

**A Novel Translocation, t(11;17)(p15;q21), in a Putative Case of Acute Promyelocytic Leukemia. A. Al Saadi, I. Jaiyesimi, J.C. Mattson, William Beaumont Hospital, Royal Oak, MI. A. Al Saadi.** Dept Anatomic Pathology, William Beaumont Hosp, Royal Oak, MI.

Acute promyelogenous leukemia (APL) is a clinical subtype of acute myelogenous leukemia characterized by a coagulopathy, bleeding at presentation, unique morphologic findings, and translocations involving the RARa gene on 17q12-21, and usually the PML gene at 15q21. To date, five partner genes have been identified to participate in the translocation with the RARa gene: PML at 15q21, PMZL at 11q23, NuMA at 11q13, NPM at 5q35, and STAT5b. We report an unusual case of APL in a 48-year-old woman who presented with ecchymoses, a high white count with 55% myeloblasts, anemia, and thrombocytopenia. There was no evidence of a coagulopathy at presentation. The normal bone marrow was replaced by leukemic blasts with reniform nuclei, Auer bodies, but without increased hypergranular promyelocytes. A variant form APL (M3v) was suspected, but standard interphase FISH, using a PML/RARa translocation probe, failed to reveal the classic t(15;17). The patient was started on induction chemotherapy achieving remission after two courses. She was then treated with high-dose Ara C for 4 cycles as consolidation, followed by maintenance therapy with Daunorubicin and Ara C. She did well for 21 months, then relapsed. A repeat bone marrow showed relapsed leukemia. Conventional and FISH cytogenetics, at times of presentation and relapse showed 46,t(11;17)(p15;q21) karyotype with the RARa gene on 17q21 was entirely translocated to 11p15. She was re-induced with Mitoxantrone, Ara C, and Etoposide. Allogenic transplantation is planned after achieving complete remission. This novel translocation, t(11;17)(p15;q21), has not been previously reported in either classic or variant APL. Each of the variant rearrangements reported thus far in putative APL may represent different clinical entities that may require different therapeutic management. Identification and cloning the genes involved in the translocations with the RARa gene may provide valuable information for the understanding of the pathogenesis of the variant APL, and hence for the treatment and management APL with variant translocations.

**The Cancer Chromosome Aberration Project (CCAP): An update.** *T.C. Brown, R. Yonescu, T. Reppert, T. Knutsen, T. Ried, I.R. Kirsch.* Genetics Branch, Center for Cancer Research, Nat'l Cancer Inst, Bethesda, MD.

The Cancer Chromosome Aberration Project (CCAP) was initiated with four goals in mind: (1) to integrate the cytogenetic and physical maps of the human genome, (2) to generate a clone repository of genetically and physically mapped (and in many cases sequenced) DNA BAC clones at a resolution of 1-2 Mb across the human genome, (3) to develop a FISH-mapped BAC clone database to provide a platform for correlation with parallel databases of cancer-associated chromosome aberrations and clinical histopathologic information, and (4) to refine the descriptive nomenclature that defines karyotypic aberrations (insertions, amplifications, deletions, and translocations) in cancer cells. This refinement is designed to supplement and complement conventional descriptions of chromosomes based on banding patterns by integrating and formatting the three data streams of state-of-the-art cytogenetic analyses: spectral karyotyping (SKY), comparative genomic hybridization (CGH), and fluorescent in situ hybridization (FISH). To date, chromosomes 1 (97 clones), 3 (95 clones), 5 (105 clones), 7 (83 clones), 12 (102 clones), 14 (44 clones), 16 (44 clones), 17 (48 clones), 18 (43 clones), 21 (25 clones), 22 (22 clones), and X (60 clones) have been completely analyzed. The data are available at the CCAP website (<http://www.ncbi.nlm.nih.gov/CCAP/>). The results of analysis of the entire set of chromosomes, using ~ 3000 BAC clones, is tentatively set to be available by early fall of this year. Analysis of the 21 mouse chromosomes will follow. CCAP will aid in the elucidation and cloning of chromosomal abnormalities. It contributes to a reagent and data resource that is becoming fundamental to our understanding and management of cancer.

**Numerical, Structural and complex reorganization detected in high resolution (HR) chromosomes in tumor cells from 36 patients with Renal Cell Carcinoma (RCC).** *A.B. Falcon de Vargas<sup>1, 2</sup>, R.E. Vargas Arenas<sup>1, 2</sup>, H. Dvila<sup>2</sup>, M. Uribe<sup>2</sup>, M. Zeeman<sup>2</sup>.* 1) Dept Genetics/Fac Medicine, Hosp Vargas Escuela Vargas UCV, Caracas Dist Fed, Dtto. Capital, Venezuela; 2) Hospital de Clinicas Caracas, Caracas, Distrito Capital, Venezuela.

Abstract: In 36 patients with diagnosis of RCC, 20 males and 16 females with a mean age of 59.94 years (range: 17 to 74), conventional and G, C, Q, NOR banding techniques were carried out in HR chromosomes obtained from tumor cell cultures (TuC) and lymphocytes from peripheral blood (BLy). A total of 644 metaphases in TuC and 1068 in BLy of patients and 1068 metaphases in BLy from 36 healthy controls matched by age and sex were then studied searching for chromosome abnormalities. Results showed numerical and structural changes of chromosomes in patients from RCC group only ( $p < 0.001$ ). Chromosome breakages were found in 60 % of TuC of 30 patients and in 10 % of BLy of 14 patients. In patients with RCC, chromosome abnormalities were found in TuC/BLy as follows: acrocentric segregation in 12/0, polyploidies in 8/0, poly  $>60$  in 24/2, endoreduplications in 12/4, double minute in 12/4, dicentric in 6/0, triradios in 6/0, quadriradios in 4/0. Numerical clonal changes were also found as in TuC/BLy as follows: +7 in 8/2, +7+7 in 4/0, +7+8 in 2/0, +8 in 14/0, +10 in 10/4, +11 in 2/0, +13 in 2/0 and 3 in 2/0, and -8 in 2/0, -10 in 4/0; -X in 4/0 and Y in 8/6. A t (3;8) (3p14-8q24) was found in TuC of two patients. We conclude that clonal numeric and structural chromosome changes are usually present in a high proportion of TuC from RCC and in lower proportion of BLy from these patients. Some of these chromosome abnormalities should be considered nonspecific, since could be seen in other conditions such as different types of cancer, hematological disorders and virus infection, and also induced by mutagenic agents. Further studies are required to determine the clinical value of these changes from the prognostic and therapeutic viewpoint. Key Words: Cancer cytogenetics. Cytogenetics. Chromosomal abnormalities. Genetics. Renal Cell Carcinoma.

**Rapid detection of minimal regions of genomic gain or loss in tumors in order to identify candidate oncogenes and tumor suppressor genes.** *B.L. Gallie<sup>1, 3</sup>, D. Chen<sup>1, 2</sup>, S. Richter<sup>3</sup>, C. Lee<sup>1</sup>, M. Harmadayan<sup>1</sup>, J. Squire<sup>1</sup>.* 1) Princess Margaret Hosp, Toronto, Ontario, Canada; 2) Department of Ophthalmology, 1st Affiliated Hospital, West China University of Medical Sciences, Chengdu, China; 3) Solutions by Sequence, Inc, Toronto Western Hospital, Toronto, Ontario, Canada.

Tumor suppressor genes and oncogenes that are important in the etiology and pathogenesis of particular cancers have been identified by localization of subchromosomal regions of gain or loss in tumors. We have utilized *in silico* methods and quantitative PCR to rapidly delineate the minimal genomic regions likely to contain tumor suppressor genes or oncogenes important in retinoblastoma. Our initial cytogenetic studies using limited numbers of retinoblastoma tumors implicated gains associated with regions of chromosome arms 1q and 6p and losses at 16q. A more comprehensive survey of retinoblastomas using comparative genomic hybridization (CGH) identified consensus regions of gain at 1q31 and 6p22 and loss at 16q22 with a resolution of 20 to 30 Mb. We have developed and validated quantitative multiplex PCR (QM-PCR) to efficiently identify RB1 copy number changes in patient samples. To narrow the consensus regions of gain and loss, we applied QM-PCR to Sequence Tagged Sites (STS) spanning the regions defined by CGH. For the 6p subchromosomal region, CGH narrowed genomic gain to 20 Mb at chromosome 6p22 on 50 retinoblastoma. QM-PCR rapidly reduced the minimal region of gain to 0.5 Mb containing three unigene clusters. A functional relationship between these novel genes and retinoblastoma oncogenesis is being sought. For the chromosomal region 16q22, loss of heterozygosity analysis defined two small regions of overlap at 16q22.1 and 16q23.2 but sample sizes have been limited by the need for matched normal and tumor DNA to define heterozygous loci. We are presently using QM-PCR with STS spanning 16q22 to search large numbers of retinoblastoma tumor DNA samples for minimal regions of deletion, indicative of a tumor suppressor gene. This study demonstrates that the resolving power of QM-PCR and CGH can in combination identify small subsets of the genome containing only a few candidate oncogenes and tumor suppressor genes.

**CGH analysis of colorectal carcinoma.** *S. Cheng.* Dept Anatomy, Chang Gung Univ, Col Medicine, Kweishan, Taiwan.

Tumor has been ranked number one killer among all the diseases in Taiwan. Among all the tumors colorectal carcinoma ranked number three in men and women. This study intends to overview the changes of chromosomal structure of the carcinoma cells. The specimen, both normal and tumor tissues of patients, were collected from the Chang Gung Memorial Hospital at Linkou. The normal and tumor DNAs were extracted and labeled with digoxigenin-16-dUTP and biotin-11-dUTP, respectively. The comparative genomic hybridization was performed on the normal metaphase chromosome spreads. The results were scored on 10 metaphase spreads for each case with the cooled-CCD camera on a fluorescent microscope. The analyses were completed by Quips software (Vysis, Inc.). The main goal is trying to identify the correlation between the metastasis and the common gain or loss of chromosomes in the cells from tumor tissues. The results are from 7 cases with Dukes stages C2 (5 cases) and D (2 cases). All cases are with ulcerative type of tumor tissue. It indicates that the common gains of these case are at chromosome 5 in three cases, at ch 8 in three cases, at ch 11 in three cases, at ch 18 in three cases, and at ch 22 in three cases.

**Sister chromatid exchange (SCE) as a possible indicator of genomic instability associated with ovarian cancer.**

*A.W. Block<sup>1</sup>, E.E. Hassan<sup>1</sup>, R.A. DiCioccio<sup>2</sup>, W.R. Greco<sup>3</sup>, S.-I. Matsui<sup>2</sup>*. 1) Clinical Cytogenetics Lab, Roswell Park Cancer Inst, Buffalo, NY; 2) Department of Cancer Genetics, Roswell Park Cancer Inst, Buffalo, NY; 3) Biomathematics/Biostatistics Resource, Roswell Park Cancer Inst, Buffalo, NY.

The transformation of a normal cell, such as an ovarian epithelial cell, to a malignant tumor cell is considered a multistep process that proceeds through an accumulation of mutations in certain genes over the course of many years. It has been proposed that inactivation of DNA repair mechanisms (base excision repair, nucleotide excision repair, mismatch repair, homologous recombination) leads to genomic instability and increased mutation rates, thereby facilitating tumor formation. The proliferation of ovarian epithelial cells following ovulation may involve errors in DNA replication resulting in mutations that may lead to cells with a proliferative advantage. Alternatively, mutations could be caused by environmental agents that reach the ovary through the genital tract. Agents that trigger base mismatch repair and excision repair are efficient inducers of sister chromatid exchange (SCE), suggesting a role for SCE in these pathways in addition to the SCE-related homologous recombination double strand break repair pathway. Using EBV-transformed lymphoblastoid cell lines established from individuals in the NCI-supported Family Registry for Ovarian Cancer and the Gilda Radner Familial Ovarian Cancer Registry, we examined SCE levels in affected individuals and unaffected female relatives. With over 100 paired cell lines available for analysis, preliminary results show an increase in SCE levels in 5/7 probands when compared to unaffected relatives. Mitomycin C challenged cells from these individuals also showed larger increases in SCE levels. Multivariate relationships will be explored between SCE findings and registry database epidemiologic factors as histology, age at diagnosis, race, family history of breast and ovarian cancer, BRCA1 status and polymorphisms in genes involved in DNA repair. [Supported in part by RPCI Alliance Foundation and CA 16056].

**Characterization of complex chromosome aberrations in lymphomas using multi-color fluorescence in situ**

**hybridization.** *J.S. Flores*<sup>1</sup>, *K.C. Kim*<sup>2</sup>, *J. Johnson*<sup>2</sup>, *J. Van Brunt*<sup>2</sup>, *M.M. Li*<sup>2, 3</sup>. 1) Diagnostic Genetic Sciences, Univ of Connecticut, Storrs, CT; 2) Hayward Genetics Center, Tulane Univ Sch of Medicine, New Orleans, LA; 3) Dept of Pediatrics, Tulane Univ Sch of Medicine, New Orleans, LA.

Multi-color fluorescence in situ hybridization (M-FISH) combined with conventional cytogenetic analysis provides a powerful tool for characterizing complex cytogenetic anomalies. Using this approach, we have clarified two lymphoma cases with complex chromosomal aberrations. M. P. was a 53-year-old male suspected to have lymphoma. Cytogenetic studies revealed a karyotype of 42,X,+X,-Y,der(2)t(1;2)(q23;q35),del(8)(q23),t(8;14)(q24;q32),-9,-10,-13,-14,-15,add(16)(q?24),del(17)(p11.2),-18,-19,+mar1,+mar2,+mar3[17]/46,XY[9]. Multi-color FISH confirmed the der(2), t(8;14) and del(17) and eliminated the del(8). It also demonstrated that the add(16) was a der(16)t(15;16)(q24;q24), and that the three markers were der(13;14)(q10;q10)t(8;14)(q24;q32), der(18)dup(18)t(2;18)(18pter@18q23::18q23@18q11.2::2q33) and der(19)t(2 or 10 or 11;19)(v;p13.3)t(13;19)(q14;q13.4). Jumping translocations have been reported in different lymphomas, to our knowledge, this is the first case with a jumping translocation involving chromosome 19 and different donor chromosomes. These results indicate a diagnosis of Burkitts lymphoma. H. S. was a 79 year-old-male referred for chromosomal study because of thrombocytopenia and blasts in peripheral blood. Cytogenetic studies showed a mosaic karyotype: 48,XY,+X,-6,add(7)(q32),+7,der(11)t(11;12)(q23;q13),+11,t(14;18)(q32;q21),der(16)t(16;?),+20,+mar[6]/46,XY[14]. With M-FISH, we were able to confirm the t(14;18) and clarify that the add(7) was der(7)t(6;7)(q23;q32), the der(16) was derived from a t(16;18)(q21;q21) and the marker was a deleted chromosome 11. M-FISH also detected a dup(12)(q13q24.1), which was erroneously identified as a der(11)t(11;12). These results are strongly associated with NHL, especially follicular lymphoma. Our experience in characterizing complex karyotypes in lymphomas demonstrates that multi-color FISH and conventional cytogenetic methods can complement each other and provide valuable information about genetic alteration in lymphomas.

**Genetic alterations in primary breast tumors and their corresponding sentinel lymph node metastasis. L.R.**

*Cavalli<sup>1</sup>, S. de Assis<sup>1</sup>, C.A. Urban<sup>2</sup>, R.S. Lima<sup>2</sup>, L.F. Bleggi-Torres<sup>3</sup>, B.R. Haddad<sup>1</sup>.* 1) Institute for Molecular and Human Genetics, Georgetown University, Washington, DC; 2) Departamento de Oncologia, Hospital Nossa Senhora das Graças, Curitiba, PR, Brazil; 3) Departamento de Patologia, Universidade Federal do Paraná, Curitiba, PR, Brazil.

Accumulation of genetic and epigenetic changes is believed to play a pivotal role in each step of tumor development and progression. Studies comparing genomic changes in metastatic tumors with those found in the corresponding primary tumors have revealed differences in the genetic alterations between these lesions, suggesting that specific events may be associated with metastasis or specific clones in the tumor undergo metastasis preferentially. In order to study this process in breast cancer, we are evaluating a group of 10 primary tumors and their matching sentinel lymph nodes metastasis using comparative genomic hybridization. This approach allows us to detect gross chromosomal aberrations present in each tumor and its corresponding node metastasis, and to identify chromosomal alterations common to both the primary and metastatic lesions. Our initial findings show that the most frequent alterations common to the tumors and metastatic lesions analyzed so far include gains of chromosomes 8q, 11q and 20q and losses of 16q and 18q. These findings should be further confirmed using a larger group of tumors. These data will lead to the development of a panel of prognostic markers by selecting FISH probes targeting specific chromosomal regions that are commonly altered in both the primary tumors and their node metastasis.

**Detection of complex chromosomal alterations and gene amplification in Wilms tumors using SKY and array-based CGH.** *M. Goldstein, A. Bar-Shira, H. Rennert, R. Shomrat, C. Legum, Y. Yaron, A. Orr-Urtreger.* Genetic Institute, Tel Aviv Sourasky Medical Cent, Tel Aviv, Israel.

In Wilms tumor (WT) aberrant karyotypes are frequently observed. The most common structural changes reported are at 16q, 11p13, 11p15, 1p, 1q and 7p. G-bands cannot always identify the origin of some chromosomal abnormalities such as markers and detect subtle DNA changes. We used a combination of conventional cytogenetic painting, 24-color spectral karyotyping (SKY) analysis and array-based CGH to characterize complex aberrations in more detail in WTs derived from 3 patients. Case 1 was a 3YO-girl with hemihypertrophy with unilateral WT and nephroblastoma in the second kidney. G-bands analysis revealed a pseudo-diploid karyotype and  $i(7)(q10)$  in 35% of the WT and in 3% of the nephroblastoma cells, respectively, in agreement with the pathologic-exam based diagnosis. Case 2 was a 9YO-boy with recurrent unilateral WT and lung metastasis that demonstrated a hypodiploid karyotype with  $i(1)(q10)$  and  $del(11p)$  in both tumor types. SKY analysis confirmed the primary origin of the lung tumor as WT. Case 3 was a 5YO-girl with metachronous WT. SKY analysis demonstrated a hyperdiploid karyotype in the first WT, and a hypodiploid karyotype in the other kidney-derived tumor. Both WT types displayed complex chromosomal changes involving chromosome 1, while monosomy 7p was observed only in the first WT. Further array-based CGH analysis for simultaneous detection of 59 oncogenes (AmpliOncI Microarray, Vysis) commonly amplified in cancer, revealed a single 3-fold amplification of the multidrug resistance protein 1 (MRP1) gene on 16p13 in patient 3, restricted only to the second tumor. Follow-up by gene expression analysis (HU95A microarray, Affymetrix) showed a 3-fold increase in MRP1 expression level when compared to the first WT and to kidney from a normal control. Increased expression of MRP1 gene was found to be associated with resistance of human tumor cells to cytotoxic drugs and thus, can result in inadequate response to treatment, and adverse prognosis. Combination of SKY and array-based CGH is powerful in characterization of complex rearrangements and detection of novel amplifications.

**Genomic Imbalances in Ovarian Borderline Serous and Mucinous Tumors.** *V. Khanna*<sup>1</sup>, *J. Hu*<sup>1,2,3</sup>, *M.W. Jones*<sup>4</sup>, *U. Surti*<sup>1,2,3,4</sup>. 1) Pittsburgh Cytogenetics Laboratory, University of Pittsburgh Center for Human Genetics and Integrative Biology, UPMC Magee-Womens Hospital, Pittsburgh, PA; 2) Magee-Womens Hospital Research Institute, Pittsburgh, PA; 3) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 4) Department of Pathology, UPMC Magee-Womens Hospital, Pittsburgh, PA.

We analyzed 25 ovarian borderline tumors (13 serous and 12 mucinous tumors) by Comparative Genomic Hybridization (CGH). Genomic imbalance was detected in 85% of serous tumors and 75% of mucinous tumors. Different patterns of the genomic alterations were identified between serous and mucinous tumors. Gain of X-chromosome was common in both serous (30%) and mucinous (42%) tumors. However, gain of chromosome 8 was detected in 38% of serous and mixed sero-mucinous tumors, but not in any pure mucinous tumors. Gain of chromosome 12 was found in 23% of borderline serous tumors, but only in 8% of mucinous tumors. Loss of 1p was found in 23% of serous tumors and in 17% of mucinous tumors. According to the present and previous studies, gain of chromosome 8 is the most common abnormality in borderline serous tumors. Gain of the same chromosome is also common in high grade and advanced stage carcinomas, but uncommon in low grade, low stage carcinomas. In addition gain of X chromosome is common in borderline tumors, while loss of X chromosome is dominant in invasive carcinomas. These findings did not support the multi-step progression theory from borderline tumor to high grade, advanced stage carcinoma, but indicates that the borderline ovarian tumor is a distinct entity. Genes of chromosome 8 may be critical for the development and the differentiation of borderline serous tumors.

**Identification of novel chromosome translocations in human thyroid carcinomas.** *W.O. Lui<sup>1</sup>, A. Svensson<sup>1, 2</sup>, A. Höög<sup>3</sup>, L.O. Farnebo<sup>2</sup>, C. Larsson<sup>1</sup>.* 1) Dept of Molecular Medicine, Karolinska Hospital, Stockholm, Sweden; 2) Dept of Surgery, Karolinska Hospital, Stockholm, Sweden; 3) Dept of Pathology, Karolinska Hospital, Stockholm, Sweden.

Cytogenetic characterization is still significantly important to identify fusion genes. A number of fusion genes are commonly observed in leukemias, lymphomas and sarcomas. In solid tumors, fusion genes have been identified in papillary thyroid carcinomas (PTC), and recently, in follicular thyroid carcinomas (FTC).

The present report describes two cases of thyroid neoplasm with novel chromosome translocations, which were identified by both G-banding and spectral karyotyping. The first case displayed a balanced translocation  $t(3;15)(q11-12;q25)$  in a papillary thyroid carcinoma. The second case demonstrated  $der(2)t(2;10)(q13;q11.2)$ ,  $der(5)t(2;5)(q13;p15.3)$ , and loss of a chromosome 22 in a follicular carcinoma of the right thyroid lobe. Interestingly, the latter case also had a papillary thyroid carcinoma in the left lobe. Unfortunately, the papillary tumor was not available for cell culturing. However, we compared the alterations between these two tumors by comparative genomic hybridization. Both of them showed loss of chromosome 22, but the follicular tumor also displayed loss of chromosome 10p.

In PTC, fusion genes often consist of one of two alternative tyrosine kinase receptor genes, RET and NTRK1. In the case of  $t(3;15)$ , NTRK3, which is mapped at 15q25, and is a member of the TRK family of tyrosine protein kinase genes, could be a putative candidate involving another new novel fusion gene. In the case of  $t(2;10)$  or  $t(2;5)$ , PAX8, which resides at 2q13, had been shown to play an important role in follicular cells differentiation. Recently, a novel fusion gene involves PAX8 and PPAR $\gamma$  was identified in a subset of FTCs. This may strongly suggest that PAX8 could be involved in a putative fusion event with another fusion partner. These findings provide starting points for the exact characterization of molecular events in thyroid neoplasm.

**Banded chromosomes vs Fluorescence In Situ Hybridization (FISH) in the diagnosis of Mantle cell lymphoma.**

*A.N. Mohamed<sup>1</sup>, W. Ali<sup>1</sup>, F. Koppitch<sup>1</sup>, A. Alkatib<sup>2</sup>.* 1) Dept of Pathology, Cancer Cytogenetics Lab, Wayne State Univ, Detroit, MI; 2) Dept of Internal Medicine, Hematology/Oncology, Wayne State Univ, Detroit, MI.

Mantle cell lymphoma (MCL) is a subtype of B cell non-Hodgkin's lymphoma (NHL) characterized by distinct clinico-pathologic features. The cells express pan-B-cell markers, surface immunoglobulin, CD5, and CD43 but typically lacking CD23 and CD10. MCL is associated with t(11;14)(q23;q32) which juxtaposes IgH gene to BCL-1 gene (CCND1, PRAD1) resulting in over-expression of cyclin D1. MCL shares many morphologic and phenotypic features with other NHL. However, it is essential to distinguish MCL from other lymphomas because MCL has an aggressive clinical course and carries poor prognosis. We present three cases with presumptive evidence of MCL that were sent for cytogenetic evaluation. Chromosome analysis was performed on short-term bone marrow aspirate cultures (cases 1,2) and on unstimulated peripheral blood cultures (case 3). The harvests from two cases yielded a normal karyotype while the third case showed the composite karyotype; 46,XY,t(1;22)(p13;q13),-3,del(10)(q22), add(15)(q22), add(17)(p13). The classic t(11;14)(q13;q32) for MCL was not observed in any case. Furthermore, we evaluated the specimens by FISH using the dual color LSI IgH/CCND1 DNA probe (Vysis Inc.). Fusion signals were observed in 65% and 85% of interphase nuclei in case1 and 2 respectively, while the metaphases from both cases revealed a normal pattern. All abnormal metaphases as well as 57% of interphase cells from case 3 displayed a fusion signal that was located on 14q32. Thus, FISH established with certainty the diagnosis of MCL by showing the IgH-CCND1 genes fusion. These findings indicate that the sensitivity of FISH is superior to that of conventional cytogenetics in detecting t(11;14)(q13;q32) associated with MCL.

**The NCI and NCBI SKY/CGH Interactive Online Database.** *T. Knutsen<sup>1</sup>, M. Augustus<sup>1</sup>, V. Gobu<sup>2</sup>, H. Padilla-Nash<sup>1</sup>, E. Schröck<sup>1</sup>, C. Shenmen<sup>2</sup>, J. Plotkin<sup>2</sup>, S. Greenhut<sup>1</sup>, J. Kriebel<sup>1</sup>, K. Sirotkin<sup>2</sup>, T. Ried<sup>1</sup>.* 1) Genetics Branch, National Cancer Institute, NIH, Bethesda, MD; 2) National Center for Biotechnology Information, NIH, Bethesda, MD.

Spectral Karyotyping (SKY) and Comparative Genomic Hybridization (CGH) are complimentary fluorescent molecular cytogenetic techniques. SKY permits the simultaneous visualization of all human or mouse chromosomes in a different color, facilitating the identification of chromosomal aberrations. CGH utilizes the hybridization of differentially labeled tumor and reference DNA to generate a map of DNA copy number changes in tumor genomes. The NCI/NCBI SKY/CGH interactive online database permits the input of clinical and research SKY and CGH data, both human and mouse, directly from the cytogenetic community and the resulting information is available for public viewing in a searchable format. In the SKY database, the submitter enters the karyotype and then describes each abnormal chromosome by typing in the beginning and ending bands of each different segment, starting from the top. The computer then builds a full ideogram, with each chromosome displayed in its unique SKY classification color, with band overlay. Each breakpoint is automatically linked by a button marked FISH to the Map View database, which provides the genes at that site and available FISH clones for that breakpoint. This allows for a seamless integration of cytogenetic aberrations with the sequence of the human genome. Detailed clinical and research information is entered for each case. The CGH database displays gains, losses, and amplification of chromosomes and chromosome segments. CGH data is entered manually, or automatically from CGH software programs. In the manual format, the submitter enters the start band and stop band for each chromosome gain or loss, and the computer program displays the final ideogram with vertical bars to the left or right indicating loss or gain, respectively. This database offers the biomedical community the opportunity to participate directly in the development of data critical to the search for new oncogenes and tumor suppressor genes, and other genetic changes which lie at the root of all cancers.

**HER-2/neu FISH on breast cancer touch imprints of core needle biopsies.** *S. Kaneko*<sup>1,2</sup>, *S.R. Young*<sup>2</sup>, *T. Gerasimova*<sup>2</sup>, *W.M. Butler*<sup>3</sup>, *T.E. Cupples*<sup>4</sup>, *G.R. Greene*<sup>4</sup>, *P.L. Guerry*<sup>5</sup>. 1) Dept OB/GYN, Nagoya City Univ, Japan; 2) Dept OB/GYN, Univ South Carolina; 3) Dept Med, Palmetto Health Alliance; 4) Dept Radiol, PHA; 5) Dept Path, PHA; Columbia, SC.

The HER-2/neu status has been used in breast carcinoma as a prognostic marker and to predict the response to chemotherapy and hormonal therapy and to select patients for HERCEPTIN treatment. Since immunohistochemistry (IHC) is thought to be less reliable, HER2/neu testing with fluorescence in situ hybridization (FISH) is preferred. The analysis of HER-2/neu is usually performed on formalin-fixed, paraffin-embedded tissue sections obtained from surgery. The use of paraffin sections is very time consuming and labor intensive. The objectives of this study were to 1) develop a simple and quick FISH protocol using HER-2/neu and #17 centromeric probes on touch imprints of core needle biopsies, eliminating the need to deparaffinize and pretreat the samples; 2) make the HER-2/neu FISH information available at the multidisciplinary pretreatment tumor conference prior to surgery. A total of 41 core samples were obtained from image guided core needle biopsy. These samples included 26 carcinomas and 15 benign/normal tissues. One carcinoma and one benign sample could not be examined by FISH because of insufficient cells. Three of 25 carcinoma cases were amplified for HER-2/neu. One of three was IHC 3+, one 2+ and one not yet studied. No samples were IHC 3+ and non-amplified. One IHC 2+ was non-amplified. None of the benign/normal samples showed amplification. Only recently has the molecular status of a tumor, such as the presence of a BRCA1/2 mutation, been used to influence surgical decision-making. It is expected that in the near future, it will become more important in the clinical management to take into account the HER-2/neu and other molecular marker status before surgery when the overall treatment plan is being developed. We conclude that HER-2/neu gene analysis by FISH on breast touch imprints is easily done and is a useful and reliable technique.

**In vitro analysis of chromosomal instability in a colon cancer cell line.** *J. Lavoie*<sup>1</sup>, *E. Przybytkowski*<sup>2</sup>, *E. Chudoba*<sup>3</sup>, *R. Drouin*<sup>1</sup>, *M. Basik*<sup>2</sup>. 1) Medical Biol Department, Hosp St Francois d'Assise, Laval Univ, Quebec, PQ., Canada; 2) Surgery Department, Hosp Notre-Dame, Montreal, PQ., Canada; 3) MetaSystems, Altlussheim, Germany.

Colon cancers are characterized by two types of genomic instability: microsatellite instability (MIN) and chromosomal instability (CIN). While the etiology of MIN has been described, little is known about the factors and mechanisms underlying CIN. In order to study CIN in colon cancer, we compared several techniques to measure genomic instability, that is, the rate of appearance of CIN-type genomic alterations over time in culture. The MIN-negative colon cancer cell line, HT-29 was subcloned without selection and two phenotypically distinct subclones were observed: C7 and B6. C7 was phenotypically similar to the parental cell line while B6 was phenotypically similar to another previously described HT-29 subclone, isolated by resistance to methotrexate and 5-fluorouracil. Karyotyping, M-FISH (Multi-fluorescence in-situ hybridization) and inter-simple sequence repeat (Inter-SSR) PCR (a genomic fingerprinting technique) were performed on the original subclones and subclones passaged 15 times (150 generations). Karyotyping revealed fourteen qualitative and quantitative chromosomal anomalies in HT-29 and its subclones: del(X)p11, ins(3;12),del(4)(q),-8,der(8),+11,-13,i(13)(q10),-17,der(19)t(17,19),iso(19q),der(18),-21 and -22. Subclone C7 was identical to the parental line while both were markedly different from B6 (18 different markers). Over the passages, there is a progressive appearance and disappearance of markers (10 changed markers for B6 and 7 different markers over time for C7). Inter-SSR PCR showed similar results to the karyotyping, and allowed the cloning of one of the differences, a loss of heterozygosity of a fragment on chromosome 10. Thus, HT-29 is genomically heterogeneous, although the rate of genomic change seems similar in the different subclones. These findings will form the basis of further studies in the quantification of genomic evolution in colon cancer cells, and allow the future elucidation of the factors underlying the major form of genomic instability in colon cancer.

**Genetic Imbalances in Korean Hepatocellular Carcinoma by Degenerate Oligonucleotide Primed PCR - Comparative Genomic Hybridization.** *G.J. Kim<sup>1, 2</sup>, H.J. Hwang<sup>1</sup>, J.Y. Lee<sup>1</sup>, N.H. Won<sup>3</sup>, S.J. Cho<sup>3</sup>, Y.H. Chun<sup>1</sup>, S.H. park<sup>1</sup>.* 1) Dept. Anatomy, Korea Univ. College of Medicin, Seoul, Korea; 2) Graduate School of Biotechnology, Korea University, seoul, Korea; 3) Dept. Pathology, Korea Univ. College of Medicine, Seoul, Korea.

Hepatocellular carcinoma (HCC) is one of the most frequent gastrointestinal malignant tumors that are prevalent in Southeast Asia. Cytogenetic analysis on HCC has been limited because of poor hepatocyte growth in vitro. Although some genetic alteration related-HCC is now well recognized, the relations between the genetic imbalance and the molecular mechanisms of HCC remain unclear. Recently, technique of degenerate oligonucleotide primed PCR (DOP-PCR) - comparative genomic hybridization (CGH) permits genetic imbalances screening of the entire genome using only small amounts of tumor DNA. Thirty-nine of hepatocellular carcinoma, five of metastatic hepatocellular carcinoma and five of metastatic adenocarcinoma to liver were investigated for chromosomal aberrations by DOP-PCR-CGH on microdissected tissues. The most frequently detected chromosomal gains involved chromosome 1q (55%), 6p (32%), 8q (42%), 17q (87.5%), 20q (75%), and 22q (70%) and the common region of gain involved 7q21-q31 (42.5%) and 12q21-q24 (45%). The most frequently detected loss of chromosomal materials involved chromosomes 4q (67.5%), 8p (30%), and 18q (25%) and the most common region of loss involved 5q14-q23 (35%) and 11q14-qter(25%). The recurrent gain and loss of chromosomal regions identified in this study provide candidate regions that may contain oncogenes or tumor suppressor genes respectively involved in the tumorigenesis of hepatocellular carcinoma.

**Analysis of homogeneous staining regions in cholangiocarcinoma cell lines by chromosome microdissection and FISH.** *Y.H. Kang, G.J. Kim, S.Y. park, H. Kim, S.H. Park.* Dept Anatomy, Korea Univ College Med, Seoul, Korea.

The generation of chromosome region specific painting probe by PCR amplification of microdissected chromosomal DNA has proven extremely useful in identification of chromosomal derivation for marker chromosomes which are indeterminable by routine cytogenetic analysis. The chromosomal derivations of homogeneous staining regions (HSRs) and abnormal band regions (ABRs) in cholangiocarcinoma cell lines, SCK, JCK, and Cho-CK, were analyzed by microdissection and FISH. It was possible to construct the region-specific painting probes for HSRs and ABRs and the probes hybridized specifically to the dissected regions. The painting probes from SCK, Cho-CK, and JCK were hybridized to the chromosome bands 6p21.1-p21.2, 7q11-q22, and 14q13-q24, respectively. Moreover, the fluorescent signals from the amplified chromosomal regions in SCK cells were also easily recognized at almost all the interphase nuclei of SCK cells. These amplified regions were analyzed in cholangiocarcinomas by microdissection and degenerate oligonucleotide-PCR comparative genomic hybridization (CGH). These probe pools for HSRs and ABRs are used to identify the cholangiocarcinoma related genes.

**A comprehensive karyotypic analysis of Korean hepatocellular carcinoma cell lines by cross species color banding and comparative genomic hybridization.** *H.J. Hwang, Y.H. Kang, S.Y. Park, H. Kim, S.H. Park.* Institute of Human Genetics, Dept. Anatomy, Korea Univ. College of Medicine, Seoul, Korea.

Hepatocellular carcinoma (HCC) is one of the most frequent gastrointestinal cancer encountered in the world. Especially incidence rate of HCC in Korea has been increasing. Although some chromosome aberrations appeared in HCC suggest that gene aberrations are involved in tumor formation, origins of many marker chromosomes remain unidentified. The purpose of this study is to establish in detail karyotypes of five HCC cell lines, SNU-368, SNU-449, SNU-398, SNU-182, and SNU-475. The origins of the unidentified marker chromosomes were analyzed by G-banding, cross species color banding (RxFISH), human chromosome-specific painting, and comparative genomic hybridization (CGH). Each cell line had unique modal karyotypic characteristics and showed a variable number of numerical and structural clonal chromosomal aberrations. The origins of the marker chromosomes of these cell lines were confirmed by fluorescence in situ hybridization with constructed painting probes. The gains were commonly detected on chromosomes 7, 20, and 6p. The losses were commonly found 1p36, 4q, 13, 16 and Y. CGH analysis largely confirmed these cytogenetic data. These data suggest that they may be the candidate regions for the isolation of the genes related to HCC.

**Characterization of a Homogeneously Stain Region (HSR) in a new Establishment Hepatocellular carcinoma Cell**

**Line.** *L. Hu*<sup>1</sup>, *J-M. Wen*<sup>2</sup>, *J-F. Huang*<sup>3</sup>, *J.S.T. Sham*<sup>1</sup>, *W-S. Wang*<sup>3</sup>, *M. Zhang*<sup>2</sup>, *D. Xie*<sup>1</sup>, *W-F. Zeng*<sup>2</sup>, *X-Y. Guan*<sup>1</sup>. 1) Clinical Oncology, The University of Hong Kong, Hong Kong, China; 2) Department of Pathology, Sun Yat-sen University of Medical Sciences, Guangzho, China; 3) Department of Sugery, Sun Yat-sen University of Medical Sciences, Guangzhou, China.

Hepatocellular carcinoma (HCC) is one of the most common malignancies worldwide and has a very poor prognosis. Recently, we established a HCC cell line from a metastatic tumor. GTG-banding analysis showed that this cell line is hypertriploid (71-78 chromosomes) with a large marker chromosome containing an HSR. A high-copy-number amplification at 11q13 was detected using comparative genomic hybridization. In order to characterize the amplicon, the HSR region was further studied by chromosome microdissection. The dissected DNA was directly PCR-amplified and then mapped to 11q13 by fluorescence in situ hybridization (FISH). DNA copy number of cathepsin F, a tumor invasion and metastasis-related gene at 11q13, has been studied by Southern blot analysis and no DNA amplification was detected. It suggests that the amplified region at 11q13 may harbor another cancer metastasis-related gene. Isolation of amplified transcriptions within the amplicon using microdissected DNA to select cDNA from the HCC cell line by hybrid selection is under the progress.

**Significance of Double Minutes in a Case of Acute Megakaryoblastic Leukemia (M7).** *R. Naeem, R. Bhargava, M. Karamian, R. Hasserjian.* Department of Pathology, Bay State Medical Ctr, Springfield, MA.

**Purpose:** We describe and evaluate the significance of cytogenetic abnormalities (double minutes) in a case of acute megakaryoblastic leukemia (FAB: AML-M7). The patient was a 79-year-old female diagnosed with AML-M7. She received induction chemotherapy with mitoxantrone and etoposide. She received Granulocyte- Colony Stimulating Factor (G-CSF) on the 15th day post induction, but died on the 19th day post induction following an increase in blast number after G-CSF therapy. **Materials and Methods:** Cytogenetic investigations were performed using conventional G-banding technique. Since c-myc oncogene amplification has been previously described in cases of acute myeloid leukemia, fluorescence in situ hybridization (FISH) using c-myc oncogene probe was performed to evaluate that possibility. Flow cytometry was performed to immunophenotype blasts in the peripheral blood. **Results:** Flow cytometry identified a population of blasts which were positive for CD34, CD13, HLA-DR, CD41(gpIIb-IIIa) and CD61(gpIb), consistent with acute megakaryoblastic leukemia (FAB-M7). Cytogenetic studies revealed the following karyotype: 45,XX,-3,del(5)(q22;q33),-7,+mar,dmin. FISH using c-myc specific DNA probe identified only two signals per cell restricted to chromosome 8 on both interphase and metaphase cells. There was no evidence of c-myc oncogene amplification. **Conclusion:** This is the first reported case of AML-M7 to reveal double minutes on cytogenetic studies. c-myc amplification, described in other cases of AML with double minutes was not identified in this case, thus the double minutes may represent amplification of other oncogenes. As has been previously reported, the increase in number of blasts following G-CSF therapy may be related to the cytogenetic finding of double minutes. These findings suggest that growth factors should be used with caution in AML patients whose blasts demonstrate double minutes by conventional cytogenetic studies.

**Identification and analysis of two novel cancer genes located in frequently rearranged chromosomal regions.** *P. Modena, M.A. Testi, T. Mastrangelo, F. Facchinetti, M.T. Radice, S. Pilotti, M.A. Pierotti, G. Sozzi.* Istituto Nazionale Tumori, Milano, Italy.

Sarcomas are rare tumors of mesenchymal origin frequently occurring in youth. Chromosomal translocations generating chimeric genes have been identified in specific tumor subtypes, contributing to the understanding of tumorigenesis and cancer progression. Interestingly, some of these genes are relevant in both haematological and solid tumors, such as FUS-ERG in AML and EWS-ERG in Ewing's tumors. Variant translocations are identified in a minority of cases, whose characterization may disclose new cancer genes. We report the cytogenetic identification and molecular cloning of a t(1;22)(p34;q12) associated with a paracentric inversion of 22q12 invisible by conventional karyotyping in a small round cell sarcoma. By means of cytogenetics and molecular genetics approaches, we cloned the breakpoints both at the genomic and at the cDNA level. All three breakpoints interrupted a gene: EWS on 22q11.2, ZSG on 22q12 and UQCRH on 1p34-35. Three novel fusion transcripts are created: EWS-ZSG and UQCRH-EWS on der22 and ZSG-UQCRH on der1. While EWS is a well-known gene responsible for Ewing's family of tumors, the other two genes have not been previously involved in cancer. ZSG is a putative transcriptional repressor containing POZ/A-T hook/Zn finger domains, and showing similarities to oncogenic proteins PLZF and BCL6. UQCRH encodes hinge protein, a mitochondrial complex III subunit essential for cytochromes c and c1 complex formation. Genomic structure of ZSG and UQCRH genes was delineated, and full length cDNAs of these genes were obtained. Expression studies of the various splicing variants of human and mouse homologs were performed. Fusion and wild type transcripts were cloned into expression vectors to test their transforming activity in in vitro assays. Since frequent LOH is observed in 22q12 and 1p34-35 in solid tumors and the presence of novel cancer genes in these regions has been postulated, we analysed ZSG and UQCRH status in more than 30 cancer cell lines by means of FISH, Spectral Karyotyping, expression studies and mutation detection, with preliminary interesting results.

**CGH analysis of thymic tumors.** *D.J. Heiber<sup>1</sup>, P. Loehrer<sup>2</sup>, G.H. Vance<sup>1</sup>, J.D. Henley<sup>3</sup>*. 1) Dept Medical & Molec Gen, Indiana Univ, Indianapolis, IN; 2) Dept Medicine, Indiana Univ Sch Med, Indianapolis, IN; 3) Dept Path and Lab Medicine, Indiana Univ Sch Med, Indianapolis, IN.

Thymic epithelial tumors include non-invasive thymomas, invasive thymomas and thymic carcinomas and represent the most common anterior mediastinal tumor in adults. Approximately 30-40% of thymomas exhibit malignant behavior and progress or recur with locally advanced, unresectable disease or distant metastases. The malignant behavior of thymic epithelial tumors determines prognosis, but can not always be predicted on histological grounds. To date, there are few reports of genetic alterations in thymic tumors. None have shown a common recurring abnormal numerical or structural pattern by cytogenetic studies. We have evaluated ten thymic tumors by CGH analysis for genome-wide genetic alterations. Specimens included four cortical type thymomas with lymphoid components, two poorly differentiated large cell carcinomas, two metastatic malignant thymomas, one benign thymoma and one thymoma of unknown histology. All ten tumors showed a gain of 10p14-15 which is the location of the BCD1 oncogene, cloned from the lymphocytes of CLL patients, and PFKFB3, found to be required for tumor cell growth. Three of the ten tumors also demonstrated a loss of 19q13.2-13.3, which is the location of the AKT2 gene, whose retrovirus, AKT8, has been isolated from thymoma tumors in mice. The gene ACTN4 also localizes to this chromosomal region and its inactivation has been associated with the metastatic potential of some human cancers. Further analysis of these genes by FISH is ongoing. These studies will potentially identify genes important in the pathogenesis of thymic tumors and may determine markers important for distinguishing indolent from invasive tumors.

**Molecular cytogenetic investigation of Endometrial Polyps by comparative genomic hybridization reveals a novel deletion at 3q27-q28.** *J. Meyer*<sup>1</sup>, *M. Huang*<sup>2</sup>, *N. Kardon*<sup>2</sup>, *K. Hirschhorn*<sup>2</sup>, *T. Mukherjee*<sup>1</sup>, *B. Levy*<sup>2</sup>. 1) Obstetrics and Gynecology, Mount Sinai School of Medicine, New York, NY; 2) Human Genetics and Pediatrics, Mount Sinai School of Medicine, New York, NY.

Endometrial polyps (EP) are common benign tumors found in approximately 25% of the population. They have been associated with menometrorrhagia and infertility. The occurrence of carcinoma in endometrial polyps is less than 0.5%. The molecular events leading to the development and progression of EP remain unclear. To date, cytogenetic studies have been limited to case reports of comparison of G-banded metaphases from cultured cells. Comparative genomic hybridization (CGH), is a molecular cytogenetic technique that permits direct analysis of genomic DNA obtained from the specimen thus obviating the need for cell culture. We used CGH to evaluate DNA sequence copy number changes in 10 EP in order to detect imbalances that are not evident using conventional cytogenetic techniques because of the poor quality of solid tumor karyotypes. In addition, CGH would also detect those cells with imbalances which are lost in culture due to their instability. Seven of the 10 patients underwent hysteroscopy for peri-menopausal bleeding and the remaining 3 patients had EP detected during routine workup for infertility. CGH analysis of EP demonstrated chromosomal imbalances in 4 of 10 (40%) specimens, 3 of which demonstrated an identical deletion at 3q27-q28. A gain at 1q21-q43 and a loss of 7p21 was evident in the other specimen. Of particular interest was the fact that the deletion of 3q27-q28 was also found in surrounding endometrium and only in those patients with infertility. A deletion at 3q27-q28 has not previously been described in endometrial polyps, endometrial hyperplasia or endometrial carcinoma and represents a novel finding. This discovery could reflect a molecular change in the endometrium which predisposes to infertility and/or polyp formation. Identifying and correlating chromosomal abnormalities in EP may provide insight into the etiology and mechanism of this disorder and thus allow for the development of strategies for clinical management and treatment.

**A complex three-chromosome rearrangement with other abnormalities in a case of refractory anemia.** *N.S. Mitter, P.O. Ivbievbiokun, V.L. Hopwood, S. Miao, R.W. Rodgers, K.H. Thompson.* Center for Medical Genetics, Houston, TX.

A hitherto unknown complex rearrangement involving one #5 chromosome and both #8 chromosomes was observed in a 72 year old woman with a significant leukopenia, refractory anemia, thrombocytopenia and severely hypocellular marrow. While 9/22 fully analyzed cells had a normal female chromosome complement of 46,XX, 13/22 cells showed the three-chromosome rearrangement and del(20q), with three of these cells also lacking a #18 chromosome. The complex three-chromosome rearrangement originated from an apparently balanced reciprocal translocation between two homologue #8 chromosomes, followed by an inverted insertion of segment q15q33 from a #5 chromosome in the long arm of one of the two derivative #8 chromosomes. The karyotype was 46,XX,t(8;8;5)(q21.2;q24.1;q15q33),del(20)(q11.2)[10]/idem,-18[3]/46,XX[9]. The long form nomenclature for the complex chromosome rearrangement would be written as t(8;8;5)(8pter->8q21.2::8q24.1->8qter; 8pter->8q24.1::5q33->5q15::8q21.2->8qter; 5pter->5q15::5q33->5qter). A deletion of the long arm of a #20 chromosome, typically seen in many cases of refractory anemia, was also present in all the cells. The complex chromosome rearrangement has not been described as associated with a specific hematologic abnormality. The breakpoint on the insertion recipient #8 chromosome (8q24.1) is the site for myc and pvt1 oncogenes, and has been implicated in many cases of acute lymphocytic leukemia and non-Hodgkin's lymphoma. However, the breakpoints on the #5 chromosome segment, inserted into #8 chromosome, have been involved in many different types of hematologic abnormalities, including myelodysplasia, acute myelogenous leukemia and acute lymphocytic leukemia. The patient responded favorably initially to a treatment with Prednisone. After three months, the patient had become more pancytopenic and a repeat bone marrow showed an 80% cellularity, with 38% blast cells and a histological diagnosis of acute myelogenous leukemia. Based on this observation, the breakpoints on the insertion donor chromosome #5 seem to have been more involved than those on the #8 chromosomes in the leukemic progression in this patient.

**Prognostic implication of chromosome 13 aberrations in B-cell hematopoietic malignancies requires FISH analysis as an upfront screening tool for accurate detection.** *J.L. Murata-Collins, L. Tcheurekdjian, P. Gaytan, M.L. Slovak.* Dept Cytogenetics, City of Hope National Med Ctr, Duarte, CA.

Deletions involving chromosome band 13q14.3 are common in chronic lymphoproliferative disorders (CLPD), including B-cell chronic lymphocytic leukemia (B-CLL) and multiple myeloma (MM); however, their prognostic impact is dissimilar. In B-CLL, patients with 13q14 abnormalities typically have a benign disease course, with overall survival equivalent to age- and sex-matched controls. In contrast, 13q14 abnormalities in MM are associated with a significantly inferior outcome and poor prognosis, suggesting the need for aggressive therapeutic options. Detection of aberrations by standard cytogenetics (SC) in CLPD is hampered by the inability to obtain mitotic malignant B-cells, identifying only a fraction of the chromosome 13 aberrations detected by fluorescence *in situ* hybridization (FISH). In a preliminary FISH study of 43 CLPD samples a dual color, dual loci FISH probe set was created to identify the minimally deleted region in 13q14.3 (BAC 480p3 which includes D13S319), distal to RB1, and 13qter (BAC 19o15), as the control chromosome 13-specific identifier. 8/23 [35%] B-CLL samples showed loss of the 13q14.3 signal, with retention of the control 13qter signal. Discordance in 6/8 samples was due to either a microscopically cryptic deletion or failure to acquire mitotic B-CLL cells. Overall, FISH increased detection of chromosome 13 aberrations by 22% in B-CLL, compared with 13% detection by SC. In 5/20 [25%] MM samples, both 13q14.3 and 13qter signals were missing, consistent with monosomy 13 or a large terminal deletion. Of the 5 abnormal MM samples, SC and FISH results were concordant in 2, single del(13) findings by SC confirmed as clonal in 2, and one normal study suggested failure to culture malignant B-cells. As expected, deletions with breakpoints proximal or distal of BAC 480p3 were negative by FISH, as was the case in 2 B-CLL and 2 MM samples. To assess prognosis in CLPD, chromosome 13 deletions by FISH should be considered an upfront screening tool.

**Evolution of clonal chromosome abnormalities in neuroblastoma studied by comparative genomic hybridization.**

*R.L. Stallings<sup>1,2</sup>, J. Howard<sup>1</sup>, A. Dunlop<sup>1</sup>, M. Mullarkey<sup>1</sup>, M. McDermott<sup>3</sup>, F. Breatnach<sup>3</sup>, A. O'Meara<sup>3</sup>.* 1) National Center for Med Genetics, Our Lady's Hosp for Sick Child, Dublin, Ireland; 2) Faculty of Medicine, University College Dublin, Dublin, Ireland; 3) Departments of Oncology and Pathology, Our Lady's Hospital for Sick Children, Dublin, Ireland.

Loss of chromosome 11q material occurs in approximately 20% of advanced stage neuroblastoma and forms a distinct genetic subtype. Loss of 11q material is strongly associated with loss of distal 3p material and unbalanced gain of 17q material, but is inversely correlated with MYCN amplification and deletion of 1p. The loss and gain of the 11q and 17q regions, respectively, is sometimes the result of an unbalanced reciprocal translocation between the long arms of these chromosomes, while the cytogenetic mechanism of 3p loss is unknown. We have performed CGH analysis on neuroblastomas from 34 different patients in order to further study the clinical behavior and chromosomal abnormalities associated with 11q- tumors. Tumors from 8 of the patients had loss of 11q material. The rearrangements leading to loss of 11q material were often associated with partial gain of genetic material from 11q13 and 11p by complex mechanisms. In one patient (No. 31), CGH, G band cytogenetic and/or FISH analysis could be carried out on neuroblastoma cells from primary tumor, an infiltrated bone marrow sample and a lymph node metastasis. Although gain or loss of genetic material from eleven different chromosomal regions could be detected, partial monosomy 11q and trisomy 17q were the only abnormalities common to tumor cells from all three sites, indicating an early origin during the development of the primary neuroblastoma. Unbalanced gain of 17q and loss of 11q material resulted from an unbalanced t(11;17)(q14;q11.2). Loss of chromosome 3p and gain of 7q was detected at two sites (primary tumor and bone marrow) by CGH and resulted from an unbalanced t(3;7)(p21;q10). We conclude that the t(3;7) is secondary to the t(11;17), and the loss of 3p material is not linked to loss of 11q by a common cytogenetic mechanism.

**Comparison of intra-abdominal leiomyosarcoma and uterine leiomyosarcoma using comparative genomic hybridization analysis** . *W.W.H. Weng<sup>1</sup>, J. Åhlén<sup>2</sup>, W.O. Lui<sup>1</sup>, J. Wejde<sup>3</sup>, C. Larsson<sup>1</sup>*. 1) Department of Molecular Medicine, Karolinska Institute, Stockholm, Sweden; 2) Department of Surgery, Karolinska Hospital, Stockholm, Sweden; 3) Department of Pathology, Karolinska Hospital, Stockholm, Sweden.

Leiomyosarcomas (LMSs) are principally tumors of adult life and are more common in women than men. Although all LMS are histologically similar, they are divided into anatomic groups because of clinical and biological differences. Herein, we used comparative genomic hybridization (CGH) to study the DNA copy number changes of 11 intra-abdominal LMSs (ALMSs) from 8 patients and compared with the CGH result of uterine LMSs (ULMSs) obtained from the literature. CGH demonstrated chromosomal imbalances in 10 of 11 ALMSs. Gains were commonly seen at chromosome 17p(55%), 17q(45%), 5(36%), 7p(36%) and 15(36%) in the ALMSs. These regions of gain are similar to ULMSs, however at a lower frequency. For those tumors exhibiting gain of 17p, high-level amplification was observed in 67%, suggesting that this region may contain an oncogene that involved in LMS tumorigenesis. The most frequently losses detected in the ALMSs were at Xp (73%), Xq (45%) and 4q (45%). However, gain is observed at the X chromosome in ULMSs. Other losses detected at 1p, 9p, 10p, 10q and 13q in the ALMSs are also seen in ULMSs. This shows that intra-abdominal and uterine LMS shared some common genetic alterations that may be involved in the tumorigenesis of this tumor.

**Marker chromosome evolution in oral squamous cell carcinoma (OSCC) cells may occur via breakage-fusion-bridge cycles.** *S. Reshmi-Skarja*<sup>1</sup>, *W.S. Saunders*<sup>2,3,4</sup>, *D.M. Kudla*<sup>1</sup>, *S.M. Gollin*<sup>1,3,4</sup>. 1) Dept. of Human Genetics, University of Pittsburgh GSPH, Pittsburgh, PA; 2) Dept. of Biological Sciences, University of Pittsburgh, Pittsburgh, PA; 3) University of Pittsburgh Oral Cancer Center of Discovery, Pittsburgh, PA; 4) University of Pittsburgh Cancer Institute, Pittsburgh, PA.

Oral squamous cell carcinomas (OSCC) are characterized by near-triploid, highly complex karyotypes. Studies of colon, breast, pancreas, prostate, and oral cancer cell lines reveal that cells within a culture express numerical and structural variations on a background of clonal chromosome aberrations. This indicates the presence of chromosomal instability. Previously, we have presented evidence that gene amplification in OSCC appears to occur through breakage-fusion-bridge (BFB) cycles. Based on our results of sequential trypsin-Giemsa banding and spectral karyotyping (SKY) analysis of OSCC cell lines, we propose that a similar mechanism explains the observation that marker chromosomes within a cell line appear to be related structurally, yet vary (marker chromosome evolution). However, between cell lines, marker chromosomes seem to be unrelated. To test the hypothesis that marker chromosome evolution occurs by BFB cycles, we analyzed at least 8 cells each from two different passages of *TP53* wild-type OSCC cell lines [UPCI:SCC070 (passages 24 and 35), UPCI:SCC122 (passages 19 and 24) and UPCI:SCC136 (passages 36 and 42)]. Each cell line was remarkably stable between the two passages despite expressing numerous shared (identical or evolved) markers and one or two new clonal marker chromosomes. Furthermore, within any cell line analyzed, no two cells had identical karyotypes. These results support the idea that intrinsic structural chromosomal alterations may disrupt chromosome integrity and lead to further chromosomal instability in OSCC. Studies are underway to determine whether the marker chromosomes are present in anaphase bridges. [Supported in part by NIH grants P60DE13059 and P30CA47904.].

**Neurofibromatosis type 2 in a female patient with a balanced de novo X;22 translocation.** *F.L. Raymond<sup>1</sup>, C. Bovie<sup>1</sup>, S. Holden<sup>1</sup>, A. Schroer<sup>2</sup>, D. Trump<sup>1</sup>.* 1) Dept Medical Genetics, Cambridge Inst Medical Res, Cambridge, England; 2) Max-Planck-Institut fur Molekulare Genetik, Ihnestrasse 73, 14195 Berlin, Germany.

Neurofibromatosis type 2 (NF2) is commonly associated with mutations in the gene, merlin. We report the first case of a women with NF2 who carries a de novo balanced reciprocal translocation 46,X,t(X;22)(p11.2;q11.2). We excluded the common mutational mechanisms for NF2 in this patient. A large whole gene deletion was excluded by fluorescent in situ hybridisation using a P1 artificial chromosome dJ76B20, smaller intragenic deletions by Southern blot analysis and point mutations in merlin by DNA sequence analysis of all 17 exons. The NF2 gene is not disrupted at the translocation breakpoint which is located 6 Mb from the 22q11.2 breakpoint. We demonstrate that in tumour tissue in contrast to peripheral blood lymphocytes there is evidence for an aberrant X inactivation pattern and this is likely to be the underlying cause of disease in this individual.

**The origin of marker chromosomes in pediatric and adult ALL elucidated by m-FISH.** *E. Rajcan-Separovic<sup>1</sup>, O. Ludkovski<sup>1</sup>, W. Duey<sup>1</sup>, C. Salski<sup>2</sup>, D. Horsman<sup>2</sup>, V. Lestou<sup>2</sup>.* 1) Cytogenetics Laboratory, BC Children's Hospital, Vancouver, Canada; 2) Cytogenetics Laboratory, BC Cancer Agency, Vancouver, Canada.

Cytogenetic analysis plays an important role in the diagnostic work-up in ALL patients. Karyotypic abnormalities have been reported in 60% of ALL patients, with hyperdiploidy having the best prognostic impact in both pediatric and adult ALL. However, the presence of structurally abnormal chromosomes in a hyperdiploid karyotype has been noticed to have an unfavorable influence on disease outcome. The identification of the composition of structurally abnormal chromosomes in ALL and other types of cancer has been one of the most challenging tasks for cytogeneticists. When the origin of a structurally rearranged chromosome cannot be recognized by standard G-banding, it is classified as a marker chromosome. In ALL, markers are reported in 30% cases and of these, 30% are found in hyperdiploid ALL. Currently, the use of multicolor fluorescence in situ hybridization (m-FISH) provides a valuable aid in elucidating the nature of almost every chromosomal rearrangement, including markers.

We have used m-FISH to identify the origin of marker chromosomes from otherwise structurally normal hyperdiploid karyotypes in six cases of pediatric ALL. In all these cases the marker chromosomes appeared to be of single chromosome origin, resulting most likely from an intrachromosomal rearrangement that prevented their identification by G-banding. On the other hand in 5/6 cases of pediatric and adult ALL with hyperdiploid or pseudodiploid karyotype and multiple structural rearrangements including markers, the markers were of multi-chromosomal origin. Our findings suggest that: 1. in hyperdiploid ALL with no structural rearrangements other than marker chromosomes, the markers are likely to be of single chromosomal origin 2. in hyperdiploid and pseudodiploid ALL with multiple structural chromosomal rearrangements including markers, the markers are more likely to be of complex, multichromosomal origin. Further studies of hyperdiploid ALL by m-FISH will help establish if the complexity of markers, and the karyotype, has an influence on disease development.

**Combined cytogenetic and multicolor-FISH analysis of chromosomal abnormalities in erythroleukemia (AML-M6).** *N.G. Wolf, M. Kochera, S. Schwartz.* Case Western Reserve Univ. and University Hospitals of Cleveland, OH.

Erythroleukemia (EL) is a relatively rare form of acute myelogenous leukemia (AML-M6) characterized by the neoplastic proliferation of erythroblasts and myeloblasts. It is a heterogeneous disease often associated with complex karyotypes and an aggressive clinical course. Analysis of EL using classical cytogenetic techniques (G-banding) can be difficult due to the frequent presence of marker chromosomes and of translocations involving chromosomal material of unknown origin. To more accurately assess EL karyotypes, we complimented G-banding analyses of five cases of EL with multicolor-FISH (M-FISH), a molecular cytogenetic technique that allows simultaneous visualization of each chromosome in a different color. M-FISH analysis allowed the delineation of 1 ring and 2 marker chromosomes, and of unidentified material on 9 derivative chromosomes, thereby indicating that apparently missing material from several of the deleted or missing chromosomes had actually been translocated or rearranged. M-FISH analysis also revealed a hidden translocation, confirmed one suspected structural rearrangement, reclassified two others, and found abnormalities (including a second cell line in one case and subclones in two others) not detected by G-banding. Two very small marker chromosomes and one derivative chromosome required additional single or dual-color FISH analysis for determination of their identity. Other aberrations were confirmed with whole chromosome paint or specific FISH probes. The only consistent abnormality, observed in all 5 cases, was loss of all or part of the long arm of chromosome 5, which has been frequently reported in AML (including M-6). This work demonstrates the importance of M-FISH in the study of EL cytogenetics because M-FISH can (1) delineate marker chromosomes and unidentifiable material not resolvable by standard banding, (2) detect cryptic rearrangements, and (3) locate material previously thought to be deleted or missing. Utilizing this approach to more accurately evaluate the chromosomal abnormalities in EL should prove helpful in resolving subclassifications of AML-M6 and provide useful diagnostic and prognostic information.

**Histological comparisons of testicular germ cell tumors by CGH analysis.** *L.R. Smith<sup>1</sup>, O. Henegariu<sup>2</sup>, V.C. Thurston<sup>1</sup>, G.H. Vance<sup>1</sup>.* 1) Dept Med & Molecular Genetics, Indiana Univ Sch Medicine, Indianapolis, IN; 2) Dept of Genetics, Yale Univ Sch Medicine, New Haven, CT.

Twenty-five fresh testicular germ cell tumors (TGCTs) were collected and identified by specific histological subtype. Whereas conventional cytogenetics is limited to the number and quality of metaphases scored, comparative genomic hybridization (CGH) screens the entire genome for chromosomal imbalances and provides a more thorough and sensitive method by which to detect changes in genome copy number. The goal of this project was to analyze the TGCTs by CGH and to delineate gains/losses of genetic material by specific histological subtype. Seven of 25 tumors analyzed were normal with the remaining 18 tumors (9 mature teratomas, 2 metastatic mature teratomas, 2 yolk sac tumors, 2 seminomas, 1 nonseminoma, 1 choriocarcinoma, and 1 mixed GCT) abnormal by CGH analysis. The amplification of 12p, a known chromosomal abnormality in TGCTs, was present in all the 18 abnormal tumors. Gains of genetic material were also identified to chromosomes 17p, 17q, and Xp; losses were identified to chromosomes 4q, 5q, 6q, and 13q. Further, of the 18 abnormal tumors with amplification of 17p, ten had selective gain of 17p13. Eight of these ten tumors (80%) were teratomas (6 mature teratomas and 2 metastatic mature teratomas) with the remaining two of different histological subtype (1 yolk sac tumor and 1 mixed GCT). Although the amplification of 17p13 detected in this study is not unique to histological subtype, it appears to be novel in the teratomas and may represent a chromosomal region containing genes important for cellular differentiation. Our data also substantiate the sensitivity of CGH over conventional cytogenetics. G-banded karyotypes from five of the 18 abnormal tumors were normal whereas the CGH analysis on these same tumors (and others) revealed previously undetected gains/losses of genomic material. Further, the data revealed a gain of 17p13, prominent in teratomas and not previously reported in the literature.

**Analysis of chromosomal imbalances in Korean non-small cell lung cancer using degenerate oligonucleotide primed - PCR comparative genomic hybridization.** *S.Y. Park<sup>1</sup>, G.J. Kim<sup>1</sup>, Y.H. Kim<sup>2</sup>, H. Kim<sup>1</sup>, S.H. Park<sup>1</sup>.* 1) Inst Human Genetics, Korea Univ College of Medicine, Seoul, Korea; 2) Division of Hemato-oncology, Korea Univ. College of Medicine, Seoul, Korea.

To identify genetic alterations associated with the development and progression of non small cell lung cancer (NSCLC) in Korea, 60 tumors were analyzed using degenerate oligonucleotide primed PCR and comparative genomic hybridization (DOP-PCR-CGH). In 59 cases chromosomal imbalances were found. Several recurrent chromosomal abnormalities were identified in the present study. The most frequently detected chromosomal gains involved chromosomes 3q (43%), 21q (43%), 1q(31%), 5p(29%), 7p(31%), 8q(31%), 17q (31%), 20p (31%), 22q (35%), and Xq (31%). Common regions of gain involved 3q26-qter, 21q13-qter, and 22q13-qter. The most frequently detected chromosomal losses involved chromosomes Yq (38%), 3p13-pter (11%), 4q25-q26 (14%), 4q31 (17%), 8p21-pter (14%), 17p12-pter (11%), and 19p (11%). The recurrent sites of chromosomal gain and loss might be candidate regions for abnormal genes involved in the tumorigenesis of NSCLC.

**A unique insertional translocation in a man who had childhood Wilms tumor, ascertained through an offspring with bilateral retinoblastoma.** *I.E. Teshima<sup>1,6</sup>, M. Krinsky<sup>1</sup>, E. Heon<sup>2,3</sup>, J. Sutherland<sup>2</sup>, B.L. Gallie<sup>3,4</sup>, H.S.L. Chan<sup>5,6</sup>.*  
1) Pediatric Lab Medicine, Hosp for Sick Children; 2) Ophthalmology, Hosp for Sick Children; 3) Ophthalmology, Univ of Toronto; 4) Cancer Informatics, UHN; 5) Pediatrics, Hosp for Sick Children; 6) Pediatrics, Univ of Toronto, Canada.

Retinoblastoma and Wilms tumor are rare embryonic neoplasms caused by the loss/inactivation of both alleles of two different tumor suppressor genes: the RB1 within 13q14 and the WT1 gene within 11p13. Interchromosomal insertional translocations are also rare with an incidence of 1:80,000. We report a unique insertional translocation between chromosomes 11 and 13, present in a man who had Wilms tumor in childhood, and whose child had bilateral retinoblastoma. The 2-year-old girl presented with bilateral leukocoria, glaucoma and diminished vision. She was noted to be mildly dysmorphic from birth and subsequently found to be developmentally delayed. Examination of her eyes under anesthesia detected severe bilateral Reese-Ellsworth Group Vb retinoblastoma. Her otherwise normal father gave a history of unilateral Wilms tumor treated with nephrectomy and chemotherapy at 7 years of age. The family history was negative for other malignancies. The retinoblastoma tumors are presently responding to chemotherapy and focal therapy. Cytogenetic studies of the child's cultured lymphocytes identified a constitutional karyotype 46,XX,del(13)(q14.1q14.3) by GTG banding. The deletion was confirmed by FISH using a probe that spanned exons 3 to 17 of the RB1 gene. Parental cytogenetic investigations revealed that this deletion was a result of an unbalanced segregant from the father who had an insertional translocation 46,XY,ins(11;13)(p13;q14.1q14.3) by GTG banding and FISH. The mother's karyotype was 46,XX. Breakpoint investigations will be done to determine whether position effect or bisection of the WT1 had caused the Wilms tumor in the father. Insertional translocations have been previously described in two families with retinoblastoma and in one with Wilms tumor, but not in a family with both tumors. This insertional translocation poses high risk for the family and has unique issues for genetic counseling.

**Structural rearrangements of *Genesis* in primitive neuroectodermal and testicular germ cell tumors.** *G.H. Vance<sup>1</sup>, T.A. Gobbett<sup>1</sup>, H. Ramsey<sup>2</sup>, L.R. Smith<sup>1</sup>, V.C. Thurston<sup>1</sup>, R.A. Hromas<sup>2</sup>.* 1) Dept Medical & Molec Gen, Indiana Univ Sch Medicine, Indianapolis, IN; 2) Dept Medicine, Indiana Univ Sch Medicine, Indianapolis, IN.

Genes that control transcriptional regulation are primary targets for investigations into the mechanisms of cancer. One family of transcriptional regulators is the winged helix family. We have previously cloned and characterized a novel member of this family, *Genesis*, important in normal and malignant germ cell development<sup>1</sup>. *Genesis* has an open-reading frame of 465 amino acids and is specifically expressed in the embryonic histological subtype of non-seminomatous germ cell tumors (GCT). It has been localized to chromosome 1p31, a region of consistent abnormalities in testicular carcinoma. We present the data from 100 tumors analyzed by dual-colored FISH for numerical abnormalities and structural rearrangements of *Genesis*. Of the 100 tumors, 11 specimens were paraffin-embedded sections from primitive neuroectodermal tumors (PNET) and 89 were cultured surgical specimens from primary and/or secondary GCT of varying histology. FISH probes included a PAC with a 145 kb insert (*Genesis* 1.5 kb) that maps to chromosome 1p31.2-1p32.2 and a control PAC mapping proximal at 1p31.1-1p31.2. Eight tumors (1 PNET and 7 GCT) examined by FISH demonstrated aberrant signal patterns characteristic of structural rearrangements of *Genesis*. Preliminary Southern analysis identified an abnormal Bam HI fragment in four of the eight tumors. The Bam HI sites flank the gene and the extra fragments indicate intragenic disruption of *Genesis*. Recurring cytogenetic abnormalities in malignancy have repeatedly provided a platform for gene identification as well as detection of the underlying biological mechanism leading to cellular deregulation and cancer. Further characterization of these abnormal fragments is underway.

<sup>1</sup>Sutton J, Costa R, Klug M, Field F, Xu D, Largaespada D, Fletcher C, Jenkins N, Copeland N, Klemsz M, Hromas R. *Genesis*, a winged helix transcriptional repressor with expression restricted to embryonic stem cells. *J Biol Chem* 271:23126-23133, 1996.

**A challenge to cytogenetic nomenclature and clinical diagnosis: Translocations, duplications and multiple insertions involving three chromosomes in a diagnostic leukemia.** *M.J. Sutcliffe<sup>1,2</sup>, D.P. Dumont<sup>1</sup>, L. Glaskova<sup>1</sup>, S. Gellatly<sup>1</sup>, R. Echevarria<sup>3</sup>, K. Washington<sup>1</sup>, P. Desai<sup>3</sup>.* 1) Cytogenetics, Dept of Pathology, All Children's Hosp, St Petersburg, FL; 2) Dept of Pediatrics, University of South Florida, Tampa, FL; 3) Depts of Hematology/Oncology and Pathology, St Anthony's Hospital, St Petersburg, FL.

A 68 year-old male patient was referred with a history of severe anemia and thrombocytopenia. Pathology revealed dysplastic features particularly of the erythroid series with less than 20% myeloblasts resulting in a diagnosis of myelodysplastic syndrome suggestive of refractory anemia with excess blasts (RAEB). Flow cytometry revealed bimodal expression of CD45 with a minor cell population expressing variable intensity myeloid associated antigens CD13, CD34 and HLA-DR. The majority of these cells were negative for CD33, however, dim CD33 may be present on a small population. Interpretation was a myelodysplastic or myeloproliferative disorder. Reasonable mitotic index and 400-450 GTG banding showed a pseudodiploid karyotype initially suggesting der(19)t(1;19), monosomy 12 and 21 plus two marker chromosomes. Of these cells, 40% also showed a deletion within 6q. Discrepant banding and fluorescence in-situ hybridization (FISH) using whole chromosome paint (WCP1) eliminated chromosome 1 involvement in the translocation with chromosome 19. Extensive FISH analysis using WCP, telomere and locus specific probes for chromosomes 12, 19 and 21 revealed a) three highly complex derivative rearrangements that include two duplications, three translocation and four insertions, and b) partial trisomy 12, trisomy 19 and tetrasomy 21. In the absence of FISH, these structural changes could not have been deduced. Even in the knowledge of the rearrangements, attempting to describe the karyotype almost defies the nomenclature possibilities of ISCN 95. Although trisomy 19 and 21 are associated with MDS, deletion 6q is usually characteristic of lymphoid malignancy. Reconciling the diverse cytogenetic outcome supportive of mixed lineage neoplasia with the pathology and flow cytometry indicating a myeloid "pre-leukemic" condition has resulted in clinical dilemma.

**Atypical FISH Signal Patterns with Chronic Myelogenous Leukemia.** *F.F. Yen<sup>1</sup>, J.H. Hersh<sup>1</sup>, M.J. Barch<sup>1</sup>, R.H. Herzig<sup>2</sup>, G.P. Herzig<sup>2</sup>, A. Ameri<sup>3</sup>, S. Bertolone<sup>3</sup>.* 1) Weisskopf Center for the Evaluation of Children/Dept. Pediatrics, Univ Louisville, Louisville, KY; 2) Dept.of Medicine/James Graham Brown Cancer Center, Univ Louisville, Louisville KY; 3) Pediatric Hematology-Oncology, Univ Louisville, Louisville, KY.

The hallmark of chronic myelogenous leukemia (CML) is the formation of a BCR-ABL fusion gene resulting from a Philadelphia chromosome (Ph) due to a balanced translocation involving 9q34 and 22q11.2. In 5-10% of patients with CML, the Ph cannot be identified cytogenetically, despite the presence of a submicroscopic rearrangement. Atypical FISH signal patterns occur occasionally, and their presence may provide clues to the clinical heterogeneity observed in affected individuals. We describe 2 patients with CML, in which only a single fusion signal on the derivative 22 chromosome was identified, using a LSI BCR/ABL es dual color dual fusion probe (Vysis cat.32-191032). In one, the cytogenetic study revealed a Ph, while in the other, the result was normal. In the patient with a Ph, we suspect that a deletion adjacent to the translocation breakpoint on the derivative 9 chromosome was present resulting in loss of one or more genes that may play a role in disease progression. In the cytogenetically normal patient, the FISH result reflected the presence of an interstitial insertion of the c-ABL oncogene at 22q11.2. Although reports of this finding suggest no effect on the clinical course, findings in both of these patients may prove to be important in further defining the heterogeneity and prognosis in CML.

**A highly unusual case of Acute Myeloid Leukemia (AML) M5a: Atypical clinical and cytogenetic findings.** *H.C. Rossbach<sup>1</sup>, L. Glaskova<sup>1</sup>, D.P. Dumont<sup>1</sup>, W. Chamizo<sup>1</sup>, J. Barbosa<sup>1</sup>, M.J. Sutcliffe<sup>1,2</sup>*. 1) Hematology/Oncology, All Children's Hospital, St Petersburg, FL; 2) Dept of Pediatrics, University of South Florida, Tampa, FL.

A 3 yr-old patient presented with a two week history of malaise, fatigue, intermittent low grade fever, bruising and leg pain. He developed massive bilateral proptosis with chloromas of the frontal cranial bones (reminiscent of metastatic neuroblastoma) and gingival hyperplasia. The clinical and pathological diagnosis of Acute Myeloid Leukemia subtype 5a suggested the non-random chromosome abnormality associated with AML M5a, i.e. t(9;11)(p21-22;q23). Translocation (9;11), however, was not observed. Cytogenetic analysis revealed a pseudodiploid karyotype involving two inversions within one copy of chromosome 11. The clone, comprising the majority of cells analyzed, also showed duplication 1q21q32. The remaining 7/20 cells showed a normal karyotype. Fluorescence In-Situ Hybridization (FISH) analyses using probe CCND1 for the 11q13 locus and the MLL probe at 11q23 clearly demonstrated the double rearrangement confirming the GTG banding result of pericentric inv(11)(p13q13) and paracentric inv(11)(q13q25). To our knowledge, the phenomenon of two inversions within one chromosome has not been previously described. The 11q deletion or translocation typically associated with M5 clusters around two breakpoint regions, 11q23-24 and 11q13-14. Two of three breakpoints in this case, however, are atypical. The 11q25 band is not specifically described in leukemia while the 11p13 band is usually associated with Acute Lymphoblastic Leukemia (ALL). In summary, although this patient has chromosome 11 rearrangements, the specific breakpoints and the double inversion appear to be a unique finding. At six months post sex mis-matched bone marrow transplant, only 25% of cells are derived from the donor. The current karyotype shows highly complex sub-clonal evolution. The significance of these karyotypic findings are reviewed in the context of the complicated clinical course.

**A Case of Undifferentiated Sarcoma with t(12;21)(q13;q11.2) and a history of Meningioma.** *K.H. Ramesh<sup>1</sup>, M. Edelman<sup>1</sup>, D. Wei<sup>1</sup>, R. Thomas<sup>1</sup>, E. Radel<sup>2</sup>, L.A. Cannizzaro<sup>1</sup>.* 1) Dept Pathology, Montefiore Medical Ctr/AECOM, Bronx, NY; 2) Department of Pediatric Oncology, Montefiore Medical Ctr., Bronx, NY.

The patient is an 18-year old female who had a several month history of right hip pain. MRI scan revealed a large right hemipelvic soft tissue mass centered within the pelvic and paraspinal muscles with extension through the right neural foramina of L4-L5 and L5-S1. Chest X-ray revealed bilateral pulmonary nodules. At age 9 years the patient had undergone resection of a spinal meningioma through an L3-L5 laminotomy. Open biopsy of the present pelvic mass revealed a "small round blue cell tumor". The tumor was immunoreactive for vimentin, neuron specific enolase, S-100 and BCL-2, but non-reactive with CD-99 (O-13), chromogranin, synaptophysin, GFAP, desmin, muscle specific actin and leukocyte common antigen. Although a diagnosis of PNET was considered, given the negative O-13 staining, the tumor was diagnosed as an undifferentiated sarcoma with neuroectodermal features. Cytogenetic information was not available on the meningioma. Chromosomal analysis of the undifferentiated sarcoma showed a 45,XX,del(9)(p13),t(12;21)(q13;q11.2),-22 karyotype. Normal cells were not seen. FISH analysis with whole chromosome paints 9,12,21 and 22 confirmed the cytogenetic diagnosis. Monosomy 22 is a characteristic cytogenetic change in meningioma and occurs less frequently in PNETs'. The deletion of 9p13 and translocation involving chromosomes 12 and 21 could be secondary changes indicating the evolving nature of the tumor. The immunoglobulin kappa J region recombination signal-binding protein-1 is on 9p13. The ERB-3 and human papillomavirus type 18 integration site-2 gene is on 12q13. The transient abnormal myelopoiesis gene is on 21q11.2. Is the current tumor related to the previous meningioma? Could the current tumor have resulted from dedifferentiation of residual tumor cells of the previous meningioma? Based on the occurrence of monosomy 22, it is reasonable to believe that the two lesions may in fact be related. After chemotherapy CT scan still shows the presence of lung nodules although there is significant reduction in size of the primary tumor. The prognosis for this patient is guarded.

**Molecular cytogenetic analysis of patients with acute lymphoblastic leukemia (ALL) utilizing multiple DNA probes for fluorescence in situ hybridization (FISH).** *L. Zhang, F. Bates, J.B. Parkhurst, J.J. Mulvihill, S. Li.*  
Department of Pediatrics, Univ Oklahoma Hlth Sci Ctr, Oklahoma City, OK.

The TEL/AML1 fusion results from a cryptic translocation between chromosomes 12 and 21 [t(12;21)(p13;q22)]. TEL/AML1-positive patients have exclusively B-cell lineage acute lymphoblastic leukemia (ALL) and a favorable prognosis compared with TEL/AML1-negative patients. However, the BCR/ABL fusion gene and MLL gene rearrangements are associated with an extremely poor outcome. These chromosomal rearrangements are too subtle to detect by conventional cytogenetic analysis, but can be readily detected using FISH techniques with commercially available DNA probes. We examined 33 patients with ALL for possible TEL/AML1, BCR/ABL fusion, and MLL rearrangements, 28 patients were pediatric patients (6 months to 19 years old) and 5 were adults (23 to 74 years old). We found that 9 out of the 28 pediatric patients (32%) were positive for TEL/AML1 fusion; all five adults were negative. All 9 patients with positive TEL/AML1 fusion had ALL pre-B cell lineage L1 according to standard immunotyping; eight were newly diagnosed leukemia, and one was in a second relapse 10 years after the first ALL. We also found that 4 pediatric patients, who were negative for the TEL/AML1 fusion, had an MLL gene deletion. All the patients lacked the BCR/ABL fusion. In agreement with previous reports, FISH testing using DNA probes specific for TEL/AML1 translocation should be a routine procedure for all patients with newly diagnosed ALL. The significance of MLL deletion found in 4 patients requires longer follow-up time to draw a definite conclusion.

**Application of molecular cytogenetic analysis (FISH) to identify a new translocation, t(11;17)(p13;q21.3), in a patient with acute myeloid leukemia.** *S. Shekhter-Levin*<sup>1,2,3,4</sup>, *S.S. Kaplan*<sup>3</sup>, *K. Cumbie*<sup>1</sup>, *M.E. Sherer*<sup>1,2</sup>. 1) Pittsburgh Cytogenetics Lab, University of Pittsburgh Center for Human Genetics at UPMC Magee Womens Hosp, Pittsburgh, PA; 2) Dept. of Human Genetics, University of Pittsburgh Graduate School of Public Health, Pittsburgh, PA; 3) Dept. of Pathology, Univ. of Pittsburgh School of Medicine, Pittsburgh, PA; 4) Univ. of Pittsburgh Cancer Institute, Pittsburgh, PA.

The patient, a 54-year old female, was diagnosed with acute myeloid leukemia (AML) FAB M5b a year ago and underwent four cycles of consolidation therapy six months ago. She now presents with blasts in her peripheral blood. Evaluation of her bone marrow revealed a hypercellular bone marrow consistent with AML, but the phenotype expressed no monocytoid characteristics noted at first presentation. Cytogenetic analysis of G-banded bone marrow cells, which had a normal karyotype previously, showed an abnormal mosaic chromosome pattern: 46,XX,del(17)(q23)[10]/46,XX[10]. FISH with the Vysis dual color *RARA* probe (17q21) and the Oncor dual color *MPO* probe (17q21.3-17q23) performed on metaphase cells showed intact *RARA* gene on the long arm of an abnormal chromosome 17, whereas the whole *MPO* gene was translocated from the abnormal chromosome 17 to the short arm of a C-group chromosome resembling an 11. Chromosome 11 and 17 paints confirmed the presence of a translocation between 11p and 17q, which was not identified by classical cytogenetic analysis. Consequently, the abnormal clone was designated as: 46,XX,t(11;17)(p13;q21.3).ish t(11;17)(p13;q21.3) (wcp11+,wcp17+,MPO+;wcp11+,wcp17+,RARA+,MPO-). The t(11;17)(p13;q21.3) translocation has not been reported previously, although translocations between 11q and 17q are well known in AML (M3 and M5 FAB types). Acquisition of this abnormal clone, which was not seen in this patient at the time of diagnosis, and the change in leukemia phenotype with loss of the monocytoid features suggest a possible association between these two events. It could be hypothesized that the transfer of the *MPO* gene from its normal position on 17q to 11p might lead to its dysregulation with consequent overexpression of the myeloperoxidase.

**Jumping translocations in childhood B-Cell malignancy.** *L.M. Pasztor<sup>1,2</sup>, L. Weems<sup>2</sup>, R. Callahan<sup>2</sup>, E. Kroman<sup>2</sup>, M. Recht<sup>3</sup>.* 1) Palo Verde Laboratory, A Division of Sonora Quest Laboratories, Tempe, AZ; 2) Clin Path Assoc., Tempe, AZ; 3) Section of Hematology/Oncology, Phoenix Children's Hospital, Phoenix, AZ.

Jumping translocations (JTs) and segmental jumping translocations (SJTs) are rare cytogenetic phenomena characterized by chromosomal amplification in which specific segments are translocated on to the ends of various chromosomes. JTs have been identified mostly in neoplastic conditions, although the first case reported in 1979 was constitutional. We report a case of Burkitt's lymphoma with peripheral involvement in a 2yr10month female. G-banding and chromosome painting characterized a 46,X,der(X)t(X;1)(q28;q21),t(8;14)(q24;q32) chromosome complement in each of the 20 bone marrow metaphases examined. In addition, there were several clones or individual cells with the donor 1q21->qter translocated to the telomeres of chromosomes 3,6,8,19 or 21. In effect, these JTs resulted in "partial tetrasomy" of the 1q segment. Interestingly, the leukemic cells were characterized as pre-B ALL(L1) by morphology and immunophenotyping.

Amplification of 1q by JTs has been reported in approximately 20 cases of acute myeloid and lymphoid leukemia and suggests that these rearrangements are secondary rather than primary cytogenetic events.

Our case supports the notion that a novel gene, perhaps JTB, at 1q21 fuses with telomeric sequences of receptor chromosomes to produce an aberrant transcript. The altered protein generated changes a critical biological feature leading to increased malignant potential of the tumor.

**Carney Complex: Cytogenetic Analysis of Tumors.** *L.D. Matyakhina<sup>1</sup>, S.D. Pack<sup>2</sup>, E. Pak<sup>2</sup>, J. Jaikumar<sup>2</sup>, P. Mannan<sup>2</sup>, L.S. Kirschner<sup>1</sup>, C.A. Stratakis<sup>1</sup>.* 1) DEB, NICHD, Bethesda, MD; 2) SNB, NINDS, Bethesda, MD.

Carney complex (CNC) is an autosomal dominant syndrome characterized by familial multiple neoplasia. The disease is heterogeneous and has been mapped to chromosomes 2p16 (CNC2) and 17q24 (CNC1). Mutations in tumor suppressor gene PRKAR1A (CNC1) were recently found in half of the CNC families, while the CNC2 gene remains unidentified. To elucidate the functional role of the CNC2 gene on 2p16, 36 tumors from CNC were studied by FISH using BAC probes from the 2p16 critical CNC region and BAC321G8 containing PRKAR1A gene. The most consistent finding from this analysis was amplification of the 2p16 region. The region of most consistent amplification is defined by BAC 400P14 (D2S2251-D2S2292), which showed the increased copy number in 20 of 26 touch preparations. A tandem duplication of dual color BAC in the interphase nuclei suggested the presence of homogeneously staining regions (HSRs). The degree of amplification varied from cell to cell within a single tumor suggesting an acquired instability process rather than monoclonal tumor cell expansion with an established amplicon. In 12 tumors this instability resulted in allelic deletion of 2p16 region. The changes of 2p16 region were observed in tumors from both groups of CNC patients with and without PRKAR1A mutations. However, in the latter case the loss of one PRKAR1A allele was revealed in 7 of 9 tumors (78%). The FISH analysis of 18 tumors from CNC patients with PRKAR1A mutations using BAC321G8 containing PRKAR1A gene showed the deletion of the 17q24 region in only 6 tumors (33%), suggesting that deletion of the normal allele on 17q24 is not necessary for tumorigenesis. Control experiments using FISH with the abovementioned BACs to normal adrenal cortex and BACs from other chromosomes to tumor cells revealed two signals of equal intensity in all cells examined. Taken together, our results suggest the presence of an oncogene on 2p16 that may be responsible for CNC in a subset of families. We speculate that activation of the CNC2 gene is triggered by inactivation or deletion of the CNC1 tumor suppressor gene or by amplification, which results in gain of function of the 2p16 gene independently of PRKAR1A.

**Evidence for deletion on chromosomes 6 and 12 in adenoid cystic carcinoma of the salivary gland.** *S. Rutherford*<sup>1</sup>, *R.M. Leu*<sup>1</sup>, *R. Saadut*<sup>1</sup>, *C.R. Marshall*<sup>1</sup>, *C.A. Rumpel*<sup>1</sup>, *W. El-Rifai*<sup>2</sup>, *S. Knuutila*<sup>3</sup>, *H.F. Frierson*<sup>1</sup>, *C.A. Moskaluk*<sup>1</sup>. 1) Dept of Pathology, University of Virginia, Charlottesville, VA; 2) Dept of Medicine, University of Virginia, Charlottesville, VA; 3) Dept of Medical Genetics, University of Helsinki, Helsinki, Finland.

Adenoid cystic carcinoma (ACC) is among the most common of malignant neoplasms that arise in salivary glands. The genetic alterations involved in the initiation and progression of ACC are not well characterized. Recently, we conducted comparative genomic hybridization (CGH) to characterize regions of genetic deletions in 24 cases of ACC. The results of this study showed loss at chromosome 6q (35% of ACC with DNA copy number changes) and at chromosome 12q (40%). To further investigate chromosomes 6 and 12, we assayed for loss of heterozygosity (LOH) using polymorphic microsatellite markers in paired tumor and normal samples of 58 cases. LOH results show hotspots of deletion occurring at the 6q24.2-q25.1 and 12q12-q13 regions. Results from LOH analysis also extended the CGH findings to show a small region of deletion occurring on the p arm of chromosome 12 indicating that one or more tumor suppressor genes may reside on this chromosome. Chromosome 12 deletion is infrequent in human neoplasms in general, and the underlying molecular defect(s) may be relatively specific for the tumorigenesis of ACC. Deletion of chromosome 6q has been described in ACC of the salivary gland, consistent with targeted inactivation of a tumor suppressor locus. Candidate tumor suppressor genes located within the chromosome 6 region of deletion include the pleomorphic adenoma of the salivary gland gene like 1 (PLAGL1/LOT1/ZAC), tumor suppressor-activated pathway 21 (TSAP21) and the large activating tumor suppressor gene (LATS1). Our results provide additional evidence for the existence of a deleted region on 6q, which may harbor one or more tumor suppressor genes important in the development of salivary gland carcinoma.

**Reciprocal Translocation 46,XY, t(1;4)(q11;q11), in a Gigantiform Cementoma. A case report.** *J.M. Aparicio<sup>1</sup>, M.P. Barrientos<sup>1</sup>, M.L. Hurtado<sup>1</sup>, B. Molina<sup>2</sup>, S. Frias<sup>2</sup>, C.F. Salinas<sup>3</sup>.* 1) Dept Genetics, Hosp para el Nino Poblano, Puebla, Mexico; 2) Dept of Cytogenetic, Inst Nacional de Pediatria, Mexico city; 3) Craneofacial Genetics, Med Univer of South Carolina, USA.

**INTRODUCTION.** *A gigantiform cementoma (GC) is a fibro-osseous tumoral lesion of Jaws, a rare entity with a dominant autosomic inheritance. Despite the reported association of tumoral lessions with autosomic chromosomal translocations, this chromosomal aberration have not been found in GC.* **CASE REPORT.** *An adolescent male with a fibro-osseous lesion of the jaws, resembling a GC clinically, radiologically and histopatologically; in addition with a flat fascies and minor phenotypic dismorfies is presented. The karyotype showed the existence of a de novo reciprocal translocation between the long arms of chromosomes 1 and 4.* **CONCLUSION** *This is the first report of a GC related to the precense of this specific genetic abnormality, consisting in a reciprocal nHCT due to a cytogenetic mutation. it was though that part of the centromere and chromosome 4 short arm was included, at the beggining of this study. However, by using fluorescence methods (FISH), this probability was eliminated. Clinical records, radiological images and histopatholgical finfings are commented, emphasizing the relevance of the genetic study and counseling in this and other entities with tumor growth, that have been related to chromosome translocations in pairs 1 and 4.* **KEEWORDS:** *Chromosome 1 and 4, gigantiform cementoma, chromosomal translocation, karyotype..*

**ENDOMETRIAL CYTOGENETIC EVALUATION IN HEALTHY WOMEN THAT INGESTING ORAL CONTRACEPTIVE.** *A.E. Rojas-Atencio<sup>1</sup>, Z. Villalobos-Vega<sup>2</sup>, K. Urdaneta<sup>1</sup>, G. Garcia<sup>1</sup>, L. González<sup>2</sup>, M. Soto-Alvarez<sup>1</sup>, F. Alvarez Nava<sup>1</sup>.* 1) Unidad de Genetica, Univ del Zulia, Maracaibo , Zulia, Venezuela; 2) Hospital Clinico de Maracaibo.

The oral contraceptives constitute the birth-control method more used by the women that want to maintain their capacity to conceive in a future. The objective of this study was to evaluate the chromosomal findings in endometrio of healthy women, assisted to the family planning, during the period of august to December of 2000. Twenty-five women were chosen at random among 18 to 40 years that ingested oral contraceptive for a time by 10 years with or without risk factor to neoplasia (obesity, smokier, gonadal dysfunction, etc) Only 12 endometrial samples were available for cytogenetic study. We were used technical of short culture and GTG banding. Of the 12 analyzed samples, 9 (75%) presented normal chromosomal features. Chromosomal aberrations was observed in 3 women (25%), being evidenced risk factors associated with the type and time of consumption of the contraceptive, obesity, smokier, polycystic ovaries, chronic anovulation, and endometrial hyperplasic. Were observed, monosomy 10, 12 and 14, endoreduplications, fragile sites specially in 11q23, tetraploidy, marker chromosome and translocation (8q;15q). These findings suggest that the presence of chromosomal anomalies associated with the consumption of oral contraceptive could be used as an indicative of beginning of endometrial adenocarcinoma. These cytogenetic anomalies have been reported in-patient with this pathology. We conclude that all patient with consupcion of oral contraceptive uninterruptedly for one year should be practiced besides their routine studies, an chromosomal analysis to detected anomalies that could be compatible precociously with the beginning of the cancer.

**Molecular heterogeneity of MLL/AF17 fusion transcripts in acute leukemias.** *S. Strehl<sup>1</sup>, M. König<sup>1</sup>, O.A. Haas<sup>1,2</sup>.*  
1) CCRI, Childrens Cancer Research Institute; 2) LBICD, Ludwig-Boltzmann Institute for Cytogenetic Diagnosis; Vienna, Austria.

The t(11;17)(q23;q21) accounts for 1-1.5% of all MLL rearrangements and results in a chimeric transcript that fuses the 5' end of the MLL gene to the 3' end of the AF17 gene. However, at the molecular level only one case of an MLL/AF17 fusion has been described. We have identified 10 patients with acute leukemia carrying a t(11;17)(q23;q21-25) by cytogenetics and/or chromosome painting, and in 9/10 rearrangement of the MLL gene was detected by FISH. Further FISH analysis using gene-specific probes suggested the presence of an MLL/AF17 fusion in 5 patients. Performing RT-PCR with published primers failed to identify the fusion transcript in 4/5 patients. Therefore, further RT-PCRs using various primer combinations were performed, and in 4 patients 4 new fusion transcript variants were detected. Two patients displayed fusion of MLL exon 8 to AF17 nt 1942 of the translated region. In one of them, an additional alternatively spliced MLL/AF17 transcript was co-expressed. In this transcript, MLL exon 8 was fused to a hitherto undefined AF17 exon. Alternative splicing of the AF17 gene in peripheral blood was confirmed by exon-specific RT-PCR. In the third patient MLL exon 9 was fused to another alternatively spliced AF17. In this case, the MLL gene fused to nt 552 of AF17, and exclusion of a 615-bp exon was detected. In the fourth patient an unusual combination of exon sequences in the chimeric transcript was observed. Both the MLL and the AF17 genes were fused within exons, namely MLL exon 10 and AF17 nt 1745. In this instance it remains to be determined whether this fusion variant is due to the activation of cryptic splice sites or whether the genomic breakpoints occur within exons. In all instances the open reading frames were maintained without frameshift, thus resulting in true fusion proteins. All predicted MLL/AF17 chimeric proteins included the most notable feature of the AF17 protein, a leucine-zipper dimerization motif. The high heterogeneity of MLL/AF17 fusion transcripts emphasizes the importance of appropriate primer selection for RT-PCR analysis in diagnostic settings.

**Multicolor FISH analysis in ten patients with acute lymphoblastic leukemia.** *G. Calabrese*<sup>1,2</sup>, *T. Taraborelli*<sup>1,2</sup>, *D. Fantasia*<sup>1,2</sup>, *E. Morizio*<sup>1,2</sup>, *P. Guanciali Franchi*<sup>1,2</sup>, *V. Gatta*<sup>1</sup>, *A. Spadano*<sup>3</sup>, *L. Stuppia*<sup>1,4</sup>, *G. Palka*<sup>1,2</sup>. 1) Dip S. Biomed/Genetica Univ DG Annunzio, Chieti, Italy; 2) Serv. Genetica U., Osp. Civ. Pescara, Italy; 3) Dip. Ematologia, Osp. Civ. Pescara, Italy; 4) Ist. Citomorfologia N&P, CNR, Chieti, Italy.

Spectral karyotyping (SKY), and multicolor FISH banding analyses allow precise identification of subtle translocations, marker chromosomes, and complex chromosomal aberrations. At present few data have been reported in acute lymphoblastic leukemia (ALL) patients using these approach. We investigated 10 ALL patients using both multicolour FISH approaches. In four patients SKY analysis confirmed normal karyotype shown by conventional G-banding. In one patient showing 15% of diploid cells with del(17)(p12) and p53 gene loss by FISH, SKY was unable to detect any anomaly likely since intrachromosomal rearrangement are not suitable for spectral investigation. In the other five patients with two or more chromosomal abnormalities SKY analysis showed in two cases the same anomalies identified by standard cytogenetics while karyotypes were precisely refined in three cases. In a T-ALL patient, a t(12;20)(p13;q12) was redefined by SKY as t(11;20)(p13;q12) with rearrangement of genes involved in hematopoietic pathway. In another patient, with a Common subtype, SKY reclassified an add(7) as der(7)t(7;8)(q3;?), a rare rearrangement in ALL. Using multicolor banding probe for chromosome 7 a deletion on 7q34-35 was also detected unraveling a cryptic more complex abnormality. In the remaining patient, with a T cell ALL, SKY analysis identified a marker chromosome as dic(1;9)(p36;p11-13) with loss of tumor related genes on 1p36 and 9p. Moreover SKY analysis also disclosed a cryptic t(10;11)(p13;q21) which harboured a specific CALM/AF10 fusion gene responsible for poor clinical outcome. In conclusion, in three cases with multiple rearrangements SKY and multicolor banding using the same digital multifuorescence apparatus resulted in a rapid cost-effective approach which allowed us to refine abnormal karyotypes and to detect cryptic rearrangements related to adverse prognosis.

**Deletions of 13q14 are significant in the diagnosis of multiple myeloma.** *C.M. Higgins, H. Blair, B. Dave, W.G. Sanger.* Human Genetics Laboratory, Univ Nebraska Medical Ctr, Omaha, NE.

Multiple myeloma (MM) is a lymphoproliferative disorder characterized by the malignant proliferation of monoclonal plasma cells. Because of the low proliferative rate of malignant plasma cells, cytogenetic abnormalities are often difficult to ascertain. Recently, FISH techniques have helped to establish a more cogent relationship between a deletion of 13q14 & the poor clinical course of this disease. Our laboratory routinely screens newly diagnosed MM patients with a DNA probe for 13q14 as an adjunct to conventional cytogenetics. This study summarizes our experience in detecting cytogenetic abnormalities & deletions of 13q14 by FISH analysis. One hundred-eight newly diagnosed MM cases were studied in our laboratory utilizing conventional cytogenetics & interphase FISH with a DNA probe specific for 13q14. Eighty-two of these cases were found to be normal by cytogenetics & by FISH. Twenty-six cases (24%) were abnormal by cytogenetics &/or by interphase FISH analysis of 13q14. Sixteen cases (15%) showed a deletion of 13q14 by FISH; 6/16 cases contained normal karyotypes by G-band analysis; 10/16 cases were cytogenetically abnormal & 8 of these cases had either a visible deletion or monosomy 13. Twenty cases (19%) with abnormal karyotypes included 10 cases without 13q14 involvement & 10 cases with deletion 13q14 (by FISH). Besides chromosome 13, which was most frequently altered, chromosomes 5, 7 & 9 were most predominantly observed as numeric abnormalities (9/20; 45%, each). Structural abnormalities frequently involved chromosomes 1 (6/20; 30%) & 11 (4/20; 20%). All 4 cases with structural abnormalities of 11 had involvement of the 11p15 region. A recurrent translocation, t(1;11)(p13;p15), was observed in 2 cases. FISH studies provided a valuable tool to complement conventional cytogenetics in detecting higher number of abnormalities in MM. A combination of interphase FISH screening for 13q14 deletions & routine cytogenetic analysis in MM patients at diagnosis may prove to be beneficial in determining the prognosis & in designing an effective therapeutic strategy for newly diagnosed MM patients.

**Quantitative PCR and IHC staining for HER-2/neu. Retrospective comparative case study of breast cancer specimens selected for chromosome 17 aneusomy by FISH.** *I. Simonic<sup>1,2</sup>, B. Manasse<sup>1</sup>, S. Smocilac<sup>1</sup>, G. Stipinovich<sup>1</sup>, P. Lombard<sup>1</sup>, T. Slavik<sup>1</sup>.* 1) Ampath Group, Pomona Rd. 29, Johannesburg, South Africa; 2) Medical Research Council, MRC, Southpansberg Rd. 1, Pretoria, South Africa.

In total 57 cases pre-selected due to ambiguous HER-2/neu IHC result were followed up by FISH analysis in our laboratory to date. 13/57 cases were identified positive for chromosome 17 aneusomy and 3/57 cases were clearly positive for penta- and hexasomy of chromosome 17, without the actual HER-2 amplification. The IHC staining was repeated on the later three specimens and followed by quantitative PCR for HER-2/neu amplification. Comparative results are presented and their clinical significance discussed with respect to the management of the patients. Moreover, two additional cases were identified in the course of the clinical HER-2/neu FISH analysis with augmented CEP17 copy number with accompanying HER-2/neu amplification.

**Detection of a variant translocation of p190 *BCR-ABL* by FISH and Multiplex RT-PCR with multicolor fragment analysis, including detection of minimal residual disease.** *J.F. Pulliam*<sup>1</sup>, *D.A. Jezek*<sup>1</sup>, *P.P. White*<sup>1</sup>, *J.A. Moscow*<sup>2</sup>, *C.D. Jennings*<sup>1</sup>, *A.L. Pettigrew*<sup>1</sup>. 1) Dept Pathology, Univ Kentucky, Lexington, KY; 2) Dept Pediatrics, Univ Kentucky, Lexington, KY.

A patient presented with acute lymphoblastic leukemia (WBC of 48,000 with 95% blasts and bone marrow replaced by FAB-L2 blasts). Karyotyping at diagnosis showed a t(9:22)(q34.1;q11.2) with multiple secondary changes. A multiplex RT-PCR method with reverse-dot blot confirmation to allow the detection of all known variants of 5 common acute lymphocytic translocations (p190 and p210 *BCR-ABL*, *ETV6-AML1*, *AF4-MLL*, *PBX1-E2A*) originally described by Scurto P, et al (*Leukemia* 12:1994 (1998)) was modified with multicolor fluorescent primers and multicolor fragment analysis to allow detection on the ABI 310 Genetic Analyzer. Application of multiplex RT-PCR to this case identified a p190 *BCR-ABL* translocation.

At 10 months post remission induction, bone marrow fluorescent *in situ* hybridization (Vysis LSI *BCR-ABL* ES Dual Color Probe) and flow cytometry showed minimal residual disease (2.6% cells with a variant *BCR-ABL* fusion and the diagnostic leukemic immunophenotype admixed with 13% normal B-lineage precursors (hematogones)). At 12 months and following delayed intensification, no evidence of the clone was identified.

This case demonstrates the successful adaptation of the multiplex RT-PCR technique with multicolor fragment analysis to the detection of ALL translocations, and the utility of minimal residual disease detection with complementary modalities.

Scurto P, Hsu Rocha M, Kane JR, Williams WK, Haney DM, Conn WP, Shurtleff SA, Downing JR. A multiplex RT-PCR assay for the detection of chimeric transcripts encoded by the risk-stratifying translocations of pediatric acute lymphoblastic leukemia. *Leukemia*, 1998 Dec; 12(12):1994-2005.

**Evidence For Genetic Anticipation in Familial Prostate Cancer.** *C.H. Bock<sup>1</sup>, P.A. Peyser<sup>1</sup>, K.L. Tedesco<sup>2</sup>, C.E. Mohai<sup>2</sup>, K.A. Cooney<sup>2,3</sup>.* 1) Department of Epidemiology, University of Michigan School of Public Health; 2) Department of Internal Medicine, University of Michigan Medical School; 3) Department of Urology, University of Michigan Medical School, Ann Arbor, MI.

Decreased age of onset in successive generations has been observed for a number of diseases with a genetic basis. Participants in the University of Michigan Prostate Cancer Genetics Project were studied to determine whether differences in age of diagnosis within vertical generations, a hallmark of genetic anticipation, exists in familial prostate cancer. Families with at least one affected father-son pair were included in the study, resulting in 309 pairs from 191 families (508 total individuals, 11% black). Average age at diagnosis among sons and fathers was 58 (sd=9.1, range = 35,81), and 72 years (sd=8.9, range = 45,93) respectively. The average difference in age at diagnosis (14 years) was highly statistically significant by a paired t-test ( $t=20.58$ ,  $p<.0001$ ). To reduce detection bias in the sample, we restricted the analysis to the 120 pairs in which the son was born prior to 1936. The statistically significant difference in age at diagnosis persisted ( $t=6.54$ ,  $p<.001$ ). Analyses were repeated in the 136 pairs that did not include the proband to reduce ascertainment bias in the sample and a highly statistically significant difference in age at diagnosis was still observed ( $t=9.33$ ,  $p<.0001$ ). Significant results were also detected in both black and white subgroups when the data was stratified by race. Study findings were supported by life table analyses, in which age at diagnosis in sons was found to be significantly younger than age at diagnosis in fathers when the Gehan's Wilcoxon generalized test statistic was computed for the entire sample. Differences in ages of diagnosis remained when the analysis was restricted to individuals born prior to 1936, when probands were excluded, and after stratification by race. Taken together, there is evidence that sons of men with prostate cancer have an earlier age of diagnosis than their fathers, which suggests anticipation. This finding, if confirmed, will have important implications for risk assessment in familial prostate cancer.

**Variants in the genes that encode the BRCA1-associated genome surveillance complex (BASC) in BRCA1 mutation carriers.** *K.L. Nathanson<sup>1,3</sup>, R. Letrero<sup>1</sup>, P.A. Kanetsky<sup>2</sup>, R. Omaruddin<sup>1</sup>, C. Issacs<sup>4</sup>, C. Lerman<sup>3</sup>, T.R. Rebbeck<sup>2,3</sup>, B.L. Weber<sup>1,3</sup>.* 1) Dept Medicine, Abramson Family Cancer Research Institute; 2) Dept Epidemiology & Biostatistics; 3) Cancer Center, Univ Pennsylvania Sch of Med, Philadelphia PA; 4) Lombardi Cancer Center, Georgetown University, Washington DC.

Mutations in BRCA1 confer a greatly increased risk of breast cancer. However, the breast cancer risk due to mutations in BRCA1 varies from 40-85% depending on the population ascertained. Therefore it has been speculated that the mutation alone does not explain the observed phenotype and that other factors, including variants in genes other than BRCA1 and BRCA2, influence the development of breast cancer in BRCA1 mutation carriers. As BRCA1 and BRCA2 function in DNA damage response pathways, variants in other DNA damage response genes that are associated in complexes with BRCA1 and BRCA2 are particularly good candidate genes to modify penetrance in BRCA1 mutation carriers. We have selected variants in genes that are part of the BASC complex (MLH1, MSH2, MSH6 and ATM) as candidate genes in which single nucleotide polymorphisms may modify penetrance in BRCA1 mutation carriers. Using 221 female BRCA1 mutation carriers we studied the following variants: ATM - 5'UTR 10805 A/G, D1853N, MLH1 - 5'UTR -93 G/A, MSH2 - IVS9 -9 T/C, IVS12 -6 T/C, and MSH6 - G36E. Female BRCA1 mutation carriers were stratified by whether or not they had a breast cancer diagnosis. Of the 6 variants, only the presence of the C at position -9 in IVS9 of MSH2 may be associated with the diagnosis of breast cancer (OR=1.9, 95% CI 0.97-3.6). As BRCA1 and MSH2 function in different pathways of DNA damage repair, double strand break repair and mismatch repair respectively, it is possible that alterations in multiple pathways may be more important than multiple alterations in the same pathway.

**Suppression of tumor formation by expression of semaphorin 3F in HEY ovarian carcinoma but not in GLC45 small cell lung cancer cells.** *S.L. Naylor*<sup>1</sup>, *A.R. Davalos*<sup>2</sup>, *C.H. Hensel*<sup>3</sup>, *RH. Xiang*<sup>1</sup>. 1) Cellular & Structural Biol, Univ Texas Health Science Ctr, San Antonio, TX; 2) Lawrence Berkeley National Laboratory, Berkeley, CA; 3) Myriad Genetics, Salt Lake City, UT.

Loss of heterozygosity on human chromosome 3p21.3 is a frequent occurrence in many tumor types. In a previous study, our laboratory demonstrated functionally that an 80 Kb P1 clone from chromosome 3 suppresses the tumorigenicity of the mouse fibrosarcoma cell line A9. Two cDNAs corresponding to genes encoded on this P1 clone, semaphorin 3F and N23, were tested for their effects on in vitro and in vivo growth characteristics following transfection into mouse A9 cells. Transfection of semaphorin 3F cDNA resulted in complete loss of tumorigenicity in nude mice whereas transfection of N23 had no effect. Moreover, semaphorin 3F also functioned to block apoptosis of transfected A9 cells treated with taxol or adriamycin. To test whether SEMA3F had an effect on human tumors, we transfected the small cell lung cancer line GLC45. Expression of semaphorin 3F in this cell line had neither in vitro nor in vivo effects. Human ovarian cancer also has a high rate of loss of heterozygosity. Upon transfecting the human ovarian adenocarcinoma cell line HEY, we found loss of the capacity for growth on soft agar. Moreover, expression of SEMA3F in HEY cells resulted in the suppression of tumor formation in nude mice. Our results indicate that the effects of semaphorin expression on in vitro and in vivo growth have a cellular specificity.

**Genetically induced pituitary tumors in POMC null mouse mutants.** *J. Costa*<sup>1</sup>, *G.Y. Li*<sup>2</sup>, *B.R. Robinson*<sup>2</sup>, *A.F. Parlow*<sup>2</sup>, *U. Hochgeschwender*<sup>2</sup>, *M.B. Brennan*<sup>3</sup>. 1) Human Medical Genetics Program, University of Colorado Health Sciences Center, Denver, CO; 2) Oklahoma Medical Research Foundation Oklahoma City, OK; 3) Eleanor Roosevelt Institute, Denver, CO.

POMC null mutant mice lack all POMC-derived peptides and recapitulate the phenotypes of obesity, pigmentation defects, and adrenal insufficiency as observed in human patients with POMC gene mutations. An additional phenotype observed in the mice is the occurrence of pituitary tumors in both homozygous and heterozygous mutants. By the age of 5-7 months > 90% of these mice begin to express symptoms of pituitary tumors, such as weight loss, and die by 7-9 months of age. Immunohistochemical examination revealed the tumors to be similar to non-functional macroadenomas in human patients: tumor tissues appear non-secreting after staining with TSH, PRL, GH, ACTH, -MSH, and LH, while the normal parts of the pituitaries produce the expected hormones. Sera of these mice were also evaluated for the presence of pituitary hormones with no significant elevation in hormones tested (GH, PRL, TSH). The involvement of POMC mutations as genetic factors in pituitary tumors was unexpected. However, as POMC null mutations are known to occur naturally in man and as clinically nonfunctioning pituitary adenomas comprise approximately 25-30% of human pituitary tumors, the etiology of pituitary tumors in POMC null mice may be relevant to human pituitary neoplasia. We are currently testing such human adenomas for the presence of POMC mutations.

**Frequent upregulation of Wnt signaling pathway in human pituitary adenoma.** *T. Aiba<sup>1</sup>, S. Semba<sup>1</sup>, C. Sun<sup>1</sup>, M. Imai<sup>1</sup>, T. Furukawa<sup>1</sup>, H. Ikeda<sup>2</sup>, A. Horii<sup>1</sup>.* 1) Department of Molecular Pathology, Tohoku University School of Medicine, Sendai, Miyagi, 980-8575 Japan; 2) Department of Neurosurgery, Tohoku University School of Medicine, Sendai, Miyagi, 980-8575 Japan.

Upregulation of the Wnt signaling pathway is playing an important role in cell proliferation. Several proteins such as APC, beta catenin (CTNNB1), GSK3beta, AXIN-1 and -2, and ICAT are known to be involved in regulation of the Wnt pathway. Recently, MYC and cyclin D were found to be the target downstream genes in the Wnt signaling pathway. As we previously observed over expression of MYC in human pituitary adenomas, it is of great interest in analyzing molecules involved in regulation of the Wnt signaling pathway. A total of 37 pituitary adenomas were analyzed in this study. Expression of CTNNB1 and cell proliferation marker Ki-67 were studied immunohistochemically. Twenty-one (57%) of 37 pituitary adenomas demonstrated abnormal nuclear accumulation of CTNNB1. Mutations in the CTNNB1 gene were found in only four tumors. We further searched for mutations in the other genes such as APC, GSK3beta, AXIN-1 and -2, and ICAT, but none of the mutations were observed. These results suggest that (1) upregulation of the Wnt signaling pathway is playing an important role, and (2) unknown molecule(s) other than CTNNB1 is playing an important role(s) in human pituitary tumorigenesis.

**A physical transcriptome map for chromosomal analysis of lung cancer microarray data.** *A.M. Levin, A.M. Levin, S.L.R. Kardia.* Epidemiology, University of Michigan School of Public Health, Ann Arbor, MI.

