler Scales of Intelligence for Children were evaluated to investigate EF and selected areas of neurodevelopment within EF. Results: 11 of the 15 47,XXY boys had composite scores less than 42 on the CTMT, indicating 73.3% of the study group had below average, mildly impaired, or severely impaired performance. Of these 11 boys, the majority also had performance below two standard deviations (SD) of average in FM (72.7%), MC (54.5%) and MP (63.9%). 45.5% were two SD below average in PSI and VM. Discussion: Our results suggest that impaired EF in 47,XXY may be highly associated with FM, MC and MP, but that no single assessment is able to diagnose executive dysfunction by itself. These results further suggest that comprehensive assessment is necessary to determine both capabilities and deficits in EF in boys with 47,XXY. These results further enhance our understanding of the most vulnerable children with 47,XXY.

LD-dependent architecture of human complex traits reveals action of negative selection. *S. Gazal[1], H.K. Finucane[1,2], P.R. Loh[1], P.F. Palamara[1], X. Liu[1], A. Schoech[1], B. Bulik-Sullivan[3,4], A. Gusev[1], B. Neale[3,4], A.L. Price[1,5].* 1) Department of Epidemiology, Harvard T.H. Chan School of Public Health, Boston, Massachusetts, USA; 2) Department of Mathematics, Massachusetts Institute of Technology, Cambridge, Massachusetts, USA; 3) Analytic and Translational Genetics Unit, Massachusetts General Hospital and Harvard Medical School, Boston, Massachusetts, USA; 4) Stanley Center for Psychiatric Research, Broad Institute of MIT and Harvard, Cambridge, Massachusetts, USA; 5) Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, Massachusetts, USA.

Understanding the polygenic architecture of complex traits, and the underlying biological processes, is a fundamental goal of human genetics. Recent work has hinted at LD-dependent architectures for several complex traits, with larger per-SNP heritability for genetic variants with low levels of linkage disequilibrium (LD) to other variants after conditioning on minor allele frequency (MAF). However, this has not been formally assessed, quantified, or biologically interpreted. We quantified the relationship between MAF-stratified LD percentile (level of LD; LLD) and per-SNP heritability by analyzing GWAS summary statistics from 22 human complex traits (average N = 62,341). To enable this analysis, we extended stratified LD score regression, a method for partitioning heritability across discrete annotation categories, to continuous-valued annotations. We determined that SNPs with low LLD have significantly larger per-SNP heritability ($P = 4.15 \times 10^{-31}$). Roughly half of the LLD signal can be explained by functional annotations that are negatively correlated with LLD, such as DHS, histone marks and enhancers. By investigating a broad set of LD-related annotations, including allele age as predicted by the ARGweaver method, we determined that the remaining LLD signal is largely driven by MAF-stratified allele age ($P = 5.65 \times 10^{-56}$), with the youngest 20% of common SNPs explaining 3.8x more heritability than the oldest 20%. This is even larger than MAF-dependent effects, in which the 20% of common SNPs with largest MAF explain 1.9x more heritability than the 20% with smallest MAF. In a joint analysis, we also inferred significant effects for other annotations related to negative selection, including recombination rate, McVicker B statistic, and nucleotide diversity. In particular, we inferred a smaller causal effect size variance for SNPs in high recombination rate regions, opposite to the direction of the LLD effect but consistent with the Hill-Robertson effect. We used forward simulations to confirm that all of these findings are consistent with the action of negative selection on deleterious variants that affect complex traits. Finally, we analyzed 11 phenotypes from the UK Biobank (N = 124,388) to replicate our results ($P = 1.80 \times 10^{-54}$ and $P = 2.40 \times 10^{-77}$ for LLD and allele age, respectively). Our empirical findings complement efforts to learn about negative selection by analyzing much smaller rare variant data sets.

1645W

Shared genetic basis of complex and rare disease. *M. Kumar[1], V. Arboleda[2], N. Mancuso[2], B. Pasaniuc[1,2].* 1) Human Genetics, David Geffen School of Medicine, University of California Los Angeles, Los Angeles, California, USA; 2) Department of Pathology and Laboratory Medicine, David Geffen School of Medicine, University of California Los Angeles, Los Angeles, California, USA.

The biological mechanisms underlying complex genetic disease and monogenic Mendelian disease are typically considered to be distinct. This mindset is reflected in the statistical approaches used to link single nucleotide polymorphisms (SNPs) with the disease of interest. Traditionally, SNPs associated with complex disease are found by genome-wide association studies (GWAS), while genetic variants causing Mendelian diseases have been identified through linkage analysis and, more recently, exome sequencing. In this work, we investigate the shared genetic basis of traits that show both complex and Mendelian presentations (e.g., height). We used publically-available GWAS summary statistics from more than 30 complex traits to identify risk genes for complex traits. We quantified the overlap of this gene set with trait-matched Mendelian disease genes from the Online Mendelian Inheritance in Man (OMIM) catalogue. For example, in the case of height, we constructed a complex-trait gene list based on distance to GWAS risk variant and quantified the degree of overlap with OMIM genes showing height-specific pathogenicity (e.g., undergrowth, short stature, small for gestational age, dwarf, tall stature, failure to thrive, hemihypertrophy). We find a significant overlap between these gene sets consistent with shared genetic basis between complex and Mendelian forms of disease. Furthermore, we expanded this approach to an array of 30 complex traits and matched Mendelian disorders and find a consistent and significant overlap across all studied traits. Overall, our results support a shared genetic basis of complex and Mendelian traits and provide insight into genetic mechanisms of complex traits. These results can be leveraged to prioritize candidate genes surrounding significant GWAS SNPs and identify modifiers of rare disease phenotypes in both large-scale association studies and clinical exome sequencing.

1646T

Targeted pharmacogenetic sequencing among 9,000 eMERGE participants with linked electronic health records. *A. Gordon[1], D.R. Crosslin[2], P. Devi[2], A.A. Burt[1], B. Almoguera[3], B.L. Cobb[4], M. de Andrade[5], J.C. Denny[6], H. Hakonarson[7], J.B. Harley[8], M.G. Hayes[9], K.M. Kaufman[4], E.B. Larson[10], N.D. Leslie[8], B. Namjou-Khales[4], C.A. Prows[8], L.J. Rasmussen-Torvik[13], M.D. Ritchie[11], D.M Roden[6], S.L. Van Driest[6], W.Q. Wei[6], Q.S. Wells[6], K. Zhang[12], G.P. Jarvik[1], The electronic Medical Records and Genomics (eMERGE) Network.* 1) Department of Medicine, Division of Medical Genetics, University of Washington, Seattle, WA; 2) Department of Biomedical Informatics and Medical Education, University of Washington, Seattle, WA; 3) The Children's Hospital of Philadelphia, Philadelphia, PA; 4) Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 5) Biomedical Statistics and Informatics, Mayo Clinic and College of Medicine, Rochester, MN; 6) Department of Medicine, Vanderbilt University, Nashville, TN; 7) Center for Applied Genomics, The Children's Hospital of Philadelphia, PA; 8) Department of Pediatrics, Cincinnati Children's Hospital, University of Cincinnati, Cincinnati, OH; 9) Division of Endocrinology, Metabolism, and Molecular Medicine, Department of Medicine, Northwestern University Feinberg School of Medicine, Chicago, IL; 10) Group Health Research Institute, Seattle, WA; 11) Biomedical and Translational Informatics, Geisinger Health System, Danville, PA; 12) Biomedical Informatics, Vanderbilt University, Nashville, TN; 13) Department of Preventive Medicine, Northwestern University, Feinberg School of Medicine, Chicago, IL.

As genome and exome sequencing becomes routine in clinical care, pharmacogenetic results are often cited as a motivation for implementing these tests. To this end, the Clinical Pharmacogenetics Implementation Consortium (CPIC) offers guidelines, denoted in 'star allele' terms, describing the evidence for specific gene-drug pairs. Although large sequencing efforts such as the NIH's Precision Medicine Initiative (PMI) will uncover many novel, deleterious variants, the phenotypic effects of these variants in combination with known alleles are unclear. To explore the extent and phenotypic effects of such variation, the Electronic Medical Records and Genomics Network (eMERGE) has deployed PGRNseq, a next-generation sequencing panel targeting 82 pharmacogenes, among 9000 diverse patients across 9 different sites. As of writing we have completed preliminary analysis of the first 5000 samples. As these data revealed that >95% of patients carried at least one variant designated as actionable by CPIC (Level A), analysis of the full dataset will yield accurate allele frequencies for alleles of known effect among individuals of diverse ancestry; as these frequencies are key components of pharmacogenetic interpretation algorithms, their accuracy in specific populations is critical. In addition to common alleles, we found at least one rare, predicted deleterious variant (CADD > 20) in 78 of 82 targeted genes, suggesting that the full dataset will even further expand this pool. To explore how these rare variants affect alleles of known function, we will use the phasing algorithm BEAGLE to construct individual diplotypes from 12 well-characterized genes for which CPIC guidelines exist. By assigning these haplotypes star allele names using commercially employed tag SNPs, we will identify individuals who carry a novel deleterious variant in combination with a level A allele for further analysis. As a strength of the eMERGE network is the linked electronic health record data linked to each participant, we will explore potential clinical consequences of these novel variants using approaches such as ICD code-based Phenome-Wide Association and expert chart review. The data presented here to quantify and evaluate individuals carrying rare variation with common CPIC alleles is an important model for massive clinical studies like PMI, which will deploy clinical decision support for pharmacogenetic results that is unlikely to provide accurate interpretations for these individuals.

1647F

Establishment of a pharmacogenomics testing platform using next-generation sequencing (NGS). *Y.S. Liu[1], Y.H. Lin[1], L.J. Shen[2,3], P.L Chen[1,4].* 1) Graduate Institute of Medical Genomics and Proteomics, National Taiwan University, Taipei, Taiwan; 2) Graduate Institute of Clinical Pharmacy/School of Pharmacy, College of Medicine, National Taiwan University, Taipei, Taiwan; 3) Department of Pharmacy, National Taiwan University Hospital, Taipei, Taiwan; 4) Department of Medical Genetics, National Taiwan University Hospital, Taipei, Taiwan.

Medical drugs show different efficacy and/or adverse drug reactions (ADRs) on patients. This is mostly due to the variations of DNA sequence. Pharmacogenomics is the study and applications about how genetic variations in individuals influence the drug response, which is composed of both pharmacokinetics and pharmacodynamics. Pharmacogenomics plays an important role in optimal drug choice and drug dosing. There are numerous genes involved in pharmacogenomics, which imposes a big challenge because of the complexity and high cost using conventional techniques like Sanger sequencing. In the present study, we set up a genetic testing platform through capture-based target enrichment followed by next-generation sequencing (NGS). Our panel covered approximately 100 major pharmacogenomics genes, including pharmacokinetics genes (for example, ADME genes regarding to absorption, distribution, metabolism and excretion) and pharmacodynamics genes, such as *ABCB1, CFTR, CYPs, DRYP, EGFR, HLAs, KRAS, NAT2, RYR1, TPMT, UGT1A1* and *VKORC1*. A great proportion of our genes overlapped with those listed on FDA labeled biomarkers and Pharmacogenomics Knowledgebase (PharmGKB). We applied this panel to 24 individuals, including 6 controls with whole genome sequencing data for technical validation and 18 individuals with ADR, trying to find specific ADR gene biomarkers. We inferred that dose-dependent adverse drug effects might have higher correlation with pharmacokinetics genes. Also, we analyzed Taiwan Biobank data to find out the reference allele frequencies in our population. We used various NGS software packages, including BWA, SAMtools, Picard, GATK, Variant Tools, ANNOVAR, IGV, etc. In conclusion, the NGS-based pharmacogenomics panel could be beneficial for precision medicine in clinical applications and academic research.

Clinical significance of genetic variation among genes involved in drug response: Pharmacogenomic interpretation in the ClinVar database. *S.A. Scott[1], G.C. Bell[2], J.S. Berg[3], U. Broeckel[4], K.E. Caudle[5], C.E. Haidar[5], E.M. Ramos[6], M.V. Relling[5], E.A. Rivera-Munoz[3], M. Whirl-Carrillo[7], K. Wiley[6], M.S. Williams[8], T.E. Klein[7], H.L. McLeod[9].* 1) Department of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY 10029; 2) Mission Health, Fullerton Genetics Center, Asheville, NC 28803; 3) Department of Genetics, The University of North Carolina at Chapel Hill, Chapel Hill, NC 27599; 4) Department of Medicine, Medical College of Wisconsin, Milwaukee, WI 53226; 5) Department of Pharmaceutical Sciences, St. Jude Children's Research Hospital, Memphis, TN 38105; 6) Division of Genomic Medicine, National Human Genome Research Institute, NIH, Rockville, MD 20892; 7) Department of Genetics, Stanford University School of Medicine, Stanford, CA 94305; 8) Genomic Medicine Institute, Geisinger Health System, Danville, PA 17822; 9) DeBartolo Family Personalized Medicine Institute, Moffitt Cancer Center, Tampa, FL 33612.

The ClinVar database archives reports of genomic variants and phenotypes submitted by clinical laboratories, researchers, clinicians, expert panels, practice guidelines, and other organizations. This repository enables more accurate and consistent variant interpretation among submitters, in part by providing detailed annotation and transparent supporting evidence for each catalogued variant. The clinical significance of variants implicated in Mendelian phenotypes in ClinVar is appropriately based on the standard terminology recommended by the American College of Medical Genetics and Genomics (ACMG); however, these widely used five categories do not effectively translate to genetic variants implicated in drug response phenotypes. To facilitate the evaluation of clinical significance for pharmacogenomic variants, the Pharmacogenomics Working Group of the Clinical Genome Resource (ClinGen), in collaboration with ClinVar, has proposed three categories of standard terminology to be used when evaluating genetic variation among genes involved in drug response – clinically actionable, clinically informative, and variants of uncertain clinical significance. Like the ACMG terminology for Mendelian variants, these terms are defined by levels of evidence supporting the association between a pharmacogenomic variant and a drug response phenotype. Variants previously curated by the Pharmacogenomics Knowledge Base (PharmGKB) are directly amenable to clinical significance translation as 'actionable', 'informative', and 'uncertain clinical significance' are defined as PharmGKB Level 1, 2 and 3/4 variants, respectively. Notably, interrogation of the star (*) alleles and/or known variants of seven genes (*CYP2C9*, *CYP2C19*, *CYP3A5*, *DPYD*, *HLA-B*, *SLCO1B1*, and *TPMT*) with Clinical Pharmacogenetics Implementation Consortium (CPIC) practice guidelines identified 49 actionable, 59 informative, and 107 variants of uncertain clinical significance. Presentation of pharmacogenomic variants in ClinVar will also be accompanied by allele function terms (when known) as recently defined by the CPIC Term Standardization Project. In addition to classifying known pharmacogenomic variants, utilization of these clinical significance terms in ClinVar will allow for more consistent pharmacogenomic variant interpretation by clinical laboratories and could facilitate more rapid agreement on the clinical significance of rare or novel pharmacogenomic variants as they are identified by ClinVar submitters.

The Million Veteran Program: A mega-biobank for precision medicine. *S. Muralidhar, MVP Executive Committee and Operations Teams.* Res & Development (10P9B), Dept Veterans Affairs, Washington, DC.

The Million Veteran Program (MVP), sponsored by the Department of Veterans Affairs, is partnering with Veterans to establish one of the world's largest databases of genomic, clinical, lifestyle and military exposure information. Leveraging VA's rich electronic health record (EHR), the ultimate goal of MVP is to create a comprehensive database for genomic discoveries that will lay the foundation for precision medicine for Veterans, and the population at large. In addition, and under the President's Precision Medicine Initiative, MVP is collaborating with the Department of Defense and expanding enrollment to active duty service members. Launched in 2011, consented participants: a) provide a blood sample for future, to-be-defined research; b) complete health and health-related questionnaires; c) provide access to their electronic health records; and d) agree to be contacted in the future. Recruitment is largely through mail invitations and publicity within 50+ VA medical centers; a web-enrollment portal is under development. Blood samples are processed at the MVP central biorepository promptly after receipt, and DNA is sent out to contracted vendors for characterization on a customized Affymetrix Axiom Array "MVP chip." Remaining DNA, buffy coat, and plasma are stored for future use. Quality control of genomic data is performed centrally by a core team. Self-reported data from questionnaires and EHR data are curated by phenomic teams; selected core variables are curated for general applications, and disease-specific variables are curated initially on a project-by-project basis. All data are stored in a central, secure data repository, and approved researchers access the data and conduct their analysis within a secure computing environment. Results of research analyses and the associated metadata, are retained and repurposed for future research. With the goal of enrolling one million participants, MVP has enrolled over 483,000 Veterans as of early June 2016. Over 400,000 samples have been genotyped, and quality control on the first 200,000 genotypes completed. Subsets of samples have been characterized by whole-exome or whole-genome sequencing. Curation of clinical data for core variables, such as demographic factors and laboratory values, has also been completed. Eight scientific projects utilizing MVP data are currently underway. An overview will be presented of the MVP infrastructure, data access policy, scientific projects, and lessons learned.

1650F

A software platform facilitating community analyses of genetic datasets for complex disease. *B. Alexander, M. Duby, M. Sanders, K. Yuksel, M. von Grotthuss, R. Koesterer, O. Ruebenacker, C. Gilbert, T. Green, J. Flannick, Accelerating Medicines Partnership for Type 2 Diabetes Knowledge Portal (AMP T2DKP). Medical Population Genetics, Broad Institute of Harvard and MIT, Cambridge, MA.*

   While genome wide association studies (GWAS) have identified numerous variants of modest effect on complex disease risk, converting these findings into biological insights has proved challenging. The large quantities of data produced by different GWAS and sequencing studies too often remain disparate, and are inaccessible to the broader biomedical community.   Here we present a new platform to facilitate analyses of genetic data for complex disease. Our platform, which powers the Type 2 Diabetes Knowledge Portal (T2DKP), includes software for aggregating and harmonizing genetic association study results, along with highly customizable genotype-phenotype association analyses across data sets, all while protecting sensitive patient data. The platform allows users to perform: 1) *Forward genetic analyses:* visualize the top association statistics from any collection of GWAS or sequencing studies in either tabular or graphical form, and customize searches across datasets based on arbitrary association criteria. As an example, we demonstrate the identification of candidate association signals proposed to affect T2D through effects on cholesterol efflux from the liver based on searches across glycemic and lipid datasets. 2) *Reverse genetic analyses:* return a list of association statistics for any variant, gene, or region across all datasets, with harmonized directions of effect, optionally drilling down to explore ethnic- or cohort-specific effects. As an example, we demonstrate the identification of secondary protective effects on T2D for a variant implicated in coronary artery disease (CAD) risk based on a simple search for the variant. 3) *Custom association analysis:* specify a phenotype, and optionally a property for stratifying samples, along with sample filters, and phenotype or property covariates, then dynamically perform association tests on one or more variants. As an example, we demonstrate the prediction of a potential method of action for a T2D association based on interactive analysis of patients with a specific disease subtype. The T2DKP is built upon this platform, and is freely and publicly available at www.type2diabetesgenetics.org. The T2DKP draws over 100 users a day, each of whom interacts with the portal for over six minutes on average. Portals for other complex genetic diseases, such as stroke and heart attack, have been demonstrated using the platform. This open source framework may be useful to the larger community. .

1651W

Association rule learning on electronic health records to identify groups of frequently co-occurring diseases among Geisinger Health System patients. *H.L. Kirchner[1], M. Byrska-Bishop[1], J.B. Leader[1], A. Verma[1], M.D. Ritchie[1,2]. 1) Biomedical and Translational Informatics, Geisinger Health System, Danville, PA; 2) Department of Biochemistry and Molecular Biology, The Pennsylvania State University, University Park, PA.*

   Diseases that a given person develops throughout his/her lifetime may be independent from one another or may be linked by shared genetic or environmental background. We used longitudinal Electronic Health Record (EHR) data spanning nearly 20 years from Geisinger Health System (GHS) to identify clusters of diseases and conditions that co-occur in individuals throughout their lifetime more often than expected by random chance. Specifically, we performed association rule learning using the Apriori algorithm on ICD-9 diagnosis codes from nearly 100,000 Geisinger primary care patients, who participate in the MyCode® Community Health Initiative project, as input. The Apriori algorithm outputs association rules, which provide information about relationships between items (in this case, ICD-9 codes) in large databases. Using this approach, we identified hundreds of co-morbid disease groups, many of them representing known associations, such as an association between type II diabetes mellitus, hyperlipidemia, and hypertension, or an association between hypothyroidism and hypertension, suggesting that association rule learning can be used successfully to identify disease relationships and patterns in EHR data. In the future, we plan to expand this analysis to all 1.5 million GHS patients to get a more comprehensive overview of disease co-occurrence during our patients' lifetime. These relationships can then be used to predict disease likelihoods based solely on a medical history of a patient. The final goal of this analysis will be to identify potential common genetic associations of co-occurring diseases – a phenomenon often referred to as pleiotropy. To accomplish this, we plan to use genome-wide genotyping data, as well as whole exome sequencing data generated as part of the Geisinger-Regeneron DiscovEHR Collaboration. DiscovEHR currently contains genotype and exome sequencing data from more than 50,000 participants of MyCode, with a goal to reach 250,000. We hope that combining frequently occurring patterns within the EHR data with genetic information will facilitate building better predictive models for diseases and subsequently improve preventative care of our patients.

1652T

Training a type 2 diabetes specific functional sequence predictor. *K.M. Lorenz[1,2,3], B.F. Voight[1,2,3]*. 1) Department of Systems Pharmacology and Translational Therapeutics, Perelman School of Medicine at the University of Pennsylvania, Philadelphia PA; 2) Department of Genetics, Perelman School of Medicine at the University of Pennsylvania, Philadelphia PA; 3) Institute for Translational Medicine and Therapeutics, Perelman School of Medicine at the University of Pennsylvania, Philadelphia PA.

Type 2 diabetes (T2D) is a complex polygenic disorder characterized by an inability to maintain glucose homeostasis. Genome wide association studies have identified >100 independent loci contributing to the disease, with evidence for hundreds more. However, much of this variation lies in noncoding regions of the genome, making causal variants and sequences difficult to identify and study. We hypothesize that the regulatory features underlying causal variants are disease specific and identifiable from data—the regulatory architecture that influences T2D susceptibility is distinct compared to other diseases. However, models that underlie contemporary functional variant predictors, such as CADD, GWAVA, and FATHMM-MKL, are disease-agnostic to maintain generalizability. To better characterize and identify T2D variants, we have trained a disease specific functional variant predictor using known disease loci and publicly available genomic and epigenomic annotations from the ENCODE and Epigenome Roadmap consortia. Our current model uses a binomial based penalized logistic regression (elastic net) for feature selection. We are better able to classify T2D loci compared to current predictors, with an area under the curve (AUC) of 0.84 compared to their AUCs of 0.76-0.79. Our model retains biologic intuition, as we observe that selected features skew towards T2D-relevant tissues. When we include additional features from T2D-specific tissue types outside of ENCODE or Roadmap, our AUC increases to 0.87. We intend to improve upon this foundation by identifying and including further T2D specific annotations, and will test additional methods of feature selection.

1653F

Multidimensional *in-silico* **analyses to elucidate structure-function relationship of** *SMPD1* **variants causal to Niemann–Pick disease.** *H. El Sokkary[1,2], H. Al-Zahrani[1,2], S. Al-Allasi[2], J. Al-Aama[1,2], R. Elango[1,2], N. Shaik[1,2], B. Banaganapalli[1,2]*. 1) Princess Al-Jawhara Al-Brahim Center of Excellence in Research of Hereditary Disorders, King Abdullaziz University, Jeddah, Saudi Arabia; 2) Department of Genetic Medicine, Faculty of Medicine, King Abdulaziz University, Jeddah, Saudi Arabia.

Niemann-Pick disease (NPD) is an autosomal recessive neurovisceral lipid storage disease caused due to SMPD1 gene mutations. The excessive lipids accumulation in multiple organs in NPD leads to the onset of spectrum of diseases ranging from a neonatal fatal disorder to an adult-onset chronic neurodegeneration. On the basis of signs and symptoms, NPD is divided into A, B, C1 and C2 types. Both type A and B NPD are known to be caused by mutations in SMPD1 gene, which encodes for a lysosomal enzyme called acid sphingomyelinase. The SMPD1 shows a broad mutational range, with the majority being missense mutations. But, the specific relationship between SMPD1 genotype-protein phenotype-clinical phenotype still remains unclear. In this context, we showed the efficacy of multidimensional computational investigations in exploring and developing a better understanding of the structural and functional impacts of SMPD1 mutations on Niemann-Pick disease. Firstly, we discovered 14 (12.61%; against total 111) most deleterious NPD causal mutations of SMPD1 gene by integrating the prediction outcomes of 9 different computational algorithms. In second stage, through 3 dimensional structures analysis we identified that amino acid substitutions induces biochemically severe changes in SMPD1 structure and functions. In the final stage, through molecular drug docking analysis, we recognized that mutant SMPD1 shows high affinity against DESPIPRAMINE drug. Our findings are expected to assist in selecting best mutations for molecular diagnosis out of a crowd of neutral ones and also to design a better competitive inhibitors against SMPD1 mutations. .

1654W

Comparison of HLA allelic imputation programs. *L. Bastarache[1], J.H. Karnes[2,3], C.M. Shaffer[3], S. Gaudieri[4,5], A.M. Glazer[3], H. Steiner[2], J.D. Mosley[3], S. Mallal[5], J.C. Denny[1], E.J. Phillips[3,5], D.M. Roden[1,3,6].* 1) Biomedical Informatics, Vanderbilt University, Nashville, TN; 2) Department of Pharmacy Practice and Science, University of Arizona College of Pharmacy, Tucson, AZ; 3) Department of Medicine, Vanderbilt University School of Medicine, Nashville, TN; 4) School of Anatomy, Physiology and Human Biology, University of Western Australia, Nedlands, Western Australia, Australia; 5) Department of Pathology, Microbiology and Immunology, Vanderbilt University School of Medicine, Nashville, TN; 6) Department of Pharmacology, Vanderbilt University School of Medicine, Nashville, TN.

   Multiple programs are now available to impute human leukocyte antigen (HLA) alleles from SNP-level data. Such imputation programs are attractive due to the importance of HLA alleles in human disease and pharmacogenomics, the widespread availability of genome-wide association study (GWAS) data, and the expertise required for HLA allele sequencing. However, a comprehensive comparison and evaluation of these programs is not available. We compared HLA imputation results of HIBAG, SNP2HLA, and HLA*IMP:02 to sequenced HLA alleles in 3,265 samples from BioVU, a de-identified electronic health record database coupled to a DNA biorepository. We performed four-digit HLA sequencing for *HLA-A, -B, -C, -DRB1, -DPB1,* and *-DQB1* using long-read 454 FLX sequencing. All samples were genotyped using the Illumina HumanExome BeadChip platform and a GWAS platform (either Illumina HumanOmni1-QUAD or HumanOmni5-QUAD). For each program and locus, we calculated number of imputed alleles, concordance with sequencing results, and call rate. Call rates and concordance rates were compared by platform, frequency of allele, and race/ethnicity. Overall concordance rates were similar between programs in European Americans (EA) with SNP2HLA being the highest (0.975 [SNP2HLA]; 0.939 [HLA*IMP:02]; 0.976 [HIBAG]). SNP2HLA also predicted the largest number of alleles overall (n=210) with the highest call rate (1.00). Concordance rates were lower overall for African Americans (AAs) (0.919 [SNP2HLA]; 0.619 [HLA*IMP:02]; 0.929 [HIBAG]). These observations were consistent when accuracy was compared across HLA loci, with the highest concordance being 0.988 for SNP2HLA and HIBAG in *HLA-DQB1* in EAs and the lowest concordance being 0.414 for HLA*IMP:02 in *HLA-DRB1* in AAs. All imputation programs performed similarly for low frequency HLA alleles. Higher concordance rates were observed when HLA alleles were imputed from GWAS platforms versus the Exome Chip. Although concordance was similar for all imputation platforms, SNP2HLA had the highest overall concordance and call rates and provided a significant advantage in the number of alleles imputed. All programs demonstrated better concordance in EAs versus AAs and performed well for low frequency alleles. Our results suggest that high genomic coverage is preferred as input for HLA allelic imputation. These findings provide guidance on the best use of HLA imputation methods and elucidate their limitations.

1655T

PyDAIR: A tool for precise determination of the diversity of immunoglobulin sequences. *X. Fu[1], J.Q Sun[2], J. Geng[1], S. Asakawa[3].* 1) State Key Laboratory of Biotherapy, Sichuan University, Chengdu, Sichuan, China; 2) Department of Biotechnology, Graduate School of Agricultural and Life Sciences, The University of Tokyo; 3) Department of Aquatic Bioscience, Graduate School of Agricultural and Life Sciences, The University of Tokyo.

   The immune system's antibody repertoire is highly plastic and can be directed to create antibodies with broad diversity and high selectivity. Large-scale repertoire analysis of antibody can provide powerful results including insight into a better understanding or a snapshot of the adaptive immune repertoire, and an improved understanding of the way by which the immune system eliminates unwanted infections. The enormous antibody diversity is generated by somatic recombination of a large number of immunoglobulin (Ig) gene segments, which involves a random recombination of tandemly arranged variable (V), diversity (D) (only in Ig heavy (H) chain) and joining (J) germline gene segments. The vast majority of the diversity in the naïve antibody repertoire is within the H chain complementarity-determining region 3 (CDR-H3), which encompasses the VDJ recombination junctions. Advances in sequencing technologies (e.g., next-generation sequencing (NGS)) enable the current data sets of the immunological repertoire. Information gained from NGS of Ig genes (Ig-seq) thus requires efficient informatics analysis tools to assist in categorizing and transforming these data into valuable biological insight. To this end, we develop a Python package, named PyDAIR (Python library for Diversity Analysis of Immune Repertoire), to study the antibody diversity based on NGS data. In detail, this package contains three main steps: (i) Ig sequences are aligned to all V and all J segments (species-specific) to determine the optimal alignment of V and J using BLAST; (ii) The CDR-H3 region is determined based on the two conserved motifs in V and J genes; (iii) Strategies used to define the un-aligned region for full D segment determination. We then apply PyDAIR to characterize the antibody repertoire of torafugu (*Takifugu rubripes*), species that possess an recognizable adaptive immune system and one of the smallest genomes (~400 Mb) among vertebrates, makes it an ideal model system for comparative adaptive immune system studies. As a result, PyDAIR efficiently defined torafugu-specific V, D, J, and CDR-H3 sequences. The analysis also highlighted the strong VDJ usage bias as well as the diverse size of the available CDR-H3 repertoire. Analysis of the published sequences data set of human is underway. The PyDAIR package will be a valuable tool for further in depth analysis of the antibody repertoire.

HLAminer: Prediction of HLA types from NGS data. *R.L. Warren, S. Yeo, J. Chu, R. Holt, I. Birol.* BC Cancer Agency, Genome Sciences Centre, Vancouver, BC, Canada.

The Human Leukocyte Antigen (HLA) is a gene locus that encodes cell-surface receptors that present epitopes to T cells, and is the foundation of immune system regulation in humans. The HLA complex enables the immune system to distinguish between a person's normal healthy cells, and cells that are infected, mutated or are derived from some other individual. Due to the necessity of recognizing diverse molecular signatures, there is extreme diversity in the genes that encode HLA proteins, and determining the specific gene variants of an individual is of considerable importance in clinical medicine and in research. For instance, knowing HLA genes and matching donor and recipients with the same HLA is key to successful organ grafts. Traditionally, HLA typing was done by PCR amplification, but often offers low allele-level resolution. The drastic decrease in sequencing costs we witnessed over the past decade is facilitating the uptake of DNA sequencing technologies in the clinic, but the bioinformatics analysis of whole genome and transcriptome shotgun data still represents a significant barrier to entry and is out of reach to many researchers and clinicians. As more shotgun datasets become available, targeted interrogation of HLA is value-added since those datasets can be mined retrospectively to predict types. We present HLAminer, the first reported and highly cited HLA prediction software for next-generation sequence data. The flexible pipeline enables HLA predictions from direct read alignments to a set of known, references and, for best results, uses targeted de novo assembly of sequence reads. The software was used to robustly predict the HLA genes of the colorectal cancer patient cohort and in over 7,000 TCGA RNA-seq samples (of which 515 from six tumor sites were published) [1-3]. We present changes to the code since publication, including the utilization of BioBloom Tools [4], an efficient sequence read partitioning software. Since January 2016, the HLAminer software had over 1,500 downloads world-wide. 1. Warren RL, et al. 2012. Derivation of HLA types from shotgun sequence datasets. Rare hematopoietic clone detection using error-corrected sequencing. *A.L. Young[1,2], G.A. Challen[3], B.M. Birmann[4], T.E. Druley[1,2].* 1) Department of Pediatrics, Washington University School of Medicine, Saint Louis, MO; 2) Center for Genome Sciences and Systems Biology, Washington University School of Medicine, Saint Louis, MO; 3) Department of Internal Medicine, Division of Oncology, Washington University School of Medicine, Saint Louis, MO; 4) Channing Division of Network Medicine, Department of Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, MA.

Acute myeloid leukemia (AML) is the most common hematopoietic malignancy, diagnosed in approximately 20,000 individuals each year in the United States. While the goal of treatment is to induce a stable and durable remission, the five year survival rate is only 25%. Accurately assessing response to treatment is essential for therapeutic selection and long term survival. Currently, the gold standard for assessing remission status is multiparameter flow cytometry (MPFC) targeting leukemia-specific cell surface markers, which is prognostic to the detection limit of 1:10,000 cells. However, only half of AML cases have a suitable immunophenotype for MPFC. Conversely, virtually every AML is marked by leukemia-specific somatic mutations, presenting an opportunity for the sequencing-based detection of persistent leukemia cells following treatment. However, previous approaches have been limited by the error rate of the sequencing technology (approximately 1%) and only interrogated specific exons of recurrently mutated genes. To circumvent these limitations, we combined targeted capture of AML-associated genes with error-corrected sequencing to create a broad platform for residual disease quantification with a limit of detection similar to MPFC, but applicable to virtually all cases of AML. Here, we present the novel wet-lab techniques and bioinformatics workflow necessary to identify rare, leukemia-associated mutations. Briefly, we use unique molecular identifiers (UMIs) to tag individual molecules captured from genomic DNA using a 54-gene panel. Sequencing errors are corrected by collapsing reads with the same UMI. Further position-specific error modelling allows us to mitigate the effect of artifacts introduced by DNA degradation (e.g. cytosine deamination to uracil and guanine oxidation to 8-oxoguanine). As a proof of principle we used these techniques to identify rare hematopoietic subclones in the blood of healthy individuals. Variants identified by this technique were validated by droplet digital PCR—an orthogonal non-sequencing-based technology. Ongoing work with the Children's Oncology Group is focused on implementing these methods for residual disease assessment in children with de novo AML.

Meta-analysis of biopsy expression profiles of kidney transplant patients identified key drivers for acute rejection targeted by minocycline. *W. Zhang[1], Z. Yi[1], K. Keung[1,2], B. Zhang[1], Z. Li[1], C. Wei[1], L. Li[1], M. Menon[1], C. Xi[1], P. O'Connell[2], B. Murphy[1].* 1) Icahn School of Medicine at Mount Sinai, New York, NY; 2) Department of Medicine, Westmead Clinical School, The University of Sydney, Sydney, NSW, Australia.

Acute rejection (AR) is a major cause of organ transplant failure and has a variable negative impact on allograft survival even among patients who recover after immunotherapy. Molecular signatures in kidney allografts with AR have been identified by several independent studies, but results have varied. A meta-analysis of gene expression data from kidney transplant biopsies in the GoCAR (Genomics of Chronic Allograft Rejection) study along with five publicly available datasets was performed to identify a meta- signature associated with AR. From 735 biopsy sampleswe identified 982 (565 up and 417 down in AR vs non-AR patients) meta genes at FDR<0.05. Genes involved in immune response, T/B cell activation and proliferation, antigen processing and presentation, protein kinase cascade and NFKB signaling pathway were upregulated, whilst genes involved in metabolism were downregulated. 14 key driver genes were further derived from the differential submodules of meta- coexpression network of metagenes in AR patients compared to non-AR patients, withCASP1 at the center of the network. The key drivers were validated in independent expression datasets of renal transplants with AR as well as native kidney diseasesincluding IgA nephropathy, diabetic nephropathy and Systemic Lupus Erythematosis (SLE) suggesting the pivotal role of these key genes in driving the inflammatory response in acute allograft rejection and immune-driven native kidney diseases. Finally, application of a drug repurposing strategy identified minocycline as a potential therapeutic agent targeting these key drivers. The administration of minocycline in a murine cardiac allograft model of AR demonstrated a significant reduction in transcript expression of a number of these key genes, as well as multiple proinflammatory cytokines and chemokines. Our study identifies potential new targets for therapeutic intervention, and suggests minocycline as potential novel candidate for the prevention of AR. .

Computational estimation of leukocyte distribution in cord blood methylation arrays using a transfer learning framework. *L. Dinh[1], M. Jones[2], O.M. de Goede[2], H.R. Razzaghian[2], J.L. MacIsaac[2], W.P. Robinson[2], P. Lavoie[2], M. Kobor[2], R. Ng*[1], S. Mostafavi*[3].* 1) Computer Science, University Of British Columbia, Vancouver, BC, Canada; 2) Child and Family Research Institute, University of British Columbia; 3) Statistics, University Of British Columbia, Vancouver, BC, Canada.

Background: Computationally quantifying cell type composition in blood, a process called cell type decomposition, is useful in disentangling the effect of cell type composition variation from differential methylation or expression in disease studies. For example, diseases like cancer or SLE leave a characteristic imprint on the leukocyte population that can be detected by quantifying cell type composition. In differential expression or methylation studies, cell type heterogeneity is a major confounding factor, resulting in false positive ('spurious') associations, if not quantified and accounted for. Because the majority of large-scale human studies use whole tissue data, developing computational algorithms that can predict and adjust for cell type composition is a key step in reducing false positive rates. **Results:** Accurate computational algorithms for quantifying cell type proportions in adult whole blood exist, however, these algorithms do not generalize well to the cord blood setting. In this study, we first comprehensively assess the accuracy of existing adult deconvolution algorithms when applied to cord blood. To understand the impacted accuracy, we examined potential culprits like increased variability of methylation within cell types, the unaccounted appearance of nucleated red blood cells, and the shift in cell type profiles attributed to adult leukocyte lineages. To resolve these difficulties, we introduce an approach, based on joint analysis of methylation profiles in purified leukocytes in adult and cord blood, to select cell type signatures that more accurately estimate cell type proportions in cord blood samples. **Summary:** In conclusion, we show that current whole-blood-based algorithms for computing cell type proportions have low accuracy when applied to cord blood samples, and that our new approach enables us to improve the accuracy of estimated cell type proportions in this setting.

Whole genome sequencing study on bronchodilator drug response in ethnically diverse children with asthma. *A.C.Y. Mak[1], M.J. White[1], Z. Szpiech[1], M. Pino-Yanes[2], S. Oh[1], D. Hu[1], S. Huntsman[1], C. Eng[1], P.Y. Kowk[1], D. Torgerson[1], J. Galanter[1], E. Ziv[1], M.A. Seibold[3], N. Zaitlen[1], R. Hernandez[1], E.G. Burchard[1], New York Genome Center.* 1) University of California, San Francisco, San Francisco, California, United States; 2) Hospital Universitario N.S. de Candelaria, Santa Cruz de Tenerife, Spain; 3) National Jewish Health, Denver, Colorado, United States.

   Introduction Albuterol, a bronchodilator medication, has been the standard of care for asthma treatment worldwide for the past three decades. Despite significant variation in bronchodilator response (BDR), albuterol is often the only medication prescribed for asthma, regardless of disease severity and the striking racial/ethnic disparity in BDR. Specifically, Puerto Rican and African American children with asthma have significantly lower BDR compared to children of European origin. Previous studies have identified a genetic contribution to variation in BDR, yet much of the heritability of BDR remains to be explained. We reason that rare, population-specific variants contribute to BDR in minority children with asthma. **Methods** We performed whole genome sequencing on 1,500 minority children with asthma from the tails of the BDR distribution. Our study included 250 high and 250 low drug responders from three racial/ethnic groups, African Americans (n=500), Puerto Ricans (n=500), and Mexican Americans (n=500). We performed association tests on pooled rare variants in 5 kb sliding windows using SKAT-O. Principal component analysis was performed using EIGENSTRAT to identify structure in our study population. All association models were adjusted for age, sex, BMI, and the top ten principal components. **Results and Conclusions** Our results identified ethnic-specific rare variants associated with BDR. This includes loci near genes previously associated with corticosteroid response (*FOXK1*), T-cell stimulation (*CD5*) and airway hyper-responsiveness (*FHL2*). Our study furthers our understanding of genetic analysis in admixed populations and may play an important role in advancing the foundation for precision medicine in "at risk" minority populations. *Authors contributed equally to this work.

The Longitudinal Pediatric Data Resource: Accelerating new knowledge discovery and translation of findings in genetic disorders identified through newborn screening. *A.M. Brower[1], M. Kuhlmann[2], J.G. Loutrel[1], G. Labilloy[3], N. Felicelli[3], B. Bowdish[1], C. Day[1], A. Rupert[3], M.S. Watson[1], M. Wagner[3], P.S. White[3].* 1) Newborn Screening Translational Research Network, American College of Medical Genetics and Genomics, Bethesda, MD 20814; 2) Division of Biostatistics and Epidemiology, Cincinnati Children's Hospital Research Foundation, Cincinnati, OH 45229; 3) Division of Biomedical Informatics, Cincinnati Children's Hospital Research Foundation, Cincinnati, OH 45229.

   Since its inception over half a century ago, state-based newborn screening (NBS) programs annually screen 4 million newborns for genetic conditions that require immediate treatment to prevent morbidity and mortality. Research that capitalizes on the NBS system offers an opportunity to improve understanding of genetic disorders in newborns, develop novel technologies, and study the effectiveness of new treatments. Researchers have begun to explore the use of genomics in NBS, and state-based NBS programs have begun screening for disorders that have a large amount of genetic heterogeneity, including onset of symptoms in childhood or beyond. Natural history studies that capture longitudinal information on cases resulting from this expanded NBS will establish the clinical validity and clinical utility of identified disorders, and pilots of novel NBS technologies will provide analytical validation. To support these efforts, the NICHD created the Newborn Screening Translational Research Network (NBSTRN). The NBSTRN is developing an infrastructure for researchers to access to robust resources and focused expertise in NBS. As part of this effort, the NBSTRN and Cincinnati Children's are developing infrastructure and software tools to securely house long-term follow-up data on children diagnosed with NBS conditions. This tool, the Longitudinal Pediatric Data Resource (LPDR), offers a common data model and a secure environment for researchers to aggregate data on these rare conditions and incorporates a set of common data elements (CDEs) established by a national panel of clinical experts. Elements are developed and managed through a custom Data Almanac application that provides opportunity for virtual co-authoring of element definitions and values. A REDCap™ based system that includes over 60 conditions and over 10,000 CDEs is available to NBS researchers. A data discovery and query application, NBSMart, enables interaction with long-term outcomes as well as genomic information across different studies. Over 100 researchers across 8 studies are utilizing the LPDR. To date, data from 1900 participants with over 1 million data points have been collected. The LPDR will also house clinical and whole-exome and genome sequencing data from the Newborn Sequencing in Genomic Medicine and Public Health (NSIGHT) project. The use of the LPDR by researchers will create unique cohorts of individuals with genetic disease and accelerate understanding of these conditions.

iReceptor: Bioinformatic platform for storing and sharing next generation sequencing (NGS) data from immune repertoires. *F. Breden[1], N. Marthandan[1,2], B. Zimonja[1], J. Jagele[1], J. Scott[1,2,3], B. Corrie[4].* 1) The IRMACS Centre, Simon Fraser University, Burnaby, British Columbia, Canada; 2) Department of Molecular Biology, Simon Fraser University, Burnaby, British Columbia, Canada; 3) Faculty of Health Sciences, Simon Fraser University, Burnaby, British Columbia, Canada; 4) Centre for eResearch, Auckland, New Zealand.

   The diversity of the human Adaptive Immune Receptor Repertoire (**AIRR**) (antibody/B-cells or T-cells) is huge; there are as many as 10^{13} possible B-cell receptor sequences, and the human body can contain up to 10^{11} B- or T-cell receptor producing cells. AIRR data are critical for vaccine and therapeutic antibody development and anti-cancer immunotherapy. Only by analyzing data across studies, with associated data on patient demography, treatment and clinical outcome, will the true potential of this NGS revolution in immunotherapy be realized. The iReceptor Gateway will link AIRR databases, thus allowing the query of these databases for sequences satisfying specific criteria, between studies and institutions. iReceptor implements a distributed data set model, such that researchers can store their data under their own IRB constraints, and release these data to other nodes in the iReceptor environment based on shared consent, reciprocal data transfer and IP agreements. In order to address all of the challenges involved in storing and sharing these data, we have formed a consortium to develop protocols and best practices for producing, reporting and analyzing AIRR data. The most recent Adaptive Immune Receptor Repertoire Community Meeting was held June 28-30 2016 at NIH Fishers Lane Facility in Rockville MD (contact breden@sfu.ca).

Novel, allele sequence signature approach enables HLA-typing for biomarker identification using gene expression data. *M.L. Buchkovich, C.C Brown, K. Robasky.* Bioinformatics and Clinical Systems, Q2 Solutions - EA Genomics, Morrisville, NC.

   The human leukocyte antigen (HLA) system encodes proteins that identify self from non-self cells, and play critical roles in immunotherapy, regenerative medicine, patient safety monitoring and autoimmunity. Studies, already generating data to quantify gene expression, can greatly benefit from HLA-typing in RNA-seq data. Genotyping efforts are limited by significant sequence similarity coupled with high polymorphic rates in the HLA region, and specialized assays are not designed to handle analysis of FFPE-preserved tumor samples. To help overcome these limitations, we developed a novel sequence signature-based approach for identifying HLA alleles in RNA-seq data. Our approach first determines the HLA gene for each sequencing read. Once all reads have been assigned, the sequence signature for each gene is used to determine the HLA type. The sequence signature reference set, generated using the full IPD-IMGT/HLA Database reference, allows for the identification of uncommon HLA alleles. We characterized the performance of this approach using two RNA-seq datasets, 1) publicly available 75-bp PE data from 342 samples with HLA types available for five HLA genes (A, B, C, DRB1 and DQB1), and 2) 50-bp PE data generated in-house for 15 FFPE hepatic tumor samples sequenced in replicate. We assigned 4-digit precision HLA types to the publicly available samples with >90% accuracy. In particular, we achieved a 29.5% gain in accuracy for 4-digit precision of DQB1 over the accuracy obtained with another leading methodology. Additionally, we sequenced 15 FFPE hepatic tumor samples in replicate and obtained 91% overall replicate concordance (93% Class I and 87% Class II) with 2-digit precision, compared to the 88% we previously presented. Reproducible and accurate HLA typing, especially in FFPE-preserved oncology samples, enables biomarker identification using HLA types in the wealth of whole transcriptome data that has already been and is being generated. Overall, our approach enables quick, accurate and reproducible HLA typing in support of those large pre-clinical research programs that are already exploring these data for differential expression and antigen presentation, with no additional lab work and with minimal additional computational resource requirements.

Denny[3].* 1) Department of Pharmacy Practice and Science, University of Arizona College of Pharmacy, Tucson, AZ; 2) Division of Clinical Pharmacology, Department of Medicine, Vanderbilt University Medical Center, Nashville, TN; 3) Department of Biomedical Informatics, Vanderbilt University Medical Center, Nashville, TN; 4) Division of Infectious Diseases, Department of Medicine, Vanderbilt University Medical Center, Nashville, TN; 5) School of Anatomy, Physiology and Human Biology, University of Western Australia, Nedlands, Western Australia, AustraliaSchool, Boston, USA; 6) Institute of Immunology & Infectious Diseases, Murdoch University, Murdoch, Western Australia, Australia; 7) Department of Biostatistics, Vanderbilt University School of Medicine, Nashville, TN; 8) Division of Rheumatology, Department of Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, USA; 9) Division of Genetics, Department of Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, USA; 10) Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, USA; 11) Partners Center for Personalized Genetic Medicine, Boston, USA; 12) Institute of Inflammation and Repair, University of Manchester, Manchester, UK; 13) Department of Medicine, Karolinska Institutet and Karolinska University Hospital Solna, Stockholm, Sweden; 14) Department of Pathology, Microbiology and Immunology, Vanderbilt University Medical Center, Nashville, TN; 15) Biomedical Informatics Research Center, Marshfield Clinic Research Foundation, Marshfield, Wisconsin, USA; 16) Center for Human Genetics, Marshfield Clinic Research Foundation, Marshfield, Wisconsin, USA; 17) Department of Pharmacology, Vanderbilt University School of Medicine, Nashville, TN.

   Human leukocyte antigen (*HLA*) genes have more phenotypic associations than any other locus. However, a systematic approach has not yet been undertaken to investigate the influence of *HLA* variation across the phenome. We set out to replicate known associations, determine novel associations, and provide a freely available reference of *HLA*-phenotype associations. We performed phenome-wide association studies (PheWAS) for *HLA* genomic variation using de-identified electronic health records (EHR) databases coupled to DNA biorepositories. Using SNP2HLA, we imputed *HLA* variation, including two and four digit *HLA* alleles, *HLA* allele haplotypes, and non-synonymous (NS) *HLA* variants, from two populations of 29,712 and 11,368 European ancestry individuals genotyped on the Illumina® HumanExome BeadChip. We tested association of *HLA* variation with 1,545 phenotypes derived from EHRs and conducted a Trait-based Association Test to determine cross-phenotype associations driven by pleiotropic effects. Significance was considered at FDR q-value<0.10 in the discovery cohort as well as p-value<0.05 in the replication cohort. A total of 115 four-digit and 96 two-digit *HLA* allele-phenotype associations were significant in both discovery and replication cohorts. Most associations were seen with Class II *HLA* loci, with the strongest being *HLA-DQB1*03:02* and type 1 diabetes (odds ratio 4.31 [3.57-5.19], meta-analysis p=1.40x10[-53]). Previously known associations were strongly represented in these results, particularly for autoimmune diseases. These included rheumatoid arthritis, ankylosing spondylitis, multiple sclerosis, psoriasis and psoriasis vulgaris, celiac disease, Sicca syndrome, and primary biliary cirrhosis, with some having strong cross-phenotype associations potentially driven by pleiotropic effects. We observed several novel associations among the phenotypes analyzed. A total of 2,044 significant associations were observed with NS variants. Novel associations were observed and replicated between NS variants and nodular lymphoma, partial epilepsy, mild cognitive impairment, and atherosclerosis of the extremities. We provide strong evidence of the validity of the PheWAS approach and further emphasize the importance of the major histocompatibility complex (MHC) region in human health and disease. We will provide a comprehensive, publicly available database of *HLA* loci to allow for in-depth evaluations of underlying genetic architectures for a range of diseases.

1665F

Large-scale gene regulatory network inference to identify novel regulators of innate inflammatory response. *T. Yang, R. Xue, M. Beste, B. Hayete, I. Khalil.* GNS Healthcare, Cambridge, MA.

   Systematic mapping of expression Quantitative Trait Loci (eQTL) has increasingly enabled the discovery of tissue- and context-specific cis-regulatory domains governing the intermediate transcriptional effects of genetic variation. Subsequent inference of gene regulatory networks provides a complementary framework for evaluating and validating causal relationships captured during initial eQTL mapping. Here we leverage context-specific eQTL maps to infer genome-scale Bayesian networks for the human monocytic response to LPS and IFNg using Reverse Engineering and Forward Simulation (REFS), a distributed high-performance computing engine for network learning and predictive simulation. REFS efficiently implements a parallelized score-based search to sample statistical ensembles of network structures from the Bayesian posterior of model structures given the data. To improve the accuracy of the learned networks, we encode a combination of structural priors encompassing (i) the adjacency matrix of the eQTL map, automating the identification of causal, reactive, and independence relations among cis- and trans- gene pairs and (ii) transcriptional regulatory annotations from high-resolution FANTOM5 profiles. The resulting networks for >30 thousand gene isoforms recapitulate a range of canonical transcriptional mechanisms, including distinct MYD88/IRAK, p38/JNK, and JAK1/STAT1 sub-networks. Prioritization of inferred regulatory modules identified 28 candidate regulators of acute transcriptional response for further validation. Finally, we demonstrate an application of REFS forward simulations to identify an optimal set of targeting perturbations to maximally rescue a quiescent phenotype from the activated LPS transcriptional response.

1666W

Imputation of gene expression implicates expected and unexpected genes associated to Crohn's disease. *K. Gettler[1], L. Chuang[2], N. Hsu[2], G. Hoffman[2], S. Kugathasan[3], J. Cho[2].* 1) Yale University, New Haven, CT; 2) Mount Sinai, New York City, NY; 3) Emory University, Atlanta, GA.

   A major limitation of GWAS has been the imprecise definition of pathogenic genes within loci. The vast majority of loci are driven by non-coding variation. Mapping specific alleles most implicated in trait association to altered gene expression has been challenging as regulation of gene expression is likely highly context-dependent. Promising approaches have been recently developed, where reference eQTL datasets are used to impute gene expression of GWAS cohorts to perform transcriptome-wide association studies (TWAS). We hypothesized that imputation of gene expression in the most relevant tissue type, here the terminal ileum in newly-diagnosed, untreated Crohn's disease (CD), will define CD-associated genes within GWAS loci. RNA-seq data were collected from intestinal biopsies taken from 302 untreated CD patients genotyped with the Illumina Omni 2.5 chip. We imputed expression of 1280 candidate genes from CD loci in 5,956 CD cases and 14,927 controls. TWAS identified 39 genes from 25 loci demonstrating Bonferroni-corrected significant association of altered gene expression to CD (P = 4 x 10-5). We confirmed the well-established role of decreased expression/function of NOD2 (chr16, 50 Mb, TWAS P = 8.2 x 10-12) and ATG16L1 (chr2, 234 Mb, TWAS P = 3.2 x 10-9) to CD. NOD2 and ATG16L1 TWAS P-values were 3- and 5- orders of magnitude more significant than the next most significant genes in their loci. Conversely, increased PTGER4 (prostaglandin receptor 4) gene expression was uniquely associated with CD (P = 6.0 x 10-8). For the loci at chr5 130Mb and chr3 at 49 Mb, TWAS patterns equally implicate multiple genes. However, for many loci, TWAS uniquely implicates one gene over others, in many cases, highlighting unexpected genes. For example, at chr6 at 167Mb, we observe much more significant association to the ribonuclease RNASET2 (TWAS P = 2.6 x 10-12) compared to other candidates (e.g. CCR6, TWAS P = 1.6 x 10-3). Similarly, TWAS implicates SEC16A (P = 1.8 x 10-10) over CARD9 (P = 2.2 x 10-5), CUL2 (P = 2.0 x 10-7) over CREM (P = 0.01), PDGFB (P = 3.7 x 10-7) over SMCR7L (P = 3.2 x 10-5) and GSDMB (P = 5.6 x 10-7) over ORMDL3 (P = 0.03). We will present the validation of the TWAS gene and gene expression predictions by testing in an exome sequencing cohort whether an excess of predicted rare deleterious alleles are observed in CD cases or controls in genes where risk alleles are predicted to decrease and increase gene expression, respectively.

1667T

Multidimensional computational structure-function relationship analysis of *FRGR3* **genetic mutations causal to achondroplasia.** *R.H. Baaqeel[1,2], R.S AlHarbi[1,2], J.Y Al-aama[1,2], R. Elango[1,2], N.A Shaik[1,2], B. Banaganapalli[1,2].* 1) Princess Al-Jawhara Al-Brahim Center of Excellence in Research of Hereditary Disorders, King Abdullaziz University, Jeddah, Saudi Arabia; 2) Department of Genetic Medicine, Faculty of Medicine, King Abdulaziz University, Jeddah, Saudi Arabia.

   Achondroplasia (ACH), a common form of short-limbed dwarfism, occurs due to FGFR3 gene mutations in 80% of cases, either sporadically or by defective allele inheritance in an autosomal dominant pattern. The two most common amino acid substitution mutations of FGFR3 gene known to cause the development of ACH are G369C and G380R. However, the specific impact of these amino acid substitutions on protein-structure functional relationship is not clear. The molecular validation of these mutations through experimental evidences is difficult owing to the requirement of time, technical expertise and huge costs. Hence, our objective was to examine the efficacy of advanced multidimensional computational strategies in understanding the structural plasticity of FRGR3 pathogenic mutations and its potential implications for protein-drug interactions. By exhaustive literature survey and database base searching, we identified 17 lethal variants of FGFR3 gene causal to ACH development. By integrating the predictions of nine different computational algorithms with different operating principles, we discovered that Y278C, S279C, L379R,N542K, T548K, K652E and T653P mutations are lethal to structure and function of FRGR3 gene. Moreover, to our surprise, we find that the deleterious impact of G369Cand G380R mutations (most common to ACH) is 2 fold less than the above mentioned 7 mutations. We identified that Y278C, S279C, L379R,N542K, T548K, K652E and T653P mutations induces structural deformities on FGFR3 protein and can also disturb its affinity towards common ACH drugs like dovitinib dilactic acid and pazopanib. Our computational findings are expected to help in recognizing lethal FGFR3 mutations causal to ACH and also to select better competitive inhibitors for mutated forms FGFR3 protein.

Skeletal phenomics in zebrafish via microCT-based barcoding. *R.Y. Kwon[1], M. Hur[1], P. Huber[1], J. Lee[1], M.H. Thompson[1], C.J. Watson[1], S.K. Mc-Menamin[3], D. Parichy[2].* 1) Department of Orthopaedics and Sports Medicine, University of Washington, Seattle, WA; 2) Department of Biology, University of Washington, Seattle, WA; 3) Department of Biological Sciences, University of Massachusetts, Lowell, MA.

Bones comprise different morphologies, compositions, and modes of developmental origin. Skeletal phenotyping has traditionally focused on intensive analysis within a single skeletal compartment, yet single genetic variants are often associated with changes in multiple traits across multiple bones. These coordinated changes may reveal gene pleiotropy, expose shared genetic mechanisms, and provide heightened sensitivity in detecting subtle changes in bone mass that would not be perceptible by studying a single bone in isolation. Motivated by the emergence of zebrafish as a rapid testbed for human gene analysis, as well as the potential to merge large-scale gene testing with phenomic discovery, we developed FishCuT, a novel algorithmic approach for microCT analysis of the adult zebrafish skeleton. We coupled supervised region growing with connectivity analysis to enable rapid (<5min per fish) computation of 288 different measures (24 vertebral bodies x 3 vertebral elements x 4 quantities per fish) of axial bone morphology and mineralization in a process we call "skeletal barcoding". As a proof of principle, we barcoded zebrafish mutants previously isolated from genetic screens, and identified two mutants with abnormal skeletal phenotypes: *puma* and *opallus*. *opallus* (which harbors a mutation in thyroid stimulating hormone receptor (*tshr*) identical to a human mutation causing constitutive TSHR activity and hyperthyroidism [1]) exhibited significantly elevated TMD across all centra. *puma* (which harbors a mutation in the alpha tubulin gene *tuba8l3a* [2]) exhibited increased volume in anterior haemal arch/rib elements only, suggesting the potential to detect both global and regional shifts in mass/mineral accrual. In humans, hyperthyroidism is associated with low BMD [3], whereas TSHR gain-of-function has been associated with high BMD [4]. Thus, this study suggests the potential for the zebrafish skeleton to predict a complex phenotype integrating competing influences at both systemic and local levels. Together, this study advances new approaches to skeletal phenomic analysis, and supports the translational value of zebrafish as a model of human genetic bone disorders. A novel method for gene set enrichment analysis of ExomeChip data, EC-DEPICT, identifies relevant biological pathways. *R.S. Fine[1,2,3], T.H. Pers[4,5], J.N. Hirschhorn[1,2,3], the deCODE Genetics, BBMRINL, GOT2D, CHARGE, and GIANT Consortia.* 1) Department of Genetics, Harvard Medical School, Boston, MA; 2) Division of Endocrinology and Center for Basic and Translational Obesity Research, Boston Children's Hospital, Boston, MA; 3) Broad Institute of MIT and Harvard, Cambridge, MA; 4) Novo Nordisk Foundation Centre for Basic Metabolic Research, University of Copenhagen, Copenhagen, Denmark; 5) Department of Epidemiology Research, Statens Serum Institut,Copenhagen, Denmark.

Pathway analysis is a powerful tool for biological interpretation of genetic association data. We developed EC-DEPICT for pathway analysis of ExomeChip (EC) data by adapting DEPICT, our genome-wide association study (GWAS) pathway analysis method. DEPICT extends and reconstitutes existing gene sets by using coexpression to assign gene set membership probabilities to every gene in the genome. These quantitative annotations are less biased and leverage signal from uncharacterized genes. In EC-DEPICT, we use these membership probabilities to generate test statistics that assess, for each gene set, the enrichment of genes with significantly associated coding variants. To control for inherent biases in the data, we convert these test statistics to empirical P values and false discovery rates (FDR) by generating test statistics from 2000 sets of null ExomeChip genotype data. We applied EC-DEPICT to EC data for height and BMI in up to ~700,000 individuals, using conditional analysis to select associations independent of known GWAS signals. For height, 496 gene sets were significantly enriched (FDR<0.01) in genes with associated coding variants. Many gene sets identified from EC data overlapped with those independently identified from noncoding GWAS variants, but EC-derived gene sets more strongly and specifically implicated growth plate-related biology and uniquely identified proteoglycan binding. Unsupervised clustering and visualization of implicated genes and gene sets revealed a cluster of genes that are known to underlie monogenic disorders of skeletal growth, contain height-associated coding variants, and have high membership probabilities for a shared group of EC-enriched gene sets. Several other genes with height-associated variants but no prior connections to growth are interspersed in the same cluster and are new, promising candidates for monogenic growth disorders. For BMI, EC-DEPICT identified neurotransmission- and synapse-related gene sets, strongly and independently replicating recent pathway analysis from BMI GWAS results. EC-DEPICT can be used for analysis of EC data for any phenotype, and can be adapted for exome sequencing. Our results indicate that pathways implicated by coding and noncoding variation often overlap but, at least for height, can also implicate specific aspects of biology. EC-DEPICT provides a useful framework for biological interpretation of exome array results and points to specific genes for follow-up studies.

Birth prevalence estimation of severe Hypophosphatasia in European populations using large-scale protein-coding genetic variation databases. *G. del Angel[1], E. Mornet[2], J. Reynders[1].* 1) Genomics and Data science, Alexion Pharmaceuticals Inc., Lexington,MA, MA; 2) Laboratoire de génétique constitutionnelle prénatale et postnatale. Centre Hospitalier de Versailles. Le Chesnay, France.

Hypophosphatasia (HPP) is a rare, inherited metabolic disorder caused by mutations in the alkaline phosphatase gene (ALPL, OMIM:171760). HPP is characterized by defective bone mineralization and reduced serum ALP activity. HPP is a clinically heterogeneous disease and is classified according to severity and age of onset: perinatal, infantile, childhood, adult and odonto HPP. We propose here a novel method to estimate severe HPP (i.e., perinatal and infantile) birth prevalence based on leveraging large-scale population genomic databases to obtain individual allele frequencies for disease mutations. This approach presents an unbiased methodology that avoids data sparsity and case ascertainment problems in previous incidence computation approaches based on case reports. We analyzed cohort and mutation data from 345 patients, out of which 182 presented perinatal or infantile forms. We classified ALPL mutations onto three tiers: Tier 1: Severe mutations: Homozygous mutations in severe HPP cases; mutations known to have dominant negative effect or low residual ALP enzymatic activity (<10% as discussed in Zurutuza (1999); loss of function mutations, and severe mutations in compound heterozygote form with high residual activity. Tier 2: Mutations with high residual activity. Tier 3: Missense mutations in public population databases not seen yet in patients with HPP but with strong computational evidence for deleteriousness. Allele frequency estimates for each mutation above were obtained using the Exome Aggregation Consortium (Lek 2016), which aggregates protein-coding mutations for over 30,000 samples from individuals with European ancestry. HPP birth prevalence was estimated using Hardy-Weinberg equilibrium. Based on this tier classification, upper and lower limits on severe HPP birth prevalence were determined. The lower bound considers Tier 1 and Tier 2 mutations, yielding an estimate of 2.6 per million births (95% CI: [1.7, 3.7]). An upper bound was obtained considering all 3 Tiers, yielding an estimate of 3.8 per million births (95% CI: [2.7, 5.1]). These bounds fall close to previously published estimates, and provide new methods to estimate birth prevalence of other rare genetic diseases. Future work will be aimed at better understanding of ALPL genotype/HPP phenotype relationships and mutation severity.

VICTOR: A pipeline for Variant Interpretation in Clinical Testing Or Research. *B.-J. Feng[1,2], K. Callis Duffin[1], G.G. Krueger[1], W. Kohlmann[2], J.D. Schiffman[2], M. Schmidt[3], A. Meindl[4], R. Berruti[5], R. Schmutzler[6], E. Hahnen[6], M. Vallée[7], A. Droit[7], D.F. Easton[8], S.V. Tavtigian[2], J. Simard[7], D.E. Goldgar[1,2].* 1) Dermatology, University of Utah, Salt Lake City, UT, USA; 2) Huntsman Cancer Institute, University of Utah, Salt Lake City, UT, USA; 3) Division of Molecular Pathology, The Netherlands Cancer Institute, Amsterdam, The Netherlands; 4) Department for Gynecology and Obstetrics, Technical University of Munich, Munich, Germany; 5) Institute of Human Genetics, Helmholtz Zentrum München, Munich, Germany; 6) Center for Hereditary Breast and Ovarian Cancer, Center for Integrated Oncology (CIO) and Center for Molecular Medicine Cologne (CMMC), Medical Faculty, University of Cologne and University Hospital Cologne, Cologne, Germany; 7) Université Laval Research Centre, Québec, Canada; 8) Centre for Cancer Genetic Epidemiology, Department of Public Health and Primary Care and Department of Oncology, University of Cambridge, Cambridge, UK.

We have developed a variant interpretation pipeline that starts from a raw genotype file in VCF format. It conducts genotype-, variant-, and sample-wise quality control of data. This pipeline implements a novel functional consequence annotation program that annotates against the predominant transcripts whenever such information is available, chooses the most biologically relevant 5' or 3' representation for short insertions or deletions (InDel), merges multi-nucleotide polymorphisms (MNP), labels loss-of-function (LoF) variants, supports non-coding regions, and is robust to reference sequence errors. For clinical testing, this pipeline quantitatively integrates multiple deleteriousness scores, allele frequencies in different populations, co-segregation within pedigrees, and association among case-control samples to calculate a posterior probability of pathogenicity for each variant. For gene discovery research, it performs gene prioritization by integrating a region-based linkage analysis, a novel rare-variant association analysis where variants are weighted by deleteriousness and call quality, the relatedness of each gene to known disease genes within a gene-gene association network, and the differential gene expression between lesional and non-lesional tissues. In both scenarios, all components are combined in a quantitative fashion. Being light-weighted and fast with low demands on memory, this pipeline is scalable to whole genome sequencing (WGS) of a large sample of individuals that is typical of a complex disease research. Components of this framework can be assembled in various ways to accommodate different study designs and analysis goals. Using this pipeline, we have re-classified a TP53 variant of unknown significance (VUS) for Li-Fraumeni Syndrome (LFS), analyzed the whole exome sequencing (WES) of 1368 breast cancer cases and 3725 healthy controls from the PERSPECTIVE project (PErsonalised Risk Stratification for Prevention and Early deteCTIon of breast cancer), and analyzed the WES of 42 cases from 16 high-risk psoriasis pedigrees in the Utah Psoriasis Initiative project (UPI). The results demonstrated the value of the VICTOR pipeline in variant classification and gene discovery applications.

Replacing MLPA by XHMM for CNV detection on targeted panel NGS data in a diagnostic setting. *E. Voorhoeve, I. Clemens, D. van Beek, I. Bakker, Q. Waisfisz, E. Sistermans, M. Weiss, A. Maugeri.* Department of Clinical Genetics, VU medical center, Amsterdam, Netherlands.

Purpose MLPA and arrays are routinely used for the detection of clinical relevant copy number variations (CNVs). Recently several tools for the detection of CNVs on NGS read-depth data have been developed. CNV detection by read-depth methods - such as XHMM (eXome-Hidden Markov Model) - is efficient, because this type of analysis uses the NGS data already available from the targeted panels. In this study we validated the use of XHMM for the detection of CNVs in a NGS based targeted connective tissue disorder (CTD) gene panel to replace the diagnostic MLPA kits (7 genes) and extent the CNV analysis to all 78 genes in the panel. We summarize the diagnostic yield after analyzing 502 CTD samples using XHMM as the first tier test for the detection of CNVs. **Method** XHMM was optimized on 1210 samples sequenced with the CTD gene panel version 1: 1176 exons were captured in solution. Default parameter settings proved to be a good choice. For single exon CNVs a separate parameter setting was validated and implemented next to the run with default settings. The performance of XHMM was tested on 318 samples sequenced with CTD panel version 2: 1977 exons were captured in solution. This set contained 37 known CNVs detected with MLPA or array: 12 duplications, 24 deletions – all heterozygous – and 1 homozygous deletion. Both the duplications and deletions range in size from single exon to over 60 exons. Based on these analyses a reference set was built and the weak performing exons (due to pseudo genic regions and low coverage) were excluded. **Results** XHMM correctly called all 37 known CNVs, including 8 single exon deletions and 4 single exon duplications. XHMM called an additional 68 CNVs. Roughly half of these CNVs were frequently detected and thus considered to be benign or artifacts. The other half were detected in genes that didn't fit the diagnosis and were therefore not confirmed by another method. **Conclusion** CNV detection by XHMM proved to be as sensitive as the current methods. Our department has implemented XHMM analysis replacing MLPA for the clinical diagnosis of CNVs in CTD samples. Since the validation of XHMM 502 samples have been tested and revealed 15 clinical relevant CNVs, 3 of which are located in CTD genes previously not tested with MLPA: 1 whole gene and 2 single exon deletions. All 15 CNVs are confirmed with MLPA or array. Implementation of XHMM has increased the diagnostic yield and saves the costs of running diagnostic MLPA (~20.000 per year in our setting).

1673T

Cross-phenotype analyses of three clinical measures of multiple sclerosis disability suggests involvement of new biological processes. *L.J. Leung[1], F.B.S. Briggs[2,3].* 1) College of Medicine, University of Vermont, Burlington, VT; 2) Department of Epidemiology and Biostatistics, School of Medicine, Case Western Reserve University, Cleveland, OH; 3) Institute of Computational Biology, Case Western Reserve University, Cleveland, OH.

Background: Multiple sclerosis (MS) is the leading cause of acquired neurological disability in young adults; patients suffer a spectrum of impairments throughout their lifetimes. Genetic studies of MS progression are few and have not yielded definitive results. These studies primarily used the Expanded Disability Severity Scale (EDSS), and the Multiple Sclerosis Severity Scale (MSSS), a derivative. No genetic studies of 9-Hole Peg Test (9HPT) and Timed 25-Foot Walk (T25FW) impairments have been conducted. We conducted a unique cross-phenotype analysis of MSSS, 9HPT, and T25FW to identify shared and distinct pathological mechanisms. **Methods:** 1,088 white participants in the Accelerated Cure Project for MS (ACP) with epidemiologic data were available. Clinical phenotypes and date of measurement were extracted from medical records for 648 subjects: N_{MSSS}=504; N_{9PHT}=313; and N_{T25FW}=471. 9PHT and T25FW were natural log transformed. The pairwise correlation between phenotypes was 20-34%. Samples were genotyped on a Human Illumina Custom BeadChip. Analyses were restricted to genic SNPs with MAF≥0.01 and genotype rate>99% in the total sample. 55,931 SNPs in 12,887 genes were investigated; models were adjusted for ancestry, gender, birth year, onset age, and disease course (6% progressive at onset, 9PHT and T25FW were adjusted for time from onset to measurement). **Results:** The top individual associations were: MSSS: *NQO1* missense, p=3x10^{-5}; T25FW: *AOC2* missense, p=7x10^{-6}; 9PHT: *NIN* missense, p=7x10^{-6}. Surprisingly, only the *NIN* missense was associated in another phenotype (p_{T25FW}=0.002). *HLA-DRB1*15:01* (rs3135388A) was not associated with any phenotype. SNPs associated (p<0.05) with all phenotypes were within 21 genes, with multiple SNPs in *CACNA1C*, *CEP104, COL2A1, HLA-DRP2* (pseudogene) and *STAT3*. These genes suggest plausible biological rationale for associated phenotypes, e.g. *CACNA1C* associates with bipolar disorder, schizophrenia and mediates hippocampal neuron survival; *COL2A1* encodes fibrillar collagen and mutations cause 16 type II collagenopathies including osteoarthritis. Pathway analyses also illustrate distinct, and shared mechanisms. **Conclusions:** These results illustrate challenges elucidating biological process mediating progression of a complex trait, and emphasizes the need for robust/diverse phenotypes. By comparing associations across clinical measurements, we have identified novel and specific MS targets for replication and functional analyses.

INFERNO – INFERring the molecular mechanisms of NOncoding genetic variants. *A. Amlie-Wolf[1,2,3], M. Tang[2,3], P.P. Kuksa[2,3], Y.Y. Leung[2,3], B. Slaff[4], J. King[3], B. Dombroski[3], G.D. Schellenberg[1,3], L.S. Wang[1,2,3,4].* 1) Genomics and Computational Biology Graduate Group, University of Pennsylvania Perelman School of Medicine, Philadelphia, PA; 2) Institute for Biomedical Informatics, University of Pennsylvania Perelman School of Medicine, Philadelphia, PA; 3) Department of Pathology and Laboratory Medicine, University of Pennsylvania Perelman School of Medicine, Philadelphia, PA; 4) Department of Computer and Information Science, University of Pennsylvania, Philadelphia, PA.

   Genome-wide association studies (GWAS) have identified genetic variants associated with many diseases, but limitations remain. First, GWAS-identified variants tag linkage disequilibrium (LD) blocks of potentially functional variants, many of which are not causal. Second, most GWAS variants are in the noncoding genome and may affect transcriptional enhancers. Enhancers are context-specific and annotations are incomplete, so information must be integrated across tissue contexts and data sources to identify enhancer variants. Finally, to translate GWAS findings into therapeutics, the affected genes and expression changes underlying disease risk must be identified. We propose INFERNO, a new tool that addresses these limitations by integrating hundreds of diverse data sets to identify the causal variants within LD blocks, the enhancers they affect, the tissue context of the enhancers, the affected target genes, and the direction of these effects. Given a list of tagging variants, INFERNO uses 1,000 Genomes Project data to define LD blocks. Each linked variant is compared with: enhancer RNA transcription sites, reflecting enhancer activity, across 112 tissue types from the FANTOM5 consortium; epigenetically-defined enhancers across 127 tissues and cell types from the Roadmap Epigenomics consortium; expression quantitative trait loci across 44 tissues from the GTEx consortium; and predicted transcription factor binding sites (TFBSs) for 332 transcription factors from HOMER. Tissues or cell types from each data source are grouped into 38 broad tissue categories for comparison, and empirical p-values for the enrichment of functional overlaps in each tissue category are obtained by bootstrapping. Application of INFERNO to 19 top Alzheimer's disease (AD) GWAS variants from the International Genomics of Alzheimer's Project (IGAP) 2013 study identified significant enrichment of functional variants affecting blood/immune enhancers in 18 of the tagged regions, bolstering the hypothesis of immune involvement in AD. Four regions contained variants supported by all three functional data sources as well as predicted TFBSs, and luciferase assays validated their effects on enhancer activity. Thus, INFERNO provides an easy and powerful approach for inferring the molecular mechanisms of noncoding genetic variants. We have implemented INFERNO in an efficient Python- and R-based pipeline with source code and access to a web server version available at lisanwanglab.org/INFERNO.

Cell specific, network-based pathway analysis of GWAS data provides further insights into pathogenesis of multiple sclerosis. *S.E. Baranzini, International Multiple Sclerosis Genetics Consortium (IMSGC).* Neurology, University of California San Francisco, San Francisco, CA.

   Hundreds of genetic studies have uncovered thousands of statistically significant associations. However, the mechanistic interpretation of those discoveries is often hampered by the difficulty in translating the statistical evidence of association into affected pathways or processes that can inform the underlying biology of the disease or phenotype in question. Here we use association data from the latest GWAS in multiple sclerosis (MS) covering up to 47,351 cases and 68,284 controls to conduct a cell-specific, network-based pathway analysis to further gain insights into the pathogenesis and heterogeneity of this disease. We integrated thousands of statistically associated variants in 200 genomic regions with regulatory information from ENCODE and Roadmap Epigenomics Project data to identify the most likely genes causative of the association signals in 10 different cytotypes (T and B lymphocytes, monocytes, brain cells, etc). Overall, more than 5 million data points were used to conduct this analysis, which enabled prioritization of likely regulated genes in each region. Further integration of these with a highly curated human protein interaction network, allowed for the identification of specific disease-associated interactomes. In all cell types studied (including those from brain), the emerging networks display higher connectivity than expected by chance, suggesting that associated regions influence transcriptional expression, and thus functional connectivity of biological pathways in multiple cell types in MS. These results lend support to the hypothesis that heterogeneity of genetic variation can result in phenotypic heterogeneity at the molecular and possibly organismal level, which has important implications for patient-specific risk evaluation and personalized disease management.

1676T

Mutational burden analysis of interaction networks in inherited neuropathies. *D. Bis[1,2], F. Tao[1,2], L. Abreu[1,2], A. Rebelo[1,2], S. Zuchner[1,2], Inherited Neuropathy Consortium.* 1) Dr. John T. Macdonald Foundation Department of Human Genetics, University of Miami, Miami, FL; 2) John P. Hussman Institute for Human Genomics, University of Miami, Miami, FL.

Inherited peripheral neuropathies are clinically and genetically heterogeneous diseases that can cause distal muscular atrophy and sensory loss. Alleles in over one hundred different genes have been shown to cause peripheral neuropathies; yet, greater than 50% of axonal neuropathy patients do not receive a genetic diagnosis. We have been involved in successful large scale exome studies to identify additional rare monogenic causes for neuropathies. For a portion of the remaining patients, the concept of oligogenic inheritance of weaker alleles is a distinct possibility. In a deviation from the classic linkage-based and heuristic approaches to gene identification, we are performing burden analyses in a large cohort of 439 families. In 117 known neuropathy genes, we saw that neuropathy cases carried on average 3.7 rare, non-synonymous variants, while 615 non-neuropathy controls harbored 2.4 variants (p=0.003, Mann-Whiney U-test). Another 400 neuropathy exomes are being added to this analysis in the coming weeks. To expand these studies into new candidates, we have created a high confidence, neuropathy-specific protein-protein interaction network from publicly available resources. The network is composed of 114 neuropathy genes and 7,514 interacting partners connected through 30,832 experimentally determined interactions. Genes within the network that interact significantly with known neuropathy genes are potential candidates. Any candidate gene with enriched alleles in cases will be studied for strong segregating alleles in neuropathy families. We designed this approach to uncover additional weak alleles, potentially important for phenotype modifying effects or oligogenic inheritance, as well as novel neuropathy genes.

1677F

In silico functional annotation of genomic variants: Application to the Alzheimer's Disease Sequencing Project. *W. Bush[1], M. Butkiewicz[1], E. Blue[2], P. Navas[2], M. Dorschner[3], C. Kang[4], S. White[5], A. Kuzma[6], A. Renton[7], X. Jian[8], D. Koboldt[4], J. Haines[1], Alzheimer's Disease Sequencing Project.* 1) Institute for Computational Biology, Case Western Reserve University, Cleveland, OH; 2) Division of Medical Genetics, University of Washington, Seattle, WA; 3) Department of Pathology, University of Washington, Seattle, WA; 4) The Genome Institute, Washington University, St. Louis, MO; 5) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 6) Department of Pathology and Laboratory Medicine, University of Pennsylvania, Philadelphia, PA; 7) Icahn Institute for Genomics and Multiscale Biology, Mt. Sinai, New York City, NY; 8) Division of Epidemiology, Human Genetics and Environmental Sciences, School of Public Health, The University of Texas Health Science Center, Houston, TX.

Large-scale genome sequencing efforts in disease oriented datasets routinely identify millions of variants. However, determining which variants warrant further attention is a significant bottleneck. The ADSP Annotation Group has tackled this problem by employing a strategy of integrating *in silico* functional information and applying it to the large scale whole-exome and whole-genome sequencing efforts within the Alzheimer's Disease Sequencing Project (ADSP). The ADSP has identified 28 million variants within its study participants. Of these, approximately 5 million are novel events not reported by the 1000 Genomes Project, Exome Aggregation Consortium (ExAC), or dbSNP releases, and both the statistical analysis and the interpretation of these variants is dependent on *in silico* functional annotation. The primary goals of the ADSP Annotation Working Group are to provide consistent, version-controlled genomic annotations for all ADSP projects and analyses, to integrate new relevant data and genomic resources that become available over the course of the ADSP, and to provide variant annotations across a range of biological contexts relevant to Alzheimer's Disease (AD) biology. Toward this end, we have developed a workflow to provide investigators with predicted functional impact (from the Ensembl Variant Effect Predictor), variant allele frequencies observed in other studies (from the Kaviar database and the Wellderly Cohort), predicted loss-of-function status (from SNPEff), and multiple scoring metrics for assessment deleteriousness (including CADD, CATO, and SPIDEX scores). Annotation of non-coding regions is especially challenging; due to the incredible depth of data available across a wide variety of cell and tissue types, we have developed approaches to collapse and combine regulatory annotations and (when possible) to assign them to downstream genes using expression QTL studies from congruent cell and tissue types. Leveraging these *in silico* annotation data in conjunction with brain and other tissue-based RNA-sequencing studies, we construct context-specific annotations of ADSP variants that enable hypothesis-driven analyses, and ultimately provide new insights into the pathogenesis of AD.

EHR data extraction shows utility for microphenotypes in genetic studies. *M.F. Davis[1], S. Sutton[1], L. Bastarache[2], R. Carroll[2], J.C. Denny[2].* 1) Microbiology and Molecular Biology, Brigham Young University, Provo, UT; 2) Biomedical Informatics, Vanderbilt University Medical Center, Nashville, TN.

Multiple sclerosis (MS) is a neurodegenerative autoimmune disease of the central nervous system with over 100 known genetic loci associated with risk of development of the disease. Disease course is incredibly varied among individuals with MS and it is unknown if disease course is also associated with genetic variation. Few genetic studies are published on the microphenotypes of MS, largely due to the difficulty in collecting long-term, detailed information of a chronic disease. We have already demonstrated the ability to extract MS microphenotypes using natural language processing approaches from 6,000 electronic health records (EHR) at Vanderbilt University, using the Synthetic Derivative. (Davis, *JAMIA* 2013) We have significantly improved these algorithms and have also identified treatment response, disease progression, and adverse drug events in our patients. Previously, our recall to extract MS diagnosis date was 33% using only referral letters as data sources. We have improved recall to 62% by using the narrative text in clinic reports (97% precision, 98% specificity). We identified diagnosis dates in 1,849 of cases. 461 of these individuals were genotyped on the ImmunoChip and passed standard quality control procedures. We performed linear regression for age at diagnosis, using the first three principle components as covariates. While no SNPs reached genome-wide significance, identifying age at diagnosis is critical for future progression studies in MS. We have shown that EHR-data extraction can create large databases that can be used for microphenotype genetic studies in MS.

1679T

A novel statistical methods for inferring causal expression-phenotype network. *Z. Hu[1,2], P. Wang[2], Y. Zhu[3], J. Zhao[3], L. Jin[2], D. Bennett[4], M. Xiong[1].* 1) Houston Health Science Center, Houston, TX; 2) Fudan University, Shanghai, China; 3) Tulane University, New Orleans, LA; 4) Rush University Medical Center, Chicago, IL.

Gene expressions are high dimensional correlated traits and strongly affect variation of multiple correlated phenotypes. However, the current statistical methods for joint analysis of gene expression and phenotypes are (1) a single variate linear model that test association of gene expressions with a single trait and (2) multivariate linear models that test association of gene expressions with multiple traits. However, both gene expressions and multiple phenotypes are highly correlated. There are lack of statistical methods to organize both phenotypes and gene expressions into networks and link expression network with phenotype network. To overcome this limitation, we first use matrix completion methods to identify a few components for representing the gene expressions in a pathway. Then, we propose to use causal graphs as a major concept and a general framework for causal expression-phenotype network analysis and develop "score and search"-based methods for exact learning causal graphs of expression-phenotype networks to find the best-scoring structures for expression-phenotype networks. As a consequences, we can infer expression-phenotype networks for whole genome gene expression and dozens of phenotypes. The proposed methods were applied to AD data with 20 phenotypes and RNA-seq data of 4,937 genes from 181 pathways measured in 448 samples. At the first stage, the matrix completion methods identifies 792 components to represent 4,937 genes. Then, 792 components and 20 traits were used to infer expression-phenotype networks. The resulting networks consists of (1) phenotype networks with 20 nodes and 33 edges and (2) expression network with 90 nodes and 144 edges and (3) expression-phenotype connect network with 77 nodes and 166 edges with FDR less than 0.05. In the expression network, 41 (28%) connections were consistent with edges in KEGG Pathway database. The proposed methods provide a highly flexible general framework for causal expression-phenotype network analysis and provide more rich information than current gene expression and phenotype analysis. The exact learning algorithms will guarantee to find optimal solutions and hence provide accurate estimations of causal graphs of expression-phenotype networks. The causal expression-phenotype networks are able to uncover the mechanism of AD development.