One important application of the current draft sequence is the development of a transcriptome map of the genes in the human genome. Cytogenetic, genetic, and radiation hybrid maps have been developed, and now with the draft sequence, we have the means to generate a physical transcriptome map of human chromosomes. We used the cDNA sequences present on the Affymetrix HuGeneFL Array as a base to develop such a map and apply it to perform chromosome level gene expression analyses. Using the Basic Local Alignment Tool (BLAT) and the Golden Path draft sequence construction (developed by Kent and Haussler, <http://genome.ucsc.edu/>), we were able to place 91.2% (n=6504) of the 7129 cDNAs present on the oligoarray. The largest query sequence alignment was used to determine the starting and ending positions within chromosomes. 83.8% (n=5451) of the 6504 cDNAs aligned within single chromosomes. We employed the Unigene and LocusLink curated databases at the National Center for Biotechnology Information to align the remaining sequences. The position of 16.2% (n=1053) of the remaining cDNAs were resolved using information from these data sources. The chromosome information provided by the BLAT search and Unigene/LocusLink conflicted for 10.3% (n=671) of the 6504 cDNAs placed. The positions given by BLAT were used in these cases. The remaining 8.8% (n=625) of the original 7129 cDNAs had no annotated information with which to infer chromosomal location and therefore remained unpositioned. We are currently developing analytical tools to analyze chromosome level gene expression profiles to identify patterns that differentiate between stage I and stage III lung tumors.

**Tree-based methods for tumor classification with gene expression microarray.** *H.P. Zhang<sup>1</sup>, C.Y. Yu<sup>1</sup>, B.H. Singer<sup>2</sup>, M.M. Xiong<sup>3</sup>.* 1) Dept Epidemiology and Public Health, Yale University School of Medicine, New Haven, CT; 2) Princeton University, Princeton, NJ; 3) University of Texas, Houston, TX.

Precise classification of tumors is both critically important for cancer diagnosis and treatment, and scientifically challenging. Recent studies have shown the improved precision of classification by using gene expression profiles. However, the success has been limited by analytic methodologies. Using a published data set for purposes of comparison, we introduce a methodology based on classification trees and demonstrate that it is significantly more accurate for discriminating among distinct colon cancer tissues than other statistical approaches used heretofore. In addition, competing classification trees are displayed. They suggest that different genes may co-regulate colon cancers.

**Comprehensive Gene Expression Profile of the Matrix Metalloproteinase (MMP) Gene Family in Normal Human Tissue and Major Cancers.** *G.L. Shen*<sup>1</sup>, *J. Cossman*<sup>1, 2</sup>. 1) Pharmacogenomics, Gene Logic, Inc, Gaithersburg, MD; 2) Georgetown University, Washington DC.

The MMPs are a large family of proteinases involved in the degradation of the extracellular matrix proteins. There has been a growing interest in the design and evaluation of MMP inhibitors as anticancer agents because a variety of malignant tumor types had been shown to overexpress MMPs. Gene expression profiles of 350 normal and tumor tissues were generated using the Human U95 Affymetrix GeneChip array platform for simultaneous analysis of 60,000 fragments, with a transcript coverage of 12,000 Full Length Genes and 48,000 Unigene ESTs. Fold-change analysis comparing normal and tumor samples from breast, ovarian, uterine, lung, colorectal, skin and pancreatic tissues were performed. Between 10-30 samples were used for each tissue set. Principal component analysis (PCA) was performed on samples from each tissue type to investigate global differences in expression profiles between tumor and normal samples. The normal and tumor-derived samples could be separated by PCA into 2 distinct populations based upon their respective gene expression patterns. The levels of expression of the various members of the MMP gene family varied significantly across the different tissue sets, ranging from undetectable expression in many of the normal tissue types to different but significant levels of increased expression in the different tumor types. For example, in comparison to normal tissue from the corresponding organ, MMP12 was upregulated, by 2-3 fold (p-value<0.01) in breast and colorectal cancer and by over 10 fold (p-value<0.01) in lung cancer. In silico, electronic-Northern analysis of more than 4000 human tissue samples of over 30 tissue types revealed that MMP2, MMP11 and MMP14 are expressed by >70% of human tissues, whereas MMP3, MMP10 and MMP13 are found to be expressed in <15% in the same tissues. The degree of expression of any MMP over a broad range of human tissue types provides a basis for designing specific MMP inhibitors and predicting their potential risk of toxic events at these anatomic sites.

**Loss of heterozygosity at the EXT and EXT-like loci in osteochondromas and secondary chondrosarcomas of hereditary multiples exostose patients.** *L. Legeai-Mallet, F. Noel, A. Cohen-Tanugi, C. Benoist-Lasselin, A. Munnich, J. Bonaventure.* Genetique INSERM U393, Hopital Necker, Paris, France.

Hereditary Multiple Exostoses (HME) is an autosomal dominant disorder characterized by ectopic growth of osteochondromas (exostoses). The malignant transformation of osteochondromas into chondrosarcomas occurs in 5% of cases. HME is genetically heterogeneous as three loci have been mapped to chromosome 8q24 (EXT1), 11p11-13 (EXT2) and 19p respectively (EXT3). Three additional loci designated EXTL1, EXTL2 and EXTL3 have been also identified and mapped to chromosome 1 (1p36 and 1p11-p12) and 8 respectively (8p12). We searched for loss of heterozygosity (LOH) at the EXT and EXT-like loci in eight hereditary osteochondromas and three secondary chondrosarcomas from 8 HME patients carrying EXT1 (5/8) and EXT2 (1/8) germline mutations. Microsatellite analysis at the EXT and EXT-like loci revealed that 5/8 osteochondromas and 3/3 chondrosarcomas displayed LOH at EXT and/or EXT-like loci. LOH was mostly found at the EXT1 locus (6/11, 54%) but also at the EXTL2 (2/11, 18%), EXT3, EXTL1 and EXTL3 loci (1/11, 9%). Multiple LOH at the EXT1, EXT3, EXTL1, and EXTL3 loci was found in a EXT1 patient harboring two osteochondromas and two chondrosarcomas. Neither LOH nor additional EXT mutation were detected in osteochondromas from two HME patients carrying EXT1 germline mutations. These results indicate that multiple LOH occur during the malignant transformation of osteochondromas and that LOH is not necessarily allelic of the germline EXT mutation. They also suggest that two hits at the EXT or EXT-like loci (one germline mutation in one EXT gene and one somatic event) are required for osteochondromas to undergo malignant degeneration.

**1p/19q deleted oligodendroglioma is a distinct histological tumour.** *C. Godfraind*<sup>1</sup>, *E. Rousseau*<sup>1,2</sup>, *C. Raftopoulos*<sup>3</sup>, *M. Ruchoux*<sup>4</sup>, *F. Scaravilli*<sup>5</sup>, *M. Vikkula*<sup>2</sup>. 1) Division of Neuropathology, Univ. catholique de Louvain, Brussels, BELGIUM; 2) Lab. of Human Molecular Genetics, Christian de Duve Institute & Univ. catholique de Louvain, Brussels, BELGIUM; 3) Division of Neurosurgery, Univ. catholique de Louvain, Brussels, BELGIUM; 4) Department of Neuropathology, Hopital R. Salingro, Lille, France; 5) Institute of Neurology, London, UK.

Oligodendroglioma is a tumour originating from oligodendrocytes, the myelin forming cells in the central nervous system. This glioma preferentially occurs in adults. It is mostly located in cerebral hemispheres with a predilection to the frontal lobe. This lesion accounts for 5-33% of all gliomas. The wide range reported for tumour occurrence reflects inter-observer discordance in histological diagnosis. Genetic analysis of oligodendroglioma has associated 1p/19q-deletions to chemosensitivity. No histological definition for this subgroup has been reported. In order to correlate 1p/19q-deleted oligodendroglioma to a histological phenotype, we underwent a retrospective study of 59 formaline fixed and paraffin embedded gliomas, mostly reported as oligodendroglioma in the Neurological Institute, London and in the Cliniques Universitaires St Luc, Brussels. Chromosomes 1, 9, 10, 17, 19 and 22 were studied by microsatellite analysis in order to define regions of loss of heterozygosity (LOH). A total of 22 1p/19q-deleted gliomas were identified. Twenty of them share common characteristic histological criteria. This allows to diagnose 1p/19q-deleted oligodendroglioma on histological criteria prior to any genetic analysis. Thus, a better identification of glioma subtypes and evaluation of their treatment can be done even in centres without genetic diagnostics. (vikkula@bchm.ucl.ac.be).

**Type 1 Neurofibromatosis 1: retrospective neuroradiologic evaluation of 79 cases.** *M.P. Fondelli<sup>1</sup>, S. Costabel<sup>2</sup>, S. Massa<sup>2</sup>, D. Sambarino<sup>2</sup>, M.L. Garre<sup>4</sup>, L. Andreussi<sup>3</sup>, C. Bellini<sup>2</sup>, E. Bonioli<sup>2</sup>.* 1) Neuroradiology; 2) Oncology; 3) Neurosurgery Departments - G. Gaslini Children Hospital, Genova; 4) Pediatrics Department, University of Genova, Italy.

A series of 79 patients affected by Type 1 Neurofibromatosis has been retrospectively evaluated from a neuroradiologic point of view. The patients have performed a neuroradiologic follow-up from 1988 to 2000. In all patients the diagnosis was performed on NIHCC criteria: in about 50% of them a molecular diagnosis with truncated protein test has been accomplished. All patients underwent a cranial MRI, according to the standard protocol for Type 1 Neurofibromatosis. The aim of this work is to focus on the neuroradiologic features of this disease, particularly the more unusual ones, stressing their clinical implications. The following findings have been observed: a *megalic corpus callosum*, due to the reduction of the glial apoptosis; this feature has also been observed in other inheritable hamartomatous syndromes, due to tumour suppressor genes spontaneous mutation, like the Bannayan Zonana Syndrome; *dural ectasies*, variously associated with osseous scalloping and more frequently located around the brainstem; *non evolutive optic nerve swelling*, at this regard a differential diagnosis must consider the simple optic nerve dural sheath ectasia, the perioptic arachnoidal gliomatosis and the true optic nerve glioma; *UBOs and histogenetic foci*, reflecting a wide spectrum of maturational and structural glial cells anomalies, where both the transient aspect and the variable proliferative potential must be considered; *true tumours* involving the optochiasmatic tract and others encephalic regions; *cystic astrocytoma-like non evolutive foci*; *associated cerebral malformations*, like Chiari 1, cortical dysplasias, megacisterna magna, arachnoidal cysts, etc. In a case on MRI a complicated mixture of type 1 neurofibromatosis and tuberous sclerosis features was observed. The neuroradiologic MRI evaluation confirms a great variability of cerebral manifestations in patients affected by Type 1 Neurofibromatosis, according to the proteiform clinical picture of the disease.

**Molecular characterization of the breakpoints in a balanced t(1;13)(q21;q12) constitutional chromosome translocation in a patient with ganglioneuroblastoma.** *K. Sossey-Alaoui, G. Su, E. Kitamura, J.K. Cowell.* Cancer Genetics, Roswell Park Cancer Institute, Buffalo, NY.

Neuroblastoma (Nb) is a malignancy of the sympathetic nervous system which affects children in their first decade. It is the most common extra-cranial solid tumor in children with an incidence of approximately 1 in 8-10,000 live births annually and accounts for approximately 10% of all children's cancers. Despite even the most aggressive treatment regimens, Nb is still one of the hardest tumors to cure and accounts for 15% of all childhood deaths due to cancer. Ganglioneuroblastoma is a relatively benign form of Nb and consists of a mixture of fibrils, mature and maturing ganglion cells, as well as undifferentiated neuroblasts. During routine cytogenetic analysis of patients with different manifestations of neuroblastoma we have identified one patient with ganglioneuroblastoma that carries an apparently balanced t(1:13)(q21;q12) reciprocal translocation. Positional cloning of the translocation breakpoint on chromosome 13 resulted in the mapping of the breakpoint between coding exon 2 and exon 3 of the WAVE3 gene, a member of WASP gene family. Although the breakpoint region on chromosome 1 was localized to within 2 kb of genomic sequence, no gene was found to be interrupted on this chromosome. No fusion transcript was detected using RACE PCR and northern analyses. SSCP analysis was performed on 24 neuroblastoma tumors from different stages. Several nucleotide changes were detected in different tumors, most of which were either silent mutations or were found in the intronic sequence flanking the splice site junctions, and therefore were considered as polymorphisms rather than the disease causing mutations. The WAVE3 transcript is mainly expressed in the nervous system and, like all the members of the WASP gene family, WAVE3 is a key element in the actin polymerization and the cytoskelton organization, and therefore is important for cell differenciation and motility. We suggest that, because of its expression pattern and its function, WAVE3 is a candidate gene for tumor suppression activity, at least in some forms of neuroblastoma.

**PAX6 Functions in Suppression of Glioblastoms.** *Y.H. Zhou<sup>1</sup>, Y.X. Shi<sup>1</sup>, T. Glass<sup>1</sup>, J.B. Zheng<sup>2</sup>, G.F. Saunders<sup>2</sup>, W.K.A. Yung<sup>1</sup>.* 1) Dept Neuro-Oncology, MD Anderson Cancer Ctr, Houston, TX; 2) Dept Biochemistry and Molecular Biology, MD Anderson Cancer Ctr, Houston, TX.

Glioblastomas (GBMs) are the most common and malignant primary brain tumors. Approximately 6.0 cases per 100,000 person-year occur as GBMs, and an estimated 13,000 deaths in 2000 were attributed to such diseases. Pax6 gene encodes a transcription factor important for regulation of cell proliferation, migration and differentiation in the development of the eye and central nervous system, including the differentiation of radial glia in the cerebral cortex and the migration of glial precursors in the ventral neural tube of spinal cords. We found that in human glioma cell lines, PAX6 expressed at a lower level in high tumorigenic and at a higher level in low tumorigenic and nontumorigenic glioma cells. This encouraged us to investigate the possibility that PAX6 be involved in suppression of glioma progression. We examined the expression of the gene by real-time reverse transcription quantitative-PCR in a series of gliomas, including 42 GBMs and 34 anaplastic astrocytomas (AAs), and 6 normal brain tissues. The cDNA copy numbers of four house keeping genes (GAPDH, enolase-alpha, beta-actin and RPS9) were measured for each tumor cDNA samples. The relative expression levels of PAX6 were normalized by these four genes in combination after being weighted to a similar level. Significant difference ( $P < 0.001$ ) was observed between the expression of PAX6 in GBMs versus AAs. Furthermore, over expression of PAX6 in the high-tumorigenic human glioma cell U251HF through stable transfection of a PAX6-expression construct (PAX6/pRC-CMV) supports this hypothesis through demonstrating that PAX6 suppressed anchorage-independent growth, cell invasion by in vitro invasion assay, and the tumor growth in nude mice by subcutaneous tumor implantation. In conclusion, our data showed that the expression level of PAX6 could be used as a diagnostic marker for glioma progression. Studies to uncover the gene regulatory networks associated with the suppression function of PAX6 in glioma will provide clues in the cure of this most common and progressive brain cancer.

To be presented by Peter Nuernberg instead of K. Uhlmann.

Program Nr: 351

**Glioma subtypes show characteristic patterns of DNA hypomethylation and hypermethylation.** *K. Uhlmann<sup>1,2</sup>, K. Rohde<sup>2</sup>, C. Zeller<sup>1,2</sup>, J. Szymas<sup>3</sup>, S. Vogel<sup>4</sup>, K. Marczynek<sup>1</sup>, G. Thiel<sup>1</sup>, P. Nürnberg<sup>1,2</sup>, P.W. Laird<sup>5</sup>*. 1) Institute of Medical Genetics, Charité, Berlin, Germany; 2) Gene Mapping Center, MDC, Berlin-Buch, Germany; 3) Katedra Patomorfologii Klinicznej, Poznan, Poland; 4) Neurochirurgie, Sankt Gertrauden Krankenhaus, Berlin, Germany; 5) Department of Biochemistry and Molecular Biology, University of Southern California, Keck School of Medicine, Norris Comprehensive Cancer Center, Los Angeles, USA.

Gliomas are CNS tumors with a wide spectrum of different tumor types. They range from pilocytic astrocytomas, with a generally good prognosis, to the extremely aggressive malignant glioblastomas multiforme. In addition to these two types of contrasting neoplasms, several other subtypes can be distinguished, each characterized by typical phenotypic, as well as genotypic features. Recently, the epigenotype, as evident from differentially methylated DNA loci, has been proposed to be useful as a further criterion to distinguish between tumor types. In this study, we screened 139 tissue samples, including 33 pilocytic astrocytomas, 53 astrocytomas of different grades, 7 oligoastrocytomas, 10 oligodendrogliomas, 3 glioblastomas multiforme, and 33 control tissues for methylation at 15 different loci to generate epigenomic fingerprints. We used the semi-quantitative high-throughput method MethyLight to analyze a gene panel comprising *ARF*, *CDKN2B*, *RB1*, *APC*, *CDH1*, *ESR1*, *GSTP1*, *TGFBR2*, *THBS1*, *TIMP3*, *PTGS2*, *CTNNB1*, *CALCA*, *MYOD1*, and *HIC1*. Eight of these loci showed tumor-specific methylation changes. Within distinct subtypes, we found tissue- as well as grade-specific methylation patterns. Interestingly, pilocytic astrocytomas showed no evidence of CpG island hypermethylation, but rather were hypomethylated, relative to control tissues, at *EGFR*, *MYC*, *MYOD1*, and *TIMP3*. Our results show that (i) glioma subtypes have characteristic methylation patterns, (ii) grade and tissue of origin reveal distinct methylation patterns, (iii) hyper- as well as hypomethylation takes place in gliomas, and (iv) pilocytic astrocytomas are hypomethylated at several gene loci in comparison to control tissues.

**Glioma gene expression profiling and hierarchical clustering.** *R. Shai*<sup>1</sup>, *B. Merriman*<sup>1</sup>, *T. Kremen*<sup>2</sup>, *L. Liau*<sup>2</sup>, *P. Mischel*<sup>3</sup>, *T. Cloughesy*<sup>4</sup>, *S. Nelson*<sup>1</sup>. 1) Human Genetics, UCLA, Los Angeles, CA; 2) Neurosurgery, UCLA, Los Angeles, CA; 3) Pathology, UCLA, Los Angeles, CA; 4) Neurology, UCLA, Los Angeles, CA.

Gliomas are the most common form of brain tumors and are classified into several groups according to their malignancy and cell lineage. Accurate diagnosis of glioma type is fundamental for proper patient management. Currently the classification of the tumors is based on histopathology. While generally accurate and reproducible, the interpretation can be subjective with gray borders between groups. Further, little data exists to make individual specific prognosis. We used gene expression profiling and hierarchical clustering in order to classify tumors. First we tested the reproducibility of the gene expression based classification. Four samples of glioblastoma (GBM), two oligodendrogliomas and one normal brain sample were micro-dissected in several distinct areas of the tissue. Gene expression profiles of each region were generated using the Affymetrix 6800 gene chip. Clustering by similarity of expression profile revealed that multiple samples of the same tumor cluster similarly, indicating that there is not excessive heterogeneity in the expression profile throughout the tumors. Interestingly, cell lines derived from those tumors did not cluster with the parental tissues but clustered tightly together into a distinct group. Further gene expression analysis was performed on 21 *de novo* GBMs, 5 progressive GBMs, 3 oligodendrogliomas, 2 astrocytomas, and 2 low grade mixed gliomas with the U95A Affymetrix gene chip. The unstructured clustering of tissues generated a pattern, which predominantly grouped the tumors by histopathology. Genes that distinguished the GBMs from the normal tissue were selected to generate a list of 212 up regulated and 229 down regulated genes that had more than 5-fold change. Among these genes, several well-established tumor related genes can be found, for example *midkine* and *EGFR*. The identified differentially expressed genes also included ESTs and other genes whose involvement in tumorigenesis has to be assessed. Additional samples need to be analyzed for molecular prediction of prognosis, survival time and efficacy of treatments.

**Sporadic Colorectal Cancer Association with LOH-RER from Genetic Markers Application on Tumor Tissue --**

**- Bioinformatics Analysis.** *K.-H. Chen*<sup>1, 2, 3</sup>, *M.-H. Tsai*<sup>4</sup>, *Y.-C. Yang*<sup>5, 6</sup>. 1) Department of Laboratory Medicine, School of Medicine, National Taiwan University, Taipei, Taiwan; 2) Biostatistics Division, Institute of Epidemiology, School of Public Health, National Taiwan University, Taipei, Taiwan; 3) Department of Mathematics, School of Natural Sciences, National Taiwan University, Taipei, Taiwan; 4) Division of Colon and Rectal Surgery, Cardinal Tien Hospital, Taipei, Taiwan; 5) School of Medical Technology, College of Medicine, National Taiwan University, Taipei, Taiwan; 6) Department of Laboratory Medicine, National Taiwan University Hospital, Taipei, Taiwan.

Primary bioinformatics findings for AWD (alive with disease) verse DOD (dead of disease) associated with LOH and RER for 10 genetic markers on colorectal cancer tissues conclude that LOH of both APC and PT53\_5 is risk only when suitable promoted factors (PFs) have to co-exist, under a certain limiting environment (LE) in terms of LOH or RER, and possibly clinical/ pathology factors. LE of excluding only the binary outcome of metastasis to liver or not (MLON) allowed the clinical associations - the appearance of risk factors of LOH for both APC and PT53\_5 when the clinical information of tumor sites supplied; risk effect for LOH of APC when the stage of Dukes C or not supplied; and differentiation or not is protective. LE of additionally excluding LOH interaction (3-LOH) of PT53\_5, D8S254 and DCC, promoted gene (PG) of LOH-PT53\_5 promoted the risk effect of LOH-APC and the LOH interaction (PT53-LOH) of PT53\_2 and PT53\_5. Under LE of excluding MLON, 3-LOH and PT53-LOH in order, LOH of APC and PT53\_2 formed the risk factors when PG was only one of LOH-NM23, LOH-DCC, LOH-PT53\_2 itself, LOH-APC itself or RER-MSH2. Under LE of excluding MLON, 3-LOH, LOH-MSH2 and PT53-LOH in order, PG of interaction of LOH-PT53\_5 and RER-PT53\_2 promoted risk of LOH for APC and PT53\_2. The newly identified XLR (exact logistic regression) exclusively for binary information, under the multinomial distribution likelihood estimation, identified PGs and LEs and made the findings to be possible. The statistics nested by the LEs qualified from PGs have to be ascertained by Fisher's exact procedure.

**Identification of four homozygous deletions in human lung carcinomas in the 21q11.1-q21.1 region.** *C.J. Cox, G.R. Bignell, H.R. Molloy, P.J. Stephens, P.A. Futreal, R. Wooster, M.R. Stratton.* Cancer Genome Project, Sanger Centre, Cambridge, Cambridgeshire, UK.

Detection of frequent loss of heterozygosity (LOH) and homozygous deletions in human cancers are often good indicators of the presence of potential tumour suppressor genes. It has been reported previously that non-small cell lung carcinomas (NSCLC) show a high incidence of LOH on chromosome 21, relative to small cell lung carcinomas (SCLC) and other cancers. Here we report genotyping analysis of 616 cell lines (including 51 NSCLC, and 46 SCLC) with 5 polymorphic micro-satellite markers (density of 5.8Mb) specific for Chromosome 21. LOH was assigned to cell lines where 3 contiguous markers were found to be homozygous. LOH was found in 49% of NSCLC compared to 23% SCLC and 20% in all other cell lines. Eighty-eight cell lines showing LOH (including 21 NSCLC and 8 SCLC) were further screened with a set of 68 Chromosome 21 specific STSs (density of 0.48Mb), utilizing a high throughput form of Taqman analysis we have developed specific for CA repeats. This revealed the presence of homozygous deletions in 3 NSCLC and 1 SCLC between D21S1911 and D21S1905, overlapping a previously identified homozygous deletion found in a NSCLC.

A more detailed map of the deletions in this area was achieved using a further 68 STSs (density of 0.124Mb). This revealed that the deletions were made up of two smaller non-overlapping deletions (approximately 2.8 and 0.7Mb in size) encompassed by two larger overlapping deletions (approximately 6.2 and 6.5Mb in size). Primers for all coding exons of the 8 known genes in the region encompassed by the larger deletions have been designed and are currently being used to evaluate 92 cell lines with LOH on chromosome 21 for point mutations to identify the putative tumour suppressor gene(s).

**Genome wide analysis of 400 microsatellite repeats through 665 cancer cell lines.** *G.R. Bignell, C.J. Cox, H.R. Molloy, P.J. Stephens, P.A. Futreal, R. Wooster, M.R. Stratton.* Cancer Genome Project, The Sanger Centre, Hinxton Cambridge, UK.

Loss of heterozygosity is a key approach in identifying the genomic localisation of putative tumour suppressor genes. To identify new tumour suppressor genes, we have undertaken a genome wide analysis of a large number of cancer cell lines using a 400-marker map with an average spacing of 10cM. This analysis has been carried out on 665 cancer cell lines obtained from public repositories and private contributions, requiring a total of 266,000 genotypes, this represents the largest such screen carried out to date. We have a further 750 cell lines awaiting analysis. The current set included 125 lung, 65 breast, 42 colorectal, 36 leukaemia/lymphoma, 30 bladder, 31 melanoma and 26 ovarian cell lines. Because no parental DNA is available LOH has been provisionally assigned if five contiguous markers are shown to be homozygous. Data from this screen is being used to target chromosomal regions for large-scale mutation detection and for targeted homozygous deletion searches. In addition this dataset lends itself to a wide range of analysis, for instance comparison of percentage LOH for each chromosome arm through the complete set of cell lines or for specific tissue types, as well as being able to assess concomitant losses of particular chromosomal regions in particular tumour types. When comparing the levels of LOH for chromosomes 21 (14%) and 22 (22%) it can be seen that chromosome 22 has a higher rate of LOH even though these chromosomes are of similar size (Chr21 44.9Mb, Chr22 47.6Mb). This lends weight to the argument for a tumour suppressor gene located on chromosome 22. Patterns of loss for primary tumours in the literature can be confirmed against this dataset, for instance patterns of LOH in lung cancer for chromosomes 4q (average LOH from literature 42%, LOH from our data 51%) indicates the location of a putative tumour suppressor gene. Studies of this scale will help provide the basis for genome wide studies of cancer.

**Overexpression of cyclins B observed in human tumors alters chromosomal segregation.** *J.M. Flaman<sup>1</sup>, N. Sarafan-Vasseur<sup>1</sup>, J. Bourguignon<sup>1</sup>, F. Le Pessot<sup>2</sup>, A. Lamy<sup>1</sup>, R. Sesboué<sup>1</sup>, C. Bastard<sup>1</sup>, P. Hieter<sup>3</sup>, T. Frébourg<sup>1</sup>.* 1) INSERM EMI 9906, IFRMP, Faculté de Médecine, Rouen, France; 2) Anatomie et Cytologie Pathologiques, CHU de Rouen; 3) CMMT, Vancouver, Canada.

The molecular basis of chromosomal instability (CIN), which is observed in most of the malignant tumors, remains to be characterized. To identify genes which overexpression results in CIN, we developed a biological approach based on the use of a yeast indicator strain for CIN. In this strain, the *ade2-* mutation, resulting into the accumulation of a red pigment, has been suppressed by an ochre suppressing tRNA, carried by a non essential artificial chromosomal fragment, and this strain is therefore spontaneously white. Induction of CIN in this strain will result into the loss, during the mitosis, of the chromosomal fragment and therefore into the appearance of red sectors within the white colonies. Screening into this CIN indicator strain of a yeast genomic library led us to identify, among the clones generating 100% of sectoring colonies, *Clb5*, one of six B-type cyclins identified in yeast. Overexpression of cyclin B2 and cyclin B1, the two human homologs of *Clb5*, into the CIN indicator strain resulted also into a sectoring phenotype and induced, like overexpression of *Clb5*, an abnormal sensitivity to benomyl, indicating that overexpression of B type cyclins alters the spindle checkpoint. Using multiplex real-time quantitative RT-PCR, we analyzed cyclins B1 and B2 mRNA expression in a serie of 58 primary colorectal cancers. In 10% of the tumors, we observed a 10 fold increase of cyclin B2 mRNA, in comparison to normal colorectal mucosa. Although we detected no overexpression of cyclin B1 mRNA, immunohistochemical staining revealed a high level of cyclin B1 expression in 12 % of the tumors. These results show that overexpression of cyclins B is observed in human cancers and could contribute, through an alteration of the spindle checkpoint, to chromosomal instability.

**Paternal uniparental disomy 11p15, hemihyperplasia and hepatoblastoma.** *L. Celle<sup>1</sup>, K.L. Russell<sup>1</sup>, D.J. Zand<sup>1</sup>, A.T. Meadows<sup>2</sup>, J. Pressey<sup>2</sup>, D. von Allmen<sup>3</sup>, R. Weksberg<sup>4</sup>, E.H. Zackai<sup>1</sup>.* 1) Division of Human Genetics and Molecular Biology; 2) Division of Oncology; 3) Department of Pediatric General and Thoracic Surgery, The Children's Hospital of Philadelphia, Philadelphia, PA; 4) Department of Genetics, Hospital for Sick Children, Toronto, Canada.

Hepatoblastoma is a rare embryonal tumor occurring most frequently before the age of 3 years. Patients with Beckwith-Wiedemann syndrome (BWS), isolated hemihyperplasia and the combination of both have an increased risk of neoplasia with Wilms' tumor being the most common, followed by adrenocortical carcinoma and hepatoblastoma. Patients with BWS and some with isolated hemihyperplasia have been shown to have deregulation of normal imprinted expression on chromosome 11p15. Here we present a child with hemihyperplasia with paternal UPD 11p15 who, after tumor surveillance, was found to have an elevated AFP and subsequent diagnosis of hepatoblastoma. A 4.5-month old boy was referred to Genetics for hemihyperplasia. He was a 9lb 1oz product of a FT pregnancy without neonatal hypoglycemia. On physical exam, there was marked hemihyperplasia of the right arm and leg, with a 1cm difference in the length of the humeri and tibiae. There was also an enlargement of the right side of the tongue. There was no umbilical defect and no abnormal ear creases. Molecular genetic studies showed paternal UPD of chromosome 11p15. He was followed with abdominal ultrasounds and alpha-feto protein (AFP) levels. At 5months, the AFP level was noted to be 325.8ng/ml (normal 0.6-28.3), fell during the next several months, and rose again at 10months. Although the ultrasound at that time was normal, a CT scan and MRI with gadolinium enhancement revealed a 2 x 1.7cm lesion in the right lobe of the liver. Following complete excision, pathology revealed hepatoblastoma, mixed histology. This report emphasizes that children with hemihyperplasia should undergo molecular testing. They should also have careful tumor surveillance, especially those with paternal UPD 11p15.

**Chromosomal amplifications and deletions determined by comparative genomic hybridization in follicular thyroid adenomas and carcinomas - similar patterns of chromosomal aberrations in a subset of thyroid**

**carcinomas.** *D.J. Marsh<sup>1</sup>, G. Theodosopoulos<sup>1</sup>, L. Delbridge<sup>2</sup>, B.G. Robinson<sup>1,3</sup>.* 1) Kolling Institute of Medical Research and University of Sydney, NSW, Australia; 2) Department of Surgery, Royal North Shore Hospital, NSW, Australia; 3) Department of Medicine, University of Sydney, NSW, Australia.

Carcinoma of the thyroid is the most frequently diagnosed endocrine malignancy. Malignant lesions of the follicular cells are comprised of the differentiated tumors follicular thyroid carcinoma (FTC) and papillary thyroid carcinoma, whilst anaplastic thyroid carcinoma is an undifferentiated malignancy. Follicular thyroid adenomas (FTAs) are benign tumors. We used comparative genomic hybridization (CGH) to elucidate regions of chromosomal gains and losses in both FTAs and FTCs. Seventy-six % (13 of 17) of FTCs showed CGH changes, however only 24 % (5 of 21) of FTAs showed changes. The number of CGH changes varied markedly, with FTAs showing between 1 - 8 (mean = 3.6) CGH changes, and FTCs showing 3 - 23 (mean = 11.5). Of the changes observed in FTAs, none were observed more than once. However, certain "hot-spots" were evident in the FTCs including gain of chromosomes 7, 5 and 12, as well as loss of chromosomes 1, 8 and 11. A number of chromosomal alterations were found in both FTAs and FTCs, including loss of 3p, 4, 8, 9p and X, as well as gains of 4q, 5p, 7, 8, 9, 12 and 17. Gain of 1p and loss of 5q were unique to FTAs. Of considerable interest, 6 of the FTCs had between 14 - 23 (mean = 20) CGH changes, and these changes appeared to be largely consistent between the tumors, including loss of chromosome 1, 2, 3, 6, 8, 11 and X, as well as gains of chromosomes 5, 7, 12, 19 and 22. This data is suggestive that activation of a mutator phenotype occurs at some point in a progression pathway during thyroid tumorigenesis and in at least a subset of tumors, leads to a non-random pattern of chromosomal gains and losses. Alternative patterns of chromosomal gains and losses may not be conducive to survival of the malignant cell. It is possible that such a mutator phenotype involves the alteration of a gene(s) functioning to regulate mitosis.

**Over-Expression of the TSPY Gene on the Y Chromosome Potentiates Cell Proliferation in vitro and in vivo. X.X. Liu, Y.F.C. Lau.** Department of Medicine, University of California, San Francisco, CA.

The testis-specific protein Y-encoded (TSPY) gene is a repeated gene on the human Y chromosome. It encodes a protein homologous to a family of cyclin B binding proteins and is postulated to serve a normal function in directing the spermatogonial cells to enter meiosis in the testis. Based on its chromosomal location, it has been considered to be a candidate for the gonadoblastoma (GBY) locus on the Y chromosome. Expression studies indeed demonstrated a high level expression of this GBY candidate gene in gonadoblastoma and testicular seminoma. We hypothesized that aberrant expression of TSPY in cells incapable of entering male meiosis is responsible for its oncogenic activities. To test this hypothesis, we used the tetracycline (Tet-off) regulation system to manipulate the expression of transfected TSPY gene in HeLa or NIH3T3 cells. Cells over-expressing TSPY exhibited a 30-45% higher proliferative activities than those under repressed conditions or transfected with the vector alone. This increase in proliferative activities paralleled with an elevated rate of colony formation in transfected cell population cultured in normal media than that cultured in media containing doxycycline. Subcutaneous inoculation of stably transfected HeLa cells in immunodeficient nude mice showed a faster rate of tumor formation in hosts fed with normal drinking water than that in hosts fed with doxycycline-containing water. Significantly, NIH3T3 cells over-expressing the stably transfected TSPY gene formed tumors in nude mice fed with normal drinking water. However, the same transformant cells inoculated in hosts fed with doxycycline-containing water did not produce any tumor. Results from this study support the hypothesis that over-expression of the Y-located TSPY gene potentiates cell proliferation in vitro and in vivo, thereby signifying TSPY as a putative proto-oncogene on the human Y chromosome.

**Loss of heterozygosity of the CUTL1 gene in uterine leiomyomata.** *S.M. Zeng, B.J. Van Voorhis, J. Yankowitz.* Dept of OB/GYN, Univ Iowa Hosps & Clinics, Iowa City, IA.

Uterine leiomyomata or fibroids are common benign smooth muscle tumors. These tumors are the single largest cause of hysterectomy in the United States, accounting for approximately one in three hysterectomies or 200,000 procedures a year in the United States. The underlying cause of fibroids is still obscure. Recent molecular genetic and cytogenetic evidence indicates several gross and microscopic genetic alterations involving five main subgroups; del(7q), 6p rearrangements, del(13q), t(12,14), and trisomy 12. The gross and microscopic deletions at 7q may involve the human Cut-like homeobox gene, CUTL1, located at 7q22. We investigated loss of heterozygosity (LOH) of this gene in patients with uterine leiomyoma.

Samples of uterine fibroids and grossly normal myometrium were obtained from women having myomectomies or hysterectomies. Tissues were digested and DNA extracted by standard techniques. DNA samples were amplified using different sets of primers specific for three microsatellite markers inside CUTL1, D7S515, D7S518 and D7S666. PCR products were run on a 6% denaturing polyacrylamide gel. LOH was evaluated by comparing allele bands between tumor and normal uterine tissue from the same patient.

Twenty patients with both fibroid tissue and normal surrounding tissue were evaluated. A CUTL1 deletion was found in three fibroid samples (15%). In one of these patients LOH was also present in one of two "normal" surrounding tissue samples. In one patient with LOH in one large fibroid another small fibroid did not show LOH for the CUTL1 markers.

Our results agree with previous findings from cytogenetic and molecular genetic studies supporting the hypothesis that CUTL1 gene may be a tumor suppressor and whose deletion or loss may play a role in the pathogenesis of uterine leiomyoma. Additional studies are needed to elucidate the relationship between DNA alterations, potential other factors, and fibroid development.

**Identification of a minimal overlapping amplified region at 19q13.1-q13.2 in four ovarian cancer cell lines.** *T.C.M. Tang, J.S.T. Sham, X.Y. Guan.* Department of Clinical Oncology, The University of Hong Kong, Hong Kong, People's Republic of China.

High-level amplification of DNA sequence at 19q13.1-q13.2 in ovarian cancer has been frequently detected by using chromosome microdissection and comparative genomic hybridization (CGH). This strongly suggests that 19q13.1-q13.2 contains a putative oncogene(s) which plays an important role in the development or progression of ovarian cancer. In order to narrow down the amplified region at 19q13.1-q13.2 (about 39cM), four ovarian cancer cell lines which have been confirmed containing amplicon at 19q13.1-q13.2 were studied for identifying a minimal overlapping amplified region (MAR). Fluorescence in situ hybridization (FISH) with cosmid clones and Southern blot analysis with cDNA probes in average genomic distance at 1 cM (from D19S425 to D19S418) were performed. At least two MARs have been identified at 19q13.12 (about 200 kb) and 19q13.13 (about 1.2 Mb), respectively. Amplification and overexpression of several candidate oncogenes within the two amplicons have been studied by Southern and Northern blot analysis in four ovarian cancer cell lines. Further study of genes within these two amplicons may lead to the isolation of the oncogene(s) which is the biological target of amplification events in ovarian cancer.

***HER2/neu* and *c-MYC* oncogene alterations in breast lesions from women with *BRCA1/2* gene mutations.** C.L. Soderberg, K.A. Anderl, C. Adem, C. Reynolds, J.M. Slezak, L.C. Hartmann, R.B. Jenkins. Mayo Clinic, Rochester, MN.

**Introduction:** Oncogene amplification is frequently observed in breast carcinogenesis. *HER2/neu* and *c-myc* are overexpressed/amplified in 25-30% and 5-50% of sporadic breast malignancies, respectively. Breast cancers arising in patients with *BRCA1* and *BRCA2* germline mutations have specific clinicopathologic features. Previous authors have reported lower levels of overexpression of *HER2/neu* protein among *BRCA1* mutation carriers. Thus, progression pathways might differ in hereditary versus sporadic cases. As part of our investigation of the pathogenesis of *BRCA1/2* related cancers, we are evaluating multiple genetic alterations in neoplastic and preneoplastic lesions from women with and without a family history of breast cancer. **Materials and Methods:** Patients with a family history of breast cancer and germline *BRCA1/2* mutations who underwent therapeutic and prophylactic mastectomy (TM, PM) were selected as cases. Patients without a family history of breast cancer and without *BRCA1/2* mutations who underwent TM and PM, matched by age and surgery date, were selected as controls. All available paraffin blocks with neoplastic and precursor lesions were evaluated by fluorescent in situ hybridization (FISH) using *HER2/neu/CEN17* and *cMYC/CEN8* dual-probe mixtures. **Results:** Currently, we have studied precursor and neoplastic lesions in 16 hereditary cases (out of 29) and 19 sporadic cases (out of 40). *BRCA1/2* related cancers had a higher incidence of amplifications/gains compared to matched controls in the in situ (50% vs 36% for *HER2/neu*, and 83% vs 45% for *cMYC*), and invasive components (57% vs 37.5% for *HER2/neu*, and 72% vs 44% for *cMYC*). All but one precursor lesion had no apparent anomalies. **Conclusion:** Our data suggest that chromosomal alterations, as measured by CEN8 and CEN17 gain and *HER2/neu* and *cMYC* gene amplification, are more frequent within breast cancers of women with a strong family history of cancer, consistent with an increased underlying chromosomal instability. Ongoing studies are directed toward the elucidation of the pathways of carcinogenesis in hereditary versus sporadic disease.

**A common founder for the V126D CDKN2A mutation in seven North American melanoma-prone families.** *A.M. Goldstein<sup>1</sup>, L. Liu<sup>2</sup>, M.G. Shennan<sup>3</sup>, D. Hogg<sup>2,4</sup>, M.A. Tucker<sup>1</sup>, J.P. Struewing<sup>1</sup>.* 1) Division of Cancer Epidemiology and Genetics, National Cancer Inst, Bethesda, MD; 2) Department of Medicine, University of Toronto, Toronto, ON; 3) Division of Medical Oncology, Toronto-Sunnybrook Regional Cancer Centre, Toronto, ON; 4) Department of Medical Biophysics, University of Toronto, Toronto, ON.

Germ-line mutations in the major known melanoma (MM) susceptibility gene CDKN2A have been observed in approximately 20 percent of melanoma-prone families. One of the most common melanoma-related CDKN2A mutations reported in North America is the V126D mutation. We examined nine markers (IFNA-D9S736-D9S1749-[CDKN2A]-D9S974- D9S942- D9S1748-D9S1604-D9S171-D9S126) surrounding CDKN2A in three American and four Canadian families carrying the V126D mutation to determine whether the mutation resulted from a single origin and to date the origination of the mutation. The Canadian families had an average of 3 MM patients per family; two families had patients with multiple primary MM. The American families had an average of 7 MM patients per family; all had patients with multiple primary MM. Six of the seven families had German/English ancestries. All seven families had a haplotype consistent with a common ancestor/founder for the V126D mutation. Using maximum likelihood methods, we estimated the mutation to have originated 34-52 generations ago (1-LOD-unit support interval 13-98 generations). Most recurrent CDKN2A mutations observed in North America can be traced back to a European country or region of origin. In contrast, the V126D mutation does not appear at high frequency in any other countries besides the United States and Canada. This phenomenon may reflect selective mutation testing or it may be related to the origination of the V126D mutation. Although six of the seven studied families immigrated to North America from Germany and England, the ancestral pathway for melanoma in these families cannot be determined. Additional families from North America and other geographic areas may help determine the geographic origin for this recurrent yet puzzling CDKN2A mutation.

**Identification of novel regions of allelic imbalance (AI) in young onset colorectal cancer (CRC) with normal mismatch repair (MMR).** *L.A. Boardman<sup>1</sup>, S.J. Schmidt,<sup>2</sup> G.M. Petersen<sup>3</sup>, N.M. Lindor<sup>4</sup>, H. Nelson<sup>6</sup>, R.M.*

*Goldberg<sup>5</sup>, A.J. French<sup>2</sup>, L.J. Burgart<sup>2</sup>, M. de Andrade<sup>3</sup>, S.N. Thibodeau<sup>2</sup>.* 1) Div Gastroenterology, Int Med, Mayo Clinic, Rochester, MN; 2) Dept of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN; 3) Sec Clinical Epidemiology, Dept of Health Sciences Research, Mayo Clinic, Rochester, MN; 4) Dept Medical Genetics, Mayo Clinic, Rochester, MN; 5) Dept Medical Oncology, Mayo Clinic, Rochester, MN; 6) Div Colorectal Surgery, Dept of Surgery, Mayo Clinic, Rochester, MN.

Between 7000 and 20,000 individuals under age 50 will develop CRC in the U.S. in 2001. Up to one third of these cases can be explained by known genetic syndromes, but the cause of the majority of young onset CRC remains unknown. Discovery of genes responsible for CRC using AI have focused on older onset CRC. We hypothesize that AI can inform gene discovery in young onset CRC. We identified a sample of 47 cases of non-FAP young onset CRC with normal DNA mismatch repair (MMR), by immunohistochemistry for hMLH1 and hMSH2 and microsatellite instability. We used two comparison groups: 100 older onset non FAP, MMR CRC tumors tested for AI and previously published reports of AI in sporadic CRC. Genome wide AI was assessed at 25 to 50 cM intervals with 65 markers. AI was assessed as positive if the ratio difference between normal and tumor allele intensity was  $> 2$ . AI was detected in  $> 20\%$  of the young onset tumors on five chromosomal arms: 5q; 15q, 17p 18q and 20p. Although AI at 8p has been reported in 50%; of CRCs tested, in our study, 8p AI occurred in  $< 20\%$  of young onset CRC. Both young and older onset CRC demonstrated similar levels of AI on chromosomal arms 5q, 17p, and 18q, corresponding to loci for the tumor suppressor genes, APC, p53 and DCC (SMAD4), respectively. AI on chromosomal arms 15q and 20p, rarely detected in the older onset group, was present in over 20% of young onset CRC with normal MMR. These results suggest that the genetic events that contribute to the development of young onset CRC may differ from those in older onset CRC. Further finer mapping with higher density AI may uncover other genetic loci leading to young onset CRC with normal MMR.

**A novel homozygous mutation in the human *MSH2* gene predisposes to leukemia and multiple cafe-au-lait spots.**

*S.E. Andrew*<sup>1</sup>, *D. Whiteside*<sup>1</sup>, *J. Steckley*<sup>1</sup>, *K. Booth*<sup>2</sup>, *G.E. Graham*<sup>2</sup>, *D.R. McLeod*<sup>2</sup>. 1) Dept Medical Genetics, Univ Alberta, Edmonton, AB., Canada; 2) Alberta Children's Hospital and University of Calgary, Calgary, AB., Canada.

Individuals with a germline mutation in one of the DNA mismatch repair (MMR) genes are at significant risk for colorectal cancer and are also susceptible to developing tumours of the endometrium, colon, urinary tract and other tumours of the gastrointestinal system. Two families have previously been reported with individuals homozygous for mutations in the MMR gene *MLH1* that are predicted to compromise MMR. These individuals develop haematological malignancies and neurofibromatosis type 1 (NF1) at an early age. Here we demonstrate a patient where a homozygous novel mutation in another MMR gene, *MSH2*, is associated with leukemia and multiple cafe-au-lait spots, a feature of NF1. The mutation occurs within an invariant splice site consensus sequence and is predicted to result in a truncated non-functional protein. Therefore, it is the general lack of mismatch repair from conception that appears to underlie the haematological malignancies and occurrence of sporadic NF1 in these families. The haematological malignancies observed in the individuals homozygous for the loss of MMR are reflective of the T and B cell lymphomas seen in homozygous mice lacking MMR and suggest that the MMR 'knock-out' mice may provide a useful model for human neoplasia. The effect of the lack of MMR on genetic instability, particularly the NF1 gene in this patient, will be discussed.

**A regular screening regimen decreases mortality in von-Hippel Lindau families.** *J.S. Green, C. Moores, S. Murphy, G. Wong, P. Parfrey.* Depts of Medical Genetics and Medicine, Memorial Univ of Newfoundland, St John's, NF., Canada.

Von-Hippel Lindau (VHL) Syndrome is an autosomal dominant condition with almost complete penetrance. Affected individuals have increased risk of vascular tumours including retinal angioma (RA), cerebellar (CH) and spinal cord (SPH) hemangioblastoma, pheochromocytoma (PH), and renal cell carcinoma (RCC), as well as cysts and adenomas of the pancreas, kidney, and other abdominal organs. There is an early age at onset (often in childhood) and affected individuals often have multiple different manifestations. The first Newfoundland (NF) VHL family was ascertained in 1982, at which point a screening protocol was designed and initiated for NF VHL families (beginning at 5 years of age). A total of 5 NF VHL families (each with a different VHL mutation) have since been identified, with a total of 131 (64 M, 67 F) affected and 50%-risk individuals. Records of screening investigations and treatment were reviewed for all family members. Within the largest family (N=49 affected) the most common tumour observed was PH (71%), followed by RA (61%), CH (51%), and RCC (31%). Genetic testing was offered to all at 50% risk and there was a high uptake of testing. The total cohort (N=131) included 64 mutation positive (59 clinically affected), 50 mutation negative, and 17 individuals of unknown mutation status. Kaplan-Meier life table analysis was used to calculate cumulative age to death in screened and unscreened groups. A mean survival time of 43.6 years (95%CI:39.3-47.8), with 62% mortality by age 50 was found for affected individuals not followed in a screening program, with the most common causes of death being PH and CH. Mortality was decreased in the 40 individuals who entered the screening program, showing a mean survival time of 56.6 years (95%CI:51.9-61.3) and 21% mortality by age 50. Only one death occurred in the 35 individuals who entered screening before age 30. Mean survival time for the mutation negative group was 76.5 years (95%CI:70.0-84.1), with 11% mortality by age 50. Screening of at-risk individuals can identify tumours at an early stage when many can be successfully treated, reducing mortality in VHL families.

**Different combinations of biallelic APC mutations confer different growth advantages in colorectal tumours.** *J.P. Cheadle, M. Krawczak, M.W. Thomas, A.K. Hodges, N. Al-Tassan, N. Fleming, J.R. Sampson.* Institute of Medical Genetics, University of Wales College of Medicine, Cardiff, UK.

Biallelic mutations of the APC gene are very early events in the development of sporadic and familial adenomatous polyposis (FAP)-associated colorectal tumours in humans. Recently, several new facets to Knudson's '2-hit' hypothesis have been proposed in relation to APC: protein inactivation may be selected weakly, if at all, and the 'two hits' may be interdependent. We carried out a review of all published data on colorectal adenomas and carcinomas with characterised somatic APC mutations and identified reports on 165 sporadic and 102 FAP-associated tumours with two defined mutations. Using a Poisson model for the observed number of mutations per amino acid residue, we redefined the mutation cluster region (MCR) to residues 1281-1556, and demonstrated that the locations of the two APC mutations, relative to the MCR, are not independent ( $p < 0.0001$  in both sporadic and FAP-associated tumours). We developed a model based upon the data for sporadic tumours which suggests that different growth advantages are being conferred by different combinations of APC mutations. Thus, genotype I/I (I: truncating mutation inside MCR) is 3.9 times more likely to be selected than genotype IO or IL (O: truncating mutation outside MCR, L: allelic loss), which in turn is 27.8 times more likely to be selected than OO or OL. The data for FAP-associated tumours did not fit the same model, which could in principle reflect different mechanisms of sporadic and FAP-associated tumourigenesis, but may also result from biased FAP patient sampling and mutation screening.

**Effect of altitude on the clinical severity of hereditary paraganglioma.** *K. Astrom<sup>1</sup>, J.E. Willett-Brozick<sup>2</sup>, E.N. Myers<sup>3</sup>, B.E. Baysal<sup>1,2,3</sup>.* 1) Hum Genet, Univ. Pittsburgh,; 2) Dept Psychiatry, Univ. Pittsburgh Med. Ctr; 3) Dept. Otolaryngology Univ. Pittsburgh Med. Ctr., Pittsburgh, PA.

Hereditary paraganglioma (PGL) is characterized by the development of benign, vascularized tumors in the head and neck. The most common tumor site is the carotid body (CB), a highly vascularized small organ that senses blood oxygen levels. PGL is primarily caused by mutations in the SDHD gene (PGL1) of the mitochondrial complex II. The SDHD mutations in PGL are likely to act by loss of function of the protein product. However, there is significant amount of phenotypic variability among the PGL patients that needs to be explained. Chronic hypoxic stimulation of high altitudes induces neoplastic growth in the CB and the incidence of sporadic paraganglioma tumors increases in proportion to the altitude. There is a marked phenotypic similarity between the CB tumors in PGL and those that develop in high altitudes. This suggests that the availability of environmental oxygen may be an important factor in determining the clinical severity of the PGL tumors. To test this hypothesis, the data on the clinical severity of the tumors in PGL patients are tabulated based on what altitude the patients lived until the first tumors were recognized. The severity of the tumors is assessed by scoring the age-of-onset, the number of tumors, tumor size and metastasis. Questionnaires have been sent to over 140 patients belonging to more than 40 PGL families who have been recruited to the PGL research study at the University of Pittsburgh. Preliminary data suggests that individuals living in higher altitudes have more severe phenotypes. For example, rare metastatic PGL tumors have been observed in two individuals in a single PGL1 family who lives in an altitude above 2000 feet. In contrast, the identification of founder mutations in almost 40% of "sporadic" patients in the Netherlands suggests a mild clinical phenotype in a location situated in very low altitudes. These preliminary findings have important implications for the management of PGL patients and suggest that the phenotypic expression of the genetic defects in PGL may be influenced by the availability of environmental oxygen.

**The Finnish R726L androgen receptor mutation is uncommon in prostate cancer families in the United States.**

*S.B. Gruber, H. Chen, L.P. Tomsho, E.E. Perrone, K.A. Cooney.* University of Michigan, Ann Arbor, MI.

The observation that prostate cancer aggregates in families has led investigators to search for germline mutations that may increase the susceptibility to prostate cancer. Since the relative risk attributed to having a brother with prostate cancer is twice as high as that conferred by an affected father, some investigators have suggested that there may be X-linked and/or recessive prostate cancer loci. The androgen receptor (AR) gene (OMIM \*313700), located at Xq11-12, has been considered to be a candidate prostate cancer susceptibility gene. Recently, Mononen et al. (*Cancer Res*, 60: 6479, 2000) reported that a germline AR R726L mutation was detected in 2% of Finnish men with sporadic or familial prostate cancer and was associated with an approximately six-fold increased risk of prostate cancer. The University of Michigan Prostate Cancer Genetics Project is a family-based study dedicated toward characterizing the molecular basis of prostate cancer. Enrollment criteria for his study include early-onset and/or a family history of prostate cancer. Five hundred forty eight men with histologically confirmed prostate cancer from 411 unrelated families were selected for this study. The average age of prostate cancer diagnosis was 61.0 +/- 9.6 years. ASO hybridization was used to detect the presence of this mutation in germline DNA extracted from lymphocytes. A Finnish DNA sample containing the R726L mutation was used as a positive control for all experiments. None of the 548 prostate cancer patients studied, including 513 White, 29 African American, 3 Asian and 3 Hispanic men, were found to carry the AR R726L allele. Therefore, the prevalence of this allele is significantly less than that observed among Finnish men with prostate cancer (Fisher's exact test,  $p = 0.002$ ). Our data is consistent with the hypothesis that the AR R726L allele is a founder prostate cancer allele in Finland, and that this mutation does not account for a significant proportion of early-onset and/or familial prostate cancer in the United States.

**Mutation and methylation analysis of the *PTEN* gene in a population-based series of endometrial carcinoma patients.** *S. Das*<sup>1</sup>, *E.I. Kretzschmar*<sup>1</sup>, *P. Gruber*<sup>1</sup>, *L.A. Akslen*<sup>2</sup>, *H.B. Salvesen*<sup>2,3</sup>. 1) Dept Human Genetics, Univ Chicago, Chicago, IL; 2) Department of Pathology, The Gade Institute, Bergen, Norway; 3) Department of Gynecology and Obstetrics, Haukeland University Hospital, Bergen, Norway.

Mutations of the *PTEN* gene are a frequent finding in endometrial carcinoma. Promoter hypermethylation, an alternative mechanism of gene inactivation, has more recently been observed in the *PTEN* gene in endometrial carcinoma. In an effort to understand the different mechanisms of *PTEN* inactivation in endometrial carcinoma and the relationship between the different mechanisms, we are studying a series of endometrial carcinoma tumors for *PTEN* mutation, methylation and loss of expression. We have available for our studies a well characterized population-based series of endometrial carcinomas with complete follow-up. We have performed mutation analysis of the *PTEN* gene in 145 endometrial carcinoma tumors by denaturing high performance liquid chromatography (DHPLC) followed by sequence analysis. To date we have found mutations in approximately 45% of our tumor set. The mutations observed are all predicted to be deleterious and include insertion, deletion, nonsense and non-conservative missense mutations. 24% of mutations were found in regions of repetitive sequence. Approximately 14% of the tumors studied so far have two different mutations in the *PTEN* gene. The *PTEN* methylation status of this tumor set has previously been determined and found to occur in approximately 20% of tumors. We are in the process of combining our mutation and methylation results to determine the overall mechanism of *PTEN* inactivation in these tumors. In addition, we are studying these tumors for *PTEN* expression and will determine how tumors with *PTEN* mutation and/or methylation correlate to expression.

**A Protease Resistant Form of DNA Ligase III Protects HT1080 Cells From Programmed Cell Death.** *L. Bordone, C. Campbell.* Department of Pharmacology Medical School, University of Minnesota, Minneapolis, MN.

A yeast two-hybrid screen identified the calcium-dependent protease calpain as a putative DNA ligase III-binding protein. Consistent with this finding, in vitro transcribed and translated recombinant DNA ligase III protein was a substrate for calpain degradation. Addition of calpain to nuclear extracts resulted in degradation of endogenous DNA ligase III. This calpain-mediated proteolysis was calcium dependent and was blocked by the specific calpain inhibitor calpeptin. Experiments revealed that calpain binds to the N-terminal region of DNA ligase III. This portion of DNA ligase III contains an acidic domain (named PEST) that is frequently present in proteins cleaved by calpain. A mutant version of DNA ligase III protein that lacked a PEST sequence did not bind to calpain in a yeast two-hybrid system. In addition, this mutant version of DNA ligase III was resistant to in vitro proteolysis by calpain. Since a variety of DNA repair enzymes are degraded during apoptosis, we hypothesized that DNA ligase III proteolysis is essential for cell death. We therefore isolated HT1080 clones that overexpressed either mutant or wild type forms of DNA ligase III. Cytotoxicity experiments were performed by treating these cells with ionizing radiation, the topoisomerase inhibitor I camptothecin, or anti-Fas antibody. Cells expressing the DNA ligase III clone that lacked the PEST sequence were more resistant to killing by all three of these agents than were cells that expressed the wild-type form of DNA ligase III. These results suggest that DNA ligase III cleavage is an essential step in programmed cell death in human cells.

**High prevalence of multiple melanoma in patients with CDKN2A mutations from melanoma-prone families. C.**

*De Bernardo*<sup>1</sup>, *C. Catricalà*<sup>2</sup>, *F. Binni*<sup>3</sup>, *P. De Simone*<sup>2</sup>, *B. Grammatico*<sup>1</sup>, *L. Eibenschutz*<sup>2</sup>, *P. Grammatico*<sup>3,1</sup>. 1) Cytogenetics and Molecular Genetics Lab., Medical Genetics Service, S. Camillo-Forlanini Hospital, Rome, Italy; 2) San Gallicano Dermatological Institute, IRCCS, Rome, Italy; 3) Medical Genetics, Experimental Medicine and Pathology Department, University of Rome "La Sapienza", Italy.

Cyclin-dependent kinase inhibitor 2A (CDKN2A) is considered the main candidate gene for melanoma susceptibility and in 1993 Petty et al. described a patient affected from multiple melanoma with a constitutional deletion of this region. Recently CDKN2A mutations were described also in other solid tumors as brain gliomas, bladder, esophagus, breast and pancreas carcinomas. We collected 56 melanoma-prone families and analyzed the three coding exons and the 5' UTR of CDKN2A gene. For each patient we elaborated a three generation pedigree in order to evidence any other subject affected from melanoma or other different tumors and consider the presence of multiple melanomas. We identified a CDKN2A mutation in 8 out of 56 families (14%), 5 already described in literature and three novel mutations. In particular we found three missense mutations (Gly101Trp, Arg24Pro, Pro48Thr), one small deletion (del201C) that produces a stop codon (145) by frameshift, and a splicing mutation (ivs1+ 2(T-C)). We think relevant that 6 out of 8 subjects were affected by multiple melanoma while among the 48 subjects without CDKN2A mutation only 2 showed a multiple melanoma. This evidence allowed us to consider the presence of a CDKN2A mutation in a patient affected by multiple melanoma as a marker sufficient to suggest the extension of the analysis to all the healthy members of the family. In fact, considering the high prevalence of the multiple melanomas in our families with CDKN2A mutations, supported by literature, we have to consider the possibility of a high neoplastic risk ( melanoma, pancreas or larinx carcinoma) associated to the presence of CDKN2A mutation.

**A predictive model of metachronous colorectal carcinoma in HNPCC.** *L. Bertario<sup>1</sup>, A. Russo<sup>2</sup>, P. Sala<sup>1</sup>, A. Viel<sup>3</sup>, M. Genuardi<sup>4</sup>, M. Ponz de Leon<sup>5</sup>, A. Cama<sup>6</sup>, C. Mareni<sup>7</sup>, P. Radice<sup>1</sup>.* 1) National Cancer Institute, Milano; 2) Local Health Authority, Milano; 3) Centro Riferimento Oncologico, Aviano; 4) Cattolica University, Rome; 5) University of Modena; 6) University of Chieti; 7) University of Genoa - Italy.

HNPCC-related colorectal carcinoma (CRC) cases show a tendency to the development of both synchronous and metachronous lesions. The identification of risk factors for multiple cancers might contribute to define the appropriate clinical treatment in these patients. We carried out a retrospective analysis of 479 CRC cases from HNPCC families fulfilling the Amsterdam Criteria I or II, recruited by six collaborating Italian institutions. Approximately 62% were early stages (Dukes A-B) and 38% advanced stages (Dukes C-D). The anatomical distribution was as follows: proximal colon in 222 cases (46%), distal colon in 108 cases (23%), rectum in 84 cases (18%), multiple locations in 32 cases (7%). A total of 203 patients (42%) belonged to families in which a germline mutations, either in the MLH1 (n = 126) or MSH2 gene (n = 77), could be identified. Metachronous CRCs developed in 49 patients, with a mean interval from the first cancer of 78 months (range 4-288 months), and a cumulative incidence at 10 years of 18.7%. The identification of the best predictive model for metachronous CRCs was carried using a training/testing technique. The largest collection of cases from a single center, that of the National Cancer Institute including 227 patients, was used as a training set. In this group, a multivariate logistic regression analysis revealed that early stage (OR 10.1), distal location of primary CRC (OR 2.9), and MLH1 mutations (OR 4.2) were associated with an increased risk for metachronous carcinoma. A logistic model derived from these observations was subsequently evaluated on a testing test composed of 252 patients collected by the other participating centers, in which 67% of metachronous cancers were correctly predicted. These findings indicate that integrating information on primary cancer stage and location and on mutational status of HNPCC individuals with CRCs may predict those at higher risk for metachronous lesions.

**CDKN2A germline mutation analysis in patients with pancreatic adenocarcinoma from Liguria.** *P. Ghiorzo<sup>1</sup>, L. Pastorino<sup>1</sup>, A.M. Nicora<sup>2</sup>, L. Bonelli<sup>2</sup>, S. Zupo<sup>1,2</sup>, B. Villaggio<sup>3</sup>, M.R. Sertoli<sup>1,2</sup>, G. Bianchi-Scarrà<sup>1</sup>, V. Pugliese<sup>1,2</sup>.* 1) Oncology Biol & Genetics, Univ Genova; 2) National Institute for Cancer Research, Genova; 3) Department of Internal Medicine, Univ Genova, Italy.

Pancreatic adenocarcinoma is one of the leading causes of cancer deaths worldwide. In some families showing aggregation of PC, malignant melanoma and breast cancer, germline mutations in the p16 tsg have been identified in populations where a founder effect is prevalent. It has been estimated that 5-10% of PC are associated with strong familial predisposition but the proportion of pancreatic cancer attributable to inherited mutations of CDKN2A remains largely unknown. The present study aims to investigate the contribution of CDKN2A mutations in unselected pancreatic cancer patients, consecutively diagnosed in Liguria, where the G101W mutation is recurrent in melanoma families which are at increased risk of developing other cancers. Between April 1, 1998 and March 31, 2001, 59 unrelated patients (33 males and 27 females, mean age at diagnosis 64.9 years, range 41-83 years) were referred to ERCP and were diagnosed with exocrine pancreatic cancer at IST in Genoa. A detailed oncologic pedigree was obtained from 55 subjects. DNA-analysis was performed in 30 consenting patients (13 males and 17 females, mean age at diagnosis 66.7 years, range 48-83 years). The neoplasm was located in the head of the pancreas in 21 cases (77.4%). A histologic diagnosis was available for 11 cases. According to pedigree information 8 of 30 pts (26.7%) were considered as belonging to cancer-prone kindreds (2 of them were diagnosed with both MM and PC). Patients in this sub-set were slightly younger than sporadic patients (mean age 62.9 year $\pm$ 11.0 vs 68.0 years $\pm$ 10.3), (P=0.25). Screening of CDKN2A showed germline CDKN2A mutations in 2/30 unselected pancreatic patients. However, these 2 mutations were identified among the 8 patients belonging to cancer-prone families. These results suggest that the occurrence of PC in multi-cancer families in Liguria may be linked to underlying genetic susceptibility due to recurrent CDKN2A germline mutations. This study was supported by Ministry of Health grants N.ICS 0701/RF 99.63 to MRS and GBS.

**Association between the occurrence of breast cancer and cartilaginous tumors: phenotypic characterization of a hitherto unrecognized potential hereditary trait.** *A.M. Cleton-Jansen<sup>1,2</sup>, M. Timmerman<sup>1</sup>, M.J. Van de Vijver<sup>4</sup>, C.J. Van Asperen<sup>3</sup>, L.C.J.M. Van den Broek<sup>1</sup>, P.C.W. Hogendoorn<sup>1</sup>.* 1) Pathology, LUMC, Leiden, The Netherlands; 2) Human and Clinical Genetics, LUMC, Leiden, The Netherlands; 3) Clinical Genetics, LUMC, Leiden, The Netherlands; 4) Dutch Cancer Institute, Amsterdam, The Netherlands.

Recently we documented a strong association between the occurrence of cartilaginous tumors (enchondroma, chondrosarcoma) and breast cancer in the same patient, using a nation-wide case-control study. This study revealed an odds ratio of 7.62 for a potential association of breast and cartilaginous tumors, pointing statistically strongly towards a genetic trait. This is furthermore corroborated by the age of onset in patients with breast cancer as the first tumor, which is about 10 years earlier than breast cancer in the general population. The Dutch BRCA1 and BRCA2 family database was searched, however no case of chondrosarcoma nor enchondroma was reported, neither within the same patient nor within the pedigree pointing to a trait which is different from the afore mentioned breast cancer syndromes. Following this statistical/epidemiological analysis we report on the phenotypic characterization of the patient group. Using the national pathology database the tissue blocks of all patients reported to fulfil the associated tumors mentioned were retrieved. Reported diagnoses were reviewed; breast cancer specimens were classified and histologically characterized according to the procedures used by the Breast Cancer Linkage Consortium. In addition the cartilaginous tumors were analyzed with emphasis on the central versus peripheral localization in the skeleton as previous studies proved a different molecular mechanism to be operative in the different subtypes. Remarkably all cartilaginous tumors are of one common histological subtype being centrally localized whereas no peripheral cartilaginous tumor was registered. The breast tumors were histologically heterogeneous with varying differentiation grade. Results on immunohistochemical staining (p53, Bcl2, neu, p16, p21 estrogen and progesterone receptor and E-cadherin) will be presented.

**Androgen Receptor CAG repeats length in Jewish Israeli women who are BRCA1/2 mutation carriers: relevance to breast/ovarian cancer morbidity.** *E. Dagan*<sup>1,2</sup>, *E. Friedman*<sup>3</sup>, *T. Paperna*<sup>1</sup>, *N. Carmi*<sup>3</sup>, *R. Gershoni-Baruch*<sup>1,4</sup>. 1) Dept Human Genetics, Rambam Medical Ctr, Haifa, Israel; 2) Dept Nursing, faculty of Welfare and Health Sciences, University of Haifa, Israel; 3) Susanne Levy Gertner Oncogenetic Unit, Sheba Medical Center, Tel Aviv, Israel; 4) Technion-Institute of Technology, Rappaport Medical School, Haifa, Israel.

BRCA1/2 mutation carriers are at an increased lifetime risk for developing breast and/or ovarian cancer. The factors that govern the phenotypic expression of mutant BRCA1/2 alleles have not been fully elucidated. The polymorphic CAG repeats within the Androgen Receptor (AR) gene which encode for polyglutamine tract may interact with BRCA1/2 via steroid hormone pathway regulation, and hence is a candidate BRCA modifier gene. Previous studies have shown that the CAG repeat size may be associated with BRCA1 mutation morbidity. To extend this observation, we genotyped 227 women, carriers of one of the predominant Jewish BRCA1/2 mutation, for the AR CAG repeats, and evaluated the contribution of this polymorphism to breast/ovarian cancer morbidity. Of 227 BRCA1/2 carriers, 169 were BRCA1 mutation carriers (185delAG, n=130; Tyr978X, n=2 and 5382insC, n=37) and 58 carried the 6174delT BRCA2 mutation. Unilateral breast cancer was diagnosed in 79 women, bilateral breast cancer in 15, ovarian cancer in 41, breast/ovarian cancer in 14 and 78 were asymptomatic mutation carriers. Mean age at diagnosis among affected women (with either or both neoplasms) 46.71±1.2 years and that of the asymptomatic group - 45.89±1.4 did not differ. The AR CAG repeats ranged from 11 to 28. None had an allele longer than 29 CAG repeats. The mean number of CAG repeats was not statistically different between the asymptomatic group (203; range, 14-28) and the patients with either early onset breast cancer (<42 years at diagnosis) (193; range, 11-26) or with both breast and ovarian cancer (193; range, 14-28). Variation in CAG repeats length was not correlated with age at diagnosis or clinical manifestation. This study does not support the notion that AR CAG repeats contribute to the phenotypic expression of mutant BRCA allele in Jewish individuals.

**Comparative analysis of methods for detecting BRCA1 rearrangements in breast-ovarian cancer families. B.**

Recent studies have identified BRCA1 rearrangements in about 10% of families with a high probability of genetic predisposition to breast and ovarian cancer and negative for BRCA1/2 coding-regions mutations. To study such families, our group compared four approaches : DNA combing, cDNA analysis of size variation and of loss of expressed allelic markers, gene dosage by real time quantitative PCR and semi-quantitative fluorescent multiplex PCR. Our goals were : (1) to compare sensitivity and specificity of these methods in the detection of BRCA1 rearrangements in routine laboratory settings (2) to estimate the contribution of BRCA1 (and subsequently BRCA2) germ-line rearrangements in French breast and ovarian cancer families. Known deletions/duplications were used to validate the performance of the three methods that rely on genomic DNA analysis. These methods were applied initially to 13 families with negative BRCA1/2 mutation test results. Family eligibility criteria were two or more cases of ovarian cancer in 1st degree relatives (2d degree if transmission was by men) or at least one case with both breast and ovarian cancer. DNA combing and cDNA analysis required carefully isolated and frozen lymphocytes or lymphoblastoid cell lines which currently limits their use for retrospective analysis of samples. Conversely, both gene dosage assays have the potential for screening large numbers of families with high sensitivity and specificity and have been selected for the second phase of our study in a larger series of French patients.

**Multiple colorectal adenomas in familial colorectal cancer: more evidence for disease diversity and genetic heterogeneity.** *K.S. Dahan<sup>1</sup>, M. Smaers<sup>1</sup>, X. Pepermans<sup>1</sup>, C. Sempoux<sup>2</sup>, P. Van Maele<sup>3</sup>, A. Kartheuser<sup>4</sup>, Ch. Verellen-Dumoulin<sup>1</sup>.* 1) Dept Genetics, UCL Saint-Luc Hosp, Brussels, Belgium; 2) Dept of Pathology, UCL, Brussels; 3) St-Jean Hospital, Brussels; 4) Dept of Surgery, UCL, Brussels.

Twenty to 30 % of colon cancers are associated with a familial risk manifested as an early-onset tumours or multiple lesions of several sites. There is evidence that low-penetrance missense variants (I1307K and E1317Q) and mutations located within the 5' and 3' regions of APC gene predispose to multiple colorectal adenomas whereas germline mutations in mismatch repair (MMR) genes are characterised by a family history of early-onset cancers of specific sites. The aim is to find out what proportion of multiple adenomas patients have disease resulting from APC or MMR genes. **Patients and methods** : we have studied adenoma specimens of 22 Belgian unrelated patients with a familial risk of cancers and 3 to 25 colorectal adenomas for microsatellite instability (MSI) and expression of MLH1 and MSH2 proteins. Germline mutation was carried out by DGGE and direct sequencing throughout the APC gene and the *MLH1* and *MSH2* genes for MSI (+) individuals. **Results**: MSI is detected in 9 adenomas (9/22) with no expression of MLH1 (1/9), of MSH2 (2/9) and with a focal expression of MSH2 (2/9). In the 4 last cases, a normal expression of the two MMR products is observed. No germline mutation of *MLH1* and *MSH2* is detected. Out of 22 individuals, only one truncating APC variant in exon 9 (R332X) is identified. **Conclusion**: Among patients with multiple adenomas and familial history of colorectal cancer, the disease seems to be correlated to a MMR deficiency due to the absence of MSH2 in 18 % whereas germline alterations of APC gene are rare in our studied group. Furthermore, to understand the implication of MMR in the genesis of multiple adenomas , a screening of an another candidate gene such *MSH6* interacting with MSH2 protein should be useful in patients with MSH2(-)adenomas.

**Uptake of Prophylactic Surgery and Screening Compliance in Hereditary Breast and Ovarian Cancer.** *J.N.*

*Everett<sup>1</sup>, M. Pritzlaff<sup>2</sup>, C. Christianson<sup>1</sup>, J. Groden<sup>3</sup>, K. Huelsman<sup>1</sup>.* 1) Human Genetics, Children's Hospital Medical Center, Cincinnati, OH; 2) University of Cincinnati, College of Allied Health Sciences, Cincinnati, OH; 3) University of Cincinnati, College of Medicine, Cincinnati, OH.

**Purpose:** To examine compliance with screening recommendations as well as interest in and uptake of prophylactic surgery after genetic counseling among women clinically evaluated for hereditary breast and ovarian cancer risk.

**Patients and methods:** Questionnaires were sent to 264 women who received genetic counseling through the Hereditary Cancer Program, Cincinnati, OH. 145 women completed the self-administered questionnaire (54.9% response rate). Responses were compared to data collected at the time of clinical evaluation in order to determine changes in screening behaviors since genetic counseling.

**Results:** Women who tested positive for BRCA1 or BRCA2 mutations showed significant improvement in breast cancer screening practices. These women were also more likely to have had or be considering prophylactic mastectomy ( $p=0.0025$ ) and prophylactic oophorectomy ( $p<0.001$ ) than were women who tested negative or did not have testing. Improvements in ovarian cancer screening after counseling were not observed in this study, regardless of mutation status. Only 55% of women over age 50 were compliant with general population guidelines for colon cancer screening.

**Conclusions:** Genetic counseling for hereditary breast and ovarian cancer in the clinic setting is associated with improvements in breast cancer screening, particularly among women testing positive for BRCA1 and BRCA2 mutations. Genetic counseling and testing also appears to have an impact on decision-making with regard to prophylactic mastectomy and prophylactic oophorectomy. Limitations of the ovarian screening may partially explain lack of improvement in compliance with this screening. Colon screening recommendations should be discussed during genetic counseling in conjunction with other cancer screening recommendations.

**FAP and HNPCC mutations in the same patient.** *C.D. DeLozier-Blanchet<sup>1</sup>, E. Arrigoni<sup>2</sup>, Z. Dobbie<sup>3</sup>, C. Rey-Berthod<sup>4</sup>, M-A. Brundler<sup>5</sup>, J-L. Blouin<sup>1</sup>, C. Soravia<sup>6</sup>, P. Hutter<sup>4</sup>.* 1) Div Medical Genetics, Geneva Univ Hospital; 2) Div Gastroenterology, Geneva Univ Hospital; 3) Human Genetics, University Hospital Basel; 4) Unit of Genetics, ICHV, Sion; 5) Div Clinical Pathology, Geneva Univ Hospital; 6) Digestive Surgery Clinic, Geneva University Hospital, SWITZERLAND.

Colonoscopy was performed in a healthy 24 year-old Italian man whose father and multiple relatives reportedly had polyposis coli. His mother was one of nine healthy sibs. Microsatellite analysis (MSI) of an excised dysplastic adenoma vs. lymphocyte DNA revealed high-level instability (MSI-H); immunohistochemistry showed absence of hMSH2 and hMSH6 proteins in the adenomas. An insertion mutation was detected in exon 7 of hMSH2 (ins1191G), leading to protein truncation 19 codons downstream. On prophylactic colectomy at age 25 a small adenocarcinoma (T1N0M0) and multiple flat adenomas and associated aberrant crypts were revealed. The father, sure of his own diagnosis of FAP, was then available; he did not have the hMSH2 mutation, but PTT revealed an truncating exon 15 mutation in the APC gene (del3471-3474GAGA). The proband thus has both a hMSH2 mutation of unknown origin and a paternally-inherited APC mutation. Gastroscopy revealed multiple glandulo-kystic polyps in the gastric fundus, but none in the duodenum. Endoscopy of upper and lower digestive tracts has been recommended every 6 months. The risk that potential offspring inherit one or both cancer-predisposing genes is 75%. We are aware of one other patient (J Med Genet 1999;36:790-93) with mutations in both the APC and a HNPCC gene: a missense mutation in exon 12 of hMSH2 and the I1307K missense variant in APC, documented in the Ashkenasi Jewish population and considered a pre-mutation.

**BRCA1 and BRCA2 Genotyping of Cases Ascertained in Year One of the Population-Based Ontario Familial Breast Cancer Registry.** *G.D. Glendon<sup>1</sup>, H. Ozcelik<sup>4,2</sup>, J.A. Knight<sup>2</sup>, N. Carson<sup>7</sup>, P. Ainsworth<sup>5</sup>, S. Taylor<sup>6</sup>, R.*

*Carter<sup>8</sup>, N.F. Boyd<sup>3</sup>, I.L. Andrulis and the Ontario Cancer Genetics Network<sup>1,2</sup>.* 1) Cancer Care Ontario, Toronto, ON, CA; 2) Samuel Lunenfeld Res. Inst., Mount Sinai Hospital, Toronto, ON, CA; 3) Ontario Cancer Institute, Princess Margaret Hospital, Toronto, ON, CA; 4) Dept. Path. and Lab. Lab., Children's Hospital of Eastern Ontario, Ottawa, ON, CA; 8) Dept. of Path. and Mol. Med., Chedoke-McMaster Hospital, McMaster University, Hamilton, ON, CA.

The OFBCR is a population-based registry that collects family and personal history information, as well as blood samples, from incident breast cancer cases and their relatives throughout Ontario for use in studies of familial breast cancer. It is one of the six sites that comprise the Cooperative Family Registry for Breast Cancer Studies. Incident invasive breast cancer cases diagnosed between Jan. 1996 and Dec. 1998 in all women aged 20-54 and 35% of those between 55-69 and all men aged 20-79 were ascertained via the Ontario Cancer Registry. Those that met additional personal or family history criteria were designated as familial and were eligible for protein truncation analysis with 5' DNA sequencing for deleterious mutations in the BRCA1/2 genes. This report is limited to probands diagnosed in 1996. Of the 315 familial cases analysed, 31 (9.8%) were found to carry BRCA mutations (17 in BRCA1 and 14 in BRCA2). As expected, multivariate analysis determined that the presence of early onset breast and ovarian cancer in either the proband ( $p=0.006$ ) or relatives ( $p=0.006$ ) was a good predictor of a BRCA1 mutation. Both the presence of multiple primary breast cancer in the proband ( $p=0.003$ ) and at least 2 second degree relatives with breast cancer ( $p=0.032$ ) were good predictors of BRCA2 mutations. As well, Ashkenazi Jewish ancestry ( $p=0.003$ ) was a good predictor of either a BRCA1 or 2 mutation. Analysis with a full 3-year ascertainment will allow us to more fully explore the predictors of harbouring a BRCA mutation.

**Follow-up molecular studies of prostate cancer families.** *D.S. Gerhard<sup>1,2</sup>, B.K. Suarez<sup>2,1</sup>, L.T. Nguyen<sup>1</sup>, M.E. Arthur<sup>1</sup>, J. Lin<sup>2</sup>, B. Haberer<sup>3</sup>, P. Humphrey<sup>4</sup>, S. Finkelstein<sup>5</sup>, O. Schirripa<sup>6</sup>, W.J. Catalona<sup>3</sup>.* 1) Dept. of Genetics, Box 8232; 2) Dept. of Psychiatry; 3) Dept. of Urology; 4) Dept. of Pathology, Washington University School of Medicine, St. Louis, MO; 5) Dept. of Pathology, University of Pittsburgh; 6) Dept. of Pathology, University of Colorado Health Sciences Center, Denver.

Prostate cancer (CaP) is the most common cancer in American men. At least 9% of the cases are due to a genetic predisposition though the mode of inheritance is unclear as autosomal dominant, recessive, X-linked or multigenic transmission was reported. In the 3 genome screens of CaP families published to date, positive findings include 3 loci on chromosome 1, at least 1 locus on chromosome X and at least 1 locus on chromosome 16. However, none of these genes have been identified, therefore, to clone at least one of the genes we followed up the results of our genome screen in 2 ways; one, testing of potential candidate genes by association, and two, characterization of the tumors for deletions.

We tested the androgen receptor (AR), in our sample of ~260 multiplex affected kindreds and 355 controls. AR is a transcription factor upon binding of androgens. It has 2 polymorphic sites within exon 1 (the transactivation domain), CAG and GGC. It has been suggested that the shorter form of the protein has increased function and may be correlated with increased frequency in CaP patients. In our sample, we did not find any association between the length of the CAG repeat and presence of CaP. The analysis of the GGC as well as of the haplotype is in progress. In our genome screen, the marker with the highest linkage signal was D16S3096. We are genotyping available tumor DNAs (not all patients underwent surgery) with markers between and including D16S3040 and D16S515. Here we report the analysis of the first 125 tumor DNAs that amplified; 64 tumors (51%) have a deletion of at least one chromosome 16 marker, though unexpectedly, not all tumors have a common region of deletion. We plan to analyze the tumors by their linked or unlinked to chromosome 16 status and determine if the deletion patterns are associated with the linkage results.

**Good response to chemotherapy (CT) and hormonotherapy (HT) in patients with *BRCA1*-related breast cancer (*BRCA1*-BC).** P.O. Chappuis<sup>1,2</sup>, J. Goffin<sup>1</sup>, N. Hamel<sup>2</sup>, N. Wong<sup>1</sup>, A.J. Paradis<sup>1</sup>, D. Roberge<sup>1</sup>, J.S. Brunet<sup>3</sup>, C. Yee<sup>4</sup>, P. Tonin<sup>2</sup>, J. Boyd<sup>4</sup>, P. Ghadirian<sup>5</sup>, L.R. Bégin<sup>1,6</sup>, W.D. Foulkes<sup>1,2</sup>. 1) SMBD-Jewish and Montreal General Hospitals, Montreal, QC, Canada; 2) Research Institute, McGill University Health Center, Montreal, QC, Canada; 3) Algorithme Pharma Inc., Montreal, QC, Canada; 4) Memorial Sloan Kettering Cancer Centre, New York, NY; 5) CHUM-Hôtel-Dieu, University of Montreal, QC, Canada; 6) Sacré-Coeur Hospital, Montreal, QC, Canada.

The prognosis of *BRCA1*-BC may be worse than that of sporadic BC. We studied the response to CT and/or HT of *BRCA1*-BC in 2 different groups of BC patients. A) We determined the impact of adjuvant CT and HT in a historical cohort of 292 women diagnosed with BC < age 65 at one hospital between 1980-95. All women were Ashkenazi Jewish and were tested for the 3 founder mutations in *BRCA1/2*. Follow-up (f/u) was available for 275 (94.2%) patients. Data were censored at 8 years (median f/u). B) We reviewed the charts of all known *BRCA1* mutation carriers identified in Montreal who received neo-adjuvant CT. A) Thirty (10.9%) *BRCA1* mutations were identified. At the median f/u, *BRCA1* mutation carriers had a significantly worse overall survival (OS) compared with non-carriers ( $P=0.016$ ). Among patients who do not receive adjuvant CT or HT, OS was significantly worse among *BRCA1* mutation carriers compared with non-carriers ( $P=0.003$  and  $P=0.011$ , respectively). No difference of OS was noted among patients who received CT or HT (both  $P > 0.45$ ). B) 5 *BRCA1* mutation carriers received pre-operative adriamycin-based CT for primary BC. Despite a relatively large tumor size (median: 6cm) and 2 cases clinically N+, a complete clinical response was noted in 4/5 cases and a complete pathological response in 3/4. One case showed no significant PR, another could not be pathologically evaluated. Patients with *BRCA1*-BC have a similar outcome compared to non-carriers only if they received adjuvant treatment. This could be crucial for small, N- tumors where the indication for adjuvant treatment might otherwise be questionable. *BRCA1* mutation carriers showed a surprisingly good response rate to neo-adjuvant CT.

**Association of the 15-kDa selenoprotein gene (*SEP15*) with malignant mesothelioma.** *S. Apostolou, Y. Mitsuuchi, J.R. Testa.* Human Genetics Program, Fox Chase Cancer Ctr, Philadelphia, PA.

Exposure to asbestos is a risk factor for malignant mesothelioma (MM) development, although little is known about the molecular pathogenesis of this cancer. Suppression subtractive hybridization was used to identify genes down regulated in MM cell lines compared to normal mesothelial cells. *SEP15* was isolated using this technique and was subsequently demonstrated to be down regulated in ~50% of MM cell lines. This gene encodes a selenium containing protein and maps to 1p31. Since loss of heterozygosity (LOH) is frequently exhibited at 1p31 in MM, and the trace element selenium is a candidate chemopreventive agent in several cancers, we decided to investigate the possible role of *SEP15* in MM.

SSCP and RFLP analyses of *SEP15* revealed a polymorphism at position 1125 in the 3'UTR SECIS recognition element. This element is necessary for decoding in-frame TGA codons as selenocysteine, rather than terminating translation. The association between polymorphism 1125G/A in 27 MM cases and 48 population controls was investigated. A significantly increased frequency of the 1125A variant was found in MM cases versus controls ( $P=0.04$ ), using the Chi-square test.

Since this variant lies within the SECIS element, we analyzed the effects of selenium on the growth of normal mesothelial cells and MM cell lines possessing wild type *SEP15* or the 1125A variant. We also analyzed MM cell lines in which *SEP15* was down regulated. Dose-dependent growth inhibition was observed in the cancer cells; however, cells with 1125A were found to be less responsive to added selenium than cells with wild type protein. Moreover, cells with down regulation of *SEP15* displayed the least growth inhibitory response to selenium.

Thus, individuals with the 1125A polymorphism may have increased risk of developing MM and may be less responsive to the protective benefits of dietary selenium. The findings of this study, together with frequent LOH at the *SEP15* locus, suggest that *SEP15* may be involved in the development of MM and/or the mechanism by which selenium functions in cancer prevention.

**Genetic counseling guidelines for families of children with acute leukemia.** *I.M. Kedar-Barnes, S.E Plon.* Baylor College of Medicine, Houston, TX.

Acute lymphoid leukemia (ALL) and acute myeloid leukemia (AML) are the most common childhood cancers yet little is known about the genetics of these disorders and guidelines for genetic counseling referral have not been developed. Most children with ALL/AML do not have a genetic predisposition for developing leukemia and in 1% of the cases there is some familial clustering. Genetic syndromes that predispose to leukemia include: Bloom syndrome, Fanconi anemia, ataxia telangiectasia, neurofibromatosis type I, Li-Fraumeni syndrome, inherited immunodeficiency syndromes and chromosomal aneuploidy including Down syndrome, Turner syndrome and Klinefelter. For these cases recurrence risk is specific to that syndrome. For "familial" ALL/AML counseling is a challenge and consists of education and understanding of recurrence risk until leukemia predisposition genes have been better identified. Siblings of children with isolated ALL/AML have about a 2-4 fold relative risk, however their absolute risk remains low. Recurrence risk is increased when there are multiple family members with hematologic cancers. Examples of such cases are included: Case 1: A 3-yr. old girl diagnosed with ALL had an aunt with leukemia at age 5. The family has an increased risk approximately 3-5 fold over that of a single affected. Case 2: A 6-yr. old boy, one of identical twins had ALL and the parents were concerned for the twin. Recurrence risk in identical twins is increased but is age dependent and is approximately 20% for twins at that age. Case 3: A 22-yr. old woman had ALL at age 12. Her concerns were focused on her future offspring and their recurrence risk. Studies have shown no increased risk of cancer in offspring of cancer survivors, however, there is still a slight increased risk due to mutagen exposure during treatment. In summary, appropriate referrals for genetic evaluation are: families with a genetic disorder known to predispose to ALL/AML; family history of other cancers in multiple relatives suggestive of Li-Fraumeni syndrome; a family history of ALL/AML in 1st or 2nd degree relatives; identical twins (< age 6) with one affected twin with ALL and finally, long term survivors of childhood ALL/AML who reach reproductive age.

**A Population-Based Survey of Colorectal Cancer Screening in HNPCC Families.** *L. Madlensky<sup>1</sup>, V. Goel<sup>2</sup>.* 1) Institute of Medical Science; 2) Dept. of Health Administration, University of Toronto, Canada.

**Objective:** To determine whether at-risk members of putative HNPCC kindreds are undergoing colonoscopic or other screening for colorectal cancer (CRC), and to compare family histories and demographics of screeners and non-screeners.

**Methods:** Relatives of CRC cases registered in a population-based familial CRC registry in Ontario, Canada were surveyed about their history of fecal occult blood testing (FOBT), sigmoidoscopy and colonoscopy. Data were collected on the types of tests, reasons for tests, demographics, and family history of CRC.

**Results:** The survey sample represents high-risk family members accrued through the proband, rather than through a high-risk clinic or genetic counselling service. Most of the respondents had not yet had genetic counselling and/or testing at the time of the survey. There were 183 respondents from putative HNPCC kindreds (3 or more 1st/2nd degree relatives with CRC) over age 35. Forty (22%) had not had any of the three tests, 56 (31%) had one type of test (37 were colonoscopy), and 85 (47%) had >1 type of test (70 include colonoscopy). Eighty respondents reported having an FOBT (64% for screening purposes), 52 had a sigmoidoscopy (46% for screening) and 115 had a colonoscopy (72% for screening). Ninety-four (51%) of the respondents could be clearly classified as "screeners", and 41 (22%) as "non-screeners"; the remainder were considered "diagnostic" or "unclear". Screeners were significantly older than non-screeners (58 yrs vs. 50 yrs,  $p=0.003$ ), but there was no significant difference in sex, marital status, education or income. The mean number of CRC-affected relatives did not differ significantly between the two groups (4.7 vs. 4.2).

**Conclusions:** While the majority of HNPCC family members are screened by colonoscopy (the recommended modality), 37% of this increased risk group have not had a colonoscopy, and 22% have not had any type of screening test. This points to a need to develop or improve counselling and educational interventions that could increase the uptake of colonoscopic screening, which has been shown to improve CRC outcomes in HNPCC families.

**Constitutive Missense *MSH6* Mutations Associated with HNPCC and Familial non-HNPCC Colon Cancer**

**Patients.** A.E. Lagarde<sup>1,2</sup>, E. Baumann<sup>1</sup>, S. Viertelhausen<sup>3</sup>, H.S. Stern<sup>1,2,3</sup>. 1) Ottawa Health Research Institute; 2) Department of Surgery, University of Ottawa; 3) Ottawa Regional Cancer Center, Ottawa, Ontario, Canada.

Germline mutations in the *MSH2* and *MLH1* DNA-mismatch repair genes are detected in 50% of HNPCC families fulfilling the Amsterdam criteria and in less than 10% of suspected HNPCC cases. Functionally inactivated *MSH2* or *MLH1* confers microsatellite instability (MSI+). *MSH6* is also part of the DNA-repair protein complex. However, the role of the *MSH6* gene in susceptibility to cancer remains uncertain. Its involvement in HNPCC and other types of familial cancers has been presented. Yet, bi-allelic *MSH6* inactivation occurs inconsistently, and tumor MSI may vary greatly. We analyzed the *MSH6* gene in a group of  $n=31$  colorectal cancer patients with known family histories and MSI tumor phenotypes, in whom *MSH2* and *MLH1* mutations had been excluded. Direct sequencing of ten PCR products covering the entire *MSH6* coding region revealed two constitutive mutations, providing a 6.5% frequency estimate (95% CI= 0.8-24). There was no association with high-(0/4 cases) or low-MSI (0/17 cases). *Val878Ala* and *Ile872Val* are missense mutations located in exon 4. Both were found in the subset of ten MSI-negative tumors. The *Val878Ala* carrier was diagnosed with rectal cancer at the age of 50, and was a member of a typical, early-onset HNPCC family. A single *MSH6* carrier was identified among all five HNPCC and five suspected HNPCC patients. The novel, *Ile872Val* mutant allele was not detected among 92 control DNAs. It was found in a 72-year old patient who reported only one affected sibling. A single *MSH6* carrier was identified among all 18 such familial non-HNPCC cases (frequency: 5.6%; 95% CI= 0.14- 27). Analysis of tumor DNAs revealed no (0/31 cases) change in the (C)<sub>6</sub> microsatellite, in exon 5, and no other alterations in the *MSH6* gene of the two carriers. Our findings extend the notion that mutations in *MSH6* contribute a significant proportion of familial colorectal cancer cases, inclusive of, but not limited to HNPCC, which do not express the severe hallmarks (MSI) of other DNA-mismatch repair gene deficiencies.

**Mammographic density in *BRCA1/2* mutation-carriers.** *G. Mitchell*<sup>1</sup>, *R. Warren*<sup>2</sup>, *D. Easton*<sup>3</sup>, *R.A. Eeles*<sup>1</sup>. 1) Section of Cancer Genetics, Inst CA Res, Sutton, Surrey, England; 2) Dept of Radiology, Addenbrooks Hospital, Cambridge, UK; 3) CRC Genetic Epidemiology Unit, Strangeways Laboratory, Cambridge, UK.

The positive association between increasing mammographic density and increasing breast cancer risk has been extensively reported for the general female population. On small report has suggested that the breasts of *BRCA1* mutation-carriers are denser than age-matched controls with implications for mammographic screening sensitivity. **AIM** To determine whether mammographic density of known *BRCA1/2* mutation-carriers and non-carriers can predict mutation status or be useful for breast cancer risk stratification in carriers. **METHODS** Mammograms of *BRCA1/2* mutation-carriers and women with a negative predictive test (negs) at our institution were collected. Mammographic density was scored using the Wolff and Boyd classification systems. **RESULTS** 71 *BRCA* mutation-carriers were identified, 47 previously affected by breast cancer (pos aff). 42 were negs. 78% of mammograms were located, 72% of pos aff, 88% of unaffected carriers (pos unaff), 79% of negs. Odds ratios (adjusted for age) were calculated for comparisons of density between all categories and the least dense category for both systems.  $X^2$  test for trend with increasing density for all carriers VS negs was 2.84 ( $p=0.09$ ). For other comparisons, pos aff VS negs or pos unaff VS negs, carriers tended to have the most dense mammographic category (non significant). ORs for weight, menopausal status and hormone use is still in progress. **CONCLUSIONS** An interesting non-significant trend to increased mammographic density in mutation-carriers was observed. A larger study is planned to confirm these observations. Funding generously provided by Breast Cancer Campaign.

**Ovarian Cancer Incidence in a Screened Population of Jewish Women.** A. Liede<sup>1</sup>, B. Karlan<sup>2</sup>, R.L. Baldwin<sup>2</sup>, K. Glover<sup>2</sup>, L. Platt<sup>2</sup>, G. Kuperstein<sup>2</sup>, S. Narod<sup>1</sup>. 1) Centre for Research in Women's Health, Univ Toronto, Toronto, ON, Canada; 2) Gilda Radner Ovarian Cancer Detection Program, Cedars-Sinai Medical Center, UCLA, Los Angeles, CA.

Risk factors for ovarian cancer include a family history of ovarian cancer, Ashkenazi Jewish ethnicity and the presence of an inherited mutation in BRCA1 or BRCA2. The Gilda Radner Ovarian Cancer Detection Program in Los Angeles was established in 1991 to study the efficacy of screening in the early detection of ovarian cancer in women at risk for ovarian cancer. We studied a historical cohort of 291 Jewish women who participated in the Gilda Radner Program. Each of these women had a family history of ovarian cancer, or of early-onset breast cancer and received biannual ultrasound and serum marker evaluations including CA 125. The women were offered BRCA testing for three common founder mutations in the Jewish population (BRCA1 185delAG, 5382insC and BRCA2 6174delT). Seventeen incident cases of cancer were observed in the cohort from 1991 to 2000 (1,120 per 100,000 per year) including eight ovarian/peritoneal/tubal cancers and six breast cancers. The majority (86%) of women with incident breast or ovarian cancer carried a mutation in the BRCA1 gene. The overall cancer incidence among carriers of mutations in the BRCA1 gene was estimated to be 5,510 per 100,000 per year, corresponding to a cumulative incidence of 47.5% at ten years (2.5% at ten years for non-carriers  $P < 10^{-8}$ ). After adjustment of sampling, risks to female carriers of germline BRCA1 mutations at ten years were estimated at 21% for ovarian/peritoneal/tubal cancer, 16% for breast cancer, and 36% for any cancer. Most of the ovarian cancers presented in symptomatic women who had evidence of cancer spread beyond the ovary. The excess risk of breast and ovarian cancer in Jewish women with a family history of ovarian cancer is largely attributable to mutations in BRCA1. Intensive surveillance using CA 125 and ultrasound does not appear to be an effective means of diagnosing stage I epithelial ovarian cancer in this high risk cohort.

**Glutathione S-transferase theta and mu (GSTM1 and GSTT1) gene expression in patients with aplastic anemia and myelodysplastic syndrome.** *C.J. Osgood<sup>1,2</sup>, A.C. Spivey<sup>1</sup>, M.W. Stacey<sup>2</sup>, A.H. Kim<sup>2</sup>.* 1) Dept Biological Sci, Old Dominion Univ, Norfolk, VA; 2) Dept of Pediatrics, Eastern Virginia Medical School, Norfolk, VA.

Aplastic anemia (AA) and myelodysplastic syndrome (MDS) are disorders of the hemopoietic bone marrow cells that are frequently associated with drug and environmental exposures. Treatment-induced MDS can follow chemotherapy. An individual's inability to detoxify ingested chemicals may increase risk for disease. Glutathione S-transferases are Phase II drug metabolizing enzymes and play key roles in detoxification. GSTM1 and GSTT1 are members of this multigene family and both exist as polymorphic deletion variants within human populations. Individuals deficient in one or both genes may be at increased risk for development of AA or MDS. The frequency of genotypic deletion may underestimate the true proportion of individuals who are phenotypically non-expressors. To test whether the null phenotype is higher than the null genotype, patients non-null for GSTM1 and or GSTT1 (or both) were tested for expression using RT-PCR. Of 9 patients who were GSTM1 positive, 1 failed to show expression. Of 36 patients who were GSTT1 positive, 5 showed no expression. In 15 patients with both genes, 2 showed no expression. In all, 20% of tested patients were phenotypic nulls. DNA methylation within the GST gene promoter regions does not appear to explain these results.

**Characterization of high-risk colon cancers in the Utah population.** *D.W. Neklason<sup>1,2</sup>, W.S. Samowitz<sup>3</sup>, R.A. Kerber<sup>1,2</sup>, G.P. Mineau<sup>1,2</sup>, R.W. Burt<sup>2,4</sup>.* 1) Dept. Oncological Sciences; 2) Huntsman Cancer Institute; 3) Dept. Surgical Pathology; 4) Dept. Medicine, Univ. Utah, Salt Lake City, UT.

A small but undetermined fraction of familial cases arise from the colon cancer syndromes of familial adenomatous polyposis (FAP), attenuated FAP (AFAP) and hereditary nonpolyposis colon cancer (HNPCC). Familial clustering of colon cancer is more common. The objective of this study is to determine the percent of high-risk colon cancer and the fraction of these high-risk cases with FAP, AFAP, and HNPCC from a unique genealogic-linked population based data set. Here, high-risk is defined as two first-degree relatives with colon cancer or one patient diagnosed with colon cancer at age 50 years or less. High-risk colon cancer patients were ascertained from Utah Population Database, which contains genealogy data, linked to the Utah Cancer Registry. To estimate the frequency of high-risk colon cancer, those cases meeting our high-risk criteria diagnosed 1966-1998 were divided by the total number of cases in that time frame resulting in a frequency of 25.5%. High-risk cases diagnosed 1965-1997 were invited to participate in research. Consent and pathology records were obtained on 648 cases, and tissue blocks or slides were collected on 385 cases. Review of medical records revealed two FAP cases (0.25%), one probable AFAP case, and 13 cases with several or >5 adenomatous polyps (2.0%). Pathology was confirmed and DNA extracted from normal and tumor regions of the tissue block. Microsatellite instability (MSI), a phenotype of HNPCC cancers, was determined on 270 of the cancers. MSI cancers constitute 13% (n=36) with an average diagnosis age of 58.5 yrs. The microsatellite stable cancers had an average diagnosis age of 59.5 yrs. We are currently using a combination of pedigree assessment, immunohistochemistry and sequencing of MLH1 and MSH2 in the MSI cases to estimate the frequency HNPCC. Six HNPCC cases from four kindreds (2.2%) have been confirmed and 5 are strongly suspected (4.1%). Since AFAP presents with a variable clinical phenotype, sequencing regions of the APC gene is currently underway to precisely estimate the fraction of AFAP in the high-risk population.

**BRCA1 and BRCA2 mutation and frequency profiles for the German population derived from more than 1000 case studies.** A. Meindl and representative of *The German Consortium for Hereditary Breast and Ovarian Cancer*. Abt Medizinische Genetik, Kinder Ludwig-Maximilians Univ, Munich, Germany Deutsche Krebshilfe, Bonn, Germany.

The Deutsche Krebshilfe supports a German-wide, multi-center study to establish a BRCA mutation profile and to determine family types with high frequencies of mutation in these genes. After screening more than 1000 unrelated index-patients from German breast/ovarian cancer families, deleterious mutations were found in about 320 cases. More than one third of these mutations may be specific for the German population. Twenty common mutations were found in 70% of the BRCA1 cases and 15 recurrent mutations in nearly 50% of the BRCA2 cases. Haplotype analysis strongly indicates that 15 out of 21 mutations originate from a common founder. Fifty-five rare variants with unknown relevance for tumorigenesis were found in another 80 families but not in 200 control individuals. As for most of them, no functional assays are available, these variants are currently characterized by LOH analysis of the corresponding tumor samples. A mutation frequency of 55% was identified in high risk families with both breast and ovarian cancer. The detection rate for high risk families with at least two premenopausal cases of breast cancer was about 40%. These data provide strong evidence for further predisposing genes in the German population and approaches have been implemented to identify such genes. These approaches include the determination of expression profiles in BRCA1/2 negative tumors and evaluation of candidate genes mapped to chromosome 8p and 11q. Less than 10% of mutations in the two known BRCA genes were found in families with two or three affected females, and having only a single or no premenopausal individuals. Families with three females affected by breast cancer can now be used for the detection of low penetrance genes by SNP analysis. In summary, the comprehensive analysis of more than a thousand families provides valuable data for genetic counselling and resources for the identification of novel genes associated with tumorigenesis.

**The Predictive Value of Established Clinical Criteria for BRCA1/2 analysis.** *S. Nanda*<sup>1</sup>, *P.J. Ainsworth*<sup>1, 2</sup>, *J.H. Jung*<sup>1</sup>, *N. Scanlan*<sup>3</sup>, *G. Sheridan*<sup>1</sup>. 1) Cancer Genetics, London Health Sciences Centre, London, ON, Canada; 2) Molecular Diagnostic Lab, London Health Sciences Centre, London, ON, Canada; 3) Cancer Genetics, London Regional Cancer Centre, London, ON, Canada.

The familial cancer histories and genotypic data for Southwestern Ontario kindreds, tested for mutations in BRCA1/2 genes between 05/96 and 05/01 were evaluated. We wished to determine if the clinical criteria established by the Ontario Cancer Genetics Network (OCGN), and more recently the Ontario Ministry of Health and Long Term Care (MOHLTC), adequately defined individuals/families at risk for the breast/ovarian syndrome. Hereditary Breast Cancer accounts for 5-10% of all cases of breast cancer and a large majority of these familial cases result from mutations in the BRCA1/2 genes. Statistical analysis was performed on 12 sub-groups outlined in the criteria. Of those eligible, a total of 401 individuals proceeded with BRCA gene testing. This was carried out by using a combination of the protein truncation test, utilizing both leukocyte genomic DNA and cDNA as template along with selective sequence analysis of genomic DNA. Individuals were recruited through the OCGN/MOHLTC and histopathological confirmations of a majority of cancers were made. 27 unique mutations in BRCA1 and 21 unique mutations in BRCA2 were detected. 119 of the 401 individuals tested demonstrated a mutation in one of the two BRCA genes, an overall positivity rate (PR) of 30%. The number of probands (individuals at highest risk who were tested first) was 225, had a 20% PR. In high risk groups significant findings include a 50% PR in families with two cases of ovarian cancer at any age in 1<sup>st</sup> or 2<sup>nd</sup> degree relatives. Individuals with both breast and ovarian cancer or bilateral breast cancer (the first breast tumour occurring at 50 or under) had a 42% PR. In an intermediate risk group, a 27% PR was observed in individuals with breast cancer, age 35 or under. A lower risk group, such as three breast cancers at any age in a pattern suggestive of inheritance, resulted in a 10% PR. These results indicate that our established clinical criteria are adequate in identifying at risk individuals in our population.

**Gynecological Malignancy as a "Sentinel Cancer" for Women with HNPCC.** *K. Lu<sup>1</sup>, M. Dinh<sup>1</sup>, W. Kohlmann<sup>1</sup>, P. Watson<sup>2</sup>, J. Green<sup>3</sup>, S. Syngal<sup>4</sup>, P. Bandipalliam<sup>4</sup>, L. Chen<sup>5</sup>, B. Allen<sup>5</sup>, P. Conrad<sup>5</sup>, J. Terdiman<sup>5</sup>, T. Burke<sup>1</sup>, D. Gershenson<sup>1</sup>, H. Lynch<sup>2</sup>, P. Lynch<sup>1</sup>, R. Broaddus<sup>1</sup>.* 1) MDACC, Houston, TX; 2) Creighton University, Omaha, NE; 3) University of Newfoundland, Canada; 4) Dana Farber Cancer Institute, Boston, MA; 5) UCSF, San Francisco, CA.

While HNPCC has been regarded as a colorectal cancer (CRC) dominated syndrome, endometrial cancer (EC) and ovarian cancer (OC) are also important components. Women with HNPCC have 40-60% and 12% lifetime risks for EC and OC, respectively. A significant number of women with HNPCC will have more than one cancer in their lifetime. Therefore, the occurrence of EC/OC as the first cancer in a young woman may indicate the presence of HNPCC. We hypothesize that EC and OC are "sentinel cancers" in women with HNPCC. The MDACC, Creighton, UCSF, Newfoundland, and Harvard registries were surveyed, and the results summarized below.

HNPCC families examined	223
Total # of women with CRC & EC/OC	126
CRC diagnosed first	47
EC/OC diagnosed first	57
CRC & EC/OC diagnosed simultaneously	22

These results show that in approximately 50% of the women studied, EC/OC was the "sentinel cancer", preceding the development of CRC. Therefore, gynecologists are essential in the identification of women with HNPCC. Such early identification is crucial for the optimal screening for subsequent cancers.

Program Nr: 395 from the 2001 ASHG Annual Meeting

**Hereditary Gastric Cancer. Results of molecular analysis and treatment.** *P. MacLeod.* Section of Genetics, Department of Laboratory Medicine, Victoria General Hospital, VICTORIA, BRITISH COLUMBIA., BRITISH COLUMBIA, Canada.

Hereditary Diffuse Gastric Cancer. Results of molecular analysis and treatment.

P.M. Macleod on behalf of the International Gastric Cancer Linkage Consortium. Division of Medical Genetics, Department of Laboratory Medicine, Victoria General Hospital. 1 Hospital Way, Victoria B.C. Canada V8R 6J4  
pmacleod@caphealth.org 250-727-4461

The calcium dependent epithelial adhesion protein e-cadherin (ECAD) plays an important role as an invasion suppressor/tumor suppressor molecule.

Inherited mutations in the e-cadherin gene (CDH1) result in reduced expression of ECAD, and is regarded as one of the main molecular events involved in dysfunction of the cell-cell adhesion system triggering cancer invasion and metastasis. Germline mutations in CDH1 predispose to some forms of an autosomal dominant early onset diffuse gastric cancer syndrome (HDGC).

Family data were collected by member groups of the Consortium. Mutation analysis identified 21 truncating and 6 missense mutations. Preliminary data estimate the penetrance to be about of 70% and the mean age of diagnosis of metastatic cancer of 46 years. The risk of developing gastric cancer is 50% at age 36. Women carrying a mutation are also at significant risk for developing lobular breast cancer. Elective prophylactic gastrectomy solely on the basis of mutation analysis has been performed on 10 individuals. In each case, detailed histopathological examination demonstrated small foci of signet-ring cells indicative of premetastatic intramucosal carcinoma. These had been missed by previous endoscopic biopsies.

Based on this experience, we have developed guidelines for ascertainment of cases, genetic counseling and molecular testing and propose a strategy for clinical and surgical management of family members at risk for this syndrome. The Consortium is offering access to molecular testing and clinical followup for additional families.

**Is there an association between Hodgkin's disease and increased risk of general cancer? - Results from a Swedish population based case-control study.** A. Kingman<sup>1</sup>, K. Hemminki<sup>2</sup>, C. Dong<sup>2</sup>, Y. Shugart<sup>3</sup>. 1) NIDR, NIH, Bethesda, MD; 2) Department of Biosciences at Novum, Karolinska Institute, Huddinge, Sweden; 3) Epidemiology Department, School of Public Health, Johns Hopkins University.

Genetic etiology of hematopoietic malignancies has been explored by various investigators (Haim et al 1982), (Eriksson and Hallberg 1992), (Lynch et al 1992), (Shpilberg et al 1994), (Mack et al 1995), (Shugart et al 2000). There have been a few attempts to look at familial occurrence of hematologic malignancies. The goal of this study is to determine whether general malignancies aggregate in families selected through probands affected with Hodgkin's lymphoma (HL) using the Family Cancer Database in Sweden (Hemminki and Vaitinen, 1998). A total of 1427 of HL diagnosed reported to the Swedish Cancer Register between 1940 and 1960 were collected, including 885 males and 542 females. Recorded information includes birth year, gender, county code, birth place, age of onset for first and second cancer, cancer types of both parents, age and birth place of each parent. For each case, a single control without any cancer was selected through a matching procedure by age and gender. Six hundred sixty three first-degree relatives affected with cancer among control families and 717 among case families were found. Analyses of covariances models were applied in the analysis of numbers of affected first-degree relatives in cases and control families. No association was detected between the HL status and the risk of general malignancies among parents, sibs or among all first-degree relatives of HL probands. However, after adjusting for differences in sibship size, the analysis suggested a weak association (P value =0.0971 ) between HL and first-degree relatives. -----

**Identification of a somatic mosaicism of the APC gene associated with adenomatous polyposis coli and germline transmission.** *S. Olschwang*<sup>1</sup>, *J. Bourguignon*<sup>2</sup>, *C. Boisson*<sup>1</sup>, *C. Martin*<sup>2</sup>, *T. Frebourg*<sup>2</sup>. 1) CEPH, Paris; 2) INSERM EMI 9906 IFRMP, Faculté de Médecine et de Pharmacie, Rouen, France.

De novo mutation of the APC gene is involved in approximately 25% of cases of adenomatous polyposis coli, post-zygotic events having been reported only twice. We report here a family in which the proband is bearing an APC post-zygotic mutation, present both in the germ-line and the colonic epithelium. This patient underwent total colectomy at age of 50 for diffuse adenomatous polyposis, that was revealed by a rectal adenocarcinoma. There was no previous family history of polyposis, suggesting that the corresponding mutation had occurred as a de novo event, but complete sequencing of the APC coding region on peripheral blood genomic DNA did not reveal any mutation. The subsequent follow-up of her 7 children found typical polyposis in 4 cases. At this stage, sequencing of the APC gene revealed a common deleterious mutation (Q541X, exon 12), present in all 4 affected children. DNA analysis of several peripheral blood samples from the proband confirmed the absence of the mutation, indicating the presence of a mosaicism with a germline component. Since the proband was herself affected, we postulated that the APC mutation should also be present within the colonic epithelium. Microdissection and direct sequencing of the APC gene confirmed the Q541X heterozygous mutation in the normal colonic epithelial cells and showed loss of the wild-type allele within the tumour cells. The mutation was absent of other colonic cells, such muscle. Thus, this mutation was only found in the germline and in the colonic epithelial cells. To our knowledge, this is the second report of a combined somatic/gonadal mosaicism for the APC gene (Farrington SM, and MG Dunlop. *Am. J. Hum. Genet.* 64:653-658, 1999), and the first report of a mosaicism affecting simultaneously the intestinal epithelium and the gonads, which respectively derived from the endoderm and the mesoderm. This observation is suggestive of an early cell migration abnormality, that could be documented only by the presence of a pathogenic mutation.

**APC mutations in Swedish FAP patients: Preliminary results.** *J. Meuller<sup>1</sup>, Y. Engwall<sup>1</sup>, A. Bergman<sup>1</sup>, J. Wahlström<sup>1</sup>, J. Björk<sup>2</sup>, M. Nordling<sup>1</sup>.* 1) Clinical Genetics, Goteborg University, Goteborg, Sweden; 2) Dep. Gastroenterology & Hepatology, Karolinska Hospital; Stockholm, Sweden.

Familial adenomatous polyposis (FAP) is an autosomal dominantly inherited disease caused by germ line mutations in the APC gene. It predisposes to the development of hundreds to thousands of colorectal polyps, of which some will progress to cancer. Additionally, FAP-patients often develop extracolonic manifestation, such as desmoids, osteomas and retinal lesions. Since the nature and frequency of APC mutations in Swedish FAP patients are largely unknown a study was initiated in order to screen all families in the Swedish polyposis registry (approximately 250 families) for APC-mutations. Samples were initially screened for truncating mutations using the protein truncation test (PTT) followed by D-HPLC, SSCP or direct sequencing if needed. Detected mutations were verified by sequencing. To date 48 samples have been completely screened. Overall 67 % (32/48) of the patients were found to carry a disease causing APC mutation. Twenty-seven (27) different pathogenic mutations were detected, of which 16 has not been described previously. One patient with attenuated FAP was found to have a truncating mutation in exon 1 (nt70C>T) which to our knowledge is the first reported truncating mutation 5- to exon 3. In another case, low level mutational mosaicism (nt 2699-2700delCT) was demonstrated for a de-novo patient with attenuated FAP. The common mutations 1309 (3927-3931del AAAGA) and 1061(3183-3187delACAAA) were found in 6% (2/32) and 9% (3/32) cases respectively.

**BRCA1 and BRCA2 analysis in 523 Austrian HBOC and HBC families.** R. Kroiss<sup>1</sup>, T. Wagner<sup>1</sup>, D. Muhr<sup>1</sup>, E. Fleischmann<sup>1</sup>, V. Korn<sup>1</sup>, Austrian Hereditary Breast and Ovarian Cancer Group<sup>1</sup>, Th. Helbich<sup>3</sup>, Ch. Zielinski<sup>2</sup>, E. Kubista<sup>1</sup>, P. Oefner<sup>4</sup>. 1) Dep of OB & GYN, Division of Senology, and Ludwig Boltzmann Institute for Clinical Experimental Oncology, University of Vienna; VIENNA, Vienna, Austria; 2) Division of Oncology, Department of Medicine I; 3) Department of Radiology, University of Vienna; 4) Stanford DNA Sequencing and Technology Center, Palo Alto.