1680F

Annotation regression for genomewide association studies. *S. Keles, S. Shin.* Biostatistics and Medical Informatics, University of Wisconsin, Madison, Madison, WI.

A key challenge for understanding GWAS results is that a large percentage of disease-associated genomic variants (GVs) are potential regulatory variants located in noncoding regions, making them difficult to interpret. Recent research efforts focus on going beyond annotating GVs by integrating functional annotation data with GWAS to prioritize GVs. However, applicability of these approaches are challenged by high dimensionality and heterogeneity of functional annotation data. Furthermore, existing methods often assume global associations of GVs with annotation data. This strong assumption is susceptible to violations for GVs involved in many complex diseases. To address these issues, we developed a general regression framework, named **A**nnotation **R**egression f**o**r **G**WAS (ARoG). ARoG is based on finite mixture of linear regression models where GWAS association measures are viewed as responses and functional annotations as predictors. This mixture framework addresses heterogeneity of effects of GVs by grouping them into clusters and high dimensionality of the functional annotations by enabling annotation selection within each cluster. Application of ARoG to autism and schizophrenia data from Psychiatric Genomics Consortium led to identification of GVs that significantly affect interactions of several transcription factors with DNA as potential mechanisms contributing to these disorders. Most notably, these analyses identified autism variants creating FOXL1 and Nkx2-5 binding sites as potential regulatory mechanisms. Computational and external data validations indicated that ARoG enhances identification of disease associated variants that would otherwise be missed due to low power or effect sizes and generates hypotheses regarding regulatory roles of the variants.

1681W

Synaptic protein-protein interaction clustering analyses identify distinct human brain regions. *G. Labilloy[1], A. Funk[2], M.R. Heaven[3], K.D. Greis[4], J. Meller[1,5,6,7,8], R.E. McCullumsmith[2].* 1) Division of Biomedical Informatics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 2) Department of Psychiatry and Behavioral Neuroscience, University of Cincinnati College of Medicine, Cincinnati, OH; 3) Vulcan Analytical, LLC, Birmingham, AL, USA; 4) Department of Cancer Biology, University of Cincinnati College of Medicine, Cincinnati, OH; 5) Department of Environmental Health, University of Cincinnati College of Medicine, Cincinnati, OH; 6) Department of Electrical Engineering and Computing Systems, University of Cincinnati College of Medicine, Cincinnati, OH; 7) Department of Biomedical Informatics, University of Cincinnati College of Medicine, Cincinnati, OH; 8) Department of Informatics, Nicholas Copernicus University, Torun, Poland.

Human brain function depends on crosstalk between layers and regions. Postsynaptic density 95 (PSD95) is a multipotent scaffolding, trafficking, and clustering protein which plays a key role in signal transduction of macromolecular and intracellular complexes within specific brain regions. We analyzed mass-spectroscopy data of 424 peptides interacting with PSD95 in four brain-regions (anterior cingulate cortex (ACC), dorsolateral prefrontal cortex (DLPFC), hippocampus (HIPP), and superior temporal gyrus (STG)) of three well-matched control subjects from the Alabama Brain Collection in order to detect region-specific protein-protein interactions. We processed the raw area under the curve from mass-spectroscopy data of sample triplicates using R version 3.1.3. Each measurement vector was normalized using PSD95 intensity to account for technical variations within measurements. We used the most abundant peptide intensity (IIPGGAAAQDGR) as normalization and then Log2-transformed the data. Only peptides with at least two out of three data points available for each sample were considered. Each sample was quantile-normalized in order to account for signal amplitude variation across measurements. Remaining missing values were taken care of by imputing the mean of the two other data. Standard deviation of each peptide was used to rank and select the 200 most variable peptides. Each peptide row was then z-transformed and a cluster was created with the Heatplot function from the made4 R-package using Pearson correlation as distance function. Each triplet of technical repeats robustly clustered together. ACC and DLPFC clustered in a similar fashion across patients, whereas HIPP and STG had specific clusters. This is consistent with the fact that ACC and DLPFC are more biologically similar compared to HIPP and STG which are more unique in their biological functions and gene expressions. This clustering analysis already produced biologically coherent results. More works needs to be done in order to improve the discriminating power of the clustering, for instance by selecting the most variable peptides by brain region in order to correct for unbalanced region representation within the peptide selection.

Expanding the ENCODE Encyclopedia: Applications for annotating non-coding variants. *J. Moore[1], M. Purcaro[1], A. van der Velde[2], T. Borrman[1], Z. Weng[1].* 1) Bioinformatics & Integrative Biology, UMass Medical School, Worcester, MA; 2) Bioinformatics Program, Boston University, Boston, Massachusetts, MA.

The Encyclopedia of DNA Elements (ENCODE) Consortium has generated hundreds of high throughput genomic datasets with the goal of cataloging functional elements in the human genome. Our goal was to integrate these complex data types to annotate regulatory elements and their target genes. We then used these annotations to functionally characterize non-coding variants associated with human disease. We began by developing an unsupervised method for predicting enhancer-like regions, which we evaluated using experimentally validated data from transgenic mouse assays. Using only H3K27ac ChIP-seq and DNase-seq data, our method shows high concordance with more complex genome segmentation methods with the advantage that it can be applied across many more cell and tissue types. Our next step was to then connect these predicted enhancers to their target genes. In order to compare different methods, we created a novel benchmark dataset by integrating eQTLs, ChIA-PET clusters and Hi-C links. We developed a Random Forest (RF) based approach using features such as the distance between the enhancer and gene, DNase and H3K27ac signals, and gene expression. With this model, we saw a dramatic increase in performance compared to methods based only on signal correlation. We then applied both methods to over 100 cell and tissues types across human and mouse and created a visualization tool (http://zlab-annotations.umassmed.edu/) where users can query and download regions of interest. Using this resource, we then sought to annotate non-coding variants in the NHGRI-EBI GWAS catalog. While there were many cases of variants residing in enhancers that targeted only the nearest gene, there were some interesting exceptions. In particular, rs1250564, which is in high LD with SNPs associated with Multiple Sclerosis (MS), resides in an enhancer-like region within the *ZMIZ1* gene. In lymphoblastoid cells, whose regulatory regions were previously determined to be enriched in MS variants, this enhancer targets both *ZMIZ1* and *PPIF*. *PPIF* encodes a protein that is part of the mitochondrial permeability transition pore which supports the hypothesis that mitochondrial dysfunction may play a role in the the onset of MS. This finding demonstrates that by using the ENCODE Encyclopedia, researchers can determine target genes of non-coding variants and gain a better understanding of the underlying disease.

1683F

Elucidating the structural and molecular etiology of hereditary cystatin C amyloid angiopathy. *K. Nguyen[1,4], M. March[1], A. Gutierrez Uzquiza[1], Y. Liu[1], L. Tian[1], P. Sleiman[1,2,3], H. Hakonarson[1,2,3].* 1) Center for Applied Genomics, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Division of Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA; 3) Department of Pediatrics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 4) Center for Dynamic Data Analytics, Rutgers University, Piscataway, NJ.

Hereditary cystatin C (CST3) amyloid angiopathy (HCCAA), also known as hereditary cerebral hemorrhage with amyloidosis – Icelandic type (HCHWA-I), is a rare, orphan disease that can cause a progressive loss of intellectual function (dementia), stroke, and other neurological disorders. It has a well-documented pathophysiology. However, its pathogenesis involving amyloid deposition is still unknown. A tandem effort involving genomic/genetic analyses and a therapeutic-driven approach were used to elucidate interactions at molecular resolution while providing viable ligands as drug candidates in a translational and precision medicine pipeline. A series of monomeric to oligomeric systems were modeled using classical simulation and enhanced sampling methods. The latter was done to quantitate the binding affinities of small low-weight compounds to large peptides satisfying the pharmacogenomic/-genetic approaches in this pipeline. Pathogenicities through mutation prediction methods were also used to initially determine the overall effect of conformational (in) stabilities. The dynamics and energetics – as well as the investigation of the partial unfolding mechanism and domain swapping for oligomerization – were observed using these methods. The L68Q mutant in CST3, as well as the V57[D,N,P], L47C/G69C, and F29C/M110C variants – were analyzed for overall comparison. As a result, a significant amount of conformational sampling was required to render the electrostatic behavior for ligand-protein and protein-protein interactions, steric interactions from the ligand and protein side chains, thermodynamically-driven processes leading to high-order and disordered systems, and long-range hydrophobic/-philic interactions from the bulk water. While these subjects are fundamentally controversial, they are required to observe the biological molecular recognition of any ligand and its respective macromolecule. Results of these *in silico* methods were also used to generate vibrational and electronic spectra, which will then be compared experimentally for validation.

NIA Genetics of Alzheimer's Disease Data Storage site (NIAGADS): 2016 update. *L. Wang[1,2,3], P. Gangadharan[1,2], A. Kuzma[1,2], O. Valladares[1,2], E. Greenfest-Allen[2,4], D.M. Childress[1,2], R. Cweibel[1,2], J. Malamon[1,2], H. Lin[1,2], Y. Zhao[1,2], L. Qu[1,2], Y.Y. Leung[1,2], A. Naj[5], C.J. Stoeckert Jr.[2,4], G. Schellenberg[1,3].* 1) Department of Pathology and Laboratory Medicine, University of Pennsylvania Perelman School of Medicine; 2) Institute for Biomedical Informatics, University of Pennsylvania Perelman School of Medicine; 3) Institute on Aging, University of Pennsylvania Perelman School of Medicine; 4) Department of Genetics, University of Pennsylvania Perelman School of Medicine; 5) Department of Epidemiology, University of Pennsylvania Perelman School of Medicine.

Statement of Purpose: NIAGADS is a national genetics data repository that facilitates access of genotypic data to qualified investigators for the study of the genetics of late-onset Alzheimer's disease (AD) as well as other neurological diseases. Collaborations with large consortia such as the Alzheimer's Disease Genetics Consortium (ADGC) and the AD Sequencing Project (ADSP) allow NIAGADS to lead the effort in managing large AD datasets that can be easily accessed by the research. NIAGADS' position as the centralized location for the storage of AD genetic data and its collaboration with the National Cell Repository for AD (NCRAD) to make available data and samples makes NIAGADS essential to the scientific community's achievement of the National Alzheimer's Project Act's (NAPA) research goal to discover therapeutic targets for the treatment and prevention of AD by the year 2025. **Methods:** Since 2012, NIAGADS has been supported by National Institute on Aging (NIA) under a cooperative agreement (U24 AG041689). This agreement expanded the NIAGADS storage and data sharing capacities for large-scale sequencing projects. All data derived from NIA funded AD genetics studies are expected to be deposited at NIAGADS or another NIA approved site. NIAGADS has partnered with the database of Genotypes and Phenotypes (dbGaP) and the Sequencing Read Archive (SRA) in this effort. In order to facilitate research, secondary data, including GWAS summary statistics and imputation data, as well as deep phenotypes, have expanded the existing ADGC collection. **Summary of Results:** As of June 2016, NIAGADS houses 37 datasets with >54k subjects and over 30 billion genotypes. With the completion of the Discovery Phase of ADSP, qualified investigators can retrieve sequencing data with ease and flexibility using the ADSP website and data portal (collaboration with dbGaP/SRA). ADSP generated sequencing data of >12,000 subjects and is currently selecting ~3000 additional subjects for WGS follow-up; BAMs and quality controlled VCF files are available through the ADSP portal and dbGaP (https://www.niagads.org/adsp/content/acknowledgement-statement). The redesigned NIAGADS Genomics Database provides a searchable annotation resource that links public NIAGADS resources to AD-relevant sequence features and genome-wide annotations. NIAGADS is a rich resource for AD researchers to utilize; datasets, guidelines, and new features are available on our website at https://www.niagads.org.

Genomic signatures in bone-marrow mesenchymal stem cells differ by disease course in Multiple Sclerosis. *P. Wilkinson[1], M. Cameron[1,3], S.M. Planchon[2], J.A. Cohen[2], F.B.S. Briggs[1,3].* 1) Department of Epidemiology and Biostatistics, School of Medicine, Case Western Reserve University, Cleveland, OH; 2) The Mellen Center for Multiple Sclerosis Treatment and Research, Cleveland Clinic, Cleveland, OH; 3) Institute for Computational Biology, Case Western Reserve University, Cleveland, OH.

Background: It is hypothesized that failures in endogenous repair mechanisms may mediate the transition from relapsing remitting (RR) to secondary progressive (SP) disease course in multiple sclerosis (MS) patients. This has precipitated efforts to explore several types of stem cells as experimental therapeutics. Adult mesenchymal stem cells (MSCs), including bone marrow (BM) MSCs, are immunomodulatory and neuroprotective. We hypothesize that these process are dysregulated/diminished in BM-MSCs of SP vs RRMS patients. **Methods:** BM-MSCs were collected, isolated and cultured using standard procedures. Cells collected at passage 1 from 3 non-Hispanic white RR cases and 3 race, age (+/- 5 yrs) and gender frequency-matched SP cases. RNA was isolated using the Qiagen AllPrep procedure. RNA-seq data was generated via an Illumina HiSeq 2500 (paired-end, 100 cycle, 50×10^6 mapped reads/sample); and were aligned using *STAR aligner* and counted with *HTSeq*. Genes with at least 1 count/10^6 for 3 subjects were analyzed using *EdgeR*. Pathway enrichment was evaluated using DAVID v6.7 of top 2% ranking (nominal p) under- (UE) and over-expressed (OE) genes in SP compared to RR patients. Global pathway activity of all genes was evaluated using gene set variation analysis (GSVA). **Results:** In BM-MSCs, multi-dimensional reduction differentiated SP from RR patients. Genes involved in axon guidance (fold enrichment (FE)=7.6; p=0.0004) and dopamine signaling (FE=5.1; p=0.007) were UE in SP vs RR patients. OE genes were involved in arachidonic acid metabolism (FE=9.3, p=0.0002). Globally, the activity in several pathways and processes differed between SP and RRMS, including: neurotransmitter activity (p=0.001), interleukin receptor activity (p=0.003), arachidonic acid metabolism (p=0.009), synaptic regulation (p=0.009) and antigen processing and presentation (p=0.02). **Conclusions and Ongoing analyses:** These results demonstrate that both immunomodulatory and neuroprotective mechanisms have differential activity across RR and SPMS; particularly under-expression of genes involved in neuronal process in SPMS. We also hypothesize there may be shared genomic signatures between BM-MSCs and PBMCs of MS patients. Analyses of RR/SP PBMCs from the same subjects are underway, including a weighted gene co-expression network analysis aimed to identify overlapping gene co-expression modules across the two tissue types to reveal higher order transcriptomic organization.

1686F

Identification of novel genetic risk factors in sporadic ALS using discordant monozygotic twins. *G.H.P. Tazelaar[1], W. van Rheenen[1], M. Seelen[1], M. Moisse[2], P. Hop[1], R.L. McLaughlin[3], A. Vajda[3], C. Neuwirth[4], M. Weber[4], V. Silani[5], A. Chio[6], M. de Carvalho[7], J.S. Mora Pardina[8], J.M. Ravits[9], O. Hardiman[10], P.M. Amyotrophic lateral sclerosis (ALS) is a fast progressive and lethal neurodegenerative disease with a lifetime risk of 1 in 400. Next-generation sequencing of pedigrees and Genome-wide association studies (GWAS) have shown to be successful tools in identifying genetic risk factors in ALS. However, especially in the case of sporadic ALS, where there are no other affected family members, these known factors only partially explain the genetic contribution as estimated by ALS concordant and discordant twin studies. This discrepancy could possibly be attributed to rare genetic variants that might be caused by *de novo* mutations. In our study, we set out to identify novel (epi)genetic risk factors for sporadic ALS by analyzing the methylation patterns and genomic DNA from whole-blood of 21 monozygotic twin pairs discordant for ALS. In order to discriminate between early and late postzygotic mutations, we additionally analyzed DNA obtained from fibroblasts and saliva in a subset of twins. So far, we have investigated the single nucleotide variants (SNVs) using whole genome sequencing. To increase the chance of detecting *de novo* SNVs, we used three different variant calling algorithms and build a custom-filtering pipeline to obtain the most reliable discordant variants. In total we identified 149,388 SNVs of which 129,387 were eligible for further validation on a custom Axiom Genotyping Array. Preliminary results of this first step validation show a mean of 3.0 (SD 3.2) *de novo* SNVs per individual. This post-zygotic mutation rate however, was determined after exclusion of three outliers. One non-ALS twin had 690 probable *de novo* mutations, which might be attributed to its comorbidity, namely leukemia. Notably, the other two outliers were both ALS affected twins, with 42 and 77 probable *de novo* SNVs. After exclusion of the twin with leukemia, we saw no significant difference in *de novo* mutation rate between ALS and controls, but we did find a significant inequality of variance (p=0.02, Levene's test). Additionally, analysis of mosaicism in one of the two ALS outliers indicates that at least 5 of the 42 SNVs are shared between blood, saliva and fibroblasts, pointing towards early postzygotic mutations. Further validation and analysis is required to confirm these *de novo* mutations and determine their possible significance as a genetic risk factor for ALS.

Are *in silico* pathogenicity tools reliable indicators of variant pathogenicity? A retrospective look at data from 46 *de novo* pathogenic missense variants identified in a clinical diagnostic setting. *C. Stanley, H. Hornung, D. Pineda-Alvarez, A. Zare, T. Foss, J. Warner, D. Smith.* Chief Director, Clinical Genomics, Courtagen Life Sciences Inc, Woburn, MA.

Next generation sequencing identifies a large number of sequence variants, which are evaluated by clinical geneticists for likelihood to cause disease based on evidence-based guidelines issued by the American College of Medical Genetics and Genomics in 2015. *In silico* prediction tools are utilized, within these standards, as a supporting line of evidence for predicting variant pathogenicity, albeit a lower-weighted line of supporting evidence. We evaluated four prediction tools (Mutation Assessor, PolyPhen2, MutationTaster and SIFT) to test *de novo* pathogenic and likely pathogenic missense variants identified in patient samples submitted for evaluation with our large epilepsy gene panels. The variants identified were in genes associated with diseases that correlated to the patient's clinical phenotype. The variants were also absent from control populations and, therefore, were not used as training sets for the development of *in silico* tools. Our results indicated that the majority (96%) of pathogenic *de novo* variants identified were considered deleterious by *in silico* prediction tools and support their utilization as a line of evidence for variant classification.

1688T

Scalable map-free typing of clinical and structural variants across heterogeneous whole-genome sequence data. *W. Salerno[1], S.N. Shekar[2], L. Herta[2], W. Nassar[1], A. English[1], A. Mangubat[2], J. Bruestle[2], E. Boerwinkle[1], R.A. Gibbs[1].* 1) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 2) Spiral Genetics, Seattle, WA.

The complexity and variety of SVs pose specific challenges to clinical whole genome applications, which require high sensitivity, low false discovery rates, rapid turnaround time and the ability to distinguish de novo and shared variation. Here we present a compressed read data format (Biograph) that allows for rapid and scalable typing of whole-genome variation. In this format, read data can be directly queried by locally assembling full reads across breakpoints, fusion junctions and novel insertions. Agnostic to reference genomes, Biograph data avoid mapping-based artifacts and thus mitigates the effects of heterogenous insert-size distributions, read length and coverage. PCA of SV calls generated from from three distinct sequencing and mapping protocols across an aggregate 578 samples and 11 detection methods reveals clear grouping by protocol and even protocol-specific substructure. Three samples were each subject to all three protocols, and on average 32% of SV calls previously described are shared across protocol replicates. Analysis of the same read data in the Biograph format shows that >96% of 30-mers occurring in at least 4 reads were common to protocol replicates. Position-based SV typing of 7393 events returns consistent breakpoints across protocol replicates for all positions with at least 4x coverage. The Biograph typing of all 7393 events across 9 individuals (66,537 events in total) was performed in less than 21 minutes. To examine sequence-based variant typing, we populated the GRCh38 FASTA with 11,511 ClinVar SNVs and simulated a 30x WGS FASTQ with ART Illumina, which was then converted to Biograph format in less than 20 hours on a 32-core machine. The Biograph data were queried by assembling reads over the SNVs, typing all the events in less than 2 minutes. Efforts are underway to spike-in all ClinVar variants, including SVs, into a single "worst genome" to generate all possible variant characteristic sequences. Biograph data can be batched across samples, with per-sample footprint scales less than linearly with number of samples. The aggregate read data for 125 30x whole-genomes was ~300 GB: <2 GB per sample of sample-specific information and ~100 GB of aggregate variant information. This lightweight multi-sample "sequence set" provides implicit anonymization and rapid whole-genome variant typing for groups of samples, suggesting a natural way for clinical sites to compare patient variation profiles without raising privacy concerns.

Genome wide expression analysis indicates the role of molecular binding genes in tumor-induced epilepsy. *M.R. Rajeswari, H.N. Singh.* Biochemistry, All India institute Of Medical Sciences, New Delhi, Delhi, India.

Epilepsy is a common cause of morbidity affecting approximately one third of patients with primary brain tumors. However, the disease mechanisms of tumor induced epilepsy are barely explored. The alteration in peritumoral microenvironments might play a crucial role in inducing epilepsy by means of gene dysregulation. Therefore, we have performed genome-wide gene expression study to find altered genes in the tumor induced epileptic human brain cells. The microarray dataset GSE32534 (http://www.ncbi.nlm.nih.gov/geo/query/acc.cgi?acc=GSE32534) was retrieved from the GEO database, which includes mRNA expression data of peritumoral cortex tissue from 5-seizure vs. 5-non-seizure low grade brain tumor patients. The bioconductor "affy" package was used to calculate mRNA expression and further pair-wise t-test was applied to find the significant differential expression (p<0.05). Several genes were found to be altered in the tumor induced epilepsy, however, only seventeen genes (LRRN4CL; CP; MIR143HG; FCGR2A; COL3A1; MGP; SP100; CYTH1; IL1R1; DKK1; PHLDA2; COL14A1; CFH; LYZ; SOAT1; CNKSR3; EXPH5) were observed with 1.5 fold expression change and showed a high concordance. Gene ontology analysis showed that significant portions of the differentially expressed genes functioned as molecular binding including enzyme binding and transcription factor binding and were found to be involved with the epilepsy disease mechanisms. In conclusion, our study showed that dysregulation of gene expression in the peritumoral tissues may be one of the major mechanisms of brain tumor induced-epilepsy. However, further validations are required and identified genes might be helpful to understand the disease etiology leading to management of tumor induced epilepsy.

1690W

SMRT sequencing of STR expansions in SCA31 brain disease. *W. Qu[1], H. Ishiura[2], K. Doi[1], D. Hsu[3], J. Yoshimura[1], J. Mitusi[2], M. Boitano[3], J. Korlach[3], S. Tsuji[2], S. Morishita[1].* 1) Department of Computational Biology and Medical Sciences, Graduate School of Frontier Sciences, The University of Tokyo, Chiba, 277-8583, Japan; 2) Department of Neurology, Graduate School of Medicine, The University of Tokyo, Tokyo, 113-8655, Japan; 3) Pacific Biosciences, Menlo Park, CA 94025, USA.

Expansions of short tandem repeats (STRs), DNA repeats of 2-6 nt, have been reported to be associated with some brain diseases. We studied a well-characterized sampleknown example, spinocerebellar ataxia type 31 (SCA31) that has ~3 kbp expansions of three STR types (TAGAA, TGGAA, and TAAAATAGAA) in an intron of genes BEAN1 and TK2 in human chromosome 16. To determine the sequences of the focal STR in SCA31 samples, we amplified the STR and performed SMRT sequencing in 2014 and 2016, independently. As the performance of PacBio RS II has remarkably improved for the last couple of years, we could obtain a sufficient number of ~5 kbp subreads that covered the STR regions of length ~3 kbp in six SCA31 samples. We assembled these long subreads into a contig with the STR and determined the sequences of the STR regions in the six individuals. Most of the STR is heterozygous and is found in one of the two alleles. To confirm this property, we calculated the length of an STR occurrence in each raw subread and generated the length distribution of STR occurrences in raw subreads. If the STR is heterozygous, we should detect one peak in the distribution that represents long STR occurrences in one allele and another peak that indicates short, normal STR occurrences in the other allele. Indeed, we observed such bimodal peaks in five of the six individuals. In the remaining one sample, the STR was homozygous because a single peak was identified in the distribution. Overall, our analysis demonstrates that SMRT sequencing enables to sequence long STR occurrences and determine their heterozygosity, simultaneously.

1691T

A multikernel approach for associating statistical interactions between genomic layers to phenotypes. *B. Ng[1], C. White[2], H.U. Klein[2], J. Xu[2], E. Patrick[2], L. Chibnik[2], C. Gaiteri[3], D.A. Bennett[3], P.L. De Jager[2], S. Mostafavi[1].* 1) Statistics, University of British Columbia, Vancouver, BC; 2) Neurology, Harvard Medical School, Boston, MA; 3) Neurological Science, RUSH University, Chicago, IL.

Introduction: The availability of large-scale multi-omic data provides a unique opportunity to investigate how interactions (i.e. epistasis) between various regulatory mechanisms give rise to complex phenotypes. However, majority of existing analysis approaches are ill-suited for studying the statistical interactions between different types of genomic measurements in a genome-wide manner. The classical approach of applying an univariate test to assess the association between each possible pair of genomic variables in relation to a phenotype would result in an explosion in the number of tested hypotheses. Increasing statistical power via devising new dimension reduction strategies that retain biological interpretability is thus crucial. Methods: We present here a multikernel machine (MKM) approach for associating the interactions between genomic layers and phenotypes. Given a set of variables, e.g. a set of SNPs within a predefined genomic window, the idea behind KM is to first estimate the similarity between all subject pairs based on their SNP patterns (alleles) in the given window. Variable sets with similarity kernels that significantly explain the variance in the observed phenotype are declared as relevant. To model interactions between genomic layers, we draw on properties of the reproducing kernel Hilbert space. Specifically, an interaction kernel between e.g. SNP and methylation, can be built by taking the Hadamard product of their respective main effect kernels. We restrict each variable set to variables within a certain window from a gene to facilitate gene level interpretation. With this approach, the number of hypotheses effectively reduces to the number of genes, which substantially increases statistical power. Results: We applied MKM to data from the ROS/MAP studies, which comprise genotype, DNA methylation, and histone modification data derived from the dorsolateral prefrontal cortices of 400 Alzheimer's disease (AD) subjects. The subjects were also phenotyped for traits, such as cognitive decline, amploid beta, and tau. We focused on modeling the interactions between SNP and DNA methylation as well as SNP and histone modification. In addition to significant main effects of each data type, we identified a number of genes where only the interactions between SNP and a cis cellular trait were significantly associated with AD phenotypes. Our results thus demonstrate the importance of additionally examining the interactions between genomic layers.

1692F

Disease profiling with multi-omics data: An application in multiple sclerosis. *Y. Natanzon[1], S.L. Andersen[2], J.H. Winnike[3], S. Maichle[5], X. Zhang[6], K.J. Knagge[3], L.K. Newby[7], F.B. Briggs[1], S.G. Gregory[2,4].* 1) Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH; 2) Multiple Sclerosis Research Group, David H. Murdock Research Institute, Kannapolis, NC; 3) Analytical Sciences Laboratory, David H. Murdock Research Institute, Kannapolis, NC; 4) Duke Molecular Physiology Institute, Duke University, Durham, NC; 5) Duke Translational Research Institute, Duke University, Durham, NC; 6) Departments of Chemistry, Pharmacology & Toxicology, University of Louisville, Louisville, KY; 7) Division of Cardiovascular Medicine, Duke Clinical Research Institute, Duke University Medical Center, Durham, NC.

Multiple sclerosis (MS) is a complex neurodegenerative disease with variable pathoetiology. Understanding the genetic architecture underlying MS onset is critical to unraveling potential downstream drug targets. Genome-wide association studies have been successfully identified >120 MS risk variants, however, the functional mediating MS onset is not yet clear. Despite several studies investigating potential biological markers (biomarkers) for MS diagnosis, no biomarker or sets of biomarkers have been identified to have sufficient diagnostic accuracy. Among the available *omics* data for biomarker development, metabolites are biologically the closest to the disease state; however, metabolites are an inherently noisy data. The goals of our study are two-prong: 1) create a metabolomic profile that discriminates MS cases from healthy controls; 2) refine MS phenotype by effectively combining multi-*omics* data to reduce the genetic search space and generate a hypothesis of biological mechanisms contributing to MS onset. Data on 427 metabolites was generated on 109 individuals (54 drug-naïve MS cases with 55 age-, sex-, and race-matched controls) using GCxGC-MS, LC-MS and Lipidomic analysis of serum. Genome-wide expression data and genotyping of 25 GWAS-confirmed SNPs was also available in 13 males in the sample (6 cases and 7 controls). We first performed Orthogonal Partial Least Squares Discriminant Analysis (OPLS-DA) to select a metabolite set that best discriminates MS case status. OPSL-DA method captures the variability in the metabolites related to MS cases status while eliminating the variability unrelated to case status. The OPSL-DA model identified 136 metabolites that statistically significantly discriminated between cases and controls based on VIP Score of ≥ 1. We selected the top 50 metabolites and performed principal component analysis (PCA) for further dimension reduction. We performed an association between the three PCs and a genetic risk score compiled from the 25 known MS SNPs. We also performed an association between the PCs and the 364 differentially expressed genes between MS cases and controls. Our analysis was able to generate a MS metabolic profile using PCA. Metabolites clustered into functional groupings, of which several are relevant to MS pathogenesis, including neurotoxicity, immunomodulation, and oxidative stress. We observed several associations between the metabolic profile, differentially expressed genes and known MS SNPs.

1693W

Post-variant calling quality control (QC) pipeline and multi-pipeline genotype consensus caller for large-scale whole genome and whole exome sequencing studies. *J. Malamon[1], A.C Naj[2], M. Schmidt[3], B.N. Vardarajan[4], Y. Ma[5], D. Lancour[5], A. Kuzma[1], O. Valladares[1], L. Qu[1], H. Lin[1], E.R. Martin[3], L.-S. Wang[1], J.L. Haines[6], R. Mayeux[4], L.A. Farrer[7], M.A. Pericak-Vance[3], G.D. Schellenberg[1], Coordinating Center for Genetics and Genomics of Alzheimer's Disease.* 1) Department of Pathology and Laboratory Medicine, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA., Select a Country; 2) Department of Biostatistics and Epidemiology, Perelman School of Medicine, University of Pennsylvania Philadelphia, PA, USA; 3) John P. Hussman Institute for Human Genomics, Miller School of Medicine, University of Miami, Miami, FL, USA; 4) Gertrude H. Sergievsky Center, College of Physicians and Surgeons, Columbia University, New York, NY, USA; 5) Biomedical Genetics Program, School of Medicine, Boston University, Boston, MA, USA; 6) Department of Epidemiology and Biostatistics, School of Medicine, Case Western Reserve University, Cleveland, OH, USA; 7) Departments of Medicine, Neurology, Ophthalmology, Genetics & Genomics, Epidemiology, and Biostatistics, School of Medicine, Boston University, Boston, MA, USA.

While pipelines exist for quality control (QC) of upstream processing of whole genome sequencing (WGS) and whole exome sequencing (WES) data, little work has been done to develop and implement QC on the downstream genotype data. Also, while systematic integration of genotype calls from multiple pipelines ensures improved overall genotype quality, limited progress has been made in developing approaches to implement "consensus calling". To analyze WGS of 578 family samples and WES of 10,692 case/control samples from the Alzheimer's Disease Sequencing Project (ADSP), structured protocols were developed and implemented for post-variant calling QC and consensus calling, and will be implemented on multiple replication sequence datasets. To provide a tool for implementing QC and consensus calling on these datasets, the Coordinating Center for Genetics and Genomics of Alzheimer's Disease (CGAD) set out to construct a pipeline based on ADSP QC/consensus calling best practices extensible to other large-scale sequencing studies. The CGAD pipeline applies QC apropos of multiple calling pipelines accounting for center-specific effects. After initial sequencing center-recommended filtering is applied, additional variant-level metrics (e.g., call rate, average read depth) are computed across all subjects for each bi-allelic single nucleotide variant or insertion-deletion, and filters specified *a priori* are applied to exclude low-quality variants. Subsequent sample-level QC examines within-subject distributions of metrics (e.g., average read depth, Ti/Tv ratio), and outliers (by center or ethnic group), and based on genome-wide sample summaries, potential low quality samples are excluded. The resulting set of QCed calls from each pipeline are then combined via a consensus protocol to integrate (a) genotypes concordant between pipelines and (b) high quality genotypes unique to one caller. For consensus calling, quality metrics such as "GQ" from GATK are used to establish additional genotype-specific filters on pipeline-unique variants. The pipeline generates fully-QCed/consensus-called genotypes in multiple formats, as well as extensive annotation of variants and genotypes both passing and failing the QC/consensus calling steps. The pipeline is currently in beta-testing, and pipeline design and results of the implementation of the pipeline on both ADSP Discovery and preliminary ADSP replication datasets will be presented.

1694T

Prioritization of ASD-associated genes by variant annotation reveals trends in rare and common variant discovery. *E. Larsen[1], I. Menashe[2], W. Pereanu[1], S. Banerjee-Basu[1].* 1) MindSpec Inc., McLean, VA; 2) Ben-Gurion University of the Negev, Beer-Sheva, Israel.

The search for genetic factors underlying autism spectrum disorders (ASD) has led to the identification of hundreds of genes containing thousands of variants that differ in their mode of inheritance, effect size, frequency and function. These data are summarized in our Autism Database (AutDB; also known as SFARI Gene), an open-access database for genetic variations associated with ASD. However, a major challenge in the field of ASD biology involves assessing the collective genetic evidence in an unbiased, systematic manner. We previously described a novel scoring algorithm for the prioritization of candidate genes based on the cumulative strength of evidence from each ASD-associated variant in curated in AutDB. Under our algorithm, each individual variant is manually annotated with multiple attributes extracted from the original report, followed by score assignment using a set of standardized scoring parameters that were summed up to yield a single score for each gene in the database. Here, we present the results using an updated dataset of ASD-associated rare and common genetic variants. A total of 534 annotated research articles were analyzed to generate a dataset of 3283 ASD-associated rare variants and 840 ASD-associated common variants distributed across 654 candidate genes (March 30, 2016 data freeze). There were remarkable variations in gene scores resulting in a log-normal distribution of scores with a mean gene score of 16.93 ± 32.68. We were able to identify a collection of high confidence candidate genes with scores deviating more than two standard deviations (SDs) from the mean score of all genes, with very high scores for eight genes (*ADNP*, *CHD8*, *DYRK1A*, *POGZ*, *PTEN*, *SCN2A*, *SHANK3*, and *SYNGAP1*). The gene scores generated by our approach were once again significantly correlated with those in the SFARI Gene scoring module, indicating a strong agreement between gene prioritization using our approach and the expert-mediated SFARI Gene scoring initiative. Finally, we performed a time course analysis of ASD-associated variants and identified important trends in rare and common variant discovery. Altogether, our scoring algorithm provides a framework for assessment of diverse types of genetic variants associated with ASD that are likely to be important for defining the genetic risk architecture in ASD.

The contribution of short tandem repeats to *de novo* **variation.** *T. Willems[1,2], D. Zielinski[2], M. Gymrek[3], Y. Erlich[2,4,5].* 1) Computational and Systems Biology, Massachusetts Institute of Technology, Cambridge, MA; 2) New York Genome Center, New York, NY; 3) Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, MA; 4) Department of Computer Science, Fu Foundation School of Engineering, Columbia University, New York, NY; 5) Center for Computational Biology and Bioinformatics, Columbia University, New York, NY.

Recent studies have obtained genome-wide estimates of the number of de novo mutations for nearly every class of genetic variant, ranging from SNPs and indels to copy number variants. Despite these results, no such estimate exists for short tandem repeats (STRs), highly repetitive loci that mutate orders of magnitude more rapidly than most genetic elements. STRs have been implicated in over 40 Mendelian diseases and evidence of their involvement in complex traits continues to accumulate, but current bioinformatics tools are too error-prone to reliably identify de novo STR mutations. To address this issue, we developed HipSTR, a state-of-the-art STR variant caller. HipSTR learns an individual error model for each STR in the genome and uses a specialized hidden Markov model to determine the STR's sequence and size. Using gold standard datasets, we demonstrate that this approach generates substantially more accurate STR genotypes than all existing variant callers, include GATK Haplotype Caller, Platypus, freebayes and various STR-specific tools. Empowered by this improved accuracy, we used HipSTR and datasets from the Illumina Platinum Genomes and Genome in a Bottle projects to genotype STRs in a deeply sequenced trio. This analysis uncovered hundreds of putative de novo STR mutations, 85% of which replicated in an orthogonal dataset. We selected a handful of the replicated de novo mutations for Sanger sequencing and in all cases, the de novo mutation experimentally validated, illustrating the extreme precision and accuracy of HipSTR. Lastly, to characterize de novo STR variation on a population scale, we used HipSTR to analyze high-coverage whole-genome sequencing data for 500 quads in which one child has been diagnosed with autism. Collectively, our work highlights the substantial contribution of STRs to de novo variation in healthy individuals and in individuals with autism spectrum disorder.

Convergent biomolecular mechanisms between bipolar disorder and schizophrenia revealed by multiscale modeling of data from GWAS, eQTL, GO and ENCODE. *J. Berghout[1,2,3], H. Li[1,2,3], I. Achour[1,2,3], J. Li[1,2,3], L.L. Pesce[4,5], I. Foster[4,6], Y.A. Lussier[1,2,3,4,7].* 1) Center for Biomedical Informatics and Biostatistics, The University of Arizona, Tucson, AZ, USA; 2) BIO5 Institute, The University of Arizona, Tucson, AZ, USA; 3) Department of Medicine, The University of Arizona, Tucson, AZ, USA; 4) Argonne National Laboratory and University of Chicago, Chicago, IL, USA; 5) Center for Genetic Medicine, Northwestern University Feinberg School of Medicine, Chicago, IL, USA; 6) Department of Computer Science, University of Chicago, Chicago, IL, USA; 7) Institute for Genomics and Systems Biology, Argonne National Laboratory and University of Illinois at Chicago, Chicago, IL, USA.

Schizophrenia and bipolar disorder are highly comorbid conditions with strong evidence for shared genetic etiology underlying much of the heritable disease risk. We computationally modeled high dimensional data from genome-wide association studies (GWAS), expression quantitative trait loci (eQTL), gene product functional annotations (GO), and high-throughput locus functional annotations (ChIP-Seq, ENCODE project) to explore biological similarity and convergence between all possible pairs of GWAS polymorphisms associated with either or both diseases. This strategy allowed us to uncover high confidence and recurrent biological signals from intergenic SNPs as well as those within candidate gene regions. SNP pairs where both polymorphisms had been mapped to schizophrenia alone reproduced a strong antigen presenting and immune/inflammatory process signal driven by the Major Histocompatibility Locus (MHC: Chr 6: 29Mb-33Mb) that was not found in bipolar disorder. However, most other biological convergence was found between the two diseases, or for SNP pairs that were mapped in comorbid samples. This underlines the molecular and mechanistic similarity for bipolar disorder and schizophrenia even in the absence of GWAS positional overlap. 384 SNP-SNP pairs (involving 66 unique SNPs) had statistically significant evidence that they each influenced a common biological process or were each bound by the same transcription factor. 16 pairs of SNPs were found to regulate the expression of at least one of the same mRNA transcripts via eQTL, including four SNP-SNP pairs mapped across two different chromosomes and acting in *trans* (regulating expression of *RAB11FIP4*, *MED29* and *HIST1H2BN*). Common biological process annotations to both diseases included additional immune responses, chromatin architecture and histone biology, with overrepresentation of binding by the transcriptional repressor *CTCF* and chromatin remodeling factor *FOXA1*. The multiomic approach used in this case study is extensible to other diseases and syndromes, with a data management system currently being built to mine preprocessed results from 400 additional GWAS traits. .

CalibrE: Data-driven methodology for the calibration and comparison of RNA-seq data across tissues and cell types. *A.E. Byrnes[1,2,3], S. Lodato[3,4], J.M. Bloom[1,2,3], A. Bloemendal[1,2,3], C. Seed[1,2,3], P. Arlotta[3,4], B.M. Neale[1,2,3].* 1) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA; 2) Medical and Population Genetics Program, The Broad Institute, Cambridge, MA; 3) The Stanley Center for Pyschiatric Reseach, The Broad Institute, Cambridge, MA; 4) Harvard Stem Cell Institute, Harvard University, Cambridge, MA.

RNA-seq is emerging as a powerful resource to aid in the interpretation of GWAS and sequencing studies. In particular, evaluating expression of GWAS genes may yield insights into which cell types and tissues are important in pathogenesis. However, a central impediment to realizing the value of RNA-seq data is that the variability in transcriptional landscape across different cell and tissue types is not well estimated and by extension controlled for in analysis. We present a data-driven statistical method for calibration and comparison of RNA-seq data from multiple cell- or tissue- types in order to correct for possible differences in overall transcription rate and transcriptional diversity. Our method, CalibrE, is based on the simple assertion that genes co-expressed as a coherent unit can be used to calibrate across tissue types; these genes must therefore have relatively constant ratios of expression to each other and so we use weighted graphical modeling to find such clusters for calibration. In both the Genotype Tissue Expression (GTEx) and Brainspan data, we find a cluster of genes encoding ribosomal components that are consistently co-expressed and as a consequence can be used to calibrate the overall transcriptional landscape of cells and tissues. We contrasted CalibrE with RPKM and TMM by assessing the rank-based correlation between each normalization approach on RNA-seq data with conventionally normalized expression microarray data on the same samples. We show that on average, CalibrE normalization correlates most strongly with the microarray data, which is less subject to sampling inherent in RNA-seq analysis. Ultimately, we aim to use RNA-seq data to prioritize cell types and tissues based on the relative abundance of expression of genes identified by genetic studies. We have performed CalibrE on a set of previously unpublished RNA-seq data from single neuron subtypes, at a variety of time points, isolated from mice. From these analyses, we see a clear enrichment of genes identified as having two or more loss-of-function (LOF) *de novo* mutations in a study of Autism Spectrum Disorder (ASD) in prenatal cerebral projection neurons, compared to other neuron types. This provides novel insights into the etiology and developement of ASD.

1698F

Genotyping and visualizing copy number variation from whole genome sequencing data. *J.T. Glessner[1,2], R.L. Collins[1,3], M.R. Stone[1], H. Brand[1,2], M.E. Talkowski[1,2,4,5].* 1) Psychiatric and Neurodevelopmental Genetics Unit, Molecular Neurogenetics Unit, Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA 02114, USA; 2) Department of Neurology, Harvard Medical School, Boston, MA 02115, USA; 3) Program in Bioinformatics and Integrative Genomics, Harvard Medical School, Boston, MA 02115, USA; 4) Program in Medical and Population Genetics, Broad Institute, Cambridge, MA 02141, USA; 5) Department of Psychiatry, Massachusetts General Hospital and Harvard Medical School, Boston, MA 02114, USA.

Copy number variation (CNV) is a highly penetrant source of genetic risk for human disease. Despite recent progress, routine detection methods remain limited for CNVs below the resolution of a traditional chromosomal microarray (<40kb), a subset encompassing >95% of all CNVs in an average human genome. Whole-genome sequencing (WGS) is the currently most sensitive approach for CNV discovery but many current algorithms suffer from low sensitivity and/or specificity. To refine and validate CNV signatures from WGS data *in silico*, we devised a CNV genotyping algorithm extensible to biallelic, complex, and multiallelic CNVs (i.e. copy number states >3 at a single locus). When evaluating a putative CNV site, our genotyping algorithm can be executed in two complementary modes. The first is designed for characterization of multiallelic CNV sites and uses c-means fuzzy clustering to yield sample-based copy state predictions and genotype probabilities. When applying this method to putative CNV calls from a WGS dataset of 160 human samples, we observed evidence that up to 23% of duplication loci may be multiallelic, which is a blind spot for most existing CNV algorithms. The second mode evaluates biallelic CNV sites using a unidirectional t-test with p-value permutation to evaluate the difference between a subset of samples predicted to harbor a CNV at the specified locus versus those samples predicted not to harbor the CNV. This test is modified for singleton CNVs where discriminatory power is insufficient (power<0.8). To assess the performance of our biallelic CNV genotyping algorithm, we used large-insert jumping library sequencing and chromosomal microarray as validation datasets for the WGS cohort of 160 individuals: upon incorporating CNV size, allele frequency, and inheritance profile as covariates, we estimated a 94% sensitivity and 95% specificity. Finally, we developed two approaches for CNV visualization from WGS data, the first output directly by our genotyping algorithm and the second, CNView, which is a stand-alone utility for CNV scoring, annotation, and normalized depth visualization across populations. Collectively, these tools provide an improved framework for distilling the massive number of candidate WGS CNV sites called by many detection algorithms to a reasonable number for automated visualization and molecular validation, and represent possible valuable additions to WGS analysis pipelines deployed for basic research and clinical applications.

1699W

The PhenX toolkit: Standard measures and bioinformatics for collaborative research. *T. Hendershot[1], H. Pan[1], W. Huggins[1], M. Phillips[1], S. Hwang[1], Y. Qin[1], V. Bakalov[1], J. Levy[1], D. Nettles[1], D. Maiese[1], R. Boyles[1], S.M. Dolan[2], L. Dixon[3], G.E. Swan[4], J.J. Prochaska[4], C.A. McCarty[5], M.L. Marazita[6], E.M. Ramos[7], C.M. Hamilton[1].* 1) RTI International, Research Triangle Park, NC; 2) Albert Einstein College of Medicine / Montefiore Medical Center, Bronx, NY; 3) Columbia University Medical Center, New York, NY; 4) Stanford University, Stanford, CA; 5) Essentia Institute of Rural Health, Duluth, MN; 6) University of Pittsburgh, Pittsburgh, PA; 7) National Human Genome Research Institute, Bethesda, MD.

The Web-based PhenX Toolkit, https://www.phenxtoolkit.org/, is a catalog of standard measures to facilitate collaborative biomedical research. Use of PhenX (consensus measures for *Phen*otypes and e*X*posures) measures helps ensure that phenotype and exposure data is collected using consistent methodology. Consistent data collection improves data quality and can enable data comparability across multiple sites in large cohorts (e.g., the Precision Medicine Initiative), facilitate combining data to validate clinically actionable variants, increase statistical power (e.g., studies of rare genetic conditions or gene-environment interactions), or compare treatment and outcomes among patients. We will present new tools that link PhenX to major informatics resources, including the database of Genotypes and Phenotypes (dbGaP) and Research Electronic Data Capture (REDCap). To help users find comparable data, a team of curators is mapping the ~22,000 PhenX variables to all 690 studies in dbGaP. We will present the process, results, and implications of this mapping effort. We will also present PhenX compatibility with the REDCap study design tool. REDCap modules are available for all protocols in the PhenX Toolkit providing an easy way to add PhenX data collection protocols directly to REDCap projects. REDCap is being used by more than 257,000 projects across numerous research areas, and is available for use on mobile devices. The PhenX Toolkit currently includes 475 measures from 23 research domains, with additional depth for Substance Abuse and Addiction, Mental Health, Tobacco Regulatory, and Sickle Cell Disease research. We will present new measures for Pregnancy and Early Psychosis (clinical and translational), as well as Core measures for Tobacco Regulatory Research studies. For each measure, the Toolkit provides detailed instructions (e.g., required training and equipment), features (e.g., Spanish language versions), and bioinformatics support (e.g., data dictionaries, REDCap compatible modules) to facilitate implementation and data analysis. Through these efforts, the PhenX Toolkit is evolving to increase content, utility and help establish connections among major informatics resources. *Funding provided by a Genomic Resource Grant (U41 HG007050) from NHGRI, with co-funding from NIDA. Supplemental funding is provided by NIMH, NHLBI, and the NIH ODP TRSP.*.

Substantial contribution of non-coding regulatory mutations to autism and identification of risk genes from whole-genome sequencing data of affected families. *Y. Liu[1], J. Li[2], E.A. Cicek[3,4], N. Knoblauch[1], Y. Jiang[2], R. Muhle[7], Y. Wang[5], E. Geller[8], J. Wu[2,6], J. Noonan[7], Z. Sun[2], X. He[1].* 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) Beijing Institutes of Life Science, Chinese Academy of Sciences, Beijing, China; 3) Lane Center for Computational Biology, School of Computer Science, Carnegie Mellon University, Pittsburgh, PA; 4) Computer Engineering Department, Bilkent University, Ankara, Turkey; 5) The institute of Psychology, Chinese Academy of Sciences, Beijing 100101, China; 6) Institute of Genomic Medicine, Wenzhou University, Wenzhou, China; 7) Department of Genetics, Yale School of Medicine, New Haven, Connecticut; 8) Department of Pathology and Laboratory Medicine, Perelman School of Medicine, University of Pennsylvania, Philadelphia, Pennsylvania.

Analyzing de novo mutations in protein coding genes from whole-exome sequencing (WES) data has emerged as a powerful tool for mapping risk genes of autism spectrum disorder (ASD). The impact of non-coding mutations in ASD, however, has been largely unknown. This represents a large gap in our understanding of genetics of ASD, as the majority of GWAS hits in a range of disorders fall into non-coding regions. To address this question, we performed meta-analysis of de novo mutations from whole-genome sequencing (WGS) data, consisting of more than 300 affected families. We found that DNMs are enriched within brain regulatory enhancers near putative autism genes and evolutionarily constrained genes. We estimate that de novo non-coding mutations make a larger contribution to the risk of autism than coding mutations, explaining about 50-70% of ASD genetic risk attributable to de novo mutations. By combining information of non-coding DNMs with published WES data, we identified five new ASD risk genes at a false discovery rate (FDR) < 0.1, and 12 at FDR < 0.2. We also show by simulation that WGS outperforms WES in power at comparable sequencing cost. Take together, our results demonstrate the pathogenic contribution of non-coding DNMs in ASD etiology and highlight some promising ASD risk genes. The analytic tools we provided in this study, for estimating contribution of de novo mutations to disease risk, for mapping susceptibility genes, and for power analysis, are applicable to any WGS studies on de novo mutations.

1701F

Improved detection and analysis of retrotransposon insertion variation in a family quartet including monozygotic twins discordant for schizophrenia. *M.E.O. Locke[1], C.A. Castellani[3], C.W. Gendron[2], S.M. Singh[2], M.J. Daley[1,2].* 1) Department of Computer Science, The University of Western Ontario, London, Canada; 2) Department of Biology, The University of Western Ontario, London, Canada; 3) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD.

Statement of Purpose Retrotransposons are a class of mobile genetic elements whose activity in germline and somatic cells has been linked to numerous phenotypes in humans. Studies have indicated that mobile element insertions(MEIs) of retrotransposon LINE1 play a role in central nervous system development and - along with another class of retrotransposon, human endogenous retroviruses (HERVs) - have been implicated in psychiatric disorders including schizophrenia. Existing next-generation-sequencing approaches to find MEI sites first align reads to the reference genome then leverage information from paired reads to find those that have one "anchor" read aligning to the reference genome and the other read aligning to a mobile element of interest (MEOI). These methods are limited by the requirement of aligning to the reference sequence first, which may miss reads that are not near-exact matches to the human reference genome used. We aim to improve the sensitivity of MEOI context detection to better assess both the context and quantity of MEOIs in a given genome dataset. Methods Used We have developed a novel approach to find sequence contexts flanking an MEOI by flipping the anchor read from the reference genome to the MEOI itself. This is accomplished by filtering all raw reads into those matching MEOIs and then performing reference-free de novo assembly of any read extending beyond the end of an MEOI. This method is highly sensitive, as it can find flanking regions not in the reference genome sequence. We have also developed a method to find the relative abundance of MEOIs, which uses read depth tempered by k-mer uniqueness. We used these methods to compare whole genome sequencing data generated by Complete Genomics of two sets of MZ twins discordant for schizophrenia and the parents of one set. This approach allowed us to measure differences in the quantity and context of LINE1s and HERVs. Results The software developed is applicable to any dataset from Complete Genomics including raw reads, and is extensible to any DNA sequence of interest larger than approximately 500bp. The software is written in C++ using the SeqAn library, and is available as open source. We have found that not all LINE and HERV locations are explained by Mendelian inheritance, and that there are significant differences in LINE1 and HERV sites between MZ twins that may explain their discordance for neurodevelopmental disorders including schizophrenia.

1702W

Integrative analysis of cell-type specific genomic annotations recovers complex physiological relationships between tissues. *R. Powles[1], Q. Lu[2], Y. Lu[3], B. Li[2], Q. Wang[1], J. He[4], H. Zhao[1,2,5].* 1) Program of Computational Biology and Bioinformatics, Yale University, New Haven, CT; 2) Department of Biostatistics, Yale School of Public Health, New Haven, CT; 3) Department of Immunobiology, Yale School of Medicine, New Haven, CT; 4) Division of Cardiovascular Medicine, Department of Internal Medicine, Yale School of Medicine, New Haven, CT; 5) VA Cooperative Studies Program Coordinating Center, West Haven, CT.

Functional annotation of the human genome has been a constant pursuit of genomics consortia with an additional emphasis on tissue- and cell type-specificity in recent years. While current methods can offer some localization of functionality to broader systems (e.g., nervous or circulatory), many human diseases are malignancies of only a few tissues. To improve upon the resolution and specificity of current functional annotation methods, we use an unsupervised learning framework to consider an expansive collection of high-throughput annotations from Roadmap Epigenomics, including DNA methylation and chromatin modification integrated from 7 histone marks. Instead of focusing on a handful of broad systems, our model considers over 100 different cell and tissue types separately. We identify a diverse collection of cell-type specific non-coding regulatory elements including long non-coding RNA (lncRNAs), micro-RNAs (miRNAs), and enhancer regions for a variety of cell types. Additionally, these integrative annotations are capable of capturing relationships between cells of similar location, morphology, and/or functional role down to single cell and tissue types. We show that we can recapitulate functional relationships between cell types using genomic annotation in a variety of case studies. Our model's predictions of genomic functionality identify miRNAs with high expression specificity for skeletal muscle that are also found to have increased functionality in the right and left ventricles of the heart, but not in the thinner, lower resistance walls of the right atria. Similarly, lncRNAs with high expression specificity for intestinal tissue are shown to share functionality regions not only with other intestinal layers (e.g., colonic mucosa, sigmoid colon), but also tissues with similar exocrine and endocrine secretory roles like the liver and pancreas. We also identify different subsets of T-cells based on functional predictions in known T-cell lineage-specific non-coding regions, such as the interleukin-17 (*IL17*) locus. Finally, we evaluate the ability of our integrated annotations to better prioritize genome-wide association study (GWAS) variants, and compare our method with other popular variant annotation metrics in complex diseases such as schizophrenia. Our findings suggest that our cell-type specific annotation is essential to understanding the intricate relationships between different cell populations and their functional genomes.

1703T

CNV analysis identifies novel duplication at the *SLIT3* locus in FTLD. *A. Desai, M. March, C. Kim, T. Kelly, H. Hakonarson, P. Sleiman.* Center for Applied Genomics, The Children's Hospital of Philadelphia, PA Philadelphia, PA 19104.

Frontotemporal lobar degeneration (FTLD) is the second most common cause of dementia in individuals under age 65. FTLD manifests clinically with progressive behavioral and/or language deficits and has a prevalence of approximately 3.5 to 15 cases per 100,000 in 45 to 64 year olds. At autopsy, atrophy is evident in the frontal and temporal poles. In addition to neuronal loss and gliosis ubiquitin inclusion bodies are present. Approximately 50% of cases manifest as FTLD-TDP with neuronal and glial TDP-43 inclusions. To identify novel variants contributing to FTD we assessed genome wide copy number variation (CNV) between unrelated 567 FTLD-TDP cases compared to 3380 controls. These genotyping studies were performed using Illumina human 610-quad V1 beadchip. The CNV analysis was performed using PennCNV software based on the XHMM model. Using stringent quality control steps we filtered out potentially false positive CNVs based on the underlying quality score of sample, the count of CNV<100 for each sample. CNVs that survived the QC steps were assessed for association with FTLD-TDP using the ParseCNV package. ParseCNV generates probe-based statistics for a given CNV in both cases and controls which can be defined as a CNV region (CNVRs). We identified a statistically significant duplication at a locus on 5q34 that spans the *SLIT3* gene (P=1.7x10^{-8}, OR=56.95). The *SLIT3* duplication CNV was only observed in FTD cases and was absent from controls. Presence of the CNV has been validated by qPCR in all 9 unrelated FTD cases. *SLIT3* is a homolog of the Drosophila SLIT gene which is critical to the formation of the midline of the central nervous system. In mammals the three Slit proteins (Slit 1-3) have been shown to mediate repulsive signaling during axon guidance and neuronal migration. In addition to known neuronal role of SLIT3, a motor neuron expressed micoRNA, miR218, and it's enhancer have also been mapped to the locus, encoded in the *SLIT3* introns. SLIT3 duplications have been associated with major depressive disorder (MDD) and *de novo* mutations reported in autism. This study represents a comprehensive CNV analysis using the Illumina 610K platform. We report the identification of a novel variant contributing to FTLD susceptibility. These results are significant not only in shedding light on the contribution of CNVs to the pathophysiology of FTLD, but they also increases the range of neurological disorders associated with *SLIT3* mutations.

1704F

Predicting the cellular impact of genotype variant to prioritize disease hits. *F. Farhadi Hassan Kiadeh[1,2,3], J. Xu[4], C. White[4], D.A. Bennett[5], P.L. De Jager[4], S. Mostafavi[2,3,6,7].* 1) Department of Bioinformatics, University of British Columbia, Vancouver, BC, Canada; 2) Centre for Molecular Medicine and Therapeutics, University of British Columbia, Vancouver, BC, Canada; 3) Child & Family Research Institute, University of British Columbia, Vancouver, BC, Canada; 4) Department of Neurology, Harvard Medical School, Boston, MA, USA; 5) RUSH Alzheimer's Disease Center, RUSH University Medical Center, Chicago, IL, USA; 6) Department of Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 7) Department of Statistics, University of British Columbia, Vancouver, BC, Canada.

Over the last decade, genome-wide association studies (GWAS) have successfully identified many disease-associated variants for several common and complex diseases. However, identifying associated variants requires huge sample sizes, because of the small effect sizes of individual variants and the typical polygenicity of common disease. In order to increase the statistical power of GWAS, several recent approaches have been devised for limiting the 'search space' of GWAS to those SNPs that are predicted to have a regulatory impact on one or multiple cellular phenotypes [1,2]. In particular, previous approaches that "impute" gene expression from genotype data present a very attractive framework for aggregating genetic variants in a gene-specific manner. Such approaches not only result in increased statistical power, but also can identify potential mechanisms through which regulatory variants impact cellular processes. In this study, we develop a "gene-based" variant aggregation method that uses expression quantitative trait loci (eQTLs) data, in order to improve prioritize SNPs for testing in GWAS. Because of the tissue-specificity of cellular phenotypes, the choice of "tissue" is critical in building such a model. Therefore, we built such a model using eQTL data for two major human tissues, the DGN study for blood (n=922) and the ROSMAP study for cortex (n=500), and compare these models on prioritization of disease variants in several GWAS studies. Finally, we propose a comprehensive "gene-based" model that effectively aggregates genetic variants for joint expression imputation from blood and brain.You may contact the first author (during and after the meeting) at ffarhadi@cmmt.ubc.ca 1. 1705W

A systematic evaluation of gene expression regulation changes in schizophrenic brains. *S. Jiang[1], C. Chao[2], E.S. Gershon[3], Y. Wang[4], G. Yu[4], C. Liu[1,2].* 1) Department of Psychiatry, the University of Illinois at Chicago, Chicago, IL, USA; 2) The State Key Laboratory of Medical Genetics, Central South University, Changsha, Hunan, China; 3) Department of Psychiatry and Behavioral Neuroscience, the University of Chicago, Chicago, IL, USA; 4) Department of Electrical & Computer Engineering, Virginia Tech, Arlington, VA, USA.

When comparing cases to controls, change in expression of a gene could be manifested as alternations of absolute expression level and/or of relative ratios to its functional partners. The two alternations are related but also distinct. Both could contribute to disease progression. They represent property changes of one gene as an individual entity and as a community member. Therefore, considering only one can lead to missed opportunities. The former change has been the major focus in the past decades of studies. However, the latter one has obtained limited attention until recent. In this study, we assessed both differential expression and differential connectivity (as correlation levels with the other genes) in postmortem brains contrasting schizophrenics to controls. Also, we implemented a new algorithm, Differential COnnectivity and Differential Expression (DiCODE), which combined differential expression and connectivity weights, to evaluate the combined effects of expression and connectivity changes for each gene. DiCODE, together with differential expression and differential connectivity analyses, constitute our new comprehensive analysis method called TRIple Differentiation (TRID). Therefore, each gene was given three different weights so that ranked gene lists can be used for further analyses. We used two independent schizophrenia (SCZ) case-control gene expression datasets for prefrontal cortex (PFC) and one dataset for parietal cortex (PC) in the present study. Pair-wise correlation coefficients among gene lists of the three datasets by TRID are all close to zero. When gene set enrichment analysis was applied to the weighted gene lists, highly replicable schizophrenia-associated pathways were identified across the three datasets by TRID. Integrating the weighted gene lists with known human PPI networks, several schizophrenia-associated modules shared by the three datasets were identified by TRID. In these PPI modules, some genes including *PTN*, *HSPA8* and *SRPK2* were mapped to the genome-wide association signals of schizophrenia for all datasets by TRID. We further compared TRID with weighted gene co-expression network analysis (WGCNA), and learned that TRID is more sensitive to changes of individual genes that could be missed by WGCNA. Our data suggests the changes in schizophrenia are highly heterogeneous at individual gene level. TRID captured different genes of the same signaling pathways or regulatory modules impaired in different patients.

1706T

NetDx: An algorithm to classify patients based on similarity networks. *S. Pai, S. Hui, R. Isserlin, H. Kaka, G.D. Bader.* The Donnelly Centre for Cellular and Biomolecular Research, University of Toronto, Toronto, Ontario, Canada.

Patient classification has widespread biomedical applications in clinical management, including tumour subtyping in cancer and the pharmacogenetic prediction of drug response. A general purpose, clinically useful prediction algorithm should be accurate, generalizable, be able to integrate diverse data types (e.g. clinical, genomic, metabolomic, imaging), handle sparse data and be intuitive to interpret. We describe netDx, a supervised patient classification framework based on patient similarity networks, that meets the above criteria. netDx models data as patient networks and uses the GeneMANIA machine learning algorithm[1] for network integration and feature selection. The results of the classifier are clinically and biologically interpretable, and can be visualized as an integrated patient similarity network. We will present two applications of netDx. In the first, we use a published gene expression dataset of medulloblastoma subtypes (N=103 tumours) and build a 4-class predictor for tumour subtype[2]. In the second, we predict case/control status in autism spectrum disorders based on the occurrence of rare copy number deletions in cellular pathways (N=3,291 patients)[3]; this predictor achieved better performance than previously published methods. Near-term extensions involve networks based on genotype similarity from dense SNP genotyping. Software will be made available as open-source R packages. Deciphering the importance of non-coding elements deleted in patients with 2p15p16.1 microdeletion syndrome. *H. Bagheri[1,2], C. Badduke[1,2], Y. Qiao[1,2], S. Martell[1,2], S. Mostafavi[2], S. Lewis[2,3], C. Gregory-Evans[4], E. Rajcan-Separovic[1,2].* 1) Dept Pathology, UBC, Vancouver, BC, Canada; 2) Child and Family Research Institute, Vancouver, Canada; 3) Dept. Medical Genetics, UBC, Vancouver, BC, Canada; 4) Dept. of Ophthalmology, UBC, Vancouver, BC, Canada.

Introduction: The 2p15p16.1 microdeletion syndrome (OMIM 612513) is first described in two phenotypically similar individuals with intellectual disability (ID). Recently, our clinical, genomic and functional analysis (Bagheri et al., JCI Insight, March 2016), using patient cells and zebrafish knockdown, identified 3 driver genes (*XPO1*, *USP34*, and *BCL11A*) for the syndrome . However, out of 33 patients reported in the literature so far, deletions in 2 patients (from 56,853,162-60,380,981 and 57,606,726-59,619,316) did not contain any of the above 3 genes. This study examines whether non-coding elements in these two regions of 2p15p16.1 may regulate the 3 driver genes. **Materials & Methods**: Our approach comprised the *in silico* analysis of the enhancer elements involved in the two deletions without the 3 candidate genes, which were extracted using UCSC and VISTA enhancer browsers. Using several webtools (e.g. braineac.org) we identified expression quantitative trait loci (eQTLs), by searching for SNPs mapping to the two 2p15p16.1 deletions that alter the expression of the 3 driver genes. **Results**: We found that chromosome 2 contains the highest number of enhancers in the genome (104 of 897 VISTA-positive and 68 of 617 brain/neuronal-expressed enhancers) of which approximately one-third are present in the 2p15p16.1 region. The enhancers did not contain eQTL SNPs that regulate expression of the 3 candidate gene, or any genes from the 2p15p16.1 region. However, there were 24 eQTL SNPs in one of the deletions that regulate the expression of one of the driver genes (*BCL11A*). The second patient's deletion did not include these SNPs, but occurred together with 2 additional small non-coding deletions in the second intron of *BCL11A* and ~40Kb upstream of *BCL11A*. The intronic deletion is in the proximity to two SNPs (rs1427407 and rs75994488) that have been previously associated with schizophrenia, autism and fetal hemoglobin expression. **Conclusions**: We described an *in silico* approach to decipher the effects of non-coding elements on the expression of 2p15p16.1 genes. The regulatory elements in both deletions that do not contain exons of the 3 critical genes could be associated with *BCL11A* function. This strengthens the role of *BCL11A*, a chromatin remodeler, in the 2p15p16.1 microdeletion syndrome and ID, as previously suggested, based on the recurrence of mutations in this gene in patients with ID.

1708W

A review of clinical NGS accuracy for mitochondrial disorders: A comparison of NGS to secondary Sanger sequencing confirmation. *S. Dames[1,3], B. Brulotte[1], G. Pont-Kingdon[1], K. Eilbeck[3], R. Mao[1,2].* 1) ARUP Laboratories Institute for Clinical and Experimental Pathology, Salt Lake City, UT; 2) University of Utah Department of Pathology, Salt Lake City, UT; 3) University of Utah Department of Biomedical Informatics, Salt Lake City, UT.

Introduction: The mitochondrial disorder (mt disorder) assay was the first clinical next generation sequencing (NGS) assay offered at ARUP. Initial validation quality control metrics required a secondary method fpr confirmation of reportable variants by Sanger sequencing. Subsequently, improvements in bioinformatics, capture technologies, and NGS sequencing platforms have been validated; however a secondary detection by Sanger is still utilized. In order to reduce turnaround time and assay costs, a comparison of concordance between Sanger and NGS for the mt disorders assay was performed to determine the overall accuracy of NGS compared to Sanger in a clinical setting. **Methods:** The mt disorder assay enriches the mitochondrial genome by long-range PCR and 108 nuclear genes associated with mt disorders by either RainDance (initial validation) or NimbleGen SeqCap technology (current methodology). All medical director Sanger variant requests that met minimum QC metrics based off of NGS data were compared to the final Sanger result (i.e. nucleotide call, zygosity, and plasmy). **Results:** Over 400 mt disorder assays have been performed at ARUP Laboratories resulting in 608 mtDNA and 421 nuclear Sanger requests. The overall concordance of NGS to Sanger sequencing for the mtDNA is 100% when heteroplasmy levels are greater than 25%. Nineteen of 608 mtDNA variants were not detected by Sanger sequencing (96.9% concordance). Of these 19 variants, all had heteroplasmy levels less than 25%. Two of these variants were further examined by allele-specific PCR and confirmed. Five of 421 nuclear gene variants were not confirmed by Sanger sequencing, yielding a concordance of 98.8%. Missed calls associated with the nuclear genes were found with variants that used probabilistic zygosity algorithms which were on the lower end of zygosity QC metrics. These false positive heterozygous variants were all homozygous. No homozygous variants were miscalled, and all heterozygous variants between calculated 25-75% alternate allele frequency were unconfirmed. **Conclusions:** Based on concordance data between NGS and Sanger sequencing, ARUP is currently considering different options bioinformatically and experimentally to reduce or eliminate the requirements of Sanger verification for all NGS assays. Examination of dual indexed libraries and/or optimization of QC metrics to provide a probabilistic metric for NGS variant calls are currently underway and will be presented.

1709T

Mitochondrial DNA clinical diagnostics through next generation sequencing. *R. Berutti[1], T. Wieland[1], T. Schwarzmayr[1], B. Lorenz-Depiereux[1], U. Ahting[1,2], M. Radivojkov-Blagojevic[1], P. Lichtner[1], T. Haack[1,2], T. Meitinger[1,2], H. Prokisch[1,2], T.M. Strom[1,2].* 1) Institute of Human Genetics , Helmholtz Zentrum München, Neuherberg, Bayern, Germany; 2) Institute of Human Genetics , Technische Universität München , Munich, Bayern, Germany.

The mitochondrial genome is an important target for clinical diagnostics. In the last one and a half year we analyzed the mtDNA of more than 8,000 samples referred for exome sequencing, 226 for targeted mtDNA analysis and 45 whole genomes.Sequencing was performed on the Illumina HiSeq and MiSeq platforms, reads were aligned using BWA-mem to a modified hg19 reference sequence, where the mtDNA sequence has been replaced with the revised Cambridge Reference Sequence (GenBank NC_012920). Contamination from NUMTs, nuclear DNA regions featuring high homology with mtDNA, is negligible. A full nuclear reference allows the discrimination of ambiguous reads. Moreover, on genomes and targeted sequencing (single amplicon of the mtDNA) the ratio of the mtDNA depth to the nuclear depth is exceptionally high. On exomes, enrichment kits not encompassing NUMT regions were used, minimising contamination.Variant calling was performed with GATK, for SNPs and short indels, and with Pindel for large deletions. Annotation uses gene definitions from ENCODE, and an extra tRNAs track. Interpretation of discovered mutations was supported by additional information from MITOMAP, like disease association and variant frequency.Detected mutations are stored in our in house variation database, which is accessible via a web front-end, providing annotation, quality, functional and frequency information.Overall, we obtained an average depth of 3800X for genomes, 45X for exomes, and 8500X for targeted sequencing. We identified on average 27 mutations per sample in the range of heteroplasmy over 15%. Within our cohort of 315 exome patients with suspect mitochondrial disorders, we found 25 disease causing mutations on the mtDNA from the exome and 41 from the targeted sequencing. The mtDNA of 14 samples was genotyped both with exome and targeted sequencing. The achieved concordance was of 98.9% on variant calls, with a sensibility of 92.3% for exomes. Heteroplasmy detection was performed down to values of ~20% for exome and ~10% for targeted DNA samples.Since most of our samples are of German origin, we additionally performed haplogroup analysis of our cohort, showing a haplogroup composition in agreement with a European population. We demonstrated the possibility of using exome sequencing data to reliably identify mitochondrial variants. Furthermore we were able to implement mtDNA sequencing for diagnostics to help solving unclear clinical cases of mitochondriopaties.

1710F

Next-generation sequencing in three Israeli families with Keratoconus. *W.A. Goar[1,2,3], P. Majdalani[5], C.C. Searby[2,3], S.S. Whitmore[1,3], A.P. DeLuca[1,3], A. Imtirat[4], E.M. Stone[1,3], R. Pavari[5], T.E. Scheetz[1,3], V.C. Sheffield[2,3].* 1) Opthalmology and Visual Sciences, University of Iowa, Iowa City, IA; 2) Department of Pediatrics, University of Iowa, Iowa City, IA; 3) Stephen A. Wynn Institute for Vision Research, University of Iowa, Iowa City, IA; 4) Department of Medicine, Ben-Gurion University in The Negev, Beersheba, Israel; 5) Microbiology, Immunology and Genetics, Ben-Gurion University in The Negev, Beersheba, Israel.

Keratoconus (KT) is the most common corneal dystrophy with an occurrence rate of 1 in every 2,000 people. KT causes the cornea to thin with age, becoming conical and leading to myopia, irregular astigmatism, and corneal scarring. The age of onset is generally the teenage years with stabilization in the third and fourth decades of life. Incidence of KT does not seem to be more prevalent in a particular gender, but does seem to occur more frequently and aggressively in Israel and Saudi Arabia. Currently, corneal transplantation is the only treatment for KT when visual acuity is no longer correctable by contact lenses. We hypothesize that KT is a genetically heterogeneous disease that is caused by mutations in one of several genes. Samples were obtained from 3 Israeli KT families (16 samples) and genotyped using an Affymetrix Genome-Wide SNP 5.0 microarray. The SNP data was analyzed for regions of autozygosity using PLINK to investigate the presence of homozygous regions of the genome shared between the affected family members. Three samples with KT (one for each family) were chosen for exome sequencing. The resulting variants were filtered based upon variant quality, predicted function, and population prevalence (1000 genomes, ExAC). Spurious variants (based upon our local set of 1000+ exomes) were removed to create a final variant list for each family, which was annotated with corneal expression (http://genome.uiowa.edu/otdb) to assist in prioritizing potential candidates. Using the autozygous regions, we have prioritized candidates and areas of the genome on which to focus our investigation. No plausible variations were found in these three families in genes previously reported to cause KT. In addition, no single gene with plausible disease-causing variations was shared across all three families. However, a few genes were found that are shared between two of the families and need further follow up. We also identified at least 3 areas of autozygosity that are shared between the 3 families. These areas need further examination to determine if they are harboring causative variants. Further work is needed to identify the causative mutations in these families. Due to the isolated population we will continue to pursue these through ascertainment of additional families and family members. This will allow us to further narrow the intervals of the genome in search of the causative mutations.

1711W

Prioritizing biology based on single-cell transcriptomics. *P. Timshel[1,2], T.H. Pers[1,2].* 1) The Novo Nordisk Foundation Center for Basic Metabolic Research, Section of Metabolic Genetics, Faculty of Health and Medical Sciences, University of Copenhagen, Universitetsparken 1, København Ø 2100, Denmark; 2) Department of Epidemiology Research, Statens Serum Institut, 2300 Copenhagen, Denmark.

Background: A key challenge for gaining biological insights from genetic associations is to identify which genes and pathways explain the associations. We have previously shown that reconstituted gene sets augment biological interpretation of genome-wide association studies (GWAS; Pers et al., 2015). 'Reconstituted gene sets' are based on multi-tissue expression data and comprise probabilities of each gene's membership for a given pathway. However, a remaining major limitation is that these gene sets are not tissue or cell type specific. **Methods**: We introduce DEPICT for single-cell (DEPICT-sc), which uses single-cell gene expression data to more accurately highlight enriched pathways. We learn robust 'single-cell transcriptional components' (scTC) from single-cell transcriptomic data by applying matrix factorization models on data from >13,000 mouse retina cells (Macosko et al., 2015). Then we use the scTCs and >14,000 predefined gene sets to construct reconstituted gene sets. **Results**: We show that scTCs reflect genuine biological differences between retina cells. We show that the top scTCs enrich for relevant retina biology, such as 'detection of light stimulus' ($P < 2.23 \times 10^{-108}$) and 'phototransduction' ($P < 3.08 \times 10^{-66}$). To illustrate the relevance of DEPICT-sc for gaining biological insights from genetic associations, we integrate the reconstituted gene sets with GWAS data for age-related macular degeneration (AMD) and successfully prioritize 'response to reactive oxygen' for age related macular degeneration ($P < 1.25 \times 10^{-10}$). **Conclusion**: Our results suggest that single-cell gene expression data leads to more specific prioritization of likely etiologic gene sets and pathways. DEPICT-sc can easily be adapted to prioritize genes, pathways and cell types for other traits and diseases.

At-a-glance" human disease model and phenotype summary data at mouse genome informatics. *C. Smith, J. Eppig, The Mouse Genome Informatics Team.* Mouse Genome Informatics, Jackson Laboratory, Bar Harbor, ME.

The mouse is widely used as a model system to investigate the genetics of human disease. Coupling human sequence, phenotypes, pathogenicity variant calls, copy number variation, and other biological evidence with mouse model data can accelerate the identification and testing of therapeutic candidates. Mouse Genome Informatics (MGI, www.informatics.jax.org) provides data sets to correlate mouse phenotype with human diseases, clinical signs and symptoms. MGI catalogs all mouse mutant alleles, including published mouse mutations and mutations produced by large-scale mutagenesis programs. Point mutations (made by ENU and CRISPR) or knock-out (null) mutations now exist for most mouse genes. In MGI, mouse genotypes are annotated to phenotype and OMIM disease model descriptions, and include links to supporting gene information such as sequence, spatiotemporal expression, genomic location, biochemical function and process, sub-cellular topology, and mammalian gene homology. Thus, the model data at MGI aids in understanding biochemical pathways and pathological processes that can further advance the knowledge of underlying mechanisms of human genetic disease. Mouse Genome Informatics has recently revised the web-based gene-level presentation of these phenotype and disease model data. In addition to the number of alleles and variants for a gene, the number of phenotype annotations from single and multigenic genotypes, images and references, MGI now provides 'at-a-glance' graphical displays into systems affected by variants in genes, with quick links to more detailed information. A section on Human Diseases gives an overview of mouse models in orthologs of human genes. In this presentation, we will show how to access the fully integrated data sets at MGI starting with summary views, and provide examples of therapeutic targets identified using data generated from mouse models.

Non-cooperative facial recognition technology enables scalable accurate facial gestalt matching of individuals with the same syndromic form of intellectual disability. *T.E. Dudding-Byth[1], A. Baxter[1], E.G. Holliday[3,4], A. Hackett[1,4], S. O'Donnell[1], S.M. White[5], J. Attia[3,4], C. Nellaker[6,7,8], H. Brunner[9], B. de Vries[9], D. Koolen[9], T. Kleefstra[9], S. Ratwatte[10], S. Brain[11], B.C. Lovell[12].* 1) Hunter Genetics, Hunter New England Health Service, Newcastle, NSW, Australia; 2) GrowUpWell, Priority of Research Excellence, The University of Newcastle, Newcastle, NSW, Australia; 3) Hunter Medical Research Institute, Newcastle, NSW, Australia; 4) The University of Newcastle, Newcastle, NSW, Australia; 5) Murdoch Childrens Research Institute, Melbourne, Australia; 6) Nuffield Department of Obstetrics & Gynaecology, University of Oxford, Radcliffe Hospital Oxford, United Kingdom; 7) Institute of Biomedical Engineering, University of Oxford, Oxford, United Kingdom; 8) Big Data Institute, University of Oxford, Oxford, United Kingdom; 9) Department of Human Genetics and Donders Institute for Brain, Cognition and Behaviour, Radboud University Medical Center, Nijmegen, the Netherlands; 10) The Department of Medicine, John Hunter Hospital, Newcastle, NSW, Australia; 11) Imagus Technology, Brisbane, Queensland, Australia; 12) School of ITEE, The University of Queensland, Brisbane, Queensland, Australia.

Massively parallel genetic sequencing allows rapid testing of known intellectual disability (ID) genes. However, the discovery of a novel ID gene often requires molecular confirmation in a second patient with an overlapping phenotype or similar facial gestalt. This study examined the accuracy of non-cooperative facial recognition technology for matching the facial images of non-identical individuals, each of whom was either affected with one of ten genetic syndromes (n~1145) or was unaffected (normal control, n~2000) (total 3145 images). The database was populated with images from published peer review manuscripts and publically available patient groups. We tested the accuracy of the facial recognition technology using the "leave one out" method, i.e., an individual image is removed from the database to be used as a test case for generating their top ten closest matches. For the analysis, we specified two research questions: 1) Using all photographs in the database, did the software correctly identify i) a top match, ii) at least one in the top five, or iii) at least one in the top ten with an individual from the same syndrome subgroup, more than would be expected by chance; 2) The relative accuracy of software-based matches and whether three experienced clinicians would have also considered the syndrome diagnosis based on the photograph alone. For the first question, expected frequencies were estimated via simulation, and frequencies compared using Chi-Square statistics. For the second question, Kappa statistics and McNemar's tests were used to assess agreement and compare the relative accuracy of software and clinician diagnoses. Statistical analysis performed to date on the first five of the ten syndromes shows that the software correctly identifies a top match, at least one correct match in the top five and at least one in the top ten far more often than expected by chance (for top match, one in five and one in ten, Chi-square statistics all > 800, >350 and >150, respectively; all P<0.00001). For the second question, we observed low agreement between the software and clinicians with higher accuracy of the software when results were discordant (most McNemar's Chi-square statistics >10, with P>0.01). The scalability of this technology on an international basis has the potential to enhance the efficacy of deep phenotyping platforms for identifying the second individual or a cluster of individuals with a similar facial gestalt. .

SolveBio FUSE: A very large genetic variant dataset generated with MapReduce. *J. Hull, P. George, D. Caplan, X. Xu.* SolveBio, New York, NY.

   Purpose: Genomic variant annotations can be found in a large number of databases containing a plethora of information ranging from clinical evidence & allele frequencies, to information curated from individual literature articles. In order to provide real-time, context-specific variant intelligence, we devised a method to generate specialized meta-datasets (FUSE datasets) containing relevant annotations from any number of sources. In addition, the meta-dataset includes data-provenance allowing it to act as a single source of truth within an application. The resulting FUSE datasets, indexed by genomic location, provide a solid foundation for novel genomic applications to be rapidly built & deployed. **Methodology**: The complete SolveBio FUSE dataset contains 385 million genomic variants comprised of multiple versions of 15 public genomic datasets. The dataset is automatically compiled using a proprietary Python application & Apache Hive which leverages MapReduce technologies. Using the SolveBio contextual knowledge hub, our solution takes an input of datasets & desired fields & dynamically generates schemas & a pipeline of Apache Hive queries to generate the final dataset. Our schema generators consolidate non-normalized fields across any number of datasets, & our Hive queries de-duplicate values from each while maintaining data provenance information. The final dataset is compatible with both SQL & NoSQL datastores. Given any genomic coordinate, querying the FUSE dataset returns a complete picture of a region or variant including all associated annotations. **Results**: We deployed our FUSE dataset to allow for intelligent search within SolveBio in Fall 2015. Since then, our dataset has been queried millions of times & has enabled SolveBio to build a contextual knowledge hub that leverages real-time search across a large number of datasets, a beacon system that conforms to the GA4GH guidelines, & a genomic entity recognition algorithm. Because of the ease in configuration & generation of the dataset & the parallel & scalable nature of MapReduce algorithms, we have been able to make rapid improvements & add new data to our dataset since its inception. The entire dataset can be generated in less than an hour. **Conclusion**: A single dataset containing a consolidated & versioned view of every genomic data point about variants creates a strong foundation for accurate, intelligent & novel applications for genomics in enterprise, research & clinical environments.

1715T

Variant-level information is critical for inferring the functional impact of spontaneous human mutations. *A. Saha Mandal[1,2,3], A. Mathankeri[1,2,3], A.P.J. De Koning[1,3,4,5].* 1) Department of Biochemistry and Molecular Biology, University of Calgary, Calgary, AB, Canada; 2) Bioinformatics Graduate Program, University of Calgary, AB, Canada; 3) Alberta Children's Hospital Research Institute, Calgary, AB, Canada; 4) Cumming School of Medicine, University of Calgary, AB, Canada; 5) Department of Medical Genetics, University of Calgary, AB, Canada.

   Computational approaches for predicting the pathogenicity of genomic variants have been recently advanced by the development of novel training strategies (*e.g.,* CADD and EIGEN). Here we evaluate some of the pitfalls of these strategies and explore how they can be overcome. Despite being very successful at distinguishing highly penetrant ClinVar variants from common polymorphisms, we show that these data integration classifiers perform no better than PolyPhen2 at distinguishing benign from pathogenic variations *at the same genomic position*. This problem is far more difficult than simply identifying mutations at functionally important positions, and is arguably the central challenge in prioritizing rare and spontaneous mutations. Here we show that the integration of additional variant-level data substantially improves sensitivity and specificity over existing approaches. We present a new classifier, TAIGA, Transformation and Integration of Genomic Annotations, which implements a rotation forests algorithm for missense variant classification and can outperform CADD and EIGEN by a substantial margin. A lack of reliable training and/or testing data continues to be a limiting problem, however, we argue that an even greater impediment to further progress is the lack of sufficiently detailed predictor information at the variant level. It is thus an urgent priority to develop new variant-level scoring systems that can make fuller use of large-scale variation data and enable quantitative assessment of the functional deficit caused by human mutations.

1716F

Lynx – An integrated bioinformatics platform to support high-throughput translational biomedicine. *D. Sulakhe[1,2], B. Xie[1,4], S. Wang[1,3], M. DSouza[1], A. Taylor[1], S. Hashemifar[1,3], G. Agam[4], T.C. Gilliam[1,2], N. Maltsev[1,2].* 1) Human Genetics, The University of Chicago, Chicago, IL., 920 E. 58th str, Chicago, IL 606037; 2) Computation Institute, The University of Chicago, Chicago, IL., USA; 3) Toyota Technological Institute at Chicago, Chicago, IL, USA; 4) Department of Computer Science, Illinois Institute of Technology, Chicago, IL, USA.