Using DHPLC the frequencies of BRCA1 and BRCA2 mutations in 268 Austrian families with hereditary breast cancer only (HBC) or breast and ovarian cancer (HBOC) were determined. Disease associated BRCA1 mutations were detected in 20% of all families. The percentage was highest in 60 HBOC families (40%) whereas the overall frequency of BRCA1 was lower in 193 HBC families (14%). In the BRCA2 gene apparently disease-associated mutations were identified in 9%. The percentage of disease-associated mutations was highest in families with male and female breast cancer (29%). In HBC families 7% could be explained by BRCA2 mutations. In HBOC families 10% BRCA2 mutations were detected. One BRCA2 founder mutation (8983-1CtoT) accounted for 36% of all BRCA2 families in Austria. Together 29% of all 268 families could be explained by BRCA1 and BRCA2 mutations. 523 HBC / HBOC families were screened for 9 recurrent BRCA1 mutations that account for 60% of all BRCA1 mutation families in Austria. In 59 (11%) families one of these 9 recurrent BRCA1 mutations could be identified. Cys61Gly in exon 5 could be detected in 13 families and 1806 CtoT in 11 families. Both mutations are found world wide. The third most frequent mutation is a frameshift mutation in exon 11 3135del4 (9 families, 15%) that so far was only detected in families from Austria. In BRCA1 and BRCA2 mutation families more than 160 carriers were identified. Two thirds of the female mutation carriers were already affected with cancer. BRCA1 mutation carriers had an earlier median age of onset for breast cancer with 38 years than BRCA2 mutation carriers with 45 years. The median age for healthy BRCA1 and BRCA2 carriers was similar, 38 years for BRCA1 and 39 years for BRCA2 carriers.

**New LFS criteria identify more p53 mutation positive families than the classical LFS criteria.** *S. Kiuru-Kuhlefelt, K. Aittomäki.* Department of Clinical Genetics, University of Helsinki and Helsinki University Central Hospital, Finland.

Li-Fraumeni Syndrome (LFS) is a dominantly inherited cancer predisposition syndrome with high penetrance. The classical criteria for LFS were proposed in 1988 by Li and Fraumeni. These included a proband with a sarcoma <45 years of age, a first degree relative with cancer before this age, and another first or second degree relative with either cancer <45 years of age or a sarcoma at any age. With such a highly penetrant cancer predisposition syndrome, affecting children and adolescents, false diagnosis should be avoided. Then again, it is important to identify individuals at risk of LFS to plan appropriate follow-up. As the molecular genetic diagnosis of LFS has become available, the classical criteria maybe too stringent and are likely to miss some LFS families. Therefore, there is a need for defining new criteria for genetic testing of LFS. Recently Chompret et al. proposed criteria for p53 mutation testing. These were: 1. A proband with a characteristic LFS-tumor (sarcoma, brain tumor, breast cancer, adrenocortical carcinoma) <36 years and at least one first or second degree relative with a characteristic LFS-tumor (other than breast cancer, if the proband had this) <46 years or with multiple tumors. 2. A proband with multiple tumors, two of which represent characteristic LFS-tumors and the first of which occurred before 36 years. 3. A proband with adrenocortical carcinoma whatever the age of onset or family history. Seven families with a suspicion of LFS were referred to our unit for genetic counselling and were tested for p53 mutations. While three of the families fulfilled the classical LFS criteria, all seven families fulfilled the criteria suggested by Chompret et al. A p53 mutation was found in five families. Only two fulfilled the classical criteria, whereas all five were identified by the new criteria. In two families, which also fulfilled the new criteria, no mutation could be detected. These results tentatively suggest that the criteria by Chompret et al. are useful in identifying families for p53 analysis, but need to be tested in a larger number of families.

**Detection of Deletions in hMLH1 and hMSH2 Genes by Multiplex Exon Probe Southern Hybridization.** *M. Mai, G. Chong, B. Bapat, KC. Halling, SN. Thibodeau.* Department of Laboratory Medicine and Pathology, Mayo Clinic, 200 First St. SW Rochester, MN. 55905.

Alterations in DNA repair genes directly contribute to the pathogenesis of hereditary nonpolyposis colorectal cancer (HNPCC). Alterations in hMLH1 and hMSH2 account for the majority of germline mutations detected in HNPCC, with large deletions occurring in a fraction of these patients. Although there are several methods available to detect hMLH1 and hMSH2 deletions, it is often difficult to detect the abnormality and to define the extent of the deletions on an exon by exon level. The goal of this study was to generate a limited number of probes for Southern blot analysis that would span the length of the hMLH1 and hMSH2 gene, and at the same time allow one to ascertain the extent of these deletions. To accomplish this, individual hMLH1 and hMSH2 exons were PCR-amplified, radioactively labeled, and hybridized to EcoR I, Bgl II or Hind III cut genomic DNA. Results revealed probe-enzyme combinations that would generate non-overlapping bands on Southern analysis. This information was used to create a recombinant DNA probe that contained equimolar amounts of 4 to 6 hMLH1 or hMSH2 exons and which would generate non-overlapping bands on Southern analysis. To create these probes, recombinant PCR was performed to link different exons together and the linked exons were then subcloned into pGEM-T easy and pCR 2.1-TOPO vectors. The recombinants and the exons they contain are as follows: MLH1 recombinant 1: exons 2, 4, 7, 11, 13, and 16, MLH1 recombinant 2: exons 1, 5, 9, 10, 15, and 18; MLH1 recombinant 3: exons 3, 6, 12, and 14; MSH2 recombinant 1: exons 2, 4, 10, 11, and 12, and 14; MSH2 recombinant 2: exons 1, 3, 5, 8, and 16; and MSH2 recombinant 3: exons 6, 7, 9, 13, and 15. We have tested these probes on patients with hMLH1 and hMSH2 alterations and found that they allow us to more clearly identify and define the extent of the deletion on an exon-by-exon basis.

**Cancer-associated somatic mutations of the NF1 gene.** *S. Han, D. Cooper, M. Upadhyaya.* Medical Genetics, Cardiff, Wales, UK.

NF1, an autosomal dominant disorder, affects 1 in 4000 individuals world-wide. The condition is characterised by multiple benign neurofibromas, café-au-lait spots, Lisch nodules and an increased risk of malignancy. The 350kb NF1 gene contains 60 exons and disease-causing mutations are spread across the gene. Neurofibromin, the NF1 gene product, appears to be involved in the control of growth and differentiation through down regulation of Ras. The NF1 germline mutation spectrum is now well characterised but only limited information is available on the nature of the somatic lesions. Somatic NF1 mutations have also been identified in several tumour types not usually associated with NF1 patients. How NF1 gene mutations contribute to the formation of both NF1-associated and un-related sporadic tumours is not known. Somatic mutational spectrum of the NF1 gene may aid in the identification of other functional domains of neurofibromin, may improve our understanding of the genotype/phenotype relationship in NF1 and would also allow us to ascertain whether the site of germline mutations determines the location and nature of somatic changes as has been reported in FAP. Denaturing high performance liquid chromatography (DHPLC) was used to screen the entire NF1 gene for mutations. The detection sensitivity of DHPLC was evaluated in a retrospective study of a cohort of 111 unrelated NF1 patients with known germline mutations; 97% of lesions were detected. In a subsequent prospective study, mutations were identified in 34 individuals (68%). We have screened 26 NF1 patients with multiple tumours and have identified somatic mutations in 30/67(45%) tumours. Loss of heterozygosity was identified in 21/67(37%) tumours using 8 intragenic polymorphic markers. Microlesions were identified in 9 tumours (R304X, 1541-2delAG, 1889delT, S637R, 2033delC, 4773-5C-T, Q1785X, R2429X), 5 of these lesions represent novel changes. Interestingly, the alteration 2033delC was identified in two tumours from the same patient and all the characterised alterations are located outside the GAP-related domain (encoded by exons 21-27a) of neurofibromin, the only domain with a known function. Our data suggest that there is a predominance of truncating somatic mutations in the NF1 gene.

**Difficult genetic counseling in a family with pathogenic BRCA2 mutation.** *I.I. Ingargiola<sup>1</sup>, M. Smaers<sup>1</sup>, P.J. Van Cangh<sup>2</sup>, C. Verellen-Dumoulin<sup>1</sup>, K. Dahan<sup>1</sup>.* 1) Dept Genetics, UCL Saint-Luc Hosp, Brussels, Belgium; 2) Dept Urology, UCL Saint-Luc Hosp, Brussels, Belgium.

The origin of a breast cancer is genetic in 5% of cases with an autosomal dominant inheritance. When a mutation is found in a family, the prevention is very important for the sibship and sibling. We have studied one family of 26 members. In this family 8 members have been affected by one or several cancers (4 breast cancers including one male, 2 lung cancers, 1 colorectal cancer, 1 endometrium cancer and 2 bladder cancers). The proband (K.E.) is a female who developed a primitive adenocarcinoma of endometrium when she was 49 years old. At age 66, she was affected by a primitive bladder cancer. Her sister (K.M.) was affected at age 66 by a primitive left breast cancer, at age 74 by a primitive left lung cancer and at age 75 by a primitive bladder cancer. The family history is highly suggestive of a hereditary cancer susceptibility syndrome. A search for mutation in the BRCA1, BRCA2 and P53 genes was carried out for K.E. We didn't find any mutation for the BRCA1 and P53 genes. By using PTT followed by a sequencing of exon 11 of BRCA2, an insertion of an adenine with apparition of a premature stop codon (TGA) in position 2003: 6171insA. This mutation was not observed in K.M. The difference between the two patients are: the age of apparition of cancers (the apparition is later for K.M. than for the proband K.E.) and the degree of differentiation of bladder carcinoma (more differentiated for the proband K.E.). **Conclusion** : Firstly we report a pathogenic BRCA2 mutation in a woman with 2 epithelial cancers not usually found in BRCA2 hereditary breast cancer. Secondly the sister with breast cancer isn't a carrier of the germline mutation after verification of new DNA samples. The 2 sisters have developed a transitional cell carcinoma of bladder after smoking exposure. These results should be explained by the existence in this family of another deleterious gene such as Mismatch Repair Gene either or by the coexistence of associated factors (genetic or environmental) responsible of a phenocopy.

***SDHC* functions as a tumor suppressor gene in autosomal-dominant paraganglioma, type 3.** *S. Niemann*<sup>1</sup>, *W. Kummer*<sup>2</sup>, *P. Rustin*<sup>3</sup>, *U. Müller*<sup>1</sup>. 1) University Giessen, Institute of Human Genetics, Giessen, Germany; 2) University Giessen, Institute of Anatomy and Cell Biology, Giessen, Germany; 3) INSERM U393 Hôpital des Enfants Malades, Paris, France.

Paragangliomas (PGLs) are usually benign, neural-crest-derived tumors of the paraganglionic system. Most common locations include the carotid bifurcation, the vagal nerve and the middle ear. PGLs occur both sporadically and in a hereditary, autosomal dominant pattern. There are at least 3 loci in autosomal dominant PGLs. Two loci are maternally imprinted and have been assigned to 11q23 (*PGL1*) and 11q13.1 (*PGL2*). *PGL1* is caused by mutations in *SDHD*, the small subunit of cytochrome b of mitochondrial complex II (succinate ubiquinone oxidoreductase). There is no evidence of imprinting at a third locus, *PGL3*. Applying a functional cloning approach we recently identified *SDHC* (encoding the large subunit of cytochrome b of mitochondrial complex II) as the disease gene in *PGL3*. A start codon mutation was discovered in constitutive DNA from all histologically verified patients. No transcript of the mutated allele was detected in both peripheral lymphocytes and tumor tissue. Furthermore, LoH was observed at several loci flanking *SDHC* in 1q21. In order to substantiate functional loss of both copies of *SDHC* in tumor tissue at the protein level, we performed immunofluorescence studies using anti-*SDHC* antiserum (rabbit anti-human *SDHC*). There was no immunoreactivity in parenchymal tumor cells. However, surrounding non-tumor cells were labelled. Furthermore, *SDHC* was clearly present in a total of 8 sporadic paragangliomas. The findings are consistent with *SDHC* functioning as a tumor suppressor in *PGL3*.

**Fanconi anemia D2 (*fancd2*) knockout mice have a phenotype more severe than *fanca* and *fancc* mice, but milder than *brca1* mutants.** *S. Houghtaling*<sup>1</sup>, *C. Timmers*<sup>1</sup>, *C. Reifsteck*<sup>1</sup>, *S. Olson*<sup>1</sup>, *S. Jones*<sup>2</sup>, *M. Grompe*<sup>1</sup>. 1) Molecular and Medical Genetics, OHSU, Portland, OR; 2) Transgenic-Knockout Animal Core Facility, UMass Medical School, Worcester, MA.

Fanconi anemia (FA) is an autosomal recessive chromosomal instability syndrome associated with birth defects, progressive bone marrow failure, and cancer susceptibility. Cells derived from FA patients show elevated levels of chromosomal breakage and an increased sensitivity to DNA cross-linking agents. Genes for 6 of 8 known complementation groups (*FANCA-G*) have been cloned. The recently cloned *FANCD2* gene consists of 44 exons and is alternatively spliced in both the human and mouse. After DNA damage, *FANCD2* is monoubiquitinated and then targeted to nuclear foci together with *BRCA1*. Wild-type function of the multimeric FA protein complex consisting of *FANCA*, *C*, *E*, *F* and *G* is required for this *FANCD2* modification. To understand the *in vivo* role of this gene, we have disrupted *fancd2* by homologous recombination and generated mice homozygous for the targeted allele. In contrast to *brca1* knockouts, viable *fancd2* mutants were born in expected Mendelian ratios. The phenotype of *fancd2* mutant mice was similar to *fanca* and *fancc* mutant mice but was more severe. Gonads of both sexes showed decreased numbers of germ cells, but no other morphological abnormalities were found. The testicular volume and histology of testes was significantly different from either *fanca* or *fancc* mutants. Testicular weights were 97 +/- 4 mg in controls, 80 +/- 3 mg in *fanca*, 56 +/- 4 mg in *fancc* and 16 +/- 2 mg in *fancd2* mutants. Fibroblasts from *fancd2* mutant mice were also more sensitive to DNA crosslinkers. Primary cells were clearly sensitive to O<sub>2</sub> in culture. No obvious hematological abnormalities nor tumor development have been observed up to 3 months of age. The phenotype of the *fancd2* mutant mice supports the presumed role of the FA proteins in response to DNA damage. Together, the genetic and biochemical data suggest that wild-type *BRCA1* is required for function of the FA pathway, possibly as an ubiquitin ligase. In contrast, neither *FANCC*, *FANCA* or *FANCD2* are necessary for *BRCA1* function.

**Novel pathogenic missense mutations in BRCA1 and BRCA2 perturb three different aspects of protein function.**

*K. Hale<sup>1</sup>, T. Walsh<sup>1</sup>, E. Swisher<sup>1</sup>, K. Peters<sup>1</sup>, E. Levy-Lahad<sup>2</sup>, M-C. King<sup>1</sup>.* 1) Depts of Medicine and of Genomic Sciences, Univ Washington, Seattle, WA; 2) Shaare Zedek Medical Ctr, Jerusalem, Israel.

Most BRCA1 and BRCA2 germline mutations detected by conventional sequencing are nonsense mutations or small insertions or deletions that lead to frameshifts. A few missense mutations that predispose to breast and ovarian cancer have been observed in high risk families, particularly substitutions of the cysteine residues of site II of the RING finger domain. Among our families at high risk of breast and ovarian cancer, we have recently identified three novel missense mutations of BRCA1 and BRCA2 that perturb three different aspects of protein function. BRCA1 Leu1407Pro was inherited by four women who developed ovarian cancer (dx ages 42-76) in an exclusively ovarian cancer kindred of English ancestry (Family 350). The leucine at codon 1407 is evolutionarily conserved and lies in the middle of a coiled-coil domain critical to transcriptional activation function of BRCA1 (Hu et al., JBC 275:40910,2000). Substitution of proline for leucine disrupts the coiled-coil structure and severely impaired the activation function. Insofar as we know, Leu1407Pro is private in family 350. It was not present in 75 ovarian tumors, 65 breast cancer probands with a family history of ovarian cancer, and 400 breast cancer cases that includes Caucasian and African American women. BRCA1 Cys44Phe was identified in a family of Arab ancestry (Israeli family 4) with four cases of breast cancer (dx ages 30-35) and three cases of ovarian cancer (dx ages 22-40). Cys44 is a conserved residue of site I of the BRCA1 RING domain. Mutations in site I are residues are predicted to have more severe effects on RING domain structure than do mutations in site II. We suggest this mutation be tested in breast or ovarian cancer families of Arab ancestry. BRCA2 Met1Arg was inherited by five women with breast cancer (dx ages 41-55) in a family of Mexican ancestry (Family 6). Because this mutation destroys the wildtype start codon, translation is predicted to begin at codon 124. If the mutant protein is translated it would lack the putative transactivation domain encoded by exon 3.

**Phenotypic variation between two probands with FAP due to large deletions in exon 15 of the APC gene.** W.K. Kohlmann, P.A. Ward, P.M. Lynch, L-K. Su. University of Texas MD Anderson Cancer Ctr, Houston, TX.

Familial adenomatous polyposis (FAP) is caused by germline mutations at *APC*. FAP patients typically present with 100s to 1000s of colorectal polyps at a young age. However, patients carrying germline *APC* mutations at the first 4 exons, the alternatively spliced region of exon 9 and the 3' half of exon 15 usually develop an attenuated phenotype. We report two female probands with large deletions of exon 15 in *APC* who have highly divergent phenotypes. Proband 1 presented at age 21 with rectal bleeding, at which time colonoscopy identified innumerable polyps in her rectum and multiple small adenomas throughout the remaining colon. At age 55, Proband 1 was found to have severe villous adenomas of the duodenum and ampulla. The patient also has a history of epidermal cysts. Based on the family history, her disease appears to be due to a new mutation. She has had one affected son who has a similar expression of the disease. Proband 2 presented at age 42 with rectal bleeding, and colonoscopy detected between 70-90 polyps predominantly in the right colon with sparing of the rectum. Pathology of one polyp indicated adenocarcinoma. Proband 2 had a normal stomach and duodenum at time of diagnosis. She has a significant family history of colon cancer, with the average age of diagnosis 46 years, ranging from 36 to 59. Polyp number in the family also varies from the attenuated presentation of the proband to approximately 300 polyps in her brother at age 38. Mutation analysis of the entire *APC* coding region using protein truncating test did not identify a mutation in either family. By analyzing cDNA and genomic DNA for intragenic polymorphic nucleotides and genome walking, we found that these two families carried two different large deletions at *APC* that both deleted the entire exon 15. The variations between these two probands and within the family of Proband 2 suggests that other genetic factors may interact with the *APC* gene to determine the phenotype of an individual.

**Sublocalization of *LOH18CR*, a tumor suppressor gene implicated in osteosarcoma, to a minimal region between *D18S87* and *D18S42*.** M.J. Nellissery<sup>1</sup>, T.L. Johnson-Pais<sup>2</sup>, C. Buller<sup>2</sup>, P. Bhatia<sup>1</sup>, D.G. Ammerman<sup>1</sup>, A.M.

Deshpande<sup>1</sup>, D. Pathmanathan<sup>1</sup>, R.S. Benjamin<sup>3</sup>, R. Gorlick<sup>4</sup>, P.A. Myers<sup>4</sup>, R.J. Leach<sup>2</sup>, M.F. Hansen<sup>1</sup>. 1) Center for Molecular Medicine, Univ. CT Health Center, Farmington, CT; 2) Department of Cellular and Structural Biology, Univ. TX Health Science Center, San Antonio, TX; 3) Department of Sarcoma Medical Oncology, Univ. TX M.D. Anderson Cancer Center, Houston, TX; 4) Department of Pediatrics, Memorial Sloan-Kettering Cancer Center, New York, NY.

Previous analysis of tumor-specific loss of constitutional heterozygosity (LOH) had identified a putative tumor suppressor gene (*LOH18CR*) that mapped to a subregion of chromosome 18q21.3-q22.1 that was linked to both familial Paget's Disease of Bone and Familial Expansile Osteolysis. We have developed a minimal tiling BAC contig which spans this critical region of LOH. Eleven new highly polymorphic STR loci were identified within this minimal region of LOH using sequence data from our BAC contig and screening the contig by BLAST analysis. These new polymorphisms have enabled us to refine the minimal region of LOH which must contain *LOH18CR* to a chromosomal region distal to *D18S87* and proximal to *D18S42*. This region appears to exclude *TNFRSF11A* (*RANK*) and *BCL2*, but includes *SKD1*, *serpin B5* (*maspin*), *serpin B13* and *serpin B3*.

***BRCA1* and *BRCA2* founder mutations are not associated with a high risk of colorectal cancer.** *B.L. Niell<sup>1</sup>, G. Rennert<sup>2</sup>, L.P. Tomsho<sup>1</sup>, J.D. Bonner<sup>1</sup>, S.B. Gruber<sup>1</sup>*. 1) University of Michigan, Ann Arbor, MI; 2) Department of Community Medicine and Epidemiology, Carmel Medical Center and Technion Faculty of Medicine, Haifa, Israel.

Mutations in *BRCA1* and *BRCA2* profoundly increase the risks of breast and ovarian cancers among women, but it is not clear whether mutations in these genes increase the risk of colorectal cancer (CRC). Three founder mutations, *BRCA1* 185delAG and 5382insC, and *BRCA2* 6174delT, have a combined prevalence exceeding 2% among Ashkenazi Jews, permitting analysis of cancer-specific odds ratios in case-control studies. The relationship of these three founder mutations to CRC was examined in the Molecular Epidemiology of Colorectal Cancer (MECC) study, a population-based case-control study in northern Israel. Eligible cases from this ongoing study included 529 Ashkenazi Jews diagnosed with incident CRC in northern Israel between March 1998 and March 2001. Controls were 386 age, sex and clinic-matched Ashkenazi individuals without CRC. Genotyping for 185delAG, 6174delT, and 5382insC was performed by PCR restriction analysis, allele specific PCR, and allele specific oligonucleotide hybridization, respectively. Genotyping was successful for 513 (97%) cases and 377 (98%) controls. No significant associations between *BRCA1* or *BRCA2* founder mutations and CRC were identified. Twelve (2.3%) cases and ten (2.7%) controls carried one of the three mutations, yielding an odds ratio = 0.9 (95% confidence interval 0.4 - 2.1). Analyses stratified by specific mutation had limited power, especially for 5382insC, but no strong relationships with CRC were identified for 185delAG, 5382insC, or 6174delT. Adjustment for age did not measurably change the results of this unmatched, interim analysis. In conclusion, these data provide direct evidence that these three *BRCA* founder mutations do not confer a risk as high as the 4-fold increase that has been reported elsewhere in the literature. Furthermore, it is unlikely that carriers of these founder mutations in *BRCA1* or *BRCA2* are at an increased risk of colorectal cancer.

**Genome-wide screen with tetra-nucleotide repeats demonstrates infrequent allelic imbalance in benign peripheral nerve sheath tumors in NF1.** *M.A. LIEW<sup>1</sup>, K. TANITO<sup>1,2</sup>, Y. ZHANG<sup>1</sup>, M.N. HANG<sup>1</sup>, L. BALLARD<sup>1</sup>, S. SAWADA<sup>2</sup>, M. NIIMURA<sup>2</sup>, D. VISKOCHIL<sup>1</sup>.* 1) PEDIATRICS, UNIVERSITY OF UTAH, SALT LAKE CITY, UT; 2) DERMATOLOGY, JIKEI UNIVERSITY, TOKYO, JAPAN.

Approximately 20-25% of patients with neurofibromatosis type 1 (NF1) have benign peripheral nerve sheath tumors (PNSTs), also known as plexiform neurofibromas. Some of these tumors undergo transformation into malignant PNSTs (MPNSTs), however pathogenesis of malignant transformation has not been determined. Stable benign PNSTs have double inactivation of NF1, therefore we hypothesize that additional genetic changes must occur to lead to malignant transformation. A genome-wide tetra-nucleotide genotyping screen was implemented to evaluate allelic imbalance in DNA derived from different sites within 8 benign PNSTs from 8 individuals with NF1. Using Genotyper<sup>TM</sup> software the area under the allele-specific peaks and the ratio of the areas for two alleles was compared between blood and tumor DNA to estimate allelic imbalance in tumor-derived DNA template. A ratio of peak areas for informative alleles that was either less than 0.75 or greater than 1.25 in tumor versus blood DNA samples was scored as allelic imbalance. Loss of heterozygosity (LOH) was scored by a ratio less than 0.2, or greater than 5.0. This allele imbalance could reflect either LOH or extensive amplification of one allele.

We genotyped 39 tetra-nucleotide markers from the distal arms of 22 chromosomes. Chromosomes 2q and 20p were not represented in the screen. 2/8 PNSTs had LOH, 1 PNST had one marker with LOH and 3 markers with allelic imbalance, while the other had 9 markers with LOH and 12 markers with allelic imbalance. The remaining PNSTs had 1-8 sites of allelic imbalance. These data were unable to identify common markers in PNSTs, but may be used to potentially classify the malignant state of a tumor based on the number of markers that show a change. Use of these markers with adjacent sets of markers in an extended set of tumors would better define candidate genes that might contribute to NF1-related tumor formation and growth.

**Is the Fanconi anemia DNA damage response pathway independent of p53 regulation?** *S. Komaki, Y.M. Akkari, R.L. Bateman, M. Grompe.* Molecular and Medical Genetics, Oregon Health Sciences University, Portland, OR.

Fanconi anemia (FA) is an autosomal recessive disorder with a complex phenotype including bone marrow failure and cancer proneness. FA is genetically heterogeneous, and to date at least 8 complementation groups (FANCA-C, D1, D2 and E-G) have been identified. FA cells are hypersensitive to agents which generate interstrand DNA cross-links (ICL) such as mitomycin-C (MMC) and psoralen. The p53 protein has a multiple important functions in genomic instability including G1/S, G2/M and mitotic checkpoints after DNA damage. MMC treatment has been reported to induce increased p53 mRNA levels in different cell types. This raises the question, whether p53 is important in cellular responses to ICL. Several groups have published experiments addressing the question of a possible interaction between the FA and p53 pathways, but no consistent interactions were found. To further address this issue we have cross-bred p53 deficient and FAC mutant mice. FANCC/p53 double mutant mice showed no embryonic lethality and no obvious phenotypic differences between p53 mutants and FANCC/p53 double mutants at birth. The survival of mice lacking of p53 protein but either mutant, heterozygous or wild type mice in FANCC was compared. The average survival of double mutants was 128 days as compared to p53 mutants 159 days ( $p < 0.05$ ), indicating modestly increased genomic instability in double mutants. However, the survival of p53 heterozygotes, did not differ significantly depending on the FANCC genotype. Cells from different combinations of FANCC and p53 genotypes were examined for their response to ionizing radiation (IR) or ICL. Wild-type and FANCC mutant cells but not p53 mutant cells displayed a long-lasting 4N cell cycle arrest after ICL treatment. Interestingly, FANCC/p53 double mutant cells also arrested after IR or ICL treatment. This suggests that FANCC works independently of p53 during growth arrest after both IR and ICL treatment. Together these data suggest that p53 function is at least partially dispensable in FANCC mutant cells and that FANCC allele provides a p53 independent mechanisms of cell cycle arrest after ICL or IR treatment.

**Database to study genetic susceptibility to Gastric Cancer.** *M. Jaju*<sup>1</sup>, *A.R. Sepulveda*<sup>2</sup>, *D.Y. Graham*<sup>3</sup>, *L.E. Peterson*<sup>1</sup>. 1) Chronic Disease Prevention and Control Research Center, Dept of Medicine, Baylor College of Medicine, Houston, TX; 2) Dept of Pathology, University of Pittsburg Medical Center, Pittsburg, PA; 3) VA Medical Center, Houston, TX.

Gastric cancer remains one of the human tumors with worst prognosis having 5-year survival rates typically below 20 percent. It is not clear if gastric cancer aggregates in families due to genetic inheritance, shared common environmental factors, or both. Several studies indicate involvement of genes and interactive factors like H.pylori. The first step towards the search for susceptibility genes is to identify families with a positive history of the cancer. In this study, patients diagnosed and treated for gastric cancer at the Methodist hospital, Houston, TX since 1990 were selected from the cancer registry. Patients for this study were recruited after obtaining IRB approval and informed consent. A detailed cancer family history questionnaire was completed and family history was confirmed by telephone interview. The second step of this study was to design a relational database using Microsoft Access software. The data obtained was organized in the form and report to analyze using database queries. The response rate from the 200 patients invited was 12 percent. These 9 families have strong family histories of gastric cancer as well as other cancers such as breast, prostate, leukemia and lymphoma. The data will be employed for segregation analysis and blood samples for single nucleotide polymorphisms and other genetic linkage studies. The detail of the preparation of the relational database and the significant factors that influence the data analysis will be shown.

**A new syndrome associated with autosomal dominant inheritance of familial paraganglioma and gastric stromal sarcoma.** *C.A. Stratakis<sup>1</sup>, J.A. Carney<sup>2</sup>.* 1) UGEN/DEB, NICHD, NIH, Bethesda, MD; 2) Mayo Clinic, Rochester, MN.

Paragangliomas occur in von Hippel-Lindau disease, neurofibromatosis and in 3 other syndromes, PGL-1, -2, and -3, all familial conditions. This report describes 12 patients, 7 men and 5 women, aged 10 to 46 years, from 5 unrelated families that manifested paraganglioma and gastric stromal sarcoma. Three sibships and 2 consecutive generations in each of 2 families were affected. Seven patients had paraganglioma, four had paraganglioma and gastric stromal sarcoma (1 from each of 4 families), and 1 patient had gastric stromal sarcoma. The 4 patients with both tumors were each misdiagnosed as having the Carney triad. The paragangliomas were transmitted in a manner consistent with autosomal dominant inheritance and incomplete penetrance. The paragangliomas were the presenting tumor in 9 patients (a symptomless mass in 6 and hypertension in 3). Eight patients had multiple tumors, located in the neck (18), retroperitoneum (8), mediastinum (2), and adrenal (1). The tumor functioned in 7 patients. Two paragangliomas "recurred" following surgery. None metastasized. The gastric tumors occurred on the lesser curvature and in the antrum, caused mucosal ulceration, bleeding and anemia in 4 patients, were multiple in 4, recurred twice in 1 patient, and metastasized to local lymph nodes and peritoneum in 3. Eleven patients (92 %) are alive, 4 with, or probably with, untreated or residual paraganglioma and 1 with recurrent gastric stromal sarcoma and paraganglioma. One patient succumbed to recurrent paraganglioma and postoperative neurologic sequelae. Because of the rarity of gastric stromal sarcoma, its multifocality, and the unlikelihood of coincidental co-occurrence of paraganglioma and gastric stromal sarcoma, it is very probable that the 2 neoplasms constitute a novel familial syndrome distinct from the familial PGLs or the previously described Carney triad.

**Identification of a deletion in the DNA mismatch repair gene MSH2 by Southern blot analysis.** R.E. Pyatt<sup>1</sup>, H. Hampel<sup>2</sup>, M. Sedra<sup>1</sup>, R.W. Schafer<sup>1</sup>, M.B. Fuchik<sup>1</sup>, I. Comeras<sup>2</sup>, A. de la Chapelle<sup>2</sup>, T.W. Prior<sup>1</sup>. 1) Department of Pathology, Ohio State Univ, Columbus, OH; 2) Division of Human Cancer Genetics, Ohio State Univ, Columbus, OH.

Hereditary nonpolyposis colorectal cancer (HNPCC) is characterized by tumors demonstrating microsatellite instability (MSI) and inherited mutations in one of the seven DNA mismatch repair genes: primarily MLH1 or MSH2. While extensive research has been done identifying small types of mutations in these genes, there is little information in the literature examining the role of large, genomic rearrangements in the etiology of HNPCC. In this study, we report the identification of a large, genomic deletion encompassing the first two exons of MSH2 in multiple members of an Ohio family. Lymphocyte DNA from an individual with an MSI + mucinous colon adenocarcinoma was examined by Southern blot analysis using a cDNA probe spanning the first seven exons of MSH2. On a *HindIII* digest, compared to the pattern seen in 110 normal controls, a new, unique band was observed and subsequently shown to be maternally inherited from an obligate carrier diagnosed with a transitional cell carcinoma of the ureter. Both smaller cDNA probes and exon specific ones were used to demonstrate that probes containing exon 3 would specifically hybridize to the unique band, while probes to either exon 2 or exon 4 would not. Additional unique bands were identified on *NsiI* and *AflIII* digests and these results suggested the presence of a deletion involving MSH2 exons 1 and 2 in this family. Quantitative PCR reactions to exon 2 demonstrated a reduction in product by approximately one half compared to normal controls while similar reactions to exon 3 showed no such reduction. While the deletion breakpoints were being identified by a vectorette PCR strategy, 5 siblings of the original individual requested the analysis of their carrier status. Southern blots were performed using *HindIII* digests hybridized with the full-length MSH2 probe and identified the unique band in 1 of 5 additional siblings. This study further supports the role of large, genomic rearrangements in the DNA mismatch repair genes as a cause of HNPCC.

**Evaluation of breast cancer linkage to the putative BRCA3 locus on chromosome 13q21 in 128 multiple case families from the International BRCA3 Linkage Consortium.** *C.I. Szabo<sup>1</sup>, D. Thompson<sup>2</sup>, J. Mangion<sup>3</sup>, R. Oldenberg<sup>4</sup>, F. Odefrey<sup>1</sup>, S. Seal<sup>3</sup>, R. Barfoot<sup>3</sup>, D. Teare<sup>2</sup>, B. Weber<sup>5</sup>, P. Devilee<sup>4</sup>, D. Easton<sup>2</sup>, D. Goldgar<sup>1</sup>, M. Stratton<sup>3</sup> and International BRCA3 Linkage Consortium (IBXLC).* 1) International Agency for Research on Cancer, Lyon, France; 2) Strangeways Reserch Laboratories, University of Cambridge, UK; 3) Institute of Cancer Research, Sutton, UK; 4) Leiden University, Leiden, Netherlands; 5) Abramson Family Cancer Research Institute, University of Pennsylvania, PA.

The known susceptibility genes for breast cancer, including BRCA1 and BRCA2, only account for a minority of the familial aggregation of the disease. Hence, other genes remain to be identified. The recent report of a putative BRCA3 locus on chromosome 13q21 (Kainu et al., 2000) that may account for 65% of non-BRCA1/BRCA2 families has raised expectations that a major breast cancer susceptibility gene has been localized. We have evaluated the contribution of this candidate BRCA3 locus to breast cancer susceptibility in 128 high-risk breast cancer families of Western European ancestry with no detected BRCA1 or BRCA2 mutation. These families consist of 650 women affected with breast cancer (median = 5/family), with 56% diagnosed under age 50. Samples from 409 affected individuals were analyzed for linkage to 13q21, yielding an overall multipoint LOD score of  $-38.0$  at D13S1308. No evidence of linkage under locus heterogeneity was found (estimated proportion of linked families,  $a=0$ ; upper 95% confidence limit of 0.13). Adjustment for possible bias due to selection of families on the basis of linkage evidence at BRCA2 did not materially alter this result ( $a=0$ , upper 95% CL 0.17). The previously reported  $a$  of 0.65 is clearly excluded in our study (HLOD =  $-11.0$ , corrected HLOD =  $-7.6$ ). In summary, we find no evidence of a breast cancer susceptibility locus on 13q21. However, if such a gene does exist, it is likely to account for only a small proportion of all non-BRCA1/2 families, indicating that other susceptibility loci must exist. Further linkage studies in large series of multiple case families will be needed to identify remaining genes underlying familial aggregation of the disease.

**Functional significance of a novel H718Y hMLH1 alteration associated with increased colorectal cancer risk among African-Americans.** *T.K. Weber<sup>1</sup>, Z. Yuan<sup>1</sup>, D. McDermott<sup>1</sup>, N. Petrelli<sup>2</sup>, M. Rodriguez-Bigas<sup>2</sup>, B. Keitz<sup>2</sup>, T.S. Ravikumar<sup>1</sup>.* 1) Department of Surgery and Molecular Genetics, Ullmann 707, Albert Einstein College of Medicine, New York, NY; 2) Department of Surgical Oncology, Roswell Park Cancer Institute, State University of New York at Buffalo, Buffalo, NY.

**Introduction:** Germline mutations in the mismatch repair(MMR) genes, hMLH1 and hMSH2 are associated with significant increased risk of colorectal cancer. The American Cancer Society reports African-Americans sustain the highest rates of colorectal cancer incidence and mortality of any U.S. population group. We previously reported (JAMA 1999 281:2316-2320) a novel highly conserved hMLH1 H718Y alteration detected in 3 unrelated African- American early age of onset colorectal cancer patients. In our present study we utilized a *Saccharomyces cerevisiae* dominant mutator model to assess the functional significance of the H718Y alteration. **Methods and Results:** hMLH1 cDNA derived from a patient with a heterozygous hMLH1 718 alteration, CAC->TAC or from a normal donor without a hMLH1 alteration was expressed in a MMR proficient strain with the reporter plasmids. The resultant transformants were assayed on a plate containing X-gal. Transformants expressing the wild type hMLH1 uniformly appeared blue. Transformants carrying the H718Y alteration produced white colonies, indicating compromised or absent hMLH1 function. **Conclusion:** This results suggests the hMLH1 H718Y alteration is associated with compromised MMR function. To date the H718Y alteration has only been reported in African-American probands. This suggests a specific population association reminiscent of the I1307K APC gene colorectal cancer association reported among Ashkenazi Jews. Further investigations including additional yeast based functional assays, case control association studies and clarification of true population frequency of H718Y are underway in our laboratory. Confirmation of loss of function would allow the H718Y alteration to serve in the identification of individuals at increased risk of developing colorectal cancer and facilitate effective clinical surveillance for those most in need.

**Improved hMLH1 and hMSH2 mutation detection using denaturing high performance liquid chromatography (DHPLC) analysis.** Z. Yuan<sup>1</sup>, TS. Ravikumar<sup>1</sup>, D. McDermott<sup>2</sup>, N. Petrelli<sup>2</sup>, M. Rodriguez-Bigas<sup>2</sup>, H.M. Chin<sup>2</sup>, L. Hazard<sup>2</sup>, B. Keitz<sup>2</sup>, L. Cuomo<sup>2</sup>, T.K. Weber<sup>1</sup>. 1) Department of Molecular Genetics & Surgery, Ullmann 707, Albert Einstein College of Medicine, New York, NY; 2) Department of Surgical Oncology, Roswell Park Cancer Institute, State University of New York at Buffalo, Buffalo, NY.

**Introduction:** Supply, labor and time costs present significant challenges to efficient and reliable laboratory germline mutation detection. Denaturing high performance liquid chromatography (DHPLC) is a new high-throughput technique for gene mutation scanning. In this study we report a novel analysis of DHPLC as a mutation detection method comparing it directly to single strand conformation polymorphism (SSCP) analysis. **Methods:** All 35 exons of the hMLH1 and hMSH2 genes respectively were amplified in 31 early age of onset colorectal cancer patients. Each of the 1085 amplified exons were screened twice, initially using SSCP and independently a second time using DHPLC analysis. All SSCP and DHPLC derived candidate sequence variations were subjected to direct nucleotide sequencing for confirmation. **Results:** SSCP suggested alterations in 168 of the 1085 exons studied (15%). However, subsequent nucleotide sequencing confirmed sequence changes in only 28 of these 168 exons for a false positive rate of 82%. DHPLC identified each of the 28 sequence confirmed alterations. DHPLC analysis of the entire 1085 exons compliment produced no false positive results. However, an additional 5 unique exon alterations (not detected by SSCP) were identified by DHPLC analysis and confirmed by direct sequencing. **Conclusion:** These results indicate a clear specificity advantage for DHPLC over SSCP based exon mutation screening of the MMR genes hMSH2 & hMLH1. The very high rate of SSCP based false positives translates into considerable costs that are avoided when DHPLC is utilized as no false positives were detected with its use. In addition, our results suggest DHPLC also provides increased sensitivity over SSCP. We conclude DHPLC offers multiple advantages compared to SSCP and deserves further study as a method of first choice for MMR gene exon mutation screening.

**Genetic analysis of BRCA1 and BRCA2 in 100 males with breast cancer.** *C.R. Richardson, A.M. Deffenbaugh, T.S. Frank.* Myriad Genetic Laboratories, Inc., Salt Lake City, UT.

Numerous studies have associated male breast cancer with the presence of germline mutations in BRCA2 but the contribution of mutations in the BRCA1 gene remains unclear. The aims of this study are to determine the contribution of BRCA1 and BRCA2 mutations in males with breast cancer, and to correlate mutation status with the reported family history information. A total of 100 males with breast cancer who underwent genetic testing between June 1997 to May 2001 were studied. The males were tested through full sequence analysis of the coding and adjacent non-coding regions of both BRCA1 and BRCA2 (n=70), sequence analysis of either BRCA1 or BRCA2 only (n=11), or analysis of three founder mutations prevalent in the Ashkenazi Jewish population (n=19). Clinical information was obtained through a test requisition form submitted with each sample. Overall, 25 males harbored deleterious BRCA mutations, consisting of 8 with mutations in BRCA1 only, 15 with mutations in BRCA2 only, and 2 with one mutation in each. The median ages of diagnosis were 51 years for men with mutations in BRCA1, 58 years for men with mutations in BRCA2, and 59 years for men in whom no mutations were identified. Of the 31 males reporting Ashkenazi Jewish ancestry, 11 (35.5%) were positive for BRCA1 or BRCA2 mutations, with one patient harboring a mutation in both BRCA1 and BRCA2. Of the 12 mutations seen in this group, 11 were one of the three founder mutations (187delAG, 5385insC, or 6174delT). Of the 69 males who did not specify Ashkenazi Jewish ancestry, 14 (20.3%) were positive for BRCA1 or BRCA2 mutations, one of whom carried one mutation in each gene. Mutations were reported in 2 Ashkenazi Jewish males with breast cancer who indicated a negative family history of breast or ovarian cancer. In contrast, no mutations were identified in the non-Ashkenazi males who reported a negative family history. Mutations in BRCA1 as well as BRCA2 are responsible for a significant proportion of men with breast cancer tested in a clinical setting. Mutations in BRCA1 and BRCA2 are overall more prevalent in men of Ashkenazi ancestry, and are especially associated with a family history of breast or ovarian cancer.

**Protocols for the investigation of large, genomic rearrangements in the DNA mismatch repair gene MLH3 by Southern blot analysis.** *T.W. Prior, M. Sedra, M.B. Fuchik, R.E. Pyatt.* Department of Pathology, The Ohio State University, Columbus, Ohio.

Hereditary nonpolyposis colorectal cancer (HNPCC) is characterized by an early age of onset and tumors demonstrating microsatellite instability (MSI). While tumors in HNPCC are primarily caused by inherited mutations in three of the six DNA mismatch repair genes (MLH1, MSH2, and MSH6), a new DNA mismatch gene termed MLH3 was recently identified and its role in HNPCC remains unknown. In this study, we report the development of Southern blot protocols for the analysis of large, genomic alterations in MLH3. Two cDNA probes were designed to encompass a majority of the gene with the first spanning exon 1 (1.8 Kb) and the second extending from the 3' portion of exon 1 to exon 10 (2.2 Kb). Using these probes, the hybridization patterns for 20 normal controls were defined on either *Hind III*, *NsiI*, *BclI*, or *PvuII* restriction enzyme digests with limited polymorphic variation noted. Smaller MLH3 cDNA probes, exon specific probes, and sequence information from both Human genome projects were used to identify the exact exons corresponding to each band seen on these patterns. Individuals manifesting MSI+ colorectal cancer who were negative for MLH1 and MSH2 mutations both by direct genomic sequencing and Southern blot analysis are currently being analyzed for the presence of genomic alterations in MLH3. The protocols outlined here demonstrate effective means by which to address the involvement of large, genomic alterations in MLH3 in the etiology of HNPCC.

**Allele Class-independent Intrafamilial correlation of Age at Onset, Age at Hearing Loss and Number of Intracranial Meningiomas in neurofibromatosis 2 (NF2).** *Y. Zhao*<sup>1</sup>, *R.A. Kumar*<sup>2</sup>, *M.E. Baser*<sup>3</sup>, *D.G.R. Evans*<sup>4</sup>, *A. Wallace*<sup>4</sup>, *G.A. Rouleau*<sup>5</sup>, *V.F. Mautner*<sup>6</sup>, *L. Kluwe*<sup>7</sup>, *H. Joe*<sup>1</sup>, *J.M. Friedman*<sup>2</sup>. 1) Dept of Statistics, U. of British Columbia, Vancouver, BC, Canada; 2) Dept of Medical Genetics, U. of British Columbia, Vancouver, BC, Canada; 3) Los Angeles, California; 4) Dept of Medical Genetics, St. Mary's Hosp, Manchester, UK; 5) Ctr. for Research in Neuroscience, McGill U., Quebec, Canada; 6) Dept. of Neurology, Klinikum Nord Ochsenszoll, Hamburg, Germany; 7) Dept. of Neurosurgery, University Hosp. Eppendorf, Hamburg, Germany.

Mutation of the *NF2* tumour suppressor gene cause NF2, an autosomal dominant disease characterized by very high frequencies of vestibular schwannomas, schwannomas of other nerves, meningiomas, and gliomas. The disease is highly penetrant but manifests variable expressivity both within and between families. We have developed statistical models to quantify familial correlations of age at onset of the presenting symptom, age at onset of hearing loss, and number of intracranial meningiomas. A random effects model employing survival techniques to account for right censoring was used for age at onset of the presenting symptom and age at hearing loss. A negative-binomial gamma mixture model with penetrance dependent on time since onset was used for number of meningiomas.

Using these models, we demonstrated a significant intrafamilial correlation for each of the three features in 377 NF2 non-probands from 154 unrelated families: age at onset ( $\tau = 0.36$ ; 95% confidence interval 0.23-0.47), age at hearing loss (0.40; 0.23-0.55) and number of meningiomas (0.20; 0.04-0.36). Significant correlations were also observed within NF2 families with various specific classes of mutations: truncating mutations--age at first symptom (0.41; 0.05-0.67) and number of meningiomas (0.09; 0.01-0.17); splice site mutations--age at first symptom (0.28; 0.04-0.49) and number of meningiomas (0.37; 0.13-0.61); and missense mutations--age at hearing loss (0.64; 0.16-0.88). Our findings are consistent with effects of both allelic and non-allelic familial factors on the clinical variability of NF2.

**The Cooperative Family Registry for Breast Cancer Studies: A Resource for Researchers.** *R.T. Senie<sup>1</sup>, I. Andrulis<sup>2</sup>, M. Daly<sup>3</sup>, J. Hopper<sup>4</sup>, S. Buys<sup>5</sup>, D. West<sup>6</sup>, H. Anton-Culver<sup>7</sup>.* 1) Sch Public Health, Columbia Univ, New York, NY; 2) Cancer Care Ontario, Toronto, Can; 3) Fox Chase Cancer Center, Cheltenham, PA; 4) Univ of Melbourne, Carlton, Aus; 5) Huntsman Cancer Center, Salt Lake City, UT; 6) Northern Calif. Cancer Canter, Union City, CA; 7) Univ of Calif, Irvine, CA.

The NCI funded the Cooperative Family Registry for Breast Cancer Studies [CFRBCS], three population-based and three clinic-based sites with an Informatics Support Center, providing a resource of family-based data and biospecimens for multidisciplinary gene-environment etiologic studies of familial breast and ovarian cancer. The participating 6,502 families [14,925 individuals] represent a broad spectrum of familial risk: a male with breast cancer, breast or ovarian cancer diagnosed <45 years, diagnosis with both cancers, or multiple relatives diagnosed with either cancer. Proband assist in recruiting maternal and paternal relatives, women and men with or without cancer. Participants provide pedigree information, health history, dietary data, and cancer treatment history on CFRBCS questionnaires. Blood and tumor tissue sections are banked at each site following rigid quality control procedures. Personal identifiers are removed assuring confidentiality; coded data are transmitted to the Informatics Center. BRCA1/2 founder mutations have been assessed in 1,417 Ashkenazi families [2,494 individuals]; 226 families with 336 mutation carriers [47 male and 289 females] were identified including one male with breast cancer and 191 females with breast or ovarian cancer. 130 carriers [36 males and 94 females] remain unaffected. Cancer and vital status are updated annually. During the 5 year renewal CFRBCS will expand minority family recruitment, increase participants per family, and maintain this invaluable resource for use by the research community at large. Studies using Registry resources, approved by the external Advisory Committee, are currently being conducted by CFRBCS investigators and international collaborators. Information about the CFRBCS and application procedures are available on the NCI website [www-dccps.ims.nci.nih.gov/CFRBCS](http://www-dccps.ims.nci.nih.gov/CFRBCS).

**Predictive heterozygote testing for multiple endocrine neoplasia type 1 (MEN 1) in Northern Finland. O.**

*Vierimaa<sup>1</sup>, T. Ebeling<sup>1</sup>, S. Kytölä<sup>2</sup>, P. Salmela<sup>1</sup>, J. Leisti<sup>1</sup>.* 1) Departments of Clinical Genetics and Internal Medicine, Oulu University Hospital, Finland; 2) Laboratory of Cancer Genetics, University of Tampere and Tampere University Hospital, Finland.

MEN 1 is an autosomal dominant disorder with susceptibility to tumors of the parathyroid glands, endocrine pancreas or duodenum (GEP tumors), and anterior pituitary gland. We have ascertained 16 families with MEN 1 in Northern Finland with two founder mutations (1466del12 in 9 and 1657insC in 4 families) and two mutations (R527X and D418N) in singular families. In one family the diagnosis was done by linkage analysis. After genetic counseling the relatives at risk for MEN 1 were contacted by the counselees and those willing to participate received genetic counseling and possibility for heterozygote testing. The phenotypes of the observed heterozygotes were evaluated biochemically and radiologically. All patients and mutation carriers have been followed up by endocrinologists. Out of the 159 individuals tested 90 were found to be heterozygotes (84 mutation positive, 5 by linkage) including 26 probands or already known MEN 1 patients. Of the 81 patients with sufficient information 40 were regarded as healthy while 15 had been treated for one or more manifestations probably related to MEN 1. During the follow up 47 of the 55 previously undiagnosed heterozygotes were found to have primary hyperparathyroidism (PHPT), 25 had GEP-tumors, 14 had pituitary adenomas and 1 had a carcinoid tumor. Of the patients with PHPT 12 were treated surgically, as well as one of the patients with GEP- and carcinoid tumors, and one patient with a pituitary adenoma, respectively. Predictive testing of MEN 1 proved to be useful in the detection of the patients for early treatment. Genetic counseling including information about the pros and cons of the testing and careful follow up are essential in this process.

**Identification of a TNF-alpha nucleotide mutation in retinoblastoma patients.** *F. Pellestor<sup>1</sup>, I. Imbert<sup>1</sup>, D. Lohmann<sup>2</sup>, F. Munier<sup>3</sup>.* 1) Inst Genetique Humaine, CNRS, UPR 1142, Montpellier Cdx 5, France; 2) Inst Humangenetik, Essen, Germany; 3) CHU Vaudois, Lausanne, Switzerland.

Investigations on retinoblastoma with abnormalities on chromosome 6p have suggested that some genes on 6p could act in the tumor process. Interindividual variation in TNF-alpha expression has been described, indicating that the existence of functionally distinct TNF-alpha alleles could play a role in susceptibility to retinoblastoma. The search for heterogeneity within the TNF-alpha gene has disclosed several polymorphisms in the 5'UTR regulatory region which is crucial for the control of transcription. We have analyzed TNF-alpha gene sequence in 70 retinoblastoma patients. Ten of these retinoblastoma samples presented chromosomal abnormalities on 6p and have revealed an increase dosage of gene on 6p by prior CGH screening. These tumors were from patients with isolated unilateral retinoblastoma and in all tumors, two RB1 gene mutations were identified. Sequencing of the 5'UTR region of the TNF-alpha gene revealed a base substitution (T to C) at the position -28 as referred to mutation nomenclature. This single nucleotide mutation was present in 40 percent of the analyzed retinoblastoma tumors and was twice more observed in samples with chromosome 6p abnormalities. Since located in the regulatory region of the first exon of the TNF-alpha gene, this mutation does not disrupt the TNF-alpha protein sequence but could have implications for the level of TNF-alpha expression. This variation could modify the stability of secondary and tertiary mRNA structure and facilitate translation initiation, leading to an enhancement of TNF-alpha expression level in retinoblastoma tumors.

**Monoallelic expression of the paternal mutated allele in the pheochromocytoma of a patient with hereditary paraganglioma (PGL1) and a constitutional SDHD-gene mutation.** *A.S. Weinhaeusel<sup>1</sup>, P. Waldner<sup>1</sup>, R. Pfragner<sup>2</sup>, B. Niederle<sup>3</sup>, O.A. Haas<sup>1</sup>.* 1) CCRI, St Anna Children's Hosp, Vienna, Austria; 2) Inst. Path., University Graz, Austria; 3) Surgical Clinic, University Vienna, Austria.

Familial paraganglioma (PGL1; OMIM 168000) is a rare familial tumor predisposition syndrome. It results from mutations in the succinate-ubiquinone oxidoreductase subunit D gene (SDHD; Science 287:848;2000) that encodes the small subunit of cytochrome b in the mitochondrial complex II. Affected individuals develop slow growing tumors of the head and neck region, most commonly the carotid body. However, this is only the case, if the carriers inherit the mutation from their father. Although this pattern of inheritance is the classic clinical example of genomic imprinting, this phenomenon still lacks a molecular genetic explanation. We have detected a germ line missense mutation in the start codon of a patient with a paraganglioma and pheochromocytoma from a PGL1 family. This mutation enabled us to study the gene expression in the peripheral blood (PB) and in the corresponding pheochromocytoma tissue. In contrast to previous reports, we were unable to detect any SDHD m-RNA expression in the PB of either mutation carriers or normal controls. However, we experienced that due to the existence of several pseudogenes such expression studies are error-prone, in case DNA contamination cannot be excluded completely. In the tumor tissue, both alleles were present at the DNA level, whereas only the mutated paternal allele was expressed. Analysis of the methylation pattern in the 5'-CpG rich UTR of the SDHD gene with methylation-sensitive PCR did not reveal any allele-specific differences. Our preliminary observations provide a first glance on the potential mechanisms involved in the development of tumors in this tumor predisposition syndrome.

**Average risks of breast and ovarian cancer in women who carry a *BRCA1* or *BRCA2* mutation: a preliminary analysis of pooled family data from unselected case series.** P. Pharoah, A. Antoniou, H. Risch, S. Narod, J. Hopper, N. Loman, H. Olsson, O. Johansson, A. Borg, B. Pasini, P. Radici, D. Eccles, N. Tang, E. Olah, H. Anton-Culver, J. Eyfjord, D.G. Evans, C. Evans, J. Peto, D. Easton. BRCA1/2 Population Studies Collaborative Group.

Several methods have been used to estimate the ovarian and breast cancer risks for women who carry *BRCA1* or *BRCA2* mutations. Studies of multiple-case families have estimated risks to age 70 of 70-80%, while studies of families identified from unselected case series have estimated risks to age 70 of 40-60%. These differences may reflect the different sources of families, but the confidence limits have been wide. The purpose of this study was to collate family data from studies of *BRCA1/2* mutation prevalence in breast or ovarian cancer cases unselected for family history, in order to provide more precise estimates of average breast and ovarian cancer risks. So far, we have collected and analysed data from 13 studies that have screened a total of 4159 female breast cancer, 124 male breast cancer and 162 ovarian cancer cases for mutations in *BRCA1* and/or *BRCA2*. Family history data were available for 93 *BRCA1+* and 124 *BRCA2+* index cases. We used the pedigree information to estimate cumulative risks using a modified segregation analysis. The conditional likelihood of the pedigree was maximised given the genotype and phenotype of the index case. We parameterised the model in terms of log relative risks for mutation carriers compared to the general population in 10 year age groups. Non carriers were assumed to have the age-specific incidence of their population. The estimated cumulative risk of breast cancer in *BRCA1* mutation carriers was 41% (31-29) by age 50 and 64% (55-72) by age 70. The breast cancer risks for *BRCA2* mutation carriers at the same ages was 20% (12-27) and 49% (36-60). For ovarian cancer the risks by age 50 and 70 were 11% (7-18) and 37% (25-52) for *BRCA1* and 1% (0-1) and 20% (12-27) for *BRCA2*. These risks estimates are lower than those derived from selected multiple-case families. Analysis of a further four studies, which will almost double the number of mutation carriers, is in progress.

**Screening for founder mutations in BRCA1/2 tumor susceptibility genes among breast cancer families from North Sardinia.** *M. Pisano*<sup>1</sup>, *A. Cossu*<sup>2</sup>, *G. Palomba*<sup>1</sup>, *M.G. Sarobba*<sup>3</sup>, *A. Farris*<sup>3</sup>, *M.F. Dedola*<sup>4</sup>, *N. Olmeo*<sup>5</sup>, *A. Contu*<sup>5</sup>, *I. Persico*<sup>1</sup>, *M.P. Satta*<sup>1</sup>, *M. Ibbà*<sup>2</sup>, *M.R. Stratton*<sup>6</sup>, *M. Pirastu*<sup>1</sup>, *F. Tanda*<sup>2</sup>, *G. Palmieri*<sup>1</sup>. 1) Institute Molecular Genetics, Alghero, Italy; 2) Institute of Pathology, University of Sassari, Italy; 3) Dept. of Medical Oncology, University of Sassari; 4) Dept. of Radiotherapy, University of Sassari; 5) Dept. of Medical Oncology, A.S.L.1, Sassari; 6) Sanger Center, Cambridge, UK.

Genetically homogeneous Sardinian population can be helpful in defining the molecular basis of cancer. To evaluate the role of disease-causing mutations in breast cancer (BC), we screened tumor susceptibility genes BRCA1 and BRCA2 in cancer patients and their families from North Sardinia. Forty-seven BC families with at least 3 affected members, apparently unrelated and originated from the northern part of the island were selected. Mutation screening was performed on DNA from blood samples by a combination of techniques: haplotype analysis, DHPLC-based analysis, and automated sequencing. Among the BC families selected, only 3 presented association with ovarian cancer and in one of them we identified a new termination-codon mutation within the exon 11 of BRCA1 (L505Term). Two BRCA2 mutations, 8765delAG and I3412V, were detected in 6 and 1 (13% and 2%, respectively) families. Frequency of these mutations were then investigated in unselected BC patients from the same area of Sardinia: 8765delAG was found in 6/473 (1.3%) cases (all positive patients were from BC families with at least 3 cases), whereas none of the 61 BC cases analyzed presented the I3412V mutation. Altogether, 13 families with BRCA2 mutations were identified. Considering the total number of BC cases among the 53 families selected, BRCA2 mutations were registered in 7/13 (54%) families with 5 affected members, 4/17 (24%) with 4 BCs, and only 2/23 (9%) with 3 BCs. Although families studied here showed a clear predisposition to BC, majority of them have remained negative for mutations in BRCA1/2, suggesting that other mechanisms or genes are involved. However, BRCA2 mutations seem to be strongly correlated to breast cancer development among Sardinian families with high recurrence of cases.

**CHK2 in familial breast cancer.** *P. Vahteristo*<sup>1</sup>, *J. Bartek*<sup>2</sup>, *J. Bartkova*<sup>2</sup>, *S. Ojala*<sup>1</sup>, *H. Eerola*<sup>3</sup>, *J. Kononen*<sup>4</sup>, *P. Heikkila*<sup>5</sup>, *OP. Kallioniemi*<sup>4</sup>, *H. Nevanlinna*<sup>1</sup>. 1) Obstetrics and Gynecology, Helsinki University Central Hospital, Helsinki, Finland; 2) Institute of Cancer Biology, Danish Cancer Society, Copenhagen, Denmark; 3) Department of Oncology, Helsinki University Central Hospital, Helsinki, Finland; 4) Cancer Genetics Branch, NHGRI/NIH, Bethesda, MD; 5) Department of Pathology, Helsinki University Central Hospital, Helsinki, Finland.

CHK2 is a cell cycle checkpoint kinase that phosphorylates p53 in response to DNA damage. p53 also reciprocally downregulates CHK2, indicating that p53 and CHK2 may play interdependent and complementary roles in cell cycle regulation after DNA damage. Rare germline mutations in CHK2 have been found in families with Li-Fraumeni syndrome (LFS) or phenotypically suggestive of LFS. Previously, we found two CHK2 positive kindreds originally recruited through breast cancer patients. Here, we have further evaluated the role of CHK2 in hereditary breast cancer by analyzing the CHK2 expression on breast tumors from breast cancer families. A mouse monoclonal anti-CHK2-antibody was used in the immunohistochemical staining of a tumor micro-array including 186 breast carcinomas from 20 BRCA1/2 positive and 76 negative kindreds. In six tumors (five BRCA1/2 negative and one BRCA2 positive), grossly aberrant CHK2 expression was observed: both the staining intensity and the number of positive cells were reduced. In these six families, germline mutations in the CHK2 gene were searched for, and in one family a protein truncating mutation was found in exon 10 (1100delC). The proband was diagnosed with breast cancer at 41 years, and her mutation was inherited from the father diagnosed with prostate cancer at 76 years. In the maternal lineage, a BRCA1 mutation segregates in the family, and the proband's sister (breast cancer at 48 years) is a double heterozygote for both mutations. The same 1100delC CHK2 mutation has previously been found in one family by Bell et al. (1999) and by us now in three families, indicating this site as a mutational hot spot. Further analyses are under way to evaluate the frequency and clinical significance of the 1100delC-mutation in a larger sample material of breast cancer families and unselected breast cancer patients.

**Selection of Chromosome 11p Loss in the tumorigenesis of VHL-related Pheochromocytoma.** *B.T. Teh<sup>1</sup>, W.O. Lui<sup>2</sup>, J.D. Chen<sup>1</sup>, S. Glasker<sup>4</sup>, E. Kort<sup>3</sup>, C. Larsson<sup>2</sup>, H.P.H. Neumann<sup>4</sup>.* 1) Lab Cancer Genetics, Van Andel Research Inst, Grand Rapids, MI; 2) Department of Molecular Molecular Medicine, Karolinska Hospital, Sweden; 3) Laboratory of Analytical Cellular and Molecular Microscopy, Van Andel Research Inst, Grand Rapids, MI; 4) Department of Nephrology and Hypertension, Albert-Ludwigs-University, Freiburg, Germany.

By using comparative genomic hybridization (CGH), we characterized the genetic profiles of 36 VHL-related pheochromocytomas. We then compared the results with sporadic and MEN2-related pheochromocytomas, which are either previously reported or included in the present study. In 36 VHL-related tumors, loss of chromosome 3 and chromosome 11p were found in 34 tumors (94%) and 31 tumors (86%), respectively. There was significant concordance of deletions in chromosomes 3 and 11p ( $Kappa = 0.64$ ,  $p=0.0095$ ), and chromosome 11p deletions were only found in tumors exhibiting chromosome 3 deletions, suggesting that they are involved in the same genetic pathway in VHL-related pheochromocytoma. The loss of chromosome 11p appears to be VHL-specific and pheochromocytoma-specific. It is not present in any of the 10 studied cases of VHL-related CNS hemangioblastomas and is significantly less common in sporadic pheochromocytomas (13%;  $p<0.0001$ ) and MEN2-related pheochromocytomas (30%;  $p=0.0012$ ). In conclusion, we identified a novel genetic abnormality (i.e., loss of chromosome 11p), which coupled with the VHL mutation, is important in the tumorigenesis of VHL-related pheochromocytoma.

**cDNA array analysis of NF1 plexiform tumor Schwann cell cultures.** *S.A.M. Thomson<sup>1</sup>, L. Fishbein<sup>1</sup>, D. Muir<sup>2</sup>, M.R. Wallace<sup>1</sup>.* 1) Molecular Genetics and Pediatric Genetics, Univ. of Florida, Gainesville, FL; 2) Pediatric Neurology, and Neuroscience, Univ. of Florida, Gainesville, FL.

Neurofibromatosis 1 (NF1) is a common dominant autosomal disease occurring in about 1 out of 3500 births worldwide. The NF1 gene produces a transcript of 11-13 kb that encodes the tumor suppressor neurofibromin. The hallmark feature of NF1 is the neurofibroma, a benign fibromatous nerve sheath tumors containing primarily Schwann cells. Dermal neurofibromas are small and arise along peripheral nerve twigs. Plexiform tumors are often much larger, arising from more deeply placed peripheral nerves. Plexiforms and spinal neurofibromas can cause considerable medical problems, and there are no treatments other than surgery (often inadequate). Malignant peripheral nerve sheath tumors (MPNST's) occur in about 5% of NF1 patients and arise in pre-existing plexiforms. Neurofibromin is reduced/absent in a population of tumor Schwann cells (due to somatic mutation) and is thus likely a common first step in tumorigenesis. Little is known about whether loci other than NF1 are altered in plexiform neurofibromas. To address this, we compared RNA from plexiform tumor and normal Schwann cell cultures using the Atlas Human Cancer cDNA arrays. Our study included 9 plexiform tumor cell cultures and one normal NF1 nerve Schwann cell culture. Overall, the expression patterns of the tumor cultures were similar to that of normal Schwann cell cultures, although there was some heterogeneity. About a dozen transcripts (e.g. TIMP3, MMP11) had consistently elevated or decreased levels in the majority of samples. In addition, we compared 4 plexiform tumor cell cultures and one normal Schwann cell culture using the Human Cancer Affymetrix chips. Several genes are differentially expressed in both types of arrays, and additional genes have been identified utilizing the Affymetrix system. These differences are being confirmed with real-time PCR and these data and discussion will be presented. Identification of commonly-altered genes may lead to improved understanding of NF1 signaling, sub-classification of plexiform tumors, and identification of therapeutic targets.

**Wild-type BRCA2 is not sufficient to complement DNA damage repair deficiency of Capan-1 cell line.** *L.-K. Su.*  
Department of Molecular and Cellular Oncology, The University of Texas M. D. Anderson Cancer Center.

People carrying a mutant allele of *BRCA2* have increased risk for breast, ovarian, pancreatic and other types of tumors. *BRCA2* has been suggested to play an important role in repairing double strand DNA breaks (DSB) based on several observations. One is that *BRCA2* interacts with *RAD51*, an evolutionary conserved protein important for repairing DSB. The other is that mouse cells deficient of *Brca2* are highly sensitive to DNA damaging agents and have aberrant chromosomes. In addition, Capan-1 cell line has been shown to be more sensitive to DNA damaging agents and deficient in repairing DSB comparing to other human cell lines. Capan-1 is a human pancreatic cancer cell line and is the only human cell line known to not express wild-type *BRCA2*. The increased sensitivity of Capan-1 to DNA damage has been attributed to its lack of wild-type *BRCA2*.

I have been investigating whether expression of the wild-type *BRCA2* is sufficient to reduce the sensitivity of Capan-1 cells to DSB. I have generated two Capan-1 derivatives that constitutively express the wild-type *BRCA2* and another one that expresses the wild-type *BRCA2* under the regulation of tetracycline. I compared the sensitivity to g-radiation of the two constitutive *BRCA2*-expressing derivatives to that of the Capan-1, there was no detectable difference. I also compared the sensitivity to g-radiation of the regulated *BRCA2*-expressing Capan-1 derivative between when it expressed the wild-type *BRCA2* and when it did not express the wild-type *BRCA2*. Again, there was no detectable difference. These results suggest that expression of the wild-type *BRCA2* alone is not sufficient to reduce the sensitivity of Capan-1 cells to DSB. I am currently examining the sensitivity of these cells to DNA damaging chemicals and the ability of *RAD-51* in these cells to form g-radiation induced foci. My results will clarify the question of whether the difference in the sensitivity to DSB between Capan-1 and other human cell lines is only due to the lack of wild-type *BRCA2* in Capan-1 cells.

**A Novel High-Density Oligonucleotide Array for Hereditary Non-Polyposis Colon Cancer.** *D. Shanmugarajah*<sup>1</sup>, *S.M. Lipkin*<sup>2</sup>, *J.G. Hacia*<sup>3</sup>, *N. Hunt*<sup>4</sup>, *S.P.A. Fodor*<sup>4</sup>, *F.S. Collins*<sup>1</sup>. 1) Genetics and Molecular Biology, NHGRI/NIH, Bethesda, MD; 2) Dept of Medicine, University of California, Irvine, CA; 3) University of Southern California, Los Angeles, CA; 4) Affymetrix Corporation, Santa Clara, CA.

Hereditary Non-Polyposis Colorectal Cancer (HNPCC) is a highly penetrant, autosomal dominant syndrome characterized by early-onset colorectal, uterine, ovarian, renal, and small bowel cancer. Germline mutations in five mismatch repair genes (MSH2, MLH1, PMS1, PMS2 and MSH6) have been identified in families with HNPCC. Technical limitations associated with current mutational screening of candidate genes have placed increased emphasis on the development of new technologies to detect sequence changes underlying disease, especially when the candidate genes are large and all possible coding region changes must be found. High density oligonucleotide arrays (DNA chips) offer an attractive alternative to direct sequencing, and have been used previously to detect mutations in the BRCA1, BRCA2 and ATM genes. In this study we describe the use of DNA chips to screen MLH1, MSH2 and MSH6 for all possible sequence variations (HNPCC DNA Chip). These arrays consist of 25-mer oligos synthesized on a silicon chip. A total of 250,000 oligonucleotide features contain the complete MLH1, MSH2 and MSH6 sense and antisense coding sequences (>11kb). All single bp substitutions, deletions of 1-5bp, and 100 known mutations are tiled on the chips as well. We are currently determining the test operating characteristics of the HNPCC DNA Chip on patient samples with known mutations to determine sensitivity and specificity for mutation detection using this novel technology. In preliminary studies, 17 samples with known mutations have been tested, and 15 mutations (88%) were found. The chips are now being applied to look for HNPCC mutations in affected individuals with a family history of colon cancer.

**A novel APC splice mutation associated with attenuated FAP.** *J.L. Scalia<sup>1</sup>, I. Tepler<sup>1</sup>, P.L. Weinstein<sup>1</sup>, V.M. Pratt<sup>2</sup>, K. Snow<sup>3</sup>.* 1) Cancer Risk and Prevention Program, Stamford Hosp, Stamford, CT; 2) LabCorp, RTP, NC; 3) Molecular Genetics Laboratory, Mayo Clinic, Rochester, MN.

Adenomatous polyposis coli (APC) germline mutations are detected in an estimated 80 to 90% of familial adenomatous polyposis (FAP) kindreds. The detection rate for attenuated FAP (aFAP) is unclear but is definitely lower than that for classical FAP. Attenuated FAP is typically associated with later onset of fewer polyps and absence of extracolonic manifestations. We report a kindred (TSH-77-98) in which the affected family member presented with multiple polyps at age 42, without familial evidence of disease. Mutation screening by CSGE and DNA sequencing demonstrated the DNA alteration c.1548G>A, which is at the last nucleotide of exon 11. The affected codon is unchanged (L516L). Using the Neural Network Splice Site Predictor, c.1548G>A results in a decreased splice donor score from 1.00 to 0.84. The Gene Feature Search program FEXH showed a decrease in donor site probability from  $w=8.60$  to  $w=3.72$ . Using the program FGENESH, c.1548G>A caused the donor site to be not predicted (from a score of 14.94 for the donor site in wild-type sequence). Protein truncation testing (PTT) of APC segment 1 (performed twice using 2 blood specimens) identified a truncated product at 55kDa. A truncated RT-PCR product for segment 1 showed skipping of exons 2 to 14 although sequencing of genomic DNA did not identify any alterations in exon 1 or adjacent intronic sequence. The 55kDa protein product may have been derived from another slightly truncated RT-PCR product that could not be adequately resolved from the normal product to allow sequence analysis. Our findings suggest that the novel exon 11 alteration is a de novo deleterious mutation causing late-onset FAP. The atypical presentation supports previous associations between 5APC mutations and aFAP. This case also demonstrates the value of PTT in confirming the significance of equivocal germline APC sequence alterations.

**Common colon neoplasia is not linked to germline APC variants.** *G.L. Wiesner*<sup>1,2,4</sup>, *D. Daley*<sup>3</sup>, *P. Platzer*<sup>4,5</sup>, *H. Yan*<sup>5,6</sup>, *C. Ticknor*<sup>4</sup>, *R. Elston*<sup>3</sup>, *B. Vogelstein*<sup>5,6</sup>, *S. Markowitz*<sup>4,5</sup>. 1) Center for Human Genetics, University Hospitals of Cleveland; 2) Department of Genetics, Case Western Reserve University; 3) Department of Epidemiology, Case Western Reserve University; 4) Ireland Cancer Center, University Hospitals of Cleveland, Case Western Reserve University, Cleveland, OH; 5) Howard Hughes Medical Institute; 6) Oncology Center, Johns Hopkins Medical Institutions, Baltimore, MD.

First degree relatives of individuals with colon adenomatous polyps or CRC demonstrate a 2 to 3 fold risk for CRC, suggesting a genetic basis to CRC susceptibility in seemingly "sporadic" colon cancer. Recently, the carriage of the I1307K variant in the APC gene has been associated with a 2-3 fold increased risk of CRC in the Ashkenazi Jewish population, suggesting that "mild" variant alleles in the APC gene might act more generally as susceptibility genes accounting for a proportion of colon neoplasia in the general population. We tested this hypothesis by performing an affected sibling pair linkage analysis of the APC locus on 116 kindreds enrolled in the CWRU Colon Neoplasia Sibling Study (CNSS). Kindreds that conformed to diagnostic criteria for FAP and HNPCC were excluded from the analysis. 164 sibling pairs with pathologically verified CRC or adenomatous polyps were genotyped for two polymorphic markers (D5S82 and D5S346) flanking the APC locus. Preliminary results found no evidence for linkage with using a single point model-free linkage analysis (estimate of allele sharing =0.507; S.E.=0.0244; P value =0.38). Further, the transmission disequilibrium test (TDT) and Haseman-Elston regression analysis yielded non-significant results. While additional markers in the region are currently being genotyped to refine the estimate of allele sharing in these affected sibpairs, our results suggest that common forms of CRC are unlikely to be caused by variant alleles of the APC gene segregating in the general population.

**Antisense inhibition of methylenetetrahydrofolate reductase reduces cell survival of methionine-dependent colon carcinoma cells *in vitro*.** *J. Sekhon<sup>1</sup>, P. Pereira<sup>1</sup>, A.R. Schievella<sup>2</sup>, R. Rozen<sup>1</sup>.* 1) Departments of Human Genetics, Pediatrics and Biology, McGill University, Montreal, QC, Canada; 2) Variagenics Inc., Cambridge, MA.

Many diverse cancer cell types have been shown to be methionine (Met)-dependent. Methylenetetrahydrofolate reductase (MTHFR) catalyzes the conversion of 5,10-methylenetetrahydrofolate to 5-methyltetrahydrofolate (5-MTHF). 5-MTHF is a co-substrate for homocysteine remethylation to Met catalyzed by the vitamin B12-dependent enzyme Met synthase. This study aimed to determine if MTHFR is critical for Met synthesis and if MTHFR downregulation in transformed lines reduces cell survival. First, we examined the growth of normal fibroblasts, of MTHFR-deficient fibroblasts (WG 1554) and of colon carcinoma lines in Met-deficient medium (M-), in M- containing homocysteine and vitamin B12 (M-H+), and in replete medium. Second, to test the effects of decreased MTHFR levels, we transfected antisense oligonucleotides (ASOs) complementary to the MTHFR mRNA into the Met-dependent colon carcinoma cell line SW620. All tested cell lines showed sensitivity to M-, demonstrating that Met is needed to sustain cell growth. WG 1554 fibroblasts, with zero MTHFR activity, were unable to maintain cell growth in M-H+, likely due to the inability to synthesize 5-MTHF. Four colon carcinoma cell lines increased proliferation only slightly in M-H+, yet the growth of two normal fibroblast lines in M-H+ approached levels obtained in replete MEM, demonstrating the increased Met requirement of these cancer cell lines. To decrease MTHFR levels, two ASOs, 677T and EX5, were tested. SW620 cells treated with 400 nM of 677T decreased cell survival by approximately 70% ( $p < 0.0001$ ), and treatment with 400 nM of EX5 decreased cell survival by approximately 80% ( $p < 0.01$ ), compared to control ASO treated cells. MTHFR activity decreased by 80% after treatment with 677T, compared to the activity of control ASO treated cells ( $p < 0.01$ ). Western blot analysis showed a decrease in MTHFR protein levels after 677T or EX5 treatment. This study supports the notion that MTHFR inhibition by antisense or by other means might be useful in cancer treatment.

**The molecular genetic basis of multiple meningiomas.** *B. Heinrich, C. Hartmann, M. MacCollin.* Department of Neurology, Massachusetts General Hospital, Charlestown, MA 02129, USA.

Meningiomas are common tumors of the linings of the central nervous system, comprising one fifth of all intracranial neoplasms. Between 1 and 8% of patients with meningioma develop multiple meningiomas, a trait rarely reported to be transmitted in an autosomal dominant fashion. The only loci associated with sporadic meningioma are *NF2* on chromosome 22, and the related cytoskeletal element *DAL-1* on chromosome 18. We investigated these two loci in multiple meningioma patients. Seven multiple meningioma patients without evidence of *NF2* were identified; three had affected relatives. Unexpectedly, all affected individuals and their affected relatives were female. Exon scanning was used to search for alterations in the *NF2* and the *DAL-1* genes in genomic samples from tumor and blood specimens. Loss of heterozygosity (LOH) analysis was performed using intragenic and flanking markers at both loci. Truncating *NF2* mutations were detected in three tumor specimens, but were not present in the corresponding blood samples. Two tumors showed LOH at the *NF2* locus. All tumors showing alteration (mutation or LOH) at the *NF2* locus were from sporadically affected patients. *DAL-1* gene analysis revealed 3 missense alterations, 1 silent mutation in a codon wobble position and 1 change in the non-conserved region of intron 9. In contrast to the *NF2* results, all exonic alterations were found in paired blood specimens. LOH for chromosome 18 was not seen in any of these tumors. These results suggest that the molecular basis of sporadic and familial multiple meningiomas is fundamentally different, with *NF2* inactivation contributing significantly to the former condition. Non-truncating alterations in the *DAL-1* gene were common in this small cohort. Their contribution to predisposition to tumor formation is under study.

***MLH1* promoter hypermethylation in endometrial carcinoma.** *L.H. Honore*<sup>1</sup>, *C. Otto*<sup>2</sup>, *K. Helmle*<sup>2</sup>, *D. Whiteside*<sup>2</sup>, *S.E. Andrew*<sup>2</sup>. 1) Dept Pathology, Univ Alberta, Edmonton, AB, Canada; 2) Department of Medical Genetics, Univ Alberta, Edmonton, AB, Canada.

Microsatellite instability (MSI+), resulting from a lack of DNA mismatch repair, is observed in approximately 20% of sporadic endometrial tumours and over 90% of the endometrial cancers arising in hereditary non-polyposis colorectal cancer patients. Despite a lack of mismatch repair, less than 10% of MSI+ endometrial tumours have known mutations in *MSH2* or *MLH1*, the two major mismatch repair genes. It has been shown that promoter hypermethylation contributes to the inactivation of *MLH1* in such MSI+ mutation-negative tumours by silencing of transcription from the *MLH1* promoter. However, the particular sites that are critical for *MLH1* silencing are not known. We used the bisulfite sequencing assay, to study the methylation status of 44 CpG sites within the *MLH1* promoter region (spanning the region 226 to -724 bp upstream of the ATG) of 19 endometrioid tumours. Over 84% (16/19) of the MSI+ endometrioid tumours are completely or nearly completely methylated throughout the region examined. Three of 19 MSI+ and 5 of 7 MSI stable samples have large unmethylated regions, perhaps decreasing the level of methylation-mediated repression of the promoter. However, MSI stable samples with methylated sites as well as some unmethylated CpG sites within otherwise highly methylated regions in MMR deficient samples highlights the importance of using assays that assess CpG sites that are important for controlling gene expression for epigenetic analysis. From preliminary results, regions closer to the coding region appear to have a greater influence the microsatellite status of the tumour, likely through controlling the expression of *MLH1*. Thus, it is important to gain an overall understanding of the methylation status of the entire promoter in relation to gene expression, as methylation patterns change between regions.

**Molecular characterisation and identification of MEN1 gene mutations in families with familial isolated hyperparathyroidism(FIHP).** A. Villablanca<sup>1</sup>, WS. Wassif<sup>2</sup>, K. Jones<sup>2</sup>, M. Kassem<sup>3</sup>, T. Carling<sup>5</sup>, P. Harris<sup>4</sup>, O.

Vierimaa<sup>6</sup>, BT. Teh<sup>7</sup>, A. Höög<sup>8</sup>, C. Larsson<sup>1</sup>. 1) Department of Molecular Medicine, Karolinska Institute, Stockholm, Sweden; 2) Department of Chemical Pathology, Bedford Hospital, Bedford, United Kingdom; 3) University Department of Endocrinology and Metabolism, Aarhus Amtssyghus, Aarhus, Denmark; 4) Department of Oral Pathology, King's College School of Medicine and Dentistry, London, United Kingdom; 5) Department of Surgery, Uppsala University Hospital, Uppsala, Sweden; 6) Department of Clinical Genetics, Oulu University Hospital, Oulu, Finland; 7) Van Andel Research Institute, Grand Rapids, MI, USA; 8) Department of Oncology and Pathology, Karolinska Hospital, Stockholm, Sweden.

Familial isolated hyperparathyroidism (FIHP) is defined as hereditary primary hyperparathyroidism without association with other diseases or tumours. To date, FIHP has been defined to exist as a variant of other familial tumour syndrome in which primary hyperparathyroidism is the main feature, e.g. multiple endocrine neoplasia (MEN 1) and the hyperparathyroidism jaw-tumour syndrome (HPT-JT). Here we describe a subset of unreported families in an attempt to investigate the genetic background of FIHP. The entire MEN1 gene was sequenced for germline mutations and in addition tumour specimens were analysed using comparative genomic hybridisation (CGH) and loss of heterozygosity (LOH) studies. Genotyping and linkage analysis was carried out with microsatellite markers in the MEN1 locus and for the suggested HPT-JT region. In this study, we found germline mutations of the MEN1 gene, segregating with primary hyperparathyroidism. Copy number changes detected in the families with germline mutations included loss of chromosome 11. Other alterations discovered was loss of chromosome 15, 16 and gain of X. These results suggest that it is likely that the detected germline mutations would result in a non-functional menin protein causing a familial predisposition to cell proliferation in the parathyroid gland, consistent with a tumour suppressor mechanism. We conclude that the altered MEN1 gene function is of importance in the development and genesis of FIHP.

**Characterization of the chimeric erythropoietin receptor fusion protein in the TF-1 erythroleukemia cell line.**

*E.W.Y. Hsieh<sup>1</sup>, N.P. Rao<sup>3</sup>, D. Chen<sup>1</sup>, M.J. Pettenati<sup>4</sup>, H.S. Shim<sup>1, 2</sup>, L.A. Schimmenti<sup>1, 2</sup>.* 1) Human Genetics, UCLA, Los Angeles, CA; 2) Pediatrics, UCLA, Los Angeles, CA; 3) Pathology and Laboratory Medicine, UCLA, Los Angeles, CA; 4) Pediatrics, Wake Forest University, Winston-Salem, NC.

Erythroleukemia is a rare hematologic malignancy that carries a poor prognosis. The role of the Erythropoietin Receptor (EpoR) in the pathogenesis of erythroleukemia has been an area of great interest. In the human erythroleukemia cell line, TF-1, a chromosome rearrangement was discovered at the EpoR locus, 19p13.3 (Ward et al, 1992, *Exp Hematol*; 20:371). The rearrangement deletes the 3'end of the EpoR gene and replaces it with a novel sequence that we call the EpoR-fusion partner. The abnormal EpoR fusion partner chimera in TF-1 cells produces a highly expressed message which is translated into a protein with deletion of the C-terminus of the EpoR. In order to understand the biological significance of the EpoR-fusion partner chimera, we transfected 32D cells, an immortalized growth factor dependent murine myeloid cell line, with cDNA constructs encoding the abnormal EpoR fusion partner chimera (EpoRTF-1) and an EpoR that is truncated at the site of the translocation (EpoRT). We assayed proliferation rates of the transfected cells growing in Epo. We observed that EpoRTF-1 and EpoRT cells proliferate at similar rates and that the EpoRTF-1 construct does not confer growth factor independence. We also obtained a BAC clone containing the fusion partner and mapped it to chromosome 8 by fluorescent-in-situ hybridization. Using this BAC clone we assembled a contig containing the EpoR fusion partner gene and analyzed the sequence using bioinformatic tools. Our results show a predicted gene in our sequence which matches a mouse protein secreted from lymphocytes. We are currently cloning the human homologue. Our results show that one copy of the EpoR locus in TF-1 cells has undergone a translocation between chromosome 19 and chromosome 8 and that this translocation may take place within a novel human gene.

**Molecular evidences that recurrent breakage at the common fragile site FRA7G, might lead to amplification of the MET oncogene in a human carcinoma.** A. Hellman<sup>1</sup>, E. Zlotorynski<sup>1</sup>, S.W. Scherer<sup>2</sup>, J. Skaug<sup>2</sup>, B. Kerem<sup>1</sup>. 1) Dept Genetics, Hebrew Univ Jerus, Jerusalem, Israel; 2) 1Department of Genetics, The Hospital for Sick Children, Ontario, Canada.

Specific chromosomal structures known as 'common fragile sites' (CFS) are prone to breakage and rearrangements in culture cells. In rodent model for oncogene amplification, the cytogenetic locations of CFS coincided with recurrent chromosomal breaks that drove breakage-fusion-bridge (BFB) cycles, leading to intra-chromosomal amplification (ICA) of selected genes. Whether BFB cycles are underlying ICA of human oncogenes, and whether CFS breaks drive these amplifications, awaited molecular analysis of amplicons and of their adjacent CFS. Here we study the structure of MET ICA in the GTL-16 cells, deriving from a human gastric carcinoma. Our analysis showed that two large amplicons (~8 and ~10 Mb), both containing MET, are organized in a head-to-head structure and in equal-spaced intervals. This organization fits well with the predictions of the BFB model. We further mapped two chromosomal breakpoints, which defined the centromeric boundaries of these amplicons. Next, we characterized the regions which harbors and flanks the CFS, FRA7G. We found two distinct regions within FRA7G: one encompassed ~700 kb including MET, comprised FISH probes that spanned the cytogenetic appearance of FRA7G. This region replicated at mid-S phase and exhibited intrinsic replication perturbation, as previously found in another CFS, FRA7H. The other FRA7G region, encompassed at least 2.8 Mb including the centromeric boundaries of the GTL-16 amplicons, comprised clones that hybridized only to the telomeric side of FRA7G, although these clones lie on the centromeric side of the physical map. We showed that this is not the result of genomic rearrangements, thus might reflect the unusual chromatin organization at active (exhibited) CFS. Our findings suggests that activation of common fragile sites might lead to amplification of oncogenes, as well as to other chromosomal rearrangements, thus may play an important role in both the generation of tumor cells and in their evolution towards increasingly malignant phenotypes.

**Detecting gene amplification in breast cancer by combining Gene expression profiling and Gene mapping.** *M.H. Polymeropoulos<sup>1</sup>, A. Baras<sup>1</sup>, T.M. Walz<sup>2</sup>, I. Kwon<sup>1</sup>, M.A. Dressman<sup>1</sup>.* 1) Pharmacogenetics, Novartis Pharmaceuticals Corporation, Gaithersburg, MD; 2) Department of Biomedicine and Surgery, Faculty of Health Sciences, Linköping University, S-581 85 Linköping, Sweden.

Global gene expression analysis using microarrays has been used to characterize the molecular profile of tumors. Gene expression variability at the mRNA level can be caused by a number of different events, including novel signaling, downstream activation of transcription enhancers or silencers, somatic mutation and genetic amplification or deletion. Gene amplifications are commonly observed in cancer and often include known oncogenes. The tyrosine kinase-type cell surface receptor, ERBB2, is an oncogene located on chromosome 17q22. ERBB2 is amplified in 25-30% of breast tumors. We report here two genes, PNMT and MLN64, which are co-expressed in 45 breast cancer biopsies with ERBB2 and also map within the same chromosomal location. Co-expression and co-localization of PNMT, MLN64 with ERBB2 suggests that the amplification of ERBB2 includes the chromosomal region that harbour these genes. This approach of combining Gene Expression profiling and gene Mapping (GEM) can be further exploited for the identification of gene deletions or amplifications.

**Multiple fragile sites are deleted in cancer cells.** *M.F. Arlt<sup>1</sup>, D.G. Beer<sup>2</sup>, T.W. Glover<sup>1</sup>*. 1) Department of Human Genetics, University of Michigan, Ann Arbor, MI; 2) Department of Surgery, University of Michigan, Ann Arbor, MI.

The colocalization of common fragile sites and translocation breakpoints has suggested that fragile sites play a role in genomic rearrangements seen in cancer. We investigated five common fragile sites (FRA3B, FRAXB, FRA7G, FRA7H, and FRA16D) for deletions in 21 cancer cell lines and 6 primary esophageal adenocarcinomas. PCR analysis revealed FRA3B to be the most frequently deleted fragile site with 6/27 (22.2%) showing homozygous deletions. 14.8% (4/27) of the samples were characterized by deletions at FRAXB. 11.1% (3/27) of the samples had homozygous deletions at FRA16D. FRA7G and FRA7H each had homozygous deletions in one tumor (3.7%). Overall, one third (9/27) of the specimens were characterized by at least one fragile site deletion. 11.1% (3/27) of the samples had deletions at more than one fragile site. None of the samples had deletions at any of the six control markers analyzed. Also, deletions were mostly restricted to within the fragile sites tested, with only one tumor (3.7%) showing deletions of sequences immediately flanking FRAXB and FRA16D. In addition, each fragile site was deleted in at least one tumor or cell line. PCR analysis revealed two cell lines with apparently identical deletion breakpoints that colocalize with the boundaries of FRAXB at DXS1130 and DXS1133 on Xp22.3. One of these cell lines, BIC-1, was treated with aphidicolin and found to lack gaps and breaks at FRAXB in 100 metaphases examined, indicating that the deletion eliminated sequence necessary for fragility. The two primary tumors with FRAXB deletions also share the same proximal deletion boundary with these two cell lines. The colocalization of fragile site boundaries and deletion breakpoints suggests that fragile sites are mechanistically involved in the deletion process in these regions. We have shown that deletions occur at multiple common fragile sites, including FRAXB and FRA3B, suggesting that instability at fragile sites is a general phenomenon in some tumors.

**Genome-wide screening of genes associated with chemosensitivity of human cancer xenografts by means of cDNA**

**microarray.** *H. Zembutsu<sup>1,5</sup>, T. Tsunoda<sup>2</sup>, Y. Furukawa<sup>1</sup>, Y. Ohnishi<sup>3</sup>, T. Katagiri<sup>1</sup>, J. Okutsu<sup>1</sup>, Y. Ueyama<sup>4</sup>, N.*

*Tamaoki<sup>3</sup>, K. Hirata<sup>5</sup>, Y. Nakamura<sup>1</sup>.* 1) Hum. Genome Center, Inst. of Med. Sci., Univ Tokyo, Tokyo, Japan; 2) Med. Inf., SNP Res. Center, The Inst. of Physical and Chemical Research, Tokyo, Japan; 3) Cent. Inst. for Experimental Animals, Kanagawa, Japan; 4) Dept. of Pathology, Tokai Univ. Sch. of Med., Kanagawa, Japan; 5) 1st Dept. of Surg., Sapporo Med. Univ., Hokkaido, Japan.

One of the most serious concerns in present cancer therapy is that we have no appropriate way to predict the sensitivity or toxicity to anticancer drugs. Hence, establishment of the predictive method is an urgent issue to be solved. In order to identify genes possibly associated with chemosensitivities to nine different anticancer drugs, we analyzed expression profiles of a panel of 85 human cancer xenografts derived from nine organs by means of cDNA microarray representing 23,040 genes. The human cancer xenografts were implanted into nude mice, and their chemosensitivities to anti-cancer drugs including 5FU, ACNU, ADR, CPM, DDP, MMC, MTX, VCR, and VLB were measured. Hierarchical cluster analysis using expression profiles of the 23,040 genes categorized the xenografts approximately into groups of organ from which they were established. We compared the expression profiles with chemosensitivities to each anti-cancer drug, and identified 1578 genes significantly correlated to the chemosensitivities. These data provide important information for identification of useful predictive markers for drug sensitivity, for the selection of personalized chemotherapy with effective anti-cancer drugs, and for improvement of their effect by modulating genes associated with drug sensitivity.

**Survival after radical radiotherapy for prostate cancer in a UK series of familial and sporadic cases. A.**

*Falconer*<sup>1</sup>, *A. Norman*<sup>2</sup>, *D. Dearnaley*<sup>1,2</sup>, *A. Ardern-Jones*<sup>2</sup>, *A. Murkin*<sup>2</sup>, *R. Eeles*<sup>1,2</sup>. 1) Cancer Genetics Unit, Institute of Cancer Research, Sutton, Surrey, UK; 2) Royal Marsden NHS Trust, Downs Road, Sutton, Surrey, UK.

Prostate cancer is a major public health problem. Approximately 13000 cases are diagnosed each year in the UK, and in the US it is the commonest malignancy in men, with over 180000 new cases expected to be diagnosed in 2000. Studies have shown that the risk of developing prostate cancer is increased 2-3 fold in the first degree relatives of cases. Other reports have indicated that familial cases have earlier onset compared to sporadic cases, but there is concern about the confounding effect of PSA screening. However no difference in survival between the two groups has been reported. A 20 year series of men with organ-confined and largely clinically detected prostate cancer treated with radical radiotherapy at the Royal Marsden Hospital further supports this finding. 1036 men were treated, of whom 107(9.7%) had a family history of prostate cancer. The 5-year overall survival was 68% in sporadic cases and 76% in familial cases (HR=0.77, 95%CI 0.52-1.03). Disease specific survival will be presented. No statistically significant difference was found in overall survival in sporadic vs. familial cases in this group of UK patients. Funded by National Lottery Charities Board.

**Prophylactic Bilateral Oophorectomy and Breast Cancer Risk Reduction: A Pilot Study.** *J.E. Olson, S.J. Iturria, J.L. Hernandez, L.C. Hartmann, T.A. Sellers.* Mayo Clinic Cancer Center, Rochester, MN.

**Background:** Estrogens are clearly implicated in the pathogenesis of breast cancer. The ovaries are the primary source of circulating estrogens in premenopausal women. Removal of the ovaries has been shown to reduce risk of breast cancer, but the benefit of this procedure in women with familial risk is not well established. **Objective:** To investigate whether removal of the ovaries is an appropriate clinical management tool for women at high or moderate risk of breast cancer (BrCa) based on family history of breast cancer. A pilot study was conducted to determine the feasibility of creating an oophorectomy cohort at Mayo Clinic. **Methods:** Women were identified from the Mayo Clinic Surgical Index whose surgical code indicated a possible bilateral oophorectomy during 1970 - 94 and who were less than age 60 at time of surgery. A random selection of charts (n=2272) was reviewed from all even-numbered years until at least 50 eligible women were identified from each year. Information was collected via mailed questionnaires with telephone follow-up of non-responders. **Results:** Of 852 eligible women, 680 women (80 percent) provided data (645 self and 35 surrogate respondents), 7 percent refused, 2 percent were deceased, 11 percent could not be located or were unable to participate for miscellaneous reasons. Women were grouped into low risk (no BrCa in 1st or 2nd degree relatives, N=237) and moderate/high risk (M/H, 1 or more relatives with BrCa, N=248). Based upon 1978-98 SEER rates (low risk) and the Gail model (M/H), 16.2 cases of BrCa were expected in M/H women, 12 were observed (p=0.25). In low risk women, 10.3 BrCa cases were expected, 5 were observed (p=0.05). Among women with surgery before age 51, there was an even more pronounced difference between the observed and expected numbers of cancers. In M/H women, 11.6 cases expected, 6 were observed (p=0.05); 6.9 cases were expected and 2 were observed in low risk women (p=0.01). **Conclusion:** In these pilot data, oophorectomy was associated with a reduction in BrCa in both M/H and low risk women. These results need to be confirmed within the entire cohort of women.

**Knowledge, Awareness, Intentions and Decisions Regarding Genetic Testing for HNPCC.** *D. Hadley<sup>1</sup>, J. Jenkins<sup>2</sup>, E. Dimond<sup>2</sup>, D. Liewehr<sup>3</sup>, S. Steinberg<sup>3</sup>, I. Kirsch<sup>2</sup>.* 1) NHGRI, NIH, Bethesda, MD; 2) NCI, NIH, Bethesda, MD; 3) NCI, Biostatistics, Bethesda, MD.

The application of genetic testing to refine cancer risks is most often discussed in the context of families with inherited breast/ovarian cancers. We seek to understand factors that affect decisions regarding genetic testing in families with Hereditary Nonpolyposis Colorectal Cancer (HNPCC). Baseline responses by the first 104 participants focusing on awareness, knowledge, intentions, and decisions regarding genetic testing for HNPCC are presented.

Adults with colon cancer (MSI+) and a family history suggestive of HNPCC complete a baseline questionnaire assessing demographic and psychological variables along with cancer screening practices. Participants are then provided a structured education session followed by counseling and the option of genetic testing. Psychological and behavioral outcomes are reassessed at 6 and 12 months. For those choosing testing, results and supportive counseling occur in person. First-degree adult relatives of probands with identified HNPCC germ-line mutations are offered participation.

Of the one hundred sixty-four (164) persons identified as eligible, one hundred four (104) elected to participate (63%). As baseline, sixty-four percent (64%) of participants had heard "almost nothing" or "relatively little" about genetic testing for colon cancer. Despite this relative lack of information, a majority of participants (97%) stated intentions (probably or definitely) to pursue genetic testing prior to education and counseling. The majority of participants (51%) identified learning about their children's risks of developing cancer as the most important reason to consider genetic testing. Thirty-nine percent (39%) identified concerns regarding the potential impact on insurance coverage as the most important reason to not undergo genetic testing. Fifty-one percent (51%) of eligible family members elected to pursue genetic testing. Of those opting to participate in the study, 96% elected to undergo testing. Further descriptive and statistical data will be presented.

**Online disease-specific variant database for familial melanoma.** *D.C-Y. Fung<sup>1</sup>, E.A. Holland<sup>1,4</sup>, B. Bressac-de Paillerets<sup>2,4</sup>, T.M. Becker<sup>1</sup>, N.K. Hayward<sup>3,4</sup>, G.J. Mann<sup>1,4</sup>.* 1) Westmead Institute for Cancer Research, University of Sydney at Westmead Millennium Institute, NSW, Australia; 2) Institut Gustav Roussy, Villejuif, France; 3) Queensland Institute for Medical Research, Herston, QLD, Australia; 4) Melanoma Genetics Consortium.

A proportion of melanoma-prone individuals in both familial and non-familial contexts has been shown to carry inactivating mutations in either *CDKN2A* or, rarely, *CDK4*. *CDKN2A* is a complex locus that encodes two unrelated proteins from alternately spliced transcripts that are read in different frames. The alpha transcript (exons 1a, 2 and 3) produces the p16INK4A cyclin-dependent kinase inhibitor, while the beta transcript (exons 1b and 2) is translated as p14ARF, a positive regulator of p53 levels through binding to hDM2. Variants in exon 2 can affect both proteins and insertions and deletions in exons 1a, 1b and 2 can theoretically generate p16INK4A-p14ARF fusion proteins. No online database currently takes into account all the consequences of these genotypes, a situation compounded by some problematic previous annotations of *CDKN2A*-related sequences and descriptions of their mutations. We are therefore establishing a database of germline variants observed in all loci implicated in familial melanoma susceptibility. It collates information for each reported genotype on its molecular outcomes, historical description, methods of detection, biological effects and population genetics. The database was developed on the Linux/Intel platform and is managed under the DBMS, PostgreSQL 7.0. Java servlets contained within an Apache Tomcat-Jakarta 3.2 server are being developed for handling the data querying logic and posting HTML reports to a client-side browser. The database is being used to organise information about melanoma susceptibility gene variants for the Melanoma Genetics Consortium and will be made publicly available to facilitate research and clinical investigation of melanoma predisposition.

**Relationship of P gene with human eye color and dysplastic nevi or melanoma.** *T.R. Rebbeck<sup>1</sup>, P.A. Kanetsky<sup>1</sup>, A.H. Walker<sup>1</sup>, R. Holmes<sup>1</sup>, A.C. Halpern<sup>2</sup>, D.E. Elder<sup>1</sup>, D. Guerry<sup>1</sup>.* 1) University of Pennsylvania School of Medicine, Philadelphia, PA; 2) Memorial Sloan-Kettering Cancer Center, New York, NY.

Multiple genes have been inferred to play a role in the determination of eye color, and eye color has been reported as a melanoma risk factor. The P gene, the human homologue to the mouse pink-eye dilution locus, is involved in the regulation of human pigmentation. Mutations in the P gene are associated with oculocutaneous albinism type 2 and other phenotypes that confer eye hypopigmentation. The P gene is located on chromosome 15q11.2-q12, which is also the location of a putative eye pigmentation gene (EYCL3) inferred to exist by linkage analysis. Therefore, the P gene is a strong candidate for determination of human eye color. We studied a sample of 681 individuals with invasive melanoma (MM) with or without dysplastic nevi (DN), DN only, and controls. Subjects were significantly less likely to have blue or gray eyes if they had P gene variants Arg305Trp ( $p=0.002$ ), Arg419Gln ( $p=0.001$ ), or the combination of both variants ( $p=0.003$ ). In individuals who carry Trp305 alleles, we also identified an increased risk of DN (OR=2.4, 95%CI: 1.2-4.8) but a protection from MM among individuals who had a previous diagnosis of DN (OR=0.4, 95%CI: 0.2-0.9). These relationships were strongest among those who carried both Trp305 alleles and who did not have blue or gray eyes (OR=3.4, 95%CI: 1.3-9.0 for DN vs. controls, and OR=0.2, 95%CI: 0.05-0.6 for DN+MM vs. DN only). These results suggest that P gene may in part determine human eye color, that Arg305Trp genotypes predict propensity to develop DN, and that these DN tend not to be associated with development of invasive melanoma. Although melanoma risk is increased overall in patients with DN, most such patients do not develop melanoma. These results suggest a possible means of prospectively identifying patients with DN who do not progress to develop melanoma.

**A conditional mouse knockout model of MEN1 develops pancreatic tumors when crossed with transgenic lines expressing Cre from the insulin promoter.** *J.S. Crabtree*<sup>1</sup>, *J.M. Ward*<sup>2</sup>, *L. Garrett-Beal*<sup>1</sup>, *P.C. Scacheri*<sup>1</sup>, *J. Hagar*<sup>3</sup>, *M. Inoue*<sup>3</sup>, *D. Hanahan*<sup>3</sup>, *H. Edlund*<sup>4</sup>, *S.C. Chandrasekharappa*<sup>1</sup>, *S.J. Marx*<sup>5</sup>, *A.M. Spiegel*<sup>5</sup>, *F.S. Collins*<sup>1</sup>. 1) NHGRI/NIH, Bethesda, MD; 2) Veterinary Pathology, NCI/NIH, Frederick, MD; 3) Dept of Biochemistry, UCSF, San Francisco, CA; 4) Dept of Microbiology, University of Umea, Umea, Sweden; 5) NIDDK/NIH, Bethesda, MD.

Multiple endocrine neoplasia, type 1 (MEN1) is an autosomal, dominant, familial cancer syndrome characterized primarily by multiple tumors in the parathyroid, endocrine pancreas and anterior pituitary. Other tumors, including gastrinoma, carcinoid, adrenal cortical tumors, angiofibroma, collagenoma and lipoma also occasionally occur. Affected families are almost invariably found to have germline loss of function mutations in the *MEN1* gene, and tumors are found to have lost the wild type allele.

To examine the mechanism by which loss of *MEN1* leads to tumor formation, we have generated a conditional mouse model through homologous recombination of the mouse homolog, *Men1*. A PGK-neomycin cassette flanked by loxP sites was inserted into intron 2 and a third loxP site was introduced into intron 8 of the *Men1* gene. These mice were then crossed with a ubiquitous cre expressing line, EIIa-Cre, to remove the PGK-neomycin cassette, generating *Men1<sup>dN</sup>* mice with a floxed allele.

*Men1<sup>dN</sup>* mice were crossed with two different transgenic lines expressing cre under the control of the rat insulin promoter (RIP-Cre). Mice that are positive for RIP-Cre develop pancreatic islet hyperplasia and frank adenoma, and there is a suggestion that the animals homozygous for the floxed allele have an earlier onset than the heterozygotes. Insulin levels in these mice increase with the onset of tumors, indicating beta cell specificity. In some cases, there is a marked decrease in blood glucose. Islet beta cell-specific knockout of the *Men1* gene appears to be an excellent animal model of insulinoma.

**Assessment of Protein Kinase A subunits expression in normal adrenal cortex and primary pigmented adrenocortical disease from patients with and without Carney Complex and *PRKARIA* mutations.** *F. Sandrini*<sup>1</sup>, *L.S. Kirschner*<sup>1</sup>, *A.J. Carney*<sup>2</sup>, *C.A. Stratakis*<sup>1</sup>. 1) UGEN, DEB, NICHD, NIH, Bethesda, MD; 2) Emeritus Staff, Mayo Clinic, Rochester, United States.

The primary pigmented nodular adrenocortical disease (PPNAD) is an endocrine tumor frequently associated to Carney Complex (CNC)- a familial multiple neoplasia syndrome. Forty percent of the families with CNC present mutation in the gene encoding the protein kinase A type I-alpha regulatory subunit (*PRKARIA*). We studied PPNAD from CNC patients with and without mutation at *PRKARIA* gene (mut or non-mut) and we compared them with a normal adrenals and ACTH induced adrenal hyperplasia. We quantitated the expression of the genes which encode the regulatory subunits (Ia, Ib, IIa, IIb) and the catalytic subunit alpha (Ca) by using a real-time reverse transcription (RT)-polymerase chain reaction (PCR) assay. We performed immunohistochemistry (IHC) with a monoclonal antibody specific for RIa, IIa, IIb and Ca (RIa- Ab, IIa- Ab, IIb-Ab and Ca- Ab ) in PPNAD and the adrenal hyperplasia. Microdissection was also done in PPNAD, and the gene expression of the tumoral cells was compared to those peritumoral cells. The *PRKARIA* gene is lower expressed in PPNADmut and hyperplastic adrenals than in PPNADnon-mut. In both of them, the *PRKARIA* is lower expressed when compared with normal adrenals. The *PRKAR2B* expression was higher expressed in both tumor cell lines than in that from normal adrenals. But the PPNADnon-mut had higher expression than the others cell lines. The *PRKACA* was lower expressed in both tumors than in normal adrenal, and the PPNADnon-mut was even lower than the others were. IHC showed low and irregular expression of the RIa subunits in the PPNADmut nodules, in contrast with other samples that showed high and regular expression. The same pattern is observed with Ca. The RIIa-Ab stained regularly the PPNADnon-mut and hyperplastic adrenals, but it irregularly stained the PPNADmut. The PPNADnon-mut expresses regularly the RIIb and it is irregularly expressed in hyperplastic adrenals and PPNADmut. There is a shift between RIa and IIb in the tumoral cells in adrenal tumors from CNC with *PRKARIA* mutate gene.

**Association between the MnSOD polymorphism (Ala-9 Val) and the adenomas of the distal colon.** *E.H. Elkhoully<sup>1</sup>, A.J. Levine<sup>1</sup>, A.T. Diep<sup>1</sup>, E.R. Lee<sup>2</sup>, H.D. Frankl<sup>3</sup>, R.W. Haile<sup>1</sup>.* 1) Preventive Medicine, USC Keck School of Medicine, Los Angeles, CA; 2) Division of Gastroenterology, Kaiser Permanente Medical Center, Bellflower, Los Angeles, CA; 3) Division of Gastroenterology, Kaiser Permanente Medical Center, Sunset, Los Angeles, CA.

Reactive oxygen species formed during normal metabolic processes can cause DNA damage and potentially increase cancer risk. MnSOD is an intramitochondrial isoenzyme of the superoxide dismutase family. The enzyme protects DNA against free radical induced DNA and protein damage by scavenging the free radicals. A common polymorphism in the mitochondrial targeting sequence, a Valine to Alanine substitution at position-9 (Shimoda-Matsubayashi, S., *Biochem. Biophys. Res. Commun.*, 266, 561-565) has been associated with increased premenopausal breast cancer risk and with colon cancer risk in individuals less than 40 years of age. Using an Alu I RFLP, we genotyped a random sample of 250 subjects (106 cases and 144 controls with a mean age of 69), from a sigmoidoscopy-based case-control study in Southern California. After adjusting for age, race, sex, cilinc and sigmoidoscopy date, we observed a borderline significant decrease in distal adenoma risk associated with the presence of at least one alanine allele: AA versus VV: OR =0.65(95% confidence interval (CI) 0.30-1.42), AV versus VV: OR=0.56(0.29-1.08), and AV+AA versus VV: OR=0.58 (0.31-1.10). If these findings are confirmed, it suggests that this MnSOD mutation might be protective against distal adenomas in older individuals.

**Methionine Synthase Reductase Polymorphism 66A-G and Sigmoid Colon Polyp.** *Y. Liu<sup>1</sup>, A.J. Levine<sup>1</sup>, A.T. Diep<sup>1</sup>, E.R. Lee<sup>2</sup>, H.D. Frankl<sup>3</sup>, R.W. Haile<sup>1</sup>.* 1) Preventive Medicine, USC Norris Cancer center, Los Angeles, CA; 2) Division of Gastroenterology, Kaiser Permanente Medical Center, Bellflower, Los Angeles CA; 3) Division of Gastroenterology, Kaiser Permanente Medical Center, Sunset, Los Angeles CA.

Methionine synthase transfers a methyl group from 5-methyltetrahydrofolate to homocysteine to form methionine in a vitamin B12 dependent reaction. The final product in this pathway is S-adenosylmethionine, the universal methyl donor for all intracellular transmethylation reactions. Methionine synthase reductase (MSR) maintains methionine synthase in a functional state for homocysteine to methionine remethylation. A mutation in MSR causes cbIE, a life-threatening genetic disorder in homocysteine methylation, documenting its functional importance in one-carbon metabolism. We assessed a common polymorphism in MSR (I66M) that has recently been associated with a 3-fold increase in the risk of a Down Syndrome as part of a larger study of risk factors for DNA methylation changes in colorectal adenoma. Since normal folate metabolism may be an important modifying factor in colorectal neoplasia risk, we tested the hypothesis that the MSR I66M polymorphism was associated with increased colorectal adenoma risk. Using a PASA method, we genotyped a random sample of 268 subjects (125 cases with distal adenomas and 143 controls), from a sigmoidoscopy-based case-control study in Southern California. 28 cases and 31 controls were homozygous for the methionine allele. Compared to homozygous wild types, those methionine homozygotes were not at greater risk for distal adenomas in this population (OR= 1.26; 95% Confidence Interval = 0.64 - 2.48). These data do not support an important role for the MSR protein in distal colorectal adenoma risk.

**The SOD2 Val 16 Ala polymorphism and Prostate Cancer.** *R.M. Sachdeva<sup>1</sup>, A-M. Martin<sup>2</sup>, M.F. Heyworth<sup>1,2</sup>, C.M. Zeigler-Johnson<sup>2</sup>, E. Spangler<sup>2</sup>, A.H. Walker<sup>2</sup>, S.B. Malkowicz<sup>2</sup>, T.R. Rebbeck<sup>2</sup>.* 1) VA Medical Center, Philadelphia, PA; 2) Univ. of Pennsylvania School of Medicine, Philadelphia, PA.

SOD2 (Mn-SOD), an oxidoreductase, is a member of the superoxide dismutase group of the antioxidant superfamily of enzymes. The human SOD2 gene is on chromosome 6q25.3-qter and encodes a 24 amino acid mitochondrial target sequence. SOD2 inactivates anionic reactive oxygen species (ROS) that are by-products of oxidative phosphorylation. ROS are known to produce noxious effects within organic macromolecules including DNA and RNA strand scission, membrane lipid peroxidation and protein cross-linking. Homozygotes for the Ala allele of the Val 16 Ala polymorphism in SOD2 have been reported to be associated with an increase in breast cancer risk among Caucasian women. To evaluate the association of this SOD2 polymorphism with risk for prostate cancer, we studied 300 incident prostate cancer cases and 235 healthy male controls ascertained from the Hospital of the University of Pennsylvania between 1995 and 2000. The Val 16 Ala polymorphism was characterized by an allele-specific oligonucleotide PCR-RFLP assay with Cac 8I and confirmed with NgoM IV. Among controls, the Ala allele frequency was similar in Caucasians (Ala frequency=0.31) and African Americans (Ala frequency=0.25;  $c^2=1.7$ ,  $df=1$ ,  $p=0.19$ ). We identified a two-fold increase in prostate cancer risk in carriers of Ala/Ala genotypes compared with Val/Val or Val/Ala genotypes (age- and race-adjusted OR= 2.1, 95% CI: 1.5-3.1), which was similar in African Americans and Caucasians. We found no association with PSA level at diagnosis, or with tumor grade, presence of extracapsular extension, or other characteristics of tumor severity. These data suggest that SOD2 is a candidate gene for prostate cancer risk.

**Linkage of hereditary breast cancer families to a novel locus at 13q21-q22: subgroup analyses and further exclusion of BRCA2 involvement.** *S.H. Joo and Nordic/NHGRI Breast Cancer Consortium.* Columbia Univ Genome Center, NY, USA; NHGRI/NIH, Bethesda, MD, USA; Univ of Tampere, Helsinki, Finland; Univ Hospital, Lund, Sweden; Univ Hospital of Iceland, Iceland.

We recently reported a putative novel breast cancer susceptibility locus at 13q21-22 based on a targeted linkage analysis focusing at this common somatic deletion area in BRCA1/2-mutation negative hereditary breast cancers. The highest 2-point lod score in 77 families from Finland, Sweden and Iceland was 2.8 at D13S1308, 25 cM distal from BRCA2. This close proximity to the BRCA2 gene prompted us to further explore 13q21 linkage using a variety of strategies in these Nordic families. First, screening of BRCA1/2 for mutations in more affecteds led to the identification of an additional BRCA2 family. Furthermore, we also excluded another family with a significant lod score of 1.3 at BRCA2, but no detectable BRCA2 mutations. These changes and deletion of a previously unidentified MZ twin increased the lod score from 2.8 to 3.1 at D13S1308. Second, we typed additional markers along chromosome 13, including ~20 cM centromeric from BRCA2 at 13q11-q12. Small lod scores (~ 0.6) were found at 13q11-12, and no evidence of linkage at BRCA2. Third, we divided the families into those that met the Breast Cancer Linkage Consortium (BCLC) criteria and those that did not. The BCLC criteria define dense and early onset families. Evidence for 13q21-q22 linkage came mainly from families that did not meet BCLC criteria. These non-BCLC families had a lod score of 2.0 at D13S1308, and no evidence of linkage at 13q11-12. In conclusion, our data indicate that elevated lod scores at 13q21-q22 in Nordic BRCA1/2-mutation-negative breast cancer families are unlikely to be due to missed BRCA2 mutations. The phenotype of these families is also different from BRCA2 families.