   Advances of high throughput genomics now allow studying biology and medicine as complex networks of interacting genetic factors in relevant biological contexts. This integrative approach holds the promise of unveiling hitherto yet unexplored levels of molecular organization and biological complexity. To support the end-to-end analytical needs of various translational projects we have developed an integrated bioinformatics platform Lynx (http://lynx.cri.uchicago.edu), a web-based knowledge base and a knowledge extraction engine. Lynx contains the following components: (a) Lynx integrated knowledge base (Lynx KB) provides a vast compendium of biomedical information integrating phenotypic, genomic, proteomic and networks information from over forty public databases. (b) Lynx analytical workbench assists the user in extracting meaningful knowledge from LynxKB and experimental data using a variety of algorithms for enrichment analysis and network-based gene prioritization. Since the last release the Lynx analytical workbench has been supplemented with new tools for reconstruction and analysis of co-expression networks, as well as a novel Cheetoh algorithm for feature-and-network-based gene prioritization. These tools facilitate the prediction of high-confidence genetic factors and molecular mechanisms contributing to the phenotypes of interest and formulating the working hypotheses to be tested experimentally. Lynx is used by a variety of translational projects for the studies of neurodevelopmental and pulmonological disorders, and cancer. The example of Lynx analysis includes the identification of high-confidence candidate genes contributing to pathogenesis of spina bifida in consanguineous family. Our analysis has predicted the deleterious mutations in the SLC19A placental folate transporter in mothers of the affected children. These mutations resulted in the narrowing of the outlet channel and consequentially to the reduced folate permeation rate and folate deficiency in affected children. Lynx is freely available on the Web. The Service Oriented Architecture provides public access to LynxKB and its analytical tools via user-friendly web services and interfaces. Future developments of Lynx include inter alia the support of the contextual isoforms-based reconstruction of biological networks and the development of the project-specific environments customized for the needs of particular interest groups and projects (e.g. cancer biomedicine).

1717W

WISEexome: Detection of copy number variations in clinical exome sequencing data based on a within-sample comparison scheme. *M.M. Weiss[1], R. Straver[1], D. van Beek[1], E.A. Sistermans[1], M.J.T. Reinders[1,2].* 1) Clinical Genetics, Genome Diagnostics, VU University Medical Center, Amsterdam, Netherlands; 2) Delft Bioinformatics Lab, Delft University of Technology, Mekelweg 4, 2628 CD Delft, The Netherlands.

   Clinical exome sequencing (CES) can provide a molecular diagnosis in families with an unexplained genetic disease. Both SNPs and CNVs can be pathogenic and are searched for in diagnostic settings. At the moment most clinical labs perform both CES and array to be able to detect SNPs and CNVs (resolution ~20 kb). To be able to replace array with CES we developed a method, based on a combination of our previous work (WISECONDOR; https://github.com/rstraver/)) and a segmentation algorithm, to find aberrated exons in exome data. Our method fully depends on an internal comparison of DNA fragments per probe, rather than comparisons with a reference set of samples. This works by comparing the amount of reads mapped to a probe to a set of probes known to behave alike in terms of read depth, which is off-line learned through a set of known normal samples (in our case 212 samples). This approach provides both the effect size and z-score per probe. These are merged in differently-sized windows to scout the sample for aberrations of any size. A segmentation algorithm applied to detected aberrated regions then determines their exact start and end positions. All 18 known CNVs in our dataset of 24 samples were correctly identified. Size ranges from 4 kb to 5,2 Mb. The smallest CNV contained a deletion of 2 exons and a partial deletion of an exon in a neighboring gene. Results can be sorted by a score that indicates the reliability of a call, usually providing the true positives in the top 5. We are now in the process of retrospectively analyzing our diagnostic exome cohort (~500 trio analysis) and expect to detect small pathogenic CNVs that may have been missed by the routinely used array analysis (resolution of 20 kb). Our work provides an alternative method to find CNVs in exome data. We do not require that reference samples are resequenced in the same run, and we are able to detect variable-sized CNVs. Consequently, WISEexome has the potential to replace array analysis and maybe even MLPA tests in a diagnostic setting in a cost-effective way. .

1718T

SuperVario: An analysis framework, DBMS, and common repository for variant data. *A.S. Wenocur[1], L. Tian[2], K. Nguyen[1,4], P.M. Abou-Sleiman[1,2,3], H. Hakonarson[1,2,3].* 1) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Department of Pediatrics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 3) Division of Human Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA; 4) Center for Dynamic Data Analytics, Rutgers University, Piscataway, NJ.

In many bioinformatic analysis pipelines, nucleic acid reads are mapped and submitted to a variant caller. Typically, the variant data are stored in flat files that often are difficult to interrogate as sample numbers increase , when queried by multiple investigators. A common problem encountered is that CNVs, point mutations, indels, SNPs, structural, and other variants are tagged for specific analyses and are not easily shared or retrieved for new *in silico* experiments. A solution to this is a centralized repository for genomic variants, which can accommodate multiple classes of variant data. We have developed a database of variants, allowing researchers to apply custom filters and visualize by frequency in a specialized genome browser. The initial prototype was an instance of Exac Browser, modified to load VCFs produced at our institution. The next experiment involved configuring a Hadoop stack to store variant data. Currently, SuperVario is a lightweight but powerful C++ framework, analysis tool, and specialized DBMS for storing variant annotations and clinical metadata, with an open architecture that can accommodate replication, sharding, concurrency, and highly efficient serialization.

1719F

Leveraging PheWAS in fine-mapping complex trait GWAS loci. *F. Sathirapongsasuti, P. Fontanillas, V. Vacic, A. Auton.* 23andMe Inc., Mountain View, CA.

The interpretation and application of complex trait loci identified in genome wide association studies (GWAS) requires the ability to fine-map the causal variants and causal genes. So far, the focus of fine-mapping has been on GWAS loci of a single trait. However, large genotype-phenotype databases have enabled interrogation of variants across multiple phenotypes, an approach known as phenome-wide association studies (PheWAS). We can leverage association patterns of multiple related phenotypes to disentangle complex trait GWAS loci. We explored the effectiveness of combining association signals across phenotypes when fine-mapping a locus by analyzing all loci associated with multiple uncorrelated phenotypes in the 23andMe dataset. The 23andMe database contains genotypes of more than one million research participants and more than 1,200 phenotypes. Using this approach, the size of the credible sets was reduced substantially. As a positive control, we found that the reduced credible set at the FTO locus included the known causal variant rs1421085. We highlight the THADA locus where we combined signals from type 2 diabetes, Crohn's disease, polycystic ovary syndrome, and prostate cancer, in order to reduce the credible set to a manageable subset. Our results suggest that leveraging multiple phenotypes from a PheWAS analysis is beneficial for fine mapping complex trait loci..

1720W

MAPPIN: A method for predicting the pathogenicity and disease inheritance modes of missense variants. *N. Gosalia[1,2], O. Gottesman[1], V. Arunachalam[1], J.D. Overton[1], J.G. Reid[1], J. Staples[1], C. O'Dushlaine[1], F.E. Dewey[1], A.N. Economides[1,2], S. Balasubramanian[1].* 1) Regeneron Genetics Center, Regeneron Pharmaceuticals Inc., Tarrytown, NY; 2) Regeneron Pharmaceuticals Inc., Tarrytown, NY.

Whole-exome sequencing (WES) is increasingly being used to identify causal mutations leading to a disease or phenotype. According to the Human Gene Mutation Database (HGMD), approximately 45% of these disease-causing mutations across 5,700 genes are missense substitutions *(Stenson et al., Hum Genetics, 2014)* and, on average, an exome contains 10,500-13,500 nonsynonymous SNVs (nsSNVs) *(Levy et al., PLoS Biol, 2007; Ng et al., PLoS Genetics, 2008; Wheeler et al., Nature 2008; Wang et al., Nature 2008)*. Therefore, it is critical to differentiate potential disease-causing variants from the tolerant ones. Several algorithms are currently in use to predict the pathogenicity of missense mutations, however they are unable to distinguish between autosomal-dominant and autosomal-recessive disease-causing mutations *(Li et al., PLoS Genetics, 2013)*. Here we present MAPPIN (Method for Annotating, Predicting Pathogenicity, and mode of Inheritance for Nonsynonymous variants), a method to annotate and predict the pathogenicity of nsSNVs. We developed a classifier to distinguish between dominant, recessive, and benign missense variants using a random forest algorithm based on over 100 features including conservation, protein domains, biological networks, and allele frequency distribution. This method classifies missense mutations into three distinct groups: tolerant, haploinsufficient (dominant), or recessive with a multiclass AUC of 0.95. The algorithm performs well even under a two-class system similar to that of SIFT or Polyphen, with AUCs of 0.95 (tolerant vs. pathogenic) and 0.94 (haploinsufficient vs. recessive). We applied MAPPIN to a set of mutations derived from the Centers for Mendelian Genomics (CMG) studies *(Chong et al., Am J Hum Genetics, 2015)* and Deciphering Developmental Disorders Study *(Nature, 2015)* for which the prediction accuracy for pathogenicity <u>and</u> mode of inheritance was 73.8% and 78% respectively. To the best of our knowledge this is the first algorithm that is able to classify missense variants as dominant or recessive-disease causing.

Phenotypic-driven prioritization of trio-based whole genome sequencing data for congenital disorders. *A. Khromykh[1], S. Shah[2], D. Richards[2], D.L. Bodian[1], N.S. Hauser[1,4], R. Iyer[1], R. Baveja[3,4], M. Kane[1], T. Vilboux[1], K.C. Huddleston[1], J. Niederhuber[1], B.D Solomon[1,4,5].* 1) Inova Translation Medicine Institute, Inova Fairfax Hospital, Falls Church, VA; 2) QIAGEN Bioinformatics, Redwood City, CA; VA; 3) Fairfax Neonatal Associates, Falls Church, VA; 4) Inova Children's Hospital, Falls Church, VA; 5) Virginia Commonwealth University School of Medicine, Richmond, VA.

Congenital anomalies and genetic disorders are a leading cause of early childhood morbidity and mortality. The goal of our IRB-approved 'Impact of Genetic Disorders' study is to use trio-based whole genome sequencing (WGS) to elucidate the genetic and genomic factors that contribute to the etiologies of congenital anomalies and other disorders that present early in life. Our analyses are bolstered by our database of >7,000 WGS (along with other biological data and clinical information) derived from multiple ongoing trio-based genomic studies. We used the QIAGEN's Ingenuity Variant Analysis to analyze cases and performed analyses both with and without inputting standardized phenotypic data. The Ingenuity Variant Analysis software classifies variants using draft ACMG-recommended assessment guidelines based on a pre-curated knowledge base of biomedical literature and clinical evidence allowing standardized and scaled annotation, filtering, classification and reporting of observed clinically relevant variants. For cases in which a genetic cause for disease is suspected based on family history, but no causal variant has been previously identified, we use QIAGEN's Ingenuity Variant Analysis to identify gene variants that may perturb biological pathways/networks upstream of known causal genes in described cases with overlapping phenotypes. Data generated from an initial subset of 46 trios reveals findings of interest in 32 (70%), including *de novo* as well as dominant and recessive inheritance patterns. We compare the results of analyses with and without the use of phenotypic data to prioritize variants. Our study demonstrates the potential of the trio-based WGS analysis to identify molecular etiologies for previously undiagnosed patients, and helps provide data about the effect of phenotypic data to prioritize identified variants.

1722F

MaCHTools improves and streamlines the GWAS workflow to determine the genetic basis of D, a latent variable representing the dementing process. *J. Mitchel[1], R. Barber[1], N. Phillips[1], J. Tilson[2], D. Royall[5,6,7,8], K. Wilhelmsen[2,3,4], Texas Alzheimer's Research and Care Consortium.* 1) Molecular and Medical Genetics, University of North Texas Health Science Center, Fort Worth, TX; 2) Renaissance Computing Institute, University of North Carolina, Chapel Hill, NC; 3) Department of Genetics, University of North Carolina, Chapel Hill, NC; 4) Department of Genetic Medicine, University of North Carolina, Chapel Hill, NC; 5) Department of Psychiatry, The University of Texas Health Science Center, San Antonio, TX; 6) Department of Medicine, The University of Texas Health Science Center, San Antonio, TX; 7) Department of Family and Community Medicine, The University of Texas Health Science Center, San Antonio, TX; 8) South Texas Veterans' Health System Audie L. Murphy Division GRECC, San Antonio, TX.

   Reliance on commercially available genotyping arrays in genome-wide association studies (GWAS) limits coverage of the genetic variation in a study cohort. Imputation allows for additional genotypes to be included in the study, increasing coverage by orders of magnitude. MaCH is a popular and well-validated Markov chain-based haplotyping program for genotype implementation, but it has limited usability. MaCHTools is a Linux tool for handling and manipulating large genotype data sets that facilitates imputation via MaCH. MaCHTools checks input files for user-defined quality control measures, and arranges, orders and cleans datasets in preparation for imputation. MaCHTools' latest version includes a user-friendly graphical user interface. At the end of the MaCHTools-MaCH workflow, the user is left with observed genotypes, imputed genotypes, and associated and quality statistics between the all genotypes and the trait or disease of interest. MaCHTools has been validated using known datasets, and this study aims to use MaCHTools to find genetic variants that are associated with "D", a latent variable that represents the dementing process. Employing structured equation models, variance in cognitive task performance can be separated from variance unrelated to a dementing process. This "dementia-relevant" variance labeled "D", is a continuous variable that has been validated in several cohorts, including the HAAS, the NACC and the Texas Alzheimer's Research and Care Consortium (TARCC), in which this GWAS was performed. This GWAS found 24 SNPs that reached genome-wide significance with a minor allele frequence greater than 5% in association with "D" and several "D" homologs in TARCC participants.

1723W

Fast and accurate detection of circular DNA reveals its prevalence in human tissue and blood. *M. Mohiyuddin[1], H.D. Møller[2], N.B. Asadi[1], J.F. Halling[2], P. Plomgaard[3], H. Pilegaard[2], H.Y.K. Lam[1], B. Regenberg[2].* 1) Roche Sequencing, Belmont, CA 94002, USA; 2) Department of Biology, University of Copenhagen, Denmark; 3) Department of Clinical Biochemistry, Rigshospitalet, Denmark.

   We have recently shown that extrachromosomal circular DNA (eccDNA) is commonly present in the eukaryotic model, S. cerevisiae. It derives from chromosomal DNA and forms by DNA circularization through homologous recombination, non-homologous end-joining or other mechanisms. It can potentially be an intermediary for copy-number variations (CNVs) which have been implicated in several diseases, cancer, aging as well as contributing to genomic diversity. eccDNAs in S. cerevisiae were recorded by a sensitive, genome-scale enrichment and detection method for eccDNA, named Circle-Seq. eccDNAs of sizes ranging from 1kb to 38kb were identified and covered 23% of the S. cerevisiae genome including thousands of genes. In another study, tens of thousands of small eccDNAs were identified in mouse and human cell lines further confirming the abundance of eccDNA in eukaryotes. In this work, we enhanced Circle-Seq to work efficiently on the human genome. Our method used a combination of alignment signals involving discordant read-pairs, large soft-clips, secondary alignments and read-depth to detect eccDNAs. We used the enhanced Circle-Seq to conduct a case-control study on the impact of physical activity on eccDNA abundance in blood and muscle samples. The study involved blood and muscle tissue DNA samples from two groups of 8 men with ages from 60 to 65 years. These groups comprised of men who had either been physically active or inactive all their life. Our approach identified tens of thousands of eccDNAs ranging in size from 52b to 53kb. eccDNA counts in muscle samples (from 1000 to 5000 per million cells) were significantly higher than those in blood samples (from 200 to 1000 per million cells). The size distribution of eccDNAs was similar for muscle samples across the two groups. However, for blood samples, we found that the physically inactive group had more than twice the abundance of eccDNA elements for sizes ranging from 100b to 1kb. PCR validation confirmed 11 out of 12 tested eccDNAs of sizes from 400b to 35kb from multiple samples. In addition, exogenous plasmids were added in varying ratios to all samples prior to eccDNA purification and were detected at an average rate of 98.8% in blood samples. The analysis was fast and took less than three days for the 32 samples on a single node. Our results show that eccDNA is common in human blood and tissue DNA and also indicate a possible link between physical inactivity and enrichment of eccDNA in human cells.

1724T

Moving towards the biophysical genome: Biophysically-driven, high-accuracy driver discovery and variant interpretation. *C.L. Araya[1,4], A. Colavin[2,4], D.M. Fowler[3], M.P. Snyder[1].* 1) Genetics, Stanford University, Stanford, CA; 2) Biophysics, Stanford University, Stanford, CA; 3) Genome Sciences, University of Washington, Seattle, WA; 4) Jungla Inc., San Francisco, CA.

Genomic sequences contain rich information associating genetic variants to the molecular mechanisms that underpin human health and disease, but our ability to uncover such associations is critically reliant on our understanding of the molecular functions encoded in the genome. Existing functional annotations in the genome rely on coarse, linear descriptions of genes that ultimately describe the transcriptional nature but not the functional nature of biomolecules in the genome. While structural data continues to increase, these today exist for only 20% of protein-coding genes and frequently describe as little as 15% of the structure of the each protein. We have developed methods that yield and leverage a biophysical view of how function is encoded within genes and the genome, without the requirement for structural data. Analyzing >4,700 tumor genomes from 21 cancer types, we recently demonstrated the discovery of novel cancer-drivers recurrently affecting precise molecular functions in as many as 10%, 14%, and 15% of melanoma, endometrial, and bladder cancers, respectively (Araya et al. 2016, Nature Genetics). Coherent molecular alterations often associated with changes in signaling. We extend these insights to describe a novel class of analytic solutions that accurately predict the impact of variants in specific disease-associated protein-coding genes with high accuracy. Our approach is a marked departure from existing in silico predictors; instead of generating a single predictor for the entire genome, we focus on generating solutions for specific gene-disease associations to reflect the diverse molecular mechanisms of disease-causing mutations. We apply this approach to generate solutions for 15 genes of critical clinical importance, including BRCA1, KCNQ1 and KCNH2, for which many individually rare missense variants are present in the population. Importantly, our classifiers achieve high diagnostic sensitivity without sacrificing specificity, vastly outperforming existing in silico variant impact predictors. Taken together, our gene-specific variant classifiers provide an opportunity to vastly improve the diagnostic value of existing genetic tests..

1725F

False negatives are a significant feature of next generation sequencing callsets. *D.M. Bobo[1], M. Lipatov[1], J.I. Rodriguez-Florez[2], A. Auton[3], B.M. Henn[1,4].* 1) Ecology & Evolution, Stony Brook University, Stony Brook, NY; 2) Department of Genetic Medicine, Weill Cornell Medical College. New York, NY, 10021, USA; 3) Department of Genetics, Albert Einstein College of Medicine, Bronx, NY, 10461, USA; 4) Graduate Program in Genetics, Stony Brook University, Stony Brook, NY, 11794, USA.

Short-read, next-generation sequencing (NGS) is now broadly used to identify rare or *de novo* mutations in population samples and disease cohorts. However, NGS data is known to be error-prone and post-processing pipelines have primarily focused on the removal of spurious mutations or "false positives" (FP) in downstream genome datasets. Less attention has been paid to characterizing the fraction of missing mutations or "false negatives" (FN) in these datasets. We design a phylogeny-aware tool to determine false negatives [PhyloFaN] and describe how read coverage, multi-allelic variants and reference bias affect the FN rate. Using thousand-fold coverage NGS data from both Illumina HiSeq and Complete Genomics platforms derived from the 1000 Genomes Project, we first characterize the false negative rate in human mtDNA NGS genomes. The false negative rate for the publically available callsets is 17-20%, even for this extremely high coverage haploid data. We demonstrate that high FN rates are not limited to mtDNA by then comparing autosomal data from 28 publically available full human genomes to intergenic Sanger sequenced regions for each individual. We examine both low-coverage (5x-10x) Illumina and high-coverage (~50x) Complete Genomics genomes. We show that the FN rate varies between ~6%-18% for these datasets and that false-positive rates are considerably lower (<3%). The FN rate is strongly dependent on calling pipeline parameters, as well as read coverage. Our results demonstrate that missing mutations are a significant feature of genomic datasets and imply additional fine-tuning of bioinformatics pipelines is needed. We provide a tool which can be used to quantify the FN rate for haploid genomic experiments, without additional generation of validation data.

1726W

MIDAS - Multiple Integration of Data Annotation Software. *R. Brumm, S. Eck, M. Schmuck, H.G. Klein.* Bioinformatics, Centre of Human Genetics, Martinsried, Bavaria, Germany.

   The implementation of Next-Generation Sequencing in a clinical diagnostic setting opens vast opportunities through the ability to simultaneously sequence all genes contributing to a certain indication at a cost and speed that is superior to traditional sequencing approaches. Especially in the case of rare, heterogeneous disorders this may lead to a significant improvement in diagnostic yield. On the other hand, the practical implementation of NGS in a clinical diagnostic setting involves a variety of new challenges which need to be overcome. Among these are the generation, analysis and storage of unprecedented amounts of data, strict control of sequencing performance, validation of results, interpretation of detected variants and reporting. Here we present MIDAS (Multiple Integration of Data Annotation Software), a central software system for data integration in a diagnostic laboratory. MIDAS is a modular constructed software system to integrate data from Laboratory Information Management System (LIMS), data from the routine Sanger sequencing workflow as well as NGS sequencing results and correlates the identified variants with the patients' phenotypical features. The phenotype is systematically recorded using the Human Phenotype Ontology standard nomenclature. In particular, Genotype-Phenotype correlations identified in one patient are made available for all other cases, to aid the interpretation and build a comprehensive knowledge base. MIDAS is implemented in Java using hibernate for database access and JavaFX as graphical user interface. Its architecture is designed modular with the basic architecture including a dynamic module loader, a user management with LDAB connection and a basic search form. According to available modules the user management and search form are adjusted; granting access for module specific views. It is possible to load every module combination, since all modules are able to run as standalone. As an advantage of this architecture, other data, such as arrayCGH or MLPA can easily be integrated by implementing new modules.

1727T

Validation of a novel, high-throughput HLA-I genotyping method based on phased, full-length sequencing. *R. Chhibber[1], D. Monaco[1], D. Wilkins[1], R. Perry[2], E. Hunter[1], J. Tang[3], D. Dilernia[1].* 1) Emory Vaccine Center, Emory University, Atlanta, GA; 2) Department of Epidemiology, University of Alabama, Birmingham, AL; 3) School of Medicine, University of Alabama, Birmingham, AL.

   Background: Current HLA genotyping methods are routinely based on partial sequencing of HLA genes or haplotype inference based on short-read Next Generation Sequencing (NGS). Obtaining the full-length sequence of each individual allele can only be achieved using phased, long-read NGS technology, but multiple technical challenges preclude its wide-spread implementation. **Objective:** To develop a novel HLA-I (A, B and C) genotyping method based on PacBio-sequencing of the complete gene and to validate this approach in Mother-Father-Child trios. **Materials and methods:** HLA class I alleles from trios were resolved using a novel NGS-based method in which SMRT technology (Pacific Biosciences) was used in conjunction with previously published computational algorithms for data analysis (Dilernia *et al* NAR 2015) to assemble the entire length of each HLA allele. The NCBI SBT interpretation tool was used for allele assignments. Accuracy was assessed by visual comparison of the sequences using Genious R9. **Results:** A total of 174 alleles were sequenced in parents to allow validation of 96 alleles obtained from offsprings. In all, 92 distinct alleles in the offsprings were readily confirmed against the parent's alleles (no mismatches). Among the four inconsistencies, three were likely missing as a result of limited number of reads in gene-specific PCR amplicons. For the remaining questionable trio sequences, we found a C*08:02:01:01 in a child instead of either C*02:01:01:01 or C*07:02:01:01, as expected from the parents' alleles. Interestingly, we found nine novel alleles of which four were among offsprings that were consistent with parental sequences (B*15:18x, A*34x, A*03x and B*35:01:01x). **Conclusions**: Our HLA-I genotyping method is able to provide the highest possible allelic resolution, with a potential to detect novel variations in sequences that are rarely covered by conventional methodology.

1728F

Detecting heterozygous Copy Number Variants (CNV) deletions in haploinsufficient genes in Clinical Whole Exome Sequencing (cWES). *T. Chiang[1], S. White[1], T.J. Wu[1], W. Bi[2], P. Liu[2], F. Xia[2], Y. Yang[2], M. Bainbridge[1], E. Boerwinkle[1,3], D. Muzny[1,2], E.B. Venner[1], W. Salerno[1], R.A. Gibbs[1,2].* 1) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 3) Human Genetics Center, University of Texas Health Science Center, Houston, TX.

Identifying CNVs in cWES is becoming routine in the clinical setting. ClinVar contains 20,546 CNV losses, 9,768 of pathogenic significance. We previously reported methods to reliably detect homozygous deletions in cWES using a dual normalization approach that examines PCA and RPKM Read Depth (RD) values to call copy number losses. Here, we extend these methods (AtlasCNV) to detect heterozygous deletions by using a Firth Logistic Regression (FLR) model trained on exon targets whose PCA-RD is less than 3 standard deviations below the mean (diploid), and RPKM-RD values less than 75% of the median RPKM. FLR models were performed for each exon of the exome capture design (VcromePK2) and the model parameters were applied to test samples. AtlasCNV results were compared with CNV calls from Illumina array (HumanExome-12v1, cSNP) for 40 samples, each with a heterozygous deletion (also detected independently on other microarrays). AtlasCNV confirmed all 40 validated CNVs (6,898 total exons). We also analyzed AtlasCNV results for 4,956 exomes, identifying 279,983 deleted exons (mean:56 exon/sample), with 95% heterozygous deletions (266,355). Evaluating these CNVs for biological significance, 55% of the samples (2708/4956) have heterozygous deletions in genes that are described in ClinGen as haploinsufficient genes linked to dosage pathogenicity. Out of 376 curated genes in ClinGen with evidence of dosage pathogenicity (289), or genes associated with autosomal recessive phenotype (85), we have samples identified with candidate heterozygous deletions in our cohort that are associated with 350 of these genes (93%). Ongoing work is focused on refining AtlasCNV precision. While approximately 50% of the exome map is not covered by the cSNP array, in regions with overlapping coverage, the concordance between cSNP and WES data for deletions is 17% at target resolution. However, 41% of exon targets in these regions have only one probe, limiting the efficacy of cSNP data in assessing the specificity and resolution of WES data. Validation data based on AtlasCNV calls was also assessed among clinical exomes in 511 Trios. Among all the heterozygous deleted targets in probands, concordant in cSNP and WES data, 68% (990/1465) follow a consistent mendelian inheritance pattern with their parents. In sum, these data demonstrate the utility of calling heterozygous CNVs in the clinical setting, and incorporating this analysis in known disease genes will boost the diagnostic rate.

1729W

Allele-specific expression from single-cell RNA-seq data. *K. Choi, N. Raghupathy, S.C. Munger, G.A. Churchill.* The Jackson Laboratory, Bar Harbor, ME.

In diploid cells, the two allelic copies of a gene can differ in the timing and the level of their expression as determined by genetic, environmental, and stochastic factors. But until recently allele-specific expression (ASE) studies were restricted to analysis of whole tissues or population of sorted cells. The application of single-cell RNA Sequencing technologies (scRNA-Seq) opens a whole new perspective on the dynamics of allelic expression that is lost in whole tissue samples. We are now aware that allele expression occurs in bursts over short time intervals. And, as a result, scRNA-Seq data delivers a snapshot of asynchronous cells in which genes are randomly expressed from either the maternal or paternal allele (a.k.a. random monoallelic expression or RME) in many cells. However scRNA-Seq data poses multiple technological challenges that result from amplification of the cellular RNA and limited size of the RNA pool in individual cells. High level of sampling noise often coupled with low depth of coverage causes larger variance in quantified allelic expressions. Due to inefficient reverse transcription process, alleles may drop out from measurements irrespective of their abundance. Low expressed alleles are frequently missed from underlying Poisson process. Sorting out the combined effect of technical dropouts and sampling noise on top of cell-to-cell stochasticity is key to understanding the genetic regulation and dynamics of allelic expression. To overcome these problems, we developed a mixture model in an empirical Bayes framework. Our model tackles data sparsity in each individual cell by partially referring to information from other cells of a kind, and controls overdispersion by allowing cellular heterogeneity on maternal/paternal allele proportion via a common prior. Our approach also classifies genes according to the cell proportions in maternal monoallelic, paternal monoallelic, and biallelic expression states resulting from RME. We found that ASE quantification based only upon uniquely-aligning reads reports hundreds of false monoallelic expressions. The timing of maternal and paternal allelic bursts was positively correlated. Our classifier identified hundreds of genes that are highly dynamic in their allele usage patterns during different stages of mouse blastocyst development.

1730T

Linking 25,000 eMERGE participants with highly-accurate imputed HLA regions to electronic health records. *D. Crosslin[1], A. Gordon[2], P. Devi[1], A. Burt[2], D. Carrell[3], X. Zheng[4], M. Hayes[5], S. Hebbring[6], K. Kiryluk[7], S. Stallings[8], L. Bastarache[9], J. Denny[9,10], E. Phillips[10,11], D. Velez[12], T. Edwards[10], D. Roden[9,10,11], B. Namjou-Khales[13], J. Harley[13], I. Kullo[14], M. de Andrade[15], E. Larson[3], G. Jarvik[2,16], The electronic Medical Records and Genomics (eMERGE) Network.* 1) Department of Biomedical Informatics and Medical Education, University of Washington, Seattle, WA; 2) Department of Medicine, Division of Medical Genetics, University of Washington, Seattle, WA; 3) Group Health Research Institute, Center for Health Studies, Seattle, WA; 4) Department of Biostatistics, Division of Medical Genetics, University of Washington, Seattle, WA; 5) Department of Medicine, Division of Endocrinology, Metabolism, and Molecular Medicine, Northwestern University Feinberg School of Medicine, Chicago IL; 6) Center for Human Genetics, Marshfield Clinic Research Foundation, Marshfield, WI; 7) Department of Medicine, Columbia University, New York NY; 8) Vanderbilt Institute for Clinical and Translational Research, Vanderbilt University Medical Center, Nashville, TN; 9) Department of Biomedical Informatics, Vanderbilt University, Nashville, TN; 10) Department of Medicine, Vanderbilt University, Nashville, TN; 11) Department of Pharmacology, Vanderbilt University, Nashville, TN; 12) Department of Obstetrics and Gynecology, Vanderbilt University, Nashville, TN; 13) Department of Pediatrics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 14) Department of Internal Medicine, Division of Cardiovascular Diseases, Mayo Clinic, Rochester, MN; 15) Department of Health Sciences Research, Division of Biomedical Statistics and Informatics, Mayo Clinic, Rochester, MN; 16) Department of Genome Sciences, University of Washington, Seattle, WA.

The Electronic Medical Records and Genomics Network (eMERGE) has developed eMERGEseq, a CLIA-grade sequencing panel of 106 genes comprising the ACMG 56 and site-requested genes focused on clinical actionability and approximately 1500 SNPs. The goal is to return these results through the electronic health record (EHR) for clinical decision support for 25,000 participants over a three-year period. Of the 1500, we selected 275 SNPs common among Illumina 1M Duo, OmniQuad, OmniExpress, 660K and 550K platforms to assist in the imputation of the HLA region using HIBAG-HLA genotype Imputation with attribute BAGging [Zheng 2013]. This is includes *HLA-A, B, C, DRB1* and *DQB1* regions. Alternative to tagging strategies, HIBAG combines the concepts of attribute bagging with haplotype inference from unphased SNPs and HLA types. Attribute bagging is a method for improving the accuracy and stability of classifier ensembles deduced using bootstrap aggregating and random subsets of variable, with pre-fit classifiers for European, Asian, Hispanic, and African ancestries [Zheng 2013]. In addition to returning results to the EHR, another goal of eMERGE is genetic discovery, and we believe having 25,000 participants with imputed common variants will provide unprecedented resolution for this region, and ultimately genotype-phenotype associations. Once such phenotype is PheWAS, which is a technique to harness a wide range of physiological and/or clinical outcomes and phenotypes by using algorithms to parse EMR data [Denny 2013]. We hypothesize that we will identify the HLA region as having strong pleiotropic effects, and will be well-powered with 25,000 participants to detect these associations. The first 1000 participants with colorectal cancer are being sequenced at the time of this abstract proposal, and will provide pilot data for this study. Many of the participants will have orthogonal data of these regions including exomes, genomes, and Sanger sequencing, which will provide validation and/or comparison for the imputation results. In addition, there are *HLA-B* tagging SNPs on eMERGEseq, which will allow comparison of imputation using tagging and attribute bagging using HIBAG. Having high-confidence calls in this region in this sample size linked to EHRs will prove beneficial both in discovery and implementation science.

1731F

Comparative analysis of global gene expression profile in mouse strains after hypoxic challenge either susceptible to or resistant to chronic hypoxia-induced pulmonary hypertension (PH). *N. Dasgupta[1], P. Hale[1], M. Pauciulo[1], T. LeCras[2], P. Pastura[2], W. Nichols[1].* 1) Division of Human Genetics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 2) Division of Pulmonary Biology, Cincinnati Children's Hospital Medical Center, Cincinnati, OH.

Pulmonary arterial hypertension (PAH), characterized by high pulmonary artery pressure and remodeling of the small pulmonary arteries, can progress to right heart failure and death if untreated. While previous studies have identified *BMPR2* and other genes in the pathogenesis of PAH, data suggest additional genetic factors contribute to the disease. The goal of our study is to identify novel genes and/or genetic modifiers and pathways contributing to the development of PH. Phenotyping of RVSP and RVH in 33 inbred strains after hypoxic exposure identified one high responding (PL/J; RVSP=85mm Hg) and two low responding (MRL/MpJ, RVSP=37mm Hg; FVB/nJ, RVSP=47mm Hg) strains. To compare responses at the molecular level in PL/J compared to MRL/MpJ and FVB/nJ, RNASeq and miRNASeq was performed using total RNA prepared from lung tissue. Global profiles of the differentially expressed mRNAs (DEGs) and microRNAs (DEmiRs) were studied for all 3 strains at 3 different exposure times (3days; 1week; 3weeks) using 0hrs as baseline. Total altered DEGs from all 3 strains and exposures were stratified into chronic and acute response using 3way Venn diagrams. There were almost twice as many upregulated DEGs compared to the downregulated DEGs in all strains and time points except at 3 weeks for MRL and FVB. PL/J had the maximum number of DEGs at all 3 time points. Similar analyses performed on the miRNAs showed that DEmiRs in PL/J and FVB/nJ strains had a comparable profile at 3 days and 1 week. The number of DEmiRs almost doubled at 3 weeks. In contrast, the number of DEmiRs in MRL/MpJ was sharply reduced at 3 weeks as compared to 3 days and 1 week. There were 35 pathways common across the 3 strains. 71 pathways were shared between MRL/MpJ and FVB/nJ but absent in PL/J. No unique pathways were identified in PL/J. IPA analyses showed the top functional pathways of the acute and chronic response DEGs were inflammation which constituted 19-24% of the total DEGs in each strain/exposure length while cell growth and proliferation DEGs constituted 17-29%. Our results suggest a differential pattern of gene expression in mouse strains demonstrating differences in response to hypoxia. The predicted interactions between DEmiRs and DEGs suggest regulation of the observed differential gene expression under hypoxic conditions. Additional studies are warranted to validate these interactions and determine their possible contribution to the development of chronic hypoxia-induced PH.

1732W

Robust lineage reconstruction from high-dimensional single-cell data. *S. Garcia[1,2], G. Giecold[1,2], E. Marco[1,2], L. Trippa[1,2], G.-C. Yuan[1,2,3].* 1) Biostatistics and Computational Biology, Dana-Farber Cancer Institute, MA; 2) Department of Biostatistics, Harvard T.H. Chan School of Public Health, Boston, MA 02115, USA; 3) Harvard Stem Cell Institute, Cambridge, MA 02138, USA.

Single-cell gene expression data provide invaluable resources for systematic characterization of cellular hierarchy in multi-cellular organisms. However, cell lineage reconstruction is still often associated with significant uncertainty due to technological constraints. Such uncertainties have not been taken into account in current methods. We present ECLAIR (Ensemble Cell Lineage Analysis with Improved Robustness), a novel computational method for the statistical inference of cell lineage relationships from single-cell gene expression data. ECLAIR uses an ensemble approach to improve the robustness of lineage predictions, and provides a quantitative estimate of the uncertainty of lineage branchings. We show that the application of ECLAIR to published datasets successfully reconstructs known lineage relationships and significantly improves the robustness of predictions. ECLAIR is a powerful bioinformatics tool for single-cell data analysis. It can be used for robust lineage reconstruction with quantitative estimate of prediction accuracy.

1733T

Ultrafast comparison of personal genomes. *G. Glusman, M. Robinson, D.E. Mauldin, Big Data for Discovery Science (BDDS) Center of Excellence.* Institute for Systems Biology, Seattle, WA.

We present here an ultra-fast solution to the problem of comparing genomes across sequencing technologies and reference genome versions; our solution also preserves privacy. Comparing genomes can be a slow, complicated and error-prone bioinformatic procedure. Personal genomes are large, consisting of millions of variants represented relative to a reference genome. The position of a genomic variant depends on the reference version used, can be "zero based" or "one based", and the chromosomes may be labeled using different schemes (e.g., "NC_000003.12", "chr3" or just "3"). Sequencing the same genome using different technologies can yield different results, as each technology has its own biases. Even sequencing the same genome repeatedly with the same technology can give somewhat different results due to the stochastic nature of genome sequencing, batch effects, or differences in the computational pipelines used. We have developed a method for transforming a standard genome representation (i.e., a list of variants relative to a reference) into a "fingerprint" of the genome involving both common and rare variants. This transformation does not require knowledge of the technology, reference and encoding used, and yields fingerprints that can be readily compared without requiring 'lifting over' coordinates. Fingerprint sizes can be tuned to adjust sensitivity for different applications. Thanks to their reduced size, computation on the genome fingerprints is fast and requires little memory. This enables scaling up a variety of important genomic analyses. Computing a fingerprint from a whole-genome VCF typically takes 10-15 seconds; comparing two fingerprints, 0.5 milliseconds. Thus, a massive all-against-all comparison of 11,726 genome fingerprints (68,743,675 pairwise comparisons) took just 10 CPU hours. The results clearly separate comparisons of the same genome, comparisons of closely related individuals, and comparisons of unrelateds. Within a family, relationships up to second cousin are recognizable. The fingerprints also enable reconstruction of population structure in a fraction of the time, and facilitate a variety of crucial tasks like selecting suitable controls for a set of cases and computing kinship matrices. Since the original genome representation cannot be reconstructed from its fingerprint, our method has significant implications for privacy-preserving genome analytics. This Big Data for Discovery Science work is supported by NIH 1U54EB020406.

Envision: Inferring the functional effects of non-synonymous variants using experimental results from large-scale mutagenesis. *V.E. Gray, R.J. Hause, J. Shendure, D.M. Fowler.* Genome Sciences, University of Washington, Seattle, WA.

Current computational predictors for mutational effect focus on the binary consequences of mutations, *e.g.,* deleterious or not. Recently, technological advances have afforded high-throughput methods to quantify mutational effects on protein function. Here, we leverage large-scale mutagenesis data sets comprising tens of thousands of quantitative mutational effect scores for several proteins and protein domains to train a computational tool for predicting mutational effect scores. Our tool, Envision, was trained using gradient boosting machine learning and uses evolutionary conservation, biochemical, and structural annotations to predict both categorical and quantitative effects of single amino acid mutations. Envision is highly accurate both for classification and regression in 10-fold cross validation. We validated Envision in several ways, including on large-scale mutagenesis data not included in model training and on other mutational databases like the Protein Mutant Database. In all cases, we find that Envision outperforms other predictors, except when those predictors were trained on the testing data in question.

1735W

Novel dog genome content revealed by pseudo-*de novo* assembly of unmapped sequence reads. *L.A. Holden[1], M. Arumilli[2], M.K. Hytönen[2], H.T. Lohi[2], K.H. Brown[1].* 1) Department of Biology, Portland State University, Portland, OR, USA; 2) 2Research Programs Unit, Molecular Neurology, University of Helsinki and Folkhälsan Institute of Genetics, Helsinki, Finland.

Dog breeds have distinct genetic backgrounds due to historical breeding practices aimed to produce desired traits. Along with the intense selective breeding for behavioral and physical characteristics comes the predilection for certain diseases. Many of the diseases found in purebred dogs also exist in humans such as diabetes, cancer, and inflammatory disease. Not only are dogs known as man's best friend, but they also serve as a unique tool for studying the genetic basis of diseases. The current dog reference genome is based on a single female Boxer and remains poorly annotated—especially breed-specific variants—yet is widely relied upon to understand the genomic components of simple and complex diseases. To examine genomic content that may not be captured by the reference genome, we evaluated whole genome sequence reads from 26 Border Collie individuals that did not align to the Boxer breed dog reference genome. We trimmed raw sequence reads on quality score and aligned trimmed reads to the reference genome producing 6.7 billion paired reads and 1.1 billion orphaned reads, of which 92% and 99% aligned to the reference genome, respectively. 7% of the Border Collie paired reads aligned discordantly and 1% of both paired and orphaned reads did not align to the Boxer reference genome. We assembled discordant and unmapped reads *de novo* for each individual. Primary assembly of contigs per individual resulted in an average of 454,934 contigs covering 143.5 Mb with an N50 of 301. All primary assembly contigs were again assembled *de novo* into a secondary assembly (all individuals combined) producing 124,488 contigs covering 125.9 Mb of non-redundant sequence with an N50 of 1158. BLASTn of 1000 randomly selected secondary assembly contigs against NCBI's non-redundant nucleotide database showed that 28% of contigs have no known matches in sequenced species and 9% of contigs preferentially align to the human genome over the dog genome. This study reveals novel genomic content present in unmapped sequence reads in the Border Collie that does not exist in the Boxer reference genome. Extending the dog genome by including information found in unmapped reads may prove critical in understanding the breed identity and the genetic component of diseases shared by humans and dogs.

1736T

A functional gene network model for pathogenic bacteria. *H. Kim[1,2], M. Lee[2], I. Lee[2].* 1) Korea Institute of S&T Evaluation and Planning, Seoul, South Korea; 2) College of Life Science and Biotechnology, Yonsei University, Seoul, South Korea.

   Purpose *Xanthomonas oryzae pv. oryzae* is a gram-negative pathogenic bacteria that causes bacterial blight. The purpose of this sutdy is to construct a functional gene network model for *Xanthomonas oryzae pv. oryzae*, dubbed XooNet. Through the predictive network model, we expect to provide better insights and explanations for infection mechanism. And also, we expect that this approach is extended to human pathogenic bacteria research.   Methods Diverse omics data types were incorporated to construct XooNet. First, we inferred co-functional links from 4 distinct omics data, i.e., co-expression, co-occurrence of prtein domains, and two types of genomic contexts between *Xanthomonas oryzae pv. oryzae* genes. In addition, co-functional links from 6 omics data of other bacteria networks, i.e., EcoliNet and PseudomonasNet, were trasnferred by associalogs. Then, all the co-functional links derived from ten distiguished omics data types were integrated to XooNet using a variant of naïve Bayesian integration.   Results XooNet is comprised of 103,426 co-functional links among 3,608 protein coding genes, which covers about 82% genome of *Xanthomonas oryzae. pv oryzae*. For assessment of prediction power, benchmarking test and receiver operating characteristic curve analysis were performed with genes involved in known biological pathways. As a result, we have confirmed that XooNet implements diverse biological pathways of interest and is useful to predict unknown gene functions.

1737F

VarSome: A free knowledge base and aggregator for human genomic variants. *C. Kopanos, V. Tsiolkas, M. Albarca, C. Chapple, A. Massouras.* Saphetor, Lausanne, Switzerland.

   There is now a wealth of information available about human genomic variants. However, this is usually distributed across multiple, independent databases, which greatly complicates the collection of available information on a given variant. Here, we present VarSome, a **novel knowledge base and aggregator for human genomic variants**. It provides an intuitive web-based interface, offering access to the more than 14 billion items of variant and gene annotation we have accumulated in less than a second per query.VarSome provides functional annotation, calculated in real time using the RefSeq and Ensemble transcript databases; it correctly matches (and displays) equivalent indels to annotations; it displays disease and phenotype associations, drug interactions, relevant clinical trials, population frequencies, and prediction scores from a multitude of sources. The large number of external sources is regularly updated to their most recent release.Variants can be searched in Varsome in many different ways including dbSNP rsIDs, explicit descriptions using HGVS notation or genomic coordinates (e.g. BRAF:V600E, chr6-161127501-A-G) or even by pasting a line from a VCF file. VarSome is not limited to known variants: the user may obtain functional annotation for any variant.Users can post comments on specific variants which will be visible to anyone else who visits that variant. This provides an easy and centralized way of sharing information about known or novel variants. VarSome also provides stable, unique links to any variant, known or not, facilitating the sharing of variants between collaborators.VarSome is freely available to the community on varsome.com.

1738W

Localized structural frustration for evaluating the impact of sequence variants. *S. Kumar[1,2], D. Clarke[1,2], M. Gerstein[1,2,3].* 1) Molecular Biophysics and Biochemistry, Yale University; 2) Program in Computational Biology and Bioinformatics, Yale University; 3) Department of Computer Science, Yale University,New Haven, CT 06520, USA.

   With rapid decline in sequencing cost, a large amount of effort has been invested in cataloging protein-coding variants in various cohorts. Growing sequence datasets are increasingly uncovering large numbers of rare single-nucleotide variants (SNVs) in coding regions of the genome. This rarity renders conventional variant-phenotype associations unfeasible when trying to evaluate the potential deleteriousness of SNVs. Protein structures may help to provide the needed means for inferring otherwise difficult-to-discern rare variant induced phenotypic effects. Previous approaches to evaluate the effect of coding variants on protein structures have primarily focused on quantifying global stability changes. However, local perturbations can severely impact functionality (such as catalysis, allosteric regulation, interactions and specificity) without strongly disrupting global stability. In this work, we utilize localized frustration as a metric to quantify the coding variant induced local structural alterations in protein structures. Many of our observations in this study are intuitively consistent; such as the finding that disease-associated SNVs tend to induce strong changes in localized frustration. However, we also find intriguing results in the context of cancer-associated genes: SNVs in oncogenes induce stronger perturbations at the surface, whereas those in tumor suppressor genes (TSGs) induce stronger perturbations in the interior. These findings clearly highlight the efficacy of quantifying local structural changes to assess the functional impact of coding variants. We believe that our study is opportune considering the imminent growth in rare genomic variation datasets through various public and private sequencing initiatives.

1739T

Highly accurate alignment and variant calling by using population genome graphs. *W. Lee[1], J. Browning[1], A. Dolgoborodov[2], K. Ghose[1], A. Jain[2], A. Komoroczi[2], D. Kural[1], B. Pollex[2], G. Rakocevic[3], V. Semenyuk[1], J. Spencer[2], I. Spulber[2], R&D Seven Bridges Genomics.* 1) Seven Bridges Genomics, Cambridge, MA; 2) Seven Bridges Genomics, London, UK; 3) Seven Bridges Genomics, Belgrade, Serbia.

   The 1000 Genomes Project (1000GP) has analyzed genomes from twenty-six populations. A key insight from 1000GP is that most of the variants in an individual are shared by the population. NA12878 is a sample from CEU and EUR as sub- and super-population. Among NA12878's four million variants, there are only 1.3% uniquely belonging to NA12878 in CEU. In other words, other samples in CEU share 98.7% variations with NA12878 which is the largest number compared with other populations. Against EUR, NA12878 has only 0.8% unique variants and the numbers for other super populations are 4.4%, 1.4%, 1.5% and 1.1% for EAS, SAS, AFR and AMR respectively. This has led to the hypothesis that, by incorporating known variants into the current linear reference, we can improve alignment, variant calling and genotyping. To address the challenges of population-scale genomics, Seven Bridges is pioneering the development of graph genomes. A directed acyclic graph (DAG) is constructed by combining the linear reference genome with a list of variants in a population. The backbone of a graph is the linear reference genome while each branch on the graph indicates a genomic variant, guiding an alternative path for read alignments. We then work on a graph read mapper that maps reads onto a DAG representing a reference population genome. The mapper is designed to be interoperable with existing bioinformatics pipelines and accepts inputs in standard format and produces alignments as BAM files. FASTA with VCF are used for graph construction while FASTQ provides short reads of a sample. Reads are mapped to the graph reference using a global search algorithm followed by a local mapping algorithm. Furthermore, highly sensitive genotype information can be provided by giving the graph path of each alignment. We simulated sixty million paired-end reads with 3.4 million variants including SNPs and INDELs. Since having a perfect graph for aligning a sample is impossible we then simulated different sizes of graphs for benchmarking, either larger or smaller. Each graph may have only fifty percent variants overlapping with the sample. Calling variants by GATK, BWA's alignments achieves 0.889 precision-recall while the graph alignments have 0.948, 0.915 and 0.88 based on the perfect, imperfect and none graphs respectively. Graph alignments of NA12878 shows that several false possible SNPs reported in dbSNP are caused by INDELs nearby which demonstrates the power of graph genomes. .

InterVar: Clinical interpretation of genetic variants by ACMG 2015 guidelines. *Q. Li, K. Wang.* Zilkha Neurogenetic Institute, University of Southern California, Los Angeles, CA.

   Statement of purpose: The American College of Medical Genetics and Genomics (ACMG) published in 2015 the updated standards and guidelines for the clinical interpretation of sequence variants, based on 28 pieces of evidence. However, for many clinical labs, implementing these variant scoring rules into a standardized workflow is difficult with available informatics tools or datasets. An automated tool or web service that combine all annotation databases and offer a one-stop shop for human interpreters is urgently needed, which can help human interpreters quickly understand the clinical significance of genetic variants. **Methods:** We present such a tool, InterVar (clinical <u>Inter</u>pretation of genetic <u>Var</u>iants), to fill these unmet needs. InterVar can take a VCF file and automatically generate necessary evidence based on the current ANNOVAR annotation results. InterVar mainly consists of two steps: 1) automated interpretation and 2) manual re-interpretation by user-supplied domain knowledge. The companion web server called wInterVar(wintervar. wglab.org) is developed for searching or re-interpreting all possible missense variants. **Results**: (I) We performed automated interpretation by InterVar on a dataset of 9,305 *de novo* variants from 12 published neurodevelopmental disorders studies with 6,515 cases and 959 controls. Comparing cases versus controls, we detected a strong enrichment of pathogenic/likely pathogenic (P/LP) variants (P=0.0087), based on InterVar's automated interpretation. There are no strong enrichment of P/LP variants using SIFT and PolyPhen. (II) We analyzed the entire ClinVar (version 2016-03-02), and compared their annotations with InterVar. InterVar is largely consistent (93.1%) with ClinVar on the benign variants, but has large differences in the pathogenic category. (III) We interpreted previously reported 616 clinically actionable variants in 112 actionable genes. For InterVar results, only 34 (5.5%) variants were classified as pathogenic/likely pathogenic variants. The vast majority of the "pathogenic" variants annotated by HGMD or other studies are probably not pathogenic, which is consistent with recent literature. In summary, InterVar can facilitate human reviewers to interpret the clinical significance of variants in human genetic studies. InterVar is especially useful to address severe congenital or very early onset developmental disorders with high penetrance.

1741W

New resources and updates at the Database of Genomic Variants (DGV). *J.R. MacDonald, M. Zarrei, J. Whitney, D. Merico, S.W. Scherer.* The Centre for Applied Genomics and Program in Genetics and Genome Biology, The Hospital for Sick Children, Toronto, Ontario, Canada.

   The Database of Genomic Variants (http:/dgv.tcag.ca) was established in 2004, and has served as a publicly accessible, curated catalogue of structural variation (SV) found in the genomes of control individuals. The current version of DGV consists of 72 published studies, comprising >6 million entries ranging from 50bp to 3 Mb in size, identified in >36,000 unique genomes. The latest release includes data from 5 new studies, and includes novel collections with > 3,000 samples from previously under-represented populations. Currently over 75% of the genome is covered by CNV and this estimate is likely inflated as a result of contributions from earlier studies, using low resolution platforms such as BAC CGH, which have been shown to overestimate the CNV boundaries. To address the overabundance of CNV, we have generated a new resource that utilizes the most current and high-resolution studies to generate a Gold Standard set of CNVs. Each study in DGV was evaluated for sensitivity and specificity and 32 studies were selected as they were found to have a low false positive rate with accurately defined boundaries. A cross study meta-analysis was performed to generate a reference set of variants found in the > 19,000 samples tested in these studies. This allowed us to leverage large unique cohorts, and complementary approaches across many studies to achieve a well-defined set of variants. To reduce the number of false positives in this dataset, the curated Gold Standard variants were required to have support from more than one study and found in more than one sample. This will help to reduce technological biases, and also remove sample specific artefacts by compensating for individual study biases. This new resource contains a total of 38,185 CNV regions which were identified from over 5 million sample level CNVs used as input. This new resource will aid the interpretation of new CNV findings for both clinical and research applications.

CNV detection from targeted next-generation panel sequencing data in routine diagnostics. *A.M. Nissen, C. Rapp, M. Locher, A. Laner, A. Benet-Pagès, E. Holinski-Feder.* Medical Genetics Center Munich, Munich, Bavaria, Germany.

In times of next generation sequencing (NGS), a single analysis approach to detect SNVs and CNVs from the same data source would be of great benefit for routine diagnostics. However, CNV detection from exon-capture NGS data has no standard methods or quality measures so far. Current approaches depend solely on read depth data which is systematically biased by exon capture. Different enrichment methods and variation within sequencing runs makes data normalization a challenging task. We developed a bioinformatics method to detect exonic CNVs using read depth data derived from targeted NGS panels. The development of our pipeline is based on: (1) utilization of more than one detection tool, (2) different reference sets for different kits, (3) normalization against samples from the same sequencing run, (4) definition of special quality thresholds for single exon events. In detail, our CNV pipeline is a combination of the open source tools ExomeDepth, Clamms, Canoes and Codex, and an in-house developed method that utilizes Mann-Whitney U test and heterozygosity check. All tools are based only on read depth data wherefore capture efficiency per exon was assessed with a reference set of CNV negative patients to identify reliable regions. In these regions, a CNV is called if at least two out of the five methods are concordant for the respective CNV. The pipeline showed a CNV detection sensitivity of 77.46% and precision of 94.83% in a test set of 71 patients with pathogenic CNVs previously detected by MLPA. We correctly detected 42 deletions and 13 duplications with high confidence. False negatives (22.54%, 16 CNVs) were proven to be one exon events or located in pseudogene regions and were detected by only one of the detection tools (mostly ExomeDepth). To minimize false negatives, the pipeline is currently adjusted to call single exon events under specifically adapted quality parameters with only one out of the five tools. Performance of the pipeline was successfully tested with different enrichment systems (Agilent, Illumina) and data from external laboratories. However, this method is only applicable for selected genes and non-reliable regions as well as single exon CNVs with low significance should be confirmed by another method.

1743F

Integrating mean and variance heterogeneities to identify differentially expressed genes. *W. Ouyang[1,2], Q. An[2,3], J.Y. Zhao[3], H.Z. Qin[1,2].* 1) Center for Bioinformatics and Genomics, Tulane University, New Orleans, LA; 2) Department of Biostatistics and Bioinformatics, Tulane University, New Orleans, LA; 3) Department of Epidemiology, Tulane University,, New Orleans, LA.

In functional genomics studies, mean heterogeneity tests have been widely employed to identify differentially expressed (DE) genes with distinct mean expression levels under different experimental conditions. Variance heterogeneity (aka, the difference between condition-specific variances) of gene expression levels is simply neglected or adjusted for as an impediment. The mean heterogeneity in the expression level of a gene reflects one aspect of its distribution alteration; and variance heterogeneity induced by condition change may reflect another aspect. Change in condition may alter both mean and some higher-order characteristics of the distributions of expression levels of susceptible genes. In this report, we put forth a conception of mean-variance differentially expressed (MVDE) genes, whose expression means and variances are sensitive to the change in condition. We mathematically proved the null independence of existent mean heterogeneity tests and variance heterogeneity tests. Hereby, we proposed an integrative mean-variance test (IMVT) to combine gene-wise mean heterogeneity and variance heterogeneity induced by condition change. The IMVT outperformed its competitors under comprehensive simulations of normality and Laplace settings. For moderate samples, the IMVT well controlled type I error rates, and so did existent mean heterogeneity test (i.e., the Welch t test (WT), the moderated Welch t test (MWT)) and the separate tests on mean and variance heterogeneities (SMVT), but the likelihood ratio test (LRT) severely inflated type I error rates. In presence of variance heterogeneity, the IMVT appeared noticeably more powerful than all the valid heterogeneity tests. Application to the gene profiles of peripheral circulating B raised solid evidence of informative variance heterogeneity. After adjusting for background data structure, the IMVT identified novel experiment-wide significant MVDE genes, while all the valid competitors did not identified any experiment-wide significant DE genes. Our results indicate tremendous potential gain of integrating informative variance heterogeneity after adjusting for confounders. The proposed informative integration test better summarizes the impacts of condition change on expression distributions of susceptible genes than do the existent competitors. Therefore, particular attention should be paid to explicitly exploit the variance heterogeneity induced by condition change in functional genomics analysis. .

1744W

ClinGen Pathogenicity Calculator. *R. Patel, N. Shah, A. Jackson, R. Ghosh, P. Pawliczek, S. Paithankar, A. Baker, K. Riehle, H. Chen, X. Feng, S. Milosavljevic, S. Plon, A. Milosavljevic. Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.*

   The American College of Medical Genetics and Genomics and the Association for Molecular Pathology (ACMG/AMP) recently provided guidelines for sequence variant interpretation. To enable automated large-scale application of the ACMG/AMP guidelines in a consistent way, we have developed the ClinGen Pathogenicity Calculator which automatically calculates provisional variant classifications based on evidence provided by users. The Calculator also makes reasoning explicit by documenting (a) applicable ACMG/AMP rules, (b) evidence codes applied for the variant and (c) links to data provided by users to support variant classification. The Calculator is accessible at http://calculator.clinicalgenome.org along with use cases and accessory services. Using the current Calculator interface, a registered user may (1) identify an allele already present in the ClinGen Allele Registry (CAR); (2) register new alleles; (3) enter ACMG/AMP-style evidence tags and links to supporting data for each tag; (4) generate ACMG/ AMP guideline-based pathogenicity classification; (5) store and share reasoning behind each conclusion; (6) generate variant reports in PDF format. The Calculator design is flexible and allows customization of guidelines, for specific genes and conditions. For example, we customized the calculator for diagnosis of inborn metabolic disorders by including evidence codes and rules that take into account metabolite levels and additional evidence codes to support the diagnosis of MYH7 related cardiomyopathy. So far there are ~100 registered users of the calculator from various parts of the world. We expect the ClinGen Pathogenicity Calculator to facilitate the improved use of the ACMG/AMP variant guidelines and sharing of variant classification.

1745T

ClinGen Allele Registry. *P. Pawliczek[1], R. Patel[1], A. Jackson[1], N. Shah[1], C. Bizon[3], S. Rynearson[6], T. Nelson[5], S. Harrison[2], D. Azzariti[2], B. Powell[7], R. Freimuth[4], L. Babb[2], A. Milosavljevic[1]. 1) Baylor College of Medicine, Houston, TX; 2) GeneInsight, Sunquest Information Systems; 3) RENCI, Chapel Hill, North Carolina; 4) Mayo Clinic Rochester Minnesota; 5) Geisinger autism and developmental medicine, Lewisburg, PA 17837; 6) UCGD,University of Utah; 7) University of North Carolina,Genetics Medicine, Chapel Hill, North Carolina.*

   Current allele naming systems define alleles in the context of specific reference sequences. It is therefore hard to collate information about an allele from various sources when they refer to the same allele in the context of different contigs, genome assemblies, transcripts, or amino acid sequences. Moreover, naming systems such as HGVS may provide numerous equivalent representations of the same allele such as indel in the context of the same reference sequence. Unique variant identifiers may currently be obtained only upon a lengthy manual process of submitting the variant to one of a few databases that provide "de-duplication" or "canonicalization" services as part of their submission or data curation processes. To address the need for fast and simple programmatic allele registration services and thus catalyze the growth of knowledge about genetic variation, we developed the ClinGen Allele Registry. The registry provides query, registration and "canonicalization" services via an interactive user interface at http://reg.clinicalgenome.org . To facilitate linking of allele data within ClinGen and globally, all the functionalities of the registry are also exposed for programmatic access via JSON-LD (W3C standard compliant) REST APIs documented at reg.clinicalgenome.org . When provided an HGVS expression, the registry returns an existing or newly-registered allele identifier within a few seconds. The canonical identifier corresponds to a dereferencable URI/URL that may be used to programmatically retrieve allele representations across genome assemblies and transcripts and obtain alternative identifiers of the allele across key resources such as ClinVar and dbSNP. The registration process includes validation and canonicalization by alignment of the allele against genome assemblies and transcripts (NCBI and ENSEMBL). The registry implements conceptual and resource models for alleles documented athttp://datamodel.clinicalgenome.org/development/allele/. We illustrate registry features by showing how it may be used to accomplish the following: (1) Resolve identity of repetitive indels in ClinVar; (2) Collate information about an allele from different sources using Linked Data methods; (3) Provide programmatically accessible registry services to applications such as the ClinGen Pathogenicity Calculator.

1746F

Disentangling expression across genes, tissues and individuals by Bayesian tensor decomposition. *I. Pe'er, S. Yang, M. Wang.* Computer Science, Columbia University, New York, NY.

   Expression profiles are standardly analyzed as matrices that run genomewide and across multiple samples. Modern data allows distinguishing samples across individuals vs. across tissues. The resulting three-dimensional tensor structure obviates the faults of two-dimensional analysis, that either averages the data along one of the tensor axis, thus losing information, or treats it as an unstructured set of profiles, introducing redundant parameters.   We propose a fully-Bayesian model for low-rank decomposition of expression tensors. The underlying assumption is that measured expression profiles tally weighted combinations of idealized ones specific to biological processes. Weights are determined by tissue and separately, by individual. Expression tensors are thus approximated by sums of outer products of vector factors. Inferring vector coefficients separately using Gibbs sampling overcomes the computational limitation of inferring such a model, while using a prior that encourages similarity facilitates sharing information across tissues, genes and individuals. The Bayesian formulation conveniently sidesteps arbitrary parameter-tuning. Initialization is conducted using two-dimensional methods akin to principal component analysis.   We demonstrate accuracy of the approach on simulated data, and apply it to real RNA-seq data of brain regions from GTeX. We validate the discovered factors in an independent dataset by the CommonMinds consortium.

1747W

Data-driven computational modeling of three-dimensional genome architecture: Lessons from CTCF-and RNAPII-mediated chromatin interactions. *D. Plewczynski[1,3], P. Szalaj[1,3,4], Z. Tang[2], P. Michalski[2], M. Kadlof[1], P. Wroblewski[1], M. Sadowski[1], G. Mazzocco[1], O. Luo[2], Y. Ruan[2].* 1) Centre of New Technologies, University of Warsaw, Warsaw, mazovia, Poland; 2) The Jackson Laboratory for Genomic Medicine, Farmington, CT, USA; 3) Centre for Innovative Research, Medical University of Bialystok, Białystok, Poland; 4) Hasselt University, Belgium.

   Chromosomal folding are important features of genome organization, which play critical roles in genome functions, including transcriptional regulation. Using 3C-based mapping technologies to render long-range chromatin interactions has started to reveal some basic principles of spatial genome organization. Among 3D genome mapping technologies, ChIA-PET is unique in its ability to generate multiple datasets (in a single experiment), including binding sites, enriched chromatin interactions (mediated by specific protein factors, like CTCF), as well as non-enriched interactions that reflect topological neighborhoods of higher-order associations. The multifarious nature of ChIA-PET data represents an important advantage in capturing multi-layer structural-functional information, but also imposes new challenges in multi-scale modeling of 3D genome.We applied an advanced ChIA-PET strategy combined with computational modelling to comprehensively map higher-order chromosome folding and specific chromatin interactions mediated by CTCF and RNAPII with haplotype specificity and nucleotide resolution in different human cell lineages. We find that CTCF/cohesin-mediated interaction anchors serve as structural foci for spatial organization of constitutive genes concordant with CTCF-motif orientation, whereas RNAPII interacts within these structures by selectively drawing cell-type- specific genes towards CTCF-foci for coordinated transcription. Haplotype-variants and allelic-interactions have differential effects on chromosome configuration influencing gene expression and may provide mechanistic insights into functions associated with disease susceptibility. Our 3D-genome simulation suggests a model of chromatin folding around chromosomal axes, where CTCF is involved in defining the interface between condensed and open compartments for structural regulation.Finally, we present 3D GeNOme Modeling Engine (3D-GNOME) - a web service which generates 3D structures from 3C data and provides tools to visually inspect and annotate the resulting structures, in addition to a variety of statistical plots and heatmaps which characterize the selected genomic region. 3D-GNOME simulates the structure and provides a convenient user interface for further analysis. 3D-GNOME is freely available at http://3dgnome.cent. uw.edu.pl/ providing unique insights in the topological mechanism of human variations and diseases.

1748T

GATTACA: Lightweight species deconvolution in metagenomes. *V. Popic[1], V. Kuleshov[1], S. Batzoglou[1], M. Snyder[2].* 1) Computer Science, Stanford University, Stanford, CA; 2) Genetics, Stanford University School of Medicine, Stanford, CA.

Despite rapid advances in sequencing technologies, determining the genomic sequences of bacterial species within complex metagenomes poses significant challenges. Existing approaches require specialized binning (Iversen et al, 2012; Albertsen et al., 2013) or complex library preparation techniques (Adey et al., 2014; Kuleshov et al, 2016), which may be expensive or inaccurate. Recent work has shown that genomes of individual bacteria can be accurately recovered from cohorts of metagenomes by clustering genomic sequences using their co-abundance patterns across multiple samples (Nielsen et al. 2014; Alneberg et al., 2014). To estimate abundance, these tools map reads of each sample against each genomic sequence (e.g. pre-assembled metagenomic contig). This methodology assumes the availability of a large cohort of samples and of sizable compute and storage resources to perform read alignment. To alleviate these requirements, we introduce GATTACA, a lightweight alignment-free tool that enables fast binning of genomic sequences from a single metagenomic sample with no significant loss of accuracy. At a high level, GATTACA builds a small index of kmer counts from a reference panel of metagenomic samples; it then uses this index to estimate co-abundance levels of arbitrary genomic sequences and cluster them using variational mixture models. The GATTACA index enables orders-of-magnitude savings in space and time for abundance estimation. We tested GATTACA on both synthetic and real data used to benchmark earlier methods aimed at cohorts of metagenomes. On the synthetic species dataset of Alneberg et al. (2014), GATTACA produces clusters with an accuracy that is comparable with their tool (CONCOCT); unlike CONCOCT, GATTACA takes as input only a single metagenomic sample and a 10GB index and runs on a standard laptop computer. Furthermore, using an index derived from 100 samples of the Human Microbiome Project study, GATTACA accurately identifies clusters of contigs corresponding to the genome of Bifidobacterium animalis within samples of the study by Nielsen et al. (2014). In summary, GATTACA enables researchers to accurately cluster genomic sequences associated with individual bacteria at a level of accuracy that was possible only using a large cohort of samples and substantial computing resources. Thus, GATTACA makes accurate metagenomic binning accessible to a much wider range of researchers.

1749F

The missing parent problem: Attempting parental reconstruction through sibling analysis. *B.N. Pusey, K.R. Chao, M. Warburton, C.C. Lau, W.A. Gahl, D.A. Adams, T.C. Markello.* Undiagnosed Diseases Program, National Human Genome Research Institute, Bethesda, MD.

Since 2009, the NIH Undiagnosed Diseases Program (UDP) has been routinely carrying out genome scale genotyping and exome, sequencing for its patients and their nuclear families, and to date, it has sequenced and analyzed over 400 families. However, for more than 100 of these families data was not available for one or both parents, rendering the analysis for these families exponentially difficult, if not impossible. While these alternative families make up 25% of the UDP cases, they account for less than 5% of the diagnosed cases. It can therefore be surmised that missing parents result in reduced variant filtration power. The resulting data contains a greater number of false positives, which constrains the practical curation and subsequent diagnostic rate. Using genotype data, a minimum of 3 siblings, and the remaining parent, we can partially reconstruct the sequence of the missing parent, provided all three siblings have the same biological parents. This approach relies on the identification of regions within the siblings that can only have been co-inherited from the missing parent. With each extra available sibling, the portion of the missing parent that can be reconstructed increases asymptotically. The strategy uses two sets of discrete mathematical expressions to define informative loci and designate region of the genome as attributable to the missing parent, excludable from the missing parent, or inconclusive. A BED file defining these regions incorporated into subsequent variant analysis steps. The resultant analysis, while still containing regions of indeterminate parentage, allows for more complete phasing of compound heterozygous variant pairs and an overall reduction of noise during filtration (i.e. suppression of false de novos). This technique has the potential to salvage previously difficult cases by striving toward a maximum Mendelian filtration potential. This research is supported by the Intramural Research Program of the National Human Genome Research Institute and Common Fund of the National Institutes of Health.

Karp: Accurate and fast classification of microbiome taxonomy using pseudomapping. *M. Reppell, J. Novembre.* Human Genetics, University of Chicago, Chicago, IL.

 The application of next generation sequencing technology to microbiome DNA samples has had a transformative impact on microbial ecology and human health. The ability to uncover associations between microbes, their environment, and host genetics is dependent on the accurate quantification of the organisms present in the sequenced samples. Many methods have been developed to perform this quantification task; few scale to the size and complexity of modern metagenomic data. Methods that scale well often sacrifice accuracy to achieve reasonable performance. Pseudomapping, a rapid k-mer based approach for query sequence matching, provides a novel way to achieve both speed and accuracy in read assignment. Pseudomapping was originally implemented in the software Kallisto and has shown superior accuracy to other classification methods. However, Kallisto ignores sequencing quality information that could help assign multiply-mapped reads more accurately. This led us to develop Karp, a program that leverages the speed and low memory requirements of pseudomapping with an EM algorithm that uses sequencing base quality scores to quickly and accurately classify the taxonomy of pooled microbiome samples. Using simulated 16S reads we tested the accuracy and performance of Karp relative to Kallisto and USEARCH for large datasets (1M reads) with a range of community compositions and read lengths. Karp consistently had higher accuracy than comparison methods. With 75bp single-end reads on average Karp's errors were 11% less than Kallisto and 55% less than USEARCH. With 301bp paired-end reads, Kallisto's strict pseudomapping threshold lowered performance, and on average Karp's errors were 90% smaller than Kallisto's and 58% smaller than USEARCH's. Karp also improved the accuracy of summary statistic estimates, the average error for pairwise beta diversity was 45% and 80% smaller than Kallisto and USEARCH's estimates, respectively. While Kallisto set the benchmark for computational speed, quantifying 1M reads in <5 minutes and 10GB RAM with 12 cores, Karp is computationally very feasible, requiring <90 minutes and 10GB. USEARCH required <75 minutes and 4GB. Modern sequencing provides us with unprecedented access to the microbial world, but its output requires careful interpretation. Quantifying the taxonomy of a pooled sample is difficult, but with the development of Karp we provide a scalable and accurate solution, of value to every researcher performing microbiome sequencing.

1751T

Motif scraper: A tool for efficient sequence motif searches in FASTA files using degenerate nucleotide queries. *E.D.O. Roberson.* Medicine and Genetics, Washington University, St. Louis, MO.

 FASTA files are a common storage format for sequence data, including reference genomes, personal genomes, cDNA sequences, and *de novo* assembly outputs. However, it is not easy to search these files for specific sequence motifs, such as miRNA binding sites, transcription factor sites, and genomic editing sites capatible with different CRISPR-based technologies. I created motif scraper to address this missing utility. The tool is open-source and freely licensed. The code is written in Python for cross-platform compatibility and ease of use. Motif scraper accepts one or more nucleic acid sequence queries, allowing for IUPAC degenerate bases. The text query is converted to a regular expression, substituting the degenerate bases for their appropriate standard bases. Motif scraper then searches for the degenerate motif using the regex module. The algorithm is amenable to multiprocessing, and can automatically spread the word load across the specified number of processors. This allows for scanning of an entire FASTA genome in minutes for any degenerate motif of interest. The utility of a motif search goes beyond the canonical use of searching reference genomes. FASTA formatted files are commonly generated using de novo assembly from both DNA and RNA, and will increasingly become important as personal genomes, and particularly phased personal genomes, are created. This tool allows for efficient search of personal genomes to annotate such features as new transcription factor or miRNA binding sites produced by an individual combination of rare and private variants. These types of changes in particular cannot be determined from available databases and require calculation per-individual.

Haplotype resolved SV assembly: Producing gold-standard SV calls on diploid genomes using PacBio and 10X sequencing data. *O. Rodriguez[1], F. Sedlazeck[2], M. Pendleton[1], C.T. Watson[3], R. Sebra[1], A.J. Sharp[1], C. Chin[4], M.C. Schatz[2], A. Bashir[1].* 1) Department of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY; 2) Department of Computer Science, John Hopkins University, Baltimore, MD; 3) Department of Biochemistry and Molecular Genetics, University of Louisville School of Medicine, Louisville, KY; 4) Pacific Biosciences, Menlo Park, CA.

Long read sequencing has dramatically improved our ability to examine large-scale genome architecture. Human de novo assembly using Pacific Biosciences (PacBio) sequencing routinely achieves N50s in the Megabases. Additionally, multiple studies have shown that long-read technologies provide more insights into both the number and the complexity of structural variants (SVs). However, traditional de novo assembly and read-mapping approaches appear unable to exhaustively characterize SVs and disambiguate zygosity. For example, these approaches have been observed to exhibit a high-rate of Mendelian violations in trio analyses. Here, we utilize long-read PacBio sequencing, and long-read sequencing supplemented with barcoded short-reads from 10X genomics, to provide highly contiguous and complete assembly of phased haplotype contigs (haplotigs). Novel algorithms are then applied to these haplotype resolved sequences to substantially improve SV inference. We employ our approach on high-depth sequencing data on EBV-immortalized B lymphoblastoid cell lines from an Askenazi Jewish trio (Coriell samples GM24835, GM24149, GM24143) provided as part of the Genome in a Bottle (GIAB) Consortium. A combination of PacBio-only and hybrid approaches are used to build paired maternal and paternal contigs (haplotigs) containing phased SVs and SNVs; together they enable haplotig contigs and scaffolds with N50s exceeding 100kb and 10Mb, respectively. This method also produces more complete calling of heterozygous, events, especially highly complex events, by disambiguating maternal and paternal variation prior to SV resolution. Fewer Mendelian violations are observed, while the absolute number of SV calls increases within the >70% of the genome that appears haplotype separable. Over 20,000 SVs are observed in the proband alone, nearly a third of the total SVs that have been catalogued in all 2,504 individuals within the Phase 3 1000 Genomes project. With the improved knowledge of where high-quality haplotype separation occurs, we can provide far more robust set of SVs which will improve our understanding of structural variation in the genome and provide a training set further method development. We believe this not only represents a critical genomic resource, but moves the community away from biases induced by overreliance on a single reference genome and even closer to automatic, complete, diploid personal genomes.

1753W

ASPIREdb – An interactive web-based system for exploration, analysis and visualization of complex phenome-genome datasets. *S. Rogic[1], P. Tan[1], A. Zoubarev[1], C. McDonald[1], F. Lui[1], G. Charathsandran[1], M. Jacobson[1], M. Belmadani[1], J. Leong[1], T. Van Rossum[1], E. Portales-Casamar[1], Y. Qiao[2,3], K. Calli[3], X. Liu[4,5], M. Hudson[4], E. Rajcan-Separovic[2], S. Lewis[3], P. Pavlidis[1].* 1) Michael Smith Laboratories, UBC, Vancouver, British Columbia, Canada; 2) Department of Pathology, BC Child and Family Research Institute, UBC, Vancouver, Canada; 3) Department of Medical Genetics, BC Child and Family Research Institute, UBC, Vancouver, Canada; 4) Department of Psychiatry, Queen's University, Kingston, Canada; 5) Ongwanada Resource Cente, Kingston, Canada.

One of the main challenges facing researchers studying complex genetic disorders using next generation sequencing technologies is identification of causal variants. Considering additional patient information and accumulated knowledge from public data repositories is necessary to enable sifting through thousands of predicted variants and identifying candidates for further validation. To address this challenge, we developed ASPIREdb, an open-source, easy to use, interactive, collaborative web application that allows researchers to search, organize, analyze and visualize variants and phenotypes associated with a set of human subjects. The data model supports all main types of genomic variants and phenotypes are recorded using Human Phenotype Ontology, whose controlled vocabulary and hierarchical structure facilitate computational inference and linking to external resources. ASPIREdb features a powerful query builder for filtering subjects and/or variants using genotype and phenotype characteristics in conjunction with data from integrated databases and external sources. It also implements several standard statistical methods for analysis and exploration of data, such as burden analysis and phenotype-based clustering. Projects can be shared, allowing researchers to work collaboratively to build queries, analyze and annotate the data. In addition to table-based view of the data, ASPIREdb provides various graphical representations: selected genomic regions and associated, color-coded variants can be viewed using interactive ideogram; the Phenotype Heatmap tool provides a visual summary of phenotype values for selected subjects phenotypic data; and the Variant Report tool plots the distributions of various variants' attributes. ASPIREdb is linked to UCSC Genome Browser, which allows the user to view selected genomic variants in the context of a large collection of aligned annotation tracks. It is also integrated with other web-based databases developed in our lab to provide information on gene networks and differential gene expression patterns of the genes associated with the variants and phenotypic associations of these genes with diseases and phenotypes. In addition, built-in reference databases of common and disease-associated variants, such as DGV and DECIPHER, can be used for variant annotation and filtering.

1754T

Identification of causal genes for rare genetic disorders using whole genome and whole exome sequencing. *Y. Shen[1], A. He[1], W. Zhang[1], N. Thiessen[1], Y. Ma[1], A. Mungall[1], R.A. Moore[1], W. Gibson[1,2], M.A. Marra[1,2], S.J.M Jones[1,2].* 1) Canada's Michael Smith Genome Sciences Centre, Vancouver, BC, Canada; 2) Department of Medical Genetics, University of British Columbia, Vancouver, BC, Canada.

There are over 7000 types of rare diseases known, with many more as-yet undescribed diseases thought to exist. Although individually rare, collectively rare diseases affect 10% of the North American population, and most patients present in childhood. These disorders manifest a variety of medical issues including birth defects, intellectual disability, growth abnormality, and organ failure. It is estimated that approximately 80% of rare disorders have a strong genetic basis, but the majority of their causal genes are unknown. Finding the causal genes has the potential to aid in diagnosis and treatment, as well as to provide an understanding of the molecular basis of the disease. Here we describe a bioinformatics platform that analyses genome and exome sequencing data to identify causal genes in rare genetic disorders. We designed and built a bioinformatics pipeline that integrates a variety of tools to detect small mutations and indels, copy number alterations, and structural variations. Identified aberrations are then filtered against public and in-house databases to detect rare genomic events, annotated with potential functional impact and pathogenicity, and ranked based on the population frequency and biological relevance. Using this pipeline, we have identified multiple genes causing or related to rare genetic disorders, such as *EZH2* in Weaver Syndrome, *EED* in a novel syndrome similar to Weaver syndrome, *ATP1A3* in CAPOS (Cerebellar ataxia, Areflexia, Pes cavus, Optic atrophy and Sensorineural hearing loss) syndrome, and *SGOL1* in CAID (Chronic Atrial and Intestinal Dysrhythmia) syndrome. Our study design also enables collection and comparison of sequencing data from patients with unusual phenotypes, such that updated analyses comparing undiagnosed patients with phenotypes similar to each other can be done.

1755F

High frequency of transcriptomics studies with sample mix-ups. *L. Toker[1,2], M. Feng[1,2,3], P. Pavlidis[1,2].* 1) Department of Psychiatry, University of British Columbia, Vancouver, BC, Canada; 2) Michael Smith Laboratories, University of British Columbia, Vancouver, BC, Canada; 3) Graduate Program in Genome Sciences and Technology, University of British Columbia, Vancouver, BC, Canada.

Concern about the reproducibility and reliability of biomedical research has been rising. An understudied issue is the prevalence of sample mislabeling, one impact of which would be invalid comparisons. We studied this issue in a corpus of human transcriptomics studies by comparing the provided annotations of sex to the expression levels of sex-specific genes. We identified apparent mislabeled samples in 46% of the datasets studied, yielding a 99% confidence lower-bound estimate for all studies of 33%. In a separate analysis of a set of datasets concerning a single cohort of subjects, 2/4 had mislabeled samples, indicating laboratory mix-ups rather than data recording errors. While the number of mixed-up samples per study was generally small, because our method can only identify a subset of potential mix-ups, our estimate is conservative for the breadth of the problem. Our findings emphasize the need for more stringent sample tracking, and that re-users of published data must be alert to the possibility of annotation and labeling errors.

Database for preeclampsia v2.0: Network visualizations and variants. *A. Uzun[1,2], D. Armanious[3], K. Deragon[1], J. Schuster[1,2], J. Padbury[1,2].* 1) Pediatrics, Women and Infants Hospital, Providence, RI; 2) Warren Alpert Medical School, Brown University, Providence, RI; 3) Computer Science, Brown University, Providence, RI.

Preeclampsia is a multi-system hypertensive disorder of pregnancy, characterized by variable degrees of maternal symptoms including elevated blood pressure, proteinuria and fetal growth retardation that affect 2-8 % of deliveries. It is a complex disease and one of the most common causes of fetal and maternal morbidity and mortality worldwide. We built a Database for Preeclampsia (dbPEC) including curated articles, clinical features, genes, and preeclampsia phenotypes. The first version of dbPEC was released on October 2015 and included 899 articles and 602 genes. It is publicly available (http://ptbdb.cs.brown.edu/dbpec). We are now releasing an updated version (v2.0) where users can visualize the interaction between the genes in our database as network maps. We extracted the data from BioGRID (version 3.4.136), a database of physical and genetic interactions, and built a visualization tool implemented using a combination of server-side Java 8 and PHP, along with client-side HTML5 and JavaScript. The Java backend uses a modified force-directed layout algorithm that performs a fine-grained layout for the connected components of the graph and a coarse-grained layout on the entire graph. On the client side, the JavaScript displays the graph on an HTML5 Canvas element and makes it interactive by handling various input events. In this updated version, we also include information on more than 100 SNPs from the curated papers in which genes were experimentally validated. By recent updates and expansions, we believe dbPEC will continue to serve as not only a preeclampsia resource but also will provide useful datasets for analysis of high-throughput experiments and genome-wide association studies.

1757T

A genome and phenome wide landscape of diagnoses in Geisinger Health System for 38,662 individuals. *A. Verma[1,3], S.S. Verma[1,3], A. Lucas[1], D.N. Hartzel[1], D.R. Lavage[1], J. Leader[1], H.L. Kirchner[1], M.D. Ritchie[1,2], S.A. Pendergrass[1].* 1) Biomedical and Translational Informatics, Geisinger Health System, Danville, PA; 2) Department of Biochemistry and Molecular Biology, The Pennsylvania State University, University Park, PA; 3) The Huck Institute of Life Sciences, The Pennsylvania State University, University Park, PA.

Genome-wide genetic studies typically focus on a genetic map of one single disease or a limited phenotype domain, whereas Phenome-Wide Association Studies (PheWAS) provide a comprehensive approach for investigating the association between genetic variants, diseases and quantitative traits. Most PheWAS to date have used a small to moderate number of SNPs for association with phenotypic data. For this study we performed a comprehensive genome-wide PheWAS in DicovEHR cohort, investigating the association between 632,574 genetic variants with minor allele frequency > 1% from 38,662 consented unrelated adult European American participants in the Geisinger Health System MyCode® biorepository and 541 ICD-9 derived case-control diagnoses, to gain insights on the genome-wide landscape of associations. We compared our results to a database of all other existing published GWAS and PheWAS results to date. The most significant association for our PheWAS was between SNP rs9273363 in *HLA-DQB1* and type I diabetes (ICD-9 250.01, p-value = 1.36 x 10^{-77}) replicating previous associations with type 1 diabetes. We also found associations with type 2 diabetes, hypothyroidism, and morbid obesity replicating previously reported associations with similar traits. We identified a series of novel associations, including a missense variant, *HLA-DRB5* SNP rs701884 associated with multiple sclerosis (ICD-9 340, p-value = 5.28x10^{-23}) and *PIGU* intronic SNP rs17305573 associated with actinic keratosis (ICD-9 702.0, p-value = 6.38x10^{-12}). Other possible novel PheWAS results include highly significant genetic associations (p-value < 1x10^{-8}) with phenotypes such as vitamin D deficiency (rs1037378, ICD-9 268.9), acute bronchitis (rs1868256, ICD-9 466.0), mitral valve disorder (rs4852126, ICD-9 424.0), macular puckering (rs12634684, 362.56), and hyperpotassemia (rs983574, 276.7). We are also evaluating our PheWAS results using regulatory and non-protein-coding information from GENCODE and ENCODE. The sweeping comprehensive nature of this PheWAS allows for novel hypothesis generation, the identification of phenotypes for further study and phenotypic algorithm development, identification of cross-phenotype associations, multiple phenotype pathway based analyses, and the identification of the networks existing between phenotypes, genes, and genetic variation.

1758F

Benchmarking distributed data warehouse solutions for storing genomic variant information. *M.S. Wiewiórka[1], D.P. Wysakowicz[1], M.J. Okoniewski[2], T. Gambin[1].* 1) Institute of Computer Science, Warsaw University of Technology, Warsaw, Mazowieckie, Poland; 2) Scientific IT Services, ETH Zurich, Zurich, Switzerland.