**Tyrosine kinase activation in breast carcinoma with correlation to HER-2/neu gene amplification.** *R. Bhargava<sup>1</sup>, R. Naeem<sup>1</sup>, S. Marconi<sup>1</sup>, J. Luszcz<sup>1</sup>, J. Garb<sup>1</sup>, R. Gasparini<sup>2</sup>, C.N. Otis<sup>1</sup>.* 1) Department of Pathology, Baystate Medical Center, Springfield, MA; 2) Ventana Medical Systems.

**Purpose of Study:** The HER-2/neu oncogene encodes a transmembrane receptor with intrinsic tyrosine kinase activity. A pilot study was performed to investigate downstream effects of HER-2/neu (or related growth factor receptor) activation in breast carcinoma by identifying phosphorylated tyrosine. **Materials and Methods:** Fifty breast carcinomas were evaluated for HER-2/neu gene amplification by fluorescence in situ hybridization (FISH) using the Ventana gene probe. To exclude the possibility of tetraploidy in tumor cells, more than four signals per nucleus was considered as an evidence of gene amplification. Phosphotyrosine (an indication of tyrosine kinase activity) was detected by an antiphosphotyrosine (APT) mouse monoclonal antibody (Upstate Biotechnology). Intense APT immunoreactivity in tumor cells was considered as evidence of increased tyrosine kinase activity. **Results:** The HER-2/neu oncogene amplification was detected in 28% (14/50) cases. Increased tyrosine kinase activity was detected in 32% (16/50) cases. There was moderate agreement between HER-2/neu gene amplification and tyrosine kinase activity ( $k = 0.43$ ). Of the 14 cases demonstrating oncogene amplification, tyrosine kinase activity was detected in 9 (64.2%) cases. Of the 16 cases demonstrating increased tyrosine kinase activity, HER-2/neu oncogene amplification was identified in 9 (57%) cases. **Conclusion:** HER-2/neu oncogene amplification correlated to increased tyrosine kinase activity, supporting the mechanism of tyrosine kinase activation by HER-2/neu amplification. However, seven cases demonstrating increased tyrosine kinase activity did not show gene amplification raising the possibility of other growth factor receptors operating via tyrosine kinase pathway. The result of this pilot study suggest that a large scale investigation into downstream activation of tyrosine kinase and correlation to clinical outcome or response to Herceptin therapy may identify subsets of patients whose clinical response or outcome may be predicted by tyrosine kinase activation.

**Identification of regions of amplification on chromosome 19 in acute myeloid leukemia.** *S.N.J. Sait<sup>1</sup>, S. Kakati<sup>1</sup>, S. Matsui<sup>2</sup>, J.M. Conroy<sup>3</sup>, N.J. Nowak<sup>3</sup>, M.R. Baer<sup>4</sup>.* 1) Clinical Cytogenetics Lab, Roswell Park Cancer Institute, Buffalo, NY; 2) Cancer Genetics, Roswell Park Cancer Institute, Buffalo, NY; 3) Microarray & Genomics Facility, Roswell Park Cancer Institute, Buffalo, NY; 4) Department of Medicine, Roswell Park Cancer Institute, Buffalo, NY.

Amplification of CMYC and MLL is well-documented in patients with acute myeloid leukemia, but reports of other gene amplifications are infrequent. Karyotypic analysis of pretreatment marrow cells from two patients with acute myeloid leukemia showed the presence of marker chromosomes with homogenously staining regions. The regions were identified to originate from chromosome 19 by spectral karyotyping and fluorescence in situ hybridization (FISH) using whole chromosome paints. BAC clones for chromosome 19 identified from the Human BAC Resource (<http://genomics.roswellpark.org>) were mapped by FISH to further define the regions of amplification. Amplification of a BAC that mapped to 19q12 and contained the markers D19S409, D19S882 and the gene for ubiquinol-cytochrome C reductase iron-sulfur subunit (UQCRC1) (<http://genome.cse.ucsc.edu>). was demonstrated in cells from one patient. Overlapping clones are being tested to map boundaries of the region involved as well as to identify what other regions on 19 are involved. Regions on chromosome 19 particularly cyclinE have been reported amplified in solid tumors. They may also play a role in hematologic malignancies.

**Altered subcellular distribution of OVCA1, a candidate tumor suppressor and its interactor, RBM8, a highly conserved RNA binding protein, in response to osmotic shock: implications for changes in mRNA processing in response to stress.** A.H. Prowse, A.M. Salicioni, A.K. Godwin. Fox Chase Cancer Ctr, Philadelphia, PA.

Allelic loss of chromosome 17p13.3 is one of the most frequently observed molecular alterations observed in ovarian, breast and other tumors. We have identified a gene, *OVCA1*, within a region of minimal allelic loss in ovarian tumors at 17p13.3 and we have shown that *OVCA1* is a strong candidate for a tumor suppressor involved in ovarian cancer (Bruening *et al.*, 1999). *OVCA1* codes for a highly conserved protein with no known function. To help determine the functions of *OVCA1*, we used a yeast-2-hybrid screen to identify *OVCA1*-associating proteins. One such protein, RBM8, was identified. The sequence of RBM8 indicates that it is a new member of an RNA-binding motif family which is highly conserved (Salicioni *et al.*, 2000). *OVCA1* exists in at least two forms: a 48kDa (p48<sup>OVCA1</sup>) and a 50kDa (p50<sup>OVCA1</sup>) protein. Immunofluorescence studies in HeLa cells using antibodies specific for p48<sup>OVCA1</sup> and p50<sup>OVCA1</sup> show that both localize throughout the cell, albeit with different patterns. Interestingly, osmotic shock induces p50<sup>OVCA1</sup> to accumulate around the nucleus, but has no dramatic effect on p48<sup>OVCA1</sup>. RBM8, which is localized predominantly in a punctate pattern in the nucleus in untreated HeLa cells, has a diffuse staining pattern throughout the nucleus and cytoplasm after osmotic shock. RBM8, also known as Y14, has been shown to be a shuttling protein, which binds preferentially to spliced mRNA in the nucleus upstream of exon-exon junctions and remains in this position in the cytoplasm (Kim *et al.*, 2001). RBM8/Y14 may therefore be involved in communicating to the cytoplasm the location of exon and intron boundaries and may play an important role in post-splicing events such as mRNA transport and nonsense mediated decay. Alterations in the cellular distribution of RBM8 may therefore have important consequences for mRNA processing. Studies are underway to further determine how these alterations in localization are mediated and the relevance of this response to how tumor cells adapt to environmental stress.

**Random Activation of Gene Expression to Identify Proteins Regulating Apoptosis.** *S. Rundlett*. Research, Athersys, Inc., Cleveland, OH.

Random Activation of Gene Expression to Identify Proteins Regulating Apoptosis Over-expression of several proteins has been shown to correlate with both increased tumorigenicity and decreased sensitivity to various apoptotic inducing agents in tumor cells. Identification of novel proteins whose over-expression promotes resistance to apoptotic inducing agents would aid in the development of therapeutic approaches to treat cancer. We have used Random Activation of Gene Expression (RAGE) technology to generate a protein expression library in the human fibrosarcoma cell line HT1080, and this library has been screened for cells (RAGE-clones) resistant to apoptosis-inducing agents. Approximately two million RAGE-clones were separated into 10 pools and screened for resistance to paclitaxol or to the combination of either cycloheximide/TNF-alpha or cycloheximide/activating FAS antibody. A number of apoptotic-resistant clones were obtained from each of these treatments, many of which were resistant to the other two apoptosis-inducing treatments. Because RAGE transcripts have 5'-sequence tags, identification of the activated genes can be readily accomplished via 3'-RACE. Experiments are currently in progress to clone RAGE-activated cDNAs from these clones and verify their ability to promote apoptotic resistance.

**Lack of association of sporadic colorectal cancer with the MTHFR C677T mutation, plasma level and daily intake of folic acid, B12 and other B group vitamins.** *L. García<sup>1</sup>, M.A. López<sup>1</sup>, J. Arteaga<sup>1</sup>, O. Barrales<sup>2</sup>, M. Candelaria<sup>2</sup>, D. Green<sup>2</sup>, E. León<sup>2</sup>, X. López K.<sup>2</sup>, O.M. Mutchinick<sup>1</sup>.* 1) Dept de Genética; 2) Dept Hemato-Oncología Inst Nac Ciencias Médicas y Nutrición Salvador Zubirán, México,D.F.

**Background:** Colorectal cancer (CRC) is the third most common cancer cause of death. CRC etiology has been related to both genetic and environmental factors. Recent publications suggest that homozygosis for the MTHFR C677T mutation has a protective effect in the occurrence of CRC, although some others reject this possibility. The very high prevalence of the mutation and the TT genotype in the Mexican population (Mutchinick et al, Mol Genet Metab, 1999) and the existing controversy, prompted us to do the present study. **Objective:** To determine the prevalence of the TT genotype in CRC patients and two comparison groups to analyze a possible association of sporadic CRC with the MTHFR genotype and plasma level and food intake of folic acid (FA) and other B vitamins. **Design:** matched case control study. **Participants:** 71 CRC patients (33 females and 38 males), 33 with sporadic breast cancer (BC) and 38 with sporadic prostate cancer (PC) matched by age and sex to those of CRC. **Methods:** identification of the C677T mutation by PCR and restriction enzyme analysis. FA and B12 plasma level by Elisa and FA, B2, B6 and B12 intake by a food frequency intake questionnaire.

**Results:** Against all odds, the frequency of TT homozygotes was higher in CRC (38.0%) than in PC (28.9%) and BC (18.2%) patients. Even though the prevalence of TT in CRC patients was twice that in BC, no statistical differences (SD) were observed. All groups were in H-W equilibrium. No SD that suggests a possible association or interaction between any genotype, plasma FA and B12 and daily intake of B2, B6 and B12 and CRC was observed.

**Conclusions:** So far, our results reject a protective effect for sporadic CRC of the TT MTHFR genotype, of folates intake and plasma level, and of the other B group vitamins studied.

**Mutational analysis of APC gene, immunoreactivity of p53, and E-Cadherin protein in gastric adenocarcinoma.**

*M.R. Abbaszadegan<sup>1</sup>, H.R. Asadzadeh<sup>2</sup>, N. Pazouki<sup>1</sup>, K. Ghafarzadegan<sup>1</sup>, K. Jami-Ahmadi<sup>1</sup>, M. Houshmand<sup>3</sup>, M.R. Zali<sup>2</sup>.* 1) Human Genetis, Bu-ali Res Inst, Mashad Univ. Med. Sci., Mashad, Iran; 2) Gastroenter & Liver Transplant. Res.Center, Shahid Beheshti Univ. Med. Sci., Tehran, Iran;; 3) NRCGEB, Tehran, Iran.

Gastric cancer is one of the most prevalent cancers in the world particularly in Asia and Middle East. Unlike colorectal cancer, genetic alterations during the tumorigenesis of gastric cancer is not well characterized. APC, p53 and E-cadherin are implemented in the gastric cancer tumorigenesis. APC, a tumor suppressor gene controls b-catenin as a proto-oncogene and is believed to play a major role in the progression of early dysplasia of gastric epithelium into adenoma and adenocarcinoma particularly in well differentiated gastric cancer. P53 mutations have also been observed in adenoma and adenocarcinoma of the same type of tumors. Expression of E-Cadherin, a cell adhesion molecule, is diminished in gastric adenocarcinoma resulting in metastasis of these tumors. Mutational analysis and expression of these genes were studied in early and advanced gastric adenocarcinoma to elucidate their role in tumorigenesis of gastric cancer. Paraffin-embedded gastric adenocarcinoma including the normal margins from 22 patients, with endoscopy and/or gastrectomy (age group 32-70yrs) were screened for mutations in APC gene. APC coding regions, including 4 Mutation Cluster Regions (MCRs) in Exon 15 (1267-1588 cds) that are the hot-spots for nonsense mutations were examined by PCR-SSCP followed by sequencing of the suspected SSCP bands. 2/22 of adenocarcinomas had a mutation. These were new mutations in MCR-D (1503-1588 cds). Expression of mutant p53 and E-cadherin protein were measured by immunohistochemistry. 15/19 (79%) of patients showed mutated p53 and 9/19(47%) were negative for expression of E-cadherin. These data correlates with the reported results. A larger study on the genetic alterations of gastric cancer is underway. These data may demonstrate that the above genetic markers could be used as early diagnostic, &/or prognostic, predisposition factors for gastric cancer.

**Microsatellite instability versus immunohistochemistry testing in phenotyping colorectal tumors.** *N.M. Lindor<sup>1</sup>, L.J. Burgart<sup>1</sup>, O. Leontovich<sup>1</sup>, R.M. Goldberg<sup>1</sup>, J.M. Cunningham<sup>1</sup>, C. Walsh-Vockley<sup>1</sup>, G. Petersen<sup>1</sup>, M. Redston<sup>6</sup>, J. Young<sup>3</sup>, M. Barker<sup>3</sup>, M.D. Walsh<sup>2</sup>, J. Jass<sup>2</sup>, B.A. Leggett<sup>3</sup>, J. Hopper<sup>4</sup>, B. Bapat<sup>5</sup>, S. Gallinger<sup>5</sup>, T. Selander<sup>5</sup>, S.N. Thibodeau<sup>1</sup>.* 1) Mayo Clinic, Rochester, MN.,USA; 2) University of Queensland, Australia; 3) Bancroft Centre, Herston, QLD,3 Australia; 4) Univ. of Melbourne, Victoria, Australia; 5) Mount Sinai Hospital, Toronto, Ontario, Canada; 6) Harvard Medical School, Boston, Mass., USA.

**Purpose:** To compare microsatellite instability (MSI) testing with immunohistochemical (IHC) detection of hMLH1 and hMSH2 in colorectal cancer. **Patients and Methods:** Colorectal tumors from 1,144 patients from four cohorts from three countries were assessed for DNA mismatch repair deficiency by two methods: microsatellite instability testing and immunohistochemical detection of hMLH2 and hMSH2 gene products. High frequency microsatellite instability (MSI-H) was defined as >30% instability of at least 5 microsatellite markers. **Results:** Of 1,144 colorectal tumors tested for MSI and IHC, 818 showed intact expression of hMLH1 and hMSH2 by IHC. Of these, 680 were microsatellite stable (MSS), 27 were MSI-H, and 111 were MSI-L (1-29% of loci unstable). 228 tumors showed absence of hMLH1 expression and 100% of these were MSI-H. 98 tumors showed absence of hMSH2 expression and all but three showed unequivocal MSI-H. Discordance between MSI and IHC was partially explained by loss of expression of hMSH6, hPMS2, and, in the three discordant hMSH2 tumors, there were insufficient tumor cells to reliably interpret the MSI assay, however these patients had known germline hMSH2 mutations. **Conclusion:** IHC in colorectal tumors for protein products hMLH1 and hMSH2 provides a rapid, cost-effective, sensitive (92.3%), and extremely specific (100%) method for screening for DNA mismatch repair defects. Testing strategies must take into account acceptability of missing some cases of MSI-H tumors if only IHC is performed. Supported by NIH and UO1-CA74800, CA74778, and CA74783 (Cooperative Family Registry for Colon Cancer Studies)and CA68535. **Purpose***hMLH1hMSH2***Patients and Methods:**≥**Results****Conclusion****Purpose.**

**Transcriptional profiling of colon carcinomas, adenomatous polyps and normal colon mucosa using 36K**

**Microarrays.** *D. Hahnloser<sup>1</sup>, A. Berger<sup>3</sup>, T. Guillemette<sup>3</sup>, E. Christensen<sup>1</sup>, L. Burgart<sup>1</sup>, J.M. Cunningham<sup>1</sup>, L. Boardman<sup>1</sup>, S. Iturria<sup>2</sup>, B. Bryant<sup>3</sup>, M. Morrissey<sup>3</sup>, R. Schlegel<sup>3</sup>, S.N. Thibodeau<sup>1</sup>.* 1) Experimental Pathology, Mayo Clinic, Rochester, MN; 2) Health Sciences Research, Mayo Clinic, Rochester, MN; 3) Millennium Predictive Medicine, Cambridge, MA.

Genome-wide monitoring of gene expression can be used to identify sets of genes involved in carcinogenesis and may help to develop a molecular approach to classify tumors. Transcript expression profiles were analyzed from 25 colon adenocarcinomas, 3 adenomatous polyps and paired normal tissues. The tumors differed in location in the colon (proximal vs. distal), in microsatellite instability status (MSI vs. MSS), in stage of disease (Dukes A,B vs. Dukes C,D) and in the patients age at onset (50 vs. >50 years). Total RNA was extracted from normal, polyp and tumor tissues and radioactive probes were hybridized to nylon arrays containing 36,000 clones, including known genes and ESTs.

Expression levels were quantitated and analyzed with Array Vision, Cluster, TreeView, and additional software developed at Millennium Pharmaceuticals. Hierarchical clustering, using 3077 clones displaying the greatest differential expression (8.8% of clones on the arrays), correctly classified all samples as tumor, polyp or normal. These findings suggest that there are systematic differences between these three types of samples. The different subgroups of colon cancers could not be as closely related to a specific pattern of expression as were the normal, polyp or tumor tissues, but up and down regulated clones, clearly different between the subgroups, were identified. This analysis might be helpful in generating a molecular classification of cancers or in discovering previously unknown and clinically important subsets of tumors. The results from this large-scale expression analysis also serve to identify possible screening and prognostic markers for colorectal cancer and can give directions for future research.

**Evidence of different repertoires of MTG (ETO/CDR) oncoproteins in human myeloid leukemia.** *N. Sacchi*<sup>1,2</sup>, *J. Schonkeren*<sup>3</sup>, *A. Fenaroli*<sup>4</sup>, *L. Schiaffonati*<sup>4</sup>, *V. Stoyanova*<sup>3</sup>, *S. Rossetti*<sup>2,3</sup>, *L. van Unen*<sup>3</sup>, *A.T. Hoogeveen*<sup>3</sup>. 1) Oncology, Johns Hopkins University, Baltimore, MD; 2) School of Medicine, University of Milan, Italy; 3) Erasmus University, Rotterdam, The Netherlands; 4) Department of Biomedical Sciences and Biotechnology, University of Brescia, Italy.

The MTG8 (ETO/CDR), MTGR1 and MTG16 oncoproteins with a very high degree of sequence similarity with the *Drosophila* neryy are a novel family of transcriptional repressor molecules implicated in human leukemia and neurodegenerative disorders. Two of these proteins, MTG8 and MTG16, are found fused to AML1, one of the subunits of the hematopoietic core binding factor (CBF), as a consequence of the t(8;21) and t(16;21) associated with acute myeloid leukemia (AML) subtypes. We found that the intranuclear localization of the wild-type MTG16 protein differs from the localization of the other two MTG proteins, MTG8 and MTGR1. MTG16 is often localized both in the nucleoplasm and/or the nucleolus whereas MTG8 and MTGR1 are localized exclusively in the nucleoplasm. In contrast, the chimeric AML-MTG16, like AML1-MTG8, is localized in the nucleoplasm. Interestingly, all the MTG proteins can interact with each other and their interaction can influence their intranuclear localization. Both wild-type and chimeric MTG proteins can form homo- and hetero-dimers. Oligomerization seems to be crucial to ensure the recruitment of additional nuclear co-repressors complexes with histone deacetylase (HDAC) activity and enhance repression of transcription of target genes. The expression profile of the MTG isoforms is distinct in myeloid leukemia subtypes suggesting that the differential expression of wild-type and chimeric MTG proteins may determine not only the repertoire of possible MTG oligomers in a given leukemia, but also their intranuclear localization, their regulatory function and, ultimately, their leukemogenic properties. **Expression Analysis of Chromosome 20 Genes in Prostate Cancers.** *L. Wang<sup>1</sup>, J. Monahan<sup>4</sup>, J. Cheville<sup>1</sup>, D.A. Elkins<sup>1,2</sup>, A. Wonsey<sup>4</sup>, J.M. Cunningham<sup>1</sup>, D.J. Schaid<sup>3</sup>, R. Schlegel<sup>4</sup>, S.N. Thibodeau<sup>1</sup>.* 1) Lab Medicine & Pathology, Mayo Clinic, Rochester, MN; 2) Urology, Mayo Clinic, Rochester, MN; 3) Health Sciences Research, Mayo Clinic, Rochester, MN; 4) Millennium Predictive Medicine, Cambridge, MA.

Prostate cancer (PC) is one of the most common human cancers, occurring in as many as 15% of men in the United States. Recent studies suggest that hereditary PC is a complex disease, involving multiple susceptibility genes and variable phenotypic expression. While conducting a genome-wide search on 162 North American families with > 3 members affected with PC, we found evidence for linkage to chromosome 20q13. This region is also known to be amplified in other tumor systems, particularly in breast cancer. As one of our efforts to clone a PC susceptibility gene (HPC20) localized to this region, we have used microarray technology to examine the expression levels of various genes localized to chromosome 20, and in particular, to 20q13. A total of 31 micro-dissected prostate cancer samples with various clinical and pathologic features and 25 normal prostate tissues were analyzed. Total RNA was extracted from normal and tumor tissue and radiolabeled probes were hybridized to a custom nylon array containing approximately 6000 clones, of which 270 were known genes and ESTs mapping to chromosome 20. Among the 270 genes/ESTs analyzed, only a few were found to have a median expression level at least 2 fold higher in the tumors when compared with the controls, and none were found to be down regulated by two fold. Increasing the number of markers on chromosome 20 and using more sophisticated algorithms for assessing chromosome location-specific expression patterns may provide the additional power needed to identify HPC20 in the 20q13 region and to test for possible regions amplification or deletion.

**Gene Expression Profiling of Clear Cell Renal Cell Carcinoma: Gene Identification and Prognostic**

**Classification.** *M. Takahashi*<sup>1</sup>, *D. Rhodes*<sup>2</sup>, *K. Furge*<sup>3</sup>, *H. Kanayama*<sup>4</sup>, *S. Kagawa*<sup>4</sup>, *B. Haab*<sup>2</sup>, *B.T. Teh*<sup>1</sup>. 1) Cancer Genetics, Van Andel Research Institute, Grand Rapids, MI; 2) DNA and Protein Microarray Technology, Van Andel Research Institute, Grand Rapids, MI; 3) Molecular Oncology, Van Andel Research Institute, Grand Rapids, MI; 4) Department of Urology, School of Medicine, University of Tokushima, Tokushima, Japan.

To better understand the molecular mechanisms that underlie the tumorigenesis and progression of clear cell renal cell carcinoma (ccRCC), we studied the gene expression profiles of 29 ccRCC tumors obtained from patients with diverse clinical outcomes using 21,632-cDNA microarrays. We identified gene expression alterations both that were common to most of the ccRCC studied and that were unique to clinical subsets. There was a significant distinction in gene expression profile between patients with a relatively non-aggressive form of the disease (100% survival after 5 years with the majority (15/17 or 88%) having no clinical evidence of metastasis) versus patients with a relatively aggressive form of the disease (average survival time 25.4 months with a 0% 5 year survival rate). Approximately 40 genes most accurately make this distinction, some of which have previously been implicated in tumorigenesis and metastasis. To test the robustness and potential clinical usefulness of this molecular distinction, we simulated its use as a prognostic tool in the clinical setting. In 96% of the ccRCC cases tested, the prediction was compatible with the clinical outcome, exceeding the accuracy of prediction by staging. These results suggest that two molecularly distinct forms of ccRCC may exist and that integration of expression profile data with other clinical parameters could serve to enhance the diagnosis and prognosis of ccRCC. Moreover, the identified genes provide insight into the molecular mechanisms of aggressive ccRCC and suggest intervention strategies.

**Genomic and chromosomal instability in endometrial cancer.** *S.P. Siah<sup>1, 2</sup>, S.L. Bawden<sup>1</sup>, G.D. Bennett<sup>1</sup>, G. Casey<sup>1</sup>, M. Davy<sup>3</sup>, T.J. Dodd<sup>4</sup>, R.L.P. Flower<sup>2, 5</sup>, A.J. Gordon<sup>2</sup>, D.M. Quinn<sup>2</sup>, A. Ruzkiewicz<sup>4</sup>, G.K. Suthers<sup>6</sup>, Z. Rudzki<sup>1</sup>.* 1) Div. Transfusion, PaLMS, RNSH, St Leonards, NSW, Australia; 6) Familial Cancer Unit, SA Familial Cancer Service, WCH, North Adelaide, SA Australia.

Microsatellite instability (MSI), a marker of genomic instability, is detected in up to 34% of unselected endometrial cancers. It has been hypothesised that chromosomal instability, indicated by chromosomal abnormalities, is involved in the pathogenesis of the remaining cases.

We studied 48 formalin-fixed paraffin embedded endometrial cancers for evidence of MSI and aneuploidy. Samples were classified as MSI positive when 2 or more of the 10 loci used showed extra alleles in the tumour tissue DNA compared to normal tissue DNA. DNA analysis by flow cytometry was used to detect aneuploidy and tumours were classified as diploid, near diploid, tetraploid or aneuploid.

MSI was detected in 13 (27.1%) of 48 cases, of which ten cases (79.6%) were diploid or near diploid. Aneuploidy and tetraploidy were detected in 2 and 1 MSI positive cases respectively. Of the MSI negative cases (n= 35), a total of 18 cases (51.4%) were diploid and near diploid. Aneuploidy and tetraploidy were detected in 15 and 2 MSI negative cases respectively.

In this study, MSI positive endometrial cancers were found to be associated with diploid or near diploid DNA status. An association between aneuploidy and MSI negative endometrial cancers was also detected. Our results further showed that CIN is more frequently detected in endometrial cancers than in MSI positive cancers. This suggests that, like genomic instability, chromosomal instability plays a valid role in endometrial tumourigenesis. A significant proportion of cases do not appear to involve either mechanisms, suggesting that other mechanisms may be at work.

**Unmasking the Masked Mutation in Large Genes: Evaluation of Haploid Conversion Technology.** *A. Ganguly, C. George, G. Tan, J. Pain, T. Ganguly.* Dept of Genetics, University of Pennsylvania, Philadelphia, PA.

It has been suggested that a significant fraction of mutation negative individuals with genetic diseases including breast and ovarian cancer or colon cancer actually harbor mutations in cancer susceptibility genes. However the mutations are masked by the presence of the normal allele. In order to unmask the hidden mutations, we have used a commercially available mouse-human somatic cell hybrid generation facility (GMP Genetics, MA) whereby the two different alleles of specific chromosomes are separated and individually assayed for expression/mutation. We have used the hybrid cells for analyzing female hemophiliacs, individuals with clinical FAP, HNPCC and breast cancer. The genetic analysis on individual alleles require careful selection of primers for PCR amplification to exclude cross hybridization with the mouse genomic DNA. This method has allowed us to rule out genomic deletions in any of the genes investigated and further work is in progress to define possible rearrangements and/or regulatory mutations. The DNA supplied by the company is adequate for PCR amplification of regular sized PCR products. But complete analysis of large exon bearing genes like Factor VIII, BRCA1/2, APC and others require expanding the cells to a culture of larger volume in order to isolate appropriate quantities of DNA. Therefore, this method is useful as a research tool. But it requires a much larger sequencing effort followed by additional molecular analysis and is therefore intensive in terms of labor and expenses. Thus far we have had success in uncovering mutations in Factor VIII gene in female hemophiliacs while work is in progress on the other genes. The completed results of multiple gene analyses will be presented.

**Identification of large genomic deletions in *BRCA1* from patients with hereditary cancer risk using SNP haplotype pair analysis derived from clinical sequence data.** *B.C. Hendrickson, D. Pruss, A.M. Deffenbaugh, D.R. Nieslen, C.A. Gaglio, T. Scholl.* Myriad Genetic Laboratories, Inc., Salt Lake City, UT.

Five novel large deletions within *BRCA1* that remove exons were detected in anonymized samples originating from patients with hereditary risk for breast/ovarian cancer. Specimens were selected for a strong family history of breast and/or ovarian cancer and a negative clinical test for mutations in *BRCA1* and *BRCA2*. SNP haplotype-pair analysis was performed on 1,000 samples meeting these criteria using DNA sequence data obtained from clinical testing. A group of fourteen samples with haplotypes suggestive of large genetic rearrangements in *BRCA1* exon 16 were assayed for genomic deletions by PCR. Seven of these samples carried various large deletions. Breakpoints for these deletions resulted from Alu-mediated recombination. Four different deletions of both exons 16 and 17 were characterized. One deletion removed a region of 6.4 kb and occurred in three unrelated patients who identified their ancestry as Caribbean/Latin American. Studies are ongoing to determine the population prevalence of this mutation. Also, a 5.6 kb deletion of exons 15 and 16 was identified in one sample. The presence of these mutations was assessed in 420 anonymized samples from patients with breast/ovarian cancer, at least two relatives with cancer, and a negative clinical test result. No additional occurrence of any of the mutations was detected in this specimen set.

These results demonstrate that clinical SNP data is useful to identify genetic mutations undetectable by conventional PCR-based clinical approaches. The method is attractive since the analysis can be applied to any gene for which sufficient SNP haplotype data is available. These results support hypotheses presented elsewhere that genomic deletions in the *BRCA* genes are diverse. An automated method to incorporate large rearrangement detection is currently under development and will be included with the highly sensitive full sequence commercial analysis available for the *BRCA* genes.

**Spinal tumor genotype-phenotype correlation in neurofibromatosis 2.** *M.E. Baser*<sup>1</sup>, *D.M. Parry*<sup>2</sup>, *J.M. Friedman*<sup>3</sup>, *A. Wallace*<sup>4</sup>, *J. Gillespie*<sup>5</sup>, *D.G.R. Evans*<sup>4</sup>. 1) Los Angeles, CA, U.S.A; 2) Genetic Epidemiology Branch, National Cancer Institute, Bethesda, MD, U.S.A; 3) Department of Medical Genetics, University of British Columbia, Vancouver, B.C., Canada; 4) Department of Medical Genetics, St. Mary's Hospital, Manchester, U.K; 5) Department of Radiology, Manchester Royal Infirmary, Manchester, U.K.

Constitutional nonsense and frameshift mutations in the neurofibromatosis 2 (*NF2*) tumor suppressor gene are associated with severe NF2, one characteristic of which is a higher number of spinal tumors. Patronas et al. (Radiology 2001;218:434-442) reported that among 37 NF2 patients, those with nonsense or frameshift constitutional *NF2* mutations had more spinal intradural extramedullary tumors, but not spinal intramedullary tumors, than those with other types of mutations. We re-examined this question in patients from the United Kingdom NF2 registry. Of 86 U.K. patients with spinal MRIs, 54 had identified *NF2* mutations; excluding seven known somatic mosaics, the study group consisted of 47 patients (14 large deletions, 12 nonsense mutations, 11 splice-site mutations, nine missense mutations, one in-frame deletion) from 30 families. Intradural extramedullary tumors were more common in patients with nonsense mutations (100%) than in those with missense mutations (33%;  $P = .006$ ), splice-site mutations (54%;  $P = .014$ ), or large deletions (64%;  $P = .042$ ). Among NF2 patients with one or more intradural extramedullary tumors, individuals with nonsense mutations had significantly more tumors (mean  $\pm$  SE,  $16.4 \pm 5.0$ ) than those with missense mutations ( $3.6 \pm 1.5$ ;  $P = .041$ ) or large deletions ( $4.8 \pm 2.0$ ;  $P = .050$ ) (splice-site mutations,  $5.2 \pm 2.8$ ;  $P = .234$ ). In contrast, the prevalence and number of intramedullary tumors did not vary significantly by type of constitutional *NF2* mutation. These results are consistent with those of Patronas et al., and studies in which other tumors (intracranial meningiomas and peripheral nerve tumors) were found to be more common in NF2 patients with nonsense or frameshift *NF2* mutations.

**Investigation of interaction between N-acetyltransferase 2 (NAT2) phenotype and heterocyclic amines as potential risk factors for colorectal cancer.** *J.H. Barrett<sup>1</sup>, D.T. Bishop<sup>1</sup>, R. Waxman<sup>2</sup>, D. Forman<sup>2</sup>, T. Lightfoot<sup>3</sup>, C. Garner<sup>3</sup>, G. Smith<sup>4</sup>, R. Wolf<sup>4</sup> and FSA Study Group.* 1) Imperial Cancer Research Fund Genetic Epidemiology Division, Leeds, UK; 2) University of Leeds, UK; 3) University of York, UK; 4) University of Dundee, UK.

Individuals who are fast NAT2 acetylators may be at increased risk of colorectal cancer through the activation of carcinogenic heterocyclic amines, which are produced by meat cooked at high temperatures and are found in cigarette smoke. To investigate this hypothesis a study of 500 incident colorectal cancer cases and population controls, matched for age, sex and general practitioner, was conducted in the United Kingdom. Usual meat intake and lifetime smoking habits were estimated using a detailed food frequency questionnaire administered by interview. Subjects indicated how well cooked they ate their meat by responding to verbal or picture prompts. Subjects were classified as fast or slow NAT2 acetylators on the basis of NAT2 genotype using previously described phenotype-genotype correlations. Complete data were available on 433 matched pairs. The risk of colorectal cancer showed a steady increase with meat intake, rising to an odds ratio of 1.68 (95% confidence interval (1.11, 2.54)) for the highest versus the lowest quartile, and this was even more pronounced for red meat (odds ratio 2.33 (1.56, 3.48)). However this effect was not influenced by the preference for well-done meat. Smoking was also associated with an increased risk (odds ratio 1.47 (1.10, 1.98) for ever- versus never-smokers). In both cases and controls approximately 40% of subjects were classified as fast acetylators, and the risks associated with (red) meat intake and smoking did not vary according to NAT2 phenotype. This study provides no support for the hypothesis that fast NAT2 acetylators are at increased risk of colorectal cancer, even if exposed to high levels of heterocyclic amines from well-cooked meat or smoking. The effect of meat, which has been observed previously, could be due to fat content or to other correlates of high meat consumption in diet or lifestyle.

**DNA polymorphisms in XRCC1, XRCC2, XRCC3, ERCC4, PCNA genes and DNA-adduct levels in healthy subjects.** *G. Matullo*<sup>1,2</sup>, *S. Polidoro*<sup>3</sup>, *S. Guarrera*<sup>1,3</sup>, *M. Peluso*<sup>4</sup>, *A. Munnia*<sup>4</sup>, *A. Piazza*<sup>1</sup>, *D. Palli*<sup>5</sup>, *P. Vineis*<sup>3</sup>. 1) Dip. Genetica, Biol. e Biochim, Univ. Torino, Italy; 2) ISI Foundation, Torino; 3) Dipartimento di Scienze Biomediche e Oncologia Umana, Univ. Torino; 4) Unit of Experimental Oncology, IST, Genova; 5) Epidemiology Unit, CSPO, Firenze, Italy.

Polymorphisms in several DNA repair genes have been identified and individuals with non-dramatic reductions in the capacity to repair DNA damage are observed in the population. We investigated in 218 Italian healthy individuals belonging to the prospective European project EPIC the relationship between DNA damage, as measured by bulky DNA adduct levels, and the following genetic polymorphisms: XRCC1-26304C/T, XRCC1-26651A/G, XRCC2-31479G/A, XRCC3-17993A/G, ERCC4-30147A/G, PCNA-6084G/C. DNA-adduct levels were measured as Relative Adduct Level (RAL) per  $10^9$  by 32P DNA postlabeling assay in white blood cells from peripheral blood. Genotyping was performed by PCR-RFLP and/or DHPLC techniques. XRCC3-17993 AA genotype was significantly associated ( $P = 0.018$ ; OR = 2.08, 95%CI, 1.16-3.74) with higher mean DNA-adduct levels ( $10.48 \pm 1.34$ ) compared to AG+GG genotypes ( $6.64 \pm 0.88$ ). The PCNA-6084 GG genotype seems also to be associated ( $P = 0.042$ ) with higher DNA adduct levels ( $9.95 \pm 1.15$ ) compared to CG+CC genotypes ( $6.54 \pm 1.19$ ). In order to identify polymorphisms possibly related to the highest DNA adduct levels we defined a cut-off value above and below the 80th percentile (RAL = 13). The genotype distribution is still significantly different for XRCC3-17993A/G polymorphism (AA vs AG+GG,  $P = 0.026$ ), whereas it is not for PCNA-6084G/C polymorphism. Moreover, a borderline significance in genotype distribution has been observed also for XRCC2-31479G/A polymorphism (GG vs GA+ AA,  $P = 0.047$ ) and XRCC1-26651A/G (GG vs GA+ AA,  $P = 0.059$ ). Our results support the possible XRCC3 involvement in DNA bulky adduct repair, as we already suggested for another XRCC3 polymorphism (Thr241Met, exon 7), indicating that this gene can possibly repair bulky adducts through alternative repair pathways or repairing DNA cross-link lesions detected by 32-P DNA postlabelling technique.

**Genotypic and Phenotypic Characterization of a Putative Tumor Suppressor Gene *GNMT* in Liver Cancer.** T.-L.

Tseng<sup>1</sup>, Y.-M. Chen<sup>2</sup>, Y.-P. Shin<sup>2</sup>, K.H. Buetow<sup>1</sup>. 1) Lab of Population Genetics, NCI, Bethesda, USA; 2) Institute of Public Health, National Yang-Ming University, Taiwan.

Glycine N-methyltransferase (GNMT) is a protein with multiple functions related to maintain the genetic stability of cells, and it has been shown to be down-regulated in human HCC. Here we are investigating the *GNMT* gene for liver cancer predisposition by genotypic and phenotypic characterization of *GNMT* in Chinese population and hepatoma cell lines. Two STRPs, one Insertion/Deletion and three SNPs were identified and confirmed. We further developed genotyping assays and quantitative methods for assessing allelic loss at the *GNMT* locus. The genotypic distribution of *GNMT* between normal and HCC PBL DNA was similar; however, it was very different between PBL DNA and the tissue DNA from HCC patients. The rates of heterozygosity of STRP1, SNP1, SNP2, and STRP2 decreased dramatically in both non-tumor and tumor liver tissues DNA from HCC patients compared with the PBL DNA. This may result from the high LOH rate within the *GNMT* gene in liver. To elucidate the functional impact of polymorphisms in the promoter region, we performed luciferase reporter gene and gel mobility shift assays with hepatoma cell lines. The reporter gene assays indicate that the transcriptional activity of the *GNMT* promoter is strongly associated with the length of GA repeats in STRP1. The transcriptional activity of the *GNMT* promoter containing long repeats was reduced to 40~60% of the promoter containing short repeats. The gel mobility assays indicate that the short allele of Ins/Del polymorphism abolishes an HNF-3 recognition site in the *GNMT* promoter. Therefore, the two polymorphisms in the promoter region could be functional polymorphisms. Based upon the phenotypic results, we selected the risk genotypes and estimated their contribution to the genetic susceptibility to liver cancer. The average of odds ratio for the risk genotypes of *GNMT* in liver tissue, as compared with non-risk genotypes, is about 1.37~3.97. Finally, the somatic instability of *GNMT* in the early event of HCC development and the diminution of *GNMT* expression in HCCs suggest that *GNMT* could be a putative tumor suppressor gene in liver cancer.

**Gene Expression Profiling of Breast Cancer Biopsies with Cellular Resolution.** *M. Erlander<sup>1</sup>, X. Ma<sup>1</sup>, R. Salunga<sup>1</sup>, T. Tuggle<sup>1</sup>, E. Enright<sup>1</sup>, T. Payette<sup>1</sup>, Y. Tran<sup>1</sup>, P. McQuarry<sup>1</sup>, M. Pistone<sup>1</sup>, K. Stecker<sup>1</sup>, D. Sgroi<sup>2</sup>, J. Wittliff<sup>3</sup>.* 1) Arcturus Applied Genomics, Calrsbad, CA; 2) Harvard Medical School Boston, MA; 3) University of Louisville, Louisville, KY.

Breast cancer biopsies contain a multitude of cell types in addition to supposed pre-cancerous cells (ductal carcinoma) and carcinoma (invasive ductal carcinoma). Because of the heterogeneous nature of breast biopsies, interpretation of gene expression profiling of whole biopsies is problematic and requires a number of assumptions in the subsequent bioinformatic analyses. In addition, subsequent validation of differential gene expression requires the determination of which cell type(s) is expressing the gene(s) of interest. To obviate these shortcomings, we have implemented a general approach of laser-capturing cells from 5 tissue sections followed global amplification of mRNA and subsequent gene expression profiling via microarrays. Currently two projects are ongoing with the most recent data from both presented. First, the progression of breast cancer is being studied by examining from individual breast biopsies the gene expression (2500 genes profiled) of captured cells from normal epithelium, DCIS and IDC. High correlations ( $r > 0.95$ ) were observed between three individual captures and amplifications (106-fold amplifications) for all three cell types. In patients profiled so far, normal, DCIS and IDC have unique gene expression patterns and this data will be presented. The second project is a retrospective gene expression profiling of breast cancer biopsies taken on average 8 years ago. In this project gene expression analysis of laser-captured IDC is being linked to pathological, biochemical, and clinical datasets to define via gene expression patterns (i.e., signatures) the molecular subtypes of breast cancer. In patients studied so far, high correlation ( $r > 0.95$ ) of gene expression patterns has been observed between captures/RNA amplifications and gene expression patterns are consistent with known biomarker data. Both projects should lead to a greater understanding of breast cancer as well as uncover novel diagnostic and prognostic markers/signatures and new therapeutic targets.

**Identifying genes involved in genetic predisposition to papillary thyroid carcinoma.** *Y. Huang<sup>1</sup>, N. Pellegata<sup>1</sup>, W. Frankel<sup>2</sup>, V. LiVolsi<sup>4</sup>, C. Eng<sup>1,3</sup>, H. Hampel<sup>3</sup>, W. Lemon<sup>1</sup>, F. Wright<sup>1</sup>, K. Kornacker<sup>5</sup>, R.T. Kloos<sup>6</sup>, W.B. Farrar<sup>7</sup>, D.E. Schuller<sup>8</sup>, R. Krahe<sup>1</sup>, A. de la Chapelle<sup>1</sup>.* 1) Human Cancer Genetics, Ohio State U, Columbus, OH; 2) Dept Pathol, OSU; 3) Clinical Cancer Genetics, OSU; 4) Dept Pathol & Lab Med, U Penn, Philadelphia, PA; 5) Dept Sensory Biophys, OSU; 6) Div Endocrinol & Nucl Med, OSU; 7) Dept Surg, OSU; 8) Dept Otolaryngol, OSU, OH.

Thyroid cancer is the most common endocrine malignancy and can occur as either familial or sporadic disorder. Papillary thyroid carcinoma (PTC), the most common type, accounts for 65-80% of all thyroid cancers. Familial PTC accounts for about 6% of all PTCs. We hypothesize that there are genes that when mutated lead to inherited predisposition to PTC. To identify such putative genes we postulated that they might be commonly down-regulated in the PTCs. We used oligo-based DNA microarrays (U95A, Affymetrix) to analyze eight PTCs in comparison with matched normal tissue from the same individual. One of the eight patients has a family history of PTC. Preliminary analyses suggest that the study design was successful. 1) Genes encoding enzymes involved in reactions responsible for the production of thyroid hormone, e.g. thyroid peroxidase, type I and type II iodothyronine deiodinase, were down-regulated in the majority of tumors, as might be expected when comparing cancer tissue with normal thyroid tissue. 2) Genes previously found over-expressed in PTC, such as MET, and those encoding galectin-3, fibronectin, a1-antitrypsin, keratin 19 and liver dipeptidyl peptidase IV, were up-regulated in all eight PTCs. The RET proto-oncogene was expressed in four PTCs. 3) We have confirmed the up-or down-regulation of selected genes by semi-quantitative RT-PCR in additional eight PTC cases. We are now studying a number of genes that we found to be down-regulated in the majority of the PTC tumors, but that have not been previously implicated in PTC. To explore their roles as tumor suppressors, and as candidates in genetic predisposition to this disease, LOH and linkage analysis in PTC kindreds will be done as well as genetic association studies in larger cohorts of PTC patients.

**Gene Expression Profiling of Uterine Leiomyomata.** *M. Mahadevappa<sup>1</sup>, H. Wang<sup>2</sup>, H. Li<sup>2</sup>, Y. Wen<sup>2</sup>, B. Chen<sup>2</sup>, M. Polan<sup>2</sup>, J. Warrington<sup>1</sup>.* 1) Health Management, Applied Research, Affymetrix, 3380 Central Expressway, Santa Clara, CA 95051; 2) Department of Gynecology and Obstetrics, Stanford University School of Medicine, Stanford, CA 94305.

Uterine leiomyomata, fibroid myomas, are common benign smooth muscle tumors occurring in 20-30% of women over 30 years of age. Despite the importance of uterine leiomyomata as a cause of most of the 200,000 hysterectomies performed annually in the United States little is known about its pathogenesis or genetic basis of development. The present study was undertaken to evaluate differences in gene expression in uterine leiomyomata with matched normal myometrium tissue. Labeled target from 8 paired myomas and myometrium was hybridized on GeneChip<sup>®</sup> HuGeneFL arrays containing probes representing approximately 6800 full-length human genes. A list of candidate genes was derived using a combination of analytical tools. Candidate genes identified include genes coding for extracellular proteins, growth factors, hormone/hormone receptors, and mitochondrial transcripts. For a number of genes, results were validated by RT-PCR. These findings will undoubtedly enhance the understanding of the molecular basis of this disease and provide information necessary to design improved diagnostics and therapeutics.

**Immune surveillance genes and breast cancer: does IL6 or TNFa modify BRCA1?** A-M. Martin<sup>1,2</sup>, G.

Athanasiadis<sup>1,2</sup>, P.A. Kanetsky<sup>3</sup>, J.D. Greshock<sup>1,2</sup>, C. Lerman<sup>4</sup>, C. Isaacs<sup>5</sup>, T.R. Rebbeck<sup>3</sup>, B.L. Weber<sup>1,2</sup>. 1) Dept Medicine; 2) Abramson Family Cancer Research Institute; 3) Center for Clinical Epidemiology and Biostatistics; 4) Cancer Center, Univ. of Pennsylvania, Philadelphia, PA; 5) Lombardi Cancer Center, Georgetown University, Washington DC.

Women who carry BRCA1 mutations have up to an 80% risk of developing breast cancer by the time they reach age 70. However, there is considerable variability in the age of diagnosis of breast cancer as well as incomplete penetrance in BRCA1 mutation carriers, suggesting that other factors play a role in BRCA1-associated breast cancer risk. There is evidence that cytokine gene polymorphisms are associated with different diseases, but the exact role of these polymorphisms in cancer is unknown. IL-6 and TNFa play an integral role in the immune response to tumors and are highly polymorphic. Therefore, we sought to determine whether polymorphisms in IL-6 (G-174C) and TNFa (G-238A, G-308A, C-850T, C-856A) were associated with breast cancer occurrence and age of diagnosis among BRCA1 mutation carriers. We studied 222 women with germline BRCA1 mutations, 140 (63%) of whom had breast cancer and 82 (37%) of whom had not been diagnosed with breast cancer. Breast cancer cases were more than twice as likely to carry two G-alleles for the TNF-238A polymorphism (OR=2.5, 95% CI: 0.9, 6.9). Overall, women with breast cancer were only 40% more likely to carry any C-allele for the IL-6-174C polymorphism (OR=1.4, 95% CI: 0.8, 2.4) compared to controls. However, when stratified by age, a significant association was noted in that women diagnosed with breast cancer 50 years of age and older were more than twice as likely to have at least one C-allele (OR=2.3 95% CI: 1.0, 5.1). This association was not seen among younger women (dx<50)(OR=0.72, 95% CI: 0.3, 1.7). We did not find other associations with the remaining 4 loci tested. These preliminary data suggest that IL-6 is associated with an altered risk for breast cancer among older women, and provide the first evidence of a role for immune surveillance genes in breast cancer.

**Stage III gene expression profiles identify a poor prognosis subgroup of stage I lung adenocarcinomas. A.M.**

*Levin<sup>1</sup>, D.G. Beer<sup>2</sup>, J.M.G. Taylor<sup>2</sup>, R. Kuick<sup>2</sup>, T.J. Giordano<sup>2</sup>, S. Hanash<sup>2</sup>, S.L.R. Kardia<sup>1</sup>.* 1) University of Michigan School of Public Health, Ann Arbor, MI; 2) University of Michigan School of Medicine, Ann Arbor, MI.

The aim of the current study is to determine whether gene expression profiles can be used to identify subgroups of stage I lung adenocarcinomas that more closely resemble stage III tumors, both molecularly and in their overall survival. Gene expression profiles of 87 newly diagnosed lung adenocarcinomas (68 stage I and 19 stage III) were determined using Affymetrix oligonucleotide microarrays, containing 7129 probe sets corresponding to approximately 6800 unique genes. The 7129 probe sets were reduced to the 2469 genes that were consistently expressed at levels high enough for detection by the microarray. To determine which genes were associated with survival in stage III tumors, 2469 univariate Cox proportional hazards models were fit and genes were rank-ordered based on p-values. The top 50 genes significantly associated with the survival of stage III patients (p-value < 0.05) were then used to compute a risk index value for each stage I patient. We define the risk index (RI) as  $RI_i = \sum_j b_j x_{ij}$ , where  $b_j$  corresponds to each of the 50 univariate regression estimates from the stage III patients and  $x_{ij}$  is the gene expression measure for each of these j genes for the ith stage I patient. The median of the distribution of risk indices was used as a cut point to delineate high and low risk stage I patients. Kaplan-Meier analysis showed a statistically significant difference in survival between these high and low risk stage I subgroups (p=0.02). These high and low risk subgroups could not be explained by differences in tumor differentiation, p53, or K-ras mutational status. We also identified statistically significant (p-value < 0.05) mean differences in the expression of 596 genes between high and low risk stage I patients. These results show that gene expression profiles which predict survival in stage III patients may be useful to molecularly discriminate good and poor prognosis stage I patient subgroups. Poor prognosis stage I patients may then benefit from more aggressive therapy beyond surgery.

**Evidence for recurrent deletions spanning the SDHC gene at chromosome 1q21 in families with hereditary paraganglioma type 3 (PGL3).** *J.E. Willett-Brozick<sup>1</sup>, K. Astrom<sup>2</sup>, E.C. Lawrence<sup>2</sup>, R.E. Ferrell<sup>2</sup>, E.N. Myers<sup>3</sup>, B.E. Baysal<sup>1,2,3</sup>.* 1) Dept. Psychiatry, Univ Pittsburgh Med Ctr.; 2) Hum Genet, Univ Pittsburgh; 3) Dept Otolaryngology Univ Pittsburgh Med Ctr, Pittsburgh, PA.

Hereditary paragangliomas (PGL) are benign slow growing tumors of the head and neck. Three loci have been implicated in their pathogenesis: PGL1 at 11q23, PGL2 at 11q13 and PGL3 at 1q21. The genes underlying the PGL1 and PGL3 loci have been identified as SDHD and SDHC, respectively. The SDHD and the SDHC genes encode the small and the large subunits of cytochrome b in mitochondrial complex II. PGL1 is the most common locus and is exclusively transmitted paternally, suggesting genomic imprinting. Many mutations have been described in the SDHD gene which are mainly composed of point mutations, microinsertions and microdeletions, all suggesting loss of function of the protein product. Only a single mutation in SDHC has been uncovered in a PGL3 family. Here, we present mutational analyses of four multiplex PGL families that show no evidence of imprinted transmission. All families excluded linkage to the PGL1 at 11q23, but they showed evidence of linkage to the PGL3 region at 1q21. We performed SSCP and direct sequence analyses of the SDHC gene and failed to identify any mutations. Discovery of several intronic polymorphisms led us to uncover presence of large genomic deletions spanning the SDHC gene in two families. To test whether these two families had the same ancestral mutation we compared their disease chromosome haplotypes. Haplotype analysis did not reveal any similarity between the two families strongly suggesting that the deletions in these families represent independent mutational events. In the other two families large deletions have been excluded by the identification of heterozygosities in the intronic polymorphisms. No intragenic deletions could be identified in any of the four families by RT-PCR analyses. These findings suggest that recurrent large genomic deletions spanning the SDHC gene cause PGL3 and that the pericentromeric region of chromosome 1q21 may contain unstable elements associated with recurrent deletions and other genomic rearrangements.

***CPA3* at 7q32 imprinted domain is a strong candidate gene for prostate cancer aggressiveness.** *T. Kishino*<sup>1,3</sup>, *T. Kayashima*<sup>2,3</sup>, *K. Yamasaki*<sup>2,3</sup>, *S. Hayashida*<sup>2,3</sup>, *N. Miwa*<sup>2</sup>, *N. Niikawa*<sup>2,3</sup>. 1) Nagasaki University Gene Research Center, Nagasaki, Japan; 2) Department of Human Genetics, Nagasaki University School of Medicine, Nagasaki, Japan; 3) CREST, JST, Kawaguchi, Japan.

*MEST/PEG1*, a gene expressed paternally in mesodermal derivatives in early embryonic stages is the first imprinted gene mapped to chromosome 7. Since imprinted genes are clustered in general at a chromosomal region, we speculated that a similar imprinted-gene cluster may exist at 7q32 and that the functions of some such genes may contribute to the phenotype of maternal UPD7. We constructed a complete contig of PAC/BAC clones and transcript map spanning the entire 1-Mb region between *D7S530* and *D7S649* (Hayashida et al., 2000). Based on the Human Transcript Map, we precisely mapped 47 genes/ESTs and analysed the imprinting status of several genes/ESTs adjacent to *MEST* (Yamasaki et al., 2000). Here we report the imprinting status of *CPA3*, carboxypeptidase A3, 200-kb centromeric to *MEST* at 7q32. *CPA3* has been identified as an upregulated gene in PC-3 cells, a prostate cancer cell line, after treatment with sodium butyrate and trichostatin A (TSA), suggesting induction of *CPA3* is mediated by histone hyperacetylation. We analyzed the imprinting status of *CPA3* in fetal tissues and cell lines with and without TSA treatment, which is reported to change expression patterns of some imprinted genes. In the fetal heart, kidney, and lung, *CPA3* revealed a consistent skewed-expression pattern; the maternal derived expression was more abundant than the paternal derived expression. In EB-virus transformed lymphoblastoid cell lines, the expression patterns were variable, i.e., biallelic expression or complete monoallelic maternal expression, and were not changed by TSA treatment. In PC-3 cell line, *CPA3* was biparentally expressed without TSA and upregulated but did not show any skewed expression pattern with TSA. Although this study so far could not demonstrate "loss of imprinting" in prostate cancer, imprinting status of *CPA3* in the prostate may play an important role in prostate cancer aggressiveness, because *CPA3* is just localized in prostate cancer aggressiveness loci reported between markers *D7S3061* and *D7S1804*.

**Association between CYP3A1 gene polymorphisms and the risk for hereditary prostate cancer.** *BL. Chang<sup>1</sup>, SL. Zheng<sup>2</sup>, GA. Hawkins<sup>2</sup>, SD. Isaacs<sup>3</sup>, KE. Wiley<sup>3</sup>, A. Turner<sup>2</sup>, JD. Carpten<sup>4</sup>, ER. Bleecker<sup>2</sup>, PC. Walsh<sup>3</sup>, JM. Trent<sup>4</sup>, DA. Meyers<sup>2</sup>, WB. Isaacs<sup>3</sup>, J. Xu<sup>2</sup>.* 1) University of Maryland School of Medicine, Baltimore, MD; 2) Center for Human Genomics, Wake Forest University School of Medicine, Winston-Salem, NC; 3) Department of Urology, Johns Hopkins Medical Institutions, Baltimore, MD; 4) National Human Genome Research Institute, National Institute of Health, Bethesda, MD.

The cytochrome P450 3A (CYP3A) genes play an essential role in steroid and drug metabolism, and are candidate genes for prostate cancer. Five processed CYP3A genes: 3A3, 3A4, 3A5, 3A7, 3A43, and two pseudogenes: 3AP1 and 3AP2, are all mapped to 7q21-q22. An allelic variant, CYP3A4V has been shown to be associated with advanced prostate cancer. The 3AP1-t369g polymorphism was found to be associated with increased CYP3A5 activity. To evaluate the respective role of CYP3A genes in hereditary and sporadic prostate cancer, we performed linkage and association studies in 159 hereditary prostate cancer (HPC) families, 249 sporadic prostate cancer cases, and 211 unaffected controls. No significant evidence for linkage was observed in the region (peak LOD assuming heterogeneity (HLOD)=0.10 at D17S1522), although the HLODs were higher in the subset of HPC families with 4 affected relatives (peak HLOD=1.03 at D17S1522). The frequencies of six SNPs in CYP3A4, 3A5, and 3AP1 were compared between the probands, sporadic cases, and unaffected controls. All the SNPs were in Hardy-Weinberg Equilibrium and all the pair-wise linkage disequilibrium tests were highly significant ( $p < 0.00001$ ). No association between CYP3A4V and the risk of prostate cancer was observed. However, increased frequencies of rare alleles were observed in HPC probands and sporadic cases, compared with unaffected controls for all the SNPs in the 3A5 and 3AP1 genes. The frequency of heterozygotes of 3AP1-t369g in HPC probands (24%) was significantly higher compared with controls (15%) (OR=1.98, 95% CI= 1.11-3.55,  $p=0.02$ ). This difference was larger in the older age of onset group. Our results suggest that sequence variants in the CYP3A5 may increase prostate cancer risk, especially in HPC.

**Mutation screen and association test of 1-a-hydroxylase gene in prostate cancer.** GA. Hawkins<sup>1</sup>, SL. Zheng<sup>1</sup>, S. Cramer<sup>1</sup>, SD. Isaacs<sup>2</sup>, KE. Wiley<sup>2</sup>, BL. Chang<sup>3</sup>, J. Mychaleckyj<sup>1</sup>, JD. Carpten<sup>4</sup>, ER. Bleecker<sup>1</sup>, PC. Walsh<sup>2</sup>, JM. Trent<sup>4</sup>, DA. Meyers<sup>1</sup>, WB. Isaacs<sup>2</sup>, J. Xu<sup>1</sup>. 1) Center for Human Genomics, Wake Forest Univ School of Medicine, Winston-Salem, NC; 2) Department of Urology, Johns Hopkins Medical Institutions, Baltimore, MD; 3) University of Maryland School of Medicine, Baltimore, MD; 4) National Human Genome Research Institute, National Institute of Health, Bethesda, MD.

1-a, 25 dihydroxyvitamin D3 (1,25(OH)2D3) is the active hormonal form of vitamin D3. Because 1,25(OH)2D3 exhibits potent antiproliferative properties on normal and neoplastic prostatic cells, it has been proposed that 1,25(OH)2D3 may have a role in regulating the growth of prostatic cancer cells. Thus any defects in the metabolic pathway of 1,25(OH)2D3 production could be implicated in increased risk for prostate cancer. The enzyme 1-a-hydroxylase catalyzes the final step of the vitamin D anabolic cascade, to convert the vitamin D prohormone 25-hydroxyvitamin D3 (25 OH)D3) to the active hormonal metabolite 1,25(OH)2D3. To test the hypothesis that sequence variants in the 1-a-hydroxylase gene may be associated with prostate cancer risk, we sequenced the entire 1-a-hydroxylase gene (exons and introns) in 96 individuals, including 72 Caucasians and 24 African Americans. Each racial group consisted of equal numbers of hereditary prostate cancer cases, sporadic cases, and unaffected controls. One SNP in the coding region was identified, and did not change an amino acid. Five other SNPs were also identified in the non-coding region. Interestingly, the four coding SNPs that had previously been identified and associated with pseudovitamin D deficiency (rickets) were not observed in the 96 samples. We then genotyped four frequent SNPs in a larger set of cases and control samples (total 249 cases and 222 controls). All genotyped SNPs were found to be in Hardy-Weinberg equilibrium and in strong linkage disequilibrium ( $P < 0.00001$ ). No significant difference was found in the allele and genotype frequencies between the sporadic cases and unaffected controls. Our results suggest that the 1-a-hydroxylase gene does not play a major role as a prostate cancer susceptibility gene.

**Mutation screen and association test of DLC1 gene in hereditary and sporadic prostate cancer patients. S.**

Zheng<sup>1</sup>, GA. Hawkins<sup>1</sup>, J. Mychaleckyj<sup>1</sup>, SD. Isaacs<sup>2</sup>, KE. Wiley<sup>2</sup>, AR. Turner<sup>1</sup>, BL. Chang<sup>3</sup>, JD. Carpten<sup>4</sup>, ER. Bleecker<sup>1</sup>, PC. Walsh<sup>2</sup>, JM. Trent<sup>4</sup>, DA. Meyers<sup>1</sup>, WB. Isaacs<sup>2</sup>, J. Xu<sup>1</sup>. 1) Center for Human Genomics, Wake Forest Univ. Sch. of Med., Winston-Salem, NC; 2) Department of Urology, Johns Hopkins Medical Institutions, Baltimore, MD; 3) University of Maryland School of Medicine, Baltimore, MD; 4) National Human Genome Research Institute, National Institute of Health, Bethesda, MD.

A gene or genes on chromosome 8p22-23 have been implicated in prostate carcinogenesis by the observation of frequent deletions of this region in prostate cancer cells, and by two recent linkage studies in hereditary prostate cancer (HPC) families. To identify prostate cancer susceptibility genes, we are currently screening candidate genes in the region, including DLC1 (deleted in liver cancer). DLC1 is a candidate tumor suppressor gene because of its 86% homology with rat p122 RhoGAP, which catalyzes the conversion of the active GTP-bound rho complex to the inactive GDP-bound form, suppressing Ras-mediated oncogenic transformation. A previous study identified a missense mutation and three intronic insertions/deletions in 126 primary human colorectal tumors. However, no mutation screening for DLC1 in prostate tumor or germ line DNA of prostate cancer patients has been previously reported. In this study, we report the results of a mutation screen and association test of DLC1 in hereditary and sporadic prostate cancer genomic DNA samples. The PCR products of all 14 exons, exon-intron junctions, and 3' UTR were directly sequenced in 159 HPC probands. Six SNPs were identified in the coding regions; all are conservative changes. In addition, 25 other SNPs were identified in the non-coding regions. Nine of the 31 SNPs were frequent (>10%) and thus were genotyped in 249 sporadic cases and 222 unaffected controls. All the genotyped SNPs were in Hardy-Weinberg Equilibrium, and all the pair-wise SNPs were in strong LD ( $P < .00001$ ). No significant difference in the allele and genotype frequencies were observed among HPC probands, sporadic cases, and unaffected controls. These results suggest that DLC1 is unlikely to be an important prostate cancer susceptibility gene.

**Analysis of linkage disequilibrium in Caucasian and African-American breast cancer cases and controls reveals different evolutionary histories of BRCA1 vs BRCA2.** *T. Walsh<sup>1</sup>, R.K. Kim<sup>1</sup>, B. Newman<sup>2</sup>, M-C. King<sup>1</sup>.* 1) Depts of Medicine and Genomic Sciences, University of Washington, Seattle, WA; 2) School of Public Health, Queensland University of Technology, Australia.

In order to understand the genomic structure and evolution during human history of BRCA1 and BRCA2, we identified multiple SNPs (with rarer allele frequency 0.2 or higher) to span 80 kb of the coding, intronic, and regulatory sequences of each gene. All SNPs were genotyped for a series of 800 breast cancer cases and matched controls, of European and African-American ancestry, from the population-based Carolina Breast Cancer Study. Frequencies of individual SNPs were the same in cases vs. controls, and allele frequencies of all SNPs were in Hardy-Weinberg equilibrium. However, linkage disequilibrium (LD) relationships differed between BRCA1 and BRCA2 and between haplotypes by continent of origin (African-Americans were assumed to carry haplotypes of both African and European origins). Results suggest very different histories of the two genes. At BRCA1, LD across the locus is 1.0 in each population. However, at BRCA1 differences in haplotype frequencies between populations suggest a founder effect and/or selection on BRCA1 after migrations to Europe. In contrast, at BRCA2, no dramatic European-specific selection is suggested. Rather, at BRCA2, LD varies across the locus, with patches of low LD embedded in regions of overall high LD. This pattern could reflect the existence of highly mutable sites. How these different histories may be associated with persistence or dispersion of cancer-predisposing alleles is still not clear to us.

**Linkage analysis in a collection of German PCA families reveals a high contribution of HPCX.** *W. Vogel<sup>1</sup>, T. Paiss<sup>2</sup>, K. Herkommer<sup>2</sup>, J. Haeussler<sup>1</sup>, S. Bochum<sup>1</sup>.* 1) Dept Human Genetics, Univ Ulm, Ulm, Germany; 2) Dept Urology, Univ Ulm, Ulm, Germany.

Obviously there are considerable differences in allele frequencies of different prostate cancer susceptibility genes between different populations yielding variable results in linkage analyses. Therefore it seems worthwhile to establish independent family collections in different countries and to assess the contribution of the different loci in these populations. We have now a collection of 222 German families (3.2 affecteds per family, and 64.9 years mean age at onset) with 104 families used here, which is a sufficiently large sample to allow for linkage studies. HPCX is one of the 5 first PCa susceptibility loci and its contribution to familial PCa had been found highly different in US populations compared to Finland (14% versus 33%). In the 104 German families analysed, we found a maximum HLOD of 1.65 and a 0.34 in the subset of 63 families that had a mean age at onset < 65 years. The corresponding NPL Z score was 2.32 ( $P = 0.009$ ) at DXS984, formally confirming the original linkage. The position of the highest LOD score is close to that of earlier studies (7cM from DXS1113). Preliminary results on the 3 loci on chromosome #1 indicate that these play only a minor role in familial PCa in Germany (highest NPL Z score 1.18 at D1S2785 in the PCaP locus, HLOD < 1 and a < 0.2 throughout). Our results confirm linkage to HPCX and are very similar to those in the Finnish families. This similarity may indicate a rather homogeneous situation in Europe. The difference to the caucasian US population remains unexplained and is difficult to understand, given the very recent European origin of this population.

**Tumour specific promoter methylation of the human homologue of the drosophila Roundabout gene DUTT1**

**(ROBO1) in human cancers** . A. Dallot<sup>1</sup>, E. Forgacs<sup>2</sup>, A. Martinez<sup>1</sup>, Y. Sekido<sup>2</sup>, P. Rabbitts<sup>3</sup>, E.R. Maher<sup>1,4</sup>, J.D. Minna<sup>2</sup>, F. Latif<sup>1,4</sup>. 1) Department of Paediatrics and Child Health, University of Birmingham, UK; 2) Hamon Center for Therapeutic Oncology Research, University of Texas Southwestern Medical Center, Texas, USA; 3) Medical Research Council Centre, Hills Road, Cambridge, UK; 4) CRC Renal Molecular Oncology Research Group, University of Birmingham, UK.

The human homologue of the drosophila Roundabout gene DUTT1 (Deleted in U Twenty Twenty) or ROBO1, a member of the NCAM family of receptors, was recently cloned from the lung cancer tumour suppressor region 2 (LCTSGR2 or U2020 region) at 3p12. DUTT1 overlaps homozygous deletions characterised in both small cell lung cancer lines (SCLC) and in a breast cancer line. We(a) defined the genomic organisation of DUTT1 gene, (b) performed mutation and expression analysis of DUTT1 in lung, breast and kidney cancers, (c) identified tumour specific promoter region methylation of DUTT1 in human cancers. The gene was found to contain 29 exons and spans at least 240 kb of genomic sequence. The 5' region contains a CpG island, and the poly A tail has an atypical GATAAA signal. We analysed DUTT1 for mutations in lung, breast and kidney cancers, however, no inactivating mutations were detected by PCR-SSCP. Seven germline missense changes were found and characterised. DUTT1 expression was not detectable in 1/14 breast tumour lines analysed by RT-PCR. Bisulphite sequencing of the promoter region of DUTT1 gene in the HTB-19 breast tumour cell line showed partial hypermethylation of CpG dinucleotides. The expression of DUTT1 was restored after demethylating with 5-aza-2-deoxycytidine. The same region was also found to be hypermethylated in 6/32 (19%) primary breast tumours and 8/44 (18%) primary clear cell renal cell carcinomas (CC-RCC) and in 1/26 (4%) primary NSCLC tumours. Furthermore 80% of breast and 75% of CC-RCC tumours showing DUTT1 methylation had allelic losses for 3p12 markers hence obeying Knudsons two hit theory. These findings suggest that DUTT1 should be considered as a candidate for the TSG at 3p12.

**RASSF1A promoter region CpG island hypermethylation in pheochromocytoma and neuroblastoma tumors. A.**

*Agathangelou<sup>1</sup>, D. Astuti<sup>1</sup>, S. Honorio<sup>1</sup>, A. Dallol<sup>1</sup>, T. Martinsson<sup>2</sup>, C. Cummins<sup>3</sup>, H.P.H Neumann<sup>4</sup>, C. Eng<sup>5</sup>, E.R. Maher<sup>1</sup>.* 1) Section of Medical and Molecular Genetics, Department of Reproductive and Child Health, University of Birmingham, Birmingham, B15 2TT, UK; 2) Department of Clinical Genetics, Gothenburg University, Gothenburg, Sweden; 3) The Birmingham Childrens Hospital, Steelhouse Lane, Birmingham, UK; 4) Medizinische Universitätsklinik, Freiburg, Germany; 5) Clinical Cancer Genetics and Human Cancer Genetics Programs, Comprehensive Cancer Center, and the Division of Human Genetics, Department of Internal Medicine, The Ohio State University, Columbus, OH, USA.

Deletions of chromosome 3p are frequent in many types of neoplasia including neuroblastoma (NB) and pheochromocytoma. Recently we isolated several candidate tumour suppressor genes (TSGs) from a 120kb critical interval at 3p21.3, defined by overlapping homozygous deletions in lung and breast tumor lines. A CpG island in the promoter region of one of the genes (RASSF1A) was found to be methylated in a majority of lung tumors. To investigate the role of 3p TSGs in neural crest tumors, we (a) analyzed 41 pheochromocytomas for allele loss in regions proposed to contain 3p TSGs, (b) examined 23 sporadic pheochromocytomas for evidence of RASSF1A methylation and (c) investigated 67 neuroblastoma tumors for RASSF1A inactivation. We found that 46% of pheochromocytomas showed allele loss at one or more 3p marker(s), and 38.5% demonstrated loss for 3p21.3 marker(s). RASSF1A promoter region hypermethylation was found in 22% (5/23) of sporadic pheochromocytomas and in 55% (37/67) of neuroblastomas analyzed but RASSF1A mutations were not identified. In a neuroblastoma cell line, methylation of RASSF1A correlated with loss of RASSF1A expression and RASSF1A expression was restored after treatment with the demethylating agent 5-azacytidine. These results indicate that RASSF1A inactivation by hypermethylation is important in neural crest tumorigenesis, particularly neuroblastoma.

**Epigenetic inactivation of the RASSF1A tumour suppressor gene (TSG) in renal cell carcinoma.** *C. Morrissey<sup>1</sup>, A. Martinez<sup>1</sup>, M. Zatyka<sup>1</sup>, A. Agathangelou<sup>1</sup>, P. Schraml<sup>2</sup>, T. Kishida<sup>3</sup>, F. Richards<sup>1</sup>, F. Latif<sup>1</sup>, E. Maher<sup>1</sup>.* 1) Medical and Molecular Genetics, University of Birmingham, Birmingham, West Midlands, UK; 2) University of Basel, Switzerland; 3) Yokohama City University, Japan.

Renal cell carcinoma (RCC), the most common adult kidney neoplasm, is histopathologically heterogeneous, with most sporadic RCC (~80%) classified as clear cell tumours (cc-RCC). Chromosome 3p allele loss is the most frequent genetic alteration in RCC, but is associated specifically with CC-RCC and is not a feature of non-clear cell RCC such as papillary. Somatic inactivation of the VHL TSG located at chromosome 3p25 occurs in up to 70% of CC-RCC tumours and cell lines. However VHL inactivation is not sufficient for CC-RCC tumourigenesis and inactivation of 3p12-p21 TSG(s) appears necessary irrespective of VHL gene status. Recently we demonstrated that the candidate 3p21 TSG, RASSF1A, is hypermethylated in most small cell lung cancers. We have now investigated the role of RASSF1A inactivation in primary RCC tumours. RASSF1A promoter methylation was detected in 23% of primary CC-RCC tumours. In CC-RCC cell lines RASSF1A methylation was associated with silencing of RASSF1A expression which was restored after treatment with 5azacytidine. The frequency of RASSF1A methylation was similar in CC-RCC with and without VHL gene inactivation (24%/29%), with no association between epigenetic silencing of the RASSF1A and VHL TSGs. Although 3p allele loss is reported rarely in papillary RCC, we identified RASSF1A methylation in 44% of papillary RCC analysed. Thus (a) inactivation of RASSF1A is frequent in both CC-RCC and papillary RCC tumours and (b) there is no relationship between epigenetic silencing of RASSF1A and VHL in CC-RCC. 54 CC-RCC analysed for RASSF1A methylation were informative for 3p21 allele loss, of which 20% demonstrated RASSF1A methylation. All informative CC-RCC with 3p21 loss and no RASSF1A methylation demonstrated allele losses elsewhere in 3p so in these cases tumourigenesis may result from (a) haploinsufficiency of RASSF1A, (b) inactivation of other 3p21 TSGs or (c) inactivation of TSGs outside of 3p21. RASSF1A is the first TSG to be inactivated frequently in both papillary and CC-RCC.

**Allele-specific methylation of the NF1 gene during development.** *T.R. Haines<sup>1</sup>, D.R. Rodenhiser<sup>1</sup>, P.J. Ainsworth<sup>1,2</sup>.*  
1) Biochemistry, University of Western Ontario, London, Canada; 2) Mol Diag Lab, LHSC, London, Canada.

Cytosine methylation is the principal base modification of vertebrate DNA. In adult tissues 5-methylcytosines are found predominantly in CpG dinucleotides, although non-CpG methylation exists in cultured murine embryonic stem cells, mainly at CpA dinucleotides. Parent-of-origin effects observed in de novo mutagenesis at the human neurofibromatosis (NF1) gene locus have led us to examine methylation patterns of the highly homologous murine Nf1 gene, both in gametes and at the earliest stages of preimplantation development. Point mutations, which form the majority of de novo NF1 mutations, have been shown to be primarily of paternal origin, while the less common larger deletion events are frequently maternally derived. We have evaluated the methylation status of a CpG dinucleotide within the murine Nf1 gene that correlates with a site of recurrent mutation (C5839T) in the human NF1 gene. Using bisulfite genomic sequencing we have shown that this CpG site was fully methylated in sperm, oocyte and in the early preimplantation embryo, with no allele-specific bias being seen. Unexpectedly, we have discovered allele-specific non-CpG methylation at the Nf1 locus, found primarily at CpA dinucleotides and to a lesser extent at CpTs. Non-CpG methylation at the Nf1 locus was specific to oocyte DNA and to the maternal allele of the 2-cell embryo. This pattern of non-CpG methylation was not found in DNA from sperm or in the paternally-derived allele of the 2-cell embryo. Non-CpG methylation was temporally restricted to early embryogenesis, and did not persist beyond the 8-cell stage of development. This non-CpG methylation may be a more widespread event in the early embryo since we have also observed the presence of similar non-CpG methylation at the murine adenosine deaminase gene in 2-cell embryos. We speculate that these transient patterns of non-CpG methylation may be related to the parent-of-origin effects seen in de novo mutation events in the NF1 (and possibly other) gene loci. As well, this type of allele-specific methylation may play a part in the control of wider patterns of gene expression in the early stages of preimplantation development.*de novo.*

**Comprehensive DNA methylation study in 40 uveal melanomas.** *M. Zeschnigk, B. Horsthemke, D.R. Lohmann.*  
Institut für Humangenetik, Universitätsklinikum Essen, Hufelandstr. 55, 45122 Essen, Germany.

Uveal melanoma is the most common form of primary eye cancer. Monosomy 3, which is an unusual finding in tumors, but present in about 50% of uveal melanomas, is significantly correlated with metastatic disease. Long-term studies have shown that 4 years after diagnosis approximately 70% of patients showing monosomy 3 in the primary tumor have died of metastases, whereas tumors with disomy 3 rarely give rise to metastatic disease. In many tumors, recurrent loss of genetic material is part of a two step inactivation of tumor suppressor genes. Inactivation of second alleles might be caused by local mutations such as point mutations, gene deletions or epigenetic silencing. The observation of isodisomy of chromosome 3 in some uveal melanomas has led to the hypothesis that epigenetic factors might play a role in tumor development and metastatic disease. We have performed a comprehensive methylation study of the promoter regions of 8 genes reported to be involved in tumorigenesis. Five of these genes are located on chromosome 3. Additionally, the SNRPN gene located in the the imprinted region on chromosome 15 was included in the study. Using the bisulfite genomic sequencing protocol or the methylation specific PCR (MSP) the methylation patterns of these genes were analyzed in 20 uveal melanomas with monosomy 3 and in 20 uveal melanomas with disomy 3. None of the tumors showed hypermethylation in the promoter regions of the fragile histidine triad (FHIT), beta-catenin, von Hippel-Lindau (VHL), E-cadherin, activated leukocyte cell adhesion molecule (ALCAM), and retinoblastoma (RB1) genes. Three tumors showed some hypermethylation in the retinoic acid receptor (RAR) promoter on chromosome 3, and in 3 other tumors the p16 gene promoter region was hypermethylated. The imprinted SNRPN and PW71 loci were hypermethylated in 3 out of 40 tumors. We conclude that methylation in the analyzed genes occurs infrequently in uveal melanoma and appears not to be associated with the chromosome 3 status.

**Epigenetic inactivation of the *RASSF1A* tumour suppressor gene in Wilms' tumour.** *K.J. Wagner<sup>1</sup>, W.N. Cooper<sup>1</sup>, R.G. Grundy<sup>1,2</sup>, R. Wadey<sup>1,2</sup>, F. Latif<sup>1</sup>, E.R. Maher<sup>1</sup>.* 1) Medical and Molecular Genetics, University of Birmingham, Birmingham, West Midlands, United Kingdom; 2) Department of Paediatric Oncology, Birmingham Childrens Hospital, Birmingham, West Midlands, United Kingdom.

Promoter methylation is an important mechanism of tumour suppressor gene (TSG) inactivation in human cancer. Although studies of classical TSGs such as *VHL* and *RBI* suggested that TSG inactivation by promoter methylation is less frequent than somatic mutations, recently epigenetic silencing has been established as the major mechanism of inactivation of the 3p21.3 TSG, *RASSF1A*. We have established that *RASSF1A* methylation is frequent in both clear cell and papillary adult renal cell carcinomas, even though 3p21.3 allele loss is rare in papillary tumours. Wilms tumour is the most common childhood kidney tumour and is thought to be derived from primitive nephroblasts. Somatic mutations in the *WT1* TSG can be detected in ~10% of Wilms tumours and although epigenetic alterations at *IGF2* and *H19* are common, inactivation of TSGs such as *p16* and *p53* occur in only a minority of Wilms tumours so the identification of major Wilms TSGs is a priority. Although 3p allele loss is infrequent in Wilms tumour, in view of its involvement in adult renal cancers we investigated *RASSF1A* as a candidate Wilms TSG. We detected *RASSF1A* hypermethylation by methylation-specific PCR (MSP) in 20 of 40 (50%) primary Wilms tumours. *RASSF1A* methylation was detected in normal tissue DNA for only 2 of 14 samples analysed (in both of these cases the corresponding tumour demonstrated *RASSF1A* methylation). We investigated the relationship between *RASSF1A*, *p16* and *H19* methylation in Wilms tumour but did not find a statistically significant association. We have demonstrated that epigenetic inactivation of *RASSF1A* is the most frequent event in Wilms tumourigenesis and that in specific tumours types a major TSG may exist in regions with a low frequency of allele loss.

**Polyomavirus Large T Antigen / MMTV Transgenic Mice as a Model of Uterine Leiomyomata.** *D.M. Neskey*<sup>1</sup>, *A.H. Ligon*<sup>2,3</sup>, *B.J. Quade*<sup>2,3</sup>, *C.C. Morton*<sup>1,2,3</sup>. 1) Dept Obstetrics, Gynecology, and Reproduction Biology, Brigham & Women's Hospital, Boston, MA; 2) Dept Pathology, Brigham & Women's Hospital, Boston, MA; 3) Harvard Medical School, Boston, MA.

Uterine leiomyomata, commonly known as fibroids, are benign smooth muscle tumors found in up to 70% of reproductive-aged women and are the cause of more than 200,000 hysterectomies performed annually in the United States. To study further the biology of these tumors and to aid in the design of nonsurgical therapies, we have characterized a transgenic mouse model (MMTV/PyVLT) expressing the polyomavirus (PyV) large T (LT) antigen driven by the mouse mammary tumor virus enhancer / promoter (Oncogene 16:1963-1972, 1998). Although a number of animal models are currently being studied in which uterine tumors are present no single model fully represents the human condition and many biological questions await evaluation. Uterine tumors were observed in 22/46 MMTV/PyVLT transgenic females and were negatively correlated with the parity of the animal. Tumors were observed as early as 6 months of age in 1/3 nulliparous mice. Histological study of these neoplasias suggested similarities with their human counterpart, including a spindle-cell appearance in culture and a generally cytologically normal appearance. Interestingly, mitotic activity varied from <1 to >10 mitotic figures per 10 HPF. Necrosis was limited to the core in most tumors, but occasionally was more extensive and geographic. Cellularity also varied from low (with increased amount of intracellular matrix) to high (with virtually no intracellular matrix), and generally correlated with mitotic activity. Cytogenetically, 40% of human leiomyomata show karyotypic abnormalities, but initial analyses of four murine tumors to date have not revealed any clonal chromosomal changes. Future studies will involve identification and characterization of orthologous genes and proteins involved in the pathogenesis of human uterine leiomyomata (i.e., HMGA1 and HMGA2) using microarray and tissue array technologies.

**Phenotypic characteristics of colon cancer in I1307K APC germline mutation carriers compared with sporadic cases.** *E. Friedman*<sup>1</sup>, *A. Figer*<sup>2</sup>, *L. Irmin*<sup>1</sup>, *R. Geva*<sup>2</sup>, *A. Tamir*<sup>3</sup>. 1) Oncogenetics Unit, Inst Gen, Chaim Sheba Medical Ctr, Tel Hashomer, Israel; 2) Institute of Oncology, Sourasky Medical Center, Tel-Aviv, Israel; 3) epidemiology Unit, Hacarmel Medical Center, Haifa, Israel.

The I1307K APC germline mutation is associated with an increased risk to colorectal cancer (CRC). Whether and to what extent the phenotype of CRC in mutation carriers differs from sporadic cases, remains unknown. To gain insight into this issue, we analyzed 307 unselected Israeli patients with CRC, who were treated in a single medical center, for harboring the I1307K mutation. Twenty-eight mutation carriers (9.1%) were detected. Two of 28 mutation carriers (7.1%) and 93/277 (33.6%) of non-carriers, were of non-Ashkenazi origin ( $p < 0.01$ ). In 74/278 (26.6%) of the sporadic cases, and only 1/28 (3.6%) of mutation carriers (3.6%) the tumor was located in the right colon ( $p < 0.01$ ). Mutation carriers had a more advanced disease stage (14/28 50% Dukes C), as compared with 60 (19.5%) of non-carriers ( $p = 0.02$ ). The mean age at diagnosis was similar: 65 (+/- 9.7) years and 66.3 (+/- 11.6) years, for mutation carriers and non-carriers, respectively. No statistical differences were noted between the two groups in sex distribution, tumor grade, and family history of cancer. We conclude that early age at diagnosis and family history of cancer are not consistent features in I1307K APC germline mutation carriers, and with the possible exception of a more advanced disease stage, this mutation probably has little effect on the phenotypic features of CRC.

**Comprehensive mutation scanning of ATM gene in patients with breast cancer reveals a higher frequency of missense mutations in breast cancer relative to ethnically matched controls.** *J. Feng<sup>1</sup>, C.H. Buzin\*<sup>1</sup>, M. Jung\*<sup>2</sup>, J. Zheng<sup>1</sup>, Q. Liu<sup>1</sup>, S.J. Jeong<sup>2</sup>, J. Moulds<sup>2</sup>, V.Q. Nguyen<sup>1</sup>, W.P. Bennett<sup>1</sup>, A. Dritschilo<sup>2</sup>, S.S. Sommer<sup>1</sup>.* 1) Dept. of Molecular Genetics, City of Hope Medical Center, Duarte, CA; 2) Dept. of Radiation Medicine, Georgetown University Medical Center, Washington, D.C. \*These authors contributed equally to this work.

Epidemiological studies have shown an increased risk of breast cancer in obligate heterozygote carriers among family members of ataxia telangiectasia (A-T) patient. However, the expected increase in levels of ATM gene mutations among unselected breast cancer patients has not been found to date. Previous methods of mutation detection were biased toward the detection of truncating mutations, and single nucleotide substitutions were likely to have been under-reported. In this study, genomic DNAs from 43 breast cancer patients and 43 controls were scanned in the entire ATM coding region (exons 4-65) and adjacent intronic splice regions using DOVAM-S (Detection Of Virtually All Mutations-SSCP), a modification of SSCP in which there is sufficient redundancy to detect virtually all mutations. Excluding D1853N found commonly in cases and controls, there were one protein truncating mutation and 14 missense changes in the cases vs. 8 missense changes in controls ( $p=0.06$ ). When all structural changes common to cases and controls were excluded, ten missense changes and one splice mutation were found in cases and two missense changes in controls ( $p=0.013$ ). This is, to our knowledge, the first study to comprehensively scan the ATM gene in control samples of known ethnicity. The background of missense changes in controls is high. There was a trend towards elevation of all structural changes in cases, but the results are not statistically significant. Cohort-specific structural changes were significantly more prevalent in the breast cancer patients. The data are compatible with certain missense mutations in ATM predisposing to breast cancer. If the results can be confirmed in additional studies, it may be of interest to determine whether women with certain missense mutations in the ATM gene respond better to radiation therapy or radiomimetic chemotherapy.

**P53 mutation analysis of breast tumors from a large unselected cohort of BRCA2 mutation carriers and non carriers.** *S. Gudlaugsdottir<sup>1</sup>, H. Hilmarsdottir<sup>1</sup>, J.G. Jonasson<sup>2</sup>, S. Thorlacius<sup>1</sup>, G. Olafsdottir<sup>1</sup>, L. Tryggvadottir<sup>1</sup>, H.M. Ogmundsdottir<sup>1</sup>, J.E. Eyfjord<sup>1</sup>.* 1) Icelandic Cancer Society; 2) University Hospital of Iceland.

It has been postulated that somatic mutations in the p53 gene or other DNA-damage signaling components, are necessary to give a growth advantage to cells with BRCA1 and BRCA2 mutations allowing the transformation of cells or the development of tumors. Consistent with this idea, our previous results and those of others have suggested that there is a higher frequency of p53 mutation in carriers of BRCA germline mutations. In the current study we have enlarged a study group from 402 unselected breast cancer cases to 1301. In our previous study, the p53 mutation frequency, testing exons 5-8, was 29% in BRCA2 carriers and 17% in non-carriers but in the current study the mutation rates are 23% in carriers and 18% in non-carriers. This indicates that the difference between the two groups is less than previously reported. The p53 mutation frequency in the group as a whole is the same, or slightly higher (18.4% as compared to 18.0%), than in the earlier study and the exon distribution is similar in both groups. According to this study there is a slightly increased frequency of p53 mutations in breast tumors from carriers of a BRCA2 999del5 germ line mutation as compared to non-carriers. The difference, however, is not statistically significant. These results differ from published data which are largely based on tumors from BRCA1 mutation carriers. As there is evidence indicating that in tumors with BRCA germline mutation, changes are common at p53 codons that are not mutation hotspots, sequencing of the entire p53 gene is now in progress. The results are also being analysed with respect to clinico-pathologic parameters.

**BRCA1 and BRCA2 founder mutations in Spanish and Mexican populations.** *M. Alvarez-Franco<sup>1</sup>, G. Llorc<sup>2</sup>, R. Gerson<sup>3</sup>, A.E. Bale<sup>1</sup>*. 1) Yale University School of Medicine, New Haven, CT; 2) Instituto Catal(á)n de Oncologia, Barcelona, Spain; 3) Hospital General de M(é)xico, DF. M(é)xico.

BRCA1 and BRCA2 account for a substantial proportion of all hereditary breast cancer. Hundreds of different BRCA mutations have been reported worldwide, but the number of different mutations present in any specific ethnic group may be limited. The Mexican population is represented mainly by Mestizos, a mixture of Spanish and Native American. The Spanish gene pool is derived from a relatively small group of Conquistadores and early colonists who arrived in the region that is now Mexico in 16th century. Based on this history, a subset of the BRCA mutations found in Spain could be present as high frequency founder mutations in Mestizos. We analyzed 77 Spanish breast/ovarian cancer families for mutations in BRCA1 and BRCA2 and identified novel mutations in 14 families and recurrent mutations in 5 families- 185delAG (family not known to be of Jewish ancestry), 189insTGTC, 5537delA and two families with 9254delATCAT. Combining our results with other published data, a total of 43 unique and 5 recurrent mutations have been reported in Spanish families. All of these mutations can be detected by sequencing 21 exons of BRCA1 and 2. We obtained DNA samples from 73 Mexican women with familial breast/ovarian cancer and have so far tested 5 families for the mutations found in Spain. A Spanish mutation in BRCA1 (Arg71Gly) predicted to alter splicing, was identified in one family. This mutation was reported before in an Hispanic family from the Caribbean region and may prove to be a common founder mutation among Hispanics. Additional sequencing of the Mexican population is in progress.

**A role of MLH3 in hereditary nonpolyposis colorectal cancer.** *R.M.W. Hofstra<sup>1</sup>, Y. Wu<sup>1</sup>, M.J.W. Berends<sup>2</sup>, R.H. Sijmons<sup>1</sup>, R.G.J. Mensink<sup>1</sup>, E. Verlind<sup>1</sup>, K.A. Kooi<sup>1</sup>, T. van der Sluis<sup>3</sup>, C. Kempinga<sup>3</sup>, A.G.J. van der Zee<sup>4</sup>, H. Hollema<sup>3</sup>, J.H. Kleibeuker<sup>2</sup>, C.H.C.M. Buys<sup>1</sup>.* 1) Dept. Medical Genetics, University of Groningen, Groningen, The Netherlands; 2) Dept. Gastroenterology, University of Groningen, Groningen, The Netherlands; 3) Dept. Pathology, University of Groningen, Groningen, The Netherlands; 4) Dept. Gynecology, University of Groningen, Groningen, The Netherlands.

The recently cloned mismatch repair (MMR) gene MLH3 might well be involved in the pathogenesis of hereditary nonpolyposis colorectal cancer (HNPCC) because it is associated with mammalian microsatellite instability (MSI) and because its product interacts with MLH1, another MMR protein involved in HNPCC. To investigate a possible involvement of MLH3 in HNPCC we scanned the 12 exons of the gene for mutations in index patients of 39 HNPCC families and in 288 patients suspected for HNPCC. Eleven different germline MLH3 variants, one frameshift and ten missense mutations, were identified in 2 members of genuine HNPCC families and 17 patients with HNPCC suspicion. From 16 of these 19 patients a total of 18 tumours were available for microsatellite analysis. Only five of the 18 tumours displayed MSI-H phenotype at the five consensus markers. Using a different set of five markers not including mono but di and tetranucleotide repeats, 16 of the 18 tumours exhibited an MSI-H phenotype, suggesting an MLH3-specific MSI profile. Five of the 19 patients with an MLH3 variation also carried a mutation in another MMR gene, four in MSH6 and one in MLH1. In some cases, it seems, therefore, that different mutant genes need to occur in combination in order to predispose to tumour development.

**Is homozygosis for the C677T mutation of the MTHFR gene a protective factor for sporadic breast cancer?** *O.M. Mutchinick, L. García, M.A. López, J. Arteaga.* Dept de Genética, Inst Nac de Ciencias Médicas y Nutrición Salvador Zubirán, D.F., México.

Breast cancer (BC) is the first cause of women cancer in the USA and the second in México. Genetic, environmental and life style determinants have been frequently associated to BC. It appears that the MTHFR C@T mutation modulates carcinogenesis by decreasing the risk for CRC and ALL and increasing the risk for endometrial and BC. Apparently, the protective effect is folate dependent. Studies from our group demonstrated a very high prevalence of the T allele (56-81%) and TT genotype (35-68%) and a low folic acid (FA) intake in diverse Mexican *mestizo* and Indian populations.

**Objevtive:** to evaluate the genetic-nutrition risk interaction for BC of the MTHFR C677T mutation and the daily intake of FA, B2, B6 and B12 vitamins. **Design:** prolective case-control study. **Participants:** 78 women with sporadic BC, 71 patients with sporadic CRC and 250 healthy females (HF) from different parts of the country. **Methods:** identification of the C@T mutation by PCR and restriction enzyme analysis and FA, B2, B6 and B12 ingestion by a food frequency intake questionnaire.

**Results:** BC patients showed a significantly lower prevalence of the TT genotype (20.5%) than CRC (38.0%) and HF (34.8%) with gene frequencies for the mutant allele of 44.8, 59.2 and 58.6% respectively. All groups were in H-W equilibrium. Comparison among groups only showed statistical differences (SD) between BC and CRC, OR:0.35 (0.13-0.93),  $p=0.03$ , and between BC and HF, OR:0.34 (0.15-0.74),  $p=0.005$ . SD were also observed for FA ( $p=0.016$ ) and B2 ( $p=0.03$ ) in BC, with a higher intake of both vitamins in TT than CC patients. Similar SD was also found for comparisons between BC-CRC and BC-HF subjects with a TT genotype.

**Conclusions:** Against others finding, our results strongly suggest that TT women have an important lower risk for sporadic BC. That this protective effect of the TT genotype appears to be folate and B2 dependent. Our data also confirm the important role recently attributed to B2 in folate metabolism and MTHFR thermolabile variant activity.

**Germline mutations in CDH1/E-Cadherin in families with hereditary prostate-gastric cancer.** *B.-A. Jonsson<sup>1</sup>, A. Bergh<sup>1</sup>, M. Emanuelsson<sup>2</sup>, H. Gronberg<sup>2</sup>.* 1) Medical Biosciences, Pathology, Umeå University, Sweden; 2) Department of Radiation Sciences, Oncology, Umeå University, Sweden.

Germline mutations of the E-cadherin gene (CDH1) have been found in families with hereditary diffuse gastric cancer. In total, 14 families from Europe, Asia and New Zealand have been reported. In an earlier study we have observed an increased risk of gastric cancer in families with hereditary prostate cancer. To evaluate the importance of possible germline mutations in the CDH1 gene in these prostate cancer families we screened exons 1-16 for mutations with the DHPLC technique. 24 samples from 18 families (15 families with hereditary prostate-gastric cancer and 3 with hereditary gastric cancer) were screened. We observed different patterns in Exons 1, 4, 5, 7, 10, 12, 13 and 15. For the samples with different patterns, a new PCR product was prepared, that was direct sequenced. In all samples but exon 10 we identified base-pair substitutions. In Exon 7 we identified a germ-line mutation, 1003C®T, that causes a stop-codon at the end of the exon in a family with hereditary diffuse gastric cancer. This mutation has previously been reported as a somatic mutation in a lobular breast tumour. In exons 1,4 and 13 we identified earlier reported polymorphisms. In exons 12 and 15 we identified 2 missense mutations with unknown significance in 2 families with hereditary prostate cancer. These mutations together with the mutation in intron 5 has not previously been reported as germline mutations. The prevalence of these three mutations were tested in 136 samples from 73 families with hereditary prostate cancer, 215 cases of sporadic prostate cancer and 422 age-matched controls using an allelic discrimination assay. None of these sequence variants were found in the extended material. In conclusion, we have identified a germline mutation in a family with hereditary gastric cancer and additional 9 sequence variants (2 missense, 6 polymorphisms in introns, 1 polymorphism in gene) of unknown significance. The three novel germline mutations found are pedigree specific and do probably not contribute to prostate cancer.

**Mutations in the BRCA1 and BRCA2 genes identified in a western Swedish patient cohort.** *J. Lundberg<sup>1</sup>, A. Bergman<sup>1</sup>, Z. Einbeigi<sup>2</sup>, Y. Engwall<sup>1</sup>, A. Flodin<sup>1</sup>, P. Karlsson<sup>2</sup>, T. Martinsson<sup>1</sup>, J. Wahlstrom<sup>1</sup>, A. Wallgren<sup>2</sup>, M. Nordling<sup>1</sup>.* 1) Dept. Clinical Genetics, Sahlgrenska Univ Hosp - East, Gothenburg, Sweden; 2) Dept. Oncology, Sahlgrenska Univ Hosp, Gothenburg, Sweden.

Germline mutations in the hereditary breast/ovarian cancer causative genes BRCA1 and BRCA2 are considered to constitute approximately 6-10% of these cancers. The frequency of mutation carriers among women with breast/ovarian cancer depends on the population studied, and displays considerable variation in coincidence with ethnic and geographical diversity. Mutations are mainly found as small insertions, deletions or substitutions, but also as exon-wide deletions. We performed mutation analyses in 103 patients, selected under informed consent, from the Sahlgrenska University Hospital, Gothenburg, Sweden. The genes were initially screened using the Protein Truncation Test (PTT) on genomic DNA (BRCA1 exon 11, BRCA2 exon 10, 11) and cDNA from RT-PCR (all other exons) for truncating mutations. All mutations but one was detected with PTT; the remaining one with dHPLC. Automated DNA sequencing of the detected mutations revealed seven different frameshift mutations, two nonsense mutations and one large deletion. Four of these have not been reported earlier: BRCA1 409-410delCA; 2229-2230delAA; 3029delA; 1912 T>G. BRCA mutations were found in 32% of the screened families; this is comparable to frequencies reported in other European studies. Notably, a western Swedish founder mutation (BRCA1 3171ins5) accounted for 24 of the 33 mutations detected in the 103 families. Our results are furthermore in accordance with the observation that frameshift mutations in the first two-thirds of BRCA1 are associated with a higher risk of ovarian relative to breast cancer than are truncating mutations in the last one-third of the gene.

**Replication error and mismatch repair gene analyses of families with strong histories of colorectal cancer.** *K. Nafa, P. Peterlongo, E. Glogowski, J. Guillem, A. Markowitz, K. Offit, N.A. Ellis.* Memorial Sloan-Kettering Cancer Center, New York, NY.

Disease-causing mutations in the mismatch repair (MMR) genes MLH1 and MSH2 strongly predispose carriers to colorectal cancer and other cancers that have been associated with hereditary nonpolyposis colorectal cancer (HNPCC), as defined by the Amsterdam criteria. Such mutations have been associated with microsatellite instability (MSI) of the tumors that arise in these families. To define new genes that confer susceptibility to colorectal cancer, we have loosened the Amsterdam criteria to admit for study families with at least three first or second degree relatives affected with colorectal cancers diagnosed at any age. We have identified probands by questionnaires administered in clinics or by referral, and detailed family history information was obtained by patient interview. In nearly all of the 96 ascertained families from whom blood and/or tumor DNA was available, the occurrence of colorectal cancer was consistent with an autosomal dominant mode of inheritance. 49 of the families met Amsterdam criteria and the remaining 47 did not. So far, we have determined MSI status in 100 neoplasms (67 colon cancers, 26 adenomatous polyps, and 7 other cancers) from 95 persons in 64 of these families. In general, MSI status was concordant in families, with 23 families classed as MSI-high and 35 nonMSI-high. 6 families were discordant for MSI status. In 3 families, MMR gene mutations were detected by DNA sequencing; the discordance was explained by failure of MSI to develop i) in a polyp, ii) in a squamous cell carcinoma, and iii) in a polyp from a person who did not carry the familys mutation. In the remaining 3, an MMR gene mutation has yet to be found, and the MSI probably arose sporadically. 22 distinct mutations have been detected in 30 families (20 exhibited MSI, 1 did not, and 12 were not typed) with no mutation being found in 3 families with MSI-high tumors. Candidate gene analysis to find modifier genes in the mutation-positive families and linkage analysis to find novel genes in the nonMSI-high families is in progress.

**D-HPLC Detection of APC mutations.** *C.J. Meldrum, R. Crooks, R.J. Scott.* Molecular Genetics, Hunter Area Pathology Service, Newcastle, NSW, Australia.

The detection of mutations in the Adenomatous Polyposis Coli (APC) gene that is associated with Familial Adenomatous Polyposis (FAP) is both laborious and time consuming. Furthermore, the techniques used combined with limited resources dictates the extent to which mutation screening routinely proceeds. The effectiveness of a screening strategy utilising D-HPLC has been assessed in relation to the APC gene. Routine APC mutation screening in our laboratory consists of DGGE analysis for exons 1-14 combined with PTT of 4 overlapping fragments covering the 8.5 kb of exon 15. As an initial evaluation, D-HPLC has been used to screen exons 1-14 of the APC gene and to examine the regions of overlap inherent in the exon 15 PTT assay. The D-HPLC system detected all 10 mutations that had previously been identified in exons 1-14 by DGGE and confirmed by DNA sequencing. Half of these mutations were single base substitutions with the remaining five being a 1,2,4 and 14 base deletion and a 1 base insertion. Based on this number of mutations D-HPLC does not show a bias towards the detection of any particular type of mutation. Three mutations that had previously gone undetected by PTT due to their position within exon 15 were detected by D-HPLC analysis of the overlapping regions. D-HPLC analysis of 26 patients with histopathology strongly suggestive of FAP and a negative routine APC gene screening result is currently being used as an indication of the relative sensitivity of D-HPLC compared with DGGE and PTT for the detection of APC mutations. Initial results indicate that D-HPLC is at least as sensitive as DGGE and in one case detected a DNA change that was undetected by routine DGGE. Analysis of exon 15 by DHPLC has thus far revealed three missense mutations that would not be detected by PTT. The semi-automated nature of D-HPLC offers the ability to routinely analyse each PCR fragment of the APC gene under a number of conditions. This alone increases the mutation detection rate for this disorder. Sensitive and accurate detection of mutations in the APC gene is vital not only for diagnostic prediction of susceptibility to FAP but also for the identification of FAP phenotypic subgroups with a possible genetic cause other than an APC mutation.

**Identification of germline ATM mutations in breast cancer patients with normal BRCA1 and BRCA2 genes.** *M. Zhu<sup>1</sup>, N. Khanlou<sup>1</sup>, S.Y. Xue<sup>2</sup>, A. Diep<sup>2</sup>, V. Cortessis<sup>2</sup>, R. Haile<sup>2</sup>, R.A. Gatti<sup>1</sup>.* 1) Dept. of Pathology, UCLA School of Medicine, Los Angeles, California 90095-1732, USA; 2) USC Dept. of Preventive Medicine, Norris Comprehensive Cancer Center, Los Angeles, CA 90033-9175.

The genetic determinants for most breast cancer cases remain elusive; however, a mutation in a tumor suppressor gene, such as BRCA1, BRCA2, p53 or ATM (ataxia-telangiectasia mutated, ATM) has been suggested to be one mechanism of breast carcinogenesis. While germline mutations in BRCA1 and BRCA2 account for a significant proportion of hereditary breast cancer, their contribution to sporadic breast cancer is low. In such cases, ATM mutations may be an important risk factor. Evidence that ATM phosphorylates BRCA1 provides a possible mechanism by which ATM might participate in the development of breast cancer. We analyzed 52 samples from breast cancer patients who were BRCA1 and BRCA2 normal for mutations in ATM. Samples were screened by PCR-SSCP. SSCP variants were observed within 23 of the 66 ATM exons. Sequencing the corresponding fragments identified 10 mutations: 6 missense and 4 truncating mutations, 2 of the missense mutations had been previously observed. We also identified 36 variants, 30 of which were new. These results suggest that ATM mutations may play a role in the development of sporadic breast cancer.

**Colorectal and endometrial carcinomas from HNPCC and HNPCC-suspected patients show different MSI-profiles.** *Y. Wu<sup>1</sup>, M.J.W. Berends<sup>2</sup>, R.G.J. Mensink<sup>1</sup>, K.A. Kooi<sup>1</sup>, T. van der Sluis<sup>3</sup>, C. Kempinga<sup>3</sup>, R.H. Sijmons<sup>1</sup>, A.G.J. van der Zee<sup>4</sup>, H. Hollema<sup>3</sup>, J.H. Kleibeuker<sup>2</sup>, C.H.C.M. Buys<sup>1</sup>, R.M.W. Hofstra<sup>1</sup>.* 1) Dept. of Medical Genetics, Univ Groningen, Groningen, the Netherlands; 2) Dept. of Gastroenterology, Univ Groningen, Groningen, the Netherlands; 3) Dept. of Pathology, Univ Groningen, Groningen, the Netherlands; 4) Dept. of Gynaecology, Univ Groningen, Groningen, the Netherlands.

Due to defective mismatch repair, tumors of HNPCC patients often show microsatellite instability (MSI). We determined the frequency of MSI in colorectal (CRC) and endometrial carcinomas (EC) from HNPCC and HNPCC-suspected patients and evaluated the use of a consensus panel of microsatellite markers (BAT25, BAT26, BAT40, D2S123, D5S346 and D17S250). MSI analysis was performed in tumors from 37 unrelated HNPCC patients and in tumors from 314 patients suspected for HNPCC. 89% (23/26) of the CRC and 82% (9/11) of EC tumors of HNPCC patients showed MSI. Tumors from patients suspected for HNPCC showed MSI in 35% (83/239) of CRC and 30% (26/88) amongst EC. Comparing the performance of the different markers in the different tumor types we found that mononucleotide repeats were much less informative in EC than in CRC. Colorectal carcinomas from HNPCC patients showed 76%-82% MSI with mononucleotide repeat markers and 73%-78% with dinucleotide markers. For HNPCC-suspected patients these figures were 44%-64% and 63%-84%, respectively. Endometrial carcinomas from HNPCC patients showed 11%-44% MSI with mononucleotide repeat markers and 56%-78% with dinucleotide repeat markers. For HNPCC-suspected patients these figures were 27%-44% and 58%-72%, respectively. Our results show that a substantial proportion of CRC and EC from HNPCC-suspected patients has an MSI-H tumor phenotype and that the different types of markers have different sensitivities for colorectal cancers and endometrial carcinomas. This implies that for MSI analysis in endometrial cancer and maybe other extracolonic cancers (a) different set(s) of consensus markers may be needed.

**An early-onset breast and colorectal cancer-prone family: Does a specific hereditary breast and colorectal cancer syndrome exist?** *I. Thiffault<sup>1</sup>, T. Pal<sup>5</sup>, N. Hamel<sup>4</sup>, J. Deschênes<sup>3</sup>, V. Marcus<sup>3</sup>, F. Odefrey<sup>5</sup>, K. Watters<sup>3</sup>, T. Graham<sup>7</sup>, W. Meschino<sup>7</sup>, S. Narod<sup>6</sup>, D. Goldgar<sup>5</sup>, D. Farber<sup>1</sup>, E. MacNamara<sup>1,2</sup>, G. Chong<sup>1,2</sup>, W. Foulkes<sup>1,2,4</sup>.* 1) SMBD-Jewish General Hospital; 2) Dept. of Medicine; 3) Dept. of Pathology; 4) RIMUHC, McGill University, Montreal, QC, Canada; 5) IARC, Lyon, France; 6) Women's College Hospital; 7) Sunnybrook Regional Cancer Centre, Toronto, ON, Canada.

We describe a large pedigree with 15 1st-, 2nd- or 3rd-degree relatives who have developed colorectal cancer (CRC) (n=4, 3 <45 yrs old); breast cancer (BC) (n=5, all <45 yrs); endometrial cancer (n=2); lung cancer (n=2), ovarian cancer, anal cancer, multiple myeloma, astrocytoma and thyroid cancer (all n=1). Linkage analysis suggested a mutation was present in BRCA2 and direct sequencing of DNA from a woman with lobular breast cancer identified a L105X mutation in BRCA2. Analysis of a 6 mm colonic villotubular polyp from her sister who had had both invasive breast and endometrial cancer with BAT26 suggested MSI. RNA analysis by PTT and cDNA sequencing revealed a deletion of MSH2 exon 8 in this patient. This case is the first reported incidence of double heterozygote for truncating mutations in BRCA2 and MSH2. Linkage and mutation analyses in this family revealed that her father is an obligate double heterozygote. Three individuals carry the MSH2 but not the BRCA2 mutation. Six other individuals carry the BRCA2 mutation, but not the MSH2 mutation. 4/4 BRCA2-related breast cancers were ER+. There has been interest in the possible existence of a gene that predisposes to both BC and CRC. In addition, the risk of BC in HNPCC families, and the risk of CRC in BRCA1/BRCA2 families has been in dispute. Our identification of a mutation in one mismatch repair (MMR) gene and one breast cancer susceptibility gene, with no evidence that women in this pedigree were susceptible to BC solely because they carried a MMR gene mutation, strikes a note of caution both to those looking for a BC-CRC gene and those who consider BC to be part of HNPCC. We suggest that BC and CRC in families with several cases of early-onset BC, in a setting of HNPCC, may be attributable to more than one gene.

**Analysis of MSH6 mutations by denaturing high performance liquid chromatography (DHPLC) in HNPCC families.** *P. Peterlongo<sup>1</sup>, K. Nafa<sup>1</sup>, G. Lerman<sup>1</sup>, S. Pawar<sup>2</sup>, J. Guillem<sup>1</sup>, A. Markowitz<sup>1</sup>, K. Offit<sup>1</sup>, N.A. Ellis<sup>1</sup>.* 1) Memorial Sloan-Kettering Cancer Center, New York, N.Y; 2) IMPATH, New York, N.Y.

Hereditary nonpolyposis colorectal cancer (HNPCC) is the most common form of hereditary predisposition to colorectal cancer. It is primarily caused by germline mutations in the mismatch repair (MMR) genes MLH1 and MSH2 and is associated with a tumor phenotype featuring instability at microsatellite repeat sequences that is referred to as the replication error (RER). Several recent studies have shown mutations in MSH6 can cause HNPCC; however, some MSH6-mutated tumors are RER-positive and some are not. In this study, we used DHPLC followed by direct sequencing of the variant fragments to screen for mutations in MSH6 in a collection of 41 HNPCC families fulfilling Amsterdam or HNPCC-like criteria and in which MMR gene mutations had not been found. The tumors in 13 of these families were RER-positive and in 28 they were not. To validate the method, genomic DNA samples from 11 additional unrelated, affected persons from RER-untyped HNPCC families were screened by both DHPLC and direct sequencing for mutations in MSH6. In 42 fragments with an abnormal profile by DHPLC a total of 12 heterozygous DNA polymorphisms were detected. All heterozygous sequence variants found by direct sequencing were also detected by DHPLC. In the 41 RER-typed HNPCC families, we found 16 known non-pathogenic polymorphisms. Not reported previously was a 39G to S missense mutation found in a person with an RER-negative tumor. One pathogenic MSH6 deletion was found, 3511delGA, that gives an immediate stop codon in exon 6 (1171A to X) in a family that fulfills the Amsterdam criteria; the probands tumor was RER-positive. This family presents 6 cases of colorectal cancer and 1 uterine cancer involving 3 generations (mean age of onset 42). Our experience suggests that mutation in MSH6 is responsible for a small proportion of HNPCC families.

**Measurement of mutation load using ethanol-fixed, paraffin-embedded and immunohistochemically-stained human tissues.** *G. Schlake, K.A. Hill, E. Heinmoeller, J. Chen, X. Li, Q. Liu, J. Still, S.S. Sommer.* Molecular Genetics, City of Hope Ntl Med Ctr, Duarte, CA.

Individuals who have a high mutation load in their normal tissues are presumably at increased risk for cancer. This presumption has not been tested because it has not been possible to measure mutation load (mutation frequency and alterations in mutation pattern and spectrum) in vivo using an endogenous human gene. We have developed a method for measuring mutation load from ethanol-fixed, paraffin-embedded human tissues immunohistochemically-stained with anti-p53 antibodies. The p53 gene is used because many missense changes in exons 5 to 9 cause accumulation of the protein. Speculation that the p53 gene is the guardian of the genome notwithstanding, compelling data indicate that the frequency and pattern of transitions, transversions, and microdeletions are unchanged in normal tissues from p53 nullizygous mice that develop cancer early. This suggests that the p53 gene is a good mutation reporter because the background rate of mutations in cells lacking functional p53 is similar to that of wild type cells. In this mutation load assay, single cells that stain positively for a mutant reporter gene such as p53 are microdissected. Genomic DNA is amplified using a novel PCR protocol specifically suited to amplify large amounts of a long (2 kb) template from single cells. The method is generally applicable to analysis of mutations from single cells in tissue sections. Somatic mutations have been identified from single cells from colon, liver, lung, breast and kidney. We have also developed the means to reduce the rate of allele dropout and polymerase error, crucial to estimates of mutation load. This method permits comparison of normal tissues and cancers and identification of individuals at risk for cancer. Individuals with putative exposure to environmental mutagens may be analyzed as well as individuals with possible DNA repair defects and a history of familial cancer.

**The nature of the stimulus affects the control of the dominant negative effect of p53 mutants.** *W. Dridi<sup>1</sup>, R. Feti<sup>2</sup>, J. Lavoie<sup>1</sup>, MF. Poupon<sup>3</sup>, R. Drouin<sup>1</sup>.* 1) Medical Biol, Hosp St Francois, Laval Univ, Quebec, Quebec, Canada; 2) Hematologie Dept, Hosp Maisonneuve-Rosemont, Montreal, Quebec, Canada; 3) Cytogenetique Moleculaire et Oncologie, Institut Curie, Paris, France.

P53 mutant proteins possess a dominant negative activity, which is under the control of several factors namely the p53 mutation and the cellular environment. In our study, we examined the cellular response of the near-diploid LoVo colon carcinoma cell line possessing two wild-type p53 alleles (wild-type clone) and three other clones transfected with different p53 mutants (273his, 173his and 143ala) to different spindle inhibitor (nocodazole and Colcemid) treatments. HCT116 cell lines, which are wild-type for the p21 allele, and three other isogenic cell lines (80p21+/-, 80S4p21-/- and 80S14p21-/-) were also studied. Flow cytometric studies, analysis of retinoblastoma protein (pRB) dephosphorylation and 5-bromo-2-deoxyuridine (BrdU) incorporation by immunocytochemistry revealed a tetraploid G1 arrest of the wild-type LoVo clone as well as the 273his mutant clone after exposure to nocodazole, preventing tetraploid cells from entering in an additional S phase. Whereas the 173his and 143ala mutant clones re-enter S phase. On the other hand, it has been shown that when the cells are exposed to ionizing radiations, the wild-type LoVo and the 143ala mutant clones possess a diploid G1 arrest, whereas the 273his and 173his mutant clones re-enter S phase. Therefore, our results suggest that p53 mutant dominant negative activity is dependent not only on cellular environment and the type of p53 mutation, but also on the nature of the stimulus.