Genomic-based personalised medicine incorporates storing, analysing and interpreting of genomic variants as its central issues. When thousands of patients sequenced exomes and genomes are becoming available, there is the growing need for the efficient database storage and querying. The answer may be application of modern distributed datastores and query engines. Still, their properties for large genomic variant databases have not been explored yet. To investigate the utility of modern columnar data stores and distributed querying engines., we have constructed a prototypic large genomic variant database, which has been built according to data warehousing paradigms adjusted to current massively parallel computing architectures using robust big data technologies . Proposed solution consisted of centralized Hive Metastore providing an abstraction layer over pluggable storage backends (e.g. HDFS with different columnar file formats - ORC, Parquet or Kudu storage system). Various query engines like Hive, SparkSQL, Presto or Impala have been evaluated. Finally application of distributed OLAP cube system - Kylin have been verified. To construct a benchmark comparison of technical solutions, the database has been loaded with simulated variant data generated for 50,000 individuals using the allele frequency information from ExAC database. Then in order to enable its time efficiency comparisons, a set of queries both requiring efficient sequential scans and random access patterns (range queries) has been run. The queries are modeling the ad-hoc approach to finding information in the data warehouse, which may be essential for both: research and medical use of the genomic variant databases. The result is a multi-sided insight into the utility of genomic data warehouse systems. It is also the proof that genomic data warehouses can be practically applied in the personalised medicine, once various technical issues related to their design, scaling and query optimization can be solved. The quantitative benchmarking results give the detailed and practical recommendations on using particular formats, querying engines, database structures and query optimization. The results of the research indicate clearly that Kudu may outperform other storage systems. Studies present also recommendations for choosing apropriate distributed query engines in specific use cases. The detailed description of the project can be found at https://github.com/ZSI-Bio/variantsdwh

1759W

Algorithmically optimized gene selection for genomic disease studies. *E. Williams, Y. Tian, Y. Zhu, C. Munroe, C. Shtir.* Thermo Fisher Scientific, Carlsbad, CA.

Selection of genes to include in genomic studies of disease remains a difficult task. Current methods rely on expert opinion or manual search engine use. With these methods, the process and result are neither repeatable nor scalable. To remedy this situation, we created the Informative Genetic Content (IGC) system, which enables the algorithmic selection of genes for inclusion in such studies, given one or more diseases to target.   The IGC system stands on three components: a database associating diseases with genes and other diseases, an algorithm to rank the genes under consideration for inclusion in a panel, and a module that clusters genes by families of diseases.   The first component, the database, maps diseases to associated genes and scores each of these mappings according to the strength of the relationship. The database also maps diseases to other diseases, such that groups of diseases or hierarchical relationships between diseases can be identified.   The second component enables the ranking of candidate genes when multiple diseases are of interest. The algorithm accounts for the common situation where two or more diseases are associated with the same gene with varying strengths of association, weighting and combining the scores across the diseases associated with each gene.   The final component, the gene clustering module, groups genes by pathogenic pathways, should the user want to consider targeting a broader family of diseases affected by a closely related set of genes.   We validated the IGC system through comparisons of our automated gene selections with expertly curated gene panel designs. We found a high degree of overlap between the IGC's gene selection and the gene lists chosen by experts, supporting the viability of our system. Together with the scalability and repeatability enabled by its automation, the IGC system greatly improves the gene panel selection process and therefore advances targeted genomic studies.

1760T

Accurate and robust estimation of DNA contamination against mis-specified population allele frequencies. *F. Zhang[1], G. Abecasis[1,2], H.M. Kang[1,2].* 1) Department of Computational Medicine and Bioinformatics, University of Michigan, Ann Arbor, MI; 2) Department of Biostatistics and Center for Statistical Genetics, University of Michigan, Ann Arbor, MI,USA.

Detecting and estimating inter-sample DNA contamination became a crucial quality assessment step to ensure high quality sequence reads and reliable downstream analysis. Our previous method *verifyBamID*, which provides DNA contamination estimates only from sequence reads and population allele frequency at selected variants, has become a part of standard sequence processing pipeline in many large sequencing centers, effectively flagging largely contaminated samples (e.g >3%). However, it has been known that the DNA contamination from *verifyBamID* could be underestimated if the population allele frequencies are mis-specified.   Small amount of contamination (e.g. 1-3%) could also affect the quality of variant calling and genotype accuracy of sequenced genomes, and it becomes more crucial for deeply sequenced genomes which is expected to provide extremely high genotype accuracy. Accurate estimation DNA contamination levels will allow us to more accurately assess the quality of sequenced genomes to determine objective QC criteria, and also will enable us to correct for the contamination in genotype calling. However, it is cumbersome and imprecise to manually annotate the genetic ancestry of every sample prior to sequencing,   Here we describe a novel method to robustly detect and estimate DNA contamination by modeling sequence reads by individual-specific allele frequencies. Instead of starting from a single population allele frequency, our method reference takes the singular value decomposition of genotypes from a diverse reference population (e.g. HGDP or 1000 Genomes), and jointly estimates principal component coordinates and contamination levels of a sequence individuals together based on a mixture model. The key idea is to precisely model individual-specific allele frequencies from principal component coordinates and estimate DNA contamination based on the allele frequencies iteratively.   We applied our method to 1000 Genomes datasets by simulating contamination levels from 1% to 20% and comparing the contamination estimates obtain from different methods. When using pooled allele frequencies, as opposed to population-specific allele frequencies, we observed that the contamination levels are underestimated by 18%, 35%, 41%, and 70% for CEU, YRI, FIN, and CHS populations, respectively. Using our new method, the underestimation bias was reduced to 1-3%. Our method is implemented in the rapid sequence quality assessment software tool FASTQuick.

1761F

Leveraging an advanced knowledge base of biological pathways and network analytics to identify disease-causing mutations from clinical genome and exome sequence data with increased efficiency and accuracy. *S. Shah[1], A. Krämer[1], S. Tang[1], A. Muthiah[1], T. Vvuong[1], G. Eley[2], B. Solomon[2], A. Khromykh[2], A. Joecker[1], R. Felciano[1], D. Richards[1].* 1) QIAGEN Bioinformatics, Redwood City, CA; 2) Inova Translational Medicine Institute, Falls Church, VA.

Identifying genetic variants underlying rare inherited diseases from Clinical Genome and Exome Sequence (CGES) data can be both challenging and time consuming, with a significant amount of time and resources invested in variant calling, annotation, and interpretation workflows. Accurate determination of true disease-causing variants requires thorough technical validation as well as in-depth assessment of both variant- and gene-level evidence supporting for causation. Here we present a Hereditary Disease and Cancer variant calling and interpretation solution that enables highly efficient identification of disease causing variants with superior accuracy and sensitivity. The high performance is achieved with a novel, streamlined, one step, end-to-end workflows that are able to identify disease causing mutations in hereditary and rare diseases as well as driver variants in cancer. All workflows were optimized for specific exome and genome applications in hereditary diseases or cancer and use large-scale causal network analytics derived from the QIAGEN Knowledge Base. The Knowledge Base is a large structured collection of observations in various experimental contexts with over 11 million integrated findings that are manually curated from the biomedical literature and third-party databases. Pathways and networks constructed from these findings that include mutations, biological interactions, and functional relationships, enable users to discover and prioritize the most interesting and relevant hypothesis and quickly visualize the causal and regulatory networks most closely associated with the disease or phenotype of interest. Additionally, we have developed and integrated a scoring method into our workflow to rank variants, using syndrome inference from phenotypes provided to accurately identify known or novel variants in disease causing gene(s). To showcase these features and capabilities, we will present the results from whole genome sequence data analysis and interpretation from 30 trios, with a child afflicted with severe congenital abnormalities, for which the causal variant was previously known. In 5 out of 6 of the cases analyzed so far, we were able to successfully reduce the number of candidate variants for follow-up to 5 or less, including the previously identified mutation.

1762W

Candidate gene prioritization with Endeavour. *A. Ardeshirdavani*[2,3]*, L. Tranchevent*[1]*, S. ElShal*[2,3]*, D. Alcaide*[2,3]*, A. Aerts*[2,3]*, D. Auboeuf*[1]*, Y. Moreau*[2,3]. 1) INSERM U1210, CNRS UMR5239, Laboratoire de Biologie et de Modélisation de la Cellule, Ecole Normale Supérieure de Lyon, Université de Lyon, Lyon, France; 2) Department of Electrical Engineering (ESAT), STADIUS Center for Dynamical Systems, Signal Processing and Data Analytics Department, KU Leuven, Leuven, Belgium; 3) iMinds Future Health Department, KU Leuven, Leuven, Belgium.

Genomic studies and high-throughput experiments often produce large lists of candidate genes among which only a few are truly relevant to the disease, phenotype, or biological process of interest. Gene prioritization tackles this problem by ranking candidate genes by profiling candidates across multiple genomic data sources and integrating this heterogenous information into a global ranking. We describe an extended version of our gene prioritization method, Endeavour, now available for 6 species and integrating 75 data sources. Users can prepare a prioritization in four simple stages. In the first stage, the species with which to work is selected among the six available species (H. sapiens, M. musculus, R. norvegicus, D. melanogaster, C. elegans, and D. rerio). Then, the set of seed genes is prepared in the second stage. These are the genes that are already associated with the process of interest. The third stage consists in selecting the data sources to use for the prioritization. Finally, the set of candidate genes is defined in the last stage. The hypothesis is that one of these candidate genes is associated with the biological process of interest, but this association is yet unknown. The single output is an ordered list of the candidate genes with on top the most promising candidate genes. In an ideal situation, the gene yet unknown associated with the process of interest should be ranked first or at least among the first genes. Validation of our results indicate that this extended version of Endeavour efficiently prioritizes candidate genes. The Endeavour web server is freely available at *https://endeavour.esat.kuleuven.be/*.

1763T

An approach for integrated gene and variant prioritization. *A. Chhibber, Y. Fu, N. Bani Asadi, H.Y.K. Lam.* Roche Sequencing, Belmont, CA 94002.

Exome sequencing has become a key tool both in clinical practice and translational research for disease diagnosis and as a tool for understanding disease biology. However, identifying causal variants for a particular disease out of the tens of thousands of variants in a typical human exome continues to be a challenge. Methods that rely on variant filters on features such as population allele frequency, conservation, and functional effect can miss variants that fall below conservative thresholds. Variants can be ranked by predicted pathogenicity using a number of different algorithms, but as every individual carries hundreds of potentially pathogenic variants, identifying those events relevant to a particular phenotype remains a challenge. In this study, we highlight the value of incorporating knowledge about the particular disease or phenotype under investigation when prioritizing pathogenic variants in an exome, and present a novel approach for disease-specific gene and variant prioritization. Network-based approaches have been widely applied to the prioritization of genes utilizing human protein-protein interaction (PPI) networks; in particular, methods that employ a random walk along PPI networks to prioritize genes have been very effective. Our approach extends these methods in a manner similar to that used by the Topic-Sensitive PageRank approach in the web search community; each "topic" is a different set of potential disease genes, drawn from phenotype or gene ontology terms specified by the user, and if available, known genes associated with the disease and additional genes related to those genes (for example, genes in the same family, with the same protein domain, in the same pathways, regulatory relationships, etc.). Topics are weighted by the information content of each set and combined into a single gene-based score. These gene-based scores are then combined with variant scores representing predicted variant pathogenicity, giving a single ranked variant list per exome that takes into account both the likelihood the variants disrupt their protein functions as well as the likelihood the gene is involved in the disease under study. We demonstrate that incorporating information about the disease context can aid in variant prioritization.

The ENCODE analysis pipelines: Repeatable and shareable analysis tools for ChIP-seq, RNA-seq, DNase-seq, and whole-genome bisulfite experiments. *J.S. Strattan[1], T.R. Dreszer[1], B.C. Hitz[1], U. Baymuradov[1], E.T. Chan[1], J.M. Davidson[1], I. Gabdank[1], J. Hilton[1], C.A. Sloan[1], F. Tanaka[1], C. Thomas[1], Z. Weng[2], A. Kundaje[1], J.M. Cherry[1].* 1) Department of Genetics, Stanford University Medical School, Palo Alto, CA; 2) University of Massachusetts Medical School, Program in Bioinformatics and Integrative Biology, Worcester, MA.

The comparability of experiments often depends on comparable experiment protocols. This applies equally to the physical manipulation of samples and to the analytical methods that transform raw data to results. Fourteen ENCODE labs have contributed over 4000 replicated ChIP-seq, RNA-seq, DNase-seq, and whole-genome bisulfite experiments on nearly 200 cell types. To ensure that the results from these experiments can be compared, the ENCODE Data Analysis Center (DAC) have specified common data processing protocols for ChIP-seq, RNA-seq, DNase-seq, and whole-genome bisulfite experiments. The Data Coordination Center (DCC) is implementing these specifications as processing pipelines, deploying these pipelines to a cloud-based platform, processing all ENCODE ChIP-seq datasets, and making the pipelines available for anyone to use. The results of these analyses, and metadata describing them, are distributed through the ENCODE Portal and illustrate general methods of accessing and interpreting ENCODE data. The cloud-based deployment of the ENCODE analysis pipelines illustrates how the DCC is creating transparent and reusable analysis tools for ENCODE data and for any primary data from experiments performed with similar protocols. The ENCODE Portal is https://www.encodeproject.org/. The DCC codebase is freely available at https://github.com/ENCODE-DCC/. .

Visualizing human genome in time and space. *W. Zheng[1], J. Zhao[1], L. Zhou[2], H. Xu[1], J. Tang[2,3].* 1) School of Biomedical Informatics, U Texas Health Science Center at Houston, Houston, TX; 2) Department of Computer Science and Engnieering, University of South Carolina, SC 29205; 3) Key Laboratory of Systems Bioengineering of the Ministry of Educatioon, Tianjin University, Tianjin, 300072, PR China.

The high order nuclear organization of mammalian genome plays significant roles in important cellular functions such as gene regulation and cell state determination. The influx of new details about the higher-level structure and dynamics of the genome requires new techniques to model, visualize and analyze the full extent of genomic information in three dimensions. While existing genome browsers have been proven as successful genome information management and visualization tools, these browsers are based on two-dimensional visual interface with limited capacity to represent structural hierarchies and long-range chromosome interactions, particularly across non-contiguous genomic segments.   We created the first model-view framework of eukaryotic genomes, *Genome3D* (http://genome3d.org), to enable integration and visualization of genomic and epigenomic data in a three-dimensional space. Our physical genome model implicitly contains all levels of structure and hierarchy, and provides an underlying platform for integrating multi-scale genomic information within three dimensions. Our viewer uses a hierarchical model of the relative positions of all nucleotide atoms in the cell nucleus. We further developed a game engine based Genome3D browser that has better performance, is platform independent and can be configured to allow users to access and visualize 3D genome models on a remote server.   In this works, we integrated various genomic databases with Genome3D software, providing a multi-scale genome information visualization system to explore and navigate eukaryotic genome in 3-dimension. The new system, iGenome3D, provides a wide spectrum of tools, ranging from model construction to spatial analysis, to decipher the relationships between 3D conformation of the genome and its functional implication. The incorporation of literature allows users to quickly identify key features from PubMed abstracts for genes in the displayed 3D genome structure. The seamless integration of UCSC Genome Browser allows genetic and epigenetic features from the 2D browser to be visualized in 3D genome structure. iGenome3D can also output 3D genome model in various forms, including one that allows these models to be explored in modern virtual reality environments such as Oculus. Eukaryotic genomes can be analyzed from a completely new angle in iGenome3D that enables researchers to make new discoveries from a truly multi-scale exploration.

SJ-Variant: An interactive genomic web portal for clinical variant annotation and visual interpretation. *A. Patel, E. Rampersaud, M. Rusch, D. Hedges, X. Zhou, S. Newman, M.R. Wilkinson, C. Pepper, S. Rice, J. Becksfort, J. Downing, J. Zhang.* St Jude Children's Research Hospital, Memphis, TN.

Clinical classification of genetic variants requires the assimilation of disparate data coupled with detailed review by an expert panel. Delivering this information to diverse audiences of clinicians, research scientists, and counselors, in an informative yet accessible format can also be challenging. To address this challenge, we developed SJ-Variant (https://pecan.stjude.org/pecan_variant_public.html), an interactive web-portal that facilitates clinical panel review and semi-automated variant classification based on ACMG-AMP (2015) guidelines. SJ-Variant houses integrated genomics data, including variant population frequency, recurrence in tumor, and functional predictions, along with additional automated and manually curated annotations. Currently, we are using SJ-Variant for variant classification at St. Jude Children's Research (SJCRH) for cancer-related genes, and in the **C**linical **Re**search in **A**LS and Related Disorders for **Th**erapeutic Development (**CReATe**) Consortium for ALS-associated genes. These classifications, along with user-definable evidence and reference information, can serve as an important resource for researchers and clinicians who themselves may not have the time or expertise to carry out the clinical panel review process. A novel feature of SJ-Variant is the incorporation of ProteinPaint, a visualization tool we recently developed for mapping variants onto isoform-specific protein diagrams (Zhou X. Nature Genetics.2016). SJ-Variant allows manually curated aspects of variant data aggregation, such as publication citations and interpretations to be captured in a structured manner for future retrieval and re-use. Currently, SJ-Variant hosts 800 germline variants with pathogenicity classification determined in a study of 1,120 pediatric cancer patients (Zhang J., NEJM 2015) and a catalogue of >100 germline variants from published ALS research and clinical studies. SJ-Variant will provide the clinical genomics community with an intuitive and easy-to-use interactive portal for tracking decisions on variant classification which may be useful when providing clinical recommendations to patients regarding the importance of known genetic variants. SJ-Variant improves the accessibility of genomic information to the biomedical community in an organized and non-technical manner.

1767F

RolyPoly: A fast and accurate method for identifying trait-relevant cell types using GWAS summary statistics and single-cell gene expression. *D. Calderon[1], D. Golan[2,3], T. Raj[8,9], A. Bhaskar[2], D. Knowles[6], A. Fu[7], J. Pritchard[2,4,5].* 1) Biomedical Informatics, Stanford University, Stanford, CA; 2) Department of Genetics, Stanford University, Stanford, CA; 3) Department of Statistics, Stanford University, Stanford, CA; 4) Department of Biology, Stanford University, Stanford, CA; 5) Howard Hughes Medical Institute, Stanford University, Stanford, CA; 6) Department of Radiology, Stanford University, Stanford, CA; 7) Department of Statistical Science, University of Idaho, Moscow, ID; 8) Department of Neuroscience, Icahn School of Medicine at Mount Sinai, New York, NY; 9) Department of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY.

The identification of relevant cell types for complex traits is important for prioritizing costly, labor-intensive follow up studies. Genome-wide association studies (GWAS) summary statistics implicitly contain information pointing to the tissues and cell types relevant to the trait. However, to our knowledge, there is no polygenic and unbiased method to identify trait-relevant cell types using gene expression information. Here we describe a polygenic method RolyPoly, which connects gene expression and GWAS summary statistics to prioritize cell types for a trait. RolyPoly inference uses a novel method of moments estimator relying on a polygenic GWAS gene score and takes advantage of asymptotic composite likelihood theory for producing calibrated standard errors in order to accurately prioritize important cell types while minimizing false positive errors. We demonstrate the robustness of our method through simulation and validate previously known tissue-trait associations using the GTEx gene expression data from 27 tissues and GWAS summary statistics for over 15 complex traits. Moreover, using single-cell gene expression data from the brain, we discover newly linked pathogenic cell types, including a significant enrichment for myeloid cell types such as microglia ($p < 5e\text{-}7$) for Alzheimer's disease, and replicating fetal cortical cells ($p < 5e\text{-}5$) for Schizophrenia. Our approach represents a powerful framework for understanding the effect of common variants on cell types or cell states, and a useful tool for prioritizing pathogenic cell types for functional follow-up studies. We implement this method in the R package rolypoly.

1768W

Partitioning heritability of complex human disease by minor allele frequency. *K. Hartman[1], R. Hernandez[2].* 1) Biological & Medical Informatics, University California, San Francisco, San Francisco, CA; 2) Bioengineering and Therapeutic Sciences, University California, San Francisco, San Francisco, CA.

   In recent years the genetic heritability of traits have been broken down into the contributions from different parts of the genome, in a technique known as partitioning of heritability. Rather than trying to determine effects of individual loci, this approach seeks the contribution in aggregate of many single-nucleotide polymorphisms (SNPs). This has previously revealed certain regions of the genome contributing disproportionately more heritability per SNP, such as sites of DNase-hypersensitivity and highly conserved non-coding elements. However, the many of regions used in previous studies differ from the background genome in terms of minor allele frequency distribution. This difference could dramatically affect the estimates of heritability coming from these regions both due to bias in the estimation procedure and the etiology of the diseases studied. This work will investigate the relationship between heritability and minor allele frequency using several previously published data sets and through genotypic and phenotypic simulation. Preliminary results show that bins containing fewer SNPs and lower frequency SNPs are subject to greater variance in their estimates of heritability.

1769T

Weighted-likelihood inference of genomic autozygosity in The 1000 Genomes Project Phase III. *A. Blant[1], M. Kwong[1], Z. Szpiech[2], T. Pemberton[1].* 1) University of Manitoba, Winnipeg, Manitoba, Canada; 2) University of California, San Francisco, United States.

   Genomic regions of autozygosity (ROA) reflect homozygosity for haplotypes inherited identical-by-descent from an ancestor common to both parents. Long ROA most likely arise from a recent ancestor; shorter ones from a more distant ancestor. Their length distributions in contemporary populations provide invaluable insight into how population history and sociogenetic practices influence genomic variation patterns. Further, while ROA have underlain the identification of recessive Mendelian disease genes for over two decades, they are now gaining importance in complex diseases studies for the identification of recessive trait variants. We previously reported an ROA detection method that uses a logarithm-of-the-odds (*LOD*) score of autozygosity in a sliding-window framework. This method is sensitive to the effects of linkage disequilibrium (LD) and recent recombination and mutation events onto similar haplotype backgrounds that give the incorrect appearance of autozygosity leading to false-positive ROA detection. In this study, we report an improved *LOD*-based ROA detection method that incorporates population allele frequencies and per-genotype error rates as well as controls for LD and the probabilities of recombination and mutation within a window to provide improved specificity in ROA detection. Using whole-genome (WGS) and whole-exome (WES) sequencing and Illumina BeadChip data available for Phase 3 of The 1000 Genomes Project, we show that ROA identification with *wLOD* becomes more robust with increasing SNP density. While appreciable variability in short ROA is observed across the different data types, intermediate and long ROA are instead highly consistent. Intriguingly, in addition to distinguishing autozygous windows from non-autozygous windows, *wLOD* also appears able to distinguish ROA due to consanguinity from ROA due to endogamy. We replicate the observation that long ROA are enriched for deleterious variation carried in homozygous form, and extend this to show that the degree of enrichment is directly proportional to the predicted strength of deleteriousness. Finally, by directly comparing per-window *wLOD* scores between pairs of populations we identify genomic regions enriched for autozygosity signals in each of the 26 populations. These findings provide additional insights into the role of population history and cultural processes in the evolution and maintenance of recessive disease loci and provide a new tool that can be used to identify them.

1770F

Quantification of sensitive information leakage from genomic linking attacks. *A.O. Harmanci[1,2], M. Gerstein[1,2,3].* 1) Program in Computational Biology and Bioinformatics, Yale University, New Haven, CT; 2) Molecular Biophysics and Biochemistry, Yale University, New Haven, CT; 3) Department of Computer Science, Yale University, New Haven, CT.

Genomic privacy has recently gained much attention. Most studies on privacy focus on identification of scientific study participants by protection of genetic variants. The phenotypic data is generally assumed to be free of individual identifying information. However, an adversary can use phenotypic information and predict genotypic information utilizing the publicly available datasets that contain phenotype-genotype correlations, e.g. quantitative trait loci (QTL). The predicted genotypes can be cross-referenced with genotype datasets and be linked to the phenotype datasets. These links can then be used to reveal sensitive information, such as disease status, that is stored within genotype/phenotype datasets. The availability of very high dimensional phenotype datasets, such as gene expressions, increases the likelihood of a successful linking attack. We present methods for quantifying leakage of information that can be used to characterize individuals. We also present a three-step protocol for instantiation of linking attacks. This enables systematic analysis of these attacks. We finally present an instance of these attacks that utilizes a simple yet highly effective genotype prediction that uses extremes of gene expressions. We finally study the effectiveness of this attack under different scenarios.

1771W

Using polygenic approaches to identify novel associations in existing datasets: Examples from HIV host genetic studies. *R.A. Power[1], C.W. Thorball[2], I. Bartha[2], T. de Oliveira[1], P.J. McLaren[3], J. Fellat[2].* 1) Africa Centre for Population Health, University College London, Durban, South Africa; 2) School of Life Sciences, Ecole Polytechnique Fédérale de Lausanne, Switzerland; 3) JC Wilt Infectious Diseases Research Centre, National Microbiology Laboratory, Public Health Agency of Canada, Winnipeg Canada.

Polygenic approaches to GWAS have been successful in confirming the heritability of complex traits and in understanding aetiology. Here we highlight their potential contribution to the identification of novel risk variants for complex traits in two ways: 1) by identifying homogenous subgroups within a phenotype, allowing a more informed SNP association analysis; and 2) by highlighting SNPs of pleiotropic effect for genetically overlapping phenotypes. Using genome-wide data from 6,315 HIV+ individuals part of the International Collaboration for the Genomics of HIV (ICGH), we first analysed heterogeneity in set point viral load (spVL) – a quantitative trait correlated with disease progression. GWAS of spVL have solely identified variants within the major histocompatibility (MHC). Using GCTA-GREML analysis we showed that while variation in spVL below the median spVL was more heritable compared to variation above the median (h^2=23% vs. 10%), the MHC almost exclusively controlled spVL variation below the median (h^2 excluding MHC: 3% vs. 8%). By restricting to only those individuals with above median spVL, GWAS identified a novel SNP outside of the MHC (rs11555096) at genome-wide significance (p= 2.43e-8). We then used LD Score Regression to test for phenotypes overlapping with HIV susceptibility, a binary trait associated with homozygosity for a 32 bp deletion in *CCR5*. By looking at 25 phenotypes with publically available GWAS summary statistics, we found two with significant genetic overlap: schizophrenia (rG=0.17, p=0.0026) and ulcerative colitis (rG=0.24, p=0.0057). BUMHBOX analyses suggested genetic overlap in both instances was not driven by heterogeneity within the HIV population but by genome-wide pleiotropy. Both these diseases have >100 associated loci, and we tested if these variants significantly predicted HIV acquisition. Three SNPs were significantly associated after correction for multiple testing. Two of these were eQTLs for genes for proteins known to be related to HIV biology: rs1819333 in *CCR6* (p=0.0002) and rs4932178 in *FURIN* (p=0.0003). While these results are preliminary and require further replication, they highlight the potential of polygenic methods to help in the identification of associations with individual variants. Such methods are diverse but crucially often leverage existing, often publically available, data. This makes them cost effective means for gaining new insights into the genomic architecture of complex traits.

1772T

High-resolution relationship inference via multi-way identical by descent sharing. *M.D. Ramstetter[1], J. Blangero[2], A.L. Williams[1].* 1) Department of Biological Statistics and Computational Biology, Cornell University, Ithaca, NY; 2) South Texas Diabetes and Obesity Institute, University of Texas Rio Grande Valley School of Medicine, Brownsville, TX.

Inferring relatedness among study samples is required to correctly perform genome-wide association studies, linkage analysis, and population genetic studies, but existing methods utilize only pairwise relatedness measures and need improvement. Current pairwise relatedness approaches perform well for close (e.g., first degree) relatives, but their accuracy drops as the relationship between two samples grows more distant. Due to the stochastic nature of Mendelian inheritance and recombination, individuals with the same pedigree-based relationship to a given individual vary in the amount of DNA shared with that person, leading to variability in the inferred relationship. This feature—while potentially confounding to traditional approaches—can be exploited by combining identical by descent (IBD) sharing information among sets of close relatives. We propose a new method that extracts and combines IBD sharing information from sets of closely-related individuals to provide more accurate relationship inference between these individuals and their shared relatives. The approach works by first computing pairwise IBD sharing information using Refined IBD and then identifying a confident set of closely-related individuals (e.g., full siblings, avuncular pairs, etc.). Next, we locate individuals that share IBD segments with these close relatives, and we infer relatedness between the close relatives and each such individual. The inference works by implicitly reconstructing the IBD sharing profile between the close relatives' (ungenotyped) common ancestor and each of the more distantly related samples. Assuming that the close relatives' IBD segments all descend from one common ancestor, we can estimate the IBD sharing profile of that ancestor by forming the union of the IBD segments among the close relatives. Descent from one ancestor can be tested by ensuring that all overlapping IBD segments have the same underlying haplotypes. Our analyses show that substantial accuracy improvements are possible via reconstruction of an ancestors' IBD sharing profile. For example, the relationship between sets of siblings and their fifth degree relatives (e.g., second cousins) can be estimated with 67.6% accuracy; by contrast, estimation using the parent of a set of siblings gives an accuracy of 85.3%. We present accuracy results using real data for relationships among 2,485 San Antonio Family Studies individuals that includes hundreds of close and distant relatives.

1773F

Impact of annotation parameter choice on exome sequence analysis pipeline output for application to metabolic disorders in newborn screening. *Y. Wang, A.N. Adhikari, S.E. Brenner.* University of California, Berkeley, CA.

Public health newborn screening (NBS) for rare metabolic disorders uses mass spectrometry (MS/MS). Identifying disease-causing variants from sequencing presents a promising opportunity for early detection and diagnosis of disorders, to complement or perhaps eventually supersede MS/MS for newborn screening. Although the efficiency of genomic data acquisition has increased dramatically, accurate identification of pathogenic variants in the human genome remains a challenge. It is not immediately obvious whether protocols designed for diagnostic clinical exomes can be readily applied for population-level screening, as these applications are quite different. Diagnostic sequencing is performed on patients likely affected by genetic disease and typically has a yield below 50%. By contrast, NBS must identify ~99% of affected individuals, yet must also have >99.5% specificity since ~99.97% of newborns are unaffected by metabolic disorders. Furthermore most clinical exome sequencing uses trios and involves multiple layers of manual review and clinical expertise, while NBS has access to individuals only, and must be overwhelmingly automated due to scale. The primary outcome of a screening pipeline is whether an individual is reported to "screen positive" or "screen negative" for any relevant disorder. Most current variant interpretation methods employ pipelines with multiple annotation features, but there is limited systematic knowledge of which parameters are more sensitive to alterations. We generated a battery of interpretation (>90) pipelines by perturbing different parameters commonly used in clinical sequencing, including the choice of variant callers, phasing methods, MAF thresholds, population reference and disease databases, pathogenicity predictors, and inheritance models. We evaluated which individuals and what fraction of the population screened positive from each pipeline (without knowing which individuals are actually affected). We systematically explored which parameters proved more sensitive to perturbations. Such perturbations can be revealing in terms of evaluating the robustness and dependencies among the parameter choices, and yielded several unanticipated choices especially sensitive to perturbation. These results will inform development of an analysis protocol to be used on the NBSeq project, which will study ~1600 exomes of California newborns found to have metabolic disorders, as well as a subset of false positive by using MS/MS in NBS.

1774W

Integrated genomic analysis with IOBIO. *A. Ward, C. Miller, T. Di Sera, Y. Qiao, G. Marth.* Human Genetics, University of Utah, Salt Lake City, UT.

As next-generation sequencing becomes ubiquitous and research MDs, clinical diagnosticians and other non-bioinformaticians become more actively involved in genomic data analysis, easy to use tools that require no installation, data upload, or computational expertize, providing users an interactive, visually intuitive environment are increasingly necessary.We present a genomic data analysis paradigm built on the innovative IOBIO platform. Starting with aligned DNA sequence and variant calls (the typical outputs of institutional level genomic pipelines), IOBIO web-based applications are used to identify problems with underlying DNA libraries (e.g. excessive PCR duplicates), sequence alignments and variant calls. Having established data quality, gene-level variant prioritization is performed using real-time functional annotation, and comparisons with multiple external variant databases and population allele frequencies are executed. False negative detection is provided using interactive, on-demand variant calling with Freebayes in conjunction with known alleles. Variant lists from external variant prioritization tools and gene-lists from phenotype-driven algorithms can be generated natively within the application or imported from external sources. All of this is achieved without the need for expensive, time-consuming data uploads or lengthy analyses.The power of this workflow to generate data-driven questions, and provide rapid methods to answer those questions is demonstrated using two examples; a real-world clinical example of a family trio, where the proband presents with the lactic acidosis phenotype, and a single individual with a family history of heart disease. Data quality is investigated using the **bam.iobio** and **vcf.iobio** applications. **Taxonomer.iobio** is used to understand the metagenomic composition of the samples and **gene.iobio** interrogates the list of variants (prioritized variants having been generated using **Gemini**), in candidate genes identified by **Phenolyzer**. We finally present some of the features and applications that will soon be augmenting this workflow making it a "one-stop-shop" genomic analysis platform for all users of sequencing data.

1775T

Structural variant calling combining Illumina and low-coverage Pacbio. *A. Carroll.* DNAnexus, Mountain View, CA.

Structural variant calling combining Illumina and low-coverage Pacbio   Detection of large genomic variation (structural variants) has proven challenging using short-read methods. Long-read approaches which can span these large events have promise to dramatically expand the ability to accurately call structural variants. Although sequencing with Pacific Biosciences (Pacbio) long-read technology has become increasingly high throughput, generating high coverage with the technology can still be limiting and investigators often would like to know what pacbio coverages are adequate to call structural variants.   Here, we present a method to identify a substantially higher fraction of structural variants in the human genome using low-coverage pacbio data by multiple strategies for ensembling data types and algorithms.   Algorithmically, we combine three structural variant callers: PBHoney by Adam English, Sniffles by Fritz Sedlazeck, and Parliament by Adam English (which we have modified to improve for speed). Parliament itself uses a combination of Pacbio and Illumina data with a number of short-read callers (Breakdancer, Pindel, Crest, CNVnator, Delly, and Lumpy).   We show that the outputs of these three programs are largely complementary to each other, with each able to uniquely access different sets of structural variants at different coverages. Combining them together can more than double the recall of true structural variants from a truth set relative to sequencing with Illumina alone, with substantial improvements even at low pacbio coverages (3x – 7x). This allows us to present for the first time cost-benefit tradeoffs to investigators about how much pacbio sequencing will yield what improvements in SV-calling.   This work also builds upon the foundational work of Genome in a Bottle led by Justin Zook in establishing a truth set for structural variants in the Ashkenazim-Jewish trio data recently released. This work demonstrates the power of this benchmark set – one of the first of its kind for structural variation data – to help understand and refine the accuracies of calling structural variants with a number of approaches.

1776F

NCBI's database of Genotypes and Phenotypes: dbGaP. *M. Feolo, R. Bagoutdinov, M. Bihan, S. Dracheva, L. Hao, Y. Jin, M. Kimura, R. Lapoint, M. Lee, N. Popova, S. Pretel, S. Sharopova, S. Stefanov, A. Stine, A. Sturcke, Z. Wang, W. Wu, M. Xu, L. Ziyabari, S. Sherry.* dbGaP, NIH/NLM/NCBI, Bethesda, MD.

Statement of PurposeThe National Center for Biotechnology Information's database of Genotypes and Phenotypes (dbGaP) is an NIH-sponsored repository charged to archive and distribute information produced by genome-scale studies investigating the interaction of genotype and phenotype. The data submitted to dbGaP include individual-level molecular and phenotype data; analysis results; medical images; general information about the study; and documents such as research protocols and questionnaires. The molecular data deposited to dbGaP include array-based, sequence-based, and imputed genotypes, as well as expression data and all types of next-generation sequencing (NGS), which are processed and distributed by NCBI's Sequence Read Archive (SRA) or by various NIH trusted partners. Many studies also include a wealth of phenotypic data pertaining to study participants with any combination of medical images, demographic, clinical, or exposure variables, plus the statistical measures of the allelic and gene association tests.MethodSubmitted data are validated for consistency and format using both computational and human curation. Valid submissions are accessioned with stable, unique identifiers that are versioned for successive updates, making it possible to cite the primary data in a very specific and stable way. Once processed, the metadata for each study is indexed for public browsing. Individual level data is packaged by consent limitations and made available for approved investigators via a controlled access system. This process supports data sharing policies for both NIH and scientific journals, and is utilized by several large scale NIH programs including The Alzheimer's Disease Sequencing Project (ADSP), Grand Opportunities - Exon Sequencing Project (GO-ESP), and Genotype-Tissue Expression (GTEx).ConclusionThe dbGaP provides unprecedented access to a vast array of genome scale studies. The submitted studies are funded both by NIH and other funding agencies worldwide. The use of the data has been cited in over a thousand published manuscripts. Through controlled access, approved researchers may obtain complete, versioned, and accessioned statistical analyses, study documents, medical images, individual phenotypes, and molecular measures. This presentation will summarize the current data content; describe dbGaP submission and access procedures; and describe how dbGaP has been successfully integrated with other archives/systems.

1777W

Practical interface and data structure in three generation family cohort study. *S. Kazuro, T. Takai, H. Metoki, S. Ogishima, M. Ishikuro, S. Mizuno, S. Nagaie, T. Obara, Y. Sato, M. Miyashita, C. Yamanaka, M. Kikuya, S. Kuriyama, H. Tanaka.* Tohoku-University, Tohoku Medical Megabank, Sendai, Miyagi, Japan.

This paper describes an input interface and data structure, used for the Tohoku Medical Megabank Project Birth and Three-Generation Cohort Study (the BirThree Cohort Study). In the field of genetic statistics, only the relationship between a child and his/her parents is used to describe family structure. This description form has enough information to use for genetics, however, it is insufficient for the operation of the BirThree Cohort Study. We have to register 70,000 of pregnant women and their family without contradiction, and all of their data must be surely input by more than 150 Research Coordinators assigned to more than 50 medical institution from a Web based DB interface, for the BirThree Cohort Study. We enhanced the basic data structure, add a structure to describe the family role. We defined a unit, consists of seven people of "Pregnant (Mother), new born (child), Father, Grand Mother, Grand Father, Grand Mother-in-law, Grand Father-in-law" for family data input. In addition, we are always maintaining this complex data structure by a system that investigates the contradiction. .

1778T

A fast and easy to use framework for automatic biological knowledge base construction. *J. Lever[1,2], M. Jones[2], S.J.M. Jones[1,2].* 1) Bioinformatics, University of British Columbia, Vancouver, BC, Canada; 2) Canada's Michael Smith Genome Sciences Centre, Vancouver, BC, Canada.

Systems biology research relies on well maintained and up-to-date knowledge bases for a wide variety of information, e.g. genetic interactions. However some areas of biology research lack the required databases and researchers need to search raw text of articles for the relevant data. Manually building a robust knowledge base requires significant investment of manpower and time. Automated knowledge base construction techniques that can be used by domain users are required. These allow a computer to read all relevant literature, identifying all relevant knowledge, and can be updated easily with the latest literature. We introduce a generalised framework for easy knowledge base construction for biological systems. It is based upon our VERSE text mining tool which excelled in the BioNLP '16 Shared Task, winning the competition for extracting knowledge on bacteria habitats. The first stage involves users identifying specific types of target entities (e.g. genes, disease) and relations of interest (e.g. treatments). PubMed abstracts and PubMed Central Open Access full text articles are searched for sentences that discussed multiple target entities. A fast and intuitive interactive annotation system allows the user to select sentences that describe relations of interest. Our VERSE text mining tool is then used to train a classifier to identify relations of interest and applied to all remaining text. The knowledge extracted using VERSE is then available for easy search by the user. As an example of the power and ease of this framework, we developed a knowledge base for cancer-related genes known as CancerMine. This resource associates specific cancer types with known driver, oncogenic and tumor suppressive genes. The initial version was developed from scratch in under three weeks, with most of the time spent computationally in order to process all available biomedical text and optimise the machine learning classifier. Using the competition-winning VERSE tool, a robust and easily updated knowledge base can be generated for any biological problem in which information is scattered within abstracts and accessible full text articles. This framework will be prove immeasurably useful to researchers in domains that lack definitive and well-updated knowledge base resources.

1779F

Integrated database "dbTMM" for genomic prospective cohort study in Tohoku Medical Megabank toward personalized healthcare. *S. Ogishima, K. Shimokawa, S. Mizuno, S. Nagaie, T. Takai-Igarashi, S. Nagase, N. Nakamura, A. Hozawa, F. Nagami, J. Sugawara, S. Kuriyama, S. Kure, Y. Suzuki, N. Minegishi, M. Nagasaki, K. Kinoshita, J. Yasuda, N. Yaegashi, H. Tanaka, M. Yamamoto, ToMMo dbTMM Project.* ToMMo, Tohoku University, Sendai-shi, Miyagi, Japan.

To revitalize medical care and realize personalized healthcare in the disaster area of Great East Japan Earthquake, the Tohoku Medical Megabank (TMM) project has developed a large-scale biobank with conducting prospective genome-cohort study. In our prospective cohort study, we will recruit 150,000 people at Tohoku University, satellites, health clinics, and Iwate medical university, and have collected specimen and health survey data (laboratory tests, questionnaire data, and physical measurements) as baseline investigation. As for follow-up cohort study, we will collect clinical data as electronic health records provided by hospitals. Our biobank is an "integrated" biobank having both biobank and sequence facility for genomic and omics analysis to provide data with highly common interest instead of distributing the raw specimen. Integrated biobank provides not only health survey and clinical data but also genomic and omics data. We have developed the integrated database what we call "dbTMM" which integrates both health survey data and genomic data as integrated biobank. We have built Release 1.0.0 (Mar 31, 2016) which consists of genomic data (SNV data over 2.1 million SNV sites) and health survey data (laboratory tests, questionnaire data) for 1,070 participants. Researchers in universities, institutes, and companies can use data from dbTMM after approval from data access committee. Our integrated database "dbTMM" realizes ultra-fast search of large-scale health survey and genomic data, and shows statistical signature of narrowed-down cohort; e.g., if narrowed-down population has statistically significant bias in sex and alcohol intake, sex and alcohol intake will be indicated to users automatically as statistical signature. This statistical signature is expected to give insights and hints to researchers. Our integrated database "dbTMM" is expected to be a platform for data sharing to promote researches aiming at realization of personalized healthcare.

Prioritizing genes for the genetics community using GTR and ClinVar to close the interpretive gap. *W.S. Rubinstein, M. Landrum, J. Lee, D.M. Maglott, M. Benson, G. Brown, C. Chen, S. Chitipiralla, B. Gu, J. Hart, D. Hoffman, W. Jang, B. Kattman, K.S. Katz, A. Malheiro, M. Ovetsky, G. Riley, A. Sethi, R. Tully.* National Center for Biotechnology Information, National Institutes of Health, Bethesda, MD.

Background The interpretation of sequence variation is the grand challenge of genomic medicine. As more sequence data are generated, the 'interpretive gap' in our understanding about the clinical significance of variation grows wider (Cutting, 2014; PMC3882730). About a quarter of variants in ClinVar have pathogenicity interpretations different enough to potentially change clinical management (e.g., variant of uncertain significance (VUS) vs. pathogenic). The actionability of a gene is moot for any variants which cannot be reliably interpreted. Methods Data in GTR and ClinVar were used to suggest priorities for ClinVar submission and methods to evaluate the pathogenicity of variants. GTR has >34,000 orderable tests. The number of tests offered for a gene reflects its clinical relevance. ClinVar's gene-specific report (ftp://ftp.ncbi.nlm.nih.gov/pub/clinvar/tab_delimited/gene_specific_summary.txt) includes numbers of VUS and variants with conflicts. ClinVar maintains a table of ACMG's 56 genes for reporting secondary findings. Results GTR has 4,129 tested genes, with the number of tests ranging from 1 to 313. All 56 ACMG genes are tested, with a significantly higher number of tests per gene than the average. ClinVar has submissions with variants specific to >4,500 explicitly reported genes, but is missing 658 GTR tested genes. Six ACMG genes have fewer than average (N=34) ClinVar submissions: *SDHC, CACNA1S, NF2, MYLK, PCSK9, SDHAF2*. 72 labs in GTR offer 292 tests for these genes. ClinVar has 2,398 genes with conflicts (average 12 per gene, range 1 – 1,758) and 565 genes with VUS (average 6 VUS per gene, range 1 – 347). The number of submissions is strongly correlated with the number of conflicts and VUS. We will also report a weighting approach to prioritize genes with more conflicts and VUS. Conclusions We encourage all who register their tests in GTR to submit their variant interpretations to ClinVar to help close the interpretive gap for all genes being tested. Submissions for the six under-represented ACMG 56 genes are especially important because the risk/benefit ratio is higher for secondary variants uncovered in the absence of a reported phenotype. However, additional submissions alone are unlikely to reduce conflicts and resolve VUS. Robust types of evidences, such as functional assays and correlation of clinical phenotype to established gene effects, are particularly needed for clinically relevant genes and welcomed as part of ClinVar submissions.

1781T

Introducing the Vertebrate Gene Nomenclature Committee (VGNC). *S. Tweedie, B. Yates, B. Braschi, K.A. Gray, R.L. Seal, E.A. Bruford.* HUGO Gene Nomenclature Committee (HGNC), European Bioinformatics Institute (EMBL-EBI), Hinxton, United Kingdom.

Standardised gene nomenclature provides an essential resource for all researchers. However an ever-increasing number of vertebrate genomes are being sequenced and the data released into the public domain without any systematic annotation or gene naming. There are only six vertebrate model organisms with an established gene nomenclature committee (mouse, rat, chicken, Anolis, Xenopus and zebrafish), all of which base their gene names on those approved by the HUGO Gene Nomenclature Committee (HGNC) for human genes. The Vertebrate Nomenclature Committee (VGNC) is a new initiative that extends the remit of the HGNC to approve consistent gene names and symbols across vertebrates. Our naming strategy for each vertebrate species starts by identifying a high confidence set of genes with 1:1 human orthologs using our HCOP tool (http://www.genenames.org/cgi-bin/hcop), which aggregates orthology predictions from multiple sources. These 1:1 orthologs are named in a semi-automated manner, with the human gene nomenclature being transferred to the orthologous gene. Genes with non-consensus orthologs, members of complex gene families, pseudogenes and RNA genes require additional manual curation. Our prototype species for VGNC naming has been chimpanzee and we have already named over 10K protein-coding chimp genes with a 1:1 human ortholog. During this process we have taken the opportunity to improve the consistency of our names and taken care to minimise transfer of species-specific information. This naming process will soon be expanded to other species, including dog and cow. An online vertebrate gene nomenclature portal has been created that stores, displays and makes this new nomenclature data accessible both to individual researchers and available for dissemination to other resources including Ensembl and NCBI Gene. Further information and requests for individual vertebrate gene names and symbols can be made via: http://www.genenames.org..

1782F

Next-generation sequencing (NGS) vs. Sanger sequencing: Defining quality parameters, reliability scores and thresholds to exclude false positive variants in a diagnostic setting. *M. Ziegler, Y. Dincer, S. Eck, J. Schulz, H.G. Klein.* Center of Human Genetics, Martinsried, Germany.

Separating true positive from false positive variants is a big challenge especially in huge exome datasets. Therefore, thresholds for NGS quality parameters (e.g. average quality, coverage, read balance) should be determined for effective filtering and maximum precision. We statistically analyzed 387 kb of data from 19 patients with various phenotypes (arrhythmia, hearing loss, nephrotic syndrome, thoracic aortic aneurysm and dissection, porphyria) sequenced simultaneously via Sanger sequencing and NGS. Statistics were performed using the in-house NGS-Pipeline (Agilent SureSelect Target Enrichment and Illumina MiSeq/NextSeq and CLC Genomic Workbench) with Sanger sequencing analysis (ABI3730 and JSI SeqPilot) as reference. The sensitivity (99.6 %), specificity (100.0 %), accuracy (100.0 %) and precision (96.6 %) were high for variants with coverage above 20. Integrating mutation confirmation data and variants with coverage from 10 to 20 in the analysis reveals 18/290 false positive called variants. On the basis of this data, a formula and reliability threshold was determined via statistical models. The reliability formula was then integrated in the in-house variant database for validation. When tested on further NGS confirmation data, the threshold reveals high precision and also represents a user-friendly application. Continuing analysis of confirmation data to increase prediction precision of the reliability threshold should be considered.

1783W

Updating continuously changing variant information in routine diagnostics. *B. Liesfeld[1], D. Schanze[2], R. Ewald[1], S. Leye[1], R. Abou Jamra[3].* 1) Limbus Medical Technologies GmbH, Rostock, Germany; 2) Institut für Humangenetik, Otto-von-Guericke-Universitaet Magdeburg, Magdeburg, Germany; 3) Institut für Humangenetik, Universitaetsklinikum Leipzig, Leipzig, Germany.

The ever increasing number of detected variants poses a great challenge for routine diagnostics. Complex software systems have been developed to integrate information from hundreds of different sources to annotate variants from a patient. New information emerges every day and previously trusted information becomes outdated at an increasing speed. While clinicians strive to provide highest-quality assessment to their patients based on the knowledge they have at the moment of diagnosis, it is extremely difficult to routinely review all previous cases in regular intervals. The large number of variants detected in every patient and the increasing number of patients submitted to genetic testing call for an automated and scalable system to perform regular reviews. We evaluate a system architecture that integrates the variant assessment service VARVIS with the ALLEXES network which provides access to a comprehensive number of different reference data sources. VARVIS is used to manage and maintain genotypic and phenotypic data of every patient of an institution. The ALLEXES network provides reference data for genomic variants across public data sources, e. g. ClinVar, as well as pathogenicity scores. In addition, the ALLEXES network links all connected VARVIS services so that variant data can be exchanged without compromising data privacy. All variants of a patient are annotated with data from the ALLEXES network. The VARVIS service highlights any inconsistencies of variant classification in comparison to local historic data or to data provided by the ALLEXES network. The data provided by ALLEXES includes allelic frequency data and variant classifications from other institutions connected to the ALLEXES network. At the same time the patient is registered with the ALLEXES network with all de-identified phenotypic and genotypic data. The improvement of this architecture over state-of-the-art genomic solutions is that the central ALLEXES network has the capability to notify any connected institution about changes in reference data that may affect the diagnosis of a patient. Rules can be configured flexibly such that the level of sensitivity to changes can be adjusted according to the standards of the local institution. The management and review is integrated into the graphical user interface of VARVIS. This system architecture is in use at several clinical genetics institutions and proves to be invaluable for the delivery of highest quality of care to our patients.

1784T

Distribution of machine images for rapid deployment of NCBI and community bioinformatics tools. *B. Busby.* NCBI-NLM, NIH, Bethesda, MD.

There is an increasing need to provide instruction on and rapid deployment for NCBI tools used on the LINUX command line, including EDirect, standalone BLAST, and the SRA toolkit, as well as community tools that are integral to using NCBI NGS data (e.g. samtools), and very popular tools that can be challenging to configure with our data structures (e.g. GATK). Setting up such environments offsite is often a challenge. We are releasing machine and docker-type images -- including popular reference genomes -- that can deploy NCBI resources and some community tools that work with them. These machine images will be launchable on several cloud platforms (e.g. Amazon and Google) and distributed computing environments (e.g. CyVerse). Please visit the NCBI learn page (ncbi.nlm.nih.gov/learn) for more information. .

1785F

A personal genome analysis course for undergraduates. *D.J. Matthes.* Genetics, Cell Biology and Development, University of Minnesota, Minneapolis, MN.

As we enter the era of personal genomics, where it will soon be common medical practice to determine the genome sequence of each patient, and where it is already possible to inexpensively obtain ones genotype at nearly a million commonly polymorphic loci, the need for personal genome-oriented genetics education has arrived. Here I describe a personal genome analysis course for undergraduates in which students (1) are genotyped by a direct-to-consumer sequencing company, (2) work in a collaborative team-based learning course to analyze how their own variants reveal their ancestry and (imperfectly) predict their traits, and (3) write their autogenomography – a collection of stories each student finds within their genome. The structure of the course, the 20 genome analyses students carry our, examples of student work, and an assessment of student learning and achievement of course objectives will be discussed. Briefly, students improve their performance on select questions on the Genetics Concept Assessment, performed uniformly well (80%) and above on a final exam of technical issues in personal genome analysis, and research and write a 50+ page document (their autogenomography) that demonstrates the level of genomic understanding they have attained. While some students grappled with ancestry results that differed from what they expected, or with the implication of learning their carrier status for some significant diseases, the overall experience, even for these students, was a transformative and extremely positive one. In anticipation of the day when nearly every biology department will offer a personal genome analysis course, here I present a template and course materials for consideration, discussion and adaptation.

1786W

Whole-exome sequencing uncovers candidate mutations for genetic suppressors of Rett syndrome symptoms in *Mecp2* **mice.** *R. Zeng[1], J. Ruston[1], M.J Monica[1,2].* 1) Genetics&Genome Medicine, SickKids hospital, Toronto, ON, Canada; 2) Department of Molecular Genetics, The University of Toronto, Toronto, Ontario Canada.

Rett syndrome is a rare neurodevelopmental disorder characterized by progressive neurological decline and breathing abnormalities after birth. Ninety-five percent of patients carry mutations in the X-linked gene methyl CpG binding protein2 (*MECP2*). The *Mecp2*-null mouse is a useful model for Rett syndrome because its symptoms include limb clasping, tremors, uneven breathing, impaired coordination and hypo-activity. To demonstrate the power of suppressor genetics to identify therapeutic pathways, we used a dominant *N*-ethyl-*N*-nitrosourea (ENU) mutagenesis screen to identify loci that suppressed symptoms in *Mecp2*-null mice. A Squalene epoxidase (*Sqle*) nonsense mutation was identified in one suppressor line, which suggested the cholesterol homeostasis pathway as a potential target for the treatment of Rett syndrome [1] We have extended the suppressor screen to isolate 46 dominant suppressor lines that show amelioration of health assessment traits. To identify gene mutations that implicate pathological disease processes and suggest new therapeutic treatments, we sequenced samples by using whole-exome DNA sequencing. To identify candidate genes, we sequenced the G1 founder and 2 - 4 samples from G3 offspring that inherit the suppressor traits. Sequencing was performed on an Illumina Hiseq 2000 system. Hard-filtering for the variants was based on a minimum SNP quality of 20 and read depth of 5. To narrow down the sequence variants (SVs), we removed common polymorphisms reported in the Wellcome Trust Sanger Institute mouse SNP database. Since it is unlikely to induce recurring variants by ENU, we further filtered SVs by removing shared polymorphisms present in other suppressor lines . By using these strategies, we reduced the potentially causative SVs from tens of thousands to a range of 22-77 mutations in different lines. Here, I report a missense mutation in Ectonucleoside triphosphate diphosphohydrolase3 (*Entpd3*), which is shared in the G1 founder and his trait-improved progenies in suppressor line 136. qRT-PCR reveals that the expression of *Entpd3* is significantly up-regulated in eight week old *Mecp2*-null mouse brain, which might indicate a perturbation in the nucleotide-hydrolyzing pathway in *Mecp2*-null mice. Altogether, we conclude that exome sequencing alone without mapping is an efficient and fast way to identify gene mutations induced by ENU mutagenesis. [1] Buckovecky CM, et al. (2013) *Nature Genetics* 45(9): 1013-1020 .

Use of electronic health records to generate one of the largest family cohorts with detailed longitudinal phenotypic data. *S. Hebbring[1], X. Huang[2], R. Elston[3], G. Rosa[4], J. Mayer[5], Z. Ye[5], T. Kitchner[1], D. Page[2].* 1) Human Genetics, Marshfield Clinic, Marshfield, WI; 2) Department of Biostatistics & Medical Informatics, University of Wisconsin-Madison, Madison, WI; 3) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH; 4) Department of Animal Science, University of Wisconsin-Madison, Madison, WI; 5) Biomedical Informatics Research Center, Marshfield Clinic Research Foundation, Marshfield, WI.

Diseases are the result of genetic and/or environmental factors. Understanding the etiology of human disease is necessary to advance precision medicine. Pedigree analysis is a longstanding approach to gain insight into the underlying genetic factors in human health. In the last decade, pedigree analysis has predominantly given way to large population-based studies on samples of independent persons as a result of high-throughput genotyping methodologies and the ability to collect significant numbers of unrelated cases and controls. A reverse paradigm shift may occur if the construction and use of family pedigrees could be combined with classical genetic analyses in a high-throughput manner. The goals of this study were to rapidly predict family pedigrees from an electronic health record (EHR) system with no human intervention and demonstrate its potential relevance in genetic research and clinical utility. Using basic demographic data in an EHR with nearly 2 million patients, we developed an algorithm that identified familial relationships among 579,561 individuals that were linked to 173,368 pedigrees. Manual validation demonstrated that over 98% of the relationships were accurately defined. To demonstrate the utility of EHR-linked families, we extracted diagnostic data for 19 congenital diseases (presumed genetic disorders) and 9 non-genetic phenotypes as controls, to determine if genetic relationships in EHR-linked pedigrees can predict disease risk. In essence, we created family histories for 28 clinical phenotypes using nothing more than readily available data in an EHR system. When comparing the predictive value of genetic relationship in the two disease categories, genetic relationship was strongly associated with congenital phenotypes (p=0.031). Of the 19 congenital disorders, genetic relatedness was predictive (p<0.0001) for 10 diseases. The strongest association was with "congenital anomalies of limbs" (p<1.0E-15). With the anticipated widespread application of genomic medicine, in combination with methods capable of predicting family pedigrees linked to extensive longitudinal phenotypic data in an EHR, a quantum leap may occur in how human genetic research is conducted for the advancement of precision medicine.

1788F

Decoding *cis*-regulatory function directly from DNA sequence. *K.A. Barr[1], J. Reinitz[2].* 1) Genetics Genomics and Systems Biology, University of Chicago, Chicago, IL; 2) Ecology and Evolution, University of Chicago, Chicago, IL.

In the last several years there have been major efforts to catalog regulatory genetic elements in both humans and model organisms, as well as to record differences in gene expression between individuals and tissues. However, the extent of sequence variation among individuals and vast number of cell types makes it impossible to record expression under every possible condition. To make matters more complicated, gene regulation is a function of large genetic loci that can span megabases and harbor numerous genetic variants that preclude the identification of functional variation. These issues may be addressed by mechanistic models of gene regulation that have the potential to calculate expression levels resulting from previously unobserved sequences or cell types, and to identify the functional regulatory variants in large loci and the means through with they act. In this work we present a thermodynamics-based model that is able to decode the regulatory function of the *even-skipped* (*eve*) genetic locus in *Drosophila melanogaster*. This locus has been studied for nearly three decades and serves as a model system for studies of gene regulation. Using confocal microscopy, our lab has quantified both transcription factor levels and mRNA levels at single-nucleus resolution along the anterior-posterior axis of developing embryos. These data amount to a set of quantitative single cell assays of transcription input and output in a native tissue context, providing an extraordinarily precise testbed for theoretical models. When our model is trained on this data – taking DNA sequence, binding preferences of transcription factors (TFs) in the form of position-weight matrices, and levels of these TFs as input – we are able to directly compute transcription levels. Our model identifies four enhancers within the *eve* locus and describes their binding site structure with single-nucleotide precision. We can identify which TFs are responsible for each expression feature of *eve* and predict the effects of mutations in *cis* and *trans*. The model code includes a dynamic-programming algorithm that scales linearly with the number of binding sites identified, which will allow it to be applied to new organisms and larger datasets.

1789W

Mixed-layered network modeling for gene expression across individuals and tissue types. *S. Yang[1], D. Pe'er[2,3], I. Pe'er[1,3].* 1) Computer Science, Columbia University, New York, NY; 2) Biological Sciences, Columbia University, New York, NY; 3) Systems Biology, Columbia University, New York, NY.

Expression quantitative loci (eQTLs) have been extensively studied, as they provide an attractive functional interpretation to sequence variation. Yet, many traditional eQTL studies had been mainly focused on *cis*- analysis of each transcript, without drawing on the complete picture of the regulatory repertoire. Furthermore, such studies standardly remove genomewide effects from data as a preprocessing step, interpreting them as artifactual batch effects rather than genetic or other biological signal. In this work, we devise a mixed-layered regression model, considering polygenic multi-loci eQTL regulation of gene expression. The model includes several layers of variables, where successive layers are connected through logistic functions whose parameters are inferred through regression with sparsity regularization. A key feature of our model is allowing *trans*-SNPs to indirectly affect a particular target gene through an intermediate hidden layer, which we call *cell environment variables*. We encourage these variables to affect gene expression in a cell-type-specific fashion. Variables in this hidden layer are designed to implicitly describe unmeasured quantities in the sampled cells, such as chromatin state, activity of a cellular pathway, level of a small molecule, or unknown mechanisms, all of which affect expression in a cell-type-specific manner. The flexibility of the model allows additional features: genomewide effects due to individual genotypes (population stratification) and samples (experimental, environmental and other sources) can be modeled directly in a non-linear fashion, which we show is required by real data; prior assumptions regarding locality and annotations of *cis*-eQTLs can be incorporated; and multiple tissues can be modeled as mixtures of cell types whose characteristic expression profiles are related according to a known hierarchy. We solve the model using stochastic gradient descent with backpropagation. Naïve implementation of such an inference procedure is computationally prohibitive at genomewide, transcriptomewide scale. We mitigate this challenge by considering only a representing subset of all SNPs, and further accelerate the computation through GPU. Results on simulated datasets allow estimation of the required number of iterations for accurate inference and thus demonstrate the model's applicability to the scale of real-data in less than a day of runtime. We test our modeling on the GTEx dataset, and present the results.

1790T

The eMERGE Network: Continuing the legacy of genomic discovery to enrich precision medicine. *M.A. Basford[1], P. Harris[1], M. Brilliant[2], J. Denny[1], B. Funke[3,4], S. Gabriel[3,4], A. Gharavi[5], R. Gibbs[6], H. Hakonarson[7], I. Holm[8], J. Harley[9], G. Hripcsak[5], G.P. Jarvik[10], E. Karlson[11], I. Kullo[12], E.B. Larson[10], R. Li[13], S. Murphy[11], H. Rehm[3,4], M.D. Ritchie[14], D. Roden[1], M. Smith[15], J. Smoller[11], S. Thibodeau[12], S. Weiss[11], C. Weng[5], K. Wiley[13], M.S. Williams[14], R. Chisholm[15], The Electronic Medical Records and Genomics (eMERGE) Network.* 1) Vanderbilt University Medical Center, Nashville, TN; 2) Marshfield Clinic Research Foundation, Marshfield, WI; 3) Partners Healthcare Laboratory for Molecular Medicine; Cambridge, MA; 4) The Broad Institute of Harvard and MIT, Cambridge, MA; 5) Columbia University, New York, NY; 6) Baylor College of Medicine Human Genome Sequencing Center (HGSC); Houston, TX; 7) Children's Hospital of Philadelphia, Philadelphia, PA; 8) Boston Children's Hospital, Boston, MA; 9) Cincinnati Children's Hospital Medical Center Cincinnati, OH; 10) Group Health Research Institute with the University of Washington and the Fred Hutchinson Cancer Research Center, Seattle, WA; 11) Harvard Medical School, Boston, MA;; 12) Mayo Clinic, Rochester, MN; 13) National Human Genome Research Institute (NHGRI), Bethesda, MD; 14) Geisinger Health System, Danville, PA; 15) Northwestern University, Chicago, IL.

The eMERGE Network is a national consortium, funded by NHGRI, NIH since 2007 to conduct genomic discovery and clinical implementation research by combining biorepositories with electronic health record (EHR) systems. Primary areas of focus include developing consistent approaches to gene and variant interpretation, establishing and improving processes for integration of genomic data into EHRs, evaluating methods for returning results, measurement of implementation and outcomes, genomic discovery, and advancing the science of electronic phenotype development. In previous cycles, the Network created a merged set of approximately 80,000 participants with genome-wide genotyping data that have been imputed using the 1000 Genomes reference. An additional 9015 samples were sequenced using the PGRNseq platform targeting 82 pharmacogenes with variant data available through SPHINX (emergeSphinx.org). Tools include an online platform for sharing clinical decision support artifacts, CDSKB.org, and a portal for developing, annotating and sharing electronic phenotypes, PheKB.org. Forty-seven computed phenotypes have been validated and implemented across the Network with 42 more in development. A large-scale survey of over 90,000 patients' attitudes regarding consent and data sharing was completed to help inform rule making for biobanks. One ultimate goal is to return genomic testing results to patients in a clinical care setting to enable precision medicine. During the next 4 years, the Network is producing targeted sequencing results on a projected 25,000 subjects with extensive EHR data to understand how returning CLIA-grade genomic results impacts clinical care, and to provide a robust dataset for discovery research, especially for assessing the contributions of rare variants in actionable genes. The Network designed a sequencing platform, eMERGEseq, containing the 56 ACMG genes, 53 other genes, and 1552 SNPs, including ancestry markers. Sequencing and clinical reporting is harmonized to the extent possible across two sequencing centers. The creation of these large sets of genotyped and sequenced patients with EHR phenotpyes will expand opportunities for discovery and implementation of genomic varants in healthcare.

1791F

Whole genome reference panel of two thousand Japanese individuals and bioinformatics in ToMMo. *M. Nagasaki.* Tohoku University, Sendai, Japan.

Tohoku University Tohoku Medical Megabank Organization (ToMMo) located at the north-eastern Japan is now developing a biobank (the final goal is 150,000 volunteers with millions samples) that combines medical and genome information during the process of rebuilding the community medical system and supporting health to foster the reconstruction from the Great East Japan Earthquake on Mar/11/2011. One of the missions of ToMMo is to reveal a fine genetic architecture of Japanese population to tackle the further genome wide associate study analysis by combining the knowledge, which is daily accumulated in the ToMMo prospective genome cohort project, e.g. questionnaire data, physiological data, medical treatment records and other omics data from serum, plasma and immortalized lymphocytes. We have created the reference panel with one thousand samples to cover MAF > 0.5% variants including short insertion, deletion, and large structural variants in Japanese for constructing the Japanese whole-genome reference panel (1KJPN). Currently, we have constructed the second reference panel with two thousand samples (2KJPN). In our panel, to minimize the biases caused by the different equipment, protocol and bioinformatics analysis, we performed whole genome sequencing of thousands samples with 30x high coverage using the HiSeq 2500 rapid run mode and analyzed by the same bioinformatics pipeline. We presents our bioinformatics analyses, e.g. HLA-typing and CNVs, preliminary findings while constructing 2KJPN, and another effort to construct Japanese reference genome.

1792W

Expanding the scope of the NHGRI-EBI genome-wide association study (GWAS) Catalog. *J.A.L. MacArthur[1], T. Burdett[1], M. Cerezo[1], F. Cunningham[1], P.N. Hall[2], E. Hastings[1], L.A. Hindorff[2], H.A. Junkins[2], A. McMahon[1], A. Milano[1], J. Morales[1], Z.M. Pendlington[1], D. Welter[1], H. Parkinson[1].* 1) European Molecular Biology Laboratory, European Bioinformatics Institute (EMBL-EBI), Cambridge, United Kingdom; 2) National Human Genome Research Institute (NHGRI), NIH, Bethesda, MD.

The GWAS Catalog (www.ebi.ac.uk/gwas) is a manually curated, publicly available resource of all published GWAS and association results. As of May 2016 the Catalog includes 2,437 studies and over 24,000 SNP-trait associations. Studies and associations must meet the Catalog's strict eligibility criteria (www.ebi.ac.uk/gwas/docs/methods) to be included; studies must include an array-based GWAS and analysis of 100,000+ SNPs, while SNP-trait associations must have a p-value $<1\times10^{-5}$. GWAS study design, genotyping technologies and user needs have evolved since the inception of the Catalog. As part of ongoing assessments of user needs, we carried out a survey which indicated demand to extend the scope of the Catalog to include targeted/non-genome-wide arrays, all SNP-trait associations and follow-on studies. Here we assess the feasibility of including these in the Catalog. Association studies using large-scale targeted/non-genome-wide arrays, including the Metabochip, Immunochip and Exome arrays, are currently not included in the Catalog. Literature searching indicates that to date at least 100 published studies of this type are eligible for inclusion and would enrich the data on immunological and cardiometabolic phenotypes. The inclusion of all SNP-trait associations, regardless of p-value, would create a more comprehensive and representative Catalog, allowing users to more accurately compare and combine data from multiple studies. Follow-on studies would provide additional information to help users refine the region of association tagged in the GWAS. Increasing the scope will require the development of efficient methods to curate an increased number of studies and associations, along with the infrastructure to cope with handling and presenting data of increased volume. A pilot for the inclusion of targeted array studies has allowed us to estimate the resources and infrastructure developments required and we are currently applying for additional funds to include these data. We have also implemented a pilot of author submission to investigate whether authors can provide structured information directly to the Catalog, reducing the burden on curators. Our user submission tools are available and we actively encourage testing by authors. Increased responsiveness to user needs, community engagement and user involvement will make this resource more comprehensive and representative. This will increase the utility of the Catalog ensuring continued increase in usage.

1793T

A graph diffusion framework for multi-scale reproducibility and differential analysis of 3D chromatin contact maps. *O. Ursu[1], N. Boley[1], M. Taranova[1], R. Wang[2], A. Kundaje[1,3].* 1) Department of Genetics, Stanford University School of Medicine, Stanford, CA; 2) Department of Statistics, Stanford University, Stanford, Stanford, CA; 3) Department of Computer Science, Stanford University, Stanford, CA.

Deciphering the three-dimensional organization of the genome is critical to understanding the role of long-range chromatin contacts in gene regulation and disease. Chromosome conformation capture techniques such as HiC, Capture-C and ChIA-PET are commonly used to experimentally measure chromatin 3D contact maps. However, the hierarchical, multi-scale organization of genomes into large-scale compartments, topologically-associated domains, looping interactions and dynamic contacts makes comparisons of contact maps particularly challenging. Here, we overcome this with a statistical framework that leverages graph diffusion to obtain 1) a novel measure of reproducibility and 2) a statistical test for dynamics in contact maps at multiple scales and with high power. We represent contact maps as graphs and use random walks on the graph to smooth the data while maintaining high resolution of contacts and boundaries of domains. This is critical as contact maps are sparse, leading to apparent changes in contacts that are the result of sampling noise and dropout, a phenomenon which is alleviated with our smoothing scheme. We develop a novel multi-scale concordance measure to assess reproducibility of contacts for random walks of increasing length. We calibrate our reproducibility scores on simulated data, and benchmark them on a variety of HiC datasets, recapitulating differences between technical replicates, biological replicates, and different cell types. Our framework generalizes seamlessly to contact maps from other assays such as ChIA-PET and CaptureC. Finally, we derive a statistical test for differential analysis of contact maps. We identify dynamics at multiple scales simultaneously, where the scales are defined naturally as clusters of genomic regions with similar changes in contact profiles. In addition to considering multiple scales, this test aggregates information across multiple neighboring genomic regions, substantially increasing statistical power to detect differences, as well as producing more robust results compared to existing methods. We quantify changes in contact maps between cell types, as well as quantify allele-specific contact differences. These are supported by orthogonal evidence from changes in histone marks, chromatin accessibility and regulatory factors defining boundary elements, suggesting that our method identifies statistically significant and biologically meaningful differences in 3D genome organization across different contexts.

Whole-genome characterization in pedigreed non-human primates using Genotyping-By-Sequencing (GBS) and imputation. *B.N. Bimber[1], M. Raboin[1], J. Letaw[1], K. Nevonen[1], J.E Spindel[2], S.R. McCouch[2], R. Cervera-Juanes[1], E. Spindel[1], L. Carbone[1], B. Ferguson[1], A. Vinson[1].* 1) Oregon National Primate Research Center, Beaverton, Oregon, and the Oregon Health & Science University, Portland, Oregon; 2) 2Section of Plant Breeding and Genetics, School of Integrative Plant Sciences, Cornell University, Ithaca, New York.

Rhesus macaques are widely used in biomedical research, but the application of genomic information in this species to better understand human disease is still undeveloped. Whole-genome sequence (WGS) data in pedigreed macaque colonies could provide substantial experimental power, but the collection of WGS data in large cohorts remains a formidable expense. Here, we describe a cost-effective approach that selects the most informative macaques in a pedigree for whole-genome sequencing, followed by low cost Genotyping-By-Sequencing (GBS) on the remaining animals to generate high accuracy, sparse genotype data. The dense, high-accuracy variants from the WGS animals are imputed into the remaining GBS individuals, providing genome-wide genotypes at greatly reduced cost. We developed GBS for the macaque genome using a single digest with *PstI*, followed by sequencing to 30X coverage, producing high-confidence genotypes over >22,000 macaque SNVs. To validate the utility of GBS data for genome-wide imputation, we focused on a 16-member pedigree, initially limited to chromosome 19. Using the approach of "Genotype Imputation Given Inheritance" (GIGI), we imputed alleles at 5,010 markers on chromosome 19, using 833 sparse markers from GBS. We evaluated multiple factors on imputation accuracy, including: 1) the strategy for selecting the individual to receive GBS, 2) the ratio of subjects with WGS to those with GBS, and 3) the density of the framework marker panel. We found that the GIGI-Pick algorithm for selection of WGS subjects out-performed other common approaches, and that a ratio of 1 WGS subject per 3-5 GBS subjects produces an optimal tradeoff between cost and number of imputed genotypes. The density of the framework marker panel had little effect on accuracy. Using these optimized conditions, we imputed an expanded set of ~7.6 million variants across all 20 macaque autosomes, achieving >99% accuracy per chromosome. This approach makes feasible the collection of accurate, dense genome-wide sequence data in large pedigreed macaque cohorts without the need for expensive WGS data on all individuals.

Efficient population-scale variant annotation and analysis through big data. *D. Gordon, H. Kuck, B. Kelly, J. Fitch, P. White.* The Genomics Institute at Nationwide Children's Hospital, Columbus, OH.

The genomics community must adopt new big data technologies to enable population-scale genomic analyses and accelerate knowledge discovery in human health. Advances in technology are empowering population-scale genome sequencing of thousands of individuals monthly, creating large volumes of variant data. Traditional methods for variant annotation and analysis are limited in scale, lack real-time functionality and impose significant bottlenecks on the process of discovery and clinical diagnosis. Facing these challenges of scale and performance requires a novel architecture, for which we have selected the Hadoop ecosystem as a foundation. Hadoop's MapReduce algorithm allows data to be seamlessly split across nodes within a computing cluster, and provides a high performant solution on commodity hardware. In addition to the MapReduce architecture, we leverage HBase, Hadoop's implementation of the BigTable storage system. HBase is a horizontally scalable data store, meaning that as the scale of genomics data increases, the system can be "scaled out" by adding more nodes to the computing cluster. Building upon our back-end storage and processing system able to process massive amounts of data, we have implemented a web-based data mining and analysis solution. Through this interface, users can submit raw variant data for annotation, manage genes of interest and pedigrees, and perform near-real-time queries of variants. As the scale and throughput of variant data continues to increase, so too does the challenge of keeping up with the flow of data and making it available in a way meaningful to researchers and clinicians. By creating a scalable, approachable, and affordable solution to this challenge, our solution significantly improve complex data mining on stored variant data and equips investigators with powerful and efficient tools for efficient querying thereby accelerating genome research and its application to human health.

Strategic interrogation of the exome for metabolic and glycomic variants in the setting of undiagnosed disease. *C.J. Adams[1], D.R. Johnson[1], T.S. Frisby[1], K.R. Chao[1], M. Davids[1], L.A. Wolfe[1], H. Ho[1], C.L. Hoppel[2], W.A. Gahl[1], D.R. Adams[1].* 1) Undiagnosed Diseases Program, National Human Genome Research Institute, Bethesda, MD; 2) Case Western Reserve University, Cleveland, OH.

The NIH Undiagnosed Diseases Program (UDP) evaluates patients with illnesses that remain undiagnosed despite extensive medical investigation. Exome or genome analyses are undertaken on UDP patients with the objective of identifying DNA sequence variants that may contribute to the causation of the presenting illness. For any given case, multiple such candidates may be found, with varying levels of bioinformatic evidence. Ancillary data sets, including metabolic and glycomic testing, may augment variant prioritization by revealing biochemical pathway associations. For instance, variants in a gene with a predicted biochemical function but no disease association can be prioritized if metabolic testing reveals abnormalities consistent with dysfunction of the given gene. Such associations may be detected even when metabolic or glycomic disease was not present in the original differential diagnosis, as clearly-apparent metabolic or glycomic diseases are likely to have been identified prior to presentation to the UDP. Here we present in-progress examples of cases where synergy between metabolic and molecular data from UDP cases has prompted follow up investigation. For instance, a UDP patient presenting with developmental regression, seizures, CNS and neuromuscular findings was found to have an abnormal metabolic profile. The pattern of abnormal metabolites did not clearly match any known metabolic disease. However, several acylcarnitine profile abnormalities supported the presence of a defect of fatty acid oxidation. This finding was used to support the prioritization of compound heterozygous variants in Acyl-CoA Synthetase Medium-Chain Family Member 5 (*ACSM5*), a fatty acid synthetase gene with a presumptive but unproven role in fatty acid activation for the metabolism of medium-chain fatty acids. We present a framework for conducting the analysis of sequence variants given additional metabolic data, family-based controls, and extensive, standardized clinical phenotyping. This research is supported by the Intramural Research Program of the National Human Genome Research Institute and the Common Fund of the National Institutes of Health.

Imputation of high-resolution *KIR* types from SNP variation data. *S. Leslie[1,2,3], D. Vukcevic[1,2,3], P. Norman[4].* 1) School of Mathematics and Statistics, University of Melbourne, Parkville, Vic 3010, Australia; 2) School of BioSciences, University of Melbourne, Parkville, Vic 3010, Australia; 3) Data Science, Murdoch Childrens Research Institute, Parkville, Vic 3052, Australia; 4) Department of Structural Biology, Stanford University, California, USA.

Large population studies of immune system genes are essential for characterizing their role in diseases. Of key interest are genes encoding the killer-cell immunoglobulin-like receptors (*KIR*s), which have known and hypothesised roles in autoimmune diseases, resistance to viruses, reproductive conditions and cancer. These genes are highly polymorphic, making typing expensive and time-consuming. Consequently, despite their importance, *KIR*s have been little studied in large cohorts. This parallels the case of the human leukocyte antigen (*HLA*) genes, whose proteins are known to interact with *KIR* and have been implicated in many autoimmune conditions. *KIR*s are highly variable in terms of gene arrangement and copy number; haplotypes can comprise 4–20 *KIR*s. Further, individual *KIR* genes are highly polymorphic, with over 600 alleles currently described. Statistical imputation methods developed for other complex loci (e.g. *HLA*), based on single nucleotide polymorphism (SNP) data, provide an inexpensive high-throughput alternative to direct laboratory typing of these loci and have enabled important findings for many diseases. KIR*IMP, the first imputation technique designed specifically to impute *KIR* copy number variation and haplotypes defined by *KIR* copy number (called *gene content*), enables accurate typing of *KIR* copy number and gene content from SNP data. One may think of this as low-resolution typing. Here we extend KIR*IMP to high-resolution *KIR* typing: overlaying the allelic polymorphisms for each *KIR* gene copy present. To develop our method, KIR*IMP:02, we have assembled a reference dataset of over 2000 individuals with high-resolution *KIR*-types, derived from sequence, for three *KIR* genes (*3DL1*, *3DL2* and *2DL4*). These samples also have dense genotyping data across the *KIR* region. To assess the accuracy of KIR*IMP:02 we use cross-validation within the reference panel, as well as validating using an independent panel of approximately 100 samples with relevant SNP and *KIR* types. We present results on the accuracy of KIR*IMP:02 and its utility for association analyses. KIR-IMP:02 allows for the first time the augmentation of large existing (e.g. UK BioBank) and novel genetic data sets with high-resolution *KIR* types, enabling detailed investigation of the role of *KIR*s in human disease.

Comparison of algorithms for error correction in Ion Torrent PGM data: Application to hepatitis B virus. *L. Song[1], W. Huang[1], J. Kang[1], Y. Huang[2], H. Ren[1], K. Ding[1].* 1) Key Laboratory of Molecular Biology for Infectious Diseases (Ministry of Education), Institute for Viral Hepatitis, Department of Infectious Diseases, The Second Affiliated Hospital, Chongqing Medical University, Chongqing, China; 2) Center for hepatobillary and pancreatic diseases, Beijing Tsinghua Changgung Hospital, Medical Center, Tsinghua University, Beijing, China.

Ion Torrent™ Personal Genome Machine (PGM) technology is a long-read, low-cost and high-speed next-generation sequencing platform, especially with applications to microbial sequencing. However, there is a relatively higher insertion and deletion (indel) error rate in PGM data, and a systematic assessment of error-correction algorithms in PGM data applications to virus (e.g., hepatitis B virus (HBV)) has yet to be fully performed. In 19 quality trimmed PGM data for HBV reverse transcriptase (RT) region, we noted a total error rate of 0.004877 ± 0.001214 and deletion errors were obviously present in the homopolymers. Comparison of algorithms indicated different performances for error-correction, leading to different sensitivity and specificity of variants called from post-corrected alignments. Simulated data showed that error rate and sequencing depth affected the performances of error-correction algorithms. In conclusion, choice of algorithms for error-correction on Ion Torrent PGM data needs full considerations. .

Automated mosaicism detection. *M.G. Gordon[1], B.N. Pusey[1], A.P. Liebendorfer[1], V.L. Arthur[2], M.O. Ombrello[2], T.C. Markello[1].* 1) Undiagnosed Diseases Program, National Human Genome Research Institute, Bethesda, MD; 2) Translational Genetics and Genomics Unit, National Institute of Arthritis and Musculoskeletal and Skin Diseases.

Introduction: Mosaicism is an important finding in both congenital genetic syndromes and Knudsen "two hit hypothesis" conditions including cancer. The percent and location of mosaicism can currently be detected using b-allele frequency data from SNP chips (Markello et al. MGM (2012) 105:665.). The intrinsic vectorial nature of that method suggested a direct route to extend and improve this tool. **Methods:** This program automates our previously described method of detecting mosaicism. It directly models the degree of bimodal separation in the heterozygous band of the b-allele frequency that we previously have shown to reflect the degree of mosaicism in populations of cells. We converted our use of the cumulative distribution function and non-linear regression searches to vector operations that run on graphics processers. The increased throughput allows greater sensitivity and specificity as well as automation of the entire process. This has allowed us to include new refinements to the original method, include automatic edge detection for the mosaic region start and stop SNP positions and correct experimental artifacts such as the use of the Manhattan distance in commercial SNP data. **Results:** Analysis of two different Illumina chips from three data sets containing over 2,000 chips demonstrate that 1% of chips include a mosaic event. Mosaic regions as small as 1Mb and as low as 4% are automatically detected and reported. We have found one example of mosaicism recurrent in 2 generations presumably due to an inherited fragile site. One unique anonymized control case had the same low level 15% mosaicism in 7 different chromosomes. Genome wide chip analysis, can exclude mosaicism in a matter of seconds; large numbers of chips can be processed in minutes using off-the-shelf commercial video cards or even faster using GPU nodes on large computer clusters. **Conclusions:** We have developed an extension to our published method that can efficiently, economically, and automatically detect and quantitate mosaicism regions across the entire genome. Noisy b-allele frequency data from saliva or Formalin-Fixed Paraffin-Embedded samples, or exome, and or genome sequence read count b-allele frequency will have dynamic range limitations that will limit the sensitivity and specificity of this technique. We are in the process of developing an outward-facing website for users to submit genome-wide b-allele frequency data for processing and plan to launch by 2017.

Integrative variation discovery in whole exome data through two-tiered mapping and *de novo* **assembly.** *S. Tian, H. Yan, M. Kalmbach, S. Slager.* Division of Biomedical Statistics and Informatics, Department of Health Sciences Research, Mayo Clinic, Rochester, MN 55905.

Whole exome sequencing (WES) is widely used for the detection of causal variants. Current variant discovery largely adopts mapping-based pipelines, which generally work well in ordinary genomic regions but are much less sensitive in "difficult regions", i.e., the regions with low complexity, segmental duplications, or high sequence divergence from reference genome. Several de novo assemblers have been developed for variant discovery. They tend to be more sensitive to INDELs, SNP clusters, and structural variation. However, these de novo assemblers are mostly tailored to whole genome sequencing (WGS) data. In principle, the mapping-based and de novo assembly-based approaches complement each other and their combination should allow more complete variant detection. Here, we present the first pipeline combining the two variant discovery strategies. The pipeline supports parallel processing of multiple WES data and individual chromosomes in computer clusters, using mapping-based methods, chromosome-level de novo assembly, or both. The mapping-based module is designed for sensitive detection of SNPs and small INDELs, using internally assessed tools. It comprises a two-tiered mapping with BWA and GSNAP, followed by a joint calling using GATK UnifiedGenotyper, HaplotypeCaller (HC) and Platypus. The de novo assembly module, which was built on top of the String Graph Assembler framework to achieve haplotype assembly, outperformed all five other de novo assemblers tested in this study. To demonstrate our strategy, we focused on the ~4-Mb human leukocyte antigen (HLA) region on chromosome 6p21; although this region is associated with over 100 diseases, it is a complex region with up to 10%-15% divergence across haplotypes and enriched for segmental duplications. We demonstrated the superiority of this pipeline in identifying SNPs, INDELs and complex variants from NA12878. The "true" call set was complied from high-confidence calls in 14 datasets and three lists from 250-bp paired-end WGS data. In detecting known SNPs from the two 150-bp datasets, it showed 98.5% and 98.6-99.1% sensitivity in the HLA and non-HLA regions, respectively, versus 87.6-87.9% and 97.0-97.4% by the widely used BWA-MEM+GATK HC; comparable results were obtained for the three 100-bp datasets. Moreover, the pipeline can detect large INDELs up to 1 kb and provide haplotype information. Thus, our pipeline should be particularly useful for cataloguing genetic variants genome-wide.