**The analysis of LOH target genes in 11q21-q24.** *M. Allinen<sup>1</sup>, L. Peri<sup>1</sup>, K. Outila<sup>1</sup>, S. Kujala<sup>1</sup>, J. Lahti-Domenici<sup>1</sup>, V. Launonen<sup>2</sup>, R. Winqvist<sup>1</sup>.* 1) Department of Clinical Genetics, University of Oulu/Oulu University Hospital, Oulu, Finland; 2) Department of Medical Genetics, Biomedicum Helsinki, University of Helsinki, Helsinki, Finland.

Loss of heterozygosity (LOH) screening has widely been used to identify locations of tumor suppressor genes. LOH at the distal half of chromosome 11q has frequently been seen in a variety of human tumors including breast cancer, and is often associated with worse prognosis. In the ongoing attempt to locate and characterize the target genes contained in the indicated chromosome region, we have first looked for aberrations in known genes indicated to be involved in tumorigenesis. We have examined 32 primary breast tumors showing LOH in 11q21-q24 for mutations in the ATM, PPP2R1B, MRE11A, TSLC1 and CHK1 genes, all of which link to pathways related to cancer development, or have been shown to suppress tumor formation. Only in one of the analyzed tumors a putative pathogenic alteration occurring in PPP2R1B was detected. No other genetic changes were seen.

The absence of intragenic mutations made us next evaluate the possibility of gene silencing by promoter region CpG hypermethylation by using the bisulfite sequencing technique. We found the ATM, PPP2R1B, MRE11A and CHK1 promoter regions mostly unmethylated, excluding some occasional residues. For TSLC1, three tumors showed methylation of the six analyzed CpG sites. However, at most the methylation occurred in 45% of the analyzed clones. Whether the hypermethylation of the TSLC1 promoter region really represents the 'second hit' along with LOH in breast cancer needs to be confirmed in more extensive studies.

**Variation of DNA sequences encoding the polymorphic polyglutamine tract of AIB1.** *P. Dai, L.J.C. Wong.* Inst Molec & Human Genetics, Georgetown Univ Medical Ctr, Washington, DC.

Amplified in breast cancer1 (AIB1) gene is a member of the steroid receptor coactivator (SRC-1) family. The gene was discovered and cloned on the long arm of chromosome 20 that was over-expressed in human breast cancers. AIB1 gene contains a polymorphic polyglutamine(polyQ) tract toward the C terminal. Recent Reports have shown conflict results on the association of shorter polyQ repeat with an increase risk of breast cancer. Since the polyQ tract was not encoded by perfect CAG repeats, the interruption by CAA codon may play a role in AIB1 gene amplification and its effect on tumorigenesis. The aim of this study is to examine the DNA sequences encoding the polyQ tract of AIB1 gene and to study its relationship with breast cancer. Due to the polymorphic heterozygous feature of the CAG repeat region, direct sequencing was not possible to clearly resolve the sequence of the two heterozygous alleles. We, thus, PCR amplified the region containing CAG repeat, and subsequently cloned these fragments into pCR2.1-TOPO vector, followed by DNA sequencing. Multiple clones(>6) from each of more than 62 DNA samples including breast cancer cell lines, tumor tissues, blood samples from patients with germline mutations in brca1/brca2, and healthy controls were sequenced. At least 13 different triplet repeat coding patterns were found. Two of these sequences were considered common because of their high frequency in both normal and cancer groups. The remaining were rare sequence patterns and most of them occurred only once or twice. The results of statistical analysis showed significant higher proportion of breast tumor or cancer cell line specimens are associated with rare sequence patterns and shorter alleles when compared to healthy individuals. Real time quantitative PCR analysis of AIB1 gene revealed gene amplification in several breast tumor cell lines and at least 1 tumor sample but not in normal controls. Our results suggest that both qualitative and quantitative difference in the polyQ encoding region may contribute to the role of AIB1 gene in the tumorigenesis of breast cancer.

**Loss of Tyrosine Aminotransferase may Contribute to the Pathogenesis of Hepatocellular Carcinoma.** *X.Y. Guan, Y.W. Xie, J.S.T. Sham.* Dept Clinical Oncology, Univ Hong Kong, Hong Kong, China.

Loss of material at chromosome arm 16q is one of the most frequent alterations in hepatocellular carcinoma (HCC) detected by comparative genomic hybridization and loss of heterozygosity studies. It suggests that the frequent deleted region at 16q may contain a tumor suppressor gene. cDNA subtraction strategy was applied to isolate down-regulated gene at 16q. cDNAs from the surrounding non-tumor liver tissue was subtracted with cDNAs from its matched primary HCC tumor and a gene at 16q22, tyrosine aminotransferase gene (TAT), was isolated. RNA expression of the TAT gene in 8 primary HCC tumors with 16q deletion was analyzed by northern blot hybridization and reverse transcriptase-polymerase chain reaction. Absence and marked reduction expression of TAT gene was detected in 5 and 2 tumors, respectively, as compared with tumor surrounding liver tissues. Homo-deletion of genomic DNA sequence of TAT gene was observed in two cases detected by PCR. Tyrosine aminotransferase is the rate-limiting enzyme for the tyrosine catabolic pathway and the deficiency of TAT gene may result in elevation of tyrosine level. Prolonged elevation of intracellular tyrosine concentrations may disrupt normal functions of hepatocytes and initiate local inflammatory responses, leading to liver diseases including HCC. Therefore, loss of TAT gene may contribute to the pathogenesis of HCC.

**Amplification and Overexpression of Multiple 17q Genes in Breast Cancer.** *A.E. ERSON*<sup>1</sup>, *B.L. NIELL*<sup>2</sup>, *E.M. PETTY*<sup>2</sup>. 1) Department of Human Genetics,; 2) Department of Internal Medicine, Division of Medical Genetics, University of Michigan, Ann Arbor, MI 48109.

Gene amplification is a common mechanism through which proto-oncogenes are overexpressed and contribute to tumor progression. Comparative genomic hybridization (CGH) and fluorescent in situ hybridization (FISH) studies have revealed several regions of amplification on chromosome 17q in breast cancer. One well-known amplicon on 17q21 is associated with overexpression of the ERBB2 (HER-2/NEU) proto-oncogene. In search of novel proto-oncogenes on 17q, we screened genes and ESTs in physical and radiation hybrid maps for amplification and overexpression in 24 breast cancer cell lines by semi-quantitative duplex PCR, semi-quantitative duplex RT-PCR, Southern and Northern blot analyses. We identified two distinct amplicons on 17q23, one including TBX2 and another proximal region including RPS6KB1 and MUL. 17q23 is of particular interest since it is a gene rich region and amplification of 17q23 has been frequently described in breast cancer. Amplification and overexpression of 17q23 genes (RAD51C, RPS6KB1 (PS6K), NACA, PAT1, SIGMA1B and TBX2) have been reported in breast cancer. We also identified significant overexpression of USP6 (TRE2 oncogene) in 2 breast cancer cell lines. USP6 is a ubiquitin specific protease and maps to 17q11. In conclusion, different regions of 17q are amplified and overexpressed in breast cancer. Further functional studies will reveal the roles of these overexpressed genes in breast tumorigenesis.

**Genetic polymorphism of CYP2D6 and lung cancer risk.** *L. Arnaud<sup>1</sup>, M.P. Gallegos<sup>1</sup>, B.C. Gomez<sup>1</sup>, G. Morgan<sup>2</sup>, M.C. Flores<sup>1</sup>, H. Rangel<sup>3</sup>, G.M. Zuiga<sup>1</sup>.* 1) Medicina Molecular, CIBO, IMSS, Guadalajara, Jalisco, Mexico; 2) Division de Oncologia, Hospital de Especialidades, CMNO, IMSS, Guadalajara, Jal. Mexico; 3) Departamento de Ciencias Basicas, Laboratorio de Genetica Molecular, Centro Universitario de Ciencias Basicas, Universidad de Guadalajara.

Previous reports of the association of debrisoquine metabolism, controlled by the cytochrome P450 CYP2D6, with increased lung cancer risk have been conflicting. We examined the hypothesis that genetic polymorphism at the CYP2D6 locus identifies individuals at increased risk for lung cancer in case-control study of 53 incident mexican lung cancer patients and 152 age, and matched controls. Using polymerase chain reaction-RFLP to detect CYP2D6 (G1943A, PM), wich revealed the presence of 18.86% poor metabolizer in the patients and 5.04% in the controls. A statistical diffence was found to compared the previous data. Our data suggest that the CYP2D6 (G1943, PM)genetic polymorphism increased 3.5 fold the risk for mexican lung cancer.

**Analysis of consequences of WT1 splicing alterations on transcription regulation in Wilms' tumors using cDNA expression arrays.** *D. Baudry, M. Rigolet, M. Hamelin, M. Faussillon, M.O. Cabanis, C. Junien, C. Jeanpierre.*  
INSERM UR383 , Hopital Necker Enfants-Malades, Paris, France.

Somatic WT1 mutations are rare in sporadic Wilms' tumors, although constitutional mutations of this gene are clearly associated with predisposition. It has been suggested that abnormal splicing may be another mode of somatic WT1 alteration. To investigate in detail WT1 changes at the somatic level, we recently analyzed the levels of the four isoform transcripts produced by alternative splicing events in a series of 50 tumors. We characterized splicing alterations in 63% of sporadic WT. Moreover, taking into account the decreased and increased overall levels of WT1 mRNA, the percentage of sporadic tumors with changes in WT1 expression reached 90% .

To investigate the relationship between the variation of the isoform ratios and the tumorigenic process, we compared the expression profiles of tumors with different isoform ratios, using a macroarray approach. Because of Wilms' tumors heterogeneity, we chose to use pools of samples. We hybridized Atlas Human Cancer cDNAs expression arrays (Clontech) with cDNA from pools of (1) 5 tumors with normal exon 5 +/- isoform ratio (T4); (2) 5 tumors with abnormal exon 5 +/- isoform ratio (T1); (3) 4 normal kidneys (NK) and (4) 5 fetal kidneys (FK). We thus identified 15 genes which present a specific expression profile in T1 compared to T4, NK and FK. We validated the approach by analysing the expression level of 4 of the 15 genes in samples taken individually and pooled by RT-PCR. Furthermore, we analyzed one candidate gene by real-time RT-PCR method in a series of 50 tumors and ascertained its differential expression in correlation with alternative splicing of WT1. By this approach, we are expecting to identify not only new WT1 targets but also the potentially alternative pathway(s) involved in Wilms' tumorigenesis.

**Suppressor of fused (SUFU), a conserved negative regulator of the hedgehog (HH) pathway, reverses the tumorigenic phenotype of a rhabdomyosarcoma cell line.** *A.F. Cooper, A.E. Bale.* Yale University School of Medicine, New Haven, CT.

Elucidating the molecular pathogenesis of cancer may allow for the development of pharmacological agents that modulate relevant pathways and set the stage for rational medical therapy. The HH signaling pathway plays a key role in embryogenesis and also regulates cell growth and differentiation in the adult. Mutations of patched (PTCH), the HH receptor, render this pathway constitutively active in almost all basal cell carcinomas, a substantial fraction of medulloblastomas, and occasionally in rhabdomyosarcomas and breast cancers. One strategy for counteracting the effects of PTCH mutations would be to activate a downstream gene that negatively regulates the pathway. Studies in *Drosophila* suggest that *sufu* may play this role in fruit flies. To test the ability of human SUFU to suppress neoplastic characteristics of tumor cells, we generated tetracycline repressible stable transfectants in the rhabdomyosarcoma cell line, TE671. TE671 has moderate levels of expression of HH target genes, suggesting some activation of the HH pathway, and very low levels of endogenous SUFU expression. To test the effects of SUFU overexpression we employed standard tissue culture-based assays that correlate with the ability of cell lines to form tumors *in vivo*. A TE671 line bearing the tetracycline repressible system but lacking a functional copy of SUFU was used as a negative control. Induction of SUFU caused a minor decrease in colony forming ability and in growth rate as assessed by thymidine incorporation assays. In contrast to the small effect on cell kinetics, there was a distinct morphologic change in which the cells became elongated and spindle shaped, consistent with myogenic differentiation. This morphologic alteration was accompanied by complete loss of anchorage-independent growth in a soft agar assay. The change in biological behavior was associated with a substantial alteration of expression of TGF $\beta$ 1, an HH pathway target gene. Evaluation of other target genes is in progress. These data show that SUFU has a specific and powerful effect on differentiation and anchorage independent growth that is probably caused by modulation of the HH pathway.

**Evaluation of candidate genes from the chromosome 20q13.2 amplified region in breast cancers.** *L. Anderson<sup>1</sup>, C. Ginther<sup>1</sup>, M. Schoenberg-Fejzo<sup>1</sup>, K. Anders<sup>2</sup>, D.J. Slamon<sup>1</sup>.* 1) Department of Medicine, University of California, Los Angeles, CA; 2) Department of Pathology, Southern California Permanente Medical Group, Woodland Hills, CA.

Comparative genomic hybridization (CGH) and fluorescence in situ hybridization (FISH) studies have demonstrated the existence of three distinct amplified regions on chromosome 20q in breast cancers, at 20q11, 20q12, and 20q13.2. We sought to evaluate several potential candidate target genes of the 20q13.2 amplified region in a series of primary breast malignancies for which matched DNA and RNA were available. We tested candidate genes ZNF217, CYP24, AURORA 2 and TFAP2C for amplification and overexpression on Southern and Northern blots in 24 primary breast cancers as well as in breast and lung cancer cell lines. The published order of these genes on chromosome 20q13.2 is Centromere--- ZNF217---CYP24---AURORA 2---TFAP2C---Telomere. Two of 24 samples (8%) showed high level (>5X) amplification for ZNF217. The amplification was matched by high level mRNA expression of ZNF217. AURORA 2 was also amplified and overexpressed in the same two samples, although at a lower (2-5X) level. CYP24 was amplified and overexpressed at a low level (2-5X) in one of the two samples. Neither sample demonstrated high or low level amplification or overexpression of TFAP2C. We did not detect amplification in any of the other 22 primary breast cancers with the candidate genes. However, AURORA 2, CYP24 and TFAP2C, but not ZNF217, had increased mRNA expression in the absence of amplification in several primary cancers. Our study supports the concept that ZNF217 is at least one of the candidate targets of the 20q13.2 amplicon in breast cancers. In addition, AURORA 2 and CYP24 cannot be ruled out as contributing to the cancer phenotype. TFAP2C does not appear to be a target gene in these samples.

**Differential Gene Expression in Malignant Breast and Colon Cancer Cells and their Suppressed Counterparts.**

*K. Banerjee<sup>1</sup>, Z.H. Arbieva<sup>1</sup>, K.A. Spanknebel<sup>2</sup>, L. Usha<sup>3</sup>, T.T. Sharma<sup>1</sup>, J. Liang<sup>4</sup>, I. Gomes<sup>1</sup>, C.A. Westbrook<sup>1</sup>.* 1) Sect Hem/Onc, Dept Medicine, Univ Illinois, Chicago, Chicago, IL; 2) Dept. of Surgical Oncology, Memorial Sloan-Kettering Cancer Center, New York, NY; 3) Dept. of Oncology, Rush Presbyterian St. Lukes Medical Center, Chicago, IL; 4) Dept. of Bioengineering, Univ Illinois, Chicago, Chicago, IL.

The majority of genes responsible for various aspects of malignancy have yet to be identified for their roles as such. To identify some of these genes, we have analyzed gene expression profiles in a pair of matched cell lines which differ greatly in their phenotypic behavior. Three hybrid cell lines were previously developed via MMCT of a normal copy of chr 8, which has been implicated as harboring a tumor suppressor gene, into two breast (MB231 and ZR75) and one colon (HT29) cancer cell lines. These hybrid cell lines differ from the parental cells by demonstrating suppression of some aspect of malignancy. The hybrid cells, HT29.X8 and MB231.X8, showed suppression of growth in soft agar and tumorigenicity in nude mice, while ZR75.X8 showed suppression of only clonicity. We performed comparative gene expression analysis of the HT29 cell line pair using GeneFilters arrays (Research Genetics). Only a small subset of genes was consistently altered upon introduction of chromosome 8. These genes were selected on the basis of (1) showing > 2-fold increase, and (2) variability of expression levels between repeat experiments less than 40%. Four genes met these criteria: RNF11, CED-6, KIAA0663, and PMEPA1. Semi-quantitative RT-PCR analysis confirmed that two genes (RNF11 and KIAA066) demonstrated 1.5-2 fold increase of expression from parent to hybrid, CED-6 showed a 2.5 fold increase, and PMEPA1 was increased in the hybrid by over 20-fold. In the breast cancer cell lines, PMEPA1 showed an increase of 45 fold in the chromosome 8-suppressed ZR75 cells, and KIAA0663 showed an increase of 2.6 fold in the chromosome 8 - suppressed MB231 cells. Studies evaluating the functional significance of these genes and their relevance to carcinogenesis are currently underway.

**Introduction of chromosome 18 suppresses the growth of the human osteosarcoma cell lines OHS50. T.L.**

*Johnson-Pais*<sup>1</sup>, *Z. Chang*<sup>1</sup>, *A.M. Murdock*<sup>1</sup>, *K.S. Weldon*<sup>1</sup>, *M.F. Hansen*<sup>2</sup>, *R.J. Leach*<sup>1</sup>. 1) Dept Pediatrics, Univ Texas Health Sci Ctr, San Antonio, TX; 2) Center for Molecular Medicine, Univ Connecticut Health Center, Farmington, CT.

Loss of heterozygosity (LOH) studies have implicated chromosome arm 18q as the site for a tumor suppressor gene important in osteosarcoma tumorigenesis. Previously, LOH studies were performed on sporadic osteosarcomas and Pagetic osteosarcomas to localize the region of LOH on chromosome 18q. Using mitotic mapping, a minimal region of LOH was defined between markers D18S60 and D18S42 on chromosome 18q. This region is lost in 65-70% of osteosarcoma tumors, which implicates this region as the site of a tumor suppressor gene. In order to develop a functional assay for this tumor suppressor gene, microcell-mediated chromosome transfer was used to introduce an intact copy of chromosome 18 into three independent osteosarcoma cell lines: SAOS-2, OHS50, and U2 OS.

From all three fusion experiments, numerous microcell hybrid clones, containing an intact chromosome 18, were analyzed by *in vitro* methods for transformed phenotypes, including analyses of doubling time and ability to grow in soft agar. Introduction of an intact chromosome 18 into the SAOS-2 and U2 OS cell lines did not cause any significant changes in *in vitro* growth parameters. However, microcell hybrids isolated from the introduction of chromosome 18 into OHS50 cells exhibited dramatic changes in the doubling time and ability to grow in soft agar. The doubling time was increased 2.1-fold compared to the OHS50 control and the ability to grow in soft agar was reduced 4-fold.

OHS50 is an ideal model system for the identification of a tumor suppressor gene on 18q involved in osteosarcoma tumorigenesis. Future experiments will explore the *in vivo* phenotype of these hybrids.

**Familial aggregation of non-melanoma skin cancer.** *G.J. Mann<sup>1</sup>, C.H-F. Thoo<sup>1</sup>, L. Morgan<sup>1</sup>, M. Stewart<sup>2</sup>.* 1) Westmead Institute for Cancer Research, University of Sydney at Westmead Millennium Institute Westmead, NSW, Australia; 2) Skin and Cancer Foundation, Australia.

Cutaneous squamous cell carcinoma (SCC) and basal cell carcinoma (BCC) are Australia's most prevalent and costly cancers, together affecting over 20% of the population at some time in their life. SCC accounts for almost one third of all non-melanoma skin cancer (NMSC), and is responsible for most of the deaths due to NMSC. However SCC is one of the few common malignancies for which major susceptibility genes are yet to be identified. We are therefore analysing familial aggregation of cancer in individuals diagnosed with early onset SCC. Family histories have been verified for first degree relatives of 28 probands under the age of 50, identified so far in Sydney from the referral pathology database of the Skin & Cancer Foundation, Australia. Among siblings (n=70), 10.0% had developed NMSC compared with 1.6% expected from national survey data. Among parents (n=36), 33.3% had developed NMSC compared with 13.4% expected. Excesses of both SCC (RR 5.7) and BCC (RR 2.7) were observed in these relatives, but are significant ( $p < 0.05$ ) only for SCC as yet. Overall, 46% of probands had a positive family history of NMSC and 14% belonged to clusters of three or more cases related in the first degree. These results confirm that NMSC exhibits significant familial aggregation and suggest that at least some of this familial risk is due to SCC-specific factors. Recruitment and extension of such kindreds will yield a useful resource for determining which genes are responsible.

**Tamoxifen and breast cancer incidence among women with inherited mutations in BRCA1 and BRCA2: A genomic resequencing study in the NSABP-P1 Breast Cancer Prevention Trial (BCPT).** *M.C. King<sup>1</sup>, H.S. Wieand<sup>2</sup>, K. Hale<sup>1</sup>, T. Walsh<sup>1</sup>, K.M. Owens<sup>1</sup>, M.K. Lee<sup>1</sup>, J.P. Costantino<sup>2</sup>, B. Fisher<sup>2</sup>, NSABP Investigators<sup>2</sup>.* 1) Depts of Medicine and Genomic Sciences, Univ Washington, Seattle, WA; 2) NSABP, Univ Pittsburgh, Pittsburgh, PA.

The randomized, double-blind BCPT demonstrated that tamoxifen reduced incidence of invasive BC by about 50% in high risk women. Specifically, tamoxifen reduced incidence of estrogen receptor (ER) positive BC: for ER positive BC, the tamoxifen-placebo risk ratio RR=0.31, 95% CI (0.22, 0.45). Tamoxifen had no effect on incidence of ER negative BC: RR=1.23, 95% CI (0.74, 2.03). In order to evaluate whether tamoxifen reduced BC incidence among women with inherited mutations in BRCA1 or BRCA2, we sequenced BRCA1 and BRCA2 (24,133 bp per sample) for women who developed invasive BC during the BCPT and for a stratified random sample of participants who remained unaffected. In all, 18.5 Mbp were evaluated. Of the 315 women who developed BC during the BCPT, DNA was obtainable and BRCA1 and BRCA2 sequenced for 288 (91%). Of these, 19 (6.6%) carried inherited, disease-predisposing mutations in BRCA1 or BRCA2: 17% of those diagnosed < 50 years and 3% of those diagnosed at age 50+. Of eight participants with BRCA1 mutations who developed BC, five were assigned to tamoxifen and three to placebo: RR=1.67, 95% CI (0.41, 8.00). Of 11 women with BRCA2 mutations who developed BC, three were assigned to tamoxifen and eight to placebo: RR=0.38, 95% CI (0.06, 1.56). For the 269 wildtype cases, RR=0.48, 95% CI (0.37, 0.61). More than 80% of BRCA1 breast tumors are ER negative, whereas ~80% BRCA2 breast tumors are ER positive. Hence, no effect of tamoxifen on BC incidence among women with BRCA1 mutations is consistent with no effect of tamoxifen on incidence of ER negative BC. In contrast, the (not significant) 62% reduction in BC incidence among women with BRCA2 mutations is consistent with the 69% reduction in incidence of ER positive BC. This study addressed incidence of new BC, not treatment by tamoxifen of existing BC. For women with ER positive BC, regardless of genotype, tamoxifen is effective in reducing risk of recurrence of disease.

**The EMX2 homeobox gene suppresses growth of the HEC-1A endometrial cancer cell line.** *F.C. Noonan<sup>1</sup>, C.R. Todd<sup>1</sup>, D.G. Mutch<sup>2</sup>, P.J. Goodfellow<sup>1</sup>.* 1) Dept Surgery, Washington Univ, St Louis, MO; 2) Dept OB/GYN, Washington Univ, St Louis, MO.

Our laboratory identified EMX2 as a candidate for the 10q15.3-q26.1 endometrial cancer tumor suppressor gene. EMX2 has known roles in embryonic development. We showed that the gene is also expressed in adult tissues, specifically in the endometrium (Noonan et al., 2001). Expression analysis in normal endometrium, tumors and endometrial cancer cell lines revealed EMX2 is expressed at higher levels in the quiescent post-menopausal endometrium than in the proliferating endometrium, consistent with a role in growth suppression. Primary endometrial cancers frequently show reduced levels of EMX2 and 4 of 6 endometrial cancer cell lines investigated do not express EMX2. Mutation analysis in primary tumors revealed a low frequency of mutations and the absence of detectable mutations in endometrial cancer cell lines (Noonan et al., 2001). Methylation studies show that 3 of the 4 cell lines that do not express EMX2 have extensive promoter methylation, suggesting that epigenetic silencing of EMX2 may be responsible for the absence of expression in the cell lines.

To further characterize the role EMX2 plays in endometrial tumorigenesis, we have performed two functional assays using HEC-1A cells (an endometrial cancer cell line that does not express EMX2) transfected with a pcDNA expression vector with or without the EMX2 gene: doubling time and clonogenic assays. We show here that cell lines that stably express the EMX2 transgene grow slower than cells that do not express EMX2. The difference in mean doubling times (76 hours for expressing lines and 46 hours for non-expressing lines) is statistically significant ( $p=0.0002$ ) and supports EMX2's role in growth suppression. Additionally, clonogenic assays with pcDNA and other expression vectors show similar results. HEC-1A cells transfected with EMX2-expression vectors form fewer colonies than cells transfected with an empty vector. A detailed functional characterization of EMX2 will help to elucidate the function of this gene in adult development and cancer progression.

**Identification of Breast Cancer Progression Genes Using Microarray Analysis.** *M.A. Unger<sup>1,2</sup>, W.F. Foster<sup>6</sup>, R. Huber<sup>6</sup>, M. Rishi<sup>5</sup>, E.A. Keiper<sup>3, 4</sup>, L.A. Chodosh<sup>3,4</sup>, M.N. Liebman<sup>2</sup>, B.L. Weber<sup>1,2</sup>.* 1) Univ. of Penn Cancer Center; 2) Abramson Family Cancer Res. Inst; 3) Dept. of Mol. and Cell Engin; 4) Div. of Endo., Diab., and Met., Univ. of Penn School of Med., Phila., PA; 5) Dept. of Path., St. Francis Hospital, Wilm., DE; 6) Applied Biotech., Dupont Pharm., Wilm., DE.

The current model for breast cancer progression describes a multistage process where normal breast epithelium is transformed to a carcinoma in situ due to the accumulation of genetic alterations, followed by a additional genetic changes that result in the transition to an invasive carcinoma and eventually metastasis. This study was designed to identify genes whose expression is altered between normal breast tissue and invasive ductal carcinoma tissue from the same individual. Fresh frozen tissue was collected and macrodissected with a pathologist to identify populations of cells that were 85% or greater homogeneous normal breast tissue or invasive carcinoma. To date, five matched tumors and normal pairs have been examined using oligonucleotide microarrays. Data analysis using Rosetta Resolver software pinpoint approximately 150probe sets representing transcripts consistently expressed at significantly lower levels in the tumors compared to the normal tissue from the same person and 50 transcripts expressed at significantly higher levels in the tumor compared to the normal. Approximately 20% of these transcripts are known markers of cancer. The 20 upregulated genes with the most significance changes reveal that 20% of these genes are histone genes and 15% are mucin genes, both of which have known implications in cancer progression. Of the down-regulated genes, 15% were genes that encode tight junction proteins, 15% were genes involved in immune surveillance, and 10% were genes with known cell cycle suppression functions. Additional data analysis suggests a clear involvement of a variety of S100 proteins and homeobox proteins, among others, in the transition of normal to invasive carcinoma as well as the contribution of a variety of genes that have not been previously implicated in breast cancer progression.

**g-synuclein, a candidate oncogene, activates RAC and ERK and contributes to the metastatic spread of breast and ovarian cancer.** Z. Pan<sup>1</sup>, W. Bruening<sup>1</sup>, B.I. Giasson<sup>2</sup>, V.M. Lee<sup>2</sup>, A.K. Godwin<sup>1</sup>. 1) Fox Chase Cancer Center, Philadelphia, PA; 2) U. of Penn. School of Medicine.

The synucleins (a, b, g, synoretin) are a family of small cytoplasmic proteins that are predominantly expressed in neurons. Although a-synuclein is known to play an important role in neurodegenerative diseases, the function of synucleins is unknown. We have previously reported that one member of the family, g-synuclein, is expressed in the majority (>85%) of late-stage breast and ovarian carcinomas, but it is not expressed in normal mammary and ovarian epithelium. Therefore, we hypothesize that g-synuclein may be a proto-oncogene and that abnormal expression of this protein may contribute to the progression of breast and ovarian cancer. In support of this hypothesis, we have observed that exogenous expression of g-synuclein in tumor cells elicits a phenotype similar to that induced by activation of the Rho/Rac/CDC42 pathway, i.e., altering the appearance of focal adhesions and stress fibers, and enhancing motility and invasion. Strikingly, levels of activated Rac (GTP-bound) are constitutively elevated in ovarian tumor cells that overexpress g-synuclein. Synuclein proteins also exhibit a weak homology to the 14-3-3 family of cytoplasmic chaperone proteins. 14-3-3 proteins help regulate different signal transduction pathways by directly binding to various protein kinases and bringing them into close proximity with substrate and regulatory proteins. We have demonstrated a novel interaction of g-synuclein with the MAPKs, ERK1/2 and JNK1, in a single complex. Overexpression of g-synuclein leads to increased ERK activation but does not activate JNK. As activated ERK1/2 specifically localize to focal adhesions, and ERK1/2 has been shown to enhance migration, these results raise the possibility that g-synuclein may enhance the metastatic potential of tumors through the activation of Rac within the Rho signaling pathway based on protein interactions at focal adhesions. We hypothesize that g-synuclein contributes to tumorigenesis by promoting cell motility as a result of altering the Rho and ERK1/2 signaling pathways and that g-synuclein may be an important therapeutic target.

**Gene expression profile comparison between tumorigenic and non-tumorigenic clones from ovarian cancer cells.**

*J. Xu<sup>1</sup>, L. Li<sup>1</sup>, H.R. Abeyasinghe<sup>1</sup>, B. Kim<sup>2</sup>, N. Wang<sup>1</sup>.* 1) Dept Pathology & Lab Med, Univ Rochester Medical Ctr, Rochester, NY; 2) Dept Microbiology & Immunology, Univ Rochester Medical Ctr, Rochester, NY.

Ovarian cancer is the leading cause of death from gynecological neoplasias. The molecular events involving the initiation and progression of ovarian cancer are not well defined. In this report we describe the utilization of a set of eight Human GeneFilters Microarrays containing > 30000 human genes to define the differences in gene expression between tumorigenic and non-tumorigenic hybrid clones derived from a human ovarian carcinoma cell line SKOV-3 with the introduction of human chromosome 11. A total of 26 differentially expressed genes with expression levels varied significantly by 2- or more fold were identified, of which three genes, lipocalin 2 (oncogene 24p3)(LCN2), DNA-damage -inducible transcript 3 (DDIT3) and prominin (mouse)-like 1 (PROML1), were up-regulated in tumorigenic hybrid clones. Among the 23 down-regulated genes in tumorigenic hybrid clones, spleen tyrosine kinase (SYK) and caveolin 1 (CAV1) have been proposed as tumor suppressor genes, while Thy-1 cell surface antigen (THY1) has been identified as a putative tumor suppressor gene for ovarian cancer in a previous study in our laboratory.

**Transfer of the FHIT gene induces apoptosis in the lung cancer cell line H460 through a caspase-8-dependent and mitochondria-independent mechanism.** *L. Roz<sup>1</sup>, C.G. Ferreira<sup>2</sup>, H. Ishii<sup>3</sup>, C.M. Croce<sup>3</sup>, G. Giaccone<sup>2</sup>, G. Sozzi<sup>1</sup>.*

1) Department of Experimental Oncology, Ist Nazionale Tumori, Milano, Italy; 2) Department of Medical Oncology, Academic Hospital Vrije Universiteit, Amsterdam, the Netherlands; 3) Kimmel Cancer Center, Jefferson Medical College, Philadelphia, PA.

Chromosome 3p alterations are one of the most frequent genetic changes associated with the development of lung cancers and the FHIT gene, located at 3p14.3, is often inactivated in these tumors. We have shown previously that adenoviral-mediated restoration of Fhit expression in non-small cell lung cancer (NSCLC) cell lines results in apoptosis and loss of tumorigenicity in nude mice through a mechanism involving caspase-8 activation. In order to investigate how this effect is achieved we used different clones of the NSCLC cell line H460 with alterations in genes involved in the regulation of the apoptotic pathway. These clones were transduced with an adenoviral vector expressing the FHIT gene and the apoptotic response was monitored using the TUNEL assay. The same clones were also treated with cytotoxic drugs to analyse their response to other apoptotic stimuli. A complete protection from Fhit-induced apoptosis was seen in clones transfected with a dominant negative form of FADD and with the viral inhibitor of caspase-1 and caspase-8 CrmA (while an inactive mutant form of CrmA didn't confer any resistance). On the contrary clones overexpressing Bcl-2 or Bcl-x<sub>L</sub>, that are protected from cisplatin, topotecan and gemcitabine induced apoptosis, remained highly susceptible to FHIT transfer. Taken together these data seem to indicate that in H460 cells the mechanism of action of Fhit mainly involves activation of a FADD-related cytoplasmic apoptotic pathway, without mitochondrial amplification of the response. Interestingly this is different from the results observed with chemotherapy-induced apoptosis (which requires mitochondrial intervention) suggesting a possible role of Fhit in facilitating caspase-8 activation at the cytoplasmic level.

**Prune and nm23-H1 and nm-23 H2 (NDP-Kinase) proteins: involvement in cancer.** *M. Zollo<sup>1</sup>, A. D'Angelo<sup>1</sup>, A. Andre'<sup>1</sup>, V. Aglio<sup>1</sup>, S. Olivieri<sup>2</sup>, G. Arrigoni<sup>2</sup>, A. Forus<sup>3</sup>, O. Myklebost<sup>3</sup>, A. Ballabio<sup>1</sup>.* 1) TIGEM, Telethon Institute of Genetics and Medicine, Naples, Italy; 2) Department of Pathology, San Raffaele Hospital (HSR), Milan, Italy; 3) Department of Tumour Biology, The Norwegian Radium Hospital, Oslo, Norway.

We have isolated the human and murine homolog of the *Drosophila* prune gene through dbEST searches 1,3. In mouse, Prune is expressed (in situ analysis) at low levels in the basal plate along the entire neural tube while at E12.5 the expression in the nervous system is definitively stronger, especially in the cranial and dorsal root ganglia and in the spinal nerves. In adult mouse and human tissues its expression is ubiquitously. Furthermore, in human adult brain tissues (IHC analysis) prune protein is present mainly on neurons and astrocytes cells. By using yeast interaction-mating and "in vitro" and "in vivo" co-immuno-precipitation experiments, we show the ability of human prune to interact with the human nm23-H1,2,3 and nm23-H2 (metastasis suppressor genes), and demonstrated that is impaired with nm-23-H1-S120G mutant, a gain-of-function mutation associated with advanced neuroblastoma. Prune protein retains the four characteristic domains of DHH phosphoesterases<sup>4</sup> and we are showing that is a new phosphodiesterase (PDE) specific for cAMP substrate. In addition, in Sarcoma tumours (MFH, MS, LS, LMS) we have found PRUNE is amplified (3-8 copies) by FISH and CGH analysis and these findings correlates at protein levels (IHC analysis). Infection of NIH3T3 cells with a PRUNE recombinant retrovirus increased cell proliferation. Possibly, amplification and overexpression of PRUNE has the same effect in the tumours. Our working hypothesis is that prune is negative regulating the anti-metastatic function of nm23 protein. REFERENCES 1. Banfi, S., et al. *Nature Genetics* 13, 167-174 (1996). 2. **Expression profiles of uveal melanomas with good and poor prognosis.** *F. Tschentscher, B. Horsthemke, D.R. Lohmann, M. Zeschnigk.* Institut fuer Humangenetik, Universitaetsklinikum, Essen, Germany.

Uveal melanoma is the most common primary intraocular tumor with an incidence of 6 per 1 million Caucasians per year. Cytogenetic analysis and comparative genomic hybridization have revealed nonrandom aberrations of chromosomes 3, 6 and 8. Monosomy 3 (ms3), which is frequently accompanied by gain of 8q material and found in about 50 % of the tumors, significantly predicts metastatic disease and poor prognosis. Conversely, tumors with disomy 3 (ds3) rarely give rise to metastatic disease. To obtain information about the molecular mechanisms underlying this striking difference in clinical behavior, we compared the expression profiles of 9 and 10 primary uveal melanomas with ms3 and ds3, respectively, using oligonucleotide arrays with probes for more than 1700 cancer related genes (Affymetrix Human Cancer G110). After exclusion of genes showing no variation in expression, a two-way hierarchical clustering algorithm was applied, by which the tumors were grouped in two distinct clusters. One contains 8 tumors with ms3 and 2 tumors with ds3, while the other consists of 8 tumors with ds3 and one tumor with ms3. Visual inspection of the expression map showed two clusters of genes with pronounced differences in expression. Cluster 1 includes 75 genes showing decreased expression in ms3 tumors compared to ds3 tumors. Most of them are not located on chromosome 3. Cluster 2 includes 24 genes showing decreased expression in ds3 tumors compared to ms3 tumors. Therefore, the expression profile of these genes correlates well with the two genetically defined classes of tumors with distinct metastatic potential. Further analyses of the differentially expressed genes may help to unravel the complex process of metastatic behavior.

**Tetracycline-regulated expression of the candidate tumor suppressor gene, RASSF1A, from a frequently affected chromosomal region 3p21.3.** A. Protopopov<sup>1</sup>, J. Li<sup>1</sup>, V. Kashuba<sup>1</sup>, K. Dreijerink<sup>2</sup>, E. Braga<sup>3</sup>, I. Kuzmin<sup>2</sup>, M. Lerman<sup>2</sup>, E. Zabarovsky<sup>1</sup>. 1) Microbiol & Tumor Biol Ctr, Karolinska Inst, Stockholm, Sweden; 2) Lab Immunobiol & Intramural Res Support Program, SAIC, NCI Frederick, MD; 3) Engelhardt Institute of Molecular Biology, Russian Academy of Sciences, Moscow, Russia.

Clear cell type renal cell carcinomas (clear RCC) are almost universally characterized by loss of heterozygosity (LOH) on chromosome 3p, which usually involves any combination of three regions: 3p25-p26 (harboring the VHL gene), 3p12-p14.2 (containing the FHIT gene) and 3p21-p22, implying inactivation of the resident tumor suppressor genes. For the 3p21-p22 region, the affected TSGs remain, at present, unknown. Recently, the RAS association family 1 gene (isoform RASSF1A), located at 3p21.3, has been identified as a candidate lung and breast TSG. We found hypermethylation of RASSF1A's GC-rich putative promoter region in most of analyzed samples, including 39 of 43 primary tumors (91%). The promoter was partially or completely methylated in all 18 clear RCC cell lines analyzed. Methylation of the GC-rich putative RASSF1A promoter Forced expression of RASSF1A transcripts in KRC/Y, a renal carcinoma cell line containing a normal and expressed VHL gene, suppressed growth on plastic dishes and anchorage-independent colony formation in soft agar. Mutant RASSF1A had significantly reduced growth suppression activity. These data suggest that RASSF1A is the candidate renal TSG gene for the 3p21.3 region. In subsequent experiments the concentration of tTA-effector (doxycycline) will be varied so as to enable estimation of the level of the gene expression required for effects on tumor cells. Engineering of SCLC and other cell lines with controlled levels of RASSF1A expression is also in the pipeline.

**Ovarian germ-cell tumor occurring in a *BRCA2* mutation carrier.** *N. Wong*<sup>1,2</sup>, *N. Hamel*<sup>6</sup>, *A. Péroquin*<sup>4</sup>, *M. Al-Saffar*<sup>5</sup>, *W.D. Foulkes*<sup>1,2,3,5,6</sup>. 1) Cancer Prevention Research Unit, SMBD-Jewish General Hospital; 2) Dept. of Oncology, SMBD-Jewish General Hospital; 3) Dept of Medicine, SMBD-Jewish General Hospital; 4) Dept. of Pathology, SMBD-Jewish General Hospital; 5) Dept. of Human Genetics, McGill University Health Centre; 6) Research Institute of the McGill University Health Centre.

Germ-cell tumors (GCT) account for about 20% of neoplastic disease of the ovary with only about 2 to 3% of GCT being malignant. *BRCA*-linked ovarian cancers are usually epithelial tumors, the more common type of ovarian cancer. We report the occurrence of a malignant ovarian GCT in an Ashkenazi Jewish woman who was recently found to carry a 6174delT *BRCA2* mutation. At age 33, six months following a normal vaginal delivery, the patient presented in 1985 with a pelvic mass and an elevated serum bHCG. She underwent a TAH-BSO, omentectomy with paraortic lymph node dissection. Pathological examination revealed a stage Ia mixed GCT in the left ovary: 50% embryonal carcinoma, 20-25% choriocarcinoma, 10-15% dysgerminoma and 10-15% immature teratoma. The tumor measured 9 x 7 x 6 cm with a multinodular surface appearance. There was no evidence of metastatic disease and peritoneal washings were negative. She was treated with 3 cycles of a combination of cyclophosphamide, actinomycin D, bleomycin, vinblastin and cisplatin. She did not receive radiation therapy. Patient has remained disease free. To assess the involvement of *BRCA2* in the GCT, LOH analysis was performed on the tumor using a marker (D13S1698) thought to be 70kb proximal to *BRCA2*. There was no evidence of LOH at this marker in the sample of dissected tumor. We believe that this is the first report of a GCT in a *BRCA2* mutation carrier. Given the infrequency of GCTs, even if the relative risk for developing it is the same as for ovarian carcinoma, GCTs are still likely to occur rarely in mutation carriers. There has been one report of a *BRCA1* mutation carrier who developed a non-epithelial malignant ovarian tumor. Further studies are needed to determine if *BRCA* genes are involved in the development of GCT or if its occurrence in mutation carriers is an unrelated chance event.

**Expression profiling of medulloblastoma: identification of therapeutic targets for metastatic disease. K.M.**

*Brown<sup>1</sup>, T.J. MacDonald<sup>1</sup>, B. LaFleur<sup>2</sup>, K. Peterson<sup>1</sup>, C. Lawlor<sup>1</sup>, Y. Chen<sup>3</sup>, R.J. Packer<sup>1</sup>, P. Cogen<sup>1</sup>, D.A. Stephan<sup>1</sup>.* 1) Research Center for Genetic Medicine, Childrens National Medical Center, Washington, DC; 2) Division of Biostatistics, Department of Preventative Medicine, Vanderbilt University, Nashville, TN; 3) NHGRI, NIH, Bethesda, MD.

Metastatic medulloblastoma is highly associated with poor outcome and little is known about the genetic regulation of medulloblastoma dissemination. Whole-brain and spine radiation therapies, which are used to prevent metastases, are non-specific and result in lowered IQ, hearing loss and growth retardation. We used expression profiling to identify molecular targets and match agents to better prevent metastatic disease. We expression profiled 23 primary medulloblastomas clinically designated as either metastatic (M+) or non-metastatic (M0) and identified 85 genes whose expression differed significantly between classes. A class prediction algorithm based on these genes assigned sample class to these tumors (M+ or M0) with 72% accuracy using a leave-one-out approach and to four additional independent tumors with a 100% accuracy. Class prediction also assigned the metastatic medulloblastoma cell line Daoy to the metastatic class. Notably upregulated in the M+ tumors were platelet derived growth factor receptor alpha (*PDGFRA*) and members of the downstream RAS/MAPK signal transduction pathway. Immunohistochemical validation on an independent set of tumors showed significant overexpression of *PDGFRA* in M+ tumors as compared to M0 tumors. Using *in vitro* assays, we showed that PDGFA enhances medulloblastoma migration and increases downstream MEK1/2 and MAPK phosphorylation in a dose-dependent manner. Finally, neutralizing antibodies to *PDGFRA*, or U0126, a highly specific chemical inhibitor of MEK1/2, blocked MEK1/2 and MAPK phosphorylation, inhibited migration, and prevented PDGFA-stimulated migration. These results provide the first insight into the genetic regulation of medulloblastoma metastasis and are the first to suggest a role for *PDGFRA* and the RAS/MAPK signaling pathway in medulloblastoma metastasis. Inhibitors of *PDGFRA* and RAS are being considered as possible novel therapeutic strategies against medulloblastoma.

**Characterization of drug resistant malignant melanoma cells by gene expression profiling.** *R. Wittig<sup>1</sup>, M. Nessler<sup>2</sup>, B. Korn<sup>3</sup>, P. Lichter<sup>2</sup>, D. Schadendorf<sup>4</sup>, A. Poustka<sup>1</sup>.* 1) Molecular Genome Analysis, German Cancer Research Center (DKFZ), Heidelberg, Germany; 2) Organisation of Complex Genomes, DKFZ, Heidelberg, Germany; 3) Ressource Center for Genome Research (RZPD), Heidelberg, Germany; 4) Clinical Cooperation Unit "Dermatooncology", DKFZ, Heidelberg, Germany.

Drug resistance of tumor cells often leads to severe problems in the treatment of cancer. We examined differences in mRNA expression patterns between a drug sensitive and 3 derived drug resistant malignant melanoma cell lines with acquired resistance to the DNA damaging agents cisplatin, etoposide and fotemustine, respectively. In order to find genes which contribute to the drug resistant phenotype the expression of about 31.500 gene and EST sequences represented in a UniGene clone collection (Human UniGene Set RZPD1) was analysed by comparative cDNA array hybridisation. Cells resistant to cisplatin and etoposide revealed strong upregulation of interferon inducible genes. Some differentially expressed genes were formerly found to be involved in stress response and cell death processes, others are less characterised or even unknown. Single genes are up- or downregulated in more than 1 resistant cell line, indicating a contribution to observed cross resistance against different drugs. Etoposide resistant cells showed the most remarkable differences. This correlates very well with the high relative degree of etoposide resistance and with the elevated number of genetic alterations, which could be confirmed by comparative genomic hybridisation. We verified the differential expression of several chemoresistance candidate genes by Northernblot analysis. Now we developed a cDNA array harboring 170 candidate genes in order to find out their importance for drug resistance in general by gene expression profiling studies in other experimental systems.

**Polymorphic Variants of Nuclear Receptor Genes Associated with Sporadic Breast Cancer.** *J.E. Curran<sup>1</sup>, S.R. Weinstein<sup>2</sup>, L.R. Griffiths<sup>1</sup>*. 1) Genomics Research Centre, Griffith University Gold Coast, Southport; 2) Pathology Department, Gold Coast Hospital, Southport, Queensland, Australia.

A cross-sectional association approach has been used in many previous studies to detect genes involved in disease development. We are using such an approach to investigate sporadic breast cancer. Recent results from our laboratory have implicated polymorphisms within the 3' region of the vitamin D receptor gene (VDR)1 as being involved in this common form of cancer. These results have prompted further investigation of other nuclear receptor genes. There is increasing evidence that genetic variations in nuclear receptor genes can cause loss of hormone dependency in different cancer types and may lead to inappropriate gene functions or tumour development. In this study, polymorphisms within the glucocorticoid (GRL), estrogen (ESR), progesterone (PgR) and androgen receptors (AR) were examined in an age and ethnic matched breast cancer affected and control population.

When tested in the case-control populations, results indicated association of tested polymorphisms of glucocorticoid and estrogen receptors with sporadic breast cancer<sup>2</sup>. A highly polymorphic dinucleotide repeat, D5S207, located within 200kb of GRL showed a significant variation in allele frequencies among populations ( $P=0.001$ ), while a codon 594 (exon 8) ESR polymorphism also showed a significant association with sporadic breast cancer ( $P = 0.005$ ). We are presently investigating other polymorphisms within these genes as well as the progesterone and androgen receptor genes for association. Our results suggest a role for nuclear receptor genes in sporadic breast cancer and justify further investigation of the role of these and other nuclear receptors in the aetiology of this disorder.

**CAG repeat length in the gene AIB1 gene modifies breast cancer risk in BRCA1/2 mutation carriers.** Z. Kote-Jarai<sup>1</sup>, L. Kadouri<sup>2</sup>, F. Durocher<sup>3</sup>, D.F. Easton<sup>3</sup>, A. Huber<sup>2</sup>, D. Abeliovich<sup>2</sup>, B. Glaser<sup>2</sup>, T. Peretz<sup>2</sup>, R. Eeles<sup>1</sup>. 1) Cancer Genetics, The Institute of Cancer Research, Sutton, UK; 2) Hadassah Medical Center, Jerusalem Israel; 3) CRC Genetic Epidemiology Unit, Cambridge, UK.

Variation in the penetrance estimates for BRCA1 and BRCA2 mutation carriers suggests that genetic polymorphisms may modify the cancer risk in carriers. Polymorphisms of genes involved in hormonal signal transduction are possible candidates. The AIB1 gene, an estrogen receptor (ER) coactivator, is frequently amplified in breast and ovarian tumors. Variation of a CAG repeat length, that encodes a polyglutamine repeat in the C-terminus of the protein, has been reported. 188 BRCA1/2 mutation carriers, (of which 156 were of Ashkenazi origin) and 156 unaffected control individuals of Ashkenazi origin, aged over 56, were genotyped for the AIB1 CAG repeat. Risk analyses were conducted using a variant of the log rank test assuming penetrance levels appropriate to the Ashkenazi population. For BRCA1/2 carriers the estimated breast cancer (BC) risk (RR) per average repeat length adjusted for population (Ashkenazi, non-Ashkenazi) was 1.56 (95%CI 1.09-2.24, p=.014). When analysis was restricted to BRCA1 carriers RR was 1.92 (95%CI 1.23-3.02, p=.004). For individuals with 2 alleles <sup>3</sup>15 CAG repeats RR of BC was 1.93 (95%CI 0.98-3.79) and 0.55 (95%CI 0.28-1.08) for those with at least one allele £12 repeats. The average age of onset was also significantly lower for individuals carrying two alleles <sup>3</sup>15 repeats (39.9 years) compared to individuals with at least one short allele of £12 repeats (48.1 years), p=.001. These results indicate elevated risk for BC in carriers of BRCA1/2 mutations with a longer CAG repeat of the AIB1 gene, especially in carriers of both alleles with <sup>3</sup>15 CAG repeats, which comprise 20% of our carrier population. In conclusion, our results suggest that the AIB1 CAG repeat length could be an important predictor of breast cancer risk among women with mutations in the highly penetrant BRCA1/2 genes.

**3'UTR polymorphisms in the CDKN2A gene and age at onset of familial and sporadic melanoma from Liguria.**

*M. Mantelli<sup>1</sup>, L. Pastorino<sup>1</sup>, F. Lantieri<sup>1</sup>, M. Barile<sup>1,2</sup>, P. Ghiorzo<sup>1</sup>, L. Padovani<sup>1</sup>, P. Queirolo<sup>2</sup>, P.L. Santi<sup>2</sup>, S. Vecchio<sup>2</sup>, G. Bianchi-Scarrà<sup>1</sup>.* 1) Department of Oncology, Biology, and Genetics Univ. of Genova, Italy; 2) National Institute for Cancer Research, Genova, Italy.

The common polymorphisms 540C®G and 580C®T in the 3'UTR of the CDKN2A (p16) gene, whose mutations are known to confer susceptibility to cutaneous malignant melanoma, have been previously studied but their influence on melanoma risk is currently debated. In particular an Australian population-based study found an association between familial risk and the 540G allele, possibly influenced by Celtic ancestry, and no association with 580T. In this study we performed molecular analysis of 255 melanoma patients from 751 familial and sporadic Ligurian patients referred to the outpatients clinic of the National Cancer Institute (IST) and the Medical Genetics Service of Genoa over a 6-year period (1/1/1995-31/12/2000). Because our goal was to establish the relevance of CDKN2A polymorphisms in Ligurian melanoma patients according to age at diagnosis we split the 751 cases into quartiles based on age at diagnosis (17-40, 41-53, 54-64, and 65-88 yr) and compared the prevalence of polymorphisms in each sub-set. A small group (67) of healthy Ligurian spouses of familial and sporadic patients served as geographical controls. The 540G allele does not seem to influence age at onset: I vs. IV, I vs. II,III,IV (Chi squares n.s). We found a higher frequency of the 580T allele in quartile IV vs. quartile I (p=0.024), vs. quartiles I,II,III (p=0.04) and vs. controls (p=0.045). When we looked at sporadic and familial melanoma separately we found the same trend with no statistical significance (p=0.077, 0.072 respectively). The 580T allele seems to be associated with a late age of onset of the disease in our Ligurian population, which is characterized by a recurrent mutation (G101W) due to a founder effect, but we can't exclude an eventual protective modifier action. This study was supported by Ministry of Health grants N.ICS. 070.1/RF/00.184 to GBS.

**APC E1317Q variant is not associated with increased colorectal neoplasia risk.** *G.M. Petersen, D. Hahnloser, K. Rabe, K. Snow, L. Boardman, N.M. Lindor, B. Koch, L. Wang, S.N. Thibodeau.* Mayo Clinic, Rochester, MN.

Genetic susceptibility may play a role in many colorectal cancers (CRC). Known syndromes such as familial adenomatous polyposis (FAP) and hereditary non-polyposis colorectal cancer (HNPCC) account for <5% of CRC. The APC variant, E1317Q, caused by G to C mutation, has been reported to be associated with increased risk of colorectal polyps and CRC; these findings are controversial. **Aim:** To evaluate whether APC E1317Q is associated with increased risk of adenomatous polyps and CRC. **Methods:** Data on clinical and family history of cancer and blood samples were prospectively collected from 6 groups of Caucasian subjects at Mayo Clinic: A) Unselected CRC, n=319, mean age 66; B) Colorectal adenomas (1 to 3), n=52, mean age 65; C) Attenuated polyposis, n=141, mean age 42; D) CRC  $\leq$  age 50 (FAP/HNPCC excluded), n=126, mean age 43; E) Asymptomatic persons with normal colonoscopy, n=201, mean age 60; and F) spouse controls of CRC patients, n=451, mean age 60. E1317Q genotyping was done on lymphocyte DNA by Pyrosequencing©, blind to disease status. **Results:** The frequency of heterozygotes for E1317Q among colorectal neoplasia patients did not differ from controls; compared to Group F (0.022), there were no statistically significant differences for Groups A (0.028,  $c^2$  test,  $p=0.6$ ), B (0.058, Fisher's exact,  $p=0.14$ ), or C (0.007, Fisher's exact,  $p=0.47$ ), though the latter two were smaller samples. No one in Group E carried E1317Q. When examined by age at onset, there was no difference in frequency of E1317Q among younger CRC (Group A age  $\leq 50$  plus Group D (0.013); n=157) vs. older CRC (Group A  $>$ age 50 (0.028); n=288),  $p=0.51$ , nor when compared to Group F ( $\leq$ age 50 (0.0), n=98,  $p=.53$ ;  $>$  age 50 (0.028), n=352,  $p=.96$ ). Similarly, no differences were found by family history of CRC in Group A (family history positive (0.036), n=56, vs no family history (0.027), n=263),  $p=0.66$ . **Conclusions:** The rare variant, APC E1317Q, does not appear to be associated with increased colorectal neoplasia risk. *Supported in part by NIH U01 CA74800 (Cooperative Family Registry for Colon Cancer Studies)..*

**Reproductive factors and ovarian cancer risk in Jewish *BRCA1* and *BRCA2* mutation carriers.** *R. Moslehi*<sup>1</sup>, *F. Modugno*<sup>2</sup>, *R. Ness*<sup>2</sup>, *S. Narod*<sup>3</sup>. 1) Division of Cancer Epidemiology & Genetics, NCI, NIH, Bethesda, MD; 2) Department of Epidemiology, University of Pittsburgh, PA; 3) Centre for Research on Women's Health, Women's College Hospital, University of Toronto, ON.

Oral contraceptive use, childbearing, breastfeeding and tubal ligation have been shown to protect women in the general population against epithelial ovarian cancer. To determine whether these factors are also protective in women carrying mutations in the cancer predisposing genes, *BRCA1* and *BRCA2*, we performed a case-only study on 242 Jewish women with invasive epithelial ovarian cancer. All were genotyped for Ashkenazi founder mutations (185delAG and 5382insC in *BRCA1* and 6174delT in *BRCA2*). We compared oral contraceptive (OC) use, childbearing, breastfeeding, gynecologic surgeries and other reproductive factors in carriers and non-carriers, using unconditional logistic-regression. Among the 242 cases, 64 carried one of the *BRCA1* founder mutations, and 31 carried the *BRCA2* mutation. Parous *BRCA1* carriers reported fewer live births than non-carriers (average of 2.1 versus 2.5 live births,  $P < 0.02$ ). Parous *BRCA2* carriers also reported fewer live births (average of 2.3 live births) although the difference was not significant. Carriers and non-carriers did not differ in their history of breastfeeding or lifetime use of OC. However, *BRCA1* carriers began OCs at a later mean age (24.0 years versus 23.2 years of age,  $P < 0.04$ ) and were also more likely to be recent users of OCs (average 19.6 versus 21.4 years since last use,  $P = 0.04$ ). *BRCA1* carriers were more likely than non-carriers to have had a tubal ligation (25.0% versus 10.2%,  $P < 0.01$ ). Oral contraceptive use, childbearing and breastfeeding appear to protect *BRCA1* and *BRCA2* carriers from ovarian cancer. The late age of OC initiation reported by cases carrying a *BRCA1* mutation suggests that the protection from OCs maybe more effective at an early age. The higher percentage of *BRCA1* carriers reporting a tubal ligation suggests that this procedure may not be as protective for carriers as it is for non-carriers.

**Prevalence of inherited mutations in BRCA2 in a population-based series of 265 African American breast cancer patients.** *R.K. Kim<sup>1</sup>, T. Walsh<sup>1</sup>, H. Mu<sup>1</sup>, B. Newman<sup>2</sup>, M-C. King<sup>1</sup>.* 1) Depts of Medicine and of Genomic Sciences, University of Washington, Seattle, WA; 2) School of Public Health, Queensland University of Technology, Australia,.

To define the prevalence of disease-predisposing BRCA2 mutations among African American women with breast cancer, we analyzed genomic DNA from 265 patients from the population-based Carolina Breast Cancer Study (CBCS). The entire coding region and flanking intronic and 5' and 3' UTR sequences of BRCA2 were screened by protein truncation test and single-stranded conformation polymorphism, followed by DNA sequencing of variant bands. BRCA2 mutations that definitely lead to protein truncation were identified in three patients (1.13%). The mutations were 7180 C to T, a nonsense mutation at codon 2318 in exon 13; 7772 insA, leading to a stop at codon 2523; and 10173 delA, leading to a stop at codon 3317. A fourth mutation in the intron 14 splice donor may also be deleterious but its effect could not be evaluated from genomic DNA. Other amino acid substitutions, silent SNPS, and mutations in the 5' and 3' UTRs were also identified. None of the BRCA2 mutations previously reported in African American families occurred in the series. Two features of the distribution of BRCA2 mutations in this series are intriguing. First, none of the mutations we found had been reported previously among African American families (one was reported independently in a family from Sweden). Second the proportion of breast cancer attributable to BRCA2 among African American women was lower than among Caucasian breast cancer patients from the same CBCS series who were screened in the same way.

**Unusual alternative splicing within the human kallikrein genes KLK2 and KLK3 gives rise to novel prostate-specific proteins.** *L. Mintz*<sup>1</sup>, *J. Bernstein*<sup>2</sup>, *Z. Levine*<sup>2</sup>, *K. Savitsky*<sup>2</sup>, *A. David*<sup>2</sup>, *I. Azar*<sup>2</sup>, *S. Engel*<sup>2</sup>, *R. Hosrabi*<sup>2</sup>, *A. Toporik*<sup>2</sup>, *J. Romano*<sup>2</sup>. 1) Compugen Inc., Jamesburg, NJ; 2) Compugen Ltd., Tel-Aviv, Israel.

Prostate-specific antigen (PSA) is considered the best cancer biomarker currently available, and is widely used for screening, diagnosis and monitoring of prostate cancer. PSA (also named human kallikrein 3, hK3) is encoded by the KLK3 gene, a member of the human kallikrein gene family. The kallikrein genes code for a group of serine proteases involved in post-translational processing events. We report here the identification of two novel polypeptides encoded by unusual mRNA splice variants of the KLK2 and KLK3 genes. These proteins, named PSA-linked molecule (PSA-LM) and hK2-linked molecule (K-LM), share only the signal peptide with the original protein product of the respective gene. The mature proteins, however, are entirely different and have no similarity to the kallikrein family or to other proteins in the databases. Similar to PSA and hK2, PSA-LM and K-LM are expressed in the secretory epithelial cells of the prostate and are upregulated in response to androgenic stimulation.

**The human endogenous retrovirus HERV-K in prostate cancer.** *R.D. Smith<sup>1,2</sup>, B. Khoubehi<sup>1,2</sup>, J.D. Beatty<sup>2</sup>, C.W. Ogden<sup>2</sup>, M.A. Penny<sup>1</sup>.* 1) Department of Medical and Community Genetics, Imperial College of Science, Technology and Medicine, London, UK; 2) Department of Urology, Northwick Park Hospital, Harrow, UK.

The ability of human endogenous retroviruses (HERVs) to retrotranspose has led to the hypothesis that their expression may have a role in carcinogenesis: 1 person in 8 may carry an endogenous insertional mutation due to a new retrotransposition event. Although their transcription is usually silenced by methylation, HERV expression has been identified in a number of malignancies including breast and colon cancer. HERV-K transcription is up-regulated by steroid hormones in the breast cancer cell line T47D. Prostate cancer is also sensitive to its hormonal environment, raising the possibility of similar regulation of HERV-K expression. We have therefore investigated HERV-K expression and possible retrotransposition in prostate cancer.

RNA and DNA were extracted from DU-145, PC3 and LNCaP prostate cancer cell lines, 27 prostate cancer (CaP) and 26 benign prostatic hyperplasia (BPH) specimens. HERV-K expression was analysed using an RT-PCR technique developed to amplify mRNA without amplifying genomic HERV sequences. cDNA sequencing and Southern hybridisation confirmed the results. HERV-K integration sites in the genomic DNA of these samples were compared by restriction enzyme analysis and Southern hybridisation with the fragment pattern of 40 control men.

HERV-K *envelope* expression was detected in the T47D positive control, all prostate cell lines, 16/27 CaP specimens (59%) and 7/26 BPH specimens (27%) ( $p=0.02$ , 2-tailed Fishers exact test). Different HERV-K restriction fragments were identified in the cell lines and CaP specimens that were not present in controls.

Our results suggest that HERV-K expression occurs in prostate tissue, and is significantly more prevalent in CaP than in BPH. Differences in the restriction fragment patterns could be the result of expressed HERVs acting as mobile elements with the potential to disrupt the function of tumour suppressor genes or enhance expression of proto-oncogenes via promoter activity in the Long Terminal Repeats (LTRs) of the viral sequence.

**Different microsatellite mutation rates in cancer cell lines with defects in different mismatch repair genes.** N.A. Yamada, A. Castro, R.A. Farber. Department of Pathology and Laboratory Medicine, University of North Carolina at Chapel Hill, Chapel Hill, NC.

The mismatch repair (MMR) system is an evolutionarily conserved DNA repair pathway, which is critical for the maintenance of a stable genome. Replication errors, including insertion-deletion loops in microsatellites, are corrected by this repair system, and microsatellite mutation rates are significantly elevated in the absence of MMR. Hereditary nonpolyposis colorectal cancer (HNPCC) is a cancer predisposition syndrome that results from defective MMR, and a significant fraction of related sporadic tumors have somatic MMR defects. There are two known major protein complexes in the human MMR pathway, hMutS and hMutL. The human MutLa complex is composed of hMLH1 and hPMS2. HCT116 is a colorectal cancer cell line with defects in the *hMLH1* gene, and HEC-1-A is an endometrial cancer cell line with defects in the *hPMS2* and *hMSH6* genes. A plasmid vector containing a (CA)<sub>17</sub> microsatellite was stably transfected into each cell line, where it integrated into the genome. The microsatellite sequence was placed upstream of the bacterial neomycin resistance gene (*neo*), such that the *neo* reading frame was disrupted. Clones with frameshift mutations that restored the normal reading frame of the *neo* gene were selected, and mutation rates were determined by fluctuation analysis. Microsatellite mutation rates were approximately ten-fold higher in HCT116 than in HEC-1-A; the majority of mutations in both cell lines were deletions of a single repeat unit. These findings indicate that the absence of hMLH1 may have a greater effect on microsatellite mutation rates than the absence of hPMS2 (even in combination with the absence of normal hMSH6). The similarity in types of mutations suggests that the difference in mutation rates is not the result of a qualitative difference in the roles that the two proteins play in MMR, but of the greater reduction in overall efficiency of MMR in HCT116. Alternatively, HCT116 may harbor mutations in additional genes that affect repair or the fidelity of replication, which could lead to the higher mutation rate of this cell line than that of HEC-1-A.

**Valproic Acid Embryopathy: Report of Two Siblings with Further Expansion of the Phenotypic Abnormalities and a Review of the Literature.** *C. Kozma*. Dept Pediatrics, Georgetown Univ, Washington, DC.

Fetal Valproate syndrome (FVS) results from prenatal exposure to Valproic acid (VPA). It is characterized by a distinctive facial appearance, a cluster of minor and major anomalies, and central nervous system dysfunction. In this report, two siblings who were exposed to monotherapy with VPA are described with documentation of long-term follow up. Both children had craniofacial findings, multiple systemic and orthopedic abnormalities, an overgrowth pattern, and developmental deficits. The literature from 1978 to 2000 is reviewed. A total of 69 cases that were solely exposed to VPA with adequate phenotypic description were identified. The clinical manifestations of FVS encompass a wide spectrum of abnormalities including consistent facial phenotype, multiple systemic and orthopedic involvement, central nervous system dysfunction, and altered physical growth. The facial appearance is characterized by a small broad nose, small ears, flat philtrum, a long upper lip with shallow philtrum, and micro/retrognathia. In this review, 62% of the patients had musculoskeletal abnormalities, 30% had minor skin defects, 26% had cardiovascular abnormalities, 22% had genital abnormalities, and 16% had pulmonary abnormalities. Less frequently encountered abnormalities included brain, eye, kidney, and hearing defects. Neural tube defects were seen in 3% of the sample. Twelve percent of affected children died in infancy and 29% of surviving patients had developmental deficits/mental retardation. While 15% of patients had growth retardation, an overgrowth pattern was seen in 9%. The data from this comprehensive review especially the developmental outcome should be added to the teratogenic risk, which arises in association with the use of VPA during pregnancy.

**A possible Y-linked nonsyndromic hereditary progressive hearing loss found in a large six generations Chinese pedigree.** *Q. Wang<sup>1</sup>, W. Yang<sup>1</sup>, N. Li<sup>2</sup>, J. Cao<sup>1</sup>, L. Yu<sup>1</sup>, D. Han<sup>1</sup>, S. Jiang<sup>1</sup>.* 1) Otolaryngology/Head/Neck Surg, PLA Otolaryngology Inst, Beijing, China; 2) National Laboratories for Agrobiotechnology, Beijing, China.

A Y-linked inheritance pattern of nonsyndromic hereditary hearing loss was found in a six-generation family from the Southern of China. The phenotype of hearing loss was only observed in patrilineal males in every generation. Females and their offspring were not affected. We assume the Y-linked inheritance pattern existed in the pedigree. The ancestor of this family can trace back to eight hundreds years ago, who settled down the town of Jiang Xi province, the Southern of China. The earliest record of hearing-impaired family member was born in 120 years ago. He died just before his first child was born. The child (son) was affected hearing loss at about age 20. He got married and had four boys and one girl. The children then were subdivided into five branches in our study. They lived in three different areas after they got marry. The first branch had ten patrilineal males in following three generations and all affected. The second branch had one boy and affected. He died before age 40. The third branch had seven patrilineal males and all affected. The fourth branch had six patrilineal affected males. Their disease phenotypes were postlingual with moderately to severe hearing loss. The last branch was from the only girl in the third generation. She had two boys. Their hearing was normal at age 46 and 58 tested on April of year 2000. Their following generations were normal. We investigated 113 individuals and found 30 affected males in the family. 94 members are alive. 38 members accepted audiometry (including PTA, ABR, Immittance testing). Blood samples were obtained from the 38 family member after informed consent, which are from 16 patrilineal affected males, 4 maternal normal male and 18 normal females. The hearing loss in family affected members was extremely similar to each other, which showed a slope down pattern from 500Hz to 8000 Hz, more severe in high frequency. From the clinical characterizations, we are coming to conclude that Y-linked inheritance pattern presented in the pedigree.

**Another patient with COFS syndrome due to a nucleotide excision repair (NER) defect.** *A. Brooks, G. Mancini, W. Kleijer, P. Willems.* Dept of Clinical Genetics, Erasmus University, Rotterdam, The Netherlands.

We report on two girls with a low birth weight and a small head circumference born to healthy, consanguineous parents of Moroccan origin. Growth remained below the 3rd centile. The youngest daughter also showed a high nasal bridge, bilateral microphthalmia, bilateral cataract and contractures of the hands. On sun exposure at the age of 9 months she developed a severe hypersensitive skin reaction with erythema. The eldest daughter was noted to have flexion contractures of the large joints. She died at the age of 8 months due to severe failure to thrive and aspiration pneumonia. Autopsy was not performed. The combination of microcephaly, cataracts and joint contractures suggested the clinical diagnosis of Cerebro-Oculo-Facial-Skeletal syndrome (COFS). Given the established clinical overlap with Cockayne syndrome, which is caused by mutations in genes involved in nucleotide excision repair (NER), DNA repair studies of UV- exposed cultured fibroblasts were performed in the youngest patient. DNA replication after exposure to a UV dose of  $6 \text{ J/m}^2$  was abnormally depressed (10% of the control). This case report underlines the importance of DNA repair studies in every patient with symptoms consistent with COFS syndrome.

**Severe hypophosphatasia due to mutations in the tissue-nonspecific alkaline phosphatase (TNSALP) gene. J.**

*Terzic<sup>1</sup>, M. Fischbach<sup>2</sup>, C. Stoll<sup>2</sup>, M.O. Vuillemain<sup>3</sup>, E. Morner<sup>4</sup>.* 1) Dept Medical Genetics, Hpital de Hautepierre, Strasbourg, France; 2) Service de Pdiatrie I, Hpital de Hautepierre, Strasbourg, France; 3) Service de Pdiatrie, Centre Hospitalier, Haguenau, France; 4) SESEP, Universit de Versailles, France.

Hypophosphatasia is one rare lethal short-limbed dwarfism occurring in approximately one per 100,000 births. It is an inherited disorder characterized by defective bone mineralisation and deficiency of serum and tissue liver / bone / kidney alkaline phosphatase activity. We report the characterisation of tissue-nonspecific alkaline phosphatase (TNSALP) gene mutation in a patient affected by infantile hypophosphatasia. This boy was the first child of non affected, non related parents, mother 21 years old and father 30 years old. Pregnancy and delivery were normal. At 1 month of age appeared palsy of the left upper limb with hypotonia. Length 51 cm was 2SD, head circumference was 36,5 cm (- 1SD). Anterior fontanel was large. There was a markedly decreased ossification of all bones. All limbs were shortened. Ultrasonographic examination of the kidneys showed nephrocalcinosis. Level of alkaline phosphatases was decreased in the child at 20 U/l. as well as in the parents : mother 37 (N=55-195) and father 54 U/l. Bone density was decreased : Z score 6. At 2 years of age development was delayed. Weight was 3,5 SD and OFC 3SD. The child had craniosynostosis. Molecular studies showed a mutation R167W and a mutation E174K, both in exon 6 of the TNSALP gene. Both are missense mutations and were reported previously at least once in European patients but not together in the same patient. These mutations were not found in 40 and 57 individuals of the general population, respectively. The major cause of short-limbed dwarfism with hypomineralization of bones include hypophosphatasia, osteogenesis imperfecta type II and achondrogenesis. Hypophosphatasia has an autosomal recessive pattern of inheritance with a 25% chance of recurrence in the next pregnancy. Characterization of the mutation allows prenatal diagnosis and preimplantation diagnosis.

**OSTEOCRANIOSTENOSIS-Skull configuration mimicking kleeblattschadel with gracile long bones. Two new cases with distinctive chondro-osseous morphology.** *A.M. Elliott<sup>1</sup>, W.R. Wilcox<sup>1</sup>, G.S. Spear<sup>2</sup>, T.S. Steffensen<sup>3</sup>, D.L. Rimoin<sup>1</sup>, R.S. Lachman<sup>1</sup>.* 1) International Skeletal Dysplasia Registry, Cedars-Sinai Medical Ctr, Los Angeles, CA; 2) University of Irvine-Irvine, CA; 3) Melrose Wakefield Hospital, Melrose, MA.

We report two unrelated male infants with osteocraniostenosis and describe the clinical, radiographic and chondro-osseous morphology findings. Osteocraniostenosis is a skeletal dysplasia characterized by a skull configuration mimicking kleeblattschadel (cloverleaf skull) and overtubulated long bones. Dysmorphic features include small palpebral fissures, short nose and philtrum and a small, inverted v-shaped mouth. Splenic hypoplasia is a constant finding. Patient #1 died shortly after birth at 39 weeks gestation. Autopsy revealed a dysmorphic baby with length -4 SD, weight 3rd centile and OFC -3 SD. Radiographic examination showed a kleeblattschadel appearance, platyspondyly and saggital clefting mainly of the thoracic region of the spine. The long bones had moderate shortening with metaphyseal flaring and rounding. The diaphyses of the long bones and short tubular bones of the hands and feet were overtubulated. Histological examination of bone revealed an abnormal growth plate with short irregular columns. The resting cartilage showed pleomorphic chondrocytes with increased cellularity and unique pseudocolumn formation. Patient #2, born at 36.5 weeks gestation, died shortly after birth. Measurements included: length -4 SD, weight -4 SD and OFC 25th centile. Patient #2 resembled patient #1 clinically and radiographically. Both patients had hypoplastic cranial bones, eye abnormalities, pulmonary hypoplasia, splenic hypoplasia and hepatomegaly. The chondro-osseous morphology was similar in both patients. Although gracile bones are uncommon in the skeletal dysplasias, they are often associated with fetal hypokinesia. The bone histology is usually normal in those patients except for thin cortices with growth plate and diaphyseal fractures. Patients with Hallermann-Streiff syndrome (HSS) also have slender tubular bones. Radiographic and histological similarities between HSS and the two patients reported here are discussed.

**A new autosomal dominant syndrome with strabismus, cleft palate, patellar dislocation, and facial dysmorphic features.** *V.M. Der Kaloustian, F. Fassier, M. Flanders, R. Crépeau, G. Rouleau.* McGill University Health Ctr., McGill Univ, Montreal, Quebec, Canada.

We report a family with four persons affected with various combinations of strabismus, cleft palate, patellar dislocation, and facial dysmorphic features. The probanda is a 5-year-old girl, the second child of a non-consanguineous French-Canadian couple. She was born at term with Apgar scores of 9 and 10 at 1 and 5 minutes respectively. At birth she had a cleft palate and was operated for it at the age of one year. She has right superior oblique muscle palsy, narrow and upslanting palpebral fissures, micrognathia, and a particular triangular shape of the pinna with a horizontal upper border. She also had bilateral congenital patellar dislocation for which she was operated at the age of 3 and a half years. The family history is positive for congenital anomalies. The brother, who is 7 years old, also has superior oblique palsy, similar ear anomalies and micrognathia. The father has the same eye and ear anomalies, micrognathia, and had bilateral patellar dislocation for which he was operated at the age of 12 years. A paternal aunt had cleft palate and eye anomalies. We think that our patients are affected with a new syndrome following the autosomal dominant pattern of inheritance with variable expressivity.

**Orthopedic manifestations in neurofibromatosis type 1.** *S. Boero<sup>1</sup>, G. Stella<sup>1</sup>, D. Sambarino<sup>2</sup>, S. Massa<sup>2</sup>, S. Costabel<sup>2</sup>, L. Costabello<sup>2</sup>, C. Bellini<sup>2</sup>, E. Bonioli<sup>2</sup>.* 1) Orthopedic Department, G. Gaslini Children Institute, Genova, Italy; 2) Pediatrics Department, University of Genova, Italy.

Scoliosis is the most common orthopedic manifestation of NF1 as it is observed in 12-20% of patients. In some patients it is indistinguishable from idiopathic scoliosis and its greatest rate of curve progression occurs during the adolescent growth spurt; the specific NF1 types of scoliosis are associated with vertebral dysplasia, most commonly in the form of a short-segment angular thoracic lesion. Congenital bowing may involve any long bone, the tibia being the most commonly affected. It occurs in a small percentage of NF1 patients (3%) and usually evolves into pseudoarthrosis. We observed 34 NF1 patients with skeletal manifestations with a yearly follow up. 21 of these showed lumbar or thoracic scoliosis and 13 showed leg deformities. Seven cases were not surgically treated: 3 of these presented a mild not evolutive scoliosis; 2 young children presented a bow tibia, and were treated with a protective brace; 2 other cases with scoliosis were not operated because of serious respiratory difficulties. 16 patients with scoliosis have been treated with a Milwaukee brace and then with anterior and/or posterior fusion, using the Harrington or C.D. instrumentation. A good consolidation has been obtained in 14, while in 1 patient the vertebral fusion was eroded by a large dural ectasia that caused relapse of the deformity and paraplegia; 1 patient died following a mediastinum and brain stem neoplasia. 11 patients with pseudoarthrosis have been treated. Most of them underwent different procedures in different times: Ilizarov's technique, fibula-pro-tibia graft, infiltration of methylprednisolone acetate. Consolidation has been obtained in 9 cases, but the tibia in 2 of these has a residual shortening. In our experience, in case of dysplastic scoliosis better results have been obtained with antero-posterior arthrodesis; in case of bow tibia the later the Ilizarov's procedure is performed the better are the results in term of rate of consolidation and stability.

**Desbuquois syndrome: clinical, radiographic and long-term outcome in 15 cases.** *V. Cormier-Daire<sup>1</sup>, L. Faivre<sup>1</sup>, P. Maroteaux<sup>1</sup>, A. Munnich<sup>1</sup>, R. Lachman<sup>2</sup>, M. Le Merrer<sup>1</sup>.* 1) Dept Genetics, Hosp Necker, Paris, France; 2) Dept Pediatric Radiology, Cedars Sinai, Los Angeles, USA.

Desbuquois syndrome is a rare condition of autosomal recessive inheritance, characterized (i) clinically by markedly decreased birth length, facial dysmorphism and joint laxity, and (ii) radiologically by a Swedish key appearance of the proximal femur, coronal clefts of the spine and characteristic hands and feet abnormalities including delta phalanx and/or duplication of the thumb, extraossification center distal to the second metacarpal and advanced bone age. Here, we report on 15 patients (12 boys, 3 girls) with Desbuquois syndrome from 4 consanguineous and 10 non-consanguineous families, originating from 7 different countries. Birth length was less than 44 cm, facial dysmorphism and joint hyperlaxity were noted in all patients. Abnormal thoracic shape was noted in 11/15 patients, and mental retardation in 4/15 patients. Out of 15 cases, 4 patients died from age 2 months to 6 years of respiratory insufficiency. The mean age of the survivors was 5 years and their long-term outcome was characterized by severe growth deficiency, from 4 to 9 standard deviations, cyphoscoliosis and marked invalidity in the older patients. Swedish key appearance of the proximal femur, flat acetabular roof, short first metacarpal and metatarsal, advanced carpal and tarsal bone age, large and flat metaphyses, coronal and sagittal clefts of the spine, and midface hypoplasia were consistent radiological features in all patients. Radioulnar dislocation was found in 4/15 cases. It is worth noting that supranumerary ossification centers of the hands and feet, delta phalanx of the thumb and finger deviation and cleft thumb were found in 5/15 cases only, and polydactyly in 1/15 cases. We therefore suggest that hand abnormalities are not mandatory for the diagnosis of Desbuquois syndrome.

**Rhizomelic Limb Shortness in NF1: A Previously Unrecognised Skeletal Manifestation?** *L. Dupuis, A.S. Teebi, M.M. Nezarati.* Hosp Sick Children, Toronto, ON, Canada.

Distinctive osseous lesions may occur in individuals with Neurofibromatosis type 1 (NF1). Commonly, these lesions affect local bone growth. We report a case of a 22-year-old woman with a clinical and molecular diagnosis of NF1 as well as severe bilateral rhizomelic shortness of the upper limbs. The proband was born to a consanguineous Portuguese couple. As a child, she had "swellings" removed in the axillary regions and the lateral aspect of the right leg. Development was reported as normal and she completed high school with some difficulty in mathematics. Examination revealed nine café-au-lait spots (>1.5 cm in diameter) with no axillary or inguinal freckling or neurofibromas. Height was 153 cm and arm span was 134 cm. She had a long face with mild mid-face hypoplasia, a narrow palate and mild dental malocclusion. Ocular examination revealed multiple Lisch nodules. Skeletal findings included diaphyseal shortness and narrowing of humeri, more pronounced on the right. Cortical thickening was seen along the medial proximal diaphysis of both femurs. She had tibial bowing on the right but not true pseudoarthrosis. The left tibia was unremarkable. She had mild scoliosis in the lower lumbar region with one anteriorly scalloped vertebral body. Protein truncation analysis revealed premature termination of protein translation in the amplified cDNA fragment spanning NF1 exons 22-28. There was no family history of NF1. One of the seven siblings was reported to have one leg thinner and longer than the other. The patient recently delivered a son with no apparent features of NF1 and no limb abnormalities. The most common types of osseous lesions associated with NF1 include pseudoarthrosis, congenitally bowed tibia without pseudoarthrosis, scoliosis and dysplastic sphenoid wing. Bony changes secondary to plexiform neurofibromas have been well documented. Our patient's skeletal findings are unusual. The asymmetric shortness of the humeri are more likely due to primary skeletal involvement, rather than secondary effects of plexiform neurofibromas. This case further expands our understanding of skeletal manifestations associated with NF1.

**Spondylo-Meta-Epiphyseal Dysplasia, Short Limb-Abnormal Calcification Type: Clinical and Radiological features in 3 patients and Exclusion of the DTD gene.** Z. Ben-Neriah<sup>1</sup>, V. Cormier-Daire<sup>2</sup>, C. Huber<sup>2</sup>, J. Sosna<sup>3</sup>, J. Bar-Ziv<sup>3</sup>, A. Raas-Rothschild<sup>1</sup>. 1) Department of Human Genetics, Hadassah Hospital, Jerusalem, Israel; 2) INSERM U393 and Department of Genetics, Hospital Necker Enfants-Malades, Paris, France; 3) Department of Radiology, Hadassah Hospital, Jerusalem, Israel.

In 1993, Borochowitz reported on three patients with a new bone dysplasia which he called, Spondylo-Meta-Epiphyseal Dysplasia (SMED), Short Limb-Hand type [MIM, 271665]. Langer et al who proposed to call it SMED, Short Limb-Abnormal Calcification type, emphasized the importance of the chondral calcifications in the diagnosis of this disorder. SMED, Short Limb-Abnormal Calcification type (SMED, SL-AC) is an autosomal recessive condition with a grave prognosis. Spinal cord compression due to atlanto-axial instability and respiratory disease are the most common causes of death. Recently, we examined 3 patients up to the age of 16 years from 2 different consanguineous Arab Muslim families with this condition. We present the clinical and radiological findings that permit the diagnosis of SMED, SL-AC. Recently, Megarbane et al reported on a child with a variant diastrophic dysplasia and a new mutation in the DTD gene. The resemblance between this patient and our patients suggested a possible common etiology but sequencing of the entire coding sequence of the diastrophic dysplasia (DTD) gene did not reveal any mutation. Since the molecular defect of this disorder is still unknown, families at risk can be offered prenatal diagnosis by means of early ultrasonographic examination as it was done for two of the families reported.

**Microcephalic Osteodysplastic Dysplasia: Progression of radiographic manifestations not previously described.**

*D.L. Earl*<sup>1</sup>, *R.S. Lachman*<sup>2</sup>, *D.L. Rimoin*<sup>1,2</sup>. 1) Medical Gen/Birth Defects Ctr, Cedars-Sinai Medical Ctr, Los Angeles, CA; 2) International Skeletal Dysplasia Registry, Cedars-Sinai Medical Ctr, Los Angeles, CA.

Microcephalic Osteodysplastic Dysplasia (Saul-Wilson Dysplasia) is a rare condition with a characteristic facies (prominent forehead with a small appearing face, midface hypoplasia, prominent eyes, downslanted palpebral fissures, narrow nasal root, beaked nose, and micrognathia), microcephaly, cataracts, severe postnatal growth deficiency, brachydactyly, clubfoot deformities, syrinx of the spinal cord, and variable developmental delay. All reported cases have been sporadic. Radiographic manifestations in reported cases of this condition include: platyspondyly, irregularity of the vertebral bodies, odontoid and L1 hypoplasia, overtubulation of the long bones with widened metaphyses, coxa valga, short metacarpals, metatarsals, and phalanges with irregular metaphyses, coned and ivory phalangeal epiphyses, and accessory ossification centers in the metacarpals and metatarsals. We describe the striking progression of radiographic manifestations, from infancy to 13 years, including odontoid with cervical spine subluxation, precocious calcification (aorta and costochondral cartilage), progressive osteopenia, unusual paddle shaped ribs, hypoplasia of the ulnae, and bowing of the ulnae and radii, accompanying other dramatic skeletal findings. These unusual radiographic findings are described in a previously reported case of microcephalic osteodysplastic dysplasia (Hersh, et.al; *Am J Med Genet* 51:194-199, 1994).

**Deletion 13q and skeletal dysplasia in a mexican patient.** *J.A. Morales<sup>1,3</sup>, N.M. Macias<sup>1,3</sup>, L.E. Wong-Ley<sup>1,3</sup>, M.P. Gallegos-Arreola<sup>2</sup>, A.I. Vasquez<sup>1</sup>, L.E. Figuera<sup>1,3</sup>.* 1) Division de Genetica, CIBO-IMSS, Guadalajara, Mexico; 2) Division de Medicina Molecular, CIBO-IMSS, Guadalajara, Mexico; 3) Doctorado en Genetica Humana, CUCS-UdeG, Guadalajara, Mexico.

Deletion of 13q is an entity with a broad clinical spectrum, ranging from psychomotor delay to hand and foot anomalies. This deletion have been reported in six other cases; one with deletion comprising region q22-q31 and the others with deletion of 13q22-q32. We report the case of a 6-year-old male with intrauterine growth retardation, recurrent infectious events in the right knee and bilateral chronic middle-ear otitis. After clinical examination he showed moderate psychomotor delay, mild bilateral hypoacusia, general shortening of the metacarpals, metatarsals and phalanxes, predominantly in the distal phalanxes of the first and fifth fingers of all limbs and a karyotype anomaly of 46,XY, del(13)(q22q31). This case exhibited the characteristic phenotype of a skeletal dysplasia and an interstitial deletion of the long arm of chromosome 13. Given the clinical and radiological features, we believe that witin 13q22-q31 possibly lays a gene involved in bone development.

**Stuve-Wiedemann syndrome : two additional cases of prenatal diagnosis.** *J. Martinovic<sup>1</sup>, J. Tantau<sup>1</sup>, F. Encha-Razavi<sup>1</sup>, M. Vekemans<sup>1</sup>, J.M. Jouannic<sup>2</sup>, M.C. Aubry<sup>2</sup>, S. Lyonnet<sup>1</sup>, M. Le Merrer<sup>1</sup>, V. Cormier-Daire<sup>1</sup>.* 1) Dept de Genetique, Hopital Necker - Enfants Malades, Paris, France; 2) Service de Gynecologie et Obstetrique, Hopital Necker-Enfants Malades, Paris, France.

The Stuve-Wiedemann syndrome (SWS) is a rare skeletal dysplasia characterised radiologically by bowing of the long bones with internal cortical thickening and large metaphyses, and clinically by malignant hyperthermic episodes, respiratory insufficiency and early lethality in the majority of cases reported. Parental consanguinity and recurrence in sibs is highly suggestive of an autosomal recessive inheritance. No data are yet available on the gene locus of SWS. Here, we report on two cases of SWS in the second and third trimester fetuses issued from two different non-consanguineous kindreds. In both cases, shortened and bowed femora and tibiae with wide metaphyses were cardinal signs prenatally. The pregnancies were interrupted at 24 and 30 weeks respectively. Radiological postnatal analysis confirmed bowed femora, tibiae, and fibulae with cortical thickening and wide, striated metaphyses, generalised skeletal hypomineralisation, strongly suggesting in both cases the diagnosis of SWS. Bone histology of femoral upper metaphyses was highly abnormal and showed irregularity of the chondroosseous junction, thick trabeculae, osteoclastic hyperactivity but normal resting cartilage. To our knowledge, this is the second report on prenatal diagnosis of SWS. Further studies are necessary to shed light on the genetic basis and pathogenesis of SWS.

**A new form of familial autosomal recessive, chondrodysplasia punctata.** *A. Pai<sup>1</sup>, S. Viero<sup>1</sup>, M. Thomas<sup>1</sup>, D. Myles Reid<sup>1</sup>, A. Toi<sup>1</sup>, R. Lachman<sup>2</sup>, D. Chitayat<sup>1</sup>.* 1) Mount Sinai Hospital, Toronto, Canada; 2) The International Registry of Skeletal Dysplasia(4), LA, California, USA.

Chondrodysplasia punctata is a heterogenous condition associated with exposure to teratogens, chromosome abnormalities and single gene disorders. Rhizomelic chondrodysplasia punctata is in most cases the result of a peroxisomal disorder. We report a new autosomal recessive type of chondrodysplasia punctata with normal peroxisomal function. A 24-year old primigravida woman was referred to us at 20 weeks gestation with fetal ultrasound findings of short limbs (the BPD measurement was consistent with 21.4 wks, the abdominal circumference with 19.7 wks, the femur 16.9 wks, the tibia 17.4 wks, the humeri 17.1 wks and the ulna 17.3 wks gestation). The chest to abdomen ratio was 82%. The facial features were abnormal with a sloped forehead, depressed nasal bridge with flat nose, micrognathia and mid-facial hypoplasia. There were abnormal vertebral calcifications and decreased movements. The patient had a premature delivery at 22 weeks gestation. The autopsy showed a globular head with midface hypoplasia, flat nose with no nasal septum and creases on both alae nasi. The eyes were prominent with hypoplastic supraorbital ridges and retrognathia. The chest was narrow, the abdomen was prominent and the long bones showed rhizomelic shortening with limitation in extension of both elbows. Radiographic assessment showed stippled epiphyses, platyspondyly with rhizomelic short long bones, anterior bowing of the femurs and clinodactyly of the fifth fingers and toes. No brain or cardiac abnormalities were found and the karyotype was normal and female (46,XX). Peroxisomal functions (Dr. A. Mosers lab) were normal. The second pregnancy was with another partner and resulted in a normal daughter. The third pregnancy was with the first partner and resulted in a fetus with gastroschisis and the same skeletal findings and facial features as in the first pregnancy. The karyotype was normal and male (46,XY). Based on the above information, we believe this is a hitherto new autosomal recessive condition associated with rhizomelic chondrodysplasia punctata and typical facial features with normal peroxisomal functions.

**Classical Ehlers-Danlos syndrome in mother and daughter.** *S. Ritz, S. Sastry, M.G. Bialer.* Dept of Pediatrics, North Shore Univ Hosp/NYU School of Med, Manhasset, NY.

Ehlers-Danlos syndromes (EDS) are inherited disorders of connective tissue characterized by skin hyperextensibility, joint laxity and tissue fragility. The nosology of EDS subtypes was revised in 1997. Occasional reports of congenital heart disease in EDS have been dismissed as coincidental. We report a mother and daughter with classical EDS (type II or mitis type) and atrial septal defect (ASD). The mother is one of 7 affected individuals over 4 generations in an autosomal dominant pedigree. She walked at 19-20 mo. Development was otherwise normal. She began dislocating joints at 10 yr and describes about 15 dislocations of her left elbow, 4-5 dislocations of the left patella and dislocations of fingers and her right thumb which required surgery. At 31 yr, she has pains in many joints. She has easy bruising, skin hyperextensibility, scarring on her shins, and still has flexible fingers, ankles and patellae. She takes a long time to heal. She was diagnosed with ASD at 17 yr and required surgery at 24 yr. Her first daughter was unaffected, but her second daughter, at 6 mo, has significant joint laxity involving fingers, toes, wrists, ankles, patellae and hips. There are no obvious skin findings. An EKG done shortly after birth for heart rate of 240 revealed supraventricular tachycardia (SVT) and she was treated with Digoxin and Inderal. There was an aneurysm of the atrial septum with a small left-to-right shunt across the foramen ovale. Follow-up echocardiogram at 6 mo revealed a 10 mm secundum ASD. She has had no clinical recurrence of SVT, but remains on medication. There is a report of 2 sisters with EDS and VSD, one of whom also had ASD. All the other cases that we are aware of are singleton. Since ASD is multifactorial, concordance of ASD and EDS would be expected to occur 1 in 50 times if the 2 conditions are unrelated. On the other hand, since some cases of classical EDS have been shown to be due to mutations in type V collagen, which is also expressed in the atrioventricular valve of the developing mouse embryo, it is possible that some EDS-causing mutations may predispose to structural congenital heart disease.

**Clinical and molecular characterisation of Frontotemporal dementia linked to Human Chromosome 3.** *L. Chakrabarti and FReJA (Frontotemporal Research in Jutland Association).* MRC Prion Unit, Imperial College, London, UK.

We are studying a large multigenerational Danish kindred in which there is autosomal dominant pre-senile dementia. Our group assigned this disease to the pericentromeric region of chromosome 3. Age of onset is between 50 and 65 years. Typically this dementia begins with a personality change. Features that follow include disinhibition, hyperorality, restlessness and dyscalculia. There are progressive behavioural problems, speech decline, and stereotypical behaviour, some motor disturbances and dystonic posturing. There is a lack of patient insight. We reported anticipation as a feature of this disease and statistical tests supported this theory. We now have data from 5 paternal transmissions and 12 maternal transmissions. A decrease in age of onset was seen in cases of paternal transmission but not when disease was inherited maternally. Maternal inheritance coincided with a similar or slightly later age of onset. The results of performing a two sample t test with unequal variances (Welch's t test) showed that there are significant differences in age of onset. The child's age of onset was significantly younger ( $P < 0.0001$ ) for paternal transmission (mean=51.6, sd=1.82, n=5) than for maternal transmission (mean=60.75, sd=3.82, n=12). When calculating the child-parent age of onset the difference was significantly less ( $P = 0.001$ ) for Paternal transmission (mean=-8, sd=2, n=5) than for Maternal transmission (mean+3.17, sd=2.76, n=12). Two new cases were diagnosed in this family last year and though both cases (they are siblings) have inherited the disease through the paternal line, they each have a later age of onset than their father. We have designed a program that can identify di, tri, tetra and penta repeats from genomic sequence and are testing these repeats to see if any are expanded in affected individuals. We are sequencing genes in the region to find a disease causing mutation. Genealogical studies are progressing in order to identify further informative meioses. Expression studies are underway using microarray technology to compare brain tissue from this family with matched tissue from Alzheimer's and non-neurodegenerative brain.

**Congenital hydrocephalus, ambiguous genitalia in males and early lethality: a new syndrome?** *L. Basel-Vanagaite*<sup>1</sup>, *G. Klinger*<sup>2</sup>, *M. Shohat*<sup>1,3</sup>, *Y. Udler*<sup>1</sup>, *O. Levit*<sup>2</sup>, *N. Linder*<sup>2</sup>, *L. Sirota*<sup>2</sup>. 1) Medical Genetics, Rabin Medical Center, Petah Tikva, Israel; 2) Department of Neonatology, Schneider Children's Medical Center of Israel, Petah Tikva, Israel; 3) Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel.

Congenital hydrocephalus can be caused by environmental and genetic factors. It can be an isolated abnormality or be a part of a syndrome. Further heterogeneity also exists among isolated cases of hydrocephalus. The X-linked form is caused by L1CAM mutations, but rarely it can be inherited as an autosomal recessive condition. We report on three infants, 2 male and 1 female, from two unrelated consanguineous Arab families living in the same village, with a previously undescribed pattern of malformations including congenital hydrocephalus, ambiguous genitalia in males, and early lethality. There are in addition five healthy children between the two families. Physical examination of the patients revealed severe hydrocephalus, low set ears and simian lines. Genital examination revealed normal genitalia in the female, but the males had micropenis with cryptorchidism and bifid scrotum. Metabolic and endocrine studies were normal. All the patients had normal karyotypes. CT scan revealed extreme dilatation of the lateral and the third ventricles but a normal fourth ventricle. Echocardiography in one of the male infants demonstrated double outlet right ventricle. All of the patients died at age 1 to 40 days despite insertion of ventriculoperitoneal shunts. In addition, each of two previous pregnancies in one of the families ended at 30-31 weeks of gestation with antepartum fetal death. Both fetuses had severe hydrocephalus. The patients in these two families seem to suffer from the same disease, inherited in an autosomal recessive pattern. The congenital heart disease in one of the patients could be a coincidental finding and not part of the syndrome, as it was not present in the other affected children. We suggest that this combination of anomalies constitutes a unique syndrome.

**"Apple-Peel" Intestinal Atresia, Ocular Anomalies and Microcephaly Syndrome. Brain Magnetic Resonance Imaging Study.** *C. Arioni, M. Mazzella, M.P. Fondelli, D. Sambarino, S. Massa, E. Bonioli, C. Bellini, G. Serra.*

Department of Pediatrics , Gaslini Institute, Genoa, Italy.

The patient was the first son of healthy, unrelated, normocephalic parents. At the 28th week of intrauterine life US scanning detected intestinal ectasia, suggesting small bowel obstruction. His birth weight (37 week pregnancy) was 1890 g and birth length was 44 cm (both at 10th centile), and head circumference was 27 cm (below the 3rd centile). X-ray examination at birth showed a intestinal ectasia. Barium roentgenogram confirmed upper jejunal obstruction. High jejunal atresia with apple-peel deformity and colonic malrotation was surgically identified. Ocular examination showed bilateral corneal leukoma which was more evident in the left eye. Fundoscopy was not possible due to corneal clouding. Ultrasound examination showed normal retina and optic nerve. MR brain examination (age two months) showed a microcephalic brain with normal brain substance and myelination pattern (neither malformations nor hydrocephalus). No ocular abnormalities were found. High resolution karyotype was normal. TORCH complex was negative. Urine culture for Cytomegalovirus was also negative. Spinal fluid analysis ruled out an infection. Association of apple-peel atresia with microcephaly and ocular anomalies has been reported only 3 times. We report on a fourth infant and the first brain MRI study in this syndrome. The absence of abnormalities of migration might be compatible with the absence of alcoholism, malnutrition, and diabetes mellitus in the mother. In this view, a genetic origin of microcephaly rather than a disruptive one is likely in our patient. Two out of the three previously reported patients have been found to be mentally retarded. Our report confirms that the association of apple-peel atresia, ocular abnormalities, and microcephaly is a distinct syndromic entity. Brain MRI evaluation should be included in the investigation protocol of such patients since it could provide important information regarding pathogenesis, genetic counseling, and patient management.

**Persistence of Mullerian Derivatives and Intestinal Lymphangiectasis in Two Newborn Brothers.** *C. Bellini<sup>1</sup>, M. Mazzella<sup>1</sup>, E. Bonioli<sup>1</sup>, C.M. Hennekam<sup>2</sup>, A.R. Sementa<sup>3</sup>, C.E. Marino<sup>3</sup>, D. Sambarino<sup>1</sup>, S. Massa<sup>1</sup>, G. Serra<sup>1</sup>.* 1) Department of Pediatrics, Gaslini Institute, Genoa, Italy; 2) Department of Pediatrics and Clinical Genetics Academic Medical Center, Amsterdam, The Netherlands; 3) Servizio di Anatomia Patologia, Istituto G. Gaslini, Genova, Italia.

The proband (case 1) was the liveborn male product of a third pregnancy (38 weeks). At birth, generalized lymphedema was immediately evident. There was a broad nasal bridge, a bulbous nasal tip, a long and prominent upper lip with smooth philtrum, and mild retrognathia, a thick alveolar ridges. The testes had descended properly, and the penis was normally formed. The presence of a uterus and the upper part of a hypoplastic vagina was US and MRI demonstrated. The anti-Mullerian hormone level was 76 ng/ml (normal). Karyotype was 46, XY; VLCF Acid and Plasmalogen, cholesterol metabolism were normal. Intestinal lymphangiectasis was demonstrated. He died of multiorgan failure caused by septic shock (three months). Autopsy showed generalized intestinal and pulmonary lymphangiectasia, a rudimentary uterus, Fallopian tubes, the upper third of a vagina, and a prostate of normal shape. The testes were situated in the scrotum. The brother's clinical course was identical. We describe two newborn brothers with a pattern of malformations characterized by the persistence of Mullerian duct derivatives (PMD) and intestinal lymphangiectasia. The syndrome was first delineated by Urioste (AJMD,47,494,1993). Our cases confirm the existence of a definite and separate entity. All patients died at a very young age. The hypogammaglobulinemia and lymphopenia can easily account for sepsis that can ensue in fatal septic shock. It is still uncertain whether this entity is compatible with longer survival. All cases reported thus far have been males and their parents were all healthy and non-consanguineous. The autosomal recessive pattern seems to be the most probable model of inheritance. An X-linked recessive pattern is also possible, but it is likely that the presence of Mullerian duct derivatives will create a bias for the recognition of the entity in males, and causes the distorted sex ratio.

**Distinguishing features for schizophrenia on MRI brain scans of 22qDS adults.** *E. Chow*<sup>1,2</sup>, *D.J. Mikulis*<sup>3</sup>, *R.B. Zipursky*<sup>1,2</sup>, *A.S. Bassett*<sup>1,2</sup>. 1) Schizophrenia Research Program, Queen St. Site, CAMH, Toronto, ON, CANADA; 2) Department of Psychiatry, Univ of Toronto, ON, CANADA; 3) Department of Medical Imaging, Univ of Toronto, ON, CANADA.

**Background:** Up to 25% of adults with 22q11 Deletion Syndrome (22qDS) may develop a psychotic disorder such as schizophrenia (SZ). We have previously reported high frequencies of certain features (e.g. bright foci, cavum vergae, ventricular enlargement, cortical atrophy, skull base abnormalities) that are clinically detectable on brain and neck magnetic resonance imaging (MRI) and magnetic resonance angiography (MRA) scans in adults with 22qDS and SZ. However, it is unclear whether these qualitative MRI features are found in similar frequencies in 22qDS adults without a psychotic illness. **Objective:** To compare the frequencies of MRI features between 22qDS adults with SZ and those without psychosis. **Method:** Brain and neck MRI and MRA scans of 24 adults with 22qDS (16 with SZ and 8 non-psychotic) were reviewed blind to psychiatric status by a neuroradiologist (DJM) for detectable cavum vergae/septum pellucidum, ventricular enlargement, cortical atrophy, bright foci, skull base abnormalities, and vessel anomalies. Frequencies of these features were compared between the two groups using Fischer's exact test. **Results:** More cavum anomalies (50% vs 0%,  $p=0.05$ ) and ventricular enlargement (50% vs 0%,  $p=0.05$ ) were noted in 22qDS subjects with SZ than those without psychosis, although the two groups had no significant difference in rates of bright foci, vessel anomalies, and skull base anomalies. **Conclusions:** Although sample size was small, results suggest that midline defects and ventricular enlargement detectable on clinical readings of brain MRI may be distinguishing features between 22qDS patients with and without SZ.

**Prenatal cerebral vasculopathy with vascular accident in an infant with neurofibromatosis 1.** *K.A. Fjelstad, J.J. Mulvihill, D.A. Wilson.* Children's Hospital of Oklahoma, University of Oklahoma Health Sciences Center, Oklahoma City, OK.

The central nervous system features of neurofibromatosis 1 (NF1) are usually neoplastic, but reports of vascular abnormalities abound. A two-month-old infant was admitted in status epilepticus. The infant was afebrile and had no current illness. He had no prior seizures and a normal birth history. His mother, brother, and four other relatives had NF1 in five generations without life-threatening complications. The infant had mild left hemiparesis after cessation of seizure activity, macrocephaly, over six cafe-au-lait spots, and a right bony temporal mass with central fluctuance. Computerized tomography and magnetic resonance imaging revealed a right sided arachnoid cyst eroding bone. Evolving infarction of the right middle and posterior cerebral artery distributions, an atrophic right hemisphere, a lesser degree of left sided atrophy of the anteriortemporal lobe, and right basal ganglia hyperdensities were present. Magnetic resonance angiography displayed a one centimeter flow gap in the right middle cerebral artery and beading with multiple areas of stenosis in the right posterior cerebral artery. The right anterior cerebral, anterior communicating, and posterior communicating arteries were absent. The left-sided cerebral vasculature was normal. Cerebral vascular accident and NF1 were diagnosed in this infant. A history of chronic ischemia and likely in utero infarction were suggested by the cerebral atrophy. This case, perhaps the first with diffuse unilateral cerebral vasculopathy and arachnoid cyst in an infant with NF1, demonstrates the extreme variability in expression of NF1 even among members of the same family. It points to the prenatal origins of the vasculopathies of NF1, although clinical presentation and recognition are usually at an older age than this patient. In an infant at risk of NF1, head asymmetry might be sufficient indication for imaging studies; prenatal imaging might also detect such vascular defects.

**Central Auditory Processing (CAP) in Huntington's Disease (HD).** *T.S. Bradham<sup>1</sup>, R.K. Abramson<sup>2</sup>, E.M. Frank<sup>3</sup>, W.A. Cooper<sup>3</sup>.* 1) Medical Univ South Carolina, Charleston, SC; 2) W.S. Hall Psych. Inst, Columbia, SC; 3) Univ. South Carolina, Columbia, SC.

The purpose of this study is to determine if HD patients (HD) and presymptomatic gene positive persons (PreHD) show impaired CAP abilities as compared to matched controls. If dysfunction is present, this may suggest why persons with HD have difficulties with components of receptive and expressive language. Little is known about CAP dysfunction in HD. Impaired language function in HD, shown by a decrease in number of words used in connected speech, word finding difficulty, and loss of prosody in conversational speech (Yorkston et al, 1995) is also seen in people with CAP deficits. Anatomic and functional evidence implicate CAP involvement in HD. Two major auditory pathways ascend through the basal ganglia in the cerebral cortex. Secondary effects could occur in HD due to changes in the striatum, lateral ventricles, and decrease in overall brain weight (Lenz and Musiek, 1996). There have been no studies involving behavioral tests of CAP function. Twelve HD and 8 PreHD participants were matched for age, education level, and gender with people with no known neurological disorders. Participants (n=40) had peripheral hearing and CAP evaluations. Peripheral hearing assessments included tympanometry, acoustic reflexes, pure tone and speech audiometry, and transient evoked otoacoustic emissions. The CAP test battery included synthetic sentence identification with ipsilateral competing message, dichotic digits, and duration pattern test. Data were analyzed using analysis of variance. Peripheral auditory functions were not significantly different between groups. HD participants scored significantly lower on the speech recognition test in each ear ( $p < .002$ ) compared to controls and on seven of the nine measures from the CAP test battery ( $p < .01$ ), indicating deficits in auditory figure ground, dichotic listening, and temporal sequencing. The PreHD group scored the same as the controls on the CAP test battery. Research is needed in this area. Testing for CAP dysfunction in HD would aid in decisions about placement, level of care, assistive technology and acoustical environment management.

**Mesial temporal lobe abnormalities in a family with 15q26qter trisomy.** *D. Facchin<sup>1</sup>, E. Kobayashi<sup>2</sup>, F. Cendes<sup>2</sup>, C.E. Steiner<sup>1</sup>, A.A.A. Leone<sup>2</sup>, N.L.V. Campos<sup>1</sup>, I. Lopes-Cendes<sup>1</sup>.* 1) Department of Medical Genetics, University of Campinas, Campinas, SP, BRAZIL; 2) Department of Neurology, University of Campinas, Campinas, SP, BRAZIL.

**Objective:** To describe the clinical, neuro-imaging and cytogenetic findings of two brothers with secondary generalized epilepsy (SGE) and mental retardation (MR).

**Methods:** Seizures and epilepsy syndrome, as well as the development milestones, were characterized by detailed clinical history. We performed neurologic examination, including cognitive evaluation with estimated IQ in both patients and all available relatives. After informed consent, we collected blood samples for cytogenetic studies on short-term culture of peripheral blood lymphocytes using standard G-banding technique. In addition, we performed routine interictal EEGs and MRI scans. Imaging studies were conducted in a 2Tesla scanner including T1 and T2 weighted images in three orthogonal planes with 3-6 mm slices. In addition, a T1 volumetric acquisition with 1mm thickness was performed. MRI analyses included detailed visual evaluation including multiplanar reconstruction.

**Results:** We report a family with two brothers presenting with 15q trisomy due to a maternal equilibrated translocation involving chromosomes 12 and 15. Clinical findings include minor dysmorphic features, mental retardation, abnormal behavior, and secondary generalized epilepsy. EEG showed left temporal slow waves in the oldest brother and background abnormality associated to generalized and multifocal epileptiform discharges in the other. Their MRI showed mesial temporal lobe malformation, including the hippocampus, parahippocampal gyrus and fusiform gyrus, with abnormal shape and axis.

**Conclusion:** To our knowledge, this is the first report of mesial temporal lobe malformation associated with chromosomal abnormalities. Our findings may contribute to the understanding of the genetic mechanisms involved in malformations of central nervous system, especially in the mesial temporal lobe structures.

**Psychosis and Ataxia in a Patient with a novel 46,XX, t(1;22)(p36.3;q11.2) translocation.** *T. Causey<sup>1</sup>, R.K.*

*Abramson<sup>2</sup>, T. Malone<sup>1</sup>, R.G. Best<sup>1</sup>.* 1) USC School Medicine, Columbia, SC; 2) W.S. Hall Psych. Inst., Columbia, SC.

A 16 yo white female was seen for withdrawal, anxiety, and bizarre jerking episodes. Physical exam revealed normal height, weight, relatively square nasal root, prominent tubular nose with bulbous nasal tip and hypernasal speech. Her IQ was 63 with problems in arithmetic, attention span, letter number sequence, matrix reasoning and symbol search. General and verbal memory, attention/concentration and delayed recall were impaired. Thyroid, B12, folate, bHCG, and ceruloplasmin were normal. Psychiatric evaluation revealed constricted, anxious and paranoid affect. She was mute, and had auditory and visual hallucinations and suicidal ideation. Neurologic evaluation to rule out seizures revealed ataxic gait, spastic paraparesis, and a history of "passing out spells". MRI and EEG were unremarkable, but the neurologist noted that the proband is at risk for a seizure disorder. Cytogenetic studies indicated a 46,XX,t(1;22)(p36.3;q11.2) translocation. The patient has features of Velocardiofacial Syndrome (VCFS) at 22q11.2 (physical features, blunt affect, psychosis and learning disability). A potassium voltage channel gene, KCNB2 is present at 1p36.3. There are no reports in the literature of a syndrome associated with this gene. However, a related gene, KCNA1 on chromosome 12 is associated with periodic ataxia with onset in the second decade, and myokymic discharges, demonstrable on electromyography but not always clinically detectable. Other potassium voltage channel genes have been associated with epilepsy. Family studies indicate that the father has the same translocation. FISH analysis for VCFS deletion was negative for both father and proband, but about 5% of these microdeletions are not detectable by this method. The father reports no psychosis or seizures, and works for a steel company. His affect was rather flat. He has one sister who did not complete high school, self isolates and has seizures. There is no maternal or paternal history of psychosis. Further studies on the proband and the extended family are in progress to better define the translocation and the clinical findings in this very interesting family.

**Thin anterior corpus callosum, dementia, spastic paraparesis and leukoencephalopathy: a distinct autosomal recessive disorder.** *G.M. Bibat<sup>1</sup>, F.M. Murillo<sup>2</sup>, E.R. Melhem<sup>3</sup>, H.W. Moser<sup>1</sup>, S. Naidu<sup>1</sup>.* 1) Div Neurology & Dev Medicine, Neurogenetics Unit, Kennedy Krieger Inst, Johns Hopkins University School of Medicine, Baltimore, MD; 2) Department of Molecular Genetics and Biochemistry, Research Center for Genetic Medicine, Children's National Medical Center, Washington, DC; 3) Department of Neuroradiology, Johns Hopkins Hospital, Baltimore, MD.

We report 7 males (3 of whom are brothers) from 5 unrelated families aged 3 to 31 years with thin anterior corpus callosum, periventricular white matter abnormalities, slowly progressive dementia and spastic paraparesis. Onset of symptoms range from birth to 25 years of age. Three of the 7 who were evaluated early in life were noted to be hypotonic and developmentally delayed. The adults, including 3 brothers and an unrelated patient, presented with early learning difficulties requiring special education. Gait worsened from the second decade of life. Progressive spasticity became prominent with age. However, all 7 had early cognitive impairment, speech difficulties and varying degrees of behavioral issues. The 3 brothers have a female sibling who is reported to have similar clinical manifestations as her brothers. Peripheral neuropathy with axonal degeneration was seen in the older males. Neuroimaging showed periventricular leukoencephalopathy and non-progressive thinning of the corpus callosum. Medial frontal atrophy was noted in those 20 years and older suggestive of progression. Screening for metabolic, lysosomal and peroxisomal disorders was unremarkable. No mutations were found in the genes that code for paraplegin, PLP and L1CAM while screening for mutations in the spastin gene is in progress. An autosomal recessive form of spastic paraparesis with varying degrees of dementia and thin corpus callosum was localized to 15q13-15. Our patients differ from this group because the dementing illness, periventricular leukoencephalopathy and consistently thin anterior corpus callosum are more prominent. In most of our families, linkage to the 15qFSP locus was excluded. These patients form a unique entity with autosomal recessive mode of inheritance, early onset of mental retardation, progressive spasticity with a distinctive MRI picture.

**Macrocephaly, macrosomia and autistic behavior due to a de novo PTEN germline mutation.** *M.J. Dasouki<sup>1</sup>, H. Ishmael<sup>1</sup>, C. Eng<sup>2</sup>.* 1) Sect Medical Gen & Molec Med, Children's Mercy Hosp, Kansas City, MO; 2) Clinical Cancer Genetics and Human Cancer Genetics Programs, Ohio State University, Columbus, OH.

Bannayan Riley Ruvalcaba (BRR) is a dominantly inherited cancer syndrome characterized by the classic triad of macrocephaly, lipomatosis and pigmented macules of the glans penis. Other BRR component features include macrocephaly, lipomatosis, haemangiomas, Hashimoto's thyroiditis, mental and developmental delay. BRR syndrome is due to germline PTEN mutations. PTEN is a recently discovered tumor suppressor gene which appears to negatively control the phosphoinositide 3-kinase signaling pathway for regulation of cell proliferation and cell survival by dephosphorylating PIP3. Autism is a neuro- developmental disorder characterized by impairments in reciprocal social interaction and communication, restricted and stereotyped patterns of interests and activities. Some autistic children are also macrocephalic. While several chromosomal and metabolic disorders cause autism, many cases are still idiopathic. A 4 year old boy presented severe speech delay, autistic like behavior, macrocephaly and macrosomia. Other features of BRRS were lacking. His father was macrocephalic and an older brother has trisomy 21. Biochemical studies including urine organic acids, acylcarnitines, head MRI and bone survey were all unremarkable. Sequencing of the PTEN gene in the proband and his parents showed a de novo, novel germline mutation in codon 93, exon 4 [CAT>CTG]. Therefore, autism in association with macrocephaly and macrosomia may suggest the possibility of a PTEN mutation. Similar patients need to be examined to determine the frequency of PTEN mutations in this selected population. Also, new insights into the function of the PTEN gene may ultimately lead to a better understanding of the pathogenesis and treatment of this form of autism.

Board #565 will now be used by Marion Gerard-Blanluet to present a poster titled **Association of agnathia and craniorachischisis in a consanguineous family.**

Program Nr: 565

**Unspecific Mental Retardation: a Critical Diagnosis.** *G.S. Oliveira, A.P. Marques-de-Faria.* Dept Genetica Medica - FCM, UNICAMP, Campinas, SP, Brazil.

Mental retardation is one of the most common complaints in the Clinical Genetics' daily practice. It is very important to determine its etiology, as for a right and specific genetic counseling, as for a better patient evaluation and follow up. During a period of 5 years, we evaluated 3,245 patients in our outpatient clinic. From these, 316 individuals had Down syndrome (9.7%), 157 had other chromosomal aberration (4.8%), and 280 had mental retardation in several degree (8.6%). Within them 5 patients had X-linked mental retardation (1.8%), 68 had the diagnosis of autism (24.3%), and 212 patients had the diagnosis of mental retardation of unknown etiology (75.7%). All of these individuals did not have any relevant history of familial, gestational, neonatal, and personal data. Most of them had normal investigation, including karyotype with fra(X) negative, metabolic screening, skeletal X-ray, and CT brain scan, among others. None of them had major neither minor dismorphism that could lead to a specific clinical condition. Most of the patients are still being followed-up by our team. We consider important the continuous evaluation of these individuals, based upon the advance of new technologies for a specific diagnosis, specially to benefit the family with counseling and recurrence risks, and the patient with the correct management, avoiding stigmatization and labeling.

**A new X-linked lissencephaly syndrome with agenesis of corpus callosum: a gene locus on the Xpter-p22. K.**

*OBATA<sup>1</sup>, T. Fukuda<sup>1</sup>, J. Tohyama<sup>2</sup>, H. Yamagata<sup>1</sup>, R. Morishita<sup>1</sup>, I. Kondo<sup>1</sup>.* 1) Hygiene, Ehime University School of Med, Onsen-gun, Ehime, Japan; 2) Department of Pediatrics, Okinawa Child Development Center, Okinawa, Japan.

Two clinical syndromes with the lissencephaly and agenesis of the corpus callosum have been reported, an X-linked lissencephaly with ambiguous genitalia and an autosomal recessive lissencephaly with neonatal death. We report here two male infants with lissencephaly and agenesis of the corpus callosum born to non-consanguineous parents. The clinical features in these patients were characterized by severe growth failure, psychomotor retardation and intractable seizures with the neonatal onset. They had normal male type of external genitalia and testes descended into normal position. No microdeletion of 17p13.3 was detected by FISH analysis. No DNA mutation was identified in the doublecortin gene(DCX1) in both patients and their mother by DNA sequencing. Based on clinical characteristics and a mode of inheritance, our family might have a new X-linked lissencephaly syndrome with agenesis of the corpus callosum. The genetic locus for this disease has been studied using polymorphic DNA markers covering the whole X chromosome in three generations of this family. Two affected males had the same alleles of DNA markers on Xpter-p22 derived from their maternal grandfather, suggesting that the gene locus is likely to be mapped to Xpter-p22.

**Cornelia de Lange syndrome: evidence for a sensory neuropathy.** *A.D. Kline<sup>1</sup>, I. Krantz<sup>2</sup>, A. Goldstein<sup>3</sup>, B. Koo<sup>3</sup>, L.G. Jackson<sup>4</sup>.* 1) Harvey Institute for Human Genetics, Greater Baltimore Medical Ctr, Baltimore, MD; 2) Division of Human Genetics & Molecular Biology, Children's Hosp of Philadelphia, Philadelphia, PA; 3) Dept of Pediatric Neurology, Children's Hosp of Pittsburgh, Pittsburgh, PA; 4) Division of Medical Genetics, Jefferson Medical College, Philadelphia, PA.

Cornelia de Lange syndrome (CdLS) is a well-known syndrome characterized by typical facial features, small stature, limb findings, neurodevelopmental abnormalities and gastrointestinal involvement. Multiple affected individuals were observed to have features typically present in the sensory and autonomic neuropathies, such as decreased tears, sensory disturbances with abnormal pain and temperature sensations, the Raynaud phenomenon and gait abnormalities.

Individuals with CdLS may also have acute episodes apparently related to pain or discomfort with no detectable cause. Because of this, a possible link between CdLS and the sensory and autonomic neuropathies was postulated.

Questionnaire data were collected from 26 individuals with CdLS. Results include: 86% with a high tolerance or delayed reaction to pain; 60% with some inexplicable blotching of skin; 56% unable to tolerate cold; 47% unable to tolerate heat; 53% with absent or unusual sweating; 48% with decreased tears; 12% with absent tears; 47% with cold extremities; and 43% with some symptoms similar to Raynaud phenomenon. 24 individuals underwent a screening intradermal histamine testing; one was positive. EMG and nerve conduction velocities demonstrated a mild peripheral neuropathy. During sensory evoked potentials, the sympathetic skin response was abnormal, which demonstrated abnormal autonomic function. The modified tilt table and other neurologic testing to further evaluate autonomic function are pending. Based on preliminary results, there is evidence for autonomic dysfunction in CdLS. Identification of an association between CdLS and sensory and autonomic neuropathies could potentially help with gene localization for CdLS, and provision of possible treatment options.

**A new autosomal recessive syndrome of profound microcephaly.** *G.H. Mochida<sup>1</sup>, A. Rajab<sup>2</sup>, A. Bodell<sup>1</sup>, C.A. Walsh<sup>1</sup>.* 1) Neurology, Beth Israel Deaconess Medical Center, Boston, MA; 2) Genetic Unit, DGHA, Ministry of Health, Sultanate of Oman.

We report 4 Omani children from 3 consanguineous families with a new syndrome of profound autosomal recessive (AR) microcephaly. These patients are characterized by 1] congenital microcephaly, which is more severe than most reported cases with AR microcephaly, 2] cognitive delay with preserved alertness, 3] mild to moderate gross motor delay, and 4] an absence of seizures. Patient 1 is a 9 year-old boy with an uncomplicated prenatal and perinatal history. He walked at age 3, and currently speaks several words. Occipito-frontal circumference (OFC) at age 8 was 39cm (-10.0SD). Brain MRI showed a mildly simplified gyral pattern, a normal thickness of the cortex, and no other major structural abnormalities. Patient 2 is a younger brother of Patient 1, and is 2 years old. He is alert and attentive, but still unable to walk and has not spoken yet. Current OFC is 37cm (-9.0SD). Patient 3 is a 5 month-old boy, whose family is distantly related to the family of Patient 1 and 2. OFC at birth was 27.5cm (-6.3SD). He is alert and has a normal neurological examination, except for a mild increase in muscle tone. Current OFC is 32cm (-7.6SD). Patient 4 is a 5 year-old boy, who is from a tribe related to that of other three patients. OFC at birth was 29cm (-5.3SD). He walked at age 2, and cannot speak. Current OFC is 37cm (-10.1SD). Microsatellite marker analysis of the family of Patient 1 and 2 has ruled out linkage to known AR microcephaly loci, *MCPHI* through 5. Patients linked to *MCPHI* through 5 generally have microcephaly of -5 to -9SD; however, the patients reported here show microcephaly of -9SD or more, except for Patient 3, who is still only 5 months old. This severe degree of microcephaly, and the presence of gross motor delay, may clinically distinguish these patients from AR microcephaly with linkage to *MCPHI* through 5. The lack of linkage to known AR microcephaly loci further supports the presence of a novel microcephaly locus that has not been mapped. GHM is a Howard Hughes Medical Institute Physician Postdoctoral Fellow. Supported by the March of Dimes and the NINDS.

**Positive family history for epilepsy anticipates age of first seizure in patients with focal cortical dysplasia.** *M.A. Montenegro<sup>1</sup>, F. Cendes<sup>1</sup>, L.M. Li<sup>1</sup>, C.A.M. Guerreiro<sup>1</sup>, I. Lopes-Cendes<sup>2</sup>, M.M. Guerreiro<sup>1</sup>.* 1) Department of Neurology, University of Campinas, Campinas, SP, BRAZIL; 2) Department of Medical Genetics, University of Campinas, Campinas, SP, BRAZIL.

**Rationale:** Focal cortical dysplasia (FCD) is a malformation of cortical development characterized by abnormal cortical lamination and dysmorphic neurons. It is diagnosed by MRI as areas of cortical thickening, abnormal gyration, blurring between gray and white matter and focal atrophy. The age of first seizure in patients with FCD depends on many factors, such as size, localization and type of lesion. To our knowledge, no familial cases of FCD have been reported.

**Objective:** To analyze the influence of genetic predisposition in the age of first seizure in patients with FCD.

**Methods:** We evaluated 19 consecutive patients with FCD diagnosed by MRI. All patients were examined and interviewed by at least one of us. Detailed pedigrees were constructed for each family. In addition, we investigated family history of seizures and/or epilepsy in the families of all patients studied. Student's t test was used to perform the statistical analysis.

**Results:** Ages ranged from 3 to 41 years (mean=10.1). The mean age of first seizure in patients with positive family history of epilepsy was 2.6 years, as opposed to 8.5 years when there were no relatives presenting with epilepsy ( $p<0.05$ ).

**Conclusion:** To date, the contribution of genetic and environmental factors in the etiology of FCD remains unclear. We have contributed to this discussion by showing that a positive family history of epilepsy anticipates the age of first seizure in patients with FCD. Thus, suggesting that clinical presentation in these patients is influenced by genetic predisposition.

**Familial Encephalopathy with Neuroserpin Inclusion Bodies (FENIB): Initial Clinical Characterization of the PI12<sub>Syracuse</sub> (S49P) Mutation.** *F.L. Lachawan<sup>1,5</sup>, R.L. Davis<sup>2</sup>, G.H. Collins<sup>2</sup>, P. Kent<sup>4</sup>, P.D. Holohan<sup>3</sup>, A.E.*

*Shrimpton<sup>2</sup>, M. Muenke<sup>5</sup>, D. Krasnewich<sup>5</sup>.* 1) Dept Medical Genetics, Children's Natl Medical Ctr, Washington, DC; 2) Dept of Pathology, SUNY Upstate University, Syracuse, NY; 3) Dept of Pharmacology, SUNY Upstate University, Syracuse, NY; 4) Dept of Neurology, SUNY Upstate University, Syracuse, NY; 5) Medical Genetics Branch, national Human Genome Research Institute, NIH, Bethesda, MD.

FENIB is a recently described autosomal dominant neurodegenerative disorder with polymers of neuroserpin (Collins bodies) in the gray matter cortical neurons and in certain subcortical nuclei that clinically presents as early-onset dementia. We report, based on review of medical records, the natural history of three deceased and two living affected individuals in the large family with the PI12<sub>Syracuse</sub> (S49P) mutation. The onset of overt clinical signs is between 45-52 years of age and may be aggravated by loss of spouse or job. They have confusion, flighty talk, communication difficulties with decreased verbal productivity, perseveration in task and thought processing, poor insight and impaired judgement. Gross memory loss, remote more than recent, poor calculation and visuo-spatial difficulties are evident but reading skills are intact. Stereotypic body movements, especially involving the extremities, include jerks, shakes, twitches or tremors. Although seizures can occur later in the course of the disorder, EEG studies usually showed diffuse slowing with disorganized background. CT scan demonstrated cortical atrophy in the living affected individuals. Working diagnoses included presenile dementia-probably Alzheimer type, severe dementia, chronic chorea and dementia, early subcortical dementia-rule out Huntington Disease and fronto-parietal lobe dysfunction, and tardive dyskinesia. The deteriorating clinical course of affected individuals runs from 10 to more than 20 years and the cause of death for the 3 members were complications of severe coronary artery disease, thromboembolism and vehicular accident. An ongoing prospective clinical study at the NHGRI-NIH is aimed at delineating the clinical manifestations of FENIB to facilitate its definitive diagnosis.

**Behavioral Phenotype of Nail-Patella Syndrome.** *I. McIntosh*<sup>1</sup>, *E. Tierney*<sup>2, 3</sup>, *I. Bukelis*<sup>2</sup>, *L. Marsh*<sup>3</sup>. 1) Inst Genetic Medicine, Johns Hopkins Medical Sch, Baltimore, MD; 2) Kennedy-Krieger Inst., Baltimore, MD; 3) Dept. Psychiatry, Johns Hopkins Medical Sch, Baltimore, MD.

Nail Patella Syndrome (NPS)(MIM 161200), is an autosomal dominant disorder that presents with dysplasia of the nails and absent or hypoplastic patellae. NPS is the result of loss-of-function mutations in *LMX1B*, a LIM-HD transcription factor essential for patterning of the developing limbs. Recently, *Lmx1b* has been shown to be expressed in mesencephalic dopaminergic neurons with high expression in the substantia nigra pars compacta and ventral tegmental area. Post-mortem studies of the substantia nigra of brains of subjects with Parkinson's disease have shown that the number of *LMX1B*-expressing neurons was reduced, correlating with the loss of dopaminergic neurons in this area (Smidt et al. *Nature Neuro.* 3:337, 2000). We hypothesize that individuals with NPS may demonstrate dysfunction in the mesencephalic dopaminergic neurons, which may present as motor abnormalities, attentional difficulties, anxiety, mood or psychotic symptoms, similar to those observed in Parkinson's disease patients.

Behavioral measures/checklists were completed by 10 female adults with NPS. These checklists have reliability and validity and are used to assess symptoms of depression, concentration, and behavior. Of the 10 subjects who completed the Beck Depression Inventory II, 5 had minimal depression symptoms and 5 had symptoms consistent with mild depression. On the NEO Personality Inventory-R, 5 of the 10 subjects reported symptoms consistent with depression, 3 with a high degree of depression. On the Conners CAARS-S:L Scale, 8 subjects completed the form and 1 had symptoms consistent with attention deficit hyperactivity disorder. On the State-Trait Anxiety Inventory, 5 of 8 subjects had trait anxiety symptoms greater than the 70th centile. Future studies will be designed with neurological testing, neuropsychological testing and psychiatric evaluations to better assess cognitive abilities, mood symptoms, motor deficits, and behavioral traits and abnormalities, and these results will be compared to the results from subjects with Parkinson's disease.

**Cranial computed tomographic findings of 20 patients with Williams-Beuren syndrome.** *S.M.M. Sugayama<sup>1</sup>, M. Valente<sup>2</sup>, J.A. Paz<sup>3</sup>, C. Leite<sup>2</sup>, L.M.J. Albano<sup>1</sup>, C.A. Kim<sup>1</sup>.* 1) Genetics, Dept Pediatrics, Instituto da Crianca, Sao Paulo, Sao Paulo, Brazil; 2) Radiology; 3) Neurology.

Williams-Beuren syndrome (WBS) is a rare neurodevelopmental disorder affecting multiple systems. The main features are typical facies, cardiovascular anomalies, mental retardation, friendly and outgoing personality and transient hypercalcemia. The syndrome is caused by a submicroscopic deletion in the chromosome region 7q11.23 which is detectable by FISH analysis in 90-95% of the patients. Reported central nervous system anomalies are decreased brain volume, overgrowth of the neocerebellum, normal development of the frontal cortical and limbic structures, underdevelopment of the cerebrum and subcortical structures and posterior temporal lobe, and Chiari I malformation. We report on CT scan findings of 20 patients (11M-9F); all sporadic cases. The main age at the diagnosis of WBS was 5.1 years. All patients presented typical elfin facies, developmental delay/mental retardation, friendly personality, skeletal and dental anomalies. Deletion of the elastin gene analysed by FISH was found in 17 patients (85%). CT scan was performed in all patients; MRI was done in 2 patients. The age at CT scan ranged between 11mo and 18y5mo (mean 8.9y). CT scan was normal in all FISH negative patients, but this exam was abnormal in 7/17 (41%) of FISH positive ones. The following anomalies were identified: agenesis of corpus callosum (1), arachnoid cyst (1), calcification of choroid plexus (3), calcification of the frontal horn of lateral ventricle (1), enlargement of adenohypophysis (1), bilateral internal capsula showing comparative hipodensity. MRI of one 4 year-old boy demonstrated mild cerebellar tonsils invagination without compressive deformity of the IV ventricle or Chiari I malformation (CMI). The majority of our patients presented nonspecific changes on CT scan/MRI. The incidence of CMI in WBS patients is unknown. Our patient is likely the tenth case of WBS patient with CMI. Shortened cranial base and underdeveloped posterior fossa may predispose WBS patients to CMI. We recommend CT scan/MRI in WBS patients because of the risk for developing fossa anomalies without neurologic symptoms.

**Structural brain abnormalities in a genetic subtype of schizophrenia.** *L.E. Scutt<sup>1</sup>, R.B. Zipursky<sup>1,2</sup>, D.J. Mikulis<sup>3</sup>, E. Chow<sup>1,2</sup>, A.S. Bassett<sup>1,2</sup>.* 1) Queen St. Site, CAMH, Toronto, ON, Canada; 2) Dept. of Psychiatry, Univ. of Toronto, ON, Canada; 3) Toronto Western Hospital, Toronto, ON, Canada.

Background: 22q11 Deletion Syndrome (22qDS) is a genetic syndrome associated with a chromosome 22q11 deletion and an increased prevalence of psychosis, and may be a genetic subtype of SZ (22qDS-SZ). Although abnormal neurodevelopment is implicated in both 22qDS and SZ, there are few studies addressing the relationship between psychosis and brain structure in adults with 22qDS. Objective: To determine if structural brain abnormalities commonly reported in SZ (enlarged ventricles and decreased temporal gray matter (GM) volumes) are associated with the expression of SZ in adults with 22qDS. Methods: Three groups were examined: 22qDS-SZ (n=12), 22qDS-NP (no psychosis, n=7) and healthy controls age and sex-matched to 22qDS-NP subjects (n=7). All subjects were quantitatively assessed with MRI scans. The three groups were compared on total and regional volumes of cerebrospinal fluid (CSF), GM and white matter (WM) using standard methods corrected for total brain volume. Group differences were assessed using ANOVA and post-hoc t-tests. Results: There were no significant group differences for sex (p=0.53) or age at scan (p=0.44). A significant effect of group was found for volumes of ventricular CSF (F=11.8, p=0.0003), sulcal CSF (F=12.7, p=0.0002) and temporal lobe GM (F=5.2, p=0.01). Post-hoc analyses revealed that the 22qDS-SZ group had greater ventricular (p=0.004), and sulcal (p=0.001) CSF and smaller temporal lobe GM (p=0.04) volumes than the 22qDS-NP group. 22qDS-NP subjects had larger ventricular CSF volumes than Controls (p=0.04); no other significant effects of group were observed. Conclusion: These results suggest that increased sulcal CSF and decreased temporal lobe GM volumes may be markers of abnormal neural development associated with the expression of SZ in adults with 22qDS, while ventricular enlargement may be a more universal finding in 22qDS.

**Detection of Y-sequences by PCR in patients with Turner stigmata.** *M. Floria, R.G.P. Queiroz, L.C. Caetano, L.H.G. Teixeira, L. Martelli, E.S. Ramos.* Department of Genetics, School of Medicine of Ribeiro Preto-SP, Brazil.

Gonadal neoplasms are frequently associated with intersex cases. Patients, who have dysgenetic gonads and a Y chromosome (normal or abnormal), have a 25-30% risk of developing gonadoblastoma. Many authors hypothesized that the gene(s) encoded by a gonadoblastoma locus on the Y chromosome (GBY) has a normal function in the testis and acts as an oncogene in the dysgenetic gonads. In some cases, structural aberrations of the Y chromosome may difficult its characterization by cytogenetics analysis. We studied 140 patients with Ullrich-Turner syndrome (UTS), by cytogenetics techniques, and selected 14 (10%) that presented a structural abnormal sex chromosome in order to determine the X or Y origin by PCR in peripheral blood samples. Among the genes so far isolated from the human Y chromosome residing on the GBY locus, we chose AMELY and TSPY. The SRY and DAZ sequences were also utilized to detect the presence of more distal regions on Yp and Yq, respectively. Molecular analysis confirmed a Y-chromosomal origin of the structural abnormal sex chromosome in two patients, but one of these showed only Yp sequences. Gonadoblastoma was confirmed in one case. The identification of the abnormal Y chromosome is important for the clinical management and prognostic counseling of the patients with UTS stigmata. Supported by: CAPES, FAEPA, CNPq, FAPESP.

**Animal model for NF1: Human neurofibroma xenotransplants into the ear of SCID mice.** *D. Babovic-Vuksanovic, B.E. Knudsen, T.B. Plummer, J.E. Parisi, L. Petrovic, S. Babovic, J.L. Platt.* Department of Medical Genetics, Department of Surgery and Transplant Biology Unit, Department of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN.

Neurofibromatosis (NF) type 1 is a common tumor-predisposing disease in humans, causing significant morbidity and mortality. Surgical treatment remains the only therapeutic option and it can be applied only in patients with resectable tumors. Study of other potential therapies is limited by the lack of the suitable animal model. We explored possibilities to transplant human tumors into the severe combined immunodeficiency (SCID) mice. We transplanted 21 human schwannomas and 106 human neurofibromas into various body locations in 37 experimental animals. A total of 127 tumors were implanted, 22 in the sciatic nerve and 105 in three subcutaneous locations, under the skin of the neck, back and skin of the ear. Tumor implants were monitored for survival, growth and morphological changes over a period of up to twelve months. The tumors were evaluated by direct measurement and inspection on autopsy examination, as well as by histology and immunostaining for presence of connective tissue and myelin. The survival of subcutaneously implanted tumors was slightly lower than that of tumors implanted into an epineurium of the sciatic nerve ( $p > 0.05$ ). Implants were stable in size and histologic appearance for an extended period of time. Our results indicate that human schwannomas and neurofibromas may be successfully grown in SCID mice in various subcutaneous locations. Tumor grafts implanted into the ear can be easily visualized and monitored for survival, change in size and vascularization. Therefore, human neural tumor xenotransplants into the ear of the SCID mice may be a useful experimental model for evaluation of pathogenesis and therapy.

**A new syndrome: Endodermal sinus tumor, complex CHD, polycystic-hypoplastic left kidney, dysplastic teeth, tapered fingers, and mild developmental delay.** *H. Druker<sup>1</sup>, M. Greenberg<sup>1</sup>, R. Weksberg<sup>1,2</sup>*. 1) Div of Haematology & Oncology, Hospital for Sick Children, Toronto, Ontario, Canada; 2) Division of Clinical & Metabolic Genetics, Hospital for Sick Children, Toronto, Canada.

Our patient presented initially with a polycystic-hypoplastic left kidney detected antenatally on routine ultrasound. At three months of age, she was found to have cardiac abnormalities: VSD, PDA, and pulmonary stenosis. She presented in the emergency department at 10 months of age with a three-week history of irritability, decreased oral intake and failure to thrive. At that time it was noted that she had abdominal distention and a palpable mass in the RLQ. A laparotomy was performed and a malrotation and volvulus of the bowel were corrected at which time an endodermal sinus tumor was discovered in her pelvis. On genetic evaluation at 12 years of age, she was >97centile for height, weight, and head circumference. She was noted to have downslanting palpebral fissures, slightly posteriorly rotated ears, small upturned nose, synophrys, conically-shaped teeth, tapered fingers, 2-3 foot syndactyly, and mild developmental delay. Fragile X and oligosaccharides were normal. Chromosomes and 22q- are pending. This unique constellation of findings represents a previously undescribed syndrome.

**POLYSYNDACTYLY, COMPLEXE CARDIOPATHY AND HEPATIC DUCTAL PLATE ANOMALIES : AN AUTOSOMAL RECESSIVE SYNDROME DIAGNOSED PRENATALLY.** *B. Gasser<sup>1</sup>, J. Messer<sup>2</sup>, B. Langer<sup>3</sup>, C. Stoll<sup>1</sup>.* 1) Service de Gntique Mdicale, Hpital de Hautepierre, Strasbourg, France; 2) Service de Pdiatrie 2, Hpital de Hautepierre, Strasbourg, France; 3) Service de Gynecologie 2, Hpital de Hautepierre, Strasbourg, France.

A distinct syndrome was ascertained in a 3 year-old girl and her brother. The proband was the first child of first cousin parents. She was born after an uneventful pregnancy. At birth multiple congenital anomalies were noted : ptosis of the left eyelid, hypertelorism, anteverted nares, large fontanel, long philtrum, ungueal hypoplasia, polysyndactyly, simian crease and complex cardiopathy : atrial septal defect with abnormal pulmonary venous return. Abdominal ultrasonographic examination showed hepatic cysts : a large median cyst, 2 cysts of the right lobe and many smaller cysts of the left lobe. She was succesfully operated on for her cardiopathy at 1 year of age. A normal sisters was born 2 years after the proband. During the next pregnancy of the mother, fetal ultrasonographic examination showed an hypertrophy of the right ventricle and atria, a dextroposition of the aorta, a bilateral pyelic dilatation and a club foot. The couple asked for termination of the pregnancy. Necropsy showed a facial dysmorphia, a small penis, a polysyndactyly, a ventricular septum defect and a malformation of the ductal plate. In a 17 year-old boy and his deceased sister Martinez Y. Martinez et al. (1981) reported a cardiac dysplasia, a peculiar facies, bilateral mesoaxial hexadactyly, synmetacarp, short stature, ocular torticollis, and delayed puberty. Bonneau et al. (1983) described a family in which 3 sibs had a complex cardiac malformation, hexadactyly of the first toe, and syndactyly of the third and fourth fingers. Rejab (1997) described two sibs with similar features in an Omani family. In conclusion another family has been described with features similar to the three previously reported families with complex congenital cardiopathy and polysyndactyly. However the sibs described in this report had anomalies of the ductal plate which were not reported in the other families. These new findings are in favour of autosomal inheritance of this condition which is amenable to prenatal diagnosis.

**Familial segregation of capillary malformations as an autosomal dominant trait.** I. Eerola<sup>1</sup>, L. Boon<sup>1</sup>, S. Watanabe<sup>2</sup>, A. Domp Martin<sup>3</sup>, J.B. Mulliken<sup>4</sup>, M. Vikkula<sup>1</sup>. 1) Lab. of Human Molec. Genetics, Christian de Duve Institute, Brussels, Belgium; 2) Showa Univ. School of Medicine, Tokyo, Japan; 3) CHU de Caen, Caen, France; 4) Childrens Hospital, Harvard Medical School, Boston, MA, USA.

Vascular anomalies comprise a heterogenous group of disorders the severity of which varies from life threatening diseases to cosmetic harm. They are defects of vasculogenesis/angiogenesis and thereby provide a tool to study the mechanisms involved in these processes. The first evidence of a mutation causing human vascular malformation was the linkage of a dominantly inherited venous malformation to a mutation in the *TIE-2* gene.

Capillary malformation (CM, or port-wine stain) is the most common vascular malformation occurring in 0,3% of newborns. CMs are small flat cutaneous lesions, which consist of an increased number of ectatic capillary-like channels within papillary dermis. Vascular birthmarks, such as salmon patch, are milder variants of CM that occur up to 10% of newborns. Unlike the vascular birthmarks, the reddish coloration of CMs does not disappear, but becomes darker with advancing age. CMs may cause distress when affecting large areas of e.g. facial skin. CMs are usually sporadic, yet some families have been reported.

The factors triggering the formation of CMs are not known. Similarly, it remains unknown whether the pathogenesis includes local overgrowth of capillaries or disturbance in the remodelling of the capillary plexus. Recent studies suggested that hemangiomas, another type of vascular anomaly affecting capillaries, arise from an intrinsic defect, e.g. somatic mutation, in vascular endothelial cells. In addition, evidence for genetic predisposition has been presented. In our study of CMs, we have found 26 families with autosomal dominant inheritance with incomplete penetrance. This suggests that single gene defects are involved in the genesis of CMs. Genome-wide linkage analysis on the CM families is currently under way to discover the locus/loci involved. (vikkula@bchm.ucl.ac.be).

**Glomuvenous malformation is clinically and genetically different from common venous malformation.** *L.M.*

*Boon*<sup>1,2</sup>, *J.B. Mulliken*<sup>3</sup>, *O. Enjolras*<sup>4</sup>, *M. Vikkula*<sup>2</sup>. 1) Centre for Vascular Anomalies, Division of Plastic Surgery, Universite catholique de Louvain, Brussels, Belgium; 2) Laboratory of Human Molecular Genetics, Christian de Duve Institute and Universite catholique de Louvain, Brussels, Belgium; 3) Division of Plastic Surgery, Children's Hospital, Boston, MA; 4) Division of Dermatology, Hopital Lariboisiere, Paris, France.

Venous malformations (VMs) are localized defects of vascular morphogenesis. They are single or multiple bluish-purple lesions that occur mainly in skin and mucosa (Vikkula et al., 1998). Histologically, two distinct subtypes have been identified; common VM and venous malformation with "glomus cells" (GVM). GVMs have previously been called as "multiple glomus tumors" and "glomangioma". To harmonize the nomenclature, and to stress the morphological and clinical similarity between these lesions and common VMs, we suggest to use the term glomuvenous malformation (GVM). With our genetic studies on venous anomalies (Vikkula et al, Cell 1996, and see abstracts Vikkula et al., and Brouillard et al. at this meeting), we have identified a causative gene for both subtypes, TIE2 for VMs and glomulin for GVMs. These genetic analyses gave the opportunity to clinically analyze 578 patients with VMs and 151 with GVMs for clinical characteristics, signs, symptoms, location, size, number, age at onset, and inheritance. Differences were noted for shape, colour and structure of the lesions, painfulness, and distribution. In addition, although both lesions can be inherited as an autosomal dominant trait with high penetrance, GVMs are familial in at least 67% of cases in contrast to only about 1% of VMs. Thus, these data create a basis for clinical differential diagnosis, genetic counseling and differential therapeutic approach for venous anomalies. (boon@chir.ucl.ac.be).

**Dilated cardiomyopathy in two infants with Prader Willi syndrome and cytogenetically visible microdeletion of 15q11-q14.** MU. Ahmad<sup>1</sup>, Y.S. Choy<sup>2</sup>, L.C. Hung<sup>2</sup>, S.K. Tan<sup>2</sup>, T. Malinee<sup>3</sup>, SK. Tan<sup>1</sup>, P.K.C. Lim<sup>1</sup>, A. Othman<sup>2</sup>, S.K. Ten<sup>4</sup>, T.B. Khoo<sup>2</sup>. 1) Molecular pathology, Institute of Medical Research, Kuala Lumpur, Malaysia; 2) Kuala Lumpur Hospital, Malaysia; 3) Selayang Hospital, Kuala Lumpur, Malaysia; 4) Cytogenetics, Institute of Medical Research, Malaysia.

Approximately 75% of patients with Prader Willi syndrome (PWS) have a microdeletion of paternal chromosome 15 between bands 15q11 and 15q13. Cardiac involvement in the form of cor pulmonale and pulmonary hypertension may occur in older patients with obesity and obstructive sleep apnoea. Here we report two unrelated infants with PWS presented with dilated cardiomyopathy associated with floppiness, respiratory distress and feeding difficulties. The first patient, the second child of a young and non-consanguineous couple, presented to us at 9 months of age with severe failure to thrive, psychomotor delay, mild dysmorphic facies and cardiac failure. Echocardiography revealed dilated cardiomyopathy. The second patient suffered from severe hypoxic ischaemic encephalopathy after recurrent episodes of cardiorespiratory respiratory failure due to dilated cardiomyopathy. Both infective screens and metabolic testings in these two patients were negative. Thyroid function tests were also normal. Methylation PCR confirmed the diagnosis of PWS. Fluorescence in situ hybridization using SNPRN probe (VYSIS) confirmed microdeletion of the PWS critical region. High resolution cytogenetic analysis revealed visible deletion of chromosome 15q which appeared to be between band q11-q14, a deletion larger than the PWS critical region of 15q11-q13. The deletion had probably also disrupted the cardiac alpha actin gene (ACTC) which causes one form of autosomal dominant dilated cardiomyopathy, located at 15q14.

**Paraesophageal hernia in Marfan syndrome.** *S.J. Davies<sup>1</sup>, A. Wardhaugh<sup>2</sup>, M. Nicol<sup>1</sup>, V. Booker<sup>2</sup>, D.G. Wilson<sup>2</sup>.* 1) Inst Medical Genetics, Univ Hosp of Wales, Cardiff, Wales; 2) Congenital Heart Disease Centre, Univ Hosp of Wales, Cardiff, Wales.

Hernias including inguinal, femoral and diaphragmatic are described as features of the autosomal dominant disorder Marfan syndrome (MFS). Parida et al in 1997 described a neonate with severe clinical features suggestive of neonatal MFS who had a large paraesophageal hernia. Within a 12-month period in the Welsh Paediatric Marfan clinic we have confirmed a diagnosis of MFS in 3 children who had surgery for paraesophageal hernia within the first year of life. Case 1 was diagnosed as MFS aged 14 years following acute aortic dissection in her mother. She was a term baby with a birth weight of 2.61kg. Prenatal ultrasound had suggested bilateral hydronephrosis and queried a heart anomaly. Postnatal investigation indicated a left diaphragmatic hernia. Surgery revealed a large paraesophageal hernia extending to the left. Case 2 is the brother of case 1 born at term with a birthweight of 2.8kg. He failed to thrive and had severe vomiting. At 4 months a right-sided diaphragmatic hernia was diagnosed. At operation aged 5 months a large paraesophageal hernia was confirmed with absence of the right crus of the diaphragm. He had recurrent pneumothoraces requiring pleurodesis at the time of diagnosis, aged 13. Case 3 was born at term weighing 3.4kg. She was a miserable baby who failed to thrive with vomiting and recurrent chest infections. At 6 months a chest Xray confirmed a left-sided diaphragmatic hernia. Surgical repair at 9 months showed a large paraesophageal hernia. Diagnosis of MFS was suggested at 8 years on the basis of skeletal features. Paraesophageal hernias are unusual in infancy and indicate investigation for Marfan syndrome or other connective tissue disorder. Parida SK, KrissVM, Hall BD. Hiatus /paraesophageal hernia in Neonatal Marfan syndrome. *Am J Med Genet*, 1997; 72:156-158.

**Three sibs with congenital left heart defects.** *G.C. Gowans<sup>1</sup>, P.R. Winter<sup>1</sup>, K.M. Christensen<sup>1</sup>, F.F. Yen<sup>1</sup>, B. Angle<sup>1</sup>, A. Parsian<sup>2</sup>, W.L. Sobczyk<sup>3</sup>, J.H. Hersh<sup>1</sup>.* 1) Genetics Unit, Department of Pediatrics, Weisskopf Center for the Evaluation of Children, University of Louisville, Louisville, KY; 2) Birth Defect Center, University of Louisville Health Sciences Center, Louisville, KY; 3) Division of Pediatric Cardiology, Department of Pediatrics, University of Louisville, Louisville, KY.

In the pathogenetic classification of congenital cardiovascular malformations (Clark 1996), abnormal intracardiac blood flow is thought to be the immediate etiology of Group II malformations that include perimembranous ventricular septal defect, right heart defects, and left heart defects. The left heart defects include bicuspid aortic valve, aortic valve stenosis, coarctation of the aorta, interrupted aortic arch (type A), hypoplastic left heart and aortic/mitral atresia. There has been scant evidence of genetic loci involved. We report on a 6-year-old girl, her 3-year-old brother and their 10-month-old sister with congenital left heart disease. All have bicuspid aortic valves, the two youngest have severe coarctation of the aorta, the eldest has a subvalvular membrane, and the youngest has a VSD. The two youngest also have spherocytosis, as does their mother. These children represent all the pregnancies of their parents. There is no consanguinity between the parents and there is no known congenital heart disease in either parent's families. Echocardiograms on the parents are pending. As expected, a microdeletion at band 22q11.2 was not identified using a Vysis DiGeorge/VCFS FISH probe on a blood sample from the youngest child. Pedigree analysis of this family will be presented and we are performing a genomic scan for possible involved loci.

**A population-based study of the 22q11.2 deletion.** *L.D. Botto<sup>1</sup>, R.M. Campbell<sup>2</sup>, K. Coleman<sup>2</sup>, A. Correa<sup>1</sup>, E.M. Elixson<sup>2</sup>, J.D. Erickson<sup>1</sup>, P. Fernhoff<sup>3</sup>, K. May<sup>3</sup>, R. Merritt<sup>2</sup>, L. O'Leary<sup>1</sup>, S.A. Rasmussen<sup>1</sup>.* 1) National Center on Birth Defects and Developmental Disabilities, Centers for Disease Control and Prevention, Atlanta, Georgia; 2) Children's Healthcare of Atlanta, Atlanta, Georgia; 3) Division of Medical Genetics, Emory University, Atlanta, Georgia.

Although several studies describe the 22q11.2 deletion, population-based data are scant. Such data are needed to evaluate the impact, distribution, and clinical presentation of the deletion in the population. Our goal was to assess the population-based prevalence of the 22q11.2 deletion, its phenotype, and its impact on the occurrence of heart defects. We evaluated data on babies born from 1994 through 1999 to mothers who resided in the 5-county metropolitan Atlanta area. We matched data from the Metropolitan Atlanta Congenital Defects Program (a population-based registry with active case-ascertainment), the Sibley Heart Center at Children's Healthcare of Atlanta, and the Division of Medical Genetics at Emory University. We identified 42 children with the deletion among 255,000 liveborn infants, for an overall prevalence of 1 in 6,087 births (95 percent confidence interval, 1 in 4,505 - 1 in 8,446 births). Of the affected children, 37 (88 percent) had a heart defect, ranging from severe (truncus arteriosus) to mild (asymptomatic muscular VSD). The remainder had other congenital anomalies. Most children had dysmorphic features described in the registry records. The deletion contributed to 1 of every 65 cases of major heart defects (37/2,396). Specifically, the deletion contributed to 1 of every 2 cases of interrupted aortic arch, 1 of every 4 cases of truncus arteriosus, and 1 of every 9 cases of tetralogy of Fallot. In this population-based study, the 22q11.2 deletion was common, though the prevalence we found likely represents a minimum estimate. Assuming the same prevalence nationwide, one can estimate that over 600 similarly affected babies are born yearly in the United States. Population-based estimates such as these will be useful to health care planners and providers to estimate the resources needed for the optimal acute and long-term care of affected individuals.

**Hereditary Haemorrhagic Telangiectasia -delineation of the different phenotypes caused by endoglin and ALK1 mutation.** *J. Berg*<sup>1</sup>, *M. Porteous*<sup>2</sup>, *D. Reinhardt*<sup>2</sup>, *S. Holloway*<sup>2</sup>, *C. Gallione*<sup>3</sup>, *A. Lux*<sup>4</sup>, *W. McKinnon*<sup>5</sup>, *A. Guttmacher*<sup>6</sup>, *D. Marchuk*<sup>3</sup>. 1) Division of Medical and Molecular Genetics, GKT School of Medicine, London, UK; 2) South-East Scotland Regional Genetics Service, Western General Hospital, Edinburgh, UK; 3) Department of Genetics, Duke University Medical School, North Carolina, USA; 4) Inst. f. Molekularbiologie u. Zellkulturtechnik, Mannheim, Germany; 5) Vermont Regional Genetics Center, Burlington, USA; 6) NHGRI, Bethesda, MD.

Hereditary Haemorrhagic Telangiectasia (HHT) is an autosomal dominant vascular dysplasia characterised by mucocutaneous telangiectasis, epistaxis, gastrointestinal haemorrhage and arteriovenous malformations in the lung and brain. Causative mutations for HHT have been identified in two different genes, endoglin and ALK1. From a postal questionnaire survey, we have obtained clinical data from 49 patients with a known endoglin mutation and 34 patients with a known ALK1 mutation. Plotting Kaplan-Meier survival curves and using the log rank test to compare the two groups, we have shown that patients with endoglin mutation have an earlier onset of epistaxis ( $P=0.01$ ) and telangiectasis ( $P=0.0001$ ). Brain arteriovenous malformations were present in 4/49 patients with endoglin mutations and 1/34 patients with ALK1 mutations (not significant). Pulmonary arteriovenous malformations were reported in 17/49 patients with endoglin mutations but 0/34 patients with ALK1 mutations ( $P<0.001$ ). We conclude that the HHT phenotype caused by endoglin mutation (HHT1) is distinct and more severe than HHT caused by ALK1 mutation (HHT2). This has significant implications for diagnosis, screening and treatment in the two different forms of HHT as well as for the understanding of the pathogenesis of the disease.

**The first autopsy series in patients with a 22q11.2 deletion.** *D.S. Huff<sup>1</sup>, D.M. McDonald-McGinn<sup>2</sup>, E.H. Zackai<sup>2</sup>.* 1) Department of Pathology; 2) Division of Human Genetics and Molecular Biology, The Children's Hospital of Philadelphia, Philadelphia, PA.

Of 413 patients with a 22q11.2 deletion, 20 expired, of whom 13 had autopsies available for review. 9 were female. Age at death ranged from stillbirth to 1.9 years. All died within the first 6 months of life; 7 within the first three weeks. Heart defects were the cause of death in 8/11 with complete autopsies. 1 with interrupted aortic arch died of tracheal agenesis, 1 died due to prematurity. The cause of the stillbirth was not determined. The thymus was absent in 3 & hypoplastic/ectopic in 7. No parathyroids were found in 5; 1 in 6 & 3 in 1. Additional anomalies were variable: 1 F-anisosplesia form of heterotaxy; 2 laryngotracheal defects: 1 tracheal agenesis with esophageal fistula, 1 malformed larynx & abnormal thyroid cartilage; 4 had abnormal pulmonary lobation, 2 with azygous lobes; 2 had small congenital diaphragmatic hernias (1 left & 1 right). No major GI malformations were found, but one patient had a short attachment of the small bowel mesentery. 2 had urinary tract anomalies; 1 right renomegaly, 1 absence of the right kidney, ureter and trigone. 3 had genital tract anomalies: 1 bilateral undescended testes at the scrotal entrance with Leydig cell hyperplasia, 1 left unicornuate uterus, 1 bilateral Mullerian agenesis. The thyroid gland was abnormal in 2: 1 absent isthmus, 1 abnormally-shaped with cysts. 3 patients had anomalies of the CNS: 1 focal cerebellar dysplasia, 1 diffuse cerebral dysplasia and a right parietal A-V malformation, & 1 craniosynostosis. In summary, patients with a 22q11.2 deletion have a known pattern of anomalies, most often including cardiac defects, hypoparathyroidism and thymic aplasia/hypoplasia. We present the first autopsy series in patients with a confirmed 22q11.2 deletion and describe additional anomalies not typically associated with the deletion. Significant findings which have implications for the care of surviving patients include: laryngotracheal esophageal abnormalities, splenic hypoplasia, heterotaxy, diaphragmatic hernia, and genito-urinary findings.

**Vasomotor Instability in Chromosome 22q11 deletion.** *V. Shashi, M.N Berry, M.H Hines.* Pediatrics, Wake Forest Univ Sch Med, Winston-Salem, NC.

Approximately, 70% of individuals with chromosome 22q11 deletion have congenital heart disease, frequently requiring surgical intervention. These conotruncal heart defects are thought to be due to abnormal neural crest migration and division. A host of other vascular problems such as tortuous carotid arteries, Raynaud's phenomenon, and small veins have been reported. These, in addition to unexplained hypotension, hypertension and hypothermia raise the possibility that there may be abnormal autonomic regulation of the vascular system (personal communication, Dr. Shprintzen). Thus far, however, there has been no formal report of autonomic dysfunction in patients with 22q11 deletion. We present two neonates with 22q11 deletion who had profound hypotension. One infant had preoperative hypotension. Both had uncomplicated surgeries for congenital heart disease, but post-operatively had unexplained hypotension that was not responsive to vasopressor treatment (and extracorporeal membrane oxygenation in one infant), resulting in death, due to multi-organ system failure. Obvious causes for the hypotension, such as poor cardiac contractility, prolonged circulatory arrest and neurological abnormalities were excluded. No abnormality was found on autopsy to account for the hypotension. We hypothesize that these infants died of severe hypotension due to dysautonomia and that this is a variable feature in individuals with 22q11 deletion. The autonomic nervous system, which is responsible for blood regulation, is formed from the neural crest cells. Thus, given that the neural crest abnormalities lead to the conotruncal heart abnormalities, abnormal autonomic regulation could also be linked to the neural crest. Our hypothesis has implications for the post-surgical management of patients with 22q11 deletion. Prior knowledge of the possibility of dysautonomia would be helpful in monitoring and treatment. Further studies on this topic would help in establishing the association between 22q11 deletion and dysautonomia.

**A new autosomal dominant syndrome with hypertrophic cardiomyopathy, heterotaxy, conduction abnormalities, atrial septal defect and pulmonary stenosis.** *M. Wessels<sup>1</sup>, S. Spitaels<sup>2</sup>, R. De Krijger<sup>3</sup>, T. Cohen-Overbeek<sup>1</sup>, M. Niermeijer<sup>1</sup>, P. Heutink<sup>1</sup>, P. Willems<sup>1</sup>.* 1) Dept of Clin. Genetics, Erasmus University, Rotterdam, The Netherlands; 2) Dept of Cardiology, Univ Hosp Rotterdam, The Netherlands; 3) Dept of Pathology, Univ Hosp Rotterdam, The Netherlands.

We present a family of 9 patients with a new autosomal dominant combination of hypertrophic cardiomyopathy, conduction abnormalities, secundum atrial septal defect and situs ambiguus. A triplet was diagnosed prenatally with hypertrophic cardiomyopathy and bradycardia in all three fetuses. One female fetus had a massive hypertrophic cardiomyopathy, pulmonary atresia, tricuspid dysplasia and an absent vena cava inferior with azygous continuation. The girl died shortly after birth and autopsy additionally revealed bilateral bi-lobed lungs, polysplenia and intestinal malrotation. Her triplet brother showed valvular pulmonary stenosis, jejunum atresia, intestinal malrotation and polysplenia. The third triplet only had bradycardia and malrotation of the bowel. Examination of the father of the triplets revealed apical concentric ventricular hypertrophy, atrial septal defect, sinus bradycardia, and bilateral bi-lobed lungs. His sister was operated in childhood on a atrial septal defect and valvular pulmonary stenosis. She additionally had absent vena cava inferior, ventricular hypertrophy, sinus bradycardia, polysplenia but normal situs. A brother was known with cardiomyopathy and sick sinus syndrome. The grandfather had apical hypertrophy of both ventricles, atrial septal defect, atrial fibrillation, left bundle branch block and polysplenia. His brother and one of his 6 sisters were diagnosed with hypertrophic cardiomyopathy. Although many hypertrophic cardiomyopathies with autosomal dominant inheritance have been described, the association with structural cardiac defects and heterotaxy represents a new syndrome. A genome-wide screen resulted in a maximal lod score approximating 3 without recombination with markers on chromosome 6p23-24. This region holds the endothelin 1 gene, which might be a candidate gene as endothelin 1 knockout mice show cardiac anomalies including septal defects and outflow tract abnormalities.

**A Jagged 1 gene mutation for abdominal coarctation of the aorta in Alagille syndrome.** *A. Raas-Rothschild<sup>1</sup>, E. Shteyer<sup>2</sup>, I. Lerer<sup>1</sup>, A.J.J.T Rein<sup>3</sup>.* 1) Human Genetics, Hadassah University Hospital, Jerusalem, Israel; 2) Department of Pediatrics, Hadassah University Hospital, Jerusalem, Israel; 3) Department of Pediatric Cardiology, Hadassah University Hospital, Jerusalem, Israel.

Structural cardiac defects such as peripheral pulmonary stenosis are well described in Alagille syndrome (AGS), which is transmitted by an autosomal dominant inheritance. Haploinsufficiency of the Jagged 1 gene (JAG1) has been shown to cause Alagille syndrome. Abdominal coarctation is an uncommon vascular congenital anomaly and has been described only twice in AGS. We report on a third patient with coarctation of the abdominal aorta in AGS and right subclavian stenosis. Recently, Loomes et al (Hum Mol Genet 1999; 8(13): 2443-2449) have shown that Jagged1 gene is expressed in the developing heart and in multiple associated vascular structure including the descending aorta. Jones et al (J Med Genet 2000;37:658-662) studied the tissue expression of JAG1 in human embryo and noticed that JAG1 was also expressed in the developing aorta. We performed molecular analysis of the Jagged1 gene in this third patient with AGS and abdominal coarctation and found a mutation deletion (1485 Del CT). This corroborates with Loomes and Jones studies and confirms that coarctation of aorta might be a part of the Alagille syndrome clinical findings.

**Zinc and Immune Function in Down Syndrome.** *M.L. Soto-Alvarez<sup>1</sup>, F. Alvarez-Nava<sup>1</sup>, A.E. Rojas-Atencio<sup>1</sup>, R. Gonzalez<sup>1</sup>, J. Caizalez<sup>1</sup>, V. Granadillo<sup>2</sup>, D. Fernandez<sup>2</sup>, A. Ocando<sup>2</sup>, A. Vasquez<sup>2</sup>, J. Herrera<sup>3</sup>, W. Fulcado<sup>3</sup>.* 1) Unidad de Genetica Medica, Univ del Zulia, Maracaibo Zulia, Venezuela; 2) Laboratorio de Instrumentacion analitica-LUZ; 3) Hospital Clinico de Maracaibo.

Down syndrome (DS) is the most common cause genetics of mental retardation, with a occurrence in 1:600 - 1:800 liveborn. Their high frequency and great clinical importance makes that this syndrome is the chromosomal anomalies most studied in human. Several studies have reported alteration of the plasma level of zinc and dysfunction of the immune system in these patients which it has associated with infectious illnesses. This represents one of the main causes of mortality in DS. To determine the plasma levels of zinc and to evaluate the immune system in patients with DS. Blood samples of 40 patients (18 females with mean age 3 year, and 22 males with mean age of 4 year) with SD. Were these patients were recluted from Unit of Medical Genetics of the University of Zulia- Venezuela. Twenty samples of healthy children were used as controls. Karyotypes were carried out according to technique of Moorhead. Plasma levels zinc were determined for atomic absorption spectrophotometry and flow cytometry were used to evaluate immune systems. All patients exhibit free trisomy chromosome 21. In regarding to the plasma levels zinc and evaluation of the immunity, 10/40 patients (25%) had the values inside normal limited; 20/40 patients (50%) presented levels of zinc below the normal values. Of these, 45% had alterations in the cellular immunity and 5% in the immunity humoral, Twenty five percent (10/40) patients presented normal levels of zinc with alterations of the cellular immunity. Several investigators have reported that the zinc is an essential cofactor in the answer of cells T , phagocityc function and possibly in the production of antibodies. These results agree with other studies and suggest that the deficiency of zinc in the patients with DS affects the immune system.

**Clinical and genetic analysis of a distinct dominantly inherited spinocerebellar ataxia with male sterility and mental deficiency.** *C.M. Gomez, G.Y. Yu, D.T. Xie, J. Pryor, J.H. Anderson, S. Frutiger.* Dept Neurology, Univ Minnesota, Minneapolis, MN.

The dominantly inherited spinocerebellar ataxias (SCA) are a clinically and genetically heterogeneous group of neurodegenerative disorders characterized by progressive imbalance, dysarthria and incoordination. Genetically distinct subtypes differ clinically, due in part to involvement of extracerebellar neuronal populations. We identified a 5-generation kindred with progressive ataxia in which all affected males are infertile. The affected individuals have an extremely broad range of onset with progressive cerebellar deficits developing sometime between childhood and the sixth decade. Detailed neuropsychological evaluations have demonstrated cognitive impairment with borderline IQ scores, especially in males. Magnetic resonance brain imaging demonstrates cerebellar atrophy. Nerve conduction studies reveal an axonal sensory neuropathy. Four of five affected males examined had testicular atrophy and six of six had azoospermia, with reduced or absent sperm. Testicular biopsy has demonstrated Sertoli-cell-only syndrome in one sterile male. Cytogenetic studies detected no chromosome anomalies or microdeletions. Mutational analyses have ruled out SCA1, SCA2, SCA3, SCA6, SCA7, SCA8, SCA12 and fragile X. Linkage analysis has excluded SCA4, SCA5, SCA10, SCA11, SCA13, SCA14, and the entire X chromosome. Clearly, this family represents a clinically and genetically new form of SCA. A genome-wide linkage scan may locate the disease locus. Identification of the gene responsible for this unique phenotype may shed additional light into the pathogenesis of ataxia, mental retardation, and male infertility.

**Morphological characterization and genotype phenotype correlation in SHFM.** *D. Basel<sup>1</sup>, S. Sifakis<sup>1</sup>, M. Arici<sup>2</sup>, P. Beighton<sup>3</sup>, C. Delozier-Blanchet<sup>4</sup>, M.W. Kilpatrick<sup>1</sup>, P. Tsipouras<sup>1</sup>.* 1) Paediatrics, UCONN Health Centre, Farmington, CT; 2) Diagnostic Imaging and Therapeutics, UCONN Health Centre, Farmington, CT; 3) Human Genetics, University of Cape Town, South Africa; 4) Medical Genetics, University of Geneva Medical School, Switzerland.

Split Hand Foot Malformation (SHFM) is a condition, with an incidence of 1:18000, characterized by median clefts, syndactyly and bone aplasias/hypoplasias without the involvement of ectodermal structures. However, 40% of individuals presenting with this abnormality, have associated anomalies suggestive of a syndromic entity. Given the clinical and genetic heterogeneity of non-syndromic SHFM we attempted to define the nosological spectrum of the condition and investigate the possibility of phenotype/genotype correlation. We reviewed radiographs from 15 affected individuals, and in addition analyzed the phenotypes of four large families, two of which have been genetically linked to 3q27 and two to 10q24. We categorized the phenotypic manifestations of SHFM into a core of skeletal defects which were then used to correlate phenotype to genotype in this large cohort of patients. Three groups of skeletal manifestations were identified: monodactyly, bidactyly and oligodactyly, the latter frequently associated with syndactyly and a median cleft. The non-core elements include clinodactyly, polydactyly and triphalangeal thumbs. Our findings showed that the pattern of malformations in the families studied was highly variable and within the same family, affected individuals presented with a combination of the core manifestations and associated anomalies. All four extremities were not necessarily affected and symmetrical changes were uncommon. The composite phenotype of the four large families studied did not differ substantively and thus no apparent phenotype-genotype correlation was noted. Oligodactyly, bidactyly and monodactyly represent a continuum of phenotypic severity, attributable to a common developmental defect of the apical ectodermal ridge. The co-segregation of these manifestations in the same individual suggests that stochastic events influence local developmental mechanisms in determining the final phenotypic outcome.

**Comparison of the Autism Diagnostic Interview-Revised (ADI) Restrictive/Repetitive Behaviors and the Aberrant Behavior Checklist (ABC) Stereotypy Scores.** *R.K. Abramson<sup>1</sup>, M.L. Cuccaro<sup>1</sup>, K. Wieduwilt<sup>2</sup>, S.A. Ravan<sup>1</sup>, K. Decena<sup>2</sup>, H.H. Wright<sup>2</sup>.* 1) WS Hall Psychiatric Inst, Columbia, SC; 2) Univ. South Carolina School of Medicine.

Autistic Disorder (AD) is a complex neurogenetic disorder with core impairments in social, communicative, and behavioral functioning. The ADI (Lord et al, 1994) is the standard instrument for the diagnosis of AD. Refinement of phenotype to better understand homogeneous clinical subgroups may be useful in dissecting genetic etiology in AD. Cuccaro et al, 2000, conducted a factor analysis of 13 ADI items believed to represent restrictive repetitive interests and found 2 factors. Factor 1 (ADI items 72,72,77,81,84) was related to sensory repetitive behavior and Factor 2 (ADI items 73,74,75) reflected insistence on sameness. The ABC (Aman & Singh, 1986) is a standardized measure of behavior in individuals with developmental disorders, providing 5 subscores, one of which is stereotypy. This study examines whether the two scales, the ADI restrictive repetitive behaviors (ADI-RRB) and the ABC (ABC-S) stereotypy subscales are related and if ADI Factors 1 and 2 refine the relationship between the ADI-RBB and the ABC-S. Males (n=122) and females (n=44), mean age=8±4.4 yrs with AD were enrolled in the study. There were no significant gender differences on the ADI-RBB algorithm score or on the ABC-S score or on the individual items which make up the scores. The ADI-RBB algorithm score and the ABC-S were significantly correlated, Pearson Correlation = 0.282, p(2-tailed)= 0.001. For the same group, the relationship between Factor 1 (ADI-RBB) and the ABC-S was evaluated. Factor 1 (ADI-RBB) and the ABC-S were highly correlated, Pearson Correlation =0.482, p(2-tailed)=0.000. Factor 2(ADI-RBB) and the ABC-S were not correlated. Use of either Factor 1 (ADI-RBB) or the ABC-S may further refine phenotype for linkage analysis of AD.

**Trisomy 12p syndrome: A unique case with involvement of 12q.** *J.E. Martinez<sup>1</sup>, M.C. Panero<sup>2</sup>, C.M. Tuck-Muller<sup>1</sup>, W. Wertelecki<sup>1</sup>.* 1) Dept Medical Genetics, Univ South Alabama, Mobile, AL; 2) Serv. de Medicina Genética Hospital de Niños Santísima Trinidad, Córdoba, Argentina.

Trisomy 12p syndrome is a recognizable condition presenting with normal to large size, characteristic craniofacial dysmorphism and severe psychomotor retardation. Most of the 33 reported cases are the result of familial reciprocal translocations (27/33). We report a new case with a de novo 12pter-q13 duplication, a distinct cytogenetic abnormality not reported thus far. A male infant was ascertained at birth when bilateral cryptorchidism, hypospadias and post-axial polydactyly of hands were noted. An ASD with significant left to right shunt required surgical correction. He later developed seizures and abnormal EEG findings. A brain CT scan at age 4 months was unremarkable. Examination at three years of age revealed large size, macrocephaly, high and broad forehead, shallow orbits, temporal alopecia, prominent cheeks, flat nasal bridge, short and anteverted nose, long and broad philtrum, large mouth, everted lower lips, thin upper vermilion, low set dysplastic ears, bilateral simian creases and a gap between first and second toes. The child has profound mental retardation, universal hypotonia, feeding and walking difficulties, hearing loss and no speech. Cytogenetic analysis revealed a 47,XY,del(12)(q13)[6]/46,XY[22] karyotype. Parental chromosomes were normal. Attempting to correlate phenotypic manifestations and cytogenetic findings, a clinical classification in five categories based on the extent of the duplication, the involvement of other chromosomes, and the presence of mosaicism was proposed by Allen et al (1996). Only three cases have been previously observed with involvement of 12q (category V), and two of them included other abnormalities derived from parental translocations. A child with a de novo mosaic trisomy of 12pter-q11 had striking similarities with our patient except for the absence of a heart defect. However, only subtle clinical differences were noted between our case and patients in other proposed categories, suggesting that involvement of proximal 12q and mosaicism, do not significantly change the phenotypic expression of this syndrome.

**Adjunct diagnostic test for Angelman syndrome: The tuning fork response.** *B.D. Hall.* Dept Pediatrics/Genetics, Univ Kentucky Col Med, Lexington, KY.

I report an apparently unique response by Angelman syndrome individuals to the vibrating tuning fork when it is held up to their ear. The response is a wide smile with an almost simultaneous outburst of laughter. A total of 5 consecutive individuals (only 1 of whom was confirmed at the time to have Angelman syndrome) with ages ranging from 3 4/12 years to 38 years, displayed this unique response. No such response was obtained from normal children/adults or individuals with fragile X, microcephaly, autism, or other multiple congenital anomaly syndromes.

The response to the vibrating tuning fork in normal individuals or those with other syndromes is quite different. They will either look forward, with a cautiously curious expression, or immediately pull away with an anxious appearance, with or without crying or screaming. Some individuals do adjust to the sound of the tuning fork and may later smile or occasionally laugh. Consequently, repetition may give a false positive response.

The tuning fork response in potential Angelman syndrome patients is a quick test that may strengthen or reduce your suspicion of Angelman syndrome. I do not know if it is useful in children under 3 years of age, but I am presently testing a 17-month-old girl.

Photographs of individual responses to the tuning fork will be presented.

**A novel autosomal dominant cerebellar ataxia associated with tremor. - Clinical features and molecular genetic analysis.** *K. Hara*<sup>1</sup>, *T. Shimohata*<sup>1</sup>, *M. Oyake*<sup>1</sup>, *H. Ishiguro*<sup>2</sup>, *K. Hirota*<sup>2</sup>, *T. Matsuura*<sup>3,4</sup>, *T. Ashizawa*<sup>3,4</sup>, *S. Tsuji*<sup>1</sup>. 1) Neurology, Brain Res Inst. Niigata univ, Niigata, Japan; 2) Department of Neurology, Akita Red Cross Hospital, Akita, Japan; 3) Department of Neurology, Baylor College of Medicine, Houston, Texas, USA; 4) Neurology Service, Veterans Affairs Medical Center, Houston, Texas, USA.

Dominantly inherited, late onset pure cerebellar ataxias are genetically heterogeneous neurodegenerative disorders. Although approximately half of the families with these disorders in the Japanese population have been shown to be caused by expansion of CAG repeats in the CACNA1A gene on chromosome 19p13 (SCA6), causative genes for the rest remain to be elucidated. We have identified a three-generation family with unique clinical presentations including cerebellar ataxia and tremor. Among the 10 family members, 6 (3 males and 3 females) were affected. The mean age of onset was 37.5 years (27~47). All the affected members showed cerebellar ataxia. Furthermore, three patients had neck tremor at rest, one patient had hand tremor at rest, and one patient had both. The age at onset of the patient exhibiting hand and neck tremor in addition to cerebellar ataxia was 27 years, which is earlier than that of her affected father (47 years) and, furthermore, earlier than those of the other affected individuals, suggesting the possibility of anticipation. Brain MRI showed cerebellar atrophy without brainstem atrophy. The diagnosis for SCA1, SCA2, MJD/SCA3, SCA6, SCA7, SCA8, SCA10, SCA12, or DRPLA was excluded by mutational analysis. The possibility for SCA4, SCA5, SCA11, SCA13 or SCA14 was also excluded by linkage analysis. Interestingly, linkage to the SCA10 locus was suggested with the highest pairwised LOD scores of 2.41 at D22S928 and D22S1141(theta=0.0). Expansion of ATTCT repeat in SCA10 gene, however, was not found. Epileptic seizures, a hallmark for SCA10, were not observed in the affected patients in this family. These results suggest that this family has a novel autosomal dominant cerebellar ataxia distinct from any of previously known SCAs.

**Identification of disease causing genes in 7p11-p14 deleted in patients with Greig syndrome and additional clinical features.** *P.M. Kroisel<sup>1</sup>, K. Wagner<sup>1</sup>, D. Kolozsvari<sup>2</sup>, C. Windpassinger<sup>1</sup>, S.W. Scherer<sup>2</sup>, E. Petek<sup>1</sup>.* 1) Med. Biology & Human Genetics, University of Graz, Graz, Styria, Austria; 2) Department of Genetics, Hospital for Sick Children, Toronto, Ontario, Canada.

We report on five Greig cephalopolysyndactyly syndrome (GCPS) patients, including one pair of monozygotic twin boys with a de novo microdeletion involving the chromosomal band 7p13, where various clinical features in addition to GCPS were recognized. Besides the twin pair all patients are unrelated. Since there is a considerable lack of well defined clinical characterizations of the few patients with microdeletions involving 7p13 with GCPS described so far, here we want to focus on the delineation of the phenotype in all patients in particular on those symptoms, that are not typically related to GCPS like a moderate psychomotor retardation, seizures, muscle fibre anomalies, cardiac anomalies, hyperglycaemia or hirsutism. In order to more easily characterize the size of the different microdeletions, we obtained, starting from lymphoblastoid cells of the patients, monoallelic hybrid cell lines. By screening with region specific STRs all deletion breakpoints were precisely mapped and based on these results in combination with genomic sequence data available by now, we were able to identify several candidate genes mapped to the deleted chromosomal segments.

**Parent of origin does not determine phenotype in the 22q11.2 deletion.** *D.M. McDonald-McGinn, D.A. Driscoll, M. Tonnesen, K. Sullivan, R. Kirschner, E. Goldmuntz, S. Weinzimer, D. Lynch, P. Wang, E. Moss, M. Gerdes, C. Solot, C. Catania, S. Saitta, B.S. Emanuel, E.H. Zackai.* The Children's Hospital of Philadelphia, Philadelphia, PA.

We previously reported findings on 250 patients with the 22q11.2 deletion (McDonald-McGinn et al., 1999), the majority of whom had the same large 3-4 megabase deletion. Males and females were equally likely to be affected and parent of origin studies revealed equal numbers of maternally and paternally inherited deletions. There was extreme variability within this cohort and no genotype-phenotype correlations could be made. Recently Eliez et al., 2001 reported significant differences in brain development in 18 patients with the deletion based on the parent of origin. Therefore, we undertook a study to examine this question more broadly. Fifty-nine de novo triads underwent parent of origin studies. Thirty were maternally inherited and 29 were paternally inherited. We reviewed these patients records to identify the presence of: congenital heart disease; palatal defects; immune deficiency; hypocalcemia; learning disability; language delay; articulation errors; and severity of cardiac disease. Specifically, of 41 patients with congenital heart disease, 24 were paternally inherited, of 20 with severe congenital heart defects, 11 were paternally derived; of 29 with definitive palatal abnormalities, 17 were paternal; of 11 with hypocalcemia, 6 were paternal; of 7 with structural brain abnormalities, 3 were paternal; of 15 with learning disabilities, 8 were paternal. This distribution was not statistically significant from the expected 1:1 ratio maternal versus paternal origin based on Chi-square analysis. The immune system including CD3, CD4, CD8, CD19 and NK cells and language delays and articulation errors were not statistically different based on SD calculations.

**Familial Pulmonary Fibrosis in the USA.** *M.M. Wahidi<sup>1</sup>, M.C. Speer<sup>1</sup>, M. Steele<sup>2</sup>, K.K. Brown<sup>2</sup>, M.I. Schwarz<sup>2</sup>, D.A. Schwartz<sup>1</sup>.* 1) Medicine, Duke University Medical Center, Durham, NC; 2) National Jewish Coalition, Denver, CO.

Pulmonary fibrosis is a rare form of lung disease that affects the interstitium of the lungs and often fatal within 3-5 of diagnosis. Families with at least two members affected by PF are recruited through a network of collaborators and advertisement on the Internet ([www.fpf.duke.edu](http://www.fpf.duke.edu)). Data on affected members includes a standardized clinical history and risk factor questionnaire, pedigree, DLCO, CXR, HRCT, and lung biopsy (when available). Asymptomatic relatives are screened with a questionnaire, DLCO, and CXR. Thirty families including 108 affected individuals have been identified. Males were more frequently affected than females (55%). The predominant race was Caucasian (94% Caucasian, 6% Hispanic). Smoking was identified in 42% of cases with available data. Exposure to known fibrotic agents such as asbestos, silica, or wood dust was recorded in 19% of cases. Mean age at diagnosis was 59 (sd=15.8) and mean age of death was 62 (sd=15.5). The diagnosis of PF was confirmed by an open lung biopsy and autopsy in 24 patients (22%). A high resolution CT scan of the chest was obtained in 47 patients (43%). In the 24 families with at least 2 documented cases, PF occurred in multiple family members in 15 families. Ten families have at least one affected sibling pair, 4 have affected parent-child pairs including one pair of affected father and son, and 4 pedigrees include more distantly related affected relative pairs. The familial aggregation documented in these families is consistent with a genetic basis in at least a subset of PF cases.

**Clinical and Genetic Aspects of Trigonocephaly: A Study of 22 Cases.** *C. Azimi*<sup>5</sup>, *S.J. Kennedy*<sup>1,3,4</sup>, *C. Forrest*<sup>2,3,4</sup>, *A.S. Teebi*<sup>1,3,4</sup>. 1) Div. of Clinical & Metabolic Genetics; 2) Div. of Plastic Surgery; 3) Hospital for Sick Children; 4) Toronto, ON, Canada; 5) Tehran Univ. of Med. Sciences, Tehran, Iran.

We reviewed 22 patients ascertained to have trigonocephaly/metopic synostosis as a prominent manifestation. In 15 patients, trigonocephaly was the only significant finding (68%) while in 7 patients trigonocephaly was a part of a syndrome (32%). Among the non-syndromic cases, 10 were males and 5 were females with a sex ratio of 2M:1F. Only 1 patient had a clearly affected parent (6.6%). All patients had normal psychomotor development. Among the syndromic cases, 3 had Jacobsen syndrome, due to deletion of chromosome 11q23 (43%). Of the remaining 4 syndromic cases, one patient had Say-Meyer syndrome, a possible X-linked recessive disorder. Another patient had multiple congenital anomalies and bilateral retinoblastoma. This patient did not have a detectable deletion in chromosome 13q14.2 by chromosomal analysis and FISH. One patient had additional sagittal synostosis, peculiar facies, Morgagni diaphragmatic hernia, stippled epiphyses, and mild psychomotor delays. A peroxisomal disorder was suspected but never confirmed. The final patient had severe micrognathia, large ears, atrioventricular septal defect, symmetrical cutaneous syndactyly of hands and feet, multiple café-au-lait spots and developmental delay in addition to trigonmicrocephaly. These findings were suggestive of a new MCA/MR syndrome. This patient was investigated for a cryptic chromosomal rearrangement, utilizing FISH and SKY, and was found to have a normal karyotype. In two of the syndromic cases FGFR2 and FGFR3 genes were studied, but no mutations were detected.

This study demonstrates that the majority of cases of non-syndromic trigonocephaly are sporadic and benign, apart from cosmetic effects on appearance. Syndromic cases involving trigonocephaly are heterogeneous with regard to their etiology and include both chromosomal and single gene disorders. This study emphasizes the importance of investigating patients with non-syndromic trigonocephaly for chromosome abnormalities.

**Goeminne Syndrome - Expansion of a rare X-linked phenotype.** *B.A. Fernandez<sup>1</sup>, A.E. MacMillan<sup>1</sup>, M. Crowley<sup>1</sup>, D. Jewer<sup>2</sup>, S.W. Scherer<sup>3</sup>.* 1) Faculty of Medicine, Discipline of Genetics, Memorial University of Newfoundland, St John's, NF; 2) Faculty of Medicine, Dept.of Surgery, Div. of Plastic Surgery, Memorial University, St John's, NF,; 3) Dept. of Genetics, The Hospital for Sick Children, 555 University Ave, Toronto, ON, M5G 1X8.

In 1968, Goeminne described a syndrome of congenital progressive torticollis, multiple keloids, and cryptorchidism in an Italian family with 4 affected males and 2 affected females. The males were more severely affected than females and McKusick (OMIM # 314300) has characterized Goeminne syndrome as X-linked with incomplete dominance. The only other reported cases are 2 females with partial features of the syndrome, each with an apparently balanced X;autosomal translocation. These female patients have been used to map a locus to Xq28, distal to *G6PD*.

We report a second male proband with this rare syndrome. He is 44 years old and was born with right-sided muscular torticollis, scoliosis and bilateral cryptorchidism. He is infertile and of normal intelligence. In mid-childhood, he developed spontaneous keloids, as well as disfiguring keloids at surgical incision sites. The first keloid formed at 5 years at the site of sternocleidomastoid surgery. Spontaneous keloids developed on the soles of the feet at 6 years. At 15, Harrington rods were removed and a thick linear keloid formed along the spinal incision.

The proband has a number of anomalies not described in Goeminne's pedigree. In the 3rd decade, he developed bilateral Dupuytren contractures, and keloids formed at the release sites. Additionally, he has macrocephaly, broad thumbs and great toes, and dysmorphic facial features including: prominent supraorbital ridges; telecanthus; a retruded midface; a wide mouth and large low set ears. His 75 year old mother may also be affected. She has Dupuytren contractures and with less aggressive keloid formation. The proband's routine karyotype was normal, as was *FISH* for the 16p13.3 (Rubinstein-Taybi) locus. Molecular studies of the Xq28 region using a candidate gene approach are in progress.

**Further Characterization of Odontotrichomelic Syndrome.** *M.N. Berry, V. Shashi.* Dept. Pediatrics, Division of Medical Genetics, Wake Forest Univ. School of Medicine, Winston-Salem, NC.

Odontotrichomelic syndrome (OS) is a rare, autosomal recessive condition associated with tetramelic deficiencies, ectodermal dysplasia and facial differences. We report on the features of a 31-year-old female who has upper limb reduction defects, abnormal facial features and findings consistent with ectodermal dysplasia. Although scant information is known about the maternal and paternal family histories, the patient was not aware of a family history of limb defects or ectodermal dysplasia. She reports that she has unilateral hearing loss, velopharyngeal insufficiency, an esophageal web, a resolved heart murmur, decreased sweating and hypodontia. She underwent surgical repair for protuberant ears. Her IQ is normal. On exam, her height, weight and head circumference are <<5th centile. She has sparse eyebrows, lowset ears, extremely small lower lacrimal punctae, absent upper lacrimal punctae, a large nose, prominent lips, a high arched palate, soft, slightly dry and prematurely wrinkled skin, scant body hair and thoracolumbar scoliosis. The right forearm is shortened with a missing radius. There is a radial club hand on the right with 3 well-formed digits, a bifid digit in place of the thumb and a cleft between the thumb and other digits. Her left upper limb is shortened, the forearm is missing, and there is ectrodactyly of the hand. There are only 2 digits on the left hand. Except for syndactyly of the 3rd and 4th left toes, the lower limbs are normal. We feel the features of limb reduction defects and ectodermal dysplasia in our patient suggest OS. We considered other ectodermal dysplasia conditions such as Ectrodactyly-Ectodermal dysplasia-Cleft lip/palate syndrome in the differential diagnosis. Although our patient has ectrodactyly and ectodermal dysplasia, the severity of the upper limb reduction defects and the typical facial features seen are more compatible with OS. Thus, our report expands the phenotype of OS and is the 4th fully described case of this rare condition.

**Functional renal abnormalities in two children with Kabuki syndrome.** *D. Genevieve*<sup>1</sup>, *C. Loirat*<sup>2</sup>, *C. Baumann*<sup>1</sup>. 1) Service de genetique, Hopital Robert Debre, Paris, France; 2) Service de Nephrologie Pediatrique Hopital Robert-Debre, Paris, France.

Kabuki (Niikawa-Kuroki) syndrome (KS) is a rare MCA/MR characterized by post natal growth retardation, mild mental retardation, a characteristic facial dysmorphism, skeletal malformations and dermatoglyphic abnormalities. Visceral malformations including renal malformations are frequent in this syndrome. Here we report, for the first time, on two patients with functional renal abnormalities. The first patient was a 3 years old girl presenting with chronic renal failure, a renal tubular acidosis type IV, hyperchloremic acidosis, urine concentration anomalies (concentrating power = 120 mosm/kg) and hypercalciuria (calcium/creatinin 1,5 to 3). Renal ultrasound showed bilateral small kidneys (< - 2 SD), and nephrocalcinosis with bilateral lithiasis. The second patient was a 17 year old boy presenting with polyuria and polydipsia, moderate chronic renal failure and urine concentration anomalies (concentrating power = 563 mosm/kg). Ultrasonography showed bilateral kidney hypoplasia (< -2 SD). We review the reported cases with KS and found that kidney malformations occur in 50/272 (18%) of KS. They include horseshoe kidneys, double renal pelvis, duplication of the collecting system, hydronephrosis, megaloureter, ureteropelvic junction obstruction, hydroureter and two cases with severe renal hypoplasia requiring renal transplantation in one case. We conclude that all patients with KS should have functional renal investigation. We propose that functional renal abnormalities could explain in part the post natal short stature in KS and larger studies are necessary to confirm this hypothesis.

**Molecular and clinical evaluation of a boy with Progeroid Variant of Ehlers-Danlos Syndrome. G.**

*Carakushansky<sup>1</sup>, T. Okajima<sup>2</sup>, K. Furukawa<sup>2</sup>, M. G. Ribeiro<sup>1</sup>, M. Carakushansky<sup>3</sup>, E. Kahn<sup>1</sup>.* 1) Dept. Pediatrics, Federal Univ. Rio de Janeiro, RJ, Brazil; 2) Dept. Biochem. II, Nagoya Univ. School of Medicine, Japan; 3) Johns Hopkins Hospital, Pediatric Endocrinology, Baltimore, USA.

Manifestations of progeroid syndrome combined with Ehlers-Danlos (E-D) features have been described in about half-dozen cases registered as a distinct nosologic entity (OMIM 130070). We have studied a 5 year-old boy who exhibited mild mental retardation, short stature, craniofacial disproportion, osteopenia, prominent ears, pectus excavatum, loose and wrinkled skin with increased prominence of veins on hands and feet, bruisability, surgically repaired inguinal hernias, joint hypermobility in digits and subluxation of hips leading to waddling gait. Our patient lacked several characteristic features of progeria such as prominent scalp veins, generalized alopecia, and joint contractures. He also did not conform with well-defined progeroid syndromes such as Hallermann-Streiff, Cockayne and Bartsy syndromes. In 1999, Okajima et al (1) isolated cDNA of the galactosyltransferase I (b4GalT7) presumed to be defective in the progeroid variant of Ehlers-Danlos syndrome. They then searched for mutations in the patient reported by Kresse et al (2) and found 2 changes in the XGPT1 gene. In our patient and in his unaffected parents the genomic sequence of galactosyltransferase I was analysed by direct sequencing of PCR products obtained from amplification of exon segments with primers located in flanking intron or UTR sequences. However, no mutations could be detected except for a single silent heterozygous mutation (R73R, CGC to CGT) in exon 2. This may imply that other related glycosyltransferase is probably mutated in our patient and that further study of its pathogenic role in this disease should be undertaken. All previously reported cases represented isolated cases considered to be the result of autosomal dominant new mutations. Our patient was the product of related and phenotypically normal parents. This fact supports an autosomal recessive mode of inheritance but by itself it is not conclusive. (1) Okajima et al. *J. Biol. Chem.* 1999; 274:22915-22918 (2) Kresse et al. *Am. J. Hum. Genet.* 1987; 41:436-453.

**A Syndrome of Deafness, Neurogenic Muscle Weakness and Optic Atrophy: Rosenberg-Chutorian Syndrome (RCS)? A Disease Looking for a Gene.** *J. Christodoulou*<sup>1, 3</sup>, *L.S. Raffaele*<sup>1, 3</sup>, *B. Bennetts*<sup>1, 3</sup>, *R.A. Ouvrier*<sup>2, 3</sup>. 1) Western Sydney Genetics Program, Royal Alexandra Hospital for Children, Sydney; 2) Neuromuscular Research Institute, Royal Alexandra Hospital for Children, Sydney; 3) Dept of Paediatrics & Child Health, University of Sydney, NSW, AUSTRALIA.

RCS is an X-linked disorder of unknown cause, noted for sensorineural deafness, muscle weakness of neurogenic origin, and progressive optic atrophy, but with preserved intellect. We report here a family in which three affected males may have this disorder, and present our progress to date with molecular studies.

Two brothers, currently aged 5 and 3.5 years, have congenital profound sensorineural deafness, and a peripheral neuropathy with generalised muscle weakness. They are predisposed to acute severe muscle weakness during intercurrent infections, which has led to mechanical ventilation on a number of occasions. More recently the older boy has developed symptomatic optic atrophy. Intellect is probably normal for both. Numerous investigations, including mitochondrial respiratory chain analyses, have been normal. Their parents and sister enjoy normal health, and their hearing is normal. A maternal uncle died of a "muscular dystrophy" at the age of 2 years, and had not developed any speech by the time of death.

Based on these findings we have made a provisional diagnosis of RCS, and have undertaken microsatellite analyses of the X chromosome using the Prism linkage mapping set, Version 2 (Applied Biosystems), using samples from the affected probands, their sister, parents, and maternal grandparents. To date we can exclude about half of the X chromosome, but 4 candidate regions remain to be excluded: a region at Xp11.21, at DXS1214 (~ 13 cM), Xq13.1, bounded by markers DXS986 and DXS8055 (~47cM), a region at Xq25, at DXS1047 (~ 22cM), and Xq28, bounded by DXS1193 and DXS1073 (~ 11cM).

Future studies will include further fine mapping with a denser collection of microsatellites, (including analyses of an unaffected maternal uncle), followed by interrogation of the available genomic databases for candidate gene mutation screening.

**Expression of schizophrenic symptoms in 22q Deletion Syndrome.** *A.S. Bassett<sup>1,2</sup>, S. O'Neill<sup>2</sup>, J. Murphy<sup>2</sup>, P. AbdelMalik<sup>2</sup>, E. Chow<sup>1,2</sup>.* 1) Dept. of Psychiatry, Univ of Toronto, Toronto, ON., Canada; 2) Queen St. Site, CAMH, Toronto, ON., Canada.

**Background:** 22q Deletion Syndrome (22qDS) may represent a genetic subtype of schizophrenia. Individuals with 22qDS are at elevated (~25%) risk for schizophrenia, as are siblings of individuals with schizophrenia (10-15%). At-risk individuals may express mild forms of psychotic or other symptoms. We compared expression of schizophrenic symptoms in two non-psychotic (NP) at-risk groups, 22qDS-NP and siblings from familial schizophrenia (FSZ) families (FSZ-NP), and two affected groups: FSZ and 22qDS-SZ. **Objective:** To determine whether there are phenotypic differences between 22qDS and other genetic forms of schizophrenia. **Method:** A standard scale for severity of schizophrenic symptoms, the Positive and Negative Syndrome Scale (PANSS), was used to assess each subject. Adult subjects with 22qDS-NP (n=15) were compared with FSZ-NP subjects (n=27); subjects with 22qDS-SZ (n=21) were compared with FSZ subjects (n=21); 22qDS groups did not differ significantly on mean age or sex from their respective FSZ group. **Results:** Total PANSS scores did not differ significantly between the two NP groups or between the two SZ groups. However, examination of symptom clusters revealed that 22qDS-NP subjects had more severe negative (e.g., emotional and social withdrawal) and cognitive (e.g., poor abstract thinking and attention) symptom scores than FSZ-NP subjects ( $t=-2.72$ ,  $p=0.01$ ;  $t=-2.08$ ,  $p=0.04$ , respectively). 22qDS-SZ subjects had more severe cognitive and excitement (e.g., poor impulse control, hostility, uncooperativeness) symptom scores than FSZ ( $t=-2.50$ ,  $p=0.02$ ;  $t=-2.35$ ,  $p=0.02$ , respectively). There were no significant differences in the non-psychotic or SZ group comparisons on positive or anxiety/depression symptoms. **Conclusion:** Expression of typical positive and negative symptoms of schizophrenia in 22qDS is similar to that in other genetic forms of schizophrenia, however temper outbursts are more common and cognitive deficits more severe in 22qDS-SZ. Social withdrawal and cognitive deficits may be prevalent in 22qDS without being associated with expression of a psychotic illness.

**Colobomas of the iris and retina in 2 patients with 22q11.2 deletion: more than a deletion?** *K.B. Coleman<sup>1</sup>, K. Kupke<sup>1,2</sup>, K.M. May<sup>3</sup>*. 1) Children's Healthcare Atlanta, Atlanta, GA; 2) Northside Hospital, Atlanta, GA; 3) Dept of Peds, Emory Univ Sch Med, Atlanta, GA.

We describe two infants with iris and chorioretinal colobomas in association with deletion 22q11.2. Case 1 was born at 38 weeks by C-section for fetal distress. The birth weight was 1976 gms, length was 42.5 cms and head circumference was 30.5 cms (all values below -2 SD). The pregnancy was complicated by oligohydramnios, short umbilical cord and IUGR. Clinical findings included bilateral iris and chorioretinal colobomas, abnormal ears, imperforate anus and a very small fistula, multiple small VSDs, mild bilateral hydronephrosis, umbilical and inguinal hernias, GE reflux, tracheal web, intestinal malrotation, hypotonia and developmental delay. Family history was significant for a maternal uncle with colobomas. Case 2 was born by vaginal delivery at 35 weeks. The birth weight was 2240 gms, length was 45 cms, and head circumference was 31 cms (all values at -1 SD). Clinical findings included iris and chorioretinal colobomas and microphthalmos of the left eye, partial iris coloboma of the right eye, pulmonary valve atresia, VSD with overriding aorta and right aortic arch, mild tracheomalacia, deficient upper helix of left ear, bilateral postaxial polydactyly, bilateral deep plantar furrows, low numbers of CD4+ and B cells. In both cases chromosome analysis revealed normal karyotypes while FISH analysis of metaphase chromosomes with the TUPLE1 probe indicated a deletion within 22q11.2. Both cases, but especially Case 1, have features of 22q11.2 deletion as well as features associated with Cat Eye Syndrome, which arises from a duplication of proximal 22q. As both disorders result from structural changes within the same chromosomal region (22q11.2), this may indicate that these cases involve more than a straightforward deletion of the region spanned by the TUPLE1 probe. These two cases expand the phenotype of 22q11.2 deletions and suggest that deletion studies should be considered in patients with colobomas and similar findings.

**Oral, facial, digital, vertebral anomalies with psychomotor delay: an OFD variant or a new syndrome? G.B.**

*Ferrero<sup>1</sup>, M. Valenzise<sup>1</sup>, L. Sorasio<sup>1</sup>, B. Franco<sup>2</sup>, C. Defilippi<sup>3</sup>, E. Pepe<sup>4</sup>, M. Silengo<sup>1</sup>.* 1) Dep. of Pediatrics, University of Torino, Torino; 2) TIGEM, Naples; 3) Dep. of Radiology and; 4) Dep. of Surgery, O.I.R.M, Torino, Italy.

The orofacioidigital syndromes (OFDs) are a group of heterogenous hereditary disorders characterized by a spectrum of overlapping clinical findings involving the oral cavity, the face, and the digits. Nine different OFD clinical entities have been recognized, with overlapping clinical findings complicating precise classification. Recently, the first gene involved in the molecular pathogenesis of OFDs has been cloned in Xp22.3, where molecular lesions of *OfdI* have been found segregating with the X-linked dominant form (Type 1) of the disease. Here we report a case of a girl, who presented at birth hypertelorism, micrognathia and a large midline palate cleft associated to an oral hairy polyp. A double labial frenulum and a pedunculated tumor of the tongue completed the clinical presentation. Associated with these oral findings were low set thumbs and clinodactyly of the fifth toe. Chromosomal analysis of the patient showed a normal karyotype. She was re-evaluated at age two and six months, when she presented with psychomotor delay and kyphoscoliosis. Radiographs and CT scan revealed partial synostosis between the atlas and the base of the occipital bone, and multiple proximal-cervical and distal-thoracic vertebral clefts. Magnetic resonance imaging (MRI) of the brain showed a myelinization delay and a smooth empty sella turcica with a negative endocrinological screening for hypopituitarism. The absence of mutations in the coding region of *OfdI* is strong evidence against the diagnosis of OFD Type I, although more complex molecular mechanisms involving this gene in the pathogenesis of the phenotype cannot be excluded. The peculiar synostosis between the atlas and the base of the occiput, are remarkably similar to those described previously by Gabrielli et al. (*Am J Med Genet* 53:290-293), suggesting that these two patients could represent a variant in the wide spectrum of OFDs, or a new unrecognized syndrome.

**Pre- and postaxial polydactyly, abnormal ears, and learning disability: A new dominant syndrome.** *K.M. Boycott, D.R. McLeod.* Dept Medical Genetics, Univ Calgary, Calgary, AB, Canada.

Polydactyly may occur either as a feature of a syndrome or as an isolated defect. Preaxial polydactyly refers to partial or complete extra digits of the radial or fibular ray and postaxial polydactyly of the ulnar or tibial ray. We report a three generation family that presents with pre- and postaxial polydactyly of the hands and feet, abnormal ears, and learning disability. The proband is now 10 months old and was born with preaxial polydactyly of the right foot presenting as a bifid great toe. On the left foot she has postaxial polydactyly type A and syndactyly of the 2nd and 3rd toes. She has type A postaxial polydactyly of the right hand and type B post-axial polydactyly of the left hand. Her mother was born with type B postaxial polydactyly of the right foot, preaxial polydactyly of the left foot, and type B postaxial polydactyly of both hands. The proband's grandmother was born with type B postaxial polydactyly of the left foot. The minor ear abnormalities include thickening and overfolding of the helix in the proband and her grandmother. The proband's mother and grandmother had significant learning difficulties in school, suggesting a learning disability is present.

This family segregates a dominant condition with pre- and postaxial polydactyly, minor ear abnormalities, and learning disability. Both pre- and postaxial polysyndactyly are seen in complex bilateral polysyndactyly, which maps to 7q36, but triphalangeal thumb is not a feature in this family. Pre- and postaxial polydactyly can also be seen in Greig syndrome, caused by mutations in the *GLI3* gene, but the facial features of this syndrome are not seen in this family. There is also some overlap with the syndrome of hallux syndactyly-ulnar polydactyly-abnormal ear lobes (Birth defects 12 (5):255, 1976), but the ear abnormalities are distinct and learning disability was not described. Mutations in human HOX genes have been shown to cause congenital malformations involving the hands and feet, making HOX genes good candidates for the condition segregating in this family.

**Complete Cranio-Fronto-Nasal Syndrome phenotype in a mexican male patient.** *L. Cornejo*<sup>1</sup>, *V. Morán*<sup>2</sup>, *G. Ramírez*<sup>2</sup>, *S. Kawa*<sup>2</sup>, *D. Saavedra*<sup>2</sup>. 1) Sch Medicine, Autonomous Hidalgo State Univ, Pachuca de Soto, Mexico; 2) Dr. Manuel Gea Gonzalez, General Hospital, Mxico, D.F.

**Introduction.** Full spectrum of Cranio-Fronto-Nasal Syndrome (CFNS) is seen mainly in females. Although the responsible gene has been located in X-chromosome and the pedigree of affected families were consistent with X-linked inheritance pattern, the males are very few affected basically in the craniofacial area. The purpose of this paper is to present the first mexican male patient with the complete phenotype of this syndrome including extracranial malformations. **Clinical report.** Propositus is a male twenty-one years old whom mildstones and intelligence were normal. Craniofacial findings are: thick, wiry, and curly hair, low anterior hairline with widows peak; left plagiocephaly, hypertelorism, bifid nose, and wide distance between upper central incisors. The extracranial abnormalities consisting on: thorax asymmetry, S- shaped clavicles abnormally positioned, pectus excavatum, left nipple lower located, left sholder with movement arch limitation; hyperextensible joints, asymmetric lower limb shortness, mild cutaneous syndactyly, grooved nails in hands and feet. A routine kariotype was 46,XY. Craniofacial CTScan confirmed left hemicoronal synostosis, 0-14 cleft, left orbital dystopia, and shortening of the midface length. **Discussion.** Few XY patients have been described world wide with the complete CFNS phenotype. In mexican population where the largest series of this syndrome has already published, none male showed extracranial anomalies. Based on the present data, the previously gene expression proposed as causing this syndrome should be requested.

**Punctata Keratoderma and gastrointestinal malignancy in a Mexican Family.** *N. Davalos*<sup>1,2</sup>, *M. Ruiz*<sup>3</sup>, *A. Garcia-Vargas*<sup>4</sup>, *I.P. Davalos*<sup>1,2</sup>, *D. Garcia-Cruz*<sup>1</sup>, *L.E. Figuera*<sup>1,2</sup>. 1) Div Genetica, CIBO-IMSS, Guadalajara, Mexico; 2) Doctorado en Genetica Humana, CUCS-UdeG, Guadalajara, Mexico; 3) Hospital General de Occidente, SSA, Guadalajara, Mexico; 4) Instituto Dermatologico Jose Barba Rubio, SSA, Guadalajara, Mexico.

The inherited Palmoplantar keratodermas are an extremely heterogeneous group of skin diseases that can be subclassified on the bases of the pattern and age of onset of hyperekeratosis on the palm and sole. In Keratosis Punctata Palmaris et Plantaris (KPPP) type, the lesions are numerous tiny keratotic papules, strictly limited to the volar aspects of the hands and feet, yellow-brown, hard, horny papules, and remain asymptomatic. The disease is inherited as an autosomal dominant trait and the onset is usually in the first decade of life. This appears to be associated with gastrointestinal carcinomas. The prevalence of KPPP in Latin America is less than 0.1%. We describe a Mexican family, with 10 affected individuals through 4 generations, showing KPPP. Clinically the 83 year-old propositus displayed numerous keratotic horny papules of the hands and feet, keratoses progress slowly, asymptomatic, no nail dystrophies associated. Histologically the lesions consist of a marked hyperkeratosis sharply defined, hypergranulosis, without evidence of dyskeratosis or hydropic degeneration in the epidermis (differentiating the condition from porokeratosis), with no neurologic associated features. He presented carcinoma of the pancreas that led to death. The alive remaining affected individuals (4 females and 2 males) only present the skin clinical features. Few other reported cases of hereditary KPPP appear to be associated with gastrointestinal carcinomas, in this family only in the propositus the carcinoma was well documented, it could be explained by the involvement of a regulator gene expressed both in skin and gastrointestinal tract. There have been identified several genes related to palmoplantar keratodermas, hence it is necessary to do linkage analysis in the family presented here in order to determine if any of the known genes is responsible or some other one could be involved.

**Russell-Silver syndrome: A family with autosomal recessive inheritance.** *I. Davalos*<sup>1,2</sup>, *L. Melo*<sup>1,2,3</sup>, *N. Davalos*<sup>1,2</sup>, *L.E. Figuera*<sup>1,2</sup>. 1) Dept Genetica, CIBO-IMSS, Guadalajara, Mexico; 2) Doctorado en Genetica Humana, CUCS-UdeG, Guadalajara, Mexico; 3) Hospital Ortopedico Infantil, Caracas, Venezuela.

The Silver-Russell syndrome (SRS) is an entity with unknown etiology. The main clinical features are intrauterine and postnatal growth retardation, broad forehead with normal head circumference, small triangular shaped face, down turned corners of the mouth, body asymmetry and delayed bone age. The etiology of SRS seems to be heterogeneous, most cases are sporadic although families with dominant or recessive inheritance and X-linked forms have been reported; over 150 cases there were four recurrences in sibs, and in five cases was suggested autosomal dominant inheritance with variable expression. The purpose of this paper is to present the SRS in 2 sisters from unrelated and healthy parents. The proposita was the product of a preterm pregnancy (36 weeks), birth weight of 1,800 gr. On physical examination at 3 months presented low birth weight, retarded growth, craniofacial disproportion, delayed close of anterior fontanelle, triangular face, thin lips, the outer angles of the mouth were down turned, clinodactyly of fifth fingers with delayed psychomotor development and bone age and normal karyotype. These features suggested a SRS. At 8 years old, craniofacial features of SRS and short stature persisted. Case 2. She was the product of a third gestation with a birthweight of 2,200 gr. At physical examination at 6th month revealed 3720g (<3p), a length of 54 cm. (<3p), a head circumference of 40.5 cm (10p), wide anterior fontanelle, prominent forehead, blue sclera, triangular face, small chin, thin lips, body asymmetry, 5th fingers with clinodactyly and delayed bone age. The cases described here presented the principal clinical features of SRS, although etiology remains unclear, the familial cases might be helpful to unveil the etiology of SRS. The fact that autosomal dominant, recessive and X-linked inheritance have been reported, reveals a genetic heterogeneity for SRS. Some molecular studies have shown linkage to chromosomes, 2,7,9,14 and 16, on the other hand, in some cases uniparental disomy of chromosome 7, suggesting that genomic imprinting plays a roll in this entity.

**Rhombencephalosynapsis associated with multiple congenital anomalies: A new syndrome with a probable somatic mutation.** *C.H. Jones<sup>1</sup>, K. Silver<sup>2</sup>.* 1) Dept Pediatrics, Section Gen, Loyola Univ, Maywood, IL; 2) Department of Pediatric Neurology Loyola Univ, Maywood, IL.

Rhombencephalosynapsis is a malformation of the posterior fossa. It is usually confined to the CNS. There are a few reported cases of rhombencephalosynapsis being seen with other congenital anomalies. The anomalies previously described include polydactyly, hypertelorism, low set ears and elongated philtrum. We present a patient with rhombencephalosynapsis in addition to pre-axial polydactyly of the left toes, left tibia longer than the fibula, absent left kidney, left lung hypoplasia, diastinomialia, scoliosis and vertebral anomalies including hemivertebrae. Blood chromosomes at birth were normal 46,XX. Fibroblast chromosomes on the left side of the body were also normal. A head ultrasound performed shortly after birth indicated hydrocephalus. A VP shunt was placed at 10 days of life. At 1 year an MRI of the brain showed absence of the cerebellar vermis with fusion of the cerebellar hemispheres. An MRI of the spine showed diastinomialia in the lower thoracic region at T9-T10. The patient is now 2 years of age. She has developmental delays however is beginning to verbalize and pull to a stand. She is still ventilator dependent at night. We hypothesize that while in some cases rhombencephalosynapsis is an isolated event, it can be part of a syndrome. Our patient had the majority of her other anomalies on the left side of her body. This likely represents a somatic mutation occurring on the left side of her body early in development. A similar mutation in a nonmosaic state would likely be lethal.

**Seckel syndrome: Report of Two Cases.** *N.L. Hatem<sup>1</sup>, S. Tayel<sup>2</sup>, I. Marzouk<sup>1</sup>*. 1) Department of Pediatrics; 2) and Clinical Cytogenetics Unit, Department of Anatomy, Alexandria Faculty of Medicine, Alex, Egypt.

This report describes two Egyptian sibs with Seckel syndrome. Their clinical manifestations included mental retardation, short stature, microcephaly, and characteristic facial appearance in the form of receding forehead, micrognathia, antimongoloid slant of palpebral fissures and large prominent nose i.e. bird-headed dwarfism. One of the two sibs had absent patella. Chromosomal examinations of both demonstrated a high percentage (26% & 31%) of chromosome endoreduplication. Absent patella and chromosome endoreduplication have not been mentioned in Seckel syndrome so warranting its citation. This is the first report from Egypt about Seckel syndrome and the second among arabs.

**Ultrasound Diagnosis of a Sacrococcygeal Teratoma Leading to Prenatal Diagnosis of Jacobsen Syndrome. V.**

*Loik Ramey, F. Bsata, R. Naeem, G.M. Cohn.* Baystate Medical Center, Springfield, MA.

Jacobsen syndrome, also known as 11q- syndrome, is characterized by a clinical phenotype due to a deletion of band 11q23-qter. The phenotype involves IUGR, mental deficiency ranging from moderate to severe, trigonocephaly, epicanthal folds, ocular hypertelorism, short nose with upturned nasal tip, a large, carp-shaped mouth, cardiac defects, and various CNS anomalies. Sacrococcygeal teratomas (SCTs) have not been previously reported in association with Jacobsen syndrome. We report a fetus diagnosed with a SCT at 19 weeks gestation in a 41 year old G5, P2022. Amniocentesis was performed and revealed a 46,XX,del(11)(q23) karyotype consistent with Jacobsen syndrome. Amniotic fluid fetoprotein was normal at 1.21 multiples of the median. The baby was born at 32 1/2 weeks gestation and found to have a coarctation of the aorta, bicuspid aortic valve and a perimembranous ventricular septal defect, and physical features consistent with Jacobsen syndrome. As cardiac surgery was immediately required, removal of the teratoma was delayed until four months of age. Karyotype analysis on tissue taken from the teratoma also revealed the 11q deletion. The literature does indicate that tumors and teratomas may be associated with various chromosome anomalies. Because of the rarity of both conditions, we could speculate that the teratoma may be related to the chromosomal deletion rather than representing an unrelated anomaly.

**Acromegaloid facial appearance (AFA) and generalized congenital hypertrichosis: variant of AFA syndrome or a new syndrome?** C.A. Kim, S.M.M. Sugayama, R.S. Coelho, L.M.J. Albano. Genetics, Dept Pediatrics, Instituto da Crianca, Sao Paulo, Brazil.

AFA syndrome is characterized by acromegaloid facial appearance and thickening of the eyelids, lips and oral mucosa associated with large doughy hands. It was first described in 1985, by Hughes et al., in 13 affected members within four generations. Dallapiccola et al., in 1992, reported more 5 patients in another family and da Silva et al. (1998) and Zelante et al. (2000) reported two other sporadic cases. Irvine et al. (1996) described 4 patients in one family with characteristic acromegaloid facial appearance and generalized hypertrichosis without intraoral lesions. They considered a new entity distinct from AFA syndrome. We studied two sporadic cases with acromegaloid facial appearance with congenital hypertrichosis. The first one, 15 year-old girl, was born with macrosomy and generalized hypertrichosis, including the pubic region. She had a good health and normal psychomotor development and a progressive coarse acromegaloid facial appearance with thickening of the lips. Other distinctive features were skin warty lesions on axilla surface and macrocephaly. Endocrinological evaluation was normal. The second one, 12 year-old girl, was born with normal birth weight and generalized hypertrichosis. She presented mild mental delay and similar coarse acromegaloid facial appearance without macrocephaly. Other distinctive features were arachnoid cyst in the posterior fossa and renal calculosis. Interestingly, arachnoid cyst and skin hemangiomatous lesions were described in association with AFA syndrome, respectively by da Silva et al. (1998) and Zelante et al. (2000). Our patients presented features more similar with that described by Irvine et al (1996): acromegaloid facial appearance and generalized hypertrichosis without intraoral involvement. Further reports are necessary to amplify and better delineate the phenotype characteristics of these rare entities.

**Further delineation of Antley Bixler syndrome.** *K. Okajima<sup>1</sup>, T. Hasegawa<sup>3</sup>, T. Kubota<sup>2</sup>, H. Seki<sup>2</sup>, Y. Sugimoto<sup>2</sup>, Y. Fukushima<sup>2</sup>, N. Yamaguchi<sup>5</sup>, MG. Butler<sup>6</sup>, BP. LeHeup<sup>4</sup>, H. Membre<sup>4</sup>, V. Smith<sup>1</sup>, AJ. Darby<sup>7</sup>, T. Stallmach<sup>8</sup>, A. Schinzel<sup>8</sup>, S. Malcolm<sup>1</sup>, W. Reardon<sup>9</sup>, RM. Winter<sup>1</sup>.* 1) Inst Child Health, London, UK; 2) Shinshu Univ, Matsumoto, Japan; 3) Shizuoka Children Hosp, Shizuoka, Japan; 4) Medical School of Nancy, Nancy, France; 5) Nagoya City Univ, Nagoya, Japan; 6) Children's Mercy Hosp, Kansas City, MO; 7) Robert Jones & Agnes Hunt Hosp, Oswestry, UK; 8) Univ Zurich, Zurich, Switzerland; 9) Our Lady's Hosp for Sick Children, Dublin, Ireland.

Antley-Bixler syndrome (ABS) was first reported as Trapezoidocephaly, midfacial hypoplasia and cartilage abnormalities with multiple synostoses and skeletal fractures. Previous reports suggest that ABS is probably an autosomal recessive condition. FGFR2 mutations and abnormal steroid metabolism are also reported in ABS. We present an evaluation of 14 patients (10 families) whose ethnic background are Asian or Caucasian, who included one of original and consanguineous patients. All patients met the minimal criteria of craniosynostosis, elbow synostosis and femoral bowing and/or fracture. Urogenital involvement was seen 6 patients. One patient had an Arnold Chiari malformation. Six patients survived the neonatal period. DNA was available from 10 patients. No mutations were found in FGFR2 gene. Pathology samples were available from 4 patients. In 3 patients, bone histology revealed that the trabeculae of the primary spongiosa contained occasional cores of cellular hypertrophic cartilage instead of the normal acellular hyaline matrix. Chondrocyte column formation was not disturbed. No microfractures, which may predispose to fracture, were seen. The adrenal glands showed no abnormality. One familial patient had abnormal mucosa outside of the tracheal cartilage. Adrenal steroid profiles were available from 3 patients, and all were within normal limits. These suggest that patients meeting the strict criteria of ABS are not likely to have FGFR2 mutations or an abnormal steroid profile. Patients with FGFR2 mutations and/or an abnormal steroid profile can present with craniosynostosis and elbow synostosis but do not have femoral abnormalities. They most likely represent a phenocopy of ABS.

**Van der Woude syndrome associated with ankyloblepharon filiforme adnatum is not linked to chromosome 1q32-q41 region.** *H. Okur<sup>1</sup>, I. Vargel<sup>2</sup>, F. Ozgur<sup>2</sup>, Y. Erk<sup>2</sup>, A.N. Akarsu<sup>1</sup>*. 1) Gene Mapping Laboratory, Research Center of Ihsan Dogramaci Children's Hospital,; 2) Department of Plastic and Reconstructive Surgery, Hacettepe University, Ankara, Turkey.

Van der Woude syndrome (VWS) is a common form of syndromic cleft lip and palate with typical manifestation of harelip and/or cleft palate, bilateral lower lip pits, hypodontia and an autosomal dominant mode of inheritance with high degree of penetrance. It has already been mapped to chromosome 1q32-q41 between the markers D1S491 and D1S205. No gene has yet been identified. Associations such as ankyloblepharon filiforme adnatum, popliteal pterygium and intraoral tissue bands (syngnathia) have commonly reported with VWS suggesting that these phenotypes might be allelic. Indeed, popliteal pterygium syndrome was further mapped to the same region of interest. We report two multiplex Turkish families with VWS. First family containing 15 affected cases manifested typical characteristics of VWS including Cleft lip (1/15); Cleft palate (5/15); cleft lip and pit (2/15); cleft palate and pit (3/15); cleft lip/palate/pit (4/15). Linkage analysis using the markers D1S245, D1S491, D1S205 and D1S414 provided positive LOD scores. A maximum two point LOD score of 4.438 was observed with D1S205 with no recombination. Thus, we supported locus homogeneity for classical form of VWS. Cleft lip and pit were the characteristic features of the second family containing 15 informative meioses, 5 of whom were affected. In addition to harelip and pit congenital filiform fusion of eyelids, syngnathia were observed in an affected member of the family. One of the affected family members with bilateral cleft lip was recombinant for the entire critical region between cen- D1S1678, D1S245, D1S491, D1S205, D1S414, D1S2141, D1S549-tel. Since this recombination event is observed in a typically affected family member rather than the complicated case we did not expect phenocopy leading to this unexpected result. This result suggests that at least one more locus is responsible for the complicated VWS phenotype.

**PRENATAL ONSET OF INFANTILE CORTICAL HYPEROSTOSIS (CAFFEY DISEASE).** *D. Myles Reid<sup>1</sup>, R. Lachman<sup>2</sup>, G. Seaward<sup>1</sup>, S. Viero<sup>1</sup>, D. Chitayat<sup>1</sup>*. 1) Medical Genetics, Mount Sinai Hospital, Toronto, Canada; 2) The International Skeletal Dysplasia Registry, Los Angeles, California, USA.

Infantile cortical hyperostosis (ICH)(Caffey disease)is a multifocal, inflammatory skeletal process with onset typically within the first few months of life and resolution by 3 years of age. Autosomal dominant inheritance with variable expression and penetrance has been reported. Prenatal onset of ICH is recognized as a distinct phenotype characterized by polyhydramnios, bowed hyperostotic long bones, hydrops, pulmonary hypoplasia and a poor prognosis. Previous case reports have suggested autosomal recessive inheritance. We report a case of prenatal ICH detected at 23 weeks gestation. The mother was a 31-year-old G3P3L0 woman of Jamaican descent and her husband was 32 years old and of the same descent. The couple was healthy, non-consanguineous and their family histories were non-contributory. The couple's first pregnancy was complicated with polyhydramnios and premature rupture of membranes at 21 weeks gestation and resulted in premature delivery and postnatal death. Neither autopsy nor chromosome analysis were completed. The couple's second pregnancy resulted in intrauterine death at 27 weeks gestation. An autopsy showed no obvious abnormalities; however, X-rays were not performed. In the third pregnancy, fetal ultrasounds performed at 12 and 18 weeks gestation reported normal fetal anatomy. At 23 weeks gestation, there was premature rupture of membranes. A repeat ultrasound revealed scalp edema, polyhydramnios, bowed long bones, echogenic gut and bilateral club feet. Postnatal examination of the fetus revealed some rhizomelia and edema of the lower limbs. The right femur appeared short and there was posterior bowing of the right calf. The facial features were mildly dysmorphic with bilateral infraorbital creases and micrognathia. Skeletal X-rays revealed findings consistent with ICH. This case supports previous findings that two distinct forms of cortical hyperostosis exist, infantile and prenatal onset. Regarding the couple's previous pregnancies, X-rays and complete autopsies were not done and thus it is possible that these were also affected with the same condition.

**Further delineation of the 7q36 terminal deletion syndrome.** A. Kwan, A.M. Cherry, I. Galperin, S. Huhn, G.M. Enns. Div Med Genet, Div Cytogenet, Div Neurosurg, Stanford Univ. School of Medicine, Stanford, CA.

The chromosomal region 7q36 contains two homeobox genes involved in the development of the rostral and caudal ends of the neural tube. Mutations in *SHH* cause holoprosencephaly and mutations in *HLXB9* result in the Currarino triad, a pattern of malformation characterized by sacral agenesis (typically a sickle-shaped or "scimitar" hemisacrum), anorectal malformations and a presacral mass. Patients with *HLXB9* mutations have normal intelligence. Isolated terminal deletion of 7q36 has been associated with significant developmental delay, growth retardation, microcephaly, holoprosencephaly and the Currarino triad. In order to further delineate the phenotypic spectrum associated with the 7q36 terminal deletion syndrome, we report the first case of a patient with a *de novo* deletion. One parent carried a balanced translocation in all previous studies of isolated 7q36 deletion that reported parental karyotypes. Our patient presented at 8-1/2 months with microcephaly, mild developmental delay, minor dysmorphic features and chordee. Head MRI and routine karyotype were normal. He developed cellulitis over the sacral area and further investigation revealed an atypical anterior sacral lipomeningocele and a tethered cord. Radiographs showed absence of the sacrum below S2. Because sacral anomalies have been associated with 7q deletions and *HLXB9* maps to the same region, a high resolution blood karyotype was performed with FISH using a 7q subtelomeric probe. A terminal deletion was identified [46,XY,del(7)(q36.2).ish del(7)(q36.3)(TelVysion7q-)]. Parental karyotypes and FISH for the deletion were normal. At 20 months the patient continues to show only mild developmental delay. This case represents a mild expression of the 7q36 terminal deletion syndrome phenotype in a patient with a *de novo* deletion and highlights the utility of combining clinical information and knowledge of the location of specific genes with molecular cytogenetic analysis. We recommend detailed evaluation of chromosome 7q36 in patients with developmental delay, microcephaly and sacral malformations.

**Unusual systemic manifestations in Kabuki syndrome: hypoglycemia, malabsorption, and autoimmune thrombocytopenia and anemia.** *J.E. Ming, K.L. Russell, D.M. McDonald-McGinn, P. Kaplan, E.H. Zackai.* Division of Human Genetics and Molecular Biology, The Children's Hospital of Philadelphia and the University of Pennsylvania School of Medicine, Philadelphia, PA.

Kabuki syndrome is characterized by postnatal growth retardation, congenital heart disease, developmental delay, skeletal anomalies, and a characteristic facies. We report three unusual systemic manifestations of this condition in our series of 14 patients at The Children's Hospital of Philadelphia: neonatal hypoglycemia, intestinal malabsorption, and autoimmune thrombocytopenia and anemia. Neonatal hypoglycemia was present in three patients in our series. Two patients presented on the first day of life with severe hypoglycemia, one of whom had hyperinsulinism. The third patient was noted to have hypoglycemia at age 11 months. Severe intestinal malabsorption has been noted in two of the patients we have evaluated. The first patient presented with malabsorption at age 4 months and was given pancreatic enzyme supplementation. The second patient presented at age 9 years with severe watery diarrhea and had decreased fat, carbohydrate, and protein absorption. Parenteral nutrition was required. Two patients have presented with a combination of autoimmune thrombocytopenia and hemolytic anemia. At age 4 years, the first patient was noted to have pancytopenia. Autoantibodies were present and he responded to steroid treatment. The second patient presented at age 13 years with thrombocytopenia. Anti-platelet antibodies were detected, and the peripheral blood smear was consistent with hemolytic anemia. The three serious medical conditions described in these patients are rare complications of Kabuki syndrome and have been occasionally noted in previous reports. Our experience suggests that these findings may occur at a greater frequency than previously recognized. In addition, as these diseases will bring a child to medical attention and could prompt a clinical genetics evaluation, recognition that these findings are associated with Kabuki syndrome may aid in diagnosis.

**Shprintzen-Goldberg syndrome and cervicomedullary compression.** *H. Kawame<sup>1</sup>, H. Shigeta<sup>2</sup>, S. Sakazume<sup>1</sup>, Y. Fukushima<sup>1</sup>.* 1) Div of Clinical and Molecular Genetics, Shinshu Univ Schl of Med, Nagano; 2) Div of Neurosurgery, Nagano Children's Hospital, Nagano, Japan.

Shprintzen-Goldberg syndrome (SGS) is a rare disorder associated with a complex phenotype of variable craniosynostosis, developmental delay, characteristic facial features, and other skeletal and connective tissue anomalies. At least 20 patients have been reported in the literature, the phenotypic spectrum of SGS are not well delineated. We report a 15 month-old female patient with SGS and stenosis of the foramen magnum with cervicomedullary compression.

The patient was the first child born to unrelated, healthy patients. At age of one month, strabismus was noted and ophthalmologic examination revealed exudative vitreoretinopathy. At 4 months, mild developmental delay was noted. At 12 months, MRI revealed stenosis at the level of the foramen magnum and cervicomedullary compression. The compression was secondary due to hypoplasia of the posterior arch of C1. On physical examination at 15 months, she had dolicocephaly, ocular proptosis, hyperterolism, high arched palate, pectus excavatum, and arachnodactyly of the fingers and toes. She was mildly delayed. She had general hypotonia, joint hyperextensibility, especially in the knee and ankle joints. Her deep tendon reflex was not brisk. She had high myopia. A 3D CT scan reveal no evidence of premature closure of cranial sutures, but skull Xp showed elevation of the lesser wing of the sphenoid bone, which was the characteristic sign for craniosynostosis.

This case demonstrates important clinical aspect of SGS. Although cervical vertebral anomalies were described in a few patients with SGS previously, those manifestations were not emphasized. Clinicians should be aware of the craniovertebral junction abnormalities in SGS. Careful evaluation of cervicomedullary region, including the sagittal MRI study, is recommended in all patients with SGS. Exudative vitreoretinopathy was reported only once. Ophthalmologic examination is should be offered to infants with SGS.

**Further evidence for the Hall-Hittner syndrome: A case report.** *T. Jewett, L. Terry.* Dept Pediatrics, Medical Gen, Wake Forest Univ Sch Medicine, Winston-Salem, NC.

CHARGE association is a non-random cluster of congenital anomalies (ocular Coloboma, Heart malformation, choanal Atresia, Retardation of growth and/or development, Genital hypoplasia, Ear anomalies with/without hearing loss) which occurs together more often than expected by chance. Historically, inclusion criteria for diagnosis include: 1) either coloboma or choanal atresia, and 2) four of the six features listed in the CHARGE acronym. Because no single, unifying etiology has been determined, CHARGE has been considered an "association" rather than a "syndrome." Several papers have now been published that have broadened the phenotype, and a significant percentage of affected individuals have been found to have partial semicircular canal hypoplasia/aplasia with or without Mondini malformation. Amiel et al recently described three individuals who had three of the four diagnostic criteria for CHARGE association without coloboma or choanal atresia; all three had semicircular canal agenesis or hypoplasia. They proposed that temporal bone malformations be included as a major criterion for diagnosis and that CHARGE is a specific enough entity to be designated a "syndrome." Graham agrees that a specific, recognizable pattern has emerged among individuals with CHARGE association and proposes that this entity be called the Hall-Hittner syndrome. We report an infant who has three out of four diagnostic criteria for CHARGE association as well as Mondini malformation and dysplasia and/or absence of the semicircular canals bilaterally, adding further evidence to support the Hall-Hittner syndrome as a diagnostic entity.

J.W. was born at 36 weeks to a 33 y.o. G2 P0 SAB1 woman. Soon after birth, he was diagnosed with tracheoesophageal fistula. In addition to the above temporal bone anomalies, he has dysplastic ears, profound sensorineural hearing loss, large secundum atrial septal defect, right facial nerve palsy, and suboptimal growth despite gastrostomy tube placement. Chromosome analysis and FISH for 22q11 deletion are normal.

**New autosomal recessive syndrome resembling Nager syndrome.** *S.J. Kennedy<sup>1,2</sup>, A.S. Teebi<sup>1,2</sup>*. 1) Clinical Genetics, Hospital Sick Children, Toronto, ON, Canada; 2) University of Toronto.

Nager syndrome is an autosomal dominant condition associating mandibulofacial dysostosis and limb anomalies. Individuals with this syndrome typically have malar hypoplasia, ear anomalies, conductive hearing loss, micrognathia, hypoplastic/absent thumbs, radial hypoplasia, and radio-ulnar synostosis. An autosomal recessive form of Nager syndrome may exist based on reports of affected sibs with unaffected parents. We report on sibs, with manifestations resembling Nager syndrome. The parents are a nonconsanguineous phenotypically normal couple of Punjabi descent from an isolated religious community. There is no family history of individuals with a similar medical and developmental problems. The proband has microcephaly, sloping forehead, malar hypoplasia, upper eyelid ptosis, long eyebrows, short and downward slanting palpebral fissures, a large beaked nose, bilateral cleft lip and palate, micrognathia, bilateral microtia and moderate to severe conductive hearing loss. In addition, she showed bilateral hypoplasia of the thumb and thenar eminence. X-rays of the hands revealed bilateral fusions of the capitus and hamate, and short 1<sup>st</sup> and 5<sup>th</sup> metacarpal bones. X-rays of the feet demonstrated bilateral shortness of the 1<sup>st</sup> metacarpal bone and an additional sesmoid bone in the distal portion of the carpal bone on the left. The left talus and lateral cuneiform bone are fused. The proband is mildly developmentally delayed. Chromosome analysis on the proband, including FISH and SKY for cryptic chromosomal rearrangement detection, was normal. The proband's younger brother was born with unilateral cleft lip and palate, beaked nose, bilateral upper eyelid ptosis, bilateral microtia and has moderate to severe conductive hearing loss. Although the spectrum of anomalies in these sibs includes those seen in patients with Nager syndrome, the presence of microcephaly, cleft lip and palate, the peculiar beaked nose, blepharophimosis, ptosis of the upper eye lids, microtia, symmetrical involvement of the thumbs and big toes and developmental delay makes it a distinct entity likely inherited in an autosomal recessive manner.

**A Patient with Supernumerary Nostril and Other Anomalies.** *J. Huber, J.B. Volpon, E.S. Ramos.* Medicine School of Ribeirao Preto, University of Sao Paulo, Ribeirao Preto, Sao Paulo, Brazil.

Nose duplication includes polirinia, double nose, and supernumerary nostril. It is an extremely rare congenital anomaly with few reports in the literature. The descriptions include only sporadic cases and rarely associated with other anomalies like naso-ocular cleft. Some authors suggest that the duplicate nose results from the evolution of four nasal pits in the embryological development of the face and the supernumerary nostril results from an accessory nasal pit located laterally to the nasal laminae, not interfering with their fusion and the formation of the one nasal septum. The objective of the present work is to report a female patient with a supernumerary nostril associated with choanal atresia, coloboma of the right lower eyelid, external genitally hypoplasia and limbs anomalies that include fifth fingers clinodactily, genu varum and knees joints with restriction movements, club feet with a syndactily between the second and third toes. An axial computed tomography scan showed an asymmetry of maxilla sinuses, larger on the left side, with normal aeration; nasal septum dislocation; malformation of the right nasal cavity with choanal atresia; a third nostril lateral of the left nostril without communication with the nasal cavities. X-ray of the hip showed asymmetry of the proximal femora epiphyses which the smaller on the right side. There is a patient reported in the literature with a supernumerary nostril, bilateral choanal atresia, microphthalmia, coloboma of the iris and a total ablatio of the retina in the right eye. The patient was diagnosed as CHARGE association. Our patient does not fulfill the diagnostic criterias for CHARGE syndrome. Furthermore the patient has limb anomalies that are rare in CHARGE syndrome. As she has not all criteria for this syndrome we believe that the set of malformations may be represents a new syndrome. Supported by: FAEPA, CAPES.

**SHPRINTZEN-GOLDBERG SYNDROME IN A FAMILY WITH AUTOSOMAL DOMINANT TRANSMISSION AND VARIABLE EXPRESSIVITY.** *V.L.G.S. Lopes, J. Zimmermann, D.Y.J. Norato.*

Departamento de Genética Médica, Faculdade de Ciências Médicas, Universidade Estadual de Campinas (UNICAMP), Campinas, SP, Brazil. Medical genetics Department, State University of Campinas, Campinas, So Paulo, Brasil.

The Shprintzen-Goldberg syndrome (SGS) is mainly characterized by craniosynostosis, marfanoid habitus and skeletal abnormalities. Mental retardation is variable. Mutations on FBN1 gene (15q21.1) have been described in some cases. Dominant pattern of transmission is suggested, but familial cases with male-to-male transmission have not been reported before. A similar picture with normal intelligence has been considered a different entity (Marfanoid habitus, craniosynostosis and normal intelligence - MHCNI) We describe a family presenting variable features of SGS in 4 individuals, a father and 3 children. The propositus is a 13 year-old boy, referred to us for evaluation for mental retardation, premature fusion of sutures and dysmorphic findings. On physical examination, we observed flattened occiput, low set and dysmorphic ears, facial asymmetry, widened frontal, ocular hypertelorism, downslanting palpebral fissures, prominent eyes, malar hypoplasia, beaked nose, shortened philtrum, thick lips, high and narrow palate, absence of upper lateral incisors, widened spaced nipples, scoliosis, dolichostenomelia and arachnodactyly. His father presented downslanting palpebral fissures, beaked nosed, pectus carinatum, scoliosis and dolichostenomelia. Ophthalmological evaluation detected severe myopia in the father and the propositus. Chromosomal analysis of the propositus and of his father were normal (46,XY). His two sisters also presented some characteristics, such as widened frontal, dysmorphic ears, high and narrow palate, pectus excavatum, widened placed and hypoplastic nipples, scoliosis, dolichostenomelia, and arachnodactyly, with normal intelligence. Cardiological evaluation of all dolichostenomelia, arachnodactyly the individuals were normal. This family would confirm dominant pattern of transmission with variable expressivity. It would also suggest that SGS and MHCNI could be extremes of a same condition.

**Congenital laryngotracheal webs and early onset colorectal carcinoma in a family with three-generation transmission of del(22q11.2).** *J. Larsen-Haidle, K. Keppler-Noreuil, A.B. Kanis, A. Muilenburg, J. Welch, Q. Qian, L. Yang, S. Patil.* Pediatrics, Univ Iowa, Iowa City, IA.

Microdeletion of chromosome 22q11.2 has a wide phenotypic spectrum with variable associated anomalies. Familial transmission of this deletion in two-generations has been reported previously. To our knowledge, we report, the first three-generation transmission of del(22q11.2) in one family who had unique findings of congenital laryngotracheal webs (CLW) and early onset colorectal carcinoma.

The proband, a 53 year-old WF, presented with psychiatric illness and mild mental retardation. As a newborn, she was diagnosed with a VSD, and severe respiratory problems secondary to a CLW. She was diagnosed with sigmoid colon adenocarcinoma at 41 years. Her daughter presented with apparent hypertelorism; while her grandson had a laryngotracheal web, hoarse voice, hypertelorism, VSD, and anal stenosis. All three individuals had del(22q11.2).

CLW are rare defects that may occur alone or in association with other anomalies. Two families with CLW, congenital heart disease, and short stature have been reported; however, analysis for del(22q11.2) was not performed. These findings suggest that CLW may be caused by the deletion. The early onset of colorectal malignancy in our case is of interest. Recently, an unidentified putative tumor suppressor gene involved in colorectal carcinoma has been localized to 22q. The loss of heterozygosity for alleles on certain chromosomes, including chromosome 22q, has been identified in nearly 50% of colorectal tumors. Further studies are needed to assess whether individuals with del(22q11.2) are at increased risk for developing this malignancy.

**Unusual GI pathology in a patient with Rett Syndrome (RS).** *K.A. Washington<sup>1</sup>, E.J. Hoffenberg<sup>2</sup>, C.-H. Tsai<sup>3</sup>, E.R. Elias<sup>1,3</sup>.* 1) Pediatrics, Children's Hospital, Denver, CO; 2) Department of Gastroenterology, Children's Hospital, Denver, CO; 3) Department of Genetics, Children's Hospital, Denver, CO.

Rett Syndrome (RS), an X-linked neurodegenerative disorder with progressive encephalopathy, was recently found to be caused by a mutation in the gene coding for production of methyl-CpG-binding protein 2 (MECP2). Girls with RS typically present with normal growth and development for the first six to eighteen months of age, then show a slow deterioration.

Patients with RS frequently present with gastrointestinal complaints, among which constipation is common. We would like to present an RS patient with very unusual gastrointestinal pathology. This 10-year-old girl with a typical neurodevelopmental course for RS, and a documented missense mutation in MECP2 (T158M, felt to be a disease-causing mutation which has been identified in many other RS patients), presented with symptoms suggestive of colitis, consisting of constipation, decreased appetite, and noticeable hematochezia. At colonoscopy, submucosal polypoid lesions were present throughout the left colon. Pathology review suggested pneumatosis cystoides intestinalis (PCI), a rare condition in pediatrics, associated with constipation. The patient's symptoms continued despite prednisone, but improved upon withdrawal of lactulose and aggressive treatment of constipation. An extensive literature search revealed no prior association between RS and PCI.

This case illustrates that bowel problems may be associated with RS, perhaps due to an effect of an MECP2 mutation on intestinal function. To further evaluate this hypothesis, and to determine if there is any genotype/phenotype correlation between specific mutations and clinical manifestations, it will be important to document the frequency and types of intestinal disorders found in RS patients with confirmed MECP2 mutations.

**Hidrotic Ectodermal Dysplasia with lacrimal duct stenosis in a mother and daughter: New disorder or variant of a known disorder?** . *M.S. Williams<sup>1</sup>, K.D. Josephson<sup>2</sup>*. 1) Dept Pediatrics, Gundersen Lutheran Medical Ctr, La Crosse, WI; 2) La Crosse Regional Genetic Services Project, La Crosse, WI.

A child was referred for evaluation of brittle hair and nasolacrimal duct obstruction. Family history suggested that the mother was also affected, but no other affected family was identified. There was no family history of clefting, limb anomalies or other features suggestive of an ectodermal dysplasia. The patients were found to have an hidrotic ectodermal dysplasia (ED) with nasolacrimal duct obstruction. The ED involved the scalp hair permanent teeth but not deciduous teeth, and nails. Both individuals had normal sweating by report. The child at age 4 still had significant nasolacrimal duct stenosis. The mother had epiphora despite two probes of the tear ducts. No other unusual features were seen in either individual. Inheritance is compatible with either Autosomal Dominant (AD) or X-linked with mild carrier expression.

Over 150 forms of ED have been clinically described. The patients do not clearly fit into any of the known AD or X-linked EDs. Clinical features match those of a Lebanese kindred with a presumed Autosomal Recessive (AR) hidrotic ED (OMIM 602401). It is possible the disorders may be allelic. Alternatively, this family could represent a variant of X-linked anhidrotic ED (OMIM 305100) or Ectodermal Dysplasia, Ectrodactyly and Clefting syndrome (EEC3, OMIM 604292). EEC3 is caused by mutations in the p63 gene. Lacrimal duct obstruction is common in EEC syndrome. Families with p63 mutations have also been reported with two of the three cardinal features, as well as isolated clefting and ectrodactyly. A pure ED associated with a p63 mutation has not been reported. Nonetheless, given the range of conditions associated with p63 mutations combined with the presence of nasolacrimal duct obstruction it seems a reasonable candidate gene for this family. Mutation analysis will be undertaken.

We suspect that this family represents a hitherto unrecognized variant of a known ED syndrome rather than a new syndrome.

**Homozygosity for a premutation of the FMR1 gene and normal phenotype in two sisters from a family with fragile X syndrome.** *H. Thiele*<sup>1</sup>, *H. Peters*<sup>2</sup>, *D. Bahrke*<sup>3</sup>, *I. Hansmann*<sup>1</sup>. 1) Institut fuer Humangenetik und Medizinische Biologie, Martin-Luther Universitaet, Halle/S; 2) Medizinische Genetik, Charité, Berlin; 3) St. Barbara Krankenhaus, Halle/S, Germany.

Fragile X syndrome is one of the most common causes of mental retardation due to an expansion of a CGG repeat motif at the 5' UTR of the FMR1 gene during transmission of a premutation in a heterozygous female. According to our knowledge no female with homozygosity for the premutation and only 3 females with compound heterozygosity (full mutation on one X chromosome and premutation on the other X chromosome) have been described so far (Mila M et al. 1996; Russo S et al. 1998; Linden MG et al. 1999). We report on an unusual family with fragile X syndrome in a boy and homozygosity for a premutation in his mother and his aunt. The 4-year-old boy was born after an uneventful pregnancy, birth weight was 3050g and length 49cm. At an age of 2 years he displayed slight dysmorphic facial features, behavioral problems, a retarded speech and language performance. Southern blot analysis revealed a full mutation with a complete methylation of the EagI-restriction site at the 5' UTR of the FMR1 gene. Analysis of his 25-year-old mother revealed a premutation in the range of 70-130 CGGs on one X chromosome and a further premutation of 54 CGGs on the second X chromosome. Her 21-year-old sister was shown to have 2 premutations as well but in the range of 100-200 repeats. Both sisters do not show any sign of intellectual impairment, motor retardation, speech problems, dysmorphic features or irregularities of menstrual cycles. This demonstrates for the first time that homozygosity for a FMR1 premutation remains without clinical consequences for carriers. Southern blotting of the clinically normal parents revealed a premutation of approx. 200 repeats in the father and of approx. 100 repeats in the heterozygous mother. Their maternal grandmother was shown to have together with a normal allele mosaicism for a full mutation and a premutation. Apparently, both daughters inherited a contracted paternal premutation. There is no evidence for consanguinity in this unusual family.

**Severe cases of femoral hypoplasia-unusual facies syndrome may have increased risk for airway obstruction.**

*P.G. Wheeler<sup>1</sup>, J.Y. Wang<sup>1</sup>, M. Volk<sup>2</sup>*. 1) Dept Pediatrics, Div Genetics, New England Medical Center, Boston, MA; 2) Div Pediatric Otolaryngology, Dept Otolaryngology, New England Medical Center, Boston, MA.

Femoral hypoplasia-unusual facies syndrome (FHUFS) is a heterogeneous disorder. Features include short femurs, hearing loss, cleft palate, and micrognathia. We report on 2 severe FHUFS patients with significant airway obstruction, which has not been previously described. Close supervision of the airways of FHUFS patients should be considered to avoid potentially lethal complications.

Case 1: Patient 1 was the product of a twin gestation born to a woman with unrecognized insulin-dependent diabetes until 16 weeks. Prenatal sonograms showed short femurs and a hypoplastic sacrum thought to be due to caudal regression. Delivery at 36 weeks gestation was via C-section for breech presentation. This infant had respiratory distress requiring intubation for the first 24 hours. Post-extubation he had severe stridor requiring re-intubation. He was extubated gradually the second time and did well. Since then he has had multiple episodes of stridor and has been diagnosed with right vocal cord paralysis. In addition, he had a recurrent left supraglottic saccular cyst, which resolved post surgery. Other problems include hypoplastic femurs, club feet, cleft palate, micrognathia, cryptorchidism, small kidneys, and partial sacral agenesis. His twin sister had no anomalies.

Case 2: Patient 2 was the product of an uncontrolled insulin-dependent diabetic. Prenatal sonograms suggested caudal regression. The infant was delivered at 36 weeks' and had respiratory distress, resulting in a difficult intubation. At 5 years, she still requires a tracheostomy tube and intermittent ventilator support at night. The cause of her airway compromise is thought to be due to micrognathia and severe tracheomalacia. She has had multiple hospitalizations for respiratory distress. Other problems include absence of her right leg, severe shortening of the left femur, hypoplasia of the lower leg, sacral agenesis, unilateral renal agenesis, camptodactyly, cleft palate, micrognathia, and mixed hearing loss.

**Autistic disorder in Sotos overgrowth syndrome.** *S. Sigurdardottir*<sup>1</sup>, *K. Kristjansson*<sup>2</sup>. 1) State Diagnostic & Counseling Center, Kopavogur, Iceland; 2) Department of Pediatrics, University Hospital of Iceland, Reykjavik, Iceland.

Sotos syndrome is a rare nonprogressive neurological condition of an unknown etiology. Behavioral patterns that frequently have been described in patients with Sotos syndrome include tantrums, destructiveness, eating and sleeping difficulties, stereotypic behavior and social withdrawal. Of the approximately 300 cases identified only one had associated autism. We describe a patient with Sotos syndrome and autistic disorder. He was a full term infant. Head circumference at birth and at the age of three was above the 98th percentile. Facial features were characteristic for Sotos syndrome, including a prominent forehead and prognathism. Cerebral gigantism was confirmed with MRI of the brain which in addition showed occipital polymicrogyria. Bone age at the age of three was slightly delayed. He had severe hypotonia in infancy with delayed motor and language milestones. The diagnosis of autism was based on results of The Autism Diagnostic Interview (ADI-R) at the age of three years and eight months and The Childhood Autism Rating Scale (CARS). Verbal IQ on the WPPSI-R at the age of five was 65 and performance IQ was 106. Although most cases of Sotos syndrome have advanced bone age and mental retardation those are not strict diagnostic criteria for this syndrome. This case adds to the description of the behavioral phenotype associated with Sotos syndrome where social withdrawal and stereotypic behaviors are prominent. These features were present in our patient to the degree that diagnostic criteria for autistic disorder were reached. Quantification of behavioral symptoms has clinical implications both for medical and behavioral treatment as well as in family counseling.

**Siblings with multiple anomalies: Crane Heise vs. new syndrome?** *D.J. Zand<sup>1</sup>, D. Huff<sup>2</sup>, D. Carpentieri<sup>2</sup>, N. Spinner<sup>1</sup>, E. Zackai<sup>1</sup>.* 1) Div of Human Genet and Mol Biol.; 2) Dept of Path, The Children's Hospital of Philadelphia, Philadelphia, PA.

We present 2 sibling fetuses with a severe phenotype. Pregnancies were electively terminated due to ultrasound identification of multiple anomalies. Both were SGA and showed absence or hypoplasia of frontal, parietal, and occipital bones. They also showed absence of hard and soft palates. Both had severe micrognathia and hypertelorism. One had absence of cervical vertebral bodies and shortened clavicles. Both showed absent middle phalanges of hands and feet, clubfeet and multiple contractures. One showed a congenital heart defect consisting of thickened walls of ascending aorta and pulmonary artery. Brain pathology for one noted agenesis of the corpus callosum and cingulate gyrus. One fetus demonstrated absence of body and scalp hair, anisospenia, and redundant loops of bowel with aberrant attachments. High-resolution karyotype on both blood and amniotic fluid cells was 46,XY (fetus 1) and 46,XX (fetus 2). FISH probes for 22q11.2 deletion, Williams syndrome, and 18p were all normal (fetus 2). Parental telomeric analyses were normal. Crane and Heise (*Pediatrics* 68: 235-237, 1981) described three SGA sibling fetuses (2 male, 1 female) with severe developmental anomalies, including: poorly mineralized calvarium, dysmorphic facies with associated cleft palate, micrognathia, upturned nares, and apparent ocular hypertelorism, and musculoskeletal anomalies including absence of cervical vertebrae and clavicles, clubfeet, and soft tissue syndactaly. Autosomal recessive inheritance was presumed. Our cases were also SGA and showed poor mineralization in one or more cranial bones, absence of cervical vertebral bodies, agenesis of hard and soft palates, severe micrognathia, hypertelorism, clubfeet. One case had shortened clavicles while the other had agenesis of the corpus callosum. In contrast, these fetuses have hypoplasia or absence of middle phalanges of both hands and feet without soft tissue syndactaly, structural cardiac defects, as well as other internal organ anomalies. These differences may represent either a phenotypic variation of Crane Heise Syndrome or a new syndrome.

**Optic Atrophy, severe epilepsy and mental retardation: A novel autosomal dominant disorder in a large family.**

*T. Sahoo<sup>1</sup>, D.W. Stockton<sup>1</sup>, D. Armstrong<sup>2</sup>, R.A. Lewis<sup>1</sup>, A.L. Beaudet<sup>1</sup>.* 1) Dept Human & Molec Gen, Baylor College Medicine, Houston, TX; 2) Dept of Pathology, Baylor College of Medicine, Houston, TX.

Although optic atrophy, seizures and mental retardation can be seen as components of a number of disorders of varying etiology including mitochondrial defects, they are not reported to occur in combination as a single gene disorder with high penetrance. We report here a six-generation family segregating optic atrophy, severe seizures with frequent status epilepticus in adolescence, and variable mental retardation; inheritance appears to be autosomal dominant with high penetrance. The family includes individuals across six generations, and the number of affected members ( from family history, medical records and clinical evaluations since 1980) is about 18. Most affected members have progressive optic atrophy of insidious onset leading to significant visual impairment in many and blindness in at least three individuals. The age of onset of the visual symptoms has been variable with earliest diagnosis at 11 years of age. Seizures of a tonic-clonic nature affects almost all the individuals with optic atrophy. Episodes of status epilepticus in some of the affecteds has required constant medication and aggressive management. In two individuals with adolescent onset seizures, progressive increase in severity and refractoriness to medical therapy led to surgical hemispherectomy. Mental retardation of a mild to moderate degree is present in a number of affecteds but is not a constant association. Initial simulation studies indicate a maximum achievable LOD score of 5.331 with a mean of 2.578 (at  $q=0.05$ ). Efforts are underway to identify linkage by a whole genome scan using markers spaced at 10 cM intervals. To our knowledge this unique family represents a new autosomal dominant optic atrophy syndrome associated with severe epilepsy and mental retardation.

**Severe growth retardation in a patient with a deletion of the short arm of chromosome 3: A case study.** *J. Van Brunt<sup>1</sup>, H. Andersson<sup>1, 2</sup>, M.M. Li<sup>1, 2</sup>.* 1) Hayward Genetics Center, Tulane University School of Medicine, New Orleans, LA; 2) Department of Pediatrics, Tulane University School of Medicine, New Orleans, LA.

Deletion of the distal portion of the short arm of chromosome 3 is a rare occurrence. To our knowledge, only 34 cases have been reported in the literature since the first description of this syndrome by Verjall and DeNef in 1978. Due to its variable phenotypic expression, it is assumed that the 3p- syndrome represents a contiguous gene syndrome with an undefined number of genes contributing to the phenotype. The most common phenotypic expressions that characterize the syndrome include intrauterine and postnatal growth retardation, psychomotor retardation, craniofacial anomalies, skeletal anomalies, congenital heart disease, urinary tract anomalies, and renal anomalies. We describe a newborn patient with a de novo deletion of 3p25.1@3pter and compare the clinical manifestations with a review of clinical features from 34 previously described cases. Our patient was female and born to a 14-year-old mother (gravida 1 para 1) and a 16-year-old father. Physical examination revealed some commonly found craniofacial anomalies including ptosis of the eyelids, microcephaly, long and flat philtrum, displastic ears with a ear pit on the left ear. She had severe, proportionate, growth retardation. The patient also manifested hypoplastic fingers and toes with absent nail beds, which have not been previously reported. This raises the possibility that there is a gene or genes located in this region with responsibility for digital development. The deletion may cause either haploinsufficiency of the gene (autosomal dominant trait), or loss of heterozygosity if the gene on the normal homologous chromosome was mutated (autosomal recessive trait). Most of the current research on 3p- syndrome has been directed at identifying genes that map in the deleted region and connecting their developmental function with specific phenotypic expressions of the syndrome. As more information about this rare syndrome is collected, a better phenotype-genotype correlation will evolve.

**Atypical presentations of Bloom syndrome.** *H. Zhao, R.J. Hopkin, H.M. Saal.* Division of Human Genetics, Children's Hosp Medical Center, Cincinnati, OH.

Bloom syndrome is a rare autosomal recessive condition caused by impaired DNA repair. Characteristic findings include congenital dwarfism, sun-sensitive telangiectatic rash, hypo- and hyperpigmented skin lesions, chromosome instability, and predisposition to malignancy. A significant number of affected individuals are of Ashkenazi Jewish ancestry, suggestive of a founder effect. We have evaluated 5 new non-Jewish patients with Bloom syndrome, all diagnosed by history of pre- and postnatal growth deficiency and microcephaly. All cases were confirmed by demonstration of increased sister chromatid exchange. No patient had a history of skin rashes or photosensitivity. Additional unexpected features include mental retardation, intestinal malrotation with intussusception, kyphosis, hypoplastic thumbs, absent ovaries, iris and retinal coloboma, glucose intolerance, and idiopathic pancreatitis. Hypoplastic thumbs in one case led to an initial erroneous clinical diagnosis of Fanconi anemia; however, DEB stimulated chromosome breakage analysis was normal. Of interest is that 3 of our patients are of Appalachian ancestry and 2 (male and female siblings) are of German ancestry. These findings are suggestive of a specific mutation with founder effect. Molecular studies are currently being pursued.

In Bloom syndrome, the presence of growth deficiency and microcephaly may be the only presenting signs. Therefore, this condition may exist in the absence of typical skin findings. Furthermore, the presence of other atypical malformations, such as radial anomalies and intestinal malrotation do not necessarily exclude Bloom syndrome as a diagnosis.

**Reynolds Acrofacial Dysostosis: Report of an Additional Family.** *A.R. Turner, D. Conrad, W. McGuirt, V. Shashi.* Department of Pediatrics, Section on Medical Genetics, Wake Forest University School of Medicine, Winston-Salem, NC.

Since the association between acral anomalies and mandibulofacial dysostosis was first described, the acrofacial dysostoses (AFDs) have been defined as a heterogeneous symptom complex. Reynolds described an Idaho family with AFD of unique presentation in 1986. Reynolds AFD is distinguished by consistent craniofacial findings, variable manifestations of acral anomalies in the radial ray, normally appearing ears, and mild congenital hearing loss. We present the second reported family with Reynolds acrofacial dysostosis. The proband was brought to our attention at 19 months, due to unusual facial features. His examination revealed all of the hallmark craniofacial features, including ptosis, hypertelorism, malar hypoplasia, and micrognathia. The ears were simple and normally set. Radiographs of the hands confirmed bilateral metacarpal shortening. Audiometry revealed no evidence for hearing loss. His development has been normal throughout four years of follow up. The proband's mother and his five year old maternal half sister have mild to moderate conductive hearing loss, normal intelligence, and both share the proband's collection of physical features. The proband has an additional maternal half sister and a half brother who have no features suggestive of acrofacial dysostosis. Pedigree analysis of the immediate family suggests dominant inheritance, with minimal variability among affecteds. The proband's mother reports a paternal first cousin once removed with marked ptosis and a facial appearance suggestive of Reynolds AFD. The intervening paternal relatives are reported to be free of any outward features of Reynolds AFD. Because extended family members may have subtle features of Reynolds AFD that would not bring them to the attention of a medical geneticist, we cannot fully evaluate the possibility of variable penetrance and expressivity. However, this family provides the first suggestion of broadly reduced penetrance and expressivity of Reynolds AFD within a single family. Additional investigation of this intriguing possibility may ultimately lead to a better understanding of this very rare form of AFD.

**Pallister-Killian Syndrome: A study of three unrelated Arab Families.** *L.A. BASTAKI, KAMAL.K NAGUIB, SADIKA.A. AL-AWADI, SAYED.A. GOUDA.* Maternity Hosp, Kuwait Medical Genetic Ctr, Khaldiya, Kuwait.

Here in, we are reporting three unrelated Arab families with Pallister-Killian Syndrome in order to highlight the clinicogenetic heterogeneity of this rare syndrome. They are presented with severe global developmental delay, Normal birth weight, hypotonia, craniofacial dysmorphism & hypopigmentation involving mainly the face. The constant craniofacial features were wide anterior fontanel, frontal and partial bossing and bolding flat nasal bridge, prominent philtrum and low set posterior rotated ears. Chromosomal study using peripheral blood was normal while fibroblast culture revealed super numerrary isochromosome for the short arm of chromosome 12 in two third of the examined cells. The pathogenesis, clinical picture, genetic counselling and prognosis are discussed. Key word: Pallister-Killian syndrome, isochromosome 12p, fibroblast culture, mosaic tetrasomy 12p, prenatal diagnosis.

**Prenatal and postnatal multiple congenital abnormalities in a girl with a telomeric X;13 unbalanced**

**translocation.** *I.M. Gaspar<sup>1</sup>, C.F. Pinto<sup>1</sup>, A.J. Macedo<sup>2</sup>, S. Azevedo<sup>3</sup>, J. Guimaraes<sup>3</sup>, L. Sampaio<sup>3</sup>, M. Goncalves<sup>3</sup>, J. Correia<sup>4</sup>, A. Ferreira<sup>4</sup>, M.J. Feijoo<sup>1</sup>.* 1) Medical Genetics Dept, Egas Moniz Hosp, Portugal; 2) Dept of Pediatric Cardiology, Sta Marta Hosp, Portugal; 3) Clinic University of Pediatric, Sta Maria Hosp, Portugal; 4) Dept of Obstetrics, Alfredo Costa Maternity Hosp, Portugal.

A 25 year old primigravida was referred for amniocentesis due to multiple congenital anomalies identified in her fetus by an obstetric ultrasound at 24 wks gestation with IUGR, a severe ventricular disproportion with a hypoplastic left ventricle. Cultured amniocytes revealed a 45,X,der(X)t(X;13);(q28;q12.1),-13 karyotype. The child was born at 40 wks gestation. Her height was 43cm, weight 2190g, and was found to have multiple dysmorphic features and congenital anomalies including turricephaly, prominent forehead, hypertelorism, downslanting palpebral fissures, broad flat nasal bridge, dysplastic ears, long thumbs and long big toes. Postnatal cytogenetics studies revealed that there was skewed X inactivation, with the normal X chromosome inactivated in 83.4% and the der(X) inactivated in 16.6% of the metaphases observed. FISH using a (TTAGGG)<sub>n</sub> probe demonstrated an interstitial telomere on the der(X) chromosome, signifying that the breakpoint was not at the terminal end of Xq28 but at qter. Cardiac exam confirmed a small, but not hypoplastic, left ventricle, a dysplastic pulmonary valve, a large patent ductus arteriosus and pulmonary hypertension. Brain CT scan revealed a partial corpus callosum agenesis. She was surgically treated for gastroesophageal reflux and a hiatal hernia at 4 mths old and was enucleated for unilateral retinoblastoma at 12 mths old. The occurrence of balanced/unbalanced structural anomalies involving X autosome translocations is very rare. Inactivation and spreading effect contribute to the severity of the phenotype and pathogenesis. This patient displays clinical manifestations of functionally monosomic 13q owing to the spreading of X inactivation.

**Y-chromosome specific sequences detection by PCR and FISH analysis in genomic- and gonadal-DNA in patients with Ullrich-Turner syndrome.** *F.J. Alvarez Nava, M. Soto-Alvarez, L. Borjas-Fajardo, M.A. Sanchez, A. Rojas-Atencio, E. Fernandez, M.C. Martinez-Basalo.* Unidad de Genetica Medica, Universidad del Zulia, Maracaibo, Zulia, Venezuela.

Ullrich-Turner syndrome (UTS) is associated in 40-60% with 45,X karyotypes, whereas the remaining cytogenetics findings have structural anomalies in second sexual chromosome (X or Y) in form pure or with mosaicism. It has been proposed that all females with UTS and 45,X karyotypes carry a cell line containing two sex chromosome at low level of mosaicism. This mosaicism is undetectable by standard cytogenetics analysis. Theoretically, this hidden mosaicism may has a chromosome Y in 40% of the cases. Gonadal dysgenesis seen in UTS patients is associated with gonadoblastoma when Y-chromosome derived material is present in their genome. So it is crucial to carry out molecular analysis in these subjects to rule out Y-sequences. The present study was performed to examine the presence of Y-chromosome material in DNA from lymphocytes and gonads in UTS patients. Fifty Venezuelan patients were screened by polymerase chain reaction (PCR) to detect Y-chromosome-derived fragments. Patients with virilization and/or with positive Y-sequences by PCR underwent gonadectomy. Three patients were positive in blood peripheral-DNA to Y-sequences specific. None exhibited signs of virilization. One of them presented gonadoblastoma and dysgerminoma contralateral at 4 years old. She had received treatment with growth hormone. All patients had Y chromosome material in gonads. FISH confirmed their Y-chromosome origin. Our results suggest that the molecular analysis must be applied for detection of Y-chromosome in UTS patients before onset of therapy with HG.

**Duplication of 8p23.1: Characterization of 8 new cases.** *S.L. Graw*<sup>1</sup>, *C.-H. Tsai*<sup>2</sup>, *L. McGavran*<sup>3</sup>. 1) Eleanor Roosevelt Inst, Denver, CO; 2) Department of Pediatrics, Division of Genetics and Metabolism, The Children's Hospital, Denver, CO; 3) Colorado Genetics Laboratory, Department of Pathology, University of Colorado Health Sciences Center, Denver, CO.

Multiple patients with rearrangements involving 8p23.1 have been reported, including inverted and tandem duplications of 8p23.1, deletions of 8p23, and pericentric inversions (p23q22). Recently, Barber et al. (1998) reported 7 new cases of duplication of 8p23.1, and reviewed 5 previously reported cases. O'Malley and Storto (1999) reported another case ascertained prenatally with isolated duplication of 8p23.1. Both studies concluded that this duplication has no clinically identifiable phenotype, and represents an inconsequential anomaly. The vast majority of these cases were ascertained through prenatal diagnosis, and in many cases there has been no long-term follow-up to examine the possibility of developmental delay or other problems that may be revealed after the neonatal period. Here we report 8 new families with duplication of 8p23.1 ascertained at a tertiary care facility with both outpatient and inpatient genetic services. Our data suggest that cardiac abnormalities, short stature, hypotonia, and mild developmental delay are preferentially associated with this chromosomal anomaly. In some cases, the cardiac defects were significant, and resulted in the deaths of 2 patients in the neonatal period. In addition, we identified a preponderance of male (9 of 13 total) carriers of duplication of 8p23.1. Other findings in individual patients with duplication of 8p23.1 include autistic-like features (found in 2 patients), seizures, scoliosis, ulnar stenosis, and mild organomegaly. Additional molecular and cytogenetic analyses are underway to determine the molecular basis behind the dup8p23.1 chromosome formation.

**Sex reversal 2001: Some answers, more questions.** *J.J. Dowhanick-Morrisette<sup>1</sup>, L. Celle<sup>1</sup>, C. Robert<sup>2</sup>, L. Bason<sup>1</sup>, D. McDonald-McGinn<sup>1</sup>, D.A. Driscoll<sup>2</sup>, E.H. Zackai<sup>1</sup>, N.B. Spinner<sup>1</sup>.* 1) Dept Human Gen & Molec Biol, Children's Hosp Philadelphia, Philadelphia, PA; 2) Department of Genetics, University of Pennsylvania, Philadelphia, PA 19104.

Sex is determined by a regulatory cascade of sex-linked and autosomal genes, with approximately 1/20,000 individuals demonstrating abnormalities of sex determination. The study of sex reversed individuals (XX males and XY females) has played a large role in the elucidation of the genes involved in these pathways. Many of the genes involved in sex determination encode transcription factors such as SRY, SOX9, DAX-1, Wnt-4 and SF1, which are expressed during gonadal development. XY females have been found to have mutation or loss of the SRY gene, the androgen receptor gene (AR), duplication of DAX-1, and several malformation syndromes. The majority of XX males have been found to have SRY translocated to an autosome, and rarely duplication of SOX9. There is no explanation for the sex reversal in 20-30% of XX males. We report 5 cases of sex reversal, two 46,XY females and three 46,XX males. Case 1 is an infant who presented with bilateral inguinal hernias and undescended testicles were identified. Family history was significant for a maternal aunt, known to be a 46,XY female. Chromosome analysis demonstrated a 46,XY,inv(X)(q11.2q28) karyotype. FISH using the AR gene demonstrated a split signal on each side of the inversion breakpoint, consistent with disruption of the AR. Case 2 is a XY female who presented at 14 years of age with short stature and mental retardation and molecular studies are pending. Cases 3 and 4 are both 46, XX males who were studied because of dysmorphic features, with normal male genitalia. PCR and FISH for SRY were done and found to be negative in both patients. Additional studies included analysis of SOX9 and Wnt-4, which were both normal by FISH analysis. Case 5 is an XX male who was found to have a submicroscopic rearrangement involving the SRY gene, with translocation to one X chromosome that was identified by FISH. These cases illustrate the wide range of explanations for sex reversal. Further studies are in progress to explain the sex reversal in patients 2,3 and 4.

**Molecular cytogenetic and phenotypic characterization of a four generation family with partial trisomy 9p. S.**

*Carlo<sup>1</sup>, J. Valencia<sup>3</sup>, D. Acevedo<sup>2</sup>, I. Ramos<sup>2</sup>, A. Santiago-Cornier<sup>2,4</sup>.* 1) Human Genetics, Mount Sinai School of Medicine, New York, NY; 2) Genetic Div, Ponce School of Medicine, Ponce, PR; 3) Dept. of Nursing, Univ. of Puerto Rico at Arecibo, Arecibo, PR; 4) Dept. of Pediatrics, Ponce School of Medicine, Ponce, PR.

Since the first case of partial or complete trisomy 9 was described in 1970, thousands of cases has been described making chromosome 9 anomalies one of the most frequent. In most of the described cases in medical literature, the trisomic segment was inherited from reciprocal translocation and to a lesser extend due to di-novo duplications. We will present a four generation family with 11 affected individuals with partial trisomy 9p and 10 asymptomatic balanced translocation carriers resulting from a familial malsegregation of an insertional translocation involving chromosomes 9 and 10. Characterization of the 9;10 translocation was performed by using Multicolor-FISH technology and confirmed with spectrum orange and green painting probes. Examination of the G-banding pattern suggested an inverted insertion of a segment of 9p into band q25.2 of chromosome 10. 82% of the non affected family members are carriers of the balanced translocation suggesting a preferential meiosis drive. No reproductive problems or miscarriages were reported in any of the balanced translocation carriers. Dysmorphic features of affected individuals include high palate, protruded and large ears, flat occiput, clinodactyly of fifth digits, small penis and testicular volume. Short as well as tall stature was observed in individuals with the partial trisomy. To our knowledge this is the first instance of partial trisomy 9p occurring in four consecutive generations.

**Double partial trisomy 15q;17q, in a boy by a 3:1 segregation of a balanced translocation.** *G. Castineyra<sup>1</sup>, J. Herrera<sup>1</sup>, M.E. Mollica<sup>2</sup>*. 1) Genetics, Lomas de Zamora, Fundacion Cientifica del Sur, Buenos Aires, Argentina; 2) Centro Nacional de Genetica Mdica, Buenos Aires, Argentina.

We report a case of 13 years old follow up since he was born. Parents are not consanguinious and had previously a normal girl and two pregnancy lost. He present severe mental retardation, psycologic impairment, self mutilation, short stature and phenotype abnormalities. from cytogenetics studies using G banding techniques and confirmed by Fish, he present an extra chromosome derivated 15. His karyotipe is 47,XY,der(15)t(15;17)(q11.2,q23). This unbalanced finding was derived from a balanced translocation (15q;17q) in the normal father, also present in his daughter. Main clinical features in the proband included those typical findings in the described distal trisomy 17q; but also some of the proximal trisomy 15q liike: moderate hearing loss, lack of speech but presence of others reasonable madurative patterns and anterior displaced anus. He doesn't present convulsive disorders and congenital heart disease. By imging techniques other anomalies were found. This patient is compared with other reported cases in the literature. We suggest that described different phenotypes are due to the chromosomes involved in the rearregment, making counseling difficult.

**Ascertainment of chromosome 22q11.2 microdeletion in congenital heart defects.** *M.G. Bialer<sup>1</sup>, A. Yenamandra<sup>2</sup>, R. Klein<sup>1</sup>, P. Koduru<sup>2</sup>, L. Mehta<sup>1</sup>.* 1) Dept Pediatrics, Div Medical Genetics; 2) Cell Genetics Lab/Pathology, North Shore Univ. Hospital/NYU Medical Center, Manhasset, NY.

Microdeletion of chromosome 22q11.2 is associated with a highly variable phenotype that includes diGeorge, velocardiofacial and Opitz syndromes as well as apparently isolated congenital heart defects and cleft palate. Results of testing at our center since 1996 are summarized. Of 106 patients tested with the diGeorge syndrome critical region probe, Oncor/TUPLE1(Vysis), 12 were deleted (11%). Information was reviewed on these 12 pts. and 68 non-deleted pts. The commonest reason for referral was congenital heart defect (CHD)(60/80). Other indications included multiple congenital anomalies or cleft palate. Most pts. were neonates (57/80). Heart defects in deleted pts. were tetralogy of Fallot (TOF)(8/12), interrupted aortic arch (IAA)(3/12)and IAA with truncus arteriosus (TA)(1/12). Overall 9/17 (50%) pts. with TOF were deleted and 4/5 (80%) pts. with IAA. Deletions were not identified in 9 pts. with transposition of great arteries, 1 pt. with TA, 3 pts. with hypoplastic left heart syndrome or pts. with multiple congenital anomalies with or without CHD. In neonates, ear and palpebral fissure anomalies and umbilical hernias were present more frequently in deleted pts. Immune deficiency was present in 6/11 deleted pts. Renal, limb, or anal anomalies and significant hypocalcemia were not documented in any deleted pt. One 7 y.o child had severe velopharyngeal incompetence. Six of 24 pts. of Hispanic ethnicity were deleted (25%) compared to 3 of 36 (8.5%) Caucasian European pts. This unexpectedly high incidence in Hispanic pts. may reflect referral bias. There were no familial cases and compliance with requests for parental testing was poor. These results confirm the value of 22q microdeletion testing in CHD, particularly TOF and IAA. Minor dysmorphisms may be clues to this diagnosis but are generally non-specific.

**Tetrasomy 15q25.3-qter Resulting from an Analphoid Supernumerary Marker Chromosome in a Patient with Multiple Anomalies and Bilateral Wilms' Tumors.** *J. Hu*<sup>1,2</sup>, *E. McPherson*<sup>1,2,3</sup>, *U. Surti*<sup>1,2,4</sup>, *S. Hasegawa*<sup>4</sup>, *S. Gunawardena*<sup>3</sup>, *S.M. Gollin*<sup>1,2</sup>. 1) Pittsburgh Cytogenetics Laboratory, University of Pittsburgh Center for Human Genetics, UPMC Magee-Womens Hospital; 2) Dept. of Human Genetics, University of Pittsburgh Graduate School of Public Health; 3) Dept. of Pediatrics, University of Pittsburgh School of Medicine; 4) Dept. of Pathology, University of Pittsburgh School of Medicine, Pittsburgh, PA.

A 4 year-old girl developed bilateral Wilms' tumors. She had been followed since birth for apparent Shprintzen-Goldberg Syndrome with macrosomia, long fingers and toes, and craniosynostosis. Cytogenetic analysis of her peripheral blood revealed a de novo supernumerary marker chromosome. This stable marker chromosome is present in 19 of 20 lymphocytes analyzed, as well as in all 40 tumor cells studied. Classical and molecular cytogenetic studies indicate that the marker is derived from an inverted duplication of chromosome 15q25.3-qter and contains a neocentromere. The presence of this marker chromosome in our patient results in tetrasomy 15q25.3-qter. The relationship between her genotype and phenotype are discussed in light of genes, including *IGF1R* and *FES*, mapped to the aneusomic segment.

**Clinical manifestations of Coffin-Lowry syndrome associated with de novo 8p23 duplication.** *T. Kondoh<sup>1</sup>, J. Takano<sup>2</sup>, H. Sugawara<sup>2</sup>, T. Ida<sup>3</sup>, N. Harada<sup>3</sup>, T. Matsumoto<sup>4</sup>, N. Matsumoto<sup>2</sup>, N. Niikawa<sup>2</sup>.* 1) Dept Pediatrics, Nagasaki Univ Sch Medicine, Nagasaki, Japan; 2) Departments of Human Genetics, Nagasaki University School of Medicine, Nagasaki, Japan; 3) Kyusyu Medical Science Nagasaki Laboratory, Nagasaki, Japan; 4) School of Allied Sciences, Nagasaki University, Nagasaki, Japan.

Coffin-Lowry syndrome (CLS) is an X-linked disorder characterized by characteristic, coarse facial appearance, skeletal anomalies, short stature, and mental retardation. Mutations in the CLS gene, *RSK2*, have been identified in a subset of CLS patients. We reported a 10-year-old Japanese boy who had clinical manifestations of CLS and an abnormal chromosome 8. Clinical manifestations included dolicocephaly, large and malformed ears, hypertelorism, antimongoloid slant of palpebral fissures, anteverted nostrils, long philtrum, thick lips, open mouth, long chin, high-arched palate, funnel chest, tapering fingers, hypotonia, short stature, and moderate mental retardation. Mutational analysis on exons 2-22 of *RSK2* in the patient revealed no nucleotide change. FISH studies using probes that are mapped at 8p23 demonstrated a tandem duplication of a segment encompassing ~2 Mb on the abnormal chromosome 8. These findings suggest that the 8p23 duplicated segment may contribute to CLS or CLS-like manifestations. Alternatively, a chromosomal imbalance effect due to the 8p23 duplication may in part contribute to the CLS manifestations.

**Trisomy 18q due to de novo unbalanced translocation, 46, XX,+der(4;18)(q35;q12) in one of the triplets, an outcome of IVF A case report and brief review.** *D.S. KRISHNA MURTHY, K.K. NAGUIB, S.J. ABUL HASSAN, L. BASTAKI, S.A. AL-AWADI.* CYTOGENETICS LABORATORY, MEDICAL GENETICS CENTER, SABAH AREA, KUWAIT.

In vitro fertilization and ICSI has become a widely accepted procedure to assist reproduction in couples with infertility problems. However, I V F, ICSI and other micro-assisted fertilization techniques have also lead to a lively debate and concern on possible associated genetics risks in the newborn. Fewer than 10% of the embryos that are transferred to the uterus after IVF?ICSI?ART implant successfully. Chromosomal abnormalities is one of the major causes for failure to implant and develop, or multiple congenital anomalies in the newborn. About 40% of oocytes recovered in stimulated cycles (super ovulation) have abnormal chromosomal complements (aneuploidy/structural). We report here a female neonate, product of a triplet (1 female and 2 males) outcome of a IVF after 5 years of infertility in the couple. On examination at birth revealed, multiple congenital anomalies including odd facial features, prominent occiput, overriding of skull bones, flat nasal bridge, micrognathia, high arched palate, blue sclera, low set ears, dental cyst, limb deformities (rocker bottom feet) and mild hirsutism, No CHD or organomegaly was noted. The other two male sibs were normal. RE-evaluation at 5 and 18months revealed some clinical features of trisomy 18q and the child is progressing well with moderate developmental delay, no major cardiac or neurological problems. Chromosomal analysis of peripheral blood in the index case showed an abnormal chromosome 4, [46,XX,+der(4),t(4;18)(q35;q12), resulting partial trisomy for 18q. Karyotype of the parents and other two sibs were normal. FISH analysis using WCP for chromosomes 4 and 18 and quint18 essential probe (18q21.2) confirmed 18q trisomy [46,XX,ish(4;18)(q;q) (WCP4++,WCP18+++,18q21.2+++)]. The clinical and karyotypic findings in trisomy 18q cases will be briefly reviewed with regard to the survival and pathogenesis. The significance of chromosomal abnormalities and genetic counselling of the families followed by IVF procedure will be briefly reviewed.

**Holoprosencephaly in sibs with a Robertsonian (14q;22q) translocation chromosome.** *D. Kamnasaran<sup>1</sup>, J.A. Gerritsen<sup>2</sup>, D.R. McLeod<sup>2</sup>, D.W. Cox<sup>1</sup>*. 1) Department of Medical Genetics, University of Alberta, Edmonton, Alberta, Canada; 2) Department of Medical Genetics, Alberta Children's Hospital, Calgary, Alberta, Canada.

We report the clinical, cytogenetic and molecular findings on two sibs with clinical signs within the broad holoprosencephaly spectrum. The proband had microcephaly, hypotelorism, cleft palate and premaxillary agenesis. After her sudden death at 8 months, an autopsy examination showed partial agenesis of the corpus callosum with an associated malformed cingulate gyri and white matter heterotopia. The other affected sib had microcephaly, brachycephaly, bilateral ptosis, strabismus, high arched palate and a prominent nasal bridge. His cranial CT scans were normal. Standard G banding karyotype analyses were performed on the chromosomes of family members using cultured peripheral blood lymphocytes and/or prenatal amniocytes. Both affected sibs were found to be carriers of a familial robertsonian translocation (14q;22q)(q10;q10) chromosome inherited from the maternal lineage. Since robertsonian translocations are common in the genesis of uniparental disomy (UPD), genotyping was performed with a panel of 32 chromosomes 14 and 22 polymorphic markers in search of uniparental disomy. DNA sample was unavailable from the proband. We found no evidence of partial or complete maternal or paternal UPD 14 or UPD 22 in the affected brother, based on 27 informative genotypes of markers mapping to chromosomes 14 and 22. The abnormal phenotypes observed in the affected sibs also suggested the presence of an additional rearrangement of the familial robertsonian t(14q;22q) chromosome. We searched for microdeletions in the affected brother in the 14q13 region, a candidate holoprosencephaly locus. We found no microdeletion based on 18 informative markers mapping between D14S297 and D14S1013, by PCR analysis of flow sorted t(14q;22q) chromosomes. The phenotype of the affected brother is not apparently due to UPD 14 or 22, or to a detectable microdeletion. The phenotype maybe due to a recessive gene inherited from both parents or dominant gene with variable expression inherited from a parent with incomplete penetrance. The possibility of an additional rearrangement in the proband cannot be excluded.

**Subtle subtelomeric deletion in 8p23.3 in a child with developmental delay and dysmorphism detected by FISH: Paternal origin and molecular confirmation.** *X.L. Huang, A. Pan, H.E. Wyandt, J.M. Milunsky.* Center for Human Genetics, Boston Univ Sch Medicine, Boston, MA.

A 1-year-old female had dysmorphic features and developmental delay suggestive of Down syndrome. Height, weight, and OFC were in the 75th centile. She had a flat face, protruding tongue, bilateral epicanthal folds, brushfield spots, a broad short nose with anteverted nares, a left simian crease, 5th-finger clinodactyly, and hypotonia. Mother and child had similar up-slanting palpebral fissures. Chromosomes of the child and her parents were normal by high resolution banding. Subtelomeric FISH revealed a weak or absent signal on a chromosome 8 (8p23.3), compared to its homolog, with the probe D8S504. Signal size-discrepancy was also noted in interphase cells, many having only one signal. D8S504 gave equal-size signals in chromosomes 8 from the mother. Signal size in chromosomes 8 from the phenotypically normal father was discrepant, but no cells were missing a signal. A probe for a more distal locus in 8p23.3, PAC580L5, showed no size-discrepancy by FISH in any of the family. Eight microsatellite markers in the subtelomeric region of 8p23.3, NIBg, WI-6641, WI-4250, D8S504, WI-5411, WI 1986, AFMB3222H9 and D8S201 (listed by Gene Bank order) were compared by PCR analysis in the child, her parents and normal controls. The first six markers were informative. The paternal allele for D8S504 is absent in the child, confirming the deletion in 8p23.3. No deletion was evident in the father. Thus, diminished signal size in the father by FISH may represent a normal variant that predisposed to a different size deletion in the child by unequal crossing-over in paternal meiosis. At 16 3/4 months of age our patient has behavioral problems in addition to her clinical findings, including head-banging, self-biting and pinching, frequent rocking behavior, tantrums and tactile defensiveness. The subtelomeric region of 8p23.3 appears to be a hotspot for chromosome rearrangement, with numerous reports of duplications and/or deletions involving breakpoints in this region. Many of the features in our patient are consistent with those reported for 8pter-microdeletions.

**Chromosomal abnormalities in patients with idiopathic hypogonadotropic hypogonadism.** *L.C. Layman<sup>1</sup>, D.P. Bick<sup>2</sup>, R.J. Sherins<sup>2</sup>, A. Kulharya<sup>3</sup>*. 1) Section of Reproductive Endocrinology, Infertility, & Genetics, Dept OB/GYN, Neurobiology Program, Institute of Molecular Medicine & Genetics, Med Col GA, Augusta, GA; 2) Genetics & IVF Institute, Fairfax, VA; 3) Cytogenetics, Dept Pediatrics, Med Col GA, Augusta, GA.

Humans with hypogonadism are generally categorized into hypergonadotropic (gonadal failure) or hypogonadotropic (hypothalamic/pituitary deficiency) hypogonadism. The probability of a chromosomal abnormality is markedly increased in patients with hypergonadotropic hypogonadism, with more than 50% of females with primary amenorrhea and 10-15% of males having an abnormal karyotype. It is generally thought that idiopathic hypogonadotropic hypogonadism (IHH) patients, except for those with Prader-Willi syndrome, do not have chromosomal abnormalities, although there are no studies of well-documented IHH patients. Identified karyotypic abnormalities would not only document the prevalence of chromosomal disorders, they might also provide clues to genes involved in the pathogenesis of IHH. The molecular basis for most patients with IHH remains unknown, although mutations in the KAL1, AHC, GNRHR, LEP and LEPR genes have been identified in a minority. We undertook a study to determine the prevalence of karyotypic abnormalities in humans with IHH. Peripheral blood white blood cells or lymphoblastoid cell lines were collected from 50 well-documented IHH patients and a metaphase karyotype, counting 20 cells, was performed. IHH was defined as absent puberty (at least age 17 in females and 18 in males), low serum levels of FSH and LH, normal levels of other pituitary hormones, and the absence of a pituitary tumor. One male had a 46,XY,t(10;12)(q26.3;q13.1) and another was 46,XY with an abnormal Y in half of cells, which is currently being characterized. The 10q26 breakpoint was involved in a previously described IHH patient, suggesting the relevance of this chromosomal region in IHH. Our findings suggest that chromosomal abnormalities may be more common (4%) than previously expected, and that these aberrations may provide clues to additional genes involved in the pathogenesis of IHH. (L.C.L. supported by PHS-NICHD HD33004).

**Pelizaeus-Merzbacher disease with unusual presentations of phrenic nerve paralysis and AV block.** *J. Lin<sup>1</sup>, S. Chang<sup>2</sup>, S. Huang<sup>3</sup>.* 1) Genetic Div Pediatric Dept, Chang Gung Children's Hosp, Taoyuan, Taiwan; 2) Dept. of GYN & OBS, Chang Gung Memorial Hospital, Taoyuan, Taiwan; 3) Dept. of Pathology, Chang Gung Memorial Hospital, Taoyuan, Taiwan.

Pelizaeus-Merzbacher disease was an dysmyelinating disorder, presented with diffuse cerebral sclerosis and projectile vomiting etc. A male newborn with IUGR was intubated after birth due to low Apgar score. Dysmorphism was noted after birth. Phrenic nerve paralysis were found later. He developed second degree AV block Mobitz type II around one month old. Temporary pacemaker was inserted. Autopsy was done after he died of septic shock at five months old. Myelination defect was found by electromicroscopy. Blood karyotyping of patient showed 46, XY, dup(X)(q21-q22). The karyotyping of mother showed 46, XX, dup(X)(q21-q22). The mother was physically normal without any dysmorphic picture noted. This is the first case of Pelizaeus-Merzbacher disease ever reported at Taiwan, with unusual presentation after birth. Blood karyotyping and nerve histopathology by electromicroscopy will be presented and discussed.

**Deletion of the 3q27-qter region associated with a congenital dyserythropoietic anemia.** *C. Michel<sup>1</sup>, V. Drouin-Garraud<sup>2</sup>, P. Schneider<sup>1</sup>, C. Bastard<sup>3</sup>, J.P. Vannier<sup>1</sup>, T. Frebourg<sup>2</sup>.* 1) hemato-cancerologie , CHU de Rouen, Rouen; 2) Service de genetique, CHU de Rouen; 3) Centre Henri Becquerel, Rouen.

The deletion of the 3q27-qter region has been described in few patients with multiple congenital abnormalities. We report the case of a 17 year-old girl with a de novo deletion of the 3q27-qter region, who presented with mental retardation, growth delay, dysmorphic features and a congenital dyserythropoietic anemia (CDA) associated to neutropenia, humoral immunodeficiency and thrombocytosis. This patient had no malformation. This is, to our knowledge, the first case of a 3q27-qter deletion associated to CDA. Three principal types of CDA have been described so far, CDAI (autosomal recessive), CDAIL (autosomal recessive) and CDAILI (autosomal dominant), and the corresponding genes have been mapped to 15q15.1-q15.3, 20q11.2 , and 15q21, respectively. Genetic heterogeneity has been demonstrated for type II. This reports suggests the location of an additional CDA locus on chromosome 3q27.

**Mosaicism for 45,X and a Cell Line with a Derivative Y Chromosome containing 2 Copies of the SRY gene resulting in a Male Phenotype.** A.A. Khan<sup>1</sup>, D. Chitayat<sup>1</sup>, M. Speevak<sup>2</sup>, R. Murphy<sup>3</sup>. 1) Division of Clinical Genetics, Hospital for Sick Children Toronto, Ontario, Canada; 2) Department of Laboratory Medicine, Credit Valley Hospital, Mississauga, Ontario, Canada; 3) Dufferine-Caledon Healthcare, Orangeville, Ontario, Canada.

Mosaicism for 45,X and a cell line containing a Y chromosome has been reported to be associated with features ranging from a male phenotype with gonadal dysgenesis to a female phenotype with normal female genitalia. We report a newborn infant with sex chromosome mosaicism, a male phenotype with complete absence of the Mullerian structures and no stigmata of Turner syndrome. The patient was born at 33 weeks gestation following a pregnancy complicated with poor fetal growth, oligohydramnios and maternal preeclampsia. Delivery was induced and the newborn's birth weight was  $< -2$  SD. On examination he had ambiguous genitalia with grade III hypospadias, chordee and penile length of 2.5 cm and a smooth scrotum. The left testis was descended and the right hemi-scrotum was hypoplastic with undescended testis and hydrocele. The anus was anteriorly placed. No Mullerian structures were noted on pelvic ultrasound and no other abnormalities were detected. Chromosome analysis done on peripheral blood revealed sex chromosome mosaicism: 45,X[99]/46,X,der(Y).ish idic(Y)(q11.2) (wcpY+,SRY++)[8]. In the second cell line, FISH revealed a dicentric Y chromosome with duplication of SRY and absence of Yq heterochromatin. Only a single active centromere was noted. Yq deletion analysis by PCR revealed the presence of the AZF loci. This analysis suggested duplication of Yp and deletion of a part of Yq in 7.5% of cells in the peripheral blood. The possible origin of this complex chromosome abnormality and the genotype/phenotype correlation will be discussed.

**Cloacal extrophy in an infant with 9q34-qter deletion resulting from a de novo unbalanced translocation between chromosome 9q and Yq.** *C. Thauvin-Robinet<sup>1</sup>, P. Khau Van Kien<sup>1</sup>, M. Fellous<sup>2</sup>, K.L. Parker<sup>3</sup>, D. Semama<sup>4</sup>, I. Luquet<sup>5</sup>, I. Sidaner-Noisette<sup>5</sup>, A. Nivelon-Chevallier<sup>1</sup>, F. Mugneret<sup>5</sup>, L. Faivre<sup>1</sup>.* 1) Centre de Genetique, Hopital d'Enfants, Dijon, France; 2) Service d'Immunogenetique Humaine, Institut Pasteur, Paris, France; 3) Department of Medicine, Howard Hughes Medical Institute, Duke University Medical Center, Durham, North Carolina, USA; 4) Service de Pediatrie 2, Hopital d'Enfants, Dijon, France; 5) Laboratoire de Cytogenetique. Hopital Le Bocage, Dijon, France.

Cloacal extrophy is a rare malformation, which occurs in 1:200,000 to 1:250,000 live births. It belongs to a spectrum of birth defects, which, in order of severity, includes phallic separation with epispadias, pubic diastasis, bladder extrophy, cloacal extrophy and OEIS complex (omphalocele, extrophy of bladder, imperforate anus, and spinal defects). The pathogenesis of cloacal extrophy is unknown to date. It may result from a single defect of early blastogenesis or a defect of mesodermal migration during the primitive streak period. Here, we report on an infant with cloacal extrophy, rectal prolaps, absence of bladder, right renal agenesis, sexual ambiguity and axial hypotonia. Chromosome analysis showed a de novo unbalanced translocation between the long arm of chromosome 9 and the long arm of chromosome Y resulting in a 9q34-qter deletion (46,XY,der(9),t(Y;9)(q34;q12)). Reviewing the literature, we did not find cloacal extrophy associated with structural chromosomal abnormality. We sequenced the gene SF1 (Steroidogenic Factor 1) included in the deleted region but no mutation was found. We hypothesize the localization of a gene, early expressed in embryogenesis and responsible of cloacal extrophy, in the 9q34-qter region.

**An additional patient with del(12)(q21.2q22): Further evidence for a candidate region for Cardio-facio-cutaneous syndrome?** *K. Rauen<sup>1</sup>, D. Albertson<sup>2</sup>, P. Cotter<sup>1,3</sup>*. 1) Division of Medical Genetics, Department of Pediatrics, University of California, San Francisco, CA 94143; 2) Cancer Research Institute, University of California, San Francisco, CA 94115; 3) Division of Medical Genetics, Childrens Hospital Oakland, 747 Fifty Second Street, Oakland, CA 94609.

Cardio-facio-cutaneous (CFC) syndrome is a rare MCA disorder in which individuals have a characteristic facial appearance, cardiac defects, ectodermal anomalies and developmental delay. Recently, we reported a girl with the phenotype of CFC who had an interstitial deletion of the long arm of chromosome 12, del(12)(q21.2q22), implicating a possible locus for CFC syndrome (AJMG.2000.93:219-222). Since that report, we have an additional patient who carries the same deletion. Standard cytogenetic analysis shows a 47,XYY karyotype containing an interstitial deletion of the long arm of one chromosome 12 observed in all metaphases examined: 47,XYY,del(12)(q21.2q22). Examination of this patient by the use of photographs reveals craniofacial features including a broad forehead, hypoplasia of the supraorbital ridges, mild down-slanting palpebral fissures, short nose with bulbous tip and low-set auricles. Ectodermal findings consist of sparse, curly hair (which was more pronounced during infancy), no eyebrows, scant eyelashes and hyperkeratosis pilaris. Prenatal history is significant for polyhydramnios, a 2-vessel cord and right hydronephrosis on ultrasound. Medical history includes a small PDA and persistent patent foramen ovale closing after several months of age, pyloric stenosis at age 3 weeks, right hydronephrosis and right cryptorchidism. The patient is delayed developmentally and has a normal brain MRI. To investigate CFC patients for submicroscopic chromosome aberrations, we have employed the use of comparative genomic hybridization microarrays (CGHa) to rapidly and efficiently screen the genome for submicroscopic deletions in the candidate region. CGHa analysis of our male patient confirmed the cytogenetically visible deletion in one chromosome 12, as well as detected the 2 copies of the Y chromosome. Current studies are underway to examine additional patients who have been clinically diagnosed with CFC using CGHa.

**High-throughput analysis of subtelomeric rearrangements using array-based CGH.** *J.A. Veltman<sup>1</sup>, A.J.A. van Kampen<sup>1</sup>, B.H. Eussen<sup>2</sup>, E.F.P.M. Schoenmakers<sup>1</sup>, C.M. van Ravenswaay<sup>1</sup>, A. de Klein<sup>2</sup>, D.F. Smeets<sup>1</sup>, H.G. Brunner<sup>1</sup>, A. Geurts van Kessel<sup>1</sup>.* 1) Human Genetics, UMC Nijmegen, Nijmegen, Netherlands; 2) Clinical Genetics, Academic Hospital Rotterdam, Rotterdam, Netherlands.

Telomeric rearrangements result in a number of clinical conditions, including mental retardation, congenital anomalies and recurrent miscarriages. Automated detection of subtle deletions or translocations involving telomeres is essential for high-throughput diagnosis but impossible with the conventional cytogenetic methods. Array-based comparative genomic hybridization (CGH) has been developed for high-resolution screening of copy number abnormalities by hybridizing differentially labeled test and reference genomes to arrays of robotically spotted clones. In this double-blinded study DNA from 40 patients with known cytogenetic abnormalities involving one or more telomeres was hybridized to an array containing a second-generation set of human chromosome-specific (sub)telomere probes. Single copy number gains and losses were accurately detected on these arrays and there was an excellent concurrence between the original cytogenetic diagnosis and the arrayCGH-based diagnosis using a single hybridization. We have confirmed the suitability of this method by analyzing DNA from a large set of patients with nonspecific mental retardation for submicroscopic rearrangements. The robustness and simplicity of this array-based telomere screening makes it highly suited for introduction into the clinic as an automated diagnostic procedure.

**Digital, spinal and other anomalies in a patient with a whole arm chromosome translocation resulting in monosomy 18p and trisomy 20p.** *K.L. Russell, N.B. Spinner, J.E. Ming.* Div Human Gen & Molec Biol, Children's Hosp Philadelphia, Philadelphia, PA.

Non-Robertsonian whole arm chromosomal translocations are rare events. We present the third case of a whole arm translocation resulting in monosomy 18p and trisomy 20p. The patient is a five month old girl born at 41 weeks gestation to a 30 year old G6P2 mother after an uncomplicated pregnancy. Length, weight and head circumference at birth and five months were normal. On the left hand, there was a duplicated index finger with two phalanges, and there was cutaneous syndactyly between the two index fingers and the thumb. The right hand had a sharply angled ulnar deviation of the second digit at the proximal interphalangeal joint. The patient also displayed brachycephaly with plagiocephaly, blepharophimosis, ptosis, low set ears, a broad nasal root, down-turned corners of the mouth, micrognathia, irregular toe placement and an umbilical hernia. Spinal anomalies included cervical spine fusion of C5-C7, thoracic lordosis and lumbar kyphosis. She also had a deep sacral dimple, developmental delay and bilateral sensorineural hearing loss. Her karyotype was 46,XX, der (18),t(18;20)(p11.1;q11.1). The centromere of the derivative chromosome contained alpha satellite sequences from both chromosomes 18 and 20. The derivative chromosomes in the two previously reported cases also had centromeric material from both chromosomes. This patient's clinical findings are similar to the two other reports of monosomy 18p/trisomy 20p. The patient presented here had more severe hand malformations than the previously reported cases and additional findings of spinal fusion and hearing loss. This case further demonstrates that 1) for this chromosomal rearrangement, the resulting derivative chromosome has a break in the centromere, possibly indicating that there are homologous sequences in the alpha satellite regions of chromosomes 18 and 20, and 2) monosomy 18p/trisomy 20p has a definable phenotype that includes brachycephaly with a distinctive facial appearance, finger anomalies, irregular toe placement, umbilical hernia and hypotonia.

**Inherited duplication of Xq26.1q27.2, including SOX3, in mother and daughter with short stature and dyslalie. I.**

*Hansmann<sup>1</sup>, H. Thiele<sup>1</sup>, M. Schlicker<sup>1</sup>, A. Czeke-Friedrich<sup>2</sup>, J.R. Lupski<sup>3,4</sup>, P. Stankiewicz<sup>3</sup>.* 1) Institut fuer Humangenetik & Medizinische Biologie, Halle/Saale, Germany; 2) Kinderklinik, Halle/Saale; 3) Dept. of Molecular & Human Genetics; 4) Pediatrics, Baylor College of Medicine, Houston TX.

Duplications of the distal long arm of the X chromosome are rare and carrier females are usually phenotypically normal. We report a short statured girl who inherited a dup(Xq26.1q27.2) chromosome from her short mother. At the age of 12 years her height was 131.6 cm (<3rd percentile), weight 30.6 kg (3rd percentile). She had minor dysmorphic features, lordosis and no menarche nor signs of puberty. She has regular, low prepuberal levels of gonadotrophins and steroids, but borderline low IGFI and IGF-Bp3 serum levels. Both the propositus and her 42-year-old mother (height 152 cm, weight 51.8 kg) with a strikingly "old" face and a prominent nose have severe speech problems with stuttering and dyslalia. Menarche was rather late at the age of 15 years. Until now, no signs for irregular cycles or POF are being reported. Both maternal sisters (155 cm, 153 cm) and her mother (150 cm) are also short. Karyotyping revealed an additional band at Xq26-q27 in all metaphases from daughter and mother. With a chromosome X paint both X chromosomes were completely labeled. By FISH, 8 out of 16 BACs were found to be duplicated on that chromosome. The proximal breakpoint maps between BAC RP11-41L14 (DXS7415) and RP11-614F19 (DXS7315) at band q26.1 and the distal breakpoint between BACs RP11-189F12 and RP11-518F7 at band q27.2. The duplicated 10-11 Mb segment include locus DXS102 and SOX3. The same segment is involved in 2 larger familial duplications, both of which were found to be associated with an abnormal phenotype in males, including short stature (Gecz et al. 1999; Hol et al. 2000). Using the androgen-receptor (AR) gene methylation assay we were able to show that despite preferential inactivation of the dup(Xq) a significant portion of lymphocytes in mother and daughter do carry an active X chromosome with the duplication. A dosage effect of genes such as SOX3 appears to be involved in features like short stature in these 3 families.

**Classical phenotype of trisomy 1q42-qter syndrome in a patient with an inv dup del (1)(pter→q44::q44→q42:).** *G. Sebastio<sup>1</sup>, D. De Brasi<sup>1</sup>, E. Rossi<sup>2</sup>, S. Giglio<sup>2</sup>, A. D'Agostino<sup>3</sup>, L. Titomanlio<sup>1</sup>, C. Di Stefano<sup>1</sup>, G. Andria<sup>1</sup>.* 1) Dept Pediatrics, Federico II Univ, Naples, Italy; 2) Dept of Medical Biology, University of Pavia; 3) Dept of Biology and Molecular and Cellular pathology, Federico II University, Naples.

Inverted duplications are cytogenetic rearrangements due to meiotic errors during homologous chromosomes pairing and are always associated with telomeric deletions. We describe a girl with an inv dup del (1)(pter→q44::q44→q42:), who showed macrocephaly with prominent forehead, down-slanting palpebral fissures, micrognathia, mild dilated cardiomyopathy and psychomotor retardation. Standard cytogenetics revealed a duplication of the tract 1q42-q44. Chromosome 1 painting revealed an uniform signal across both chromosomes 1. FISH performed with telomere specific clones demonstrated a terminal deletion of one chromosome 1 within region q44. Double-colour FISH with YACs from 1q demonstrated a duplication of more than 30 cM and an inversion of the duplicated region. Eventually, complete karyotype was: 46,XX, inv dup(1)(q44q42).ish(dup del 1)(q44q42)(D1S446x2, D1S423x2, tel1q-). "Direct" and "inverted" duplications should be accurately differentiated as inverted duplications are invariably associated with telomeric deletions. To distinguish between these two types of rearrangements, FISH analysis is often necessary. The phenotypic effects of these complex rearrangements are only partially known. The location and extension of the deleted segment and the breakpoints of the inversion, as well as the length of the trisomic region, may influence the phenotype. Clinical findings of the present patient mostly overlap that observed in patients affected by the typical trisomy 1q42-qter syndrome. This is probably because of the small extension of the deleted chromosomal segment, with a limited phenotypic effect. Though not included in the minimal clinical criteria, mental retardation, observed in our patient and described with variable degree in all the cases of the trisomy 1q42-qter reported so far, should be considered as a constant feature of the syndrome.

**Ambiguous Genitalia: Clinical, Chromosomal and Ultrasonographic Study..** *N.A. Abukarsh<sup>1</sup>, N.L. Hatem<sup>2</sup>, N.E. El-Kholi<sup>3</sup>, A. Abdel-Kareem<sup>4</sup>, F.M. Kamel<sup>2</sup>, S.M. Tayel<sup>5</sup>.* 1) Histology Department, Faculty of Medicine, Great Al-Fateh University, Tripoli, Libya; 2) Pediatrics Department; 3) Department of Pediatric Surgery; 4) Radiology Department; 5) and Clinical Cytogenetics Unit, Anatomy Department, Faculty of Medicine, Alexandria University, Egypt.

Ambiguous genitalia (AG) in the newborn represents a true medical emergency. It may be accompanied with other serious birth defects and it may lead to family psychosocial crisis. Diagnosis of AG has to be started as early as possible to allow proper sex assignment and to avoid any change in the sex of rearing. Twenty patients with AG (age range: 1 week - 11 years, mean = 3.8 years) were subjected to general and local genital examination including measurement of clitoral breadth and stretched penile length, karyotyping by GTG- banding, pelvic ultrasonography, and hormonal assay. Results showed 13 patients (65%) as male pseudohermaphrodites due to testosterone and 5 $\alpha$ - reductase deficiencies, and testicular feminization syndrome (TFS), 2 (10%) of patients were diagnosed as female pseudohermaphrodites due to congenital adrenal hyperplasia (CAH), and 5 patients (25%) had AG due to nonendocrine/non sex chromosome defects in the form of VATER association, trisomy 13, Russell-Silver, Prader-Willi, and Frazer syndromes. Parental consanguinity was present in 15 cases (75%). Eleven of them (55%) showed autosomal recessive disorders. One of the male pseudohermaphrodites (5 $\alpha$ - reductase deficiency) had 5 sibs affected, 3 of them (aged 20, 21, and 22 years) were wrongly assigned the female sex. Three patients (15%) changed gender after proper sex diagnosis. Gender role has to obey chromosomal sex in certain disorders as CAH, testosterone and 5 $\alpha$ - reductase deficiencies. It goes to the opposite sex in TFS. Phallus size, pattern of pubertal change expected at adolescence and family desire are the factors to be taken into consideration when deciding the more appropriate gender of patients with AG. Genetics work-up is crucial for early and proper sex assignment in case of AG to avoid gender change and to give accurate recurrence risk estimation in other sibs especially in communities with high consanguinous mating as arab countries.

**Low Sex Ratio in Patients With Clinical Diagnosis of Down Syndrome.** *N.V. Kovaleva.* Institute of Obstetrics and Gynaecology RAMS, St.Petersburg, Russia.

Male to female ratio (sex ratio, SR) was studied in 1329 cases of cytogenetically confirmed trisomy 21 (group I) and in 538 clinically diagnosed cases of Down syndrome (group II) born in St. Petersburg in 1970-1999. SR was increased in cases confirmed cytogenetically (731 males and 595 females, SR=1.23), but not in patients who did not receive chromosome analysis (263 males and 275 females, SR=0.96), the difference in SR between groups is significant ( $p=0.0143$ ). Mothers of girls from group II were younger than mothers of girls from group I, the difference between proportion of mothers aged 35 and older (23% versus 33%) is significant,  $p=0.0046$ . Infant mortality was higher in group II (79.5%) than in group I (53.9%), the difference is highly significant ( $p<0.001$ ). Previous reports indicate that mosaic trisomy 21 cases show a SR  $<1.0$ , suggesting that a large proportion of the group II cases represents mosaics. However these results do not support an excess of mosaic trisomy in the group II. Among children referred to geneticists because of having some clinical features resembling Down syndrome but with normal karyotypes in blood (group III), a high female preponderance was found; there were 55 cases of 46,XY males and 141 of 46,XX females (SR=0.39), significantly different from population value 1.06,  $p<0.0001$ . Therefore, low SR in clinically diagnosed cases may be explained by an excess of false-positive diagnosis of Down syndrome in females. Thus, these results would suggest that epidemiological data collected on Down syndrome, prior to routine cytogenetic analysis, should be considered suspect and perhaps discarded. Furthermore, the high proportion of females in group III suggests an etiology specific to females, such as Rett syndrome, X-inactivation anomalies, UPD, or other aberrations of the X chromosome.

**Pericentric inversion of chromosome 12(p13q24) in a family; phenotypic variability and reproductive risk.** *P.D. Power<sup>1</sup>, L.T. Arbour<sup>1</sup>, H. Bruyere<sup>1</sup>, C. Pushpanathan<sup>2</sup>, E.J. Ives<sup>1</sup>.* 1) Medical Genetics, UBC, Vancouver, BC, Canada; 2) Pathology, Memorial University of Newfoundland, St. John's, NF, Canada.

Among previously reported pericentric inversions of chromosome 12 there is only one report with breakpoints at p13 and q24 (Speleman et al. 1993). We report a further large family with these breakpoints in which information is available on five abnormal cases, including an aborted fetus, all of which were female. Four have the same unbalanced karyotype, 46, XX, rec (12) dup (12q) inv (12) (p13q24), and it is presumed in the fifth. Four of the five cases were examined by the authors. Features of affected individuals include a normal head circumference at birth with subsequent microcephaly in some and macrocephaly in others, bitemporal narrowing, frontal bossing, with supraorbital hypoplasia, and generalized post-natal failure to thrive. Septal heart defects were present in 3 cases. An iris coloboma was present in one infant, and bilateral retinal colobomas were present in another. One child died of primary pulmonary hypertension at age 9 months as a result of generalized congenital capillary hemangiomas. Another died at 3 years of age, and the remaining two are alive at ages 9 and 33 years. All affected individuals were cognitively impaired, but the degree varied. The phenotypic presentations in this kindred are dissimilar to that of the previously reported family (Speleman et al. 1993). In our family, the risk for a carrier of a balanced inversion to have an abnormal pregnancy that will proceed to viability is 20%, with a 10% risk for spontaneous abortion. Male carriers are as likely to transmit as females and there appears to be no impact on fertility or early pregnancy loss in this family. This information may be useful for other families with a similar chromosome rearrangement.

**Proteus Syndrome: Analysis of 7 Cases of a Clinical Genetic Service.** *A.X. Acosta, D. Nunes-Silva, C. Fortuna, M.B. Toralles.* Hospital Universitário Professor Edgard Santos Universidade Federal da Bahia, Salvador-Bahia-Brasil Condomínio das Bolandeiras 2, Imbuí-Salvador, Brazil.

Proteus Syndrome (PS) is a rare and highly variable hamatomatous disorder comprising malformations and overgrowth of multiple tissues. It is characterized by a mosaic distribution of lesions, progressive course, sporadic occurrence, hyperplastic lesions of connective tissue, vascular malformations, linear verrucous epidermal nevi, and hyperostoses. The diagnoses of this pathology are difficult because it is so variable on its presentation, and is frequently confused with hemihyperplasia. At the period of 1998 to 2001, the genetic ambulatory from the University Federal Hospital from Bahia, Salvador - Brazil received close to 750 patients. Seven of these patients were remitted to our service because they were questioned to have PS. There were 4 female and 3 male, and the age at the moment of the attendance varied of five months to eleven years old. All of them were examined and we used the diagnostic criteria proposed by Biesecker [Am J Med Genet 84:389-395 (1999)]. In our sample, the most common characteristic was the hemihyperplasia (6 of 7). Five of them were considered affected to PS. The epidermal nevi were present in all patients that were diagnosed with PS (5 of 7), although none of them had connective tissue nevus. Hemangioma was quite common (2 of 5), and lipoma was rare (1 of 5). The diagnosis of this disorder is difficult because PS has a variable presentation that can appear in the evolution of this illness. It is important to use a clinical protocol to make a correct diagnosis for this syndrome; be attempt and follow cases presenting hemihyperplasia. Finally, this syndrome doesn't appear to be so rare, maybe the suspected cases are not being correctly evaluated.

**The serotonin connection: a family history study of the possible association between autism and migraine headaches.** *E.S. Gordon, N.J. Minshew, E. Gettig, B.J. Devlin.* University of Pittsburgh, Pittsburgh, PA.

Objective: Evaluate the odds of experiencing migraine headaches (without aura) in autistic probands and their first degree relatives compared to a control population. Background: Approximately 30% of individuals with autism are known to have increased platelet serotonin levels. Serotonin levels have also been found to be increased in the parents of autistic individuals. Migraine headaches are thought to have a serotonin component due to the successful treatment of migraine headaches with selective serotonin reuptake agonists. Methods: A questionnaire to determine the presence of migraine headaches was developed based on the diagnostic criteria for migraine without aura designed by the International Headache Society. The questionnaire was sent to 224 families (137 families with an autistic proband; 87 families of control subjects) already enrolled in a study of autism at the University of Pittsburgh. Data was entered into a Microsoft Access database, from which a computer algorithm was designed to evaluate the presence or absence of migraine headache in each individual. The statistical package SAS was used to determine any statistically significant differences between the presence of migraine in the family members of autistic probands compared to family members of control subjects. Other headache variables such as location of the headaches, feeling of headache and frequency of headaches were also analyzed. Results: Responses were collected from 65 families (44 families with an autistic proband; 21 control families). A total of 105 responses were collected from parents in these two groups (75 parents of autistic probands; 30 parents of control subjects). No significant differences were found between odds of reporting symptoms meeting diagnostic criteria for migraine in the parents of these two groups. Previous analyses using only 51 families showed no significant differences between the children (siblings and probands combined) in these two groups. Conclusion: There is no evidence to support a common serotonin basis for migraine and autism. Further studies are warranted to investigate the role of serotonin in both autism and migraine.

**Cleft lip and palate anomalies in Patagonia.** *H. Oh, C. Brodsky, J. Mir, T. Mosby, M. Tolarova.* Dpt of orthodontics, UOP School of Dentistry, San Francisco, CA.

**INTRODUCTION.** Cleft lip and palate anomalies represent a major problem in oral health worldwide. Every two minutes, a child affected with orofacial cleft is born somewhere in this world. On average, one out of every 500 newborns has a cleft. As a necessary step towards prevention, epidemiological studies evaluating etiological roles of environmental factors (including nutrition) and of genetic factors are performed.

**MATERIAL AND METHODS.** We studied 72 individuals affected with orofacial cleft and 38 unaffected (control) individuals from the Argentinean Patagonia province Chubut. A diagnostic spectrum, birth weight, birth order, age of parents and month of birth were evaluated.

**RESULTS.** Following results were obtained from an initial analysis of epidemiological characteristics of cases and controls examined in the city of Trelew: The mean age of our cleft patients was 17.8 years. The majority (83%) had cleft lip and palate. In unilateral cases, the left side was affected more often (69%). Children affected with cleft were more likely to be first born or of parity 4 or higher. The mean birth weight was 3209 grams. Evaluation of maternal age revealed a higher prevalence of mothers younger than 24 years for cases, but not for controls. Detailed analyses of epidemiological characteristics were performed in subcategories classified according to cleft severity and laterality. Ongoing analyses include environmental, nutritional and genetic data.

The field work for this study was supported by funding from ROTAPLAST International, Inc.

**Associated factors evaluation in recurrent and/or severe infections in Down's syndrome patients. L.M.A.**

*RIBEIRO<sup>1</sup>, A.C. PASTORINO<sup>1</sup>, C.A. KIM<sup>2</sup>, A.P.M. CASTRO<sup>1</sup>, A.B.F. FOMIN<sup>1</sup>, C.M.A. JACOB<sup>1</sup>.* 1) DEPT PEDIATRICS - ICr, ALLERGY & IMMUNOLOGY UNIT, SAO PAULO, BRAZIL; 2) DEPT PEDIATRICS - ICr, GENETIC UNIT, SAO PAULO, BRAZIL.

Down's Syndrome (DS) is the most common cause of mental retardation among the genetic syndromes, with incidence of 1/700 live births, reaching 1/50 live births of mothers with age above 45 years old. Recurrent infections are frequent in DS patients, being considered important cause of morbidity. In this study there were evaluated 45 SD patients with recurrent and/or severe infections, through epidemiological, clinical and laboratorial protocol, including immunological aspects, from jan/90 to jul/99. The sex distribution was 1,6male:1female, with age average=2years 7months (ranging=1y to 12y10mo). Forty patients referred recurrent infections (RI) and five sepsis. Out of all patients with RI, 31 fulfilled the repeated infection criteria, with pneumonia and rhinopharyngitis as the most common infections. The chromosome analysis revealed 41 patients with simple trisomy, 3 mosaicisms and one translocation. Congenital heart diseases were found in 62.5% of cases, more frequent in the repeated pneumonia group. Immunological evaluation showed 2 cases with IgG2 deficiency, 2 with low lymphocytes CD4+ count, 13 cases without response to delayed cutaneous hypersensitivity tests and one of these cases without response to PHA in lymphocytes culture. One patient showed no response to PWM and OKT3 mitogens and 5 with reduced NK cells activity. Two cases presented hypergammaglobulinemia with autoantibodies detected (anti-peroxidase and anti-tireoglobulin). Transitory neutropenia was found in 2 cases. Positivity sorology to citomegalovirus was found in 23/36 cases analysed, and there are no response to hepatitis B in 5/21 evaluated children. The data found in this study are valid for this specific population, although the immunodeficiencies research in DS patients should be done in the cases with maintenance of infections besides the appropriated control of associated diseases.

**Syndactyly type-I: study of four large Indian pedigrees.** *U. Radhakrishna<sup>1</sup>, V.K Patel<sup>1</sup>, M. Ravindra Babu<sup>1</sup>, U. Ratnamala<sup>1</sup>, J.V. Solanki<sup>2</sup>.* 1) Genetics, Green Cross Blood Bank & Genetics, Paldi, Ahmedabad, Gujarat, India; 2) Department of Animal Genetics & Breeding, Veterinary college, Gujarat Agriculture University, Anand, India.

Hereditary syndactyly was classified into five different types. Syndactyly type-I (SDTY1) (OMIM 185900) involves complete or partial bilateral syndactyly between third and fourth fingers which is occasionally associated with fusion of the distal phalanges. Feet are rarely affected. It may be an isolated condition. The genes responsible for SDTY1 and SDTY2 have been mapped to chromosome 2q34-q36 (Am J Hum Genet 67:492-97,2000 and 2q31(Hum Molec Genet 4:1453-1458,1995), respectively. We have studied four large Indian pedigrees with an autosomal dominant SDTY1. Pedigrees consist of 81 individuals, including 36 affected (20 males/16 females). Severity of the phenotype was quite variable among the families and no skipping of generation was observed. In three families, 12 members were bilaterally affected with typical features of syndactyly affecting the 3rd and 4th fingers and 10 members had only unilateral findings. Few of these also had unilateral partial syndactyly of 2nd and 3rd toes. In the fourth family, complete unilateral or bilateral syndactyly affecting 3rd, 4th and 5th fingers was observed. Few of the affecteds in this family had unilateral elongation of 2nd and 3rd toes with syndactyly. Phalangeal bones were not affected in any of these families, even though the nails are involved in few affecteds. Linkage studies with markers closely linked to SDTY1 and SDTY2 will either confirm allelism to these loci or provide evidence for genetic heterogeneity.

**Limb Reduction Defects In Aljahra Region of Kuwait(1983-1990):Prevalence and Clinical presentation.** *R.L. Al-Naggar<sup>1</sup>, S.A Al-Awadi<sup>1</sup>, S.A Madi<sup>2</sup>, M.M Abuhenedi<sup>1</sup>, T.I Farag<sup>1</sup>, L. Bastaki<sup>1</sup>.* 1) Obstetric&Gynecology, Kuwait Medical Genetics Center, Kuwait, Capital, Kuwait; 2) Pediatric Department, Aljahra Hospital,Kuwait.

Limb reduction defects(LRD)are of special interest,as they are the natural means of communications and possible indicators of environmental teratogens.Out of 60271 births,37 cases of LRD were ascertained.The data were collected from the Rigestry for congenital malformations of KMGC,Aljah.Hospital and patients clinical records.LRD represented 3.5% of total congenital anomalies and 18.7% of total limb malformations.The birth prevalence/10,000 births was 6.1 for total LRD,3.65 for isolated and 2.48 for cases with assaciated anomalies of other systems.The overall LRD had a high significant decline in 1989&1990 ( $P=0.01$ ),isolated cases also had a significant decrease ( $P=0.05$ ).LRD were classified into 9 categories,the most common LRD were terminal/transverse 24.4% and digital deficiency 16%,while the least LRD were rudimentary and postaxial defects,5.4%.The upper limbs were more affected than LL,54% vs 19%.The genetic causes were found in 66.7%,M:F ratio was1.8:1 and 64.8 of parents were blood relatives.There was also a significant increase of paternal age.The present study showed high prevalence of LRD,genetic factors were important added to that the advanced paternal age.We recommend further studies to evaluate the effect of mutagens/teratogens resulted from the 2nd Gulf War.

**Intestinal atresia, gallbladder agenesis/hypoplasia and severe IUGR in two siblings - A new autosomal recessive syndrome?** *B. Lo<sup>1</sup>, P. Shah<sup>2</sup>, R. Windrim<sup>3</sup>, S. Farrell<sup>4</sup>, K. Chong<sup>1</sup>*. 1) Div Clinical Genetics, Hospital for Sick Children, Toronto, ON., Canada; 2) Department of Neonatology, Hospital for Sick Children, Toronto, ON., Canada; 3) Division of Maternal-Fetal Medicine, Mount Sinai Hospital, Toronto, ON., Canada; 4) Department of Laboratory Medicine, Credit Valley Hospital, Mississauga, ON., Canada.

We describe here two siblings who presented with severe IUGR, gallbladder agenesis/hypoplasia, and multiple intestinal atresias. The first sibling was female and died of liver, renal and respiratory failure following surgery for repair of jejunal and pyloric atresias. Autopsy confirmed the aforementioned MCAs as well as a short pancreas and thymic atrophy. Postmortem cholangiogram revealed no gallbladder and two bile ducts draining separately into the pylorus and duodenum. The second sibling was male, born at 38 weeks gestation. Prenatally, intestinal atresia and IUGR were noted in the third trimester. Postnatally, during the surgical repair of the intestinal atresias, a hypoplastic gallbladder was noted. The siblings' features were not dysmorphic and their karyotypes were normal.

Review of the literature indicates that severe IUGR, intestinal atresia and gallbladder agenesis without biliary atresia has previously not been reported as a syndrome. Although Martinez-Frias et al (Am. J. Med. Gen., 1992) reported on two siblings with a similar pattern of gastrointestinal malformations, that syndrome included TEF, hypospadias, and extrahepatic biliary atresia, none of which were evident in our affected siblings. The MCA pattern reported here likely represents a new autosomal recessive syndrome. Prenatal diagnosis is possible when signs of IUGR, intestinal atresia and gallbladder agenesis/hypoplasia are present.

**Differential diagnosis and decision analysis in the management of low second trimester unconjugated estriol**

**(uE3).** *N.A. Hueppchen<sup>1</sup>, J. Hill<sup>1</sup>, C.J. Macri<sup>2</sup>.* 1) OB/GYN, National Naval Medical Center, Bethesda, MD; 2) Department of OB/GYN, USUHS, Bethesda, MD.

**BACKGROUND:** During the second trimester, alpha-fetoprotein (AFP), human chorionic gonadotropin (hCG) and unconjugated estriol (uE3) in plasma are often measured as markers for fetal abnormalities. Several studies have shown that very low or undetectable levels of second trimester unconjugated estriol are associated with a variety of disorders, to include chromosomal abnormalities, steroid sulfatase deficiency, congenital adrenal hyperplasia, Smith-Lemli-Opitz syndrome (SLO), adrenocorticotropin deficiency, anencephaly, and miscarriages. **OBJECTIVE:** The purpose of this study was to examine the relationship between low maternal serum levels of uE3, sonographic findings, and adverse perinatal outcomes in series of pregnancies undergoing prenatal diagnosis in our Prenatal Assessment Center(PAC). Subsequently, we attempted to use this information to develop a management scheme to assist in the prenatal diagnosis of abnormal pregnancies identified by low maternal serum uE3 in the second trimester. **CASES:** Ten patients were identified who presented to the PAC with low maternal serum levels of uE3. The fetal biometry and sonographic findings were documented, and each patient was offered amniocentesis for karyotype and other biochemical testing as deemed necessary. The following conditions were diagnosed: aneuploidy, anencephaly, SLO, and X-linked ichthyosis. **CONCLUSION:** The finding of a very low or undetectable unconjugated estriol level on the second trimester maternal serum triple screen should be a warning sign, and prompt the clinician to additionally investigate for evidence of disorders, other than trisomy 18, for which biochemical or genetic testing is available.

**A nonsense mutation of *PVRL1* (W185X) is associated with non-syndromic cleft lip/palate in northern Venezuela.**

*M. Sözen*<sup>1</sup>, *K. Suzuki*<sup>1</sup>, *M. Tolarova*<sup>2</sup>, *T. Bustos*<sup>3</sup>, *J. Iglesias*<sup>4</sup>, *R. Spritz*<sup>1</sup>. 1) Univ Colorado Hlth Sci Ctr, Denver; 2) Univ Pacific, San Francisco, CA; 3) Univ Ctr Venezuela, Caracas; 4) Ctr Diag Odontol, Porlamar, Venezuela.

Cleft lip ± cleft palate (CL/P) is among the most common of major birth defects, with an incidence of 0.4-2.0/1000. About 70% of cases are non-syndromic (nsCL/P), with complex inheritance. CL/P also occurs in many single-gene syndromes, and we have shown that autosomal recessive CLPED1 syndrome results from mutations of *PVRL1*, encoding a developmental cell-cell adhesion molecule. CLPED1 is common on Margarita Island, just north of Venezuela, due to homozygosity for a *PVRL1* nonsense mutation, W185X. On the island, ~1/26 normal persons carry the W185X mutation, many having a broad, flat upper lip, possibly a *form fruste* of CL/P. Further, the incidence of nsCL/P is very high on Margarita Island, ~5.4/1000. These findings suggested that the *PVRL1* W185X mutation might be a risk factor for nsCL/P in this region. We carried out a pilot case-control survey for the W185X mutation among patients with nsCL/P versus normals from Margarita Island, and found that 2 of 30 (q=.067) nsCL/P patients were W185X heterozygotes, versus 2 of 52 (q=.039) unrelated normals. This 1.7-fold increase, while suggestive, is not significant due to the high rate of heterozygosity among normals. Accordingly, we carried out a larger case-control study of the Cumaná region on the north coast of Venezuela, just south of Margarita Island, where the incidence of nsCL/P is also relatively high, ~2.5 per 1000. In Cumaná, 14 of 243 unrelated nsCL/P patients were heterozygous for the W185X mutation (q=.057), versus 1 of 245 unrelated normals from the region (q=.004) ( $P=.0004$ ). Further, the frequency of the W185X mutation among Cumaná nsCL/P patients (5.7%) was essentially the same as on Margarita Island (6.7%), suggesting that the degree of association between the mutation and nsCL/P is similar ( $P=0.691$ ) in these two populations. The *PVRL1* W185X mutation thus appears to be a significant, albeit moderate, genetic risk factor for nsCL/P in the Cumaná region of north-central Venezuela, the first thus far identified in any population.

**Distal 10q deletion and VUR.** *S. Sakazume*<sup>1,4</sup>, *Y. Kobayasi*<sup>4</sup>, *T. Nagai*<sup>4</sup>, *T. Ogata*<sup>2</sup>, *K. Muroya*<sup>2</sup>, *H. Ohashi*<sup>3</sup>, *Y. Fukushima*<sup>1</sup>. 1) Department of Hygiene & Med Genetics, Shinshu Univ, Matsumoto Nagano, Japan; 2) Department of Pediatrics, Tokyo Electric Power Company Hospital; 3) Division of Medical Genetics, Saitama Childrens Medical Center; 4) Department of Pediatrics, Dokkyo University School of Medicine Koshigaya hospital.

We report on a patient with chromosome 10q del. associated with VUR and a hypo/dysplastic kidney. The deleted site is a rather distal region than the reported genes, suggesting the existence of novel genes responsible for VUR in this region. The patient is a 3-year-old girl. She was born normally to a healthy 34y/o mother and a 30y/o father as a second baby. Her birth weight was 2358g. She showed several abnormal features, including mild hypotonia, micrognathia, low set ears and hypoplastic abdominal wall. At three month of age she developed UTI. Bilateral VUR (grade 5 and 3) complicated with right hypo/dysplastic kidney was diagnosed. Her karyotype, 46, XX, del (10) (q25.3). rev ish del (10) (q25.3) (WCP10+), was confirmed using G banding and FISH. The micro-satellite marker study confirmed that the paternal chromosomal region was deleted, and that the range of the deletion was from D10S587 to D10S215. There are several genes related to urinary tract formation, such as RET, PAX2, GFRA1 and EMX2, on chromosome 10. The patients break point is distal site of these genes. These genes are conserved in this patient. Ogata (2000) summarized that urinary tract abnormality is complicated more than 70% in the 10q del syndrome. It is possible that (an) unrecognized gene(s) responsible for VUR and urogenital anomalies is (are) located at the 10q terminal region.

**Pedigree Review to Determine Cancer-Related Deaths in Individuals with Neurofibromatosis type 1 in a Pediatric-based NF Clinic.** *K. Dent, B. Baty, J. Palumbos, S. Lewin, J. Carey, D. Viskochil.* Dept Pediatrics, Univ Utah Health Sci Ctr, Salt Lake City, UT.

Neurofibromatosis type 1 (NF1) is a progressive, multi-system disorder affecting approximately 1 in 3500 individuals worldwide. The recent report by Rasmussen et. al. (AJHG 2001) showing decreased life expectancy of individuals with NF1 led to our review of multi-generation NF1 pedigrees to identify cause of death in a Utah cohort. We focused on cancer-related deaths, specifically a common NF1-related cancer, malignant peripheral nerve sheath tumor (MPNST). MPNSTs are spindle cell sarcomas that often arise in the context of plexiform neurofibromas. The incidence of these tumors is estimated to be 2-5% in individuals with NF1, and they are detected most often in the 3rd or 4th decade of life. The 5-year survival rate is approximately 40 - 50%. We hypothesize that MPNSTs contribute significantly to the decreased life expectancy in NF1. We analyzed 155 individuals affected with NF1 within 20 three-generation families ascertained in the NF Clinic at the University of Utah. Only 19 deaths were reported. Twelve individuals (from 10 families) reported malignancies leading to death. Five of the 12 individuals experienced MPNSTs (3%) and 7 (4%) were described as having NF-related cancers including glioblastoma, intra-cranial tumor, lymphoma, and four of unspecified type. The remaining 7 deaths were not cancer related. These findings correlate with the expected incidence of MPNSTs in NF1 and support the conclusions by Rasmussen et. al. that malignancies of connective and other soft tissues occur more frequently than expected in individuals who die of NF1. Upon review of the pedigrees of these 20 families and several two-generation families, we recognized the potential for under-ascertainment of cancer-related deaths in NF1, specifically MPNSTs. To address this issue, providers of genetic services must routinely ask about causes of death and history of cancer when obtaining family history information. Longitudinal studies and more accurate collection of causes of death in extended pedigrees are needed to determine the true incidence of MPNST-related deaths in NF1.

**A mild phenotype of Incontinentia Pigmenti in a male child: DNA confirmation of a somatic mosaicism. S.**

*Rugolotto<sup>1</sup>, T. Bardaro<sup>2</sup>, T. Esposito<sup>2</sup>, F. Soli<sup>3</sup>, A. Turco<sup>3</sup>, P.F. Pignatti<sup>3</sup>, M. D'Urso<sup>2</sup>.* 1) Pediatric Intensive Care Unit, Mayor Civil Hospital, Verona, Italy; 2) International Institute of Genetics and Biophysics c/o Area di Ricerca del CNR di Napoli, Naples, Italy; 3) Section of Biology and Genetics, Mother and Child Department, University of Verona, Verona, Italy.

Familial Incontinentia Pigmenti (IP) is an X-linked dominant genodermatosis, lethal in males. Affected females demonstrate abnormalities of the skin, teeth, and central nervous system. Eighty-five percent of IP cases are due to a gene rearrangement within the NEMO gene which deletes exons 4-10. We describe an affected male showing an IP female-like phenotype who was born after a normal pregnancy with a birth weight of 2670 g. Family history was negative for skin and neurologic disorders, IP and abortions. At birth, erythematous blisters scattered over the body surface, according to the distribution of Blaschko lines. At 10 days of life, a skin biopsy was consistent with IP. The standard karyotype was 46, XY, normal. At 30 days of life, some warty lesions were evident on the hands. At 5 months of age, some linear yellowish streaks were present in the areas previously affected by vesicular lesions. Now, at 23 months of age, the child is growing well, shows very light yellowish streaks on the skin, has a conic tooth in his mouth and has a normal neurological development. DNA from patient's peripheral blood lymphocytes was analysed for the presence of NEMO gene deletion of exons 4-10, using a previously established protocol. The analysis showed the identical gene deletion carried by most of the IP patients. Moreover, using other specific primers for the wild type NEMO gene, we detected the usual band of the normal allele as well. Parents' DNA was negative for gene rearrangement. These results suggest an early postzygotic mutation ending in a possible somatic mosaicism, which explains the survival and mild phenotype of our male patient. Further molecular tests are in progress to show the mosaicism rate in tissues other than blood. Our case report provides a possible genetic mechanism for X-linked dominant disorders in surviving males.

**DNA evaluation of a Marfan syndrome mutation with high phenotypic variability and the counseling issues about heart disease.** *F.V. Schaefer<sup>1</sup>, P. O'Laigue<sup>2</sup>, L. Whetsell<sup>1</sup>, C. Curry<sup>2</sup>*. 1) Dept Molecular Genetics, HA Chapman Inst Medical Gen, Tulsa, OK; 2) Genetic Medicine Department, Valley Children's Hospital, Maderia, CA.

A large percentage of patients who undergo direct DNA testing at the HA Chapman Institute present with possible Marfan syndrome but do not fulfill sufficient clinical criterion nor have sufficient family history to be definitively diagnosed. However, correct diagnosis is critically important due to the life-threatening aspects of Marfan syndrome, heart disease. This family illustrates a compounding difficulty of DNA diagnosis in Marfan syndrome and the protocol that we use in order to pursue the clinical significance. In contrast to most patients we receive for testing, this family had several cases of diagnosed Marfan syndrome. An Ala882Thr gene alteration was discovered but there was a concern as to its clinical significance. Consequently, 7 other family members were examined and the mutation was identified in 3 with a Marfan diagnosis and not found in 3 members without the Ala882Thr change. However, one family member with no phenotypic signs was also found with the DNA alteration. As a result of the DNA studies, the counselor made a recommendation for baseline heart and eye studies to be performed on all 3 offspring (all in their 20s) of the proband including the daughter without any phenotypic signs of Marfan syndrome. During the baseline exam this daughter was discovered to be undergoing aortic dissection and was operated on the day after the exam. On balance, the evidence suggests that the Ala882Thr alteration is a mutation. Most importantly, however, it demonstrates that a life-threatening heart problem can occur in an individual with no outward phenotypic signs of Marfan syndrome. Without the DNA testing and the resulting echocardiogram the consequences of the daughters dissecting aorta could have been fatal. Combined with our previous survey data on our cases, this family illustrates that the heart involvement the major life-threatening aspect of the disease - may be the common denominator in most cases and DNA analysis is an especially important part of the clinical evaluation.

**A Clinical and molecular study of 20 German patients with Fibrodysplasia Ossificans Progressiva. G.G.**

*Gillessen-Kaesbach<sup>1</sup>, C. Grünberg<sup>1</sup>, E.M. Shore<sup>2</sup>, G. Feldman<sup>2</sup>, F.S. Kaplan<sup>2</sup>.* 1) Institut für Humangenetik, Universitätsklinikum, Essen, Germany; 2) Dep. of Orthopedic Surgery and Medicine, University of Pennsylvania School of Medicine, Philadelphia, USA.

Fibrodysplasia ossificans progressiva (FOP) is a rare disorder of connective tissue where there is progressive ectopic ossification and characteristic skeletal malformations. The FOP phenotype has previously been linked to markers located in the 4q27-31 region. We report on the clinical and molecular findings in 20 German patients with FOP (9 male, 11 female) with an age ranging from 3 to 38 years. All were sporadic cases. The patients were examined personally (CG, GG-K) and had to answer a questionnaire. Ectopic ossification started on average at 3.8 years (birth to 11 years) leading to extra-articular bony ankylosis of nearly all joints of the axial and appendicular skeleton. Hypoplasia of big toes was present in 12/20 patients, 10 patients had a hypoplastic thumb. Hearing loss was found in 7/20 individuals. Average paternal age was 30.6 years (19-40y). There are a number of interesting candidate genes in 4q27-q31 such as *FGF-2* (Fibroblast-Growth Factor 2), *EGF* (Epidermal Growth factor), *SMAD-1*, *IL-15*, *NFκ-B1* and others. We performed mutational analysis in the Toll-like receptor 2 (*TLR2*) but were unable to find any mutations. A further search for mutations will help to understand the biological pathway of the disease and help to provide evidence for future treatment.

**Evidence for a common ancestor in 2 large families with phenotypically variable spastic ataxia.** *K.K. Grewal<sup>1</sup>, M.G. Stefanelli<sup>1</sup>, I.A. Meijer<sup>2</sup>, C.K. Hand<sup>2</sup>, G.A. Rouleau<sup>2</sup>, E.J. Ives<sup>1</sup>.* 1) Discipline of Medical Genetics and Division of Neurology, Faculty of Medicine, Health Sciences Centre, Memorial University, St. John's, Newfoundland, A1B 3V6 Canada; 2) Centre for research in Neuroscience, McGill University, Montreal General Hospital research Institute, Montreal, H3G 1A4 Canada.

A slowly progressive neurodegenerative disorder in which both spasticity and ataxia are common features is described in 2 large independently ascertained Newfoundland families, family 71 and family 13. Despite the marked phenotypic diversity, clinical similarities exist between these families and both pedigrees show linkage to a new locus which includes a 13.6cM haplotype shared by all affected members. Family 71 has 16 clinically affected living members (ages 22-76 yrs) and family 13 has 34 (ages 21-71 yrs). Segregation and sex ratios are consistent with autosomal dominant inheritance. The disorder is difficult to classify but often presents with hypertonicity, hyperreflexia and eye movement abnormalities and could be termed a spastic ataxia. The range of expression is very variable in both families with some members exhibiting mild symptoms whilst others have a broader more severe phenotype even within the same sibship. Onset for most cases occurs within the first 2 decades with leg spasticity, clumsiness and an involuntary head jerk recognised by family members. More difficulties are encountered by the third decade with progression of spasticity, significant dysarthria with characteristic scanning nasal speech and intermittent dysphagia. Supranuclear gaze palsy, dystonia and proprioceptive errors are also observed. By the fourth decade the broad-based spastic and ataxic gait creates major problems for independent mobility but neither cognition nor life span are noticeably affected. There is no evidence for a sex influence on the phenotype. Families 71 and 13 both originate in a rural historically isolated geographic area of the island of Newfoundland where it is presumed that the occurrence of the condition reflects a common ancestor. The disorder contributes disproportionately to the burden of adult neurological degenerative disease in the area and identification of the specific mutation will facilitate appropriate genetic testing.

**Ectodermal dysplasia syndrome with mental deficiency, joint laxity, nystagmus, cerebellar ataxia, periventricular nodular heterotopia, osteopenia and hyperglycinuria.** *R. Zannolli*<sup>1</sup>, *C. Miracco*<sup>2</sup>, *M.M. de Santi*<sup>2</sup>, *G. Vatti*<sup>3</sup>, *P. Galluzzi*<sup>5</sup>, *A. Malandrini*<sup>4</sup>, *E. Conversano*<sup>1</sup>, *L. Serracca*<sup>1</sup>, *M. Molinelli*<sup>1</sup>, *G. Coviello*<sup>6</sup>, *P. Terrosi-Vagnoli*<sup>7</sup>, *S. Gonnelli*<sup>8</sup>. 1) Dept of Pediatrics, Obstetrics, and Reproductive Medicine, Section of Pediatrics, Policlinico le Scotte, University of Siena, Siena, Italy; 2) Institute of Pathological Anatomy and Histology, Policlinico le Scotte, University of Siena, Siena, Italy; 3) Dept of Neurosciences, Section of Neurology, Policlinico le Scotte, University of Siena, Siena, Italy; 4) Institute of Neurological Sciences, Policlinico le Scotte, University of Siena, Siena, Italy; 5) Neuroradiology Unit, Azienda Ospedaliera Senese, Policlinico le Scotte, Siena, Italy; 6) Radiology Unit, Azienda Ospedaliera Senese, Policlinico Le Scotte, Siena, Italy; 7) Dept of Radiology and Orthopedics, Policlinico Le Scotte, University of Siena, Siena, Italy; 8) Institute of Internal Medicine, Policlinico le Scotte, University of Siena, Siena, Italy.

We may be seeing a novel ectodermal dysplasia (ED) syndrome with a pseudo-cranioectodermal dysplasia phenotype (MIM 218330) associated with a wide spectrum of features (mental deficiency, joint laxity, cerebellar ataxia, periventricular nodular heterotopia, osteopenia and hyperglycinuria). The proposita is a seven-year-old girl, the second child born from consanguineous parents (first cousins born from two of five siblings). The older sister, 13 years old, was referred as being apparently normal. The mother, apparently healthy and mentally unimpaired, had a subtle set of ED traits (hair, teeth and minimal skeletal dysmorphisms). The father was described as a normal healthy man with minimal hair and teeth problems. Both the proband's sister and the parents had hyperglycinuria. Of interest, several other members of both the mother's and father's family have suffered from thin and sparse hairs with subtle areas of alopecia, dental health failure and/or hyperglycinuria.

**Limb reduction defect associated with  $\alpha$ -thalassemia homozygous state.** *M. Thomas<sup>1</sup>, D. Myles Reid<sup>1</sup>, D. Chui<sup>2</sup>, D. Chitayat<sup>1</sup>*. 1) The Prenatal Diagnosis and Medical Genetics Program, Mount Sinai Hospital, University of Toronto, Toronto, Ontario, Canada; 2) Provincial Hemoglobinopathy DNA Laboratory, Chedoke-McMaster Hospital, Hamilton, Ontario, Canada.

The association between limb reduction defect and  $\alpha$ -thalassemia is rare but has been reported before. The etiology of this association has not been delineated. We report a pregnancy who presented with limb reduction defect and hydrops fetalis and who was found to have  $\alpha$ -thalassemia homozygous state. The parents were of Filipino origin. The couple has one healthy daughter and this was their second pregnancy. The mother presented at 22.8 weeks gestation with fetal ultrasound findings of hydrops fetalis, oligohydramnios, pleural effusion, severe cardiomegaly, missing fingers on left hand and missing toes on both feet. Hematological investigation revealed that both parents were heterozygous for  $\alpha$ -thalassemia. The mother was a carrier of the Filipino  $\alpha$ -thalassemia-1 deletion (--FIL/aa) mutation and the father was a carrier of the southeast Asian  $\alpha$ -thalassemia-1 mutation (--SEA/aa). DNA analysis showed that the fetus was compound heterozygote for the Filipino  $\alpha$ -thalassemia-1 deletion and the southeast Asian  $\alpha$ -thalassemia-1 mutation (--FIL /--SEA). The pregnancy was terminated and the autopsy confirmed the fetal ultrasound findings including hepatosplenomegaly and extensive extramedullary hematopoiesis. Advances in antenatal diagnosis, intrauterine intervention, and postnatal treatments have resulted in possible survival of fetuses with alpha thalassemia homozygous. When the parents consider prenatal treatment with fetal blood transfusion a detailed fetal ultrasound including detailed survey of fetal limbs is mandatory and discussion of limb reduction defects should be included in the genetic counselling.

**Mechanism of cardiac malformations in patients with bilateral pulmonary agenesis.** *R.S. Colby, R.E. Stevenson, L.H. Seaver, N.R. Cooley, Jr.* Greenwood Genetic Ctr, Greenwood, SC.

Pulmonary agenesis is defined by complete absence of the bronchus and all lung tissue below the bifurcation of the trachea. It can occur as a unilateral or bilateral defect. Bilateral pulmonary agenesis (BPA) is rare, reported in 18 patients. BPA is associated with other malformations and is always associated with specific cardiovascular malformations. The cardiovascular structures affected are those related to pulmonary perfusion. All cases have had agenesis of the pulmonary veins and the pulmonary artery is agenic or joins the aorta at the ductus without giving off branches. A fetal autopsy at the Greenwood Genetic Center with BPA confirmed these associations. A dizygotic twin born at 35 weeks showed agenesis of the pulmonary valve, artery, and veins, agenesis of the ductus arteriosus, and a VSD with an overriding aorta. Other malformations included bilateral microphthalmia, GI malformations, and GU malformations. The cotwin was normal.

The laryngo-tracheal diverticulum develops as a ventral outgrowth from the foregut just caudal to the pharynx. Lung buds develop from this structure at the end of the fourth week. Angioblasts proliferate around the lung buds and form the primordium of the common pulmonary vein. Likewise a pulmonary vascular plexus forms around the developing lung buds and eventually connects to the pulmonary arteries that come from the sixth aortic arch.

If the lung buds or vascular plexuses around the lung buds fail to form then the entire architecture of the heart destined to perfuse the lungs will also fail to form. The heart may not have the typical divisions, the pulmonary veins and arteries will not form, and the truncus arteriosus may not divide. This results in the cardiac malformations seen with BPA.

BPA is associated with other malformations. These include anophthalmia/microphthalmia, gastrointestinal anomalies, and genitourinary anomalies. Many of these structures begin to form around the fourth week of development, suggesting a common mechanism acting during this period. A time limited defect in angiogenesis is a possible explanation.

**Molecular confirmation of somatic mosaicism in a karyotypically normal male with X-linked dominant chondrodysplasia punctata 2 (CDPX2).** *D.J. Aughton*<sup>1</sup>, *R.I. Kelley*<sup>2</sup>, *A. Metzenberg*<sup>3</sup>, *R.M. Pauli*<sup>4</sup>. 1) Wm. Beaumont Hospital, Royal Oak, MI; 2) Kennedy Krieger Institute, Baltimore, MD; 3) California State U.-Northridge, CA; 4) U. of Wisconsin-Madison, WI.

CDPX2 (Conradi-Hünemann syndrome [McK #302960]), an X-linked dominant condition lethal in hemizygous males, is characterized by epiphyseal stippling, skin changes that follow Blaschko's lines, patchy alopecia, and short stature. It is associated with increased levels of 8-dehydrocholesterol and 8(9)-cholestenol; it is caused by abnormal function of *EBP*, which maps to Xp11.22-p11.23. In 1995, Happle proposed either a postzygotic mutation or a gametic half-chromatid mutation to explain the observation of CDPX2 in 3 46,XY males. Both gonadal and somatic mosaicism have been described in CDPX2, but somatic mosaicism in a karyotypically normal male with CDPX2 has not previously been demonstrated. We report such a case.

A 6-month-old boy presented with macrocephaly, mild scoliosis, and equivocally short limbs. Skeletal survey showed punctate epiphyseal calcifications, scoliosis, butterfly vertebræ, and mild long bone shortening. Examinations through the first 3 years of life also showed facial characteristics of CDPX2, spotty alopecia, linear hypotrophic skin lesions, and mild asymmetry of the legs and feet, findings consistent with a diagnosis of CDPX2. Additional studies included routine chromosome analysis (46,XY), plasma sterol analysis (8[9]-cholestenol and 8-dehydrocholesterol), and FISH analysis of sex chromosomes in buccal cells (all XY). Molecular analysis of *EBP* demonstrated 2 populations of cells, 1 with the wild-type allele and 1 with an altered allele (G238A, E80K) often seen in affected females. Clinical, biochemical, and molecular assessment of the boy's mother showed macrocephaly but no other evidence of CDPX2.

The proband therefore has mosaicism for a *de novo* mutation of *EBP*. His linear skin lesions, spotty alopecia, and asymmetries thus arose from somatic mosaicism rather than X inactivation. His case provides independent support for the Happle hypothesis.

**Lymphedema, unique facial features and tapered fingers in three females in three generations: A new lymphedema/multiple congenital anomaly syndrome or an expanded phenotype of the lymphedema/distichiasis syndrome?** *R.G. Cadle, B.D. Hall.* Dept Pediatrics/Genetics, Univ Kentucky Medical Ctr, Lexington, KY.

There are several syndromes partially characterized by lower extremity lymphedema, including Milroys disease, and the less common Hennekam syndrome and lymphedema/distichiasis syndrome (LD). We report a mother, daughter and grand daughter with a lymphedema/multiple congenital anomaly syndrome.

The proband, ED, was a 16-year-old pregnant Caucasian female with unique facial features and lymphedema of the lower extremities which was first noted at 14 years of age. EDs mother, JD, developed lymphedema of the legs at approximately ten years of age. Both ED and JD have a full, broad nasal tip, wide nasal bridge, dystopia, long, simple philtrum, broad neck, and tapered fingers. JD has developed pes cavus with age. Both ED and JD have chronic red and irritated eyes of unknown etiology. Both have had numerous negative allergy evaluations. Neither has had a formal eye exam, but both have disorganized eyelashes, which may be the cause of their eye irritation. Distichiasis has not been confirmed. We evaluated EDs baby, AD, at five weeks of age. She had epicanthal folds, hypertelorism, broad nasal bridge, prominent pre-maxilla, redundant skin on the nape of the neck and mildly tapered fingers. No lower extremity edema was noted.

A skeletal survey of JD indicated no major bone abnormalities. FISH analysis (done by Dr. Thomas Glover at the University of Michigan) did not detect a microdeletion in FOXC2, mutations in which have recently been found to cause LD. However, based on the age of onset of the lower extremity lymphedema in our family, and the suspicion that there are abnormalities of the eyelashes, the possibility of LD is considered. Patients with LD, though, do not share the facial dysmorphology noted in our three patients. Further molecular testing will be necessary to better determine whether or not our family has a new mutation in the FOXC2 gene or whether they represent a new lymphedema/multiple congenital anomaly syndrome.

**OSA syndrome (ocular, skeletal, and abdominal abnormalities): Confirmation of the autosomal recessive syndrome in a sporadic male.** *B. Bender, B.D. Hall.* Department of Pediatrics, University of Kentucky, Lexington, KY.

In 1996, Mingarelli, et al, described two adult sisters with a unique pattern of ocular, facial, skeletal, and abdominal abnormalities including short, downslanting palpebral fissures and ptosis with thin high-arched eyebrows, high nasal bridge, flat malar bones, high-arched palate, and diastasis recti. One sister had limitation to supination secondary to radioulnar synostosis, while the other had carpal fusion. The older sister also demonstrated aortic incompetence. In addition, the two girls each had lumbosacral spina bifida and normal intellectual functioning. (*J Med Genet* 1996; 33:884-886) We report an 11-year-old boy with remarkably similar facial features, including the very distinctive high-arched eyebrows and flat malar bones, who originally presented at 6 months of age. He is the full-term product of a non-consanguineous, uncomplicated pregnancy to a 33-year-old G2P1 mother. Birth weight was 8 pounds, 14 ounces and birth length was 20 1/2 inches. He was noted at birth to have a sacral appendage and a small mid-sternal skin tag. Other unique features include a PDA that was ligated at 2 years of age, inability to supinate past the neutral position, and a lumbosacral dysraphism (L4 to S2). Our patient did not have a diastasis recti. He has normal psychomotor development. Chromosome analysis revealed a pericentric inversion on the Y, which his father also carries; consequently, it is thought to be unrelated to these anomalies. The similarity between our patient and those reported by Mingarelli, et al. is impressive, and we conclude that this is indeed a distinct entity. The distinctive eyebrow configuration with additional dysmorphism is a good indicator to consider this syndrome.

**Redefining a case of Jarcho-Levin Syndrome as Oculo-Auriculo-Vertebral Spectrum.** *S.F. Cheng<sup>1</sup>, G.M. Enns<sup>2</sup>, M. Golabi<sup>1</sup>, B. Blumberg<sup>1</sup>, D.R. Kostiner<sup>1</sup>.* 1) Dept Pediatrics/Div Genetics, UC San Francisco, CA; 2) Dept Pediatrics/Div Genetics, Stanford University, CA.

OAV spectrum is a condition typified by hemifacial microsomia, lipodermoids, facial skin tags, ear anomalies and vertebral defects. Less common features include anal atresia and defects of the heart, lungs, kidneys and CNS. Many features of OAV overlap those of VATER and CHARGE. Discordant presentation of OAV in twins has been documented. Jarcho-Levin syndrome (JLS) is a type of short trunk dwarfism characterized by crab-like thorax, infant mortality and autosomal recessive (AR) inheritance. We present the case of a 5 y.o. boy diagnosed with JLS as a neonate whose features are now more consistent with the severe end of OAV spectrum. Assuming this child truly has OAV, the recurrence risk for his parents decreases from 25% (AR) to 2-3% (sporadic). The proband and his unaffected same-sex twin were born at 33 weeks to a 29 y.o. woman. Newborn exam revealed asymmetric ears, unilateral ear tags, short neck, misshapen chest, anal atresia, GU anomalies and camptodactyly. Karyotype showed 46,XY with no 22q deletion. X-rays showed various vertebral defects, fused ribs and crab-like thorax. A presumptive diagnosis of JLS was made. Annual follow-up for 5 years revealed developmental delay, short stature, lipodermoids and some improvement in thoracic defects. The diagnosis of JLS was questioned based on the child's hemifacial microsomia and improvement with time. Literature review revealed that Mortier et al. (1996) reclassified JLS into 4 categories, one of which describes sporadic inheritance, various thoracic defects, additional structural defects (craniofacial anomalies, anal atresia) and survival beyond childhood. Features of this category overlap those seen in severe OAV, suggesting the two may be in the same spectrum. Furthermore, since features of OAV, VATER and CHARGE overlap, there is growing consensus that all 3 are in the same spectrum. Variations in presentation are likely due to genetic heterogeneity and intrauterine factors (such as twinning). Longitudinal follow-up is helpful in genetic diagnosis, since reassignment of diagnosis can change recurrence risks for families.

**A new autosomal dominant syndrome of dermal ridge hypoplasia and palpebral hypertrichosis.** *J. Doucet<sup>1</sup>, A. Lirette<sup>1</sup>, S.M. Robichaux<sup>1</sup>, Y. Lacassie<sup>2</sup>*. 1) Dept Biological Sci, Nicholls State University, Thibodaux, LA; 2) Dept Pediatrics, LSU Health Sciences Center, New Orleans, LA.

We report a large kindred expressing a constellation of dermal abnormalities that describe a new syndrome. The features of the syndrome include dermal ridges hypoplasia of both the palmar and plantar surfaces, distichiasis and hypertrichotic growth across the eyelids as the brows thicken and descend toward the lateral canthi, raised and pyramidal fingerpads and toepads, under-keratinized and sweaty palmar and plantar surfaces, dorsal hyperpigmentation of the phalangeal surfaces, excessive tearing of the eyes, and coarse body hair. The syndrome affects four generations of an extended southern Louisiana family of Acadian descent and is inherited in an autosomal dominant fashion.

**Robert's-SC phocomelia Syndrome in two Infants with Different Ethnicity in Kuwait : Brief clinical report.**

*M. Mostafa, Henedi, S.A Alawadi, L. Bastaki, A. Alwadani, K. Murthy, R.L Alnaggar.* Obstetric&Gynecology, Kuwait Medical Genetics Center, Kuwait, Capital, Kuwait.

We describe two cases with tetraphocomelia/unusual facial features and cytogenetic findings in Pakistani& Kuwaiti boys. The described phenotype is consistent with Robert's-SC phocomelia. We did a comparison between ours and the previously reported. The 1st case was Pakistani, newborn and preterm baby having oxycephaly, sparse/silvery hair, shallow orbit, exophthalmos, ectropion, cloudy corneas, bilateral cleft lip/palate, hypoplastic ears and facial hemangioma. There were symmetrical limb reduction defects, flexion/contracture of joints and ambiguous genitalia. Skeletal survey revealed hypoplastic joints, deficient carpal/metacarpal bones, adactylia/aphalandia in both hands, rudimentary 12th rib, short/deformed tibiae, absent left fibula and deficient metatarsal/phalanges in both feet. Karyotype showed absence of premature separation of centromeres. The 2nd case was 1 year and 8 months old, Bedouin boy having IUGR and postnatal growth delay. His phenotype included facial capillary hemangioma, short nose, dysplastic ears retrognathia, short neck and pectus excavatum. Upper limbs showed bilateral phocomelia, short hands, oligodactylia/aphalangia and dysplastic nails/skin with dysplastic creases. Bilateral hip joints hypoplasia/dislocation, knee aplasia, ankle hypoplasia, phocomelia, absent fibulae, deficient metatarsals and oligodactylia have been found in lower limbs. External genitalia showed pigmented, empty scrotum and macrophallus. Skeletal survey revealed short humeri, bilateral humeroradial fusion, hypoplastic radii, absent ulnae, absent/deficient carpal/metacarpal bones and aphalangia. Hypoplastic hip bones, shallow acetabulum, short/angulated and dysplastic femora, short tibiae absent fibula/tarsal, metatarsal bones with aphalangia. Cytogenetic & FISH studies revealed balanced, reciprocal translocation,  $t(1q:3q)(q32-q21)$ , like his normal daughter transmitted from the father. Both phenotypes share in common the severe symmetric limb reduction defects, recessive inheritance and absence of premature separation of centromere, but slightly differ in some craniofacial features. These two cases could be allelic variants?.

**Paternal UPD 14 unrelated to translocation.** *E. McPherson*<sup>1,2</sup>, *R. Pinter*<sup>1</sup>, *S. Parida*<sup>2</sup>. 1) Dept Genetics, Magee Womens Hosp, Pittsburgh, PA; 2) Dept Pediatrics, Childrens Hosp of Pittsburgh.

Paternal uniparental disomy for chromosome 14 (pat UPD 14) is associated with a recognizable phenotype including narrow thorax, short limbs, webbed neck, contractures and characteristic facial appearance (short palpebral fissures, broad nose, prominent philtrum, small posteriorly rotated ears). Only 4 cases have been reported, all with translocations or isochromosomes involving 14q. We report a newborn with mildly short limbs and small thorax, who was referred because of suspected Jeunes Asphyxiating Dystrophy, but was noted to have additional anomalies including short palpebral fissures, broad nasal bridge, prominent philtrum, posteriorly rotated ears, excess nuchal skin, hypospadias. The mother had been followed prenatally for polyhydramnios and ultrasound had shown short fetal limbs. The karyotype at amniocentesis was 46XY. The fetus was born at 35 weeks with weight 2166g (40%), length 43cm (5%) and OFC 32cm (50%). His chest was extremely small (circumference 23 cm) and he had mild rhizomelic shortening of his limbs. X-rays confirmed short ribs, and short limbs, but there was no generalized skeletal dysplasia and the spine and pelvis appeared normal. The normal 46 XY karyotype was confirmed in lymphocytes. Because of clinical resemblance to reported UPD 14 patients, uniparental disomy studies were obtained and the child was found to have paternal isodisomy 14. He had a difficult clinical course due to chronic respiratory insufficiency and died at 3 months during a respiratory infection. To our knowledge, this is the first case of pat UPD 14 unrelated to a translocation. The possible mechanisms are non-disjunction in paternal meiosis 2 with subsequent trisomy rescue or maternal non-disjunction with monosomy rescue by duplication of the paternal 14. These events may be more common than previously recognized. UPD 14 studies are recommended for children who have thoracic dystrophy and short limbs with additional anomalies not expected in classical Jeune syndrome.

**A familial t(6;22) translocation resulting in both Duane syndrome and Velo-Cardio-Facial syndrome in siblings.**

*M.M. Li<sup>1, 2</sup>, K. Jackson<sup>1, 2</sup>, G. Pridjian<sup>1, 2, 3</sup>.* 1) Hayward Genetics Center,; 2) Dept of Pediatrics,; 3) Dept of Obstetrics & Gynecology, Tulane Univ School of Medicine, New Orleans, LA.

Balanced translocation carriers may bear a high risk of having abnormal children with different dysmorphic features. We report a t(6;22) in a family where the two brothers each inherited a different derivative chromosome from their phenotypically normal father who carried a balanced t(6;22). The proband was a 41-year-old male and was referred for chromosome study as part of the evaluation of his wife's recurrent pregnancy loss. His history was significant for Duane retraction anomaly, absence of one kidney and oligospermia. Cytogenetic study revealed that the proband had a supernumerary marker chromosome. Fluorescence in situ hybridization (FISH) demonstrated that the marker was derived from chromosome 22 and contained the DiGeorge syndrome chromosome region (DGCR). Hence, he had three copies of 22pter@q11. Parental studies discovered that the father carried a balanced translocation of t(6;22)(p25;q11). FISH studies proved that the breakpoint on the chromosome 22 was distal to the DGCR. The proband's only sibling was a 35-year-old male with signs of Velo-Cardio-Facial syndrome (VCFS) and azoospermia. His history was noticeable for nasal speech, frequent infection, developmental delay and learning difficulties. A testicular biopsy in evaluation of infertility showed absence of sperm. Cytogenetic studies exhibited a karyotype of 45,XY,der(6)t(6;22)(p25;q11),-22. FISH studies found that the der(6) did not contain the DGCR as was seen in his father; therefore, he is monosomic for the DGCR. Two previous cases of Duane syndrome associated with marker chromosome derived from chromosome 22pter@q11 were reported. In both cases, the marker was bisatellited, indicating the presence of four copies of the 22pter@q11 region. These findings suggest that a gene or genes located in the region of 22pter@q11 may be associated with Duane syndrome and the development of the urogenital system. In addition to the features of VCFS, the proband's brother had azoospermia. Since most of the VCFS patients of reproductive age are fertile, the azoospermia may have been caused by the deletion of band 6p25.

**Application of GenDis (an original computer software) for diagnosis of malformation syndromes.** *K. Naritomi<sup>1</sup>, T. Tohma<sup>2</sup>*. 1) Dept Medical Genetics, Univ Ryukyus Sch Medicine, Nishiraha, Okinawa, Japan; 2) Dept Pediatr, Univ Ryukyus Sch Medicine, Nishiraha, Okinawa, Japan.

UR-DBMS (University of the Ryukyus-Database for Malformation Syndromes) is an original database created and collected data since 1986, mainly from well-known English written textbooks, O-MIM and magazines. The latest version 8 includes clinical and molecular genetic informations of more than 6,500 genetic diseases and genes (total volume is about 700 MB). This year, UR-DBMS Ver. 8 has developed to a computerized diagnostic software (GenDis). Following an input of all findings of the patient, the GenDis automatically selects candidate syndromes in order of increasing matched number of findings. This GenDis was applied to 393 pooled patients with multiple congenital anomalies for the diagnosis, and tested its usefulness. In 141 patients (36%), tentative diagnoses were confirmed. In 111 patients (28%), an appropriate diagnosis was given by GenDis. In 66 patients, a diagnosis was suggested but not conclusive with some questions. In 75 patients, an appropriate diagnosis was not suggested, mainly due to lack of critical data and clinical information, or an excess of candidates. Two patients were considered to have a broadened spectrum of known syndromes. As a whole, appropriate diagnosis was suggested in 64% of the patients tested. Thus, application of the GenDis is considered useful diagnostic tool in clinical genetics for quick diagnosis and further examinations to confirm.

**Autosomal Dominant Robinow Syndrome in 11 Affected Family Members: Marked Phenotypic Variability.** *D.*

*Kostiner<sup>1</sup>, V. Cox<sup>1</sup>, M. Golabi<sup>1</sup>, H.E. Hoyme<sup>2</sup>.* 1) Dept Pediatrics/Div Genetics, UC San Francisco, CA; 2) Dept Pediatrics/Div Genetics, Stanford University, CA.

Robinow syndrome (RS) is a genetic disorder exhibiting both autosomal dominant and recessive modes of inheritance. Typical features include short stature, hypertelorism, cleft lip/palate, small hands, rib/vertebral defects, renal defects, genital abnormalities and normal intelligence. We report on a male baby with multiple anomalies who has 10 maternal relatives with similar but less severe phenotypes. We propose that all 11 members have RS and that the proband also has diabetic embryopathy. The proband was born to a 27 yo G2P1-2 mother at 34 weeks. Pregnancy was complicated by gestational diabetes treated with insulin starting at 26 weeks. Birth WT, HT, and HC were all ~40%. Multiple anomalies were noted at birth, including marked hypertelorism, facial dysmorphism, bilateral cleft lip/palate, dextrocardia, rib/vertebral anomalies, tethered cord, 2-vessel cord, single kidney, posterior urethral valves and cryptorchidism. Later complications included laryngotracheomalacia, obstructive apnea, respiratory arrests, inguinal hernias, fibrous subvalvar LV outflow obstruction, and multiple infections. At age 19 months, HT and HC were < 3%, WT was 15%, dysmorphism was striking and development was 2 months delayed. The proband's mother has short stature, hypertelorism and short fingers. Her father has similar features plus cleft lip/palate, and her grandmother had similar features plus 3 kidneys. Seven other family members have striking hypertelorism. Intelligence of all members is normal. This child's multiple anomalies are consistent with RS. The presence of 10 relatives with less severe phenotypes suggests dominant inheritance with marked variability in expression. The proband's dextrocardia and tethered cord are likely related to teratogenic effects of maternal diabetes and illustrate the role that the intrauterine environment may play in altering phenotype in genetic disorders. Data from this family imply that fitness may not be markedly reduced in autosomal dominant RS. The genes for RS have not been identified, but linkage analysis on this family might help in their discovery.

**Primary Hypothyroidism and Osteoporosis in Neuhauser Syndrome.** A. Sarkozy<sup>1</sup>, R. Mingarelli<sup>1</sup>, F. Brancati<sup>1</sup>, B. Dallapiccola<sup>1,2</sup>. 1) CSS-Mendel Institute, Rome, Italy; 2) Department of Molecular Medicine and Pathology, University La Sapienza, Rome, Italy.

Megalocornea-Mental Retardation (MMR) or Neuhauser Syndrome, is a rare autosomal recessive disorder first reported in 1975 by Neuhauser in nine patients. We examined an Italian 18 month old female child with MMR. Development milestones were delayed in the first months and myoclonic seizures became manifest at 8 months. She presented as a well-built brown girl, with head circumference of 41.8 cm (> -2 SD), weight 10.3 kg (25th centile), and length 77 cm (10th -25th centile). Main features were megalocornea, microcephaly, hypertelorism, bilateral epicanthal folds, micrognathia and asymmetric ears. Clinical examinations disclosed primary hypothyroidism, osteoporosis and hypercholesterolemia. The karyotype was normal. The clinical outline of MMR syndrome is tricky, because of the wide clinical variability. Comprehensive review of published MMR patients indicates that mental and growth retardation are invariably present, megalocornea occurs in 25 of 29 patients (86%), while a number of features recorded in MMR are found only in individual patients. This child showed the features shared by the majority of MMR subjects. In addition, she had primary hypothyroidism and osteoporosis, which were previously recorded only in individual patients. Hypercholesterolemia, which was likely related to hypothyroidism, has not been previously associated to MMR. Recurrence of thyroid and bone defects is arguing for a non random association with this disorder, suggesting that these anomalies are additional features of Neuhauser syndrome.

**Congenital Generalized lipodystrophy of Berardinelli-Seip : a study of 47 patients belonging to 9q34 and non-9q34 subgroups.** *L. Van Maldergem<sup>1</sup>, J. Magre<sup>2</sup>, E. Khallouf<sup>3</sup>, T. Gedde-Dahl Jr<sup>4</sup>, and the Berardinelli-Seip study group<sup>1</sup>.* 1) Centre Genetique Humaine, Inst Pathology & Genetics, Loverval, Belgium; 2) Inserm U 402, Faculte de Medecine Saint Antoine, Paris, France; 3) Institue of Forensic Medicine and Dept of Pediatrics, Rijkshospitalet, Oslo, Norway; 4) Service de pediatrie, Hotel-Dieu de France, Beyrut, Lebanon.

A series of patients with congenital generalized lipodystrophy, belonging to two groups designated according to their disease-causing mutation or their assigned locus after linkage study have been studied through an international consortium. We carried out a comparison between 9q34 and non-9q34. No genotype-phenotype correlation emerged and no distinctive phenotypic relationship could be distinguished between the two major loci. By contrast, although lipodystrophy was present from birth in a majority of affected patients, severe and mild phenotypes were observed with some patients coming to medical attention only in their second or third decades. The latter finding raises questions on the generally accepted classification between so-called congenital and acquired forms of generalized lipodystrophy. Facial lipodystrophy was less pronounced in infancy among patients of African ancestry.

**Partial Pentasomy of Proximal 15q: Clinical and Molecular Cytogenetic Characterization.** *H.E. Roberts<sup>1</sup>, B. Levy<sup>2</sup>, H.A. Creswick<sup>1</sup>, P.R. Papenhausen<sup>3</sup>*. 1) Children's Hospital of The King's Daughters, Norfolk, VA; 2) Mount Sinai-NYU Medical Center, New York, NY; 3) LabCorp of America, Research Triangle Park, NC.

Numerous studies of the proximal portion of chromosome 15q have been published because this region is often involved in structural rearrangements, and it also contains several imprinted genes. To date, partial pentasomy of proximal 15q has never been reported.

**Case Report:** The patient was born to a 29-year-old mother. The prenatal history was uncomplicated. A female was born at 40 weeks by a vaginal delivery without any complications. The infant was found to have significant developmental delay at 7 months of age. On physical examination at 13 months of age at a genetics evaluation, her head circumference was less than the 5th percentile. Epicanthal folds, flat nasal bridge, and a high arched palate were present. Three areas of patchy hypopigmentation were present on the neck, shoulders and chest. Five, small cafe-au-lait spots were present on the trunk and extremities.

**Molecular Cytogenetics:** Chromosome analysis revealed an abnormal karyotype, 48, XX, +2mar. FISH analysis identified both markers to be ring chromosomes derived from chromosome 15. Further analysis using a 15q11.2 SNRPN DNA probe showed a single SNRPN hybridization signal on the smaller of the two rings and two SNRPN hybridization signals on the larger ring chromosome. The mother's karyotype was normal. Uniparental disomy for chromosome 15 was not present. The rings were found to be maternal in origin. A comparative genomic hybridization analysis is in progress to better delineate the break points.

In the literature, patients with 4 copies of the Prader-Willi/Angelman syndrome (PWS/AS) region consistently have mental retardation and minor dysmorphic features. Since our patient has 5 copies of the PWS/AS region, it is predicted that her phenotype would be more severely affected than those with 4 or fewer. Numerous patients with 3 or 4 copies of apparently the same molecularly defined region of 15q11.2 allow gene dosage-phenotypic comparisons with our patient.

**Growth Failure in a child with 47,XXX and Angelman syndrome due to an imprinting error.** *J. Siegel-Bartelt<sup>1</sup>, J. Greenberg<sup>1</sup>, D.R. Rada<sup>1</sup>, E. Louie<sup>2</sup>, M. Jamehdor<sup>1</sup>.* 1) Kaiser-Permanente, Los Angeles, CA; 2) Northern California Kaiser, San Jose, CA.

The phenotype in Angelman syndrome (AS) has been reported to vary based on etiology. Here we report a child with sex chromosomal aneuploidy, growth failure and AS due to a putative imprinting error. This 2.5 year old girl was born at term following amniocentesis for maternal age which showed 47,XXX. Her birth weight was 2600 gm. At age 2.5 years, she was proportionate, but very petite: length 72.4cm; weight 7.8k; and OFC 42.5cm. Facies showed deeply set eyes and bilateral preauricular sinus. Hands and feet were very small for her size, and she was hypotonic. She was preverbal, but able to roll, and sit briefly if placed. Pincer grasp had not yet developed. She has had no seizures. Growth hormone therapy was instituted after 2 failed growth hormone stimulation tests. Chromosome analysis showed 47,XXX.ish15q11~q13(D15S10x2). Methylation specific PCR analysis revealed a single 100 bp band only, typical of Angelman syndrome. Uniparental disomy studies show biparental inheritance of chromosome 15.

Gillessen-Kaesbach et al (*EurJHumGenet* 7:638-44) report a series of patients presenting with obesity and hypotonia reminiscent of Prader-Willi syndrome (PWS), but who have methylation studies characteristic of AS. The small hands and feet, growth failure, and hypotonia in this child support this expanded Angelman phenotype. This is the first report of growth hormone deficiency in AS (though it is seen in PWS). Of note, the bilateral preauricular sinus in this child is unusual for both 47,XXX and PWS/AS. Clinicians should be alert to this broader spectrum of findings in Angelman syndrome, including growth failure.

The relationship of the sex chromosome aneuploidy and imprinting defect is not clear, and may be coincidental. However, it is interesting to speculate a possible potentiating effect of the extra X on the imprinting defect, especially to explain the more severe phenotype in this child compared to the group described by Gillessen-Kaesbach et al.

**X-linked chondrodysplasia punctata due to ARSE mutations expansion of the phenotype and genotype. T.**

*Rupar*<sup>1,2</sup>, *V.M. Siu*<sup>2</sup>, *J. Jung*<sup>2</sup>, *J.W. Rip*<sup>1,2</sup>. 1) Biochemical Genetics Lab, Child and Parent Resource Inst; 2) Departments of Pediatrics and Biochemistry, University of Western Ontario, London, Ontario, Canada.

At least five types of chondrodysplasia punctata (CDP) have been described. Mutations in the ARSE gene which codes for arylsulfatase E have been identified as a cause of chondrodysplasia punctata CDPX1 and brachytelephalangi type chondrodysplasia punctata in 9 patients. The skeletal defects seen in ARSE deficiency are clinically similar to warfarin embryopathy and vitamin K deficient embryopathy. We describe two unrelated infant males who were born at 29 and 32 weeks gestational age with chondrodysplasia punctata. Both infants had hydrocephalus, Dandy Walker cysts and upper airway difficulties. One patient also had alobar holoprosencephaly, multiple ventriculoseptal defects, atrial septal defect, patent ductus arteriosus, bilateral hydronephrosis and died at 2 days age. Dandy - Walker cysts have been reported in patients with CDP due to vitamin K deficient embryopathy (Menger et al,1997) and warfarin embryopathy (Kaplan,1985). Other CNS malformations have been observed in warfarin embryopathy. The activities of arylsulfatase E in cultured fibroblast membranes were 0.02 and 0.01 nmoles /hr/mg membrane protein respectively (same day control 0.78 nmoles/hr/mg) using 4-MUS as substrate as previously described ( Franco et al 1995). All 11 exons of the ARSE gene were PCR amplified using primers placed in flanking introns. Sequencing of the exons demonstrated in one patient a single base deletion in exon 8 in the codon for amino acid 426 which resulted in the creation of a premature stop codon 431 in exon 9. The other patient had mutations in adjacent codons that resulted in R394P and W395G amino acid changes. The first mutation resulted in the loss of an Mps II restriction site that was present in 68 normal alleles. The second mutation introduced an Apa I restriction site that was absent in 32 normal alleles. These patients extend the clinical phenotype of arylsulfatase E deficiency to include premature birth, Dandy-Walker cysts, cardiac and other congenital malformations. ARSE deficiency represents another multiple congenital anomaly syndrome caused by a metabolic defect.

**Impaired glucose tolerance in Williams syndrome.** *B.R. Pober<sup>1</sup>, E. Wang<sup>1</sup>, K. Petersen<sup>3</sup>, L. Osborne<sup>4</sup>, S. Caprio<sup>2</sup>.* 1) Dept Genetics, Yale Univ Sch Medicine, New Haven, CT; 2) Dept Pediatrics, Yale Univ Sch Medicine, New Haven, CT; 3) Dept Internal Med, Yale Univ Sch Medicine, New Haven, CT; 4) Dept Medicine, Univ Toronto, Toronto, Canada.

Williams syndrome (WS) is a clinically complex disorder caused by a chromosome 7 microdeletion. Several endocrine problems have been previously identified; we now report impaired glucose tolerance as an additional medical complication that requires anticipatory guidance, monitoring and treatment.

We administered a standard oral glucose tolerance test to 16 WS adults (mean age of 37) and 4 WS teenagers (mean age of 14). Patients were classified as having normal glucose tolerance, impaired glucose tolerance (IGT), or "silent" diabetes according to established criteria (Diabetes Care.22:S1;1/99).

Among the adult subjects, 5/16 (31%) had silent diabetes while 7/16 (44%) had IGT. The diabetics tended to be obese (mean body mass index, BMI, =30), the patients with IGT were overweight (mean BMI=26), while those with normal glucose tolerance had normal BMIs. Older subjects were more likely to have IGT or diabetes. The mean fasting @ 120 minute glucose values for subjects with diabetes, IGT, and normal glucose tolerance were: 121 @ 239 mg/dl; 94 @ 162 mg/dl; and 86 @ 104 mg/dl, respectively. The mean fasting @ 120 minute insulin values for these groups were: 11 @ 44 uU/ml; 13 @ 68 uU/ml; and 17 @ 42 uU/ml. Only 1 subject had an elevated HemoglobinA1C. Among the 4 WS adolescents, 3 had IGT and 1 had normal glucose tolerance.

Our data show that 75% of subjects with WS have silent diabetes or IGT following oral glucose tolerance testing. The general population frequencies of these disorders are ~5% and ~15%. Elevated insulin levels in those with IGT suggest that insulin resistance plays a role in the pathogenesis of their diabetes. One of the genes commonly deleted in WS must confer vulnerability to diabetes. Syntaxin1A plays a role in exocytotic insulin release; further research will be needed to determine if hemizygoty for syntaxin1A contributes to the development of diabetes in patients with WS.

**Phenotype of Pigment Dispersion Syndrome (PDS) in Italian families.** *A.M. Bovell<sup>1</sup>, G. Calabrese<sup>2</sup>, G. Palka<sup>2</sup>, M. Ciafrè<sup>2</sup>, L. Mastropasqua<sup>2</sup>, D. Ciancaglini<sup>2</sup>, K.F. Damji<sup>1</sup>*. 1) Univ of Ottawa Eye Institute, Canada; 2) Università di Chieti, Italy.

**Purpose:** PDS affects up to 4% of the caucasian population and is a common cause of secondary open angle glaucoma (OAG). This study describes the phenotypic characteristics of Italian families with PDS. **Methods:** Probands were identified, through a glaucoma clinic, as individuals with both PDS and glaucoma. Probands and willing family members were examined in a standardized manner. Individuals were classified for PDS into affected (2 or more of: heavy trabecular meshwork(TM) pigmentation, iris transillumination defects(TID), Krukenberg (K) spindle), suspect (1 of the 3 characteristics listed above), and unaffected (no characteristics listed above). Each individual was also classified, independently, for OAG status as affected (2 or more of: glaucomatous optic nerve damage, intraocular pressure > 21 mm Hg, glaucomatous visual field defect), suspect (1 of the 3 characteristics listed above), and unaffected (no characteristics listed above). Data were entered into Excel and analysis performed. **Results:** 7 families with 65 individuals were examined. There were 18 PDS affecteds, 10 suspects, 35 unaffecteds, & 2 unknown. The average age was approximately 40 in all groups. The male:female ratio was 2:1 for affecteds and 1:1 for unaffecteds. The affecteds were more myopic (-2.8D vs. -1.6D) and had higher IOP's (23.9 mmHg vs. 17.8 mmHg) than the unaffecteds. On a scale of 0 to +4, the affecteds had more TM pigmentation than unaffecteds (3.3 vs. 0.8). 66.7% of affecteds had K spindles and 55.6% had TID. There was no evidence of K spindles or TID in the suspect or unaffected groups. The percentage of those with OAG in PDS affected, suspect and unaffected categories was 44.4%, 0% and 3.1%, respectively.

**Conclusion:** We have identified seven Italian families with PDS and glaucoma. These families will form the basis for future molecular studies in the hopes of identifying the gene(s) involved in this important disorder.

**Phenotypic features of families with angle closure glaucoma in Chongqing, China.** *K.F. Damji<sup>1</sup>, Y. Tu<sup>2</sup>, A.M. Bovell<sup>1</sup>, C. Yuan<sup>2</sup>, P. Li<sup>3</sup>, W.G. Hodge<sup>1</sup>, H. Peng<sup>3</sup>.* 1) University of Ottawa Eye Institute, Canada; 2) Chongqing Fourth People's Hospital Eye Institute, China; 3) Chongqing University of Medical Science, China.

**Purpose:** Angle closure glaucoma (ACG) is a leading cause of blindness in China. Although evidence of heritability exists, a molecular basis has not yet been identified. We describe the phenotypic characteristics of families with ACG from Chongqing, China. **Methods:** We identified probands with gonioscopic evidence of ACG. We examined families comprised of probands and at least one family member willing to participate. Individuals were classified into affected ( $\geq 180$  appositional or synechial closure = N3 or N4 Scheie), suspect ( $\geq 180$  closure Scheie N2 with iris bombe), or unaffected (wide open angle) categories. Exclusion criteria included any secondary cause of ACG, trauma, or pseudoexfoliation. Data were entered into Excel and analysis was performed.

**Results:** 16 families with 69 individuals were identified: 27 affecteds (A), 4 suspects (S), and 38 unaffecteds (U). Eight families had  $\geq 2$  affecteds. There was a preponderance of females in each category (M:F ratio for A=22:4, S=4:0, U=28:10). Affecteds had significant differences vs. unaffecteds ( $p=0.002$ ): they were older (A=59.7, U=36.0 years), had higher IOPs (A=33.5, U=17.9 mmHg), more hyperopia (A=1.04, U= -0.95 diopters), shallower central (A=1.64, U=2.42 mm), and peripheral (A=0.42, U=0.94 Van Herrick) anterior chamber depths, fewer angle structures visible by gonioscopy (A=3.35, U=0.23 Scheie method), thicker lenses (A=4.30, U=3.88 mm), and shorter axial lengths (A=21.67, U=22.68 mm).

**Conclusion:** We describe phenotypic characteristics of Chinese families with ACG. These families may form the basis for future molecular analysis of this important disorder.

**A new locus for Seckel syndrome on chromosome 18p11.31-q11.2.** *A.D. Borglum<sup>1</sup>, T. Balslev<sup>2</sup>, A. Haagerup<sup>1</sup>, N. Birkebæk<sup>2</sup>, H. Binderup<sup>1</sup>, T.A. Kruse<sup>3</sup>, J.M. Hertz<sup>4</sup>.* 1) Institute of Human Genetics, Aarhus University, Aarhus, Denmark; 2) Department of Paediatrics, Aarhus University Hospital, Denmark; 3) Department of Clinical Biochemistry and Genetics, KKA, Odense University Hospital, Denmark; 4) Department of Clinical Genetics, Aarhus University Hospital, Denmark.

Seckel syndrome (MIM 210600) is a rare autosomal recessive disorder with a heterogeneous appearance. Key features are growth retardation, microcephaly with mental retardation, and a characteristic bird-headed facial appearance. We have performed a genome-wide linkage scan in a consanguineous family of Iraqi descent. By homozygosity mapping a new locus for the syndrome was assigned to a 30 cM interval between markers D18S78 and D18S866 with a maximum multipoint lod score of 3.1, corresponding to a trans-centromeric region on chromosome 18p11.31-q11.2. This second locus for Seckel syndrome demonstrates genetic heterogeneity and brings us a step further towards molecular genetic delineation of this heterogeneous condition.

**Acalvaria: Case report of a rare malformation.** *L.H. Seaver, N.R. Cooley, Jr.* Greenwood Genetic Ctr, Greenwood, SC.

Acalvaria is a rare defect. The bones of the membranous neurocranium are absent or extremely hypoplastic and the bony defect is skin covered. The viscerocranium and chondrocranium are intact. There have been approximately 24 cases reported previously, although only 3 have adequate neuropathologic data and are unquestionably skin-covered. Underlying brain defects have been described, including holoprosencephaly (Harris 1993). All well documented cases have been sporadic. The ultrasonographic differential diagnosis includes acrania due to anencephaly or amniotic bands, severe microcephaly, and hypocalvaria due to osteogenesis imperfecta, hypophosphatasia, or ACE inhibitor fetopathy. We report autopsy data from another case of this rare malformation.

The mother was a 21-year-old G3P0Ab2. The pregnancy was complicated by positive MSAFP (3.56 MoM). Ultrasonogram revealed acrania with dilated cerebral ventricles, split cerebral hemispheres and increased size of the cisterna magna. Labor was induced at 21 weeks gestation. Autopsy revealed absence of the frontal and parietal bones. The anterior margin of the foramen magnum was ossified; the posterior margin was cleft and unossified. There was agenesis of the vertebral arches at C1-C2. The entire defect was covered with intact skin except the occipital region where there was a large area of aplasia cutis congenita. The brain revealed cleaved cerebral hemispheres with short blunted frontal lobes. The olfactory nerves were absent. The skull base was poorly differentiated. The corpus callosum was intact. The lateral ventricles were moderately dilated. Karyotype was normal 46,XX.

The etiology and pathogenesis of this defect is unknown. It may be due to failure of migration or differentiation of neural crest derived mesenchyme that forms the membranous bones of the skull. Mutations in the genes *MSX2* and *ALX4* have recently been identified as having a role in skull development with mutations found in families with parietal foramina/hereditary cranium bifidum (Wilkie 2000; Wuyts 2000; Mavrogiannis 2001). Some individuals with this condition also have occipital scalp defects.

**Vascular disruption-related birth defects in 22q11.2 deletion syndromes.** *K.J. Galenzoski<sup>1</sup>, C. Prasad<sup>1</sup>, A.J. Dawson<sup>1,2</sup>, A.E. Chudley<sup>1</sup>.* 1) Pediatrics and Child Health, Health Sciences Centre, Winnipeg, Manitoba, Canada; 2) Cytogenetics Laboratory, Health Sciences Centre, Winnipeg, Canada.

The 22q11.2 deletion syndrome has a variable phenotype involving craniofacial, cardiac and developmental features. The many anomalies characteristic of 22q11.2 deletion may be the result of a vascular disruption or a vascular developmental anomaly sequence. We describe two patients with deletions of 22q11.2: one with cutis aplasia and the other with gastroschisis, both suspected to be caused by vascular compromise. The first patient presented at birth with craniofacial dysmorphism including a cleft palate, dysplastic ears and micrognathia as well as an atrial septal defect and a right-sided aortic arch. He also had two circular lesions in his scalp, measuring two centimeters in diameter. Fluorescent-in-situ-hybridization analysis with D22S75 revealed a deletion on one chromosome 22, confirming the suspected diagnosis of a 22q11.2 deletion syndrome. The second patient presented antenatally with gastroschisis, and was found to have craniofacial dysmorphisms not typical for a 22q11.2 deletion syndrome. He had a cleft palate, an atrial septal defect and a bifid right thumb. FISH studies were positive for a 22q11.2 deletion. Vascular disruption has been implicated as a cause of aplasia cutis congenita (ACC) in patients with Adams-Oliver syndrome and ACC with terminal transverse limb defects. Aplasia cutis congenita is also seen in patients with teratogen exposure such as alcohol and cocaine, both of which are thought to cause vascular compromise. The gene Claudin-5/TMVCF (transmembrane protein deleted in Velo-cardio-facial syndrome) codes for a transmembrane protein that acts as a regulator of vascular permeability. It is located in the region of 22q11.2. Hemizygous expression of Claudin-5/TMVCF in individuals affected by 22q11.2 deletions may cause the secondary vascular disruption and resultant vascular anomalies in patients with 22q11.2 deletions. In addition, Claudin-5/TMVCF may be a potential candidate gene for familial forms of cutis aplasia and gastroschisis.

**A de novo 9q terminal deletion detected by subtelomere FISH analysis in a mildly affected child.** *M. He<sup>1</sup>, C. Lytle<sup>1</sup>, P. Challinor<sup>1</sup>, M. Sapeta<sup>1</sup>, B. Ravnar<sup>1</sup>, M. Irons<sup>2</sup>, A. Lamb<sup>1</sup>.* 1) FISH, Genzyme Genetics, Santa Fe, NM; 2) Boston Children's Hospital, Boston, MA.

Mental retardation is found in 3% of the general population. Of these, 40% of moderate to severe cases and 70% of the mild cases are unexplained. In a search for subtle rearrangements involving the ends of chromosomes, one large study (Knight et al., *Lancet* 354: 1676-1681, 1999) detected unbalanced rearrangements in 7.4% of the moderate-severe MR group and in only 0.5% of the mild MR group. We report on a 3-year-old male with normal chromosomes that was referred for subtelomere FISH analysis. His features include: moderate global delay, hypotonia, minor dysmorphic facies, hypertelorism, telecanthus, anteverted nares, borderline low set ears with folded helices. His head circumference was slightly less than the 25th centile, with his weight at the 50th centile, and height at the 50th to 75th centiles. Subtelomere FISH analysis (Totelvysion probes; Vysis, Inc) showed a 9q subtelomere deletion, with no other rearrangements observed. Follow-up studies using conventional FISH confirmed the deletion. Parental FISH studies were normal. Although the study cited above suggests a very low detection rate, subtelomere FISH analysis may yield useful information when all other testing is exhausted. As rearrangements are found in additional mildly affected individuals, it will be interesting to see if certain phenotypic features provide clues as to which of these individuals may warrant subtelomere FISH studies.

**Familial cryptogenic cirrhosis.** *J.L. Williams, M.S. Williams.* Gundersen Lutheran Medical Ctr, La Crosse, WI.

A family was identified with 6 individuals in 5 generations with liver disease. Medical records were available on 3 individuals (a mother and two daughters). All were diagnosed with cirrhosis. Extensive evaluation did not identify an etiology leading to categorization as cryptogenic cirrhosis. Pedigree suggests autosomal dominant (AD) inheritance, although X-linked inheritance cannot be ruled out. Age of onset for the confirmed cases was between 50-60 years. All three individuals had Type II diabetes. The family history was also positive for a variety of possible autoimmune disorders (pancytopenia, alopecia and vitiligo), although there was no evidence of autoantibodies directed against the liver. Iron studies and mutation analysis ruled out hemochromatosis. Alpha-1-antitrypsin levels were normal.

Cryptogenic cirrhosis accounts for 10% of all cases of cirrhosis. Familial cryptogenic cirrhosis has been reported rarely in the literature. Most of the families have not been as extensively investigated as this family therefore could represent other disorders. Recently some individuals with cryptogenic cirrhosis have been identified with dominant mutations in the keratin-8 and keratin-18 genes. Mouse mutants demonstrate AD inheritance of susceptibility to cirrhosis in some strains while other strains show a combination of cirrhosis with intestinal disease that resembles inflammatory bowel disease. It is not clear whether presence of the mutation is sufficient in and of itself to produce cirrhosis, or whether the mutation predisposes to abnormal hepatocyte response to toxins or stress. In transfected hepatocytes, mutations do not affect the organization of keratin filaments under basal conditions, but result in substantial abnormal reorganization of the filaments in response to a variety of stressors. Keratin mutation analysis in this family is being undertaken.

**A Gender Assessment Team: Experience with 183 patients over a period of 20 years.** *M.A. Parisi<sup>1,2</sup>, M.W. Burns<sup>1,2</sup>, R.E. Grady<sup>1,2</sup>, D. Gunther<sup>1,2</sup>, G.B. Kletter<sup>1,2</sup>, E. McCauley<sup>1,2</sup>, M.E. Mitchell<sup>1,2</sup>, C. Pihoker<sup>1,2</sup>, L.A. Ramsdell<sup>1</sup>, M.R. Soules<sup>2</sup>, R.A. Pagon<sup>1,2</sup>.* 1) Children's Hosp & Reg Med Ctr, Seattle, WA; 2) University of WA, Seattle, WA.

In 1981, the Gender Assessment Team was created at the University of Washington and Children's Hospital and Regional Medical Center to provide a multi-disciplinary approach to the diagnosis, medical and surgical treatment, and psychosocial evaluation of patients with ambiguous genitalia, intersex disorders, and other congenital anomalies of the genitalia. This group, consisting of specialists from medical genetics, cytogenetics, gynecology and the pediatric specialties of urology, endocrinology, and psychology, has meet bimonthly for 20 years. The findings of the 183 patients evaluated during this period are reviewed. Through a variety of laboratory and clinical tests, a determination of the chromosomal sex, gonadal sex, and phenotypic sex was made for each patient. This information was used in consultation with the family to reach decisions regarding management, including sex of rearing.

Categories of patients included infants with ambiguous or anomalous genitalia (128), of which 72 had Y chromosomal material and 56 had 46,XX karyotypes. 10 infants had intersex problems, in which the chromosomal sex did not match the phenotypic sex. 34 patients were referred in childhood or adolescence for intersex problems and anomalous genitalia. An additional 11 patients had ambiguous genitalia associated with a known multi-system genetic syndrome, such as Denys-Drash (3). Of specific diagnoses, the most common were: congenital adrenal hyperplasia (14%); clitoral and/or labial anomalies (9%); mixed gonadal dysgenesis (9%); hypogonadotropic hypogonadism with micropenis (8%); 46,XY SGA males with micropenis (7%), a previously recognized but underreported condition; and complete androgen insensitivity (7%). As a result of this experience, patients with 2 new syndromes have been identified: 1 46,XY female with agenesis of the corpus callosum and lissencephaly; and 3 males with micropenis, distinctive gonadotropin profile, microcephaly and learning delays.

**Is mosaicism at the origin of the extreme variability of 13q deletion phenotype?** *G. Andria, D. Melis, L. Perone, M.P. Sperandeo, A. Passariello, M. Sibilio, G. Sebastio.* Dept Pediatrics, Federico II Univ, Naples, Italy.

We observed a 13 month-old-female presenting facial dysmorphic features, skeletal anomalies (vertebral synostosis, multiple hemivertebrae, 13 ribs bilaterally), severe mental retardation and brain developmental anomalies (agenesis of the corpus callosum and Dandy-Walker variant). Eye fundoscopic examination revealed corioretinal yellowish lacunae in the right eye, similar to those seen in Aicardi syndrome. Karyotype analysis on peripheral lymphocytes was normal whereas del(13)(q12qter) was present in all mitoses from skin fibroblasts. Chromosome 13 painting excluded the translocation of the deleted segment. The mosaic pattern of the deletion was confirmed by molecular analysis of DNA microsatellites. Parents peripheral blood karyotypes were normal. Somatic mosaicism for del(13)(q12qter) has been reported in another patient only, presenting DK phocomelia phenotype which includes: radial ray defects, occipital encephalocoele and urogenital abnormalities. Large 13q deletions have been rarely observed whereas many patients with interstitial deletions have been reported. Considering all the clinical findings observed in both group of patients, the resulting phenotype might include: mental retardation, failure to thrive, developmental anomalies of brain, eye, heart and kidney, gastrointestinal system malformations and limb defect. No straight correlation between cytogenetic data and phenotype could be obtained. Surprisingly, the patient with the most extended deletion (13)(q12qter) was affected by a mild phenotype resembling the Moebius syndrome. The only two patients with a demonstrated mosaic pattern of the deletion, the one with the DK phocomelia phenotype and the present one, exhibit severe clinical pictures, only partially overlapping. We hypothesize that, beside to the extent and location of the deleted segment, the mosaicism for haploinsufficiency may underlie the wide variability of 13q- syndrome phenotype. Therefore, when possible, karyotype analysis of patients with 13q deletion seen in peripheral lymphocytes, should be extended to skin fibroblasts.

**Genotype-phenotype correlations in hypochondroplasia: progress report from an international collaborative project.** *A.S. Aylsworth<sup>1</sup>, G.A. Bellus<sup>2</sup>, S.H. Blanton<sup>3</sup>, T.E. Kelly<sup>3</sup> and The Genentech Hypochondroplasia Study Group.*  
1) Depts Pediatrics & Genetics, Univ North Carolina, Chapel Hill; 2) Dept Dermatology, Univ Colorado Health Sciences Center, Denver; 3) Dept Pediatrics, Univ Virginia, Charlottesville.

**BACKGROUND:** Hypochondroplasia is a common, autosomal dominant, genetically heterogeneous, skeletal dysplasia with variable clinical features that are similar to, but milder than those of achondroplasia. Molecular studies have shown that 50-70% of cases are caused by mutations that result in an Asn®Lys substitution in codon 540 of fibroblast growth factor receptor 3 (FGFR3). We are assembling a large cohort of patients with clinical diagnoses of hypochondroplasia to determine genotype-phenotype correlations and to search for mutations other than the common ones. The standardized study data set includes clinical findings, radiographs, and FGFR3 mutation analysis. **RESULTS:** We now have some data on approximately 250 patients, but complete datasets on only one third of these. Molecular testing on 236 patients shows that 58% have FGFR3 mutations (N540K or K650N/Q). There is little difference in height, arm span, or head circumference between adults with and without FGFR3 mutations. Both groups have a higher than expected incidence of neurological problems (»50%). Data regarding radiological findings and growth curves for FGFR3(+) and FGFR3(-) patients will be presented. **FUTURE PLANS and ACKNOWLEDGEMENTS:** It is becoming more difficult to organize and participate in multicenter studies because IRB requirements have become much more stringent during the past two years. We greatly appreciate those collaborating members of the Study Group who have submitted complete datasets. Their names and affiliations are listed on the poster. We will be working over the next year to obtain missing data, add new patients to the database, help submit local IRB protocols where necessary, and identify candidates for the human growth hormone trial arm of the study. Web access to protocols and consent forms should help study group collaborators add data or new study subjects more easily, and construct local IRB consent forms when necessary.

**Angelman syndrome with OCA2 due to an intragenic deletion of the P gene.** *C.P. Koiffmann<sup>1</sup>, C. Fridman<sup>1</sup>, N. Hosomi<sup>2</sup>, M.C. Varela<sup>1</sup>, A.H. Souza<sup>3</sup>, K. Fukai<sup>2</sup>.* 1) Dept of Biology, Univ of Sao Paulo, Sao Paulo, Brazil; 2) Dept of Dermatology Osaka City University Graduate School of Medicine, Osaka, Japan; 3) Instituto Materno-Infantil de Pernambuco, Neurologia Infantil, PE, Brazil.

Angelman syndrome (AS) is characterized by mental retardation, speech impairment, ataxia and happy disposition with frequent smiling. AS results from the loss of expression of a maternal imprinted gene in the 15q11q13 region, due to deletion (70%), paternal uniparental disomy (5%), IC mutation (1-2%) or UBE3A mutation (10%); in the remaining cases the cause is unknown. Deletion AS patients may exhibit hypopigmentation of skin, eye and hair correlating with deletion of one copy of the P gene mapped in the distal part of PWS/AS region. AS patients may occasionally present features of OCA2, the most prevalent type of albinism worldwide, due to a mutated P gene in the remaining paternal chromosome 15. Our patient presented albinism (his parents were of African ancestry), developmental delay, severe mental retardation, absence of speech, outbursts of laughter, microcephaly, ataxia, hyperactivity, seizures. The study of SNRPN gene showed the methylation pattern of AS; microsatellite analysis of chromosome 15 disclosed deletion with breakpoints in BP2 and BP3. All of the 25 exons and flanking introns of the P gene of the patient and his parents were investigated. The father carries the deleted allele and the patient is hemizygous for the deleted exon 7 of the P gene paternally inherited. The patient manifests OCA2 associated with AS due to the loss of the maternal chromosome 15 with the normal P allele, since the paternal breakpoints include the P gene. The intragenic deletion of the paternal P gene results in a frameshift mutation predicting a non-functional protein reflecting in the patient's white skin, gold hair and no retinal pigmentation. As various degrees of hypopigmentation are associated with PWS/AS deletion patients, the study of the P gene present in a hemizygous state could contribute to the understanding of its effect on human pigmentation during development and to disclose the presence of modifier pigmentation gene(s) in the PWS/AS region. **Molecular Diagnosis of Smith-Lemli-Opitz Syndrome (SLOS) in a Fetus with Renal Agenesis. M.J.M.**

*Nowaczyk*<sup>1,2,3</sup>, *S.A. Farrell*<sup>2,4</sup>, *W.S. Sirkin*<sup>5</sup>, *B. Eng*<sup>3</sup>, *J.S. Wray*<sup>1,2,3</sup>. 1) Dept. of Pathology and Molecular Medicine, McMaster University, Hamilton, Canada; 2) Dept. of Pediatrics, McMaster University, Hamilton, Canada; 3) Hamilton Regional Laboratory Medicine Program, Hamilton, Canada; 4) Division of Genetics, The Credit Valley Hospital, Mississauga, Canada; 5) Dept. of Laboratory Medicine, North York General Hospital, North York; Canada.

We report on a fetus with oligohydramnios and renal agenesis detected sonographically in the second trimester of pregnancy, in whom the diagnosis of SLOS was made based on molecular testing of *DHCR7* in the parents. Amniocentesis showed a normal male karyotype, 46,XY. The pregnancy was stopped because of the severity of fetal anomalies. The parents were not consanguineous; their ethnicities were Tatar-Tatar and Russian-Ashkenazi.

The fetus had facial features of Potter oligohydramnios sequence; there was a cleft posterior palate, and bilateral postaxial polydactyly of the toes with syndactyly of the fifth and sixth toes. External genitalia were ambiguous; internal genitalia were male. The right kidney was absent; the left was markedly hypoplastic as were both ureters. There were multiple accessory spleens, as well as a spleen in the usual location. There was bilateral pulmonary hypoplasia with a bilobed right lung and unilobar left lung; an atrioventricular septal defect; and, in the brain, agenesis of the corpus callosum and a Dandy-Walker malformation. In the hypoplastic kidney there was incomplete nephrogenesis with markedly decreased glomerular generations. Clinical severity score was 72.

As there was no amniotic fluid or cultured cells available for biochemical testing, the parents underwent molecular analysis of *DHCR7*: the mother's genotype was IVS8-1G>C/+, the father's W151X/+. Both of these *DHCR7* mutations are null mutations which are associated with a severe phenotype.

This report demonstrates the utility of carrier molecular testing for SLOS in situations where samples are not available from the proband. This is also a first report of confirmed SLOS in fetus of this ethnicity (Ashkenazi and Tatar).

**Defining the deletion breakpoints in WS patients using somatic cell hybrids.** *K.A. Metcalfe<sup>1</sup>, M.J. Carette<sup>1</sup>, D. Donnai<sup>1</sup>, A. Karmiloff-Smith<sup>2</sup>, A.P. Read<sup>1</sup>, M. Tassabehji<sup>1</sup>.* 1) University Department of Medical Genetics and Regional Genetics Service, St Mary's Hospital, Manchester, UK. , St Mary's Hosp, Manchester, England; 2) Neurocognitive Development Unit, Institute of Child Health, 30 Guilford Street, London, U.K.

Williams-Beuren syndrome (WS) is a developmental disorder caused by a hemizygous microdeletion of ~1.5Mb at chromosomal location 7q11.23. Homologous recombination between flanking repeats accounts for high incidence of de novo deletions. Up to 20 genes have been identified within the WS critical region, many of which are predicted to encode transcription factors, some have roles inferred from motif homologues, and some have no known function. Hemizyosity for ELN causes SVAS and currently there is no evidence implicating any of the other genes in the aetiology of the syndrome. Our studies of rare patients ascertained through SVAS who have partial deletions but not WS, suggest that the telomeric end of the common deletion is important for determining the WS phenotype. Mapping the exact deletion breakpoints is difficult because they lie within the repeated regions. In order to define the deletion breakpoints more precisely we have made somatic cell hybrids from 30 WS patients and designed a series of specific PCR primers using SNP technology to identify the centromeric and telomeric breakpoints. There appear to be two main breakpoints at the centromeric end and at least three at the telomeric end which has allowed us to group the patients according to their genotype for further detailed phenotype analysis. This should aid future genotype-phenotype correlations.

**Craniofacial anthropometry in cleido-cranial dysplasia using three dimensional surface laser imaging studies.** *B. Lee, S. Carter, CA. Bacino.* Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX.

Cleidocranial dysplasia (CCD) is a skeletal disorder that results from loss of function of the RUNX2/CBFA1 gene. This gene is a transcriptional determinant of osteoblast cell fate. Patients with CCD present with classical dysmorphic craniofacial features including: prominent forehead, hypertelorism, flat nasal bridge, receding midface, and prognathism. Multiple studies have addressed the craniofacial changes in CCD mainly by cephalometric measurements and by CT scans with 3D reconstructions. A number of abnormalities have been observed including delayed ossification of calvaria, abnormalities of the cranial base, delayed ossification of the cranial base bones, poorly developed maxillary and zygomatic bones, absent or hypoplastic nasal bones, and mandibular anomalies. While these approaches can demonstrate the bony abnormalities, they do not evaluate the total soft tissue contribution to the dysmorphic facies. The use of laser surface scans potentially offers a different approach to the study and diagnosis of craniofacial abnormalities by enabling linear and volumetric measurements. This technique allows the analysis of surface texture with the inclusion of soft tissues in the evaluation of morphological changes in CCD patients as well as in other craniofacial disorders. We have studied six individuals with CCD with known CBFA1 mutations by 3-D laser surface imaging studies to address this issue. Six age matched control individuals were also studied for comparison purposes. Preliminary results indicate that CCD patients have characteristic craniofacial anomalies, in particular abnormalities of the midface which are evident on both linear and volumetric measures. Our final goal is the translation of mutation analysis into the clinical phenotype. Genotype-phenotype correlations will help to elucidate variable clinical expressivity of mutations that may result in haploinsufficiency vs. hypomorphic mutations. Ultimately, the generation of volumetric measures of soft tissues of the different facial sections in age matched-control populations will enable diagnostic quantitative assessment of dysmorphic features in this and other craniofacial disorders.

**Nonsense and frameshift mutations in *ZFHX1B*, encoding Smad interacting protein-1, cause a complex developmental disorder with a variety of neurocristopathies.** *K. Yamada*<sup>1</sup>, *Y. Yamada*<sup>1</sup>, *N. Nomura*<sup>1</sup>, *K. Miura*<sup>3</sup>, *R. Wakako*<sup>4</sup>, *C. Hayakawa*<sup>5</sup>, *A. Matsumoto*<sup>7</sup>, *T. Kumagai*<sup>5</sup>, *I. Yoshimura*<sup>4</sup>, *S. Miyazaki*<sup>7</sup>, *K. Kato*<sup>2</sup>, *S. Sonta*<sup>1</sup>, *H. Ono*<sup>7</sup>, *T. Yamanaka*<sup>5</sup>, *N. Nagaya*<sup>6</sup>, *N. Wakamatsu*<sup>1</sup>. 1) Dept Genet; 2) Dept Biochem, Inst Developmental Res; 3) Dept Pediatr Neurol; 4) Dept Psychiatr; 5) Dept Pediatr; 6) Dept Pediatr Surg Central Hosp; 7) Resid Fac Child Mentl Physic Disabil, Aichi Human Service Center, Kasugai, Aichi, Japan.

Mutations in *ZFHX1B*, encoding Smad interacting protein-1, have been recently described to cause a form of Hirschsprung disease (HSCR). To investigate the breadth of the clinical variations of *ZFHX1B* deficiency, we have analyzed *ZFHX1B* from five patients presenting with mental retardation, delayed motor development, epilepsy, microcephaly and mild facial dysmorphism. These clinical features are quite similar to those of reported earlier except that they are not typical HSCR cases. The results showed that a previously reported R695X mutation could be identified in three patients. Moreover, a 2-bp insertion (254fs262) and a single bp deletion (91fs107X) were also newly found in two cases. All mutations occurring in one allele were de novo events. These data demonstrate that *ZFHX1B* deficiency is an autosomal dominant complex developmental disorder and that patients carrying functional null mutations of *ZFHX1B* present delayed physical and mental development and epilepsy with a wide spectrum of clinically heterogeneous neurocristopathies at the cephalic, cardiac and vagal levels.

**A novel syndrome of elevated serum IgE, recurrent infections, vasculitis, and neurocognitive impairment with myoclonus.** *B.N. Hay<sup>1</sup>, J. Davis<sup>1</sup>, D. Darnell<sup>2</sup>, B. Karp<sup>3</sup>, J.E. Martin<sup>4</sup>, B.I. Solomon<sup>5</sup>, M.L. Turner<sup>6</sup>, J.M. Puck<sup>1</sup>, S.M. Holland<sup>7</sup>.* 1) Genetics and Mol. Biol. Branch, NHGRI, NIH, Bethesda, MD; 2) Clinical Center, NIH, Bethesda, MD; 3) NINDS, NIH, Bethesda, MD; 4) Dept. of Internal Medicine, Johns Hopkins Bayview Medical Center, Baltimore, MD; 5) Rehab. Med., Clinical Center, NIH, Bethesda, MD; 6) National Cancer Institute, NIH, Bethesda, MD; 7) Lab of Host Defenses, NIAID, NIH, Bethesda, MD.

We present a family with 5 of 6 siblings (including male twins) affected with a complex immune disorder resembling Hyper-IgE syndrome (HIES), which typically manifests as recurrent boils, cyst-forming pulmonary infections, extremely elevated serum IgE levels and non-immunologic connective tissue abnormalities. The 3 affected male and 2 affected female children had severe eczema starting at 9 months of age, recurrent infections, episodes of post-infectious Stevens-Johnson syndrome in early childhood, and IgE levels ranging from 9,400 to 34,500 IU/ml. Three children have had chronic sinusitis or otitis, cutaneous vasculitis, and recurrent bacterial pneumonias leading to bronchiectasis and pulmonary compromise. Although no one in this family had documented pneumatoceles characteristic of HIES, one child died of respiratory failure at 27 years of age. One surviving child has severe destruction of pulmonary parenchyma due to recurrent infections with streptococci and staphylococci. In addition, one of the twins has had recurrent parotitis requiring parenteral antibiotics. Of the non-immunologic features of HIES, mild to moderate scoliosis was found in 3 of the children, but retained primary teeth and hyper-extensible joints were not present. Neurologic features, not typically part of HIES, were documented in all of the affected family members including oral motor deficits and dysarthria, low average IQ (75-80), increased deep tendon reflexes and essential myoclonus. The nonconsanguineous parents and one sibling had no significant findings, suggesting an autosomal recessive mode of inheritance. This family exhibits a unique constellation of immunologic and neurologic abnormalities that to our knowledge has not previously been reported.

**SHOX gene deletion in a male patient without short stature and Madelung deformity.** *f. faravelli<sup>1</sup>, g. camera<sup>2</sup>, m. pierluigi<sup>1</sup>, m. baldi<sup>1</sup>, f. dagna<sup>1</sup>.* 1) Laboratory of Human Genetics, Ospedale Galliera, Genova, Italy; 2) Pediatric Department, Ospedale San Paolo, Savona, Italy.

Deletions and mutations in the SHOX gene are responsible for Leri-Weill disease (LWD), a skeletal dysplasia characterised by mesomelic shortening of limbs and Madelung deformity. Recently, the same gene has been proposed to be responsible for as many as 2% of cases of idiopathic short stature. We report on a patient who has been ascertained because he is member of a family where Leri-Weill disease is segregating. His affected mother and sister presented with the full clinical picture of the disorder (short stature and Madelung deformity). The propositus asked for genetic counselling concerning his reproductive risk for LWD. No physical anomalies were detected on examination and height was 1.74 m (mother has LWD AND is 1.45 m height, the father is 158 cm). X Rays of the upper limb was performed and excluded Madelung deformity although a minor anomaly was detected and described as ulna minus. On the basis of this finding, both FISH and molecular analysis were performed on affected members of the family and the propositus and revealed a SHOX gene deletion in the affected mother, affected sister and, surprisingly, in the propositus. This observation confirms the extreme phenotypic variability which is associated with LWD, providing a further example of difficult tasks faced in genetic counselling. Moreover, the lack of short stature in our propositus further complicates the discussion about the role of this gene as a major determinant in the pathogenesis of short stature, both syndromic and idiopathic.

**Lacunar skull and limb defect with 22q11 microdeletion: novel features of velo-cario-facial syndrome? S.E.**

*Hansing<sup>1</sup>, P.S. Garcia<sup>1,3</sup>, D.D. Rosa<sup>2</sup>, M.L. Machado<sup>1</sup>, G.A.S. Passos-Jr.<sup>3</sup>, E.S. Ramos<sup>1</sup>.* 1) Genetics Department of School of Medicine of Ribeirao Preto - USP - Ribeirao Preto, Sao Paulo, Brazil; 2) Department of Cardiology of Santa Casa de Ribeirao Preto, Sao Paulo, Brazil; 3) Genetics Department of School of Odontology of Ribeirao Preto, USP, Ribeirao Preto, Sao Paulo, Brazil.

We describe a male patient showing at birth lacunar skull, cleft palate, thoracolumbar kyphoscoliosis, congenital cardiopathy, intercalar defect of limb at cost of left femur and retardation of neuropsychomotor development. As obstetric antecedents he presented intrauterine low motion and retardation of development. At the age of 15 years 3 months the patient became dead due to cardiac complications secondary to cardiac arrhythmia. The cariotype of peripheral blood lymphocytes was normal, 46,XY in 11 cells. By virtue of facial likeness with Velo-Cardio-Facial Syndrome (VCFS) a molecular analysis was performed and revealed a 22q11.2 interstitial deletion. It is discussed in this article the differential diagnosis between VCFS and Adams-Oliver Syndrome (AOS) among others, based on clinical features showed by the patient because up to the moment there are no studies in molecular biology relative to AOS. The authors conclude that this is the first described case of lacunar skull and intercalar defect of limbs with 22q11.2 microdeletion.

**Etiological Classification of Congenital Limb Anomalies.** *S.M. Tayel<sup>1</sup>, S.A. Al-Awadi<sup>1</sup>, L. Bastaki<sup>1</sup>, K.K. Naguib<sup>1</sup>, S.J. Abulhasan<sup>1</sup>, F.M. Mustafa<sup>1</sup>, S. Gouda<sup>1</sup>, N. Al-Naqeeb<sup>2</sup>.* 1) Kuwait Medical Genetics Centre, Maternity Hospital, Kuwait; 2) Neonatology Department, Adan Hospital\*, Kuwait.

Limb anomalies rank behind congenital heart disease as the most common birth defects in infants. More than 50 classifications for limb anomalies based on description of the morphology and osseous anatomy are drafted over the past 150 years. The present study aims at providing a concise summary for the most common congenital limb anomalies based on its etiology using a recent etiological classification first presented in 1996. Seventy cases with anomalies of the upper and/ or lower limb(s) were ascertained through clinical examination, chromosomal analysis, skeletal surveys and other relative investigations. Fetal causes of limb anomalies presented 55.8% of the cases in the form of 9 cases (12.9%) with chromosomal aberrations (trisomies 13, 18, 21, 13q duplication, and 22q deletion) and 30 cases (42.9%) with single gene disorders. Environmental etiology of limb anomalies was diagnosed in 11 cases (15.7%) in the form of amniotic band disruption, monozygotic twin with abnormal circulation, vascular disruption (Poland sequence, sirenomelia, and general vascular disruption), and an infant of diabetic mother. Twenty cases (28.5%) had limb anomalies as part of a sporadic syndrome of unknown etiology. Etiological classification of limb anomalies adopted in the present work looks valuable for understanding the mechanisms involved in limb anomalies and appears crucial for its prevention through genetic counseling which provides ways for prenatal detection and recurrence risk estimation.

**Tuberous sclerosis associated with pulmonary vascular lesions, emphysema and Klippel-Trenaunay-Weber syndrome.** *D.K. Grange, J.S. Kemp, G.K. Singh, T.R. Weber, A.Z. Miklos, D.E. deMello, C. Sotelo-Avila.* Departments of Pediatrics, Surgery and Pathology, Saint Louis University School of Medicine, St. Louis, MO.

We report a patient with tuberous sclerosis (TS) associated with pulmonary vascular abnormalities and emphysema, as well as Klippel-Trenaunay-Weber syndrome (KTW) of the upper extremity. TS is associated with hamartomatous lesions of brain, kidney, skin and, rarely, lung. KTW is associated with vascular malformations and asymmetric limb overgrowth and may have pulmonary involvement. A 2-year-old boy was born with an enlarged right upper limb with overlying cutaneous vascular lesions. MRI/MRA scan showed soft tissue hypertrophy of the limb and vascular abnormalities involving the arm, forearm and thenar eminence. In addition, multiple cardiac rhabdomyomata, hamartomas in the brain and shagreen patches were identified. He has had infantile spasms, complex seizures and developmental delays. At 17 months, he suddenly developed hemoptysis. Angiogram demonstrated a pulmonary artery malformation in the right lower lobe, requiring a lobectomy. Pathologic examination revealed large tortuous hilar bronchial arteries containing thrombi, with adjacent hemorrhage into the bronchial lumen, consistent with hemorrhage from a bronchial vascular malformation. Large pulmonary arteries had medial muscular hypertrophy and altered elastic fibers. There was also patchy emphysema. Abnormal arteries were seen in the periphery of the lobe within the emphysematous area, and there were increased numbers of dilated capillaries in the visceral pleura. Localized gigantism has been reported rarely in TS, including isolated macrodactyly and segmental hemihypertrophy. The association of TS and KTW has been previously described (*J Neuro Neurosurg Psych* 38:500-504,1975). Lymphangioliomyomatosis (LAM) and cystic disease are known pulmonary complications in TS, usually found in adult females, however, a male with KTW and pulmonary lymphatic involvement similar to LAM has been reported (*Chest*, 102:1274-77,1992), suggesting there may be overlap in the pulmonary manifestations of TS and KTW. Mutational analysis of TSC genes may provide insight into the pathogenesis of the defects seen in this and other patients.

**A Novel PTEN missense mutation in a patient with macrocephaly, ventricular dilatation and features of VATER association.** *W. Reardon<sup>1</sup>, X-P. Zhou<sup>2</sup>, C. Eng<sup>2</sup>.* 1) Dept Clin Gen, Ctr Medical Gen, Our Lady's Hosp Sick Children, Dublin, Ireland; 2) Human Cancer Genetics Program, The Ohio State University, Columbus, OH.

Initially described in the autosomal dominant condition of Cowden syndrome, germline mutations at the PTEN locus on 10q22-23 have now been extended to a wider range of phenotypes. Pathogenic mutations have additionally been described in Bannayan-Riley-Ruvalcaba syndrome and patients with Proteus and clinically overlapping syndromes. In contrast a molecular basis to VATER association remains undetermined in almost all cases of that condition. We report a novel missense mutation H61D at the PTEN locus in a patient with macrocephaly associated with significant ventricular dilatation on cranial imaging but whose additional phenotypic features of radial hypoplasia, bilateral thumb malformations and tracheo-esophageal fistula significantly overlap with the VATER phenotype. The mutation has arisen de novo in the patient, parental analyses being normal. Previous clinical experience of patients with VATER association and macrocephaly/hydrocephalus has highlighted this phenotype as a possible clinical presentation of chromosome breakage disorders. Our observation, in a patient with normal chromosomes, no increased sister chromatid exchange and a normal response to alkylating agents extends the range of phenotypes associated with PTEN mutation and offers clinicians a new investigative approach in patients with macrocephaly/hydrocephalus and VATER association.

**Phenotypic variation in individuals with or without cleft palate and their unaffected family members. K. Neiswanger, S.S. Petiprin, K.M. Bardi, M.D. Ford, A.S. Sauder, R.F. Giles, S.M. Weinberg, E.S. Carter, M.E. Cooper, M.L. Marazita.** School of Dental Medicine, University of Pittsburgh, PA.

Non-syndromic cleft lip with or without cleft palate (CL/P) is a common birth defect of unknown etiology that involves genetic and environmental factors. The Pittsburgh Oral-Facial Cleft Study is collecting a large series of multiplex CL/P families for linkage and segregation analyses. In addition to obtaining a blood sample, all family members--along with controls from families with no history of clefts, are evaluated for a number of sub-clinical developmental and laterality phenotypes that may reflect a genetic predisposition to clefting. These include a speech evaluation, a series of anthropological traits, and laterality measures such as handedness and dermatoglyphics. Pilot data from 66 individuals in 18 families have been collected. Results of the speech assessment suggest that velopharyngeal competence (measured by the University of Pittsburgh Weighted Values for Speech Symptoms Associated with Velopharyngeal Incompetence) does not differ between affected and unaffected family members ( $p = 0.19$ ). Dermatoglyphics include total ridge count (TRC) and fingerprint pattern frequencies, neither of which differ between CL/P individuals and unaffected relatives (mean TRC: 148.4 vs 134.9,  $p = 0.8$ ; pattern frequencies:  $p = 0.96$ ). Among the thirteen anthropological traits with sufficient data, only the presence of an elongated second toe shows a significant increase in CL/P individuals (60% vs 27%,  $p = 0.02$ )--a likely artifact of multiple testing. Handedness data (assessed by a modification of the Edinburgh Handedness Inventory) suggest that there may be more non-righthandedness among affected individuals than unaffected family members ( $p = 0.03$  or  $0.08$ , depending on the definition of non-righthandedness). Except for handedness, all phenotypic frequencies are similar in CL/P individuals and their unaffected relatives, suggesting that common genetic factors underlie these traits for all family members. Thus, these sub-clinical traits may be useful for family studies of CL/P and for refining recurrence risk estimates. Supported by NIH grant# DE13076.

Program Nr: 719 from the 2001 ASHG Annual Meeting

**Natural history, and genotype/phenotype correlation in a large cohort of Italian RTT patients with MECP2 mutations.** *M.L. Giovannucci Uzielli, L. Giunti, E. Lapi, U. Ricci, S. Guarducci, A. Cecconi, I. Sani, A. Elena.* Genetics and Molecular Medicine University of Florence Department of Paediatrics (Italy).

The collection of a large number of RTT patients with identified MECP2 mutations in the coding regions, included in the Register of our Center, allows us to get some consistent data concerning the natural history and clinical spectrum of the disorder. These data are especially useful for a genotype/phenotype correlation within the single groups of patients with the same MECP2 mutation. We identified 85/105 mutations (78%): T158M and R270X representing the most consistent types of mutations. The reconstruction of the natural history was facilitated, in this study, by the long period of follow-up, about 17 years, carried out in a large, and more and increasingly significant number of RTT patients. We have a special RTT Programme established in collaboration with the Italian Rett Syndrome Families Association (AIR). Other data are periodically collected by using special information forms, sent to the families. No consistent correlations were so far observed, neither for the genotype/phenotype correlation, nor for the patterns of X-inactivation. The study is in progress and we are also comparing our data with these collected by other groups of scientists involved in Rett Syndrome studies.

Program Nr: 720 from the 2001 ASHG Annual Meeting

**MECP2 mutation analysis and genotype/phenotype correlation in 26 Dutch Rett Syndrome patients.** *J. Herbergs, E. Smeets, U. Moog, D. Tserpelis, H. Smeets.* Genetics and Cell Biology, Maastricht University, Maastricht, Netherlands.

Rett syndrome is an X linked neurodevelopmental disorder that almost exclusively affects girls. The prevalence of the disease is estimated at 1/10.000 to 1/15.000. After an apparently normal prenatal and postnatal development a developmental stagnation appears, followed by regression of mental and motor abilities. In our lab the MECP gene was screened in 26 patients with classical and atypical RETT syndrome. In 7 patients (27%) a pathological mutation was detected which was not found in one of the parents. In 4 out of 7 patients the R306C mutation was detected, which is a mutation in the transcription repression domain. Most of the patients were adult women and in those patients a possible relationship between clinical outcome and DNA mutation type was investigated, especially for the R306C mutation. No clear correlation was detected between the detected mutations and the severity of the phenotype. More predictive for the clinical outcome appear to be the severity of the motor impairment, the progress of the corresponding neurological signs, and the age at onset of stagnation.

**Severe penicillamine embryopathy in an infant born to a woman with Wilson Disease.** *R.A. Pinter<sup>1</sup>, W.A. Hogge<sup>1</sup>, E. McPherson<sup>1, 2</sup>*. 1) Dept Genetics, Magee-Womens Hosp, Pittsburgh, PA; 2) Dept Pediatrics, Childrens Hosp Pittsburgh.

A 2190 gram male was born at 36 weeks to a 35 year-old G2P2 woman who took D-penicillamine (DP) 1g/d for Wilson disease throughout the first half of her pregnancy. The dose was reduced when a fetal ultrasound showed contractures and callosal agenesis. Maternal copper and zinc levels were not measured. The infant was born with severe cutis laxa, joint contractures, severe micrognathia, and callosal agenesis/colpocephaly on MRI. Amniocentesis karyotype was 46XY. His older half-sibling, also born to the mother while taking DP, has agenesis of the corpus callosum, but is otherwise normal. The proband's post-natal course was complicated by a tracheostomy due to micrognathia, mandibular distraction surgery, and orthopedic casting. At 6 mo follow-up, his cutis laxa and his joint contractures had improved, but he had profound developmental delay and apparent cortical blindness. Embryopathy is a rare complication of chronic use of DP during pregnancy. Roubenoff et al. in 1988 reported congenital anomalies in only 4/93 DP exposed infants. Arthrogryposis and CNS anomalies are documented in rats receiving DP prenatally, but only mild contractures are reported in humans. Two cases of embryopathy have been reported in offspring of mothers being treated with DP for Wilson Disease, and three born to mothers using DP for other purposes (collagen-vascular disease or cystinuria). Only two survived, both born to mothers with Wilson disease. All 5 were born with cutis laxa, thought to be secondary to copper and/or zinc deficiency, or as a result of direct toxic effect of DP on collagen and elastin crosslinks. In the surviving infants, the cutis laxa improved over several months and by age two months wound healing was normal. Neither had joint problems and both were neurologically normal. In summary, this is the most severe case of penicillamine embryopathy reported for an infant born to a woman with Wilson disease. Measurement of copper and zinc levels during pregnancy may have been helpful in predicting embryopathy and is suggested in other pregnant patients taking DP.

**Clinical and genetic analysis of Primary Open Angle Glaucoma (POAG).** *A. Renieri<sup>1</sup>, P. Frezzotti<sup>2</sup>, B. Palumbo<sup>1</sup>, R. Ciappetta<sup>2</sup>, M.G. Bucci<sup>3</sup>, S. Gandolfi<sup>4</sup>, M.T. Rolle<sup>5</sup>, N. Orzalesi<sup>6</sup>, I. Zucca<sup>7</sup>, L. Tomazzoli<sup>8</sup>, R. Frezzotti<sup>2</sup>.* 1) Dept. Mol. Biol., Medical Genetics, University of Siena, Italy; 2) Dept. Ophthalmol. Science, University of Siena, Italy; 3) Dept. Ophthalmol. Science, University of Rome Tor Vergata, Italy; 4) Dept. Ophthalmol. Science, University of Parma, Italy; 5) Dept. Physiopathol., Sez. Ophthalmol., University of Torino, Italy; 6) Dept. Ophthalmol. Science, University of Milano, Italy; 7) Dept. Ophthalmol. Science, University of Cagliari, Italy; 8) Dept. Ophthalmol. Science, University of Verona, Italy.

We have collected 52 families in which more than one individual was affected with glaucoma (G). Four families had six to eight affected members. The remaining families were small and the DNA of proband and two healthy relatives were only available, with few exceptions. All families had an apparent autosomal dominant inheritance on the basis of formal genetic analysis.

An accurate clinical examination of all families revealed some degree of variability of phenotype. In one family there was the simultaneous presence of Primary Open Angle G. -POAG-(4 individuals), Normal Pressure G. -NPG-(2 individuals) and Chronic Angle Closure G. -CACG-(1 individual). NPG and PAOG also coexisted in a smaller family. In another family CACG (1 individual) and Acute Angle Closure G (1 individual) coexisted with POAG (4 individuals). In one family one patient had POAG and the other Intermittent Angle Closure G. In one family with two affected members the Pseudo Exfoliation variety of Primary Open Angle Glaucoma segregated. In nine families one or two individuals among three affected members fulfilled the criteria for Juvenile Open Angle G.

Molecular analysis of Myocilin gene performed by SSCP and direct sequencing on proband's DNA of each family did not reveal pathogenic alterations. Our results confirm that mutations in Myocilin gene are rare in autosomal dominant POAG. Moreover, our analysis suggests a common molecular basis for entities distantly related on clinical ground only.

**Compound heterozygosity for FGFR3 gene mutations in a family with hypochondroplasia.** *A. Winterpacht<sup>1</sup>, C. Steglich<sup>1</sup>, K. Salzgeber<sup>2</sup>, D. Glaeser<sup>3</sup>.* 1) Inst Human Genetics, Univ Hamburg, Hamburg, Germany; 2) Childrens Hospital, Bismarckstr. 23, Memmingen, Germany; 3) Gregor Mendel Laboratorien (GML), Wegenerstr. 15, Neu-Ulm, Germany.

Hypochondroplasia (HCH) (MIM 146000) is an autosomal dominant skeletal dysplasia which is caused by mutations in the fibroblast growth factor receptor 3 (FGFR3)- gene and which is allelic with other dwarfism and craniosynostosis syndromes, like Achondroplasia, Thanatophoric dysplasia and Muenke syndrome. In HCH patients five different mutations in the FGFR3 gene have been identified, so far: a N540K exchange (caused by two different base substitutions) which is present in about 40-60% of the patients, a N540T and N540S as well as an I538V and N328I exchange which have been reported in rare cases. Most of the mutations affect the first portion of the split intracellular tyrosine kinase domain of the receptor and, like the other FGFR3 mutations, cause a ligand independent activation of the receptor. Here, we report the case of an 11 year old girl with a rather severe form of HCH (originally diagnosed as mild Achondroplasia) while her parents presented with the typical (mild) clinical signs of this disorder. Molecular analysis of DNA from the patient revealed compound heterozygosity for the N540K and the N540S exchange. As expected, the parents are heterozygous for one of the mutations each. To our knowledge this is the first report of a compound heterozygosity for HCH mutations. Clinical and molecular findings of the three affected family members are discussed.

**A Decade of Marfan Syndrome.** *D.M. Gilchrist.* Dept Medicine, Univ Alberta, Edmonton, AB., Canada.

**Objective:** To review a decade of experience in Marfan Syndrome in the Northern Alberta Medical Genetics Clinic (catchment approx. 1 million) **Method:** All patients were reviewed by a single geneticist who used diagnostic criteria outlined in the Berlin Nosology (1988) and, subsequently, the Revised Criteria (1996). **Results:** Of all referrals for inherited disorders of connective tissue, 49 patients from 30 families were felt to have definite Marfan and 43 patients from 28 families were felt to have possible Marfan. Of the definite cases, the average age at diagnosis was 27 with 4 being <10 (all from known families) and 13 of ages between 10 and 18 (5 from known families). Family history was secure for 32 patients in 15 families (50%). In those with family history, only 4 patients had major criteria in eye, heart and skeleton. In all patients with family history, 8 had ectopia lentis whereas 26 had aortic dilatation and/or dissection. Of the cases without family history, 6 had major findings in 3 systems and 1 had minor eye with major heart and major skeleton. Ten adults without family history had major findings in heart and skeleton only. Although these latter patients do not formally meet criteria, we consider them to have Marfan Syndrome. On analysis by feature of all definite cases, 25% had ectopia lentis and 84% had aortic dilatation/dissection. Most reliable MSK features included joint hypermobility (79%), dolicoostenomelia (67%), some degree of pectus deformity (68%), pes planus (58%), and striae (50%). Of 43 patients from 28 families with possible Marfan, major skeletal features with family history of same occurred in 18 from 8 families and mild aortic changes plus skeletal features occurred in 13 from another 8 families. **Interpretation:** Diagnostic criteria for Marfan syndrome are helpful but in the absence of family history and ocular findings, the diagnosis of Marfan Syndrome can still be compelling. We find major findings of the heart and multiple findings in the skeleton to be of more assistance than ocular findings in the diagnosis of patients presenting in adult years for Marfan Syndrome.

**Malignant peripheral nerve sheath tumors in neurofibromatosis 1.** *D.G.R. Evans<sup>1</sup>, M.E. Baser<sup>2</sup>, J.M. Friedman<sup>3</sup>, J. McGaughran<sup>1</sup>, B. Timms<sup>4</sup>, A. Moran<sup>4</sup>.* 1) Department of Medical Genetics, St. Mary's Hospital, Manchester, U.K; 2) Los Angeles, CA, U.S.A; 3) Department of Medical Genetics, University of British Columbia, Vancouver, B.C., Canada; 4) Centre for Cancer Epidemiology, Manchester University, Manchester, U.K.

Most cross-sectional studies have shown that 1-2% of people with neurofibromatosis 1 (NF1) develop malignant peripheral nerve sheath tumors (MPNST). However, no population-based longitudinal studies have assessed lifetime risk. We ascertained MPNST patients from the North West (U.K.) regional NF1 genetic register and from reviewing notes of patients with MPNST in the North West Regional Cancer Register (regional population, 4.1 million) for the period 1984-1996. Twenty-four NF1 patients developed MPNST (equivalent to an annual incidence of 1.6 per 1,000 and a lifetime risk of 8-13%), and there were 38 patients with sporadic MPNST. The median age at diagnosis in NF1 patients with MPNST was 26.3 years (range, 15.5-77.2 years), compared to 62.1 years (range, 18.8-89.4 years) in those with sporadic MPNST (Mann-Whitney U test,  $P < .001$ ). In Kaplan-Meier analyses, the median survival from diagnosis in NF1 patients with MPNST was 1.0 year (95% C.I., 0.0-2.0 years), compared to 2.7 years (95% C.I., 1.2-4.1 years) in people with sporadic MPNST ( $P = .09$ ). The five-year survival rate was 25% in NF1 patients with MPNST and 45% in patients with sporadic MPNST. One NF1 patient developed two separate MPNST in the radiation field for a previous optic glioma. These results indicate that the lifetime risk of MPNST in NF1 is much higher than previously estimated, and warrants careful surveillance for improved detection.

**Walker-Warburg Syndrome; a report of long term survival.** *N.J. Mendelsohn<sup>1,2,3</sup>, J. Roggenbuck<sup>1,2</sup>, C. Ludowese<sup>1,2</sup>, W.B Dobyys<sup>4</sup>, R. Kriel<sup>1,2,3</sup>, S. Smith<sup>2</sup>.* 1) Dept Pediatrics/Med Genetics, Hennepin Co Med Ctr/Univ MN, Minneapolis, MN; 2) Gillette Children's Hospital, St. Paul, MN; 3) Dept. of Pediatrics, University of Minnesota; 4) University of Chicago, Chicago Illinois.

Walker-Warburg syndrome (WWS) is an autosomal recessive disorder marked by severe cobblestone complex brain malformation, anterior chamber and retinal malformations, and congenital muscular dystrophy. The brain abnormalities consist of severe cobblestone cortex (lissencephaly), abnormal white matter, enlarged lateral ventricles often with hydrocephalus, severe brainstem and cerebellar hypoplasia, and sometimes occipital cephaloceles. WWS is similar to but more severe than muscle-eye-brain disease (MEB), but maps to a different locus. Infants with WWS are considered to have extremely poor prognosis with severe mental retardation and limited survival. Dobyys et al. (1989) established diagnostic criteria, which have recently been revised (Cormand et al., 2001). A median survival for all liveborn infants has been reported to be 18 weeks, although two patients reported by Cormand et al. (2001) survived to age 3 years. A few of the affected children were noted to survive more than 5 years, all described as individuals with less severe mental retardation, reaching the milestones of rolling and sitting between 1 and 3 years of age. Recent review of these cases indicates that all probably had MEB, a separate disorder. Kanoff (1998) et al reported 2 children with WWS. The first died at 6 months of age and the second child survived beyond 18 months. He attributed the shorter survival time of the first patient to more severe myopathic changes. We report a young girl now 5 years of age (date of birth 9/9/1996), who was born with aqueductal stenosis, hydrocephalus, cobblestone lissencephaly, optic nerve colobomas, and congenital muscular dystrophy. MRI changes were typical of WWS and not MEB. She has profound developmental delay, yet clear evidence of survival well beyond the first year of life. This case suggests that survival in WWS may extend into the school age years and may correlate with factors other than severity of mental retardation, such as severity of hydrocephalus, seizures and myopathy.

**Natural history of Gelophysic Dysplasia: report of one case with 30 years old.** *S.F. Mesquita<sup>1</sup>, D.R. Bertola<sup>2</sup>, L.M.J. Albano<sup>2</sup>, A.C. Pereira<sup>1</sup>, J.E. Krieger<sup>1</sup>, C.A. Kim<sup>2</sup>.* 1) INCOR, Instituto do Coracao, Lab Genetica e Cardiologia Molecular, Sao Paulo, Brazil; 2) Genetics, Instituto da Crianca, University of Sao Paulo, Brazil.

Spranger et al. (1971), characterized geleophysic dwarfism: pleasant and happy-looking faces, small stature and dysostosis-multiple-like changes, predominantly in the hands and feet. A metabolic pathogenesis was suspected, but has not yet been identified. Koiffmann et al (1984) reported the disorder in a 11-year-old Brazilian girl. She was born at home, short with small hands and feet. She was the product of the 2nd pregnancy of her mother, healthy, young and nonconsanguineous parents. The first child was small with tiny hand and died at 3 years of cardiac failure. The patient had 2 normal sisters and 2 normal brothers. Clinical findings at 11 years old were a peculiar but pleasant and happy-looking facial appearance, with "tip-toe" gait because of bilateral talipes equinovarus, joint limitation at the elbows and hepatomegaly. She had an important subaortic stenosis and left ventricle hypertrophy. We report on the same patient at 30 years old with favorable evolution. She is still short stature (1,42 m), 42 kg, microcephaly (OFC=51 cm), same pleasant and happy facies, thin upper lip, small ears, high-pitched voice, short arms with elbow restriction, brachydactyly, small hands and feet, "tip-toe" gait, atrophic left limb. She had normal sexual and mental development. She was submitted to a subaortic fibrous ring resection and partial left ventricle muscle resection, at 24 years old. This proceeding improved her cardiac performance with normal ventricle function. Current echocardiography shows mild left ventricle hypertrophy and mild aortic insufficiency. Both left and right ventricle function are normal. Interestingly, although geleophysic dysplasia is suggested to be a lysosomal storage disease, no clinical progression was evident. Therefore, more aggressive and surgical corrections should be indicated to improve prognosis and quality of life of these patients.

**The clinical significance of heteromorphism chromosome 4p10.** *T.I. Datkhaeva, E. Sujansky, C.-H. Tsai.* Genetics and Metabolism, University of Colorado School of Medicine; 1056 East 19th Avenue, Denver, CO 80218.

Heteromorphic sites have been reported on many chromosomes, including chromosome 4p. We report a mother and 3 children with developmental delay (DD) and heteromorphic sites on chromosome 4p10. Heteromorphic sites have been reported in normal population (8%). However, they were found with higher frequency in people with congenital malformations (Lubs et al., 1976), in parents of children with chromosome abnormalities (Nielsen et al., 1974). Bardhan et al. (1981) compared 8% rate of heteromorphism of chromosome 4 in general population with 36% rate of heteromorphism in mental retardation, 43% in developmental delay and hyperactivity and 40.9% in schizophrenia. Barr et al. (2000) reported higher polymorphism in ADHD and mental illness, Vincent (1998) in obesity and NIDDM, Inoe et al. (1997) in cerebellar ataxia and MR, Faivre et al. (2000), Cotton et al. (1998) and Kennedy et al. (1998) in alcoholism. Although chromosomal heteromorphism has been studied extensively, its clinical significance is unclear. In our family all 4 members had heteromorphism of 4p10. The mother's IQ was reportedly <70. Her 1st child died of SIDS. His karyotype was unavailable. Three other children are alive. Her two sons age 4 years and 1 year respectively are developmentally delayed and dysmorphic. Her daughter was morphologically and developmentally normal at age 1 month except nipples asymmetry, but reportedly hypotonic at age 2 months. Unaffected family members were not available for chromosomal analysis. Our findings support the hypothesis that a causal relationship may exist between presence of the heteromorphic sites and developmental problems and/or malformations. It has been suggested that heteromorphic regions contain polygenes. The high frequency of heteromorphia in birth defects, developmental, mental and physical abnormalities suggest that the heteromorphia may be one of the factors contributing in polygenic disorders.

**GASTROSCHISIS AND OMPHALOCELE IN THE GENETICS CLINIC.** *B.G. Kousseff.* Pediatrics and Genetics, USF Regional Genetics Program, Tampa, FL.

Since 1960s improved definition, diagnosis, and reporting of gastroschisis (G) and omphalocele (O) have shown that the frequency of gastroschisis is on the increase. While most large studies document this increase, the textbooks in English still state that O (incidence of 1:4,000) is more common than G (incidence 1:6,000). Retrospective analysis of all 36,665 probands/families evaluated at the USF genetics clinic between January 2, 1982 and December 31, 1999 showed 121 patients with G and 98 with O. The higher number of G reversed the customary G: O incidence ratio of 1/6,000:1/4,000. Of the G patients 37/121 had karyotypes, all were normal. In the O cohort 75/98 had karyotypes and 18 were abnormal (24%); 12/18 had trisomy 18, 2/18-trisomy 21, 1/18-trisomy 13, 1/18-del (18p)/i(18q), 1/18-inv (2)(p11q12)mat and 1/18-inv (3)(p13q11) mat. In the G cohort 43/121 (36%) had associated anomalies compared to the O cohort with 67/98 (68%). 5/121 pregnancies with G were interrupted; 2/121-miscarried and there were 2 stillbirths. 33 pregnancies remained with unknown to us outcome (lost to reevaluations. Among the 79 liveborn the prematurity rate was 57%. 11/98 O pregnancies were electively interrupted; additional 6/98 miscarried and 23 remained with unknown outcome. Among the 58 liveborn patients the prematurity rate was 36%. The mortality rate in the G cohort was 9% (7/79) and in the O cohort it was 15% (9/58).

This study contributed to several issues in these abdominal defects: G is more common than O, has lower mortality rate, and higher rate of prematurity compared to O.

**International network to investigate the genetics of Chronic Obstructive Pulmonary Disease.** *A. Ashley-Koch, A. Agusti, P. Calverley, H. Coxon, C. Donner, B. Make, N. Muller, P. Pare, S. Rennard, J. Vestbo, E. Wouters, A. Franklin, M. Hall, C. Haynes, J. Butrim, M.A. Pericak-Vance, L.T. Middleton, C. Foster, E.K. Silverman, D.A. Lomas.* All on behalf of the Genetics of Chronic Obstructive Pulmonary Disease International Network.

Chronic Obstructive Pulmonary Disease (COPD), including emphysema and chronic bronchitis, is a major public health concern, affecting over 44 million people worldwide. The etiology of COPD is complex, with both genetic and environmental factors implicated. Alpha1-antitrypsin deficiency is the only well-established genetic factor, but accounts for only 1-2% of all emphysema cases. Cigarette smoking is the most significant environmental risk factor, although smoking history explains only 15% of the variability in forced expiratory volume (FEV1), and only 10-20% of smokers develop COPD. The goal of the present study is to identify additional genetic risk factors that contribute to COPD susceptibility. We have ascertained thus far 423 COPD families, without A1AT deficiency, across 10 international sites. These families include 169 independent affected sibpairs with airflow obstruction (FEV1<80%, FEV1/VC<90% predicted). Of the probands for whom ascertainment has been completed (n=335), 59.4% are male, median age is 59.0 (range 45-65), median FEV1% predicted is 31.3 (range 13.3-59.7), median FEV1/VC% predicted is 42.8 (range 19.0-89.0), and median pack-years smoking is 46 (range 5.75-159.5). Among smoking siblings, 36% met the criteria for airflow obstruction. Of these completely ascertained affected siblings (n=194), 55.2% are male, median age is 57 (range 44-66), median FEV1% predicted is 53 (range 24.0-79.6), median FEV1/VC% predicted is 68.0 (range 36.7-89.0), and the median pack-years smoking is 41.0 (range 6.0-156.0). In addition to standard clinical and environmental variables, both objective and subjective analysis of High Resolution CT scans are performed on all siblings > 40 years of age with at least a 5 pack-year smoking history. Preliminary HRCT analysis suggests that as many as 29% of asymptomatic siblings can exhibit significant emphysema. These data will be used to stratify sub-phenotypes in a genomic screen.

**Familial pleural fibrosis with ocular telangiectasia and male infertility: a new syndrome?** *E. Bieth<sup>1</sup>, N.*

*Chassaing<sup>1</sup>, R. Mieusset<sup>2</sup>, M. Benahmed<sup>3</sup>, J. Bienvenu<sup>4</sup>, H. Hamel<sup>5</sup>, P. Calvas<sup>1</sup>, D. Lauque<sup>6</sup>.* 1) Genetique, hopital Purpan, Toulouse, France; 2) CECOS, hopital La Grave, Toulouse, France; 3) Inserm U407, faculte de medecine Lyon-sud, Lyon, France; 4) Immunologie, hopital Lyon-sud, Pierre-Benite, France; 5) Centre hospitalo-universitaire, Dijon, France; 6) Medecine interne, hopital Purpan, Toulouse, France.

We report on three sibs, two sisters and a brother affected with a progressive bilateral pleural fibrosis. The parents were first cousins and the siblings had identical symptoms with similar severe evolution suggesting autosomal recessive inheritance. The brother was the oldest (30 years) and the most severely affected with a severe restrictive pattern of the pulmonary function testing. Chest computed tomography showed bilateral apical pleural thickening. As his two sisters he had conjunctival telangiectasia. In addition, he had an infertility due to a secretory oligoasthenospermia. None of the sibs were exposed to mineral dusts.

Because of his demonstrated involvement in fibrotic diseases of the lung as asbestos and in angiogenesis, the transforming growth factor beta (TGF- $\beta$ ) was investigated. It has been also shown that TGF- $\beta$  is expressed in human seminiferous tubules. The TGF- $\beta$ 1 levels in serum, supernatants of cultured skin fibroblasts and seminal fluid were normal. Furthermore, genetic analysis of three polymorphic markers linked to the TGF- $\beta$ 1 failed to find homozygosity in the three sibs suggesting that the TGF- $\beta$ 1 gene was not directly implicated. On the other hand, we hypothesized that the disease of the siblings could be due to mutations affecting one component of the TGF- $\beta$ 1 pathway. However, genotypic analysis of markers linked to several Smad genes was not conclusive to date. Other candidate gene studies coupled to homozygosity mapping are in progress.

**DYSMORPHOLOGICAL ANALYSIS OF FETAL ALCOHOL SYNDROME (FAS) CLINIC REFERRALS: A REPORT OF 300 CASES RECEIVING MULTIDISCIPLINARY EVALUATION.** *R.D. Blackston<sup>1</sup>, C.D. Coles<sup>2,3</sup>, J.A. Kable<sup>3</sup>, K.K. Howell<sup>2</sup>, J. Bertrand<sup>2</sup>, B. Meeks<sup>3</sup>, J. Haar<sup>3</sup>.* 1) Div Med Gen, Dept Pediatrics, Emory Univ Sch Medicine, Atlanta, GA; 2) Department of Psychiatry at EUSM, Atlanta, GA; 3) Marcus Institute a Division of the Kennedy-Krieger Institute at EUSM, Atlanta, GA.

We report initial dysmorphological and demographic data from a cohort of 300 referrals to a large FAS Clinic. The cohort was 51%- Caucasian, 46%-African-American (A-A) and 3%- other. The male/female distribution was 55.4% to 44.6%. Average age at evaluation was 5.3 years (SD: 3.4 yrs) with a range of 0 to 20 years. Most (83%) were not living with biological parents with 50.1% in foster care. Neonatal problems were noted frequently (57.6%) and birthweight was in the SGA range (M=2412 GMS). Growth (height, weight, and head circumference) appeared to normalize over time. Subjects were examined using a 30-item Dysmorphia Checklist. Findings of greater than 10, plus positive maternal history of alcohol use yielded, a partial FAS diagnosis. Scores >15 resulted in a FAS diagnosis. Thirty-two referrals were found to have no evidence of prenatal alcohol exposure or symptomatology consistent with FAS. While dysmorphia scores dropped over age, certain features persisted, particularly, hypoplastic philtrum and increased inner-ocular distance. Using a univariate ANOVA, there was a significant effect of ethnicity with AA's, (15.00 vs 11.16) having higher mean dysmorphic scores. Observed amelioration of alcohol effects on physical characteristics may be accounted for in several ways. Alteration in dysmorphia may occur with age and growth. Improved height, weight, head size are likely attributed to improved living environments outside the biologic home, associated with better nutrition, medical care, early intervention services, and consistent parenting, as opposed to neglect, abuse, undernutrition, poor medical care, addiction, and violence characteristics of many alcoholic homes. Further studies are underway to validate initial positive results.

**The long-term effects of prenatal exposure to anti-epileptic drugs.** *U. KINI, J. Clayton-Smith and The Liverpool and Manchester Neurodevelopmental Study Group.* Dept. of Clinical Genetics, St. Mary's Hospital, Hathersage Road Manchester, Lancashire, United Kingdom.

**Objective:** Children born to mothers with epilepsy are at a 2-3 fold increased risk of congenital abnormalities. This has been attributed in part to exposure to specific antiepileptic drugs (AED) in utero. However the effects of these drugs on neuropsychological development is less clear. The purpose of our study is to examine the long-term effects of prenatal exposure to AED with regards to dysmorphic features, structural abnormalities, cognitive impairment and behavioural problems. **Methods:** In a retrospective study of 218 mothers who had attended regional epilepsy clinics in the last 10 years, we assessed 370 children exposed to different AEDs. Structured interviews, hospital records, clinical examination and psychometric tests such as NART (maternal IQ), WISC (child's IQ) and the Rivermead memory test (memory) were the tools used in the study. **Results:** Of the 370 children examined: 62 were exposed to valproate (VPA) monotherapy, 96 to carbamazepine (CBZ) monotherapy, 73 to polytherapy and 100 were non-exposed (NE). Those exposed to VPA had significantly more dysmorphic features (median 5) in contrast to the CBZ group (median 2,  $p=0.01$ ) and to the NE group (median 2,  $p=0.05$ ). Major malformations were also more common in the VPA group - 24.2% (Odds ratio 3.7, CI 1.4-9.2). Those exposed to VPA monotherapy had a significantly lower mean verbal IQ (82.26) than CBZ (94.63) and NE groups (91.81) at the  $p<0.05$  level. Also, VPA monotherapy resulted in the lowest full scale IQ when compared to all groups. Memory impairment and special educational needs (SEN) were more common in the VPA group, with only 41% having normal memory function and 42% registered as having SEN. Behavioural problems such as poor attention span and hyperactivity were more commonly reported in the VPA group. **Conclusion:** Prenatal exposure to VPA, although confounded by seizure type and frequency, appears to result in increased dysmorphism, structural abnormalities, cognitive impairment and a higher incidence of behavioural problems and SEN. This has significant implications for the management of women with epilepsy.

**Parkinsonism phenotype in a large Azorean family affect with Machado-Joseph Disease.** *L. Mota-Vieira<sup>1</sup>, A. Ferro<sup>2</sup>, I. Silveira<sup>2</sup>, J. Sequeiros<sup>2</sup>, P. Coutinho<sup>3</sup>, J. Lopes<sup>1</sup>.* 1) Hosp. Divino Espirito Santo, Ponta Delgada, Azores Islands, Portugal; 2) UnIGENE, IBMC - Univ. Porto, Porto, Portugal; 3) Hosp. São Sebastião, Feira, Portugal.

Machado-Joseph Disease (MJD/SCA3) is an autosomal dominant neurodegenerative disease characterized by different clinical forms (types I - IV). Here we present a clinical and genetic study of a large MJD family from the Azorean island of São Miguel (Portugal), with 8 affected individuals through five generations. In this family there are at least 2 patients with the usual clinical phenotype of late onset of MJD (type III), and 2 patients, in consecutive generations, with the rare early onset parkinsonism phenotype associated with MJD (type IV). The propositus (V generation) is a 31-year-old woman. At age 30 she showed parkinsonism features (mild bradykinesia with weakness of spontaneous facial movements, diminished blinking and slowness of all voluntary movements) associated with hypertonia/rigidity, impaired postural reflexes and peripheral neuropathy. Her mother (IV generation) also developed an early onset parkinsonism at age of 35. Both of them obtained substantial benefit from L-dopa (levodopa-carbidopa) therapy. The maternal grandfather (III generation) and great-grandmother (II generation) noted only an onset of difficulty walking at ages 65 and 60, respectively. In order to obtain a pathological confirmation of MJD in this family, we analyzed the (CAG)<sub>n</sub> tract localized on the *MJD1* gene of the propositus. This analysis revealed an expanded allele and a normal allele with 74 and 15 CAG repeats, respectively (mutated alleles, 56-86 repeats; normal alleles, 7-47 repeats). This finding confirms that parkinsonism phenotype associated with peripheral neuropathy could be caused by MJD/SCA3 mutation. Moreover, the identification of this mutation will facilitate the genetic counseling in this family, in which the inheritance of MJD shows an anticipation of 30 years from type III to type IV. However, the reason(s) for different MJD phenotypes in the same family is(are) not known. The possible explanations will be discussed. (lmv.hospdelgada@mail.telepac.pt).

**Ultrasound analysis of orbicularis oris muscle defects in individuals with cleft lip with or without cleft palate and their relatives.** *S.M. Weinberg<sup>1</sup>, K. Neiswanger<sup>1</sup>, M.P. Mooney<sup>1</sup>, R.S. Faix<sup>2</sup>, D.A. Richardson<sup>2</sup>, S.S. Petiprin<sup>1</sup>, K.M. Bardi<sup>1</sup>, R.F. Giles<sup>1</sup>, E.S. Carter<sup>1</sup>, A. Bowen<sup>2</sup>, M.L. Marazita<sup>1</sup>.* 1) School of Dental Medicine, University of Pittsburgh, Pittsburgh PA; 2) Childrens Hospital, Pittsburgh PA.

Every year, oral-facial clefts affect between 1 in 500 to 1000 births worldwide. Despite this fact, only a few genetically linked phenotypic markers have been identified. Recently, however, a sub-clinical defect of the orbicularis oris (OO) muscle, was detected through ultrasound in the first-degree relatives of children with CL/P. Furthermore, these first-degree relatives displayed significantly more OO defects compared to controls ( $p=.002$ ). It was, therefore, hypothesized that these sub-epithelial clefts may represent a useful feature for estimating recurrence risks. Unfortunately, prior ultrasound analyses of OO have been restricted to first-degree relatives in non-multiplex families and failed to characterize the defect. Therefore, as part of a large multiplex family study on the cleft phenotype and genotype, ultrasound images were collected from affected (CL/P) probands and their affected and unaffected extended relatives ( $n=66$ ). The goal of this preliminary study was to develop a protocol for the analysis of OO ultrasounds and to compare data collected from unaffected relatives ( $n=43$ ) to unaffected controls ( $n=52$ ). Due to a lack of normative control data at this time, however, figures from the literature were utilized for comparison. The images were rated for defects on a scale from 1 to 4 (1 = normal, 2 = thinning, 3 = minor defect, and 4 = major/multiple defects) independently by three raters. The combined proportion of relatives with OO defects (rated as 2, 3 or 4 by at least two raters) was then calculated. The results of chi-square analysis revealed significant ( $\chi^2=12.9356$ ;  $DF=1$ ;  $p<.001$ ) differences in the proportion of unaffected relatives (44%) with OO defects compared to controls (11%). These results strongly agree with previous figures from the literature and lend support to the notion that such sub-clinical defects may indicate an increased susceptibility to CL/P. NIH grants DE13076 and RR00084.

**Maturity onset diabetes mellitus in a patient with maternal uniparental disomy for chromosome 14. T.**

*Kayashima*<sup>1,6</sup>, *M. Katahira*<sup>2</sup>, *N. Harada*<sup>1,6</sup>, *N. Miwa*<sup>1,3</sup>, *T. Kishino*<sup>4,6</sup>, *Y. Nakamura*<sup>3</sup>, *T. Kajii*<sup>5</sup>, *N. Niikawa*<sup>1,6</sup>. 1) Human Genetics, Nagasaki Univ., Nagasaki, Japan; 2) Okazaki City Hospital, Aichi, Japan; 3) Inst. Med. Sci., Univ. of Tokyo, Tokyo, Japan; 4) Nagasaki Univ. Gene Research Center, Nagasaki, Japan; 5) Hachioji, Tokyo, Japan; 6) Core Research for Evolutional Science and Technology (CREST), Japan Science and Technology Corporation (JST), Kawaguchi, Japan.

We report a 20-year-old man with maternal uniparental disomy for chromosome 14 [upd(14)mat] and diabetes mellitus, the second case reported with such an association. The first such instance was a 19-year-old man described by Carozzo (Clin Genet 57;406-408, 2000) with probable maternal isodisomy for the entire length of chromosome 14, but the diagnosis was uncertain in the absence of genetic studies of the father. The man we are reporting had pre- and postnatal growth retardation, and at age 20 years developed diabetes mellitus without any autoimmune antibody. His chromosomes were 45,XY,der(14;14)(q10;q10)[29]/46,XY,+14,der(14;14)(q10;q10)[1]. Studies of CA-repeat markers covering the entire length of chromosome 14 indicated maternal isodisomy of the 14q21-q24 segment and maternal heterodisomy of the remaining regions. It is thus tempting to speculate that homozygosity of a mutant gene at the isodisomic segment caused his diabetes mellitus. The IDDM11 gene is such a candidate with its locus situated close to the segment.

**Post-zygotic somatic recombination between maternal and paternal #13 in a child with Angelman syndrome and facial findings of Trisomy 13 homologues.** *C.H. Tsai<sup>1</sup>, T. Gibby<sup>1</sup>, L. Beischel<sup>3</sup>, L. McGavran<sup>2</sup>, J.P. Johnson<sup>3</sup>*. 1) Dept Pediatrics/Div Genetics, Childrens Hosp, Denver, CO; 2) Colorado Genetics Laboratory, Departments of Pathology/Pediatrics, UCHSC; 3) The Molecular Genetics Laboratory at Shodair Childrens Hospital, Helena, Montana.

We describe a child with findings of Angelman syndrome and trisomy 13 with a paternally derived Robertsonian translocation of 13 and 15. Molecular studies showed paternal uniparental heterodisomy (UPD) 15 and segmental paternal isodisomic UPD 13. This 6- year old boy was seen for global developmental delay associated with a karyotype of 45,XY,t(13;15)(q10;q10). He was AGA born to a 25-year old G3P2 mother at 32 weeks by vaginal delivery. Bilateral grooved lip and cleft palate were noted at birth, with early feeding difficulties. There were no clinically recognized seizures. Brain MRI was normal. He is nonverbal. Physical examination showed a happy child with global developmental delay, normal growth, a deviated uvula, a scalp scar from cutis aplasia, bilateral Sydney lines, sandal gap, and a hypopigmented spot. Neurologically, he had hypertonia, clonic movements, and ataxic gait. FISH on 200 cells showed no evidence for mosaic trisomy 13 or 15. Paternal chromosome studies showed a balanced carrier, 45,XY,t(13;15)(q10;q10). UPD studies for chromosome 15 showed paternal uniparental heterodisomy for four informative loci consistent with the diagnosis of Angelman syndrome. UPD studies for chromosome 13 showed segmental paternal uniparental isodisomy for three informative loci at 13q14.3. Paternal UPD 15 and segmental UPD 13 consistent with a post-zygotic somatic recombination between maternal and paternal #13 homologues in Angelman syndrome has not been reported. This patients clinical findings point to a possible critical region for cleft lip and palate and cutis aplasia in 13q14.3 resulting from paternal segmental UPD13. These unusual results demonstrate the importance of recognizing characteristic physical features in making a syndromic diagnosis and of fully exploring such cases cytogenetically and molecularly to determine their genetic etiology.

**Maternal uniparental disomy 14 presenting as language delay.** *K.A. Worley<sup>1</sup>, V.R. Rundus<sup>1</sup>, E.B. Lee<sup>1</sup>, V.L. Hannig<sup>1</sup>, L.K. Hedges<sup>1</sup>, K. Tsuchiya<sup>2</sup>, J.A. Phillips III<sup>1</sup>.* 1) Dept Pediatrics, Vanderbilt Univ Sch Medicine, Nashville, TN; 2) Dept Pathology, Vanderbilt Univ Sch Medicine, Nashville, TN.

Maternal uniparental disomy of chromosome 14 (MUPD14) is a rare disorder characterized by low birth weight, hypotonia and feeding difficulties in infancy followed by short stature, small hands and early puberty. Affected individuals may have translocations involving 14. We report here a case of MUPD14 that presented at 3 years of age with severe language delay, normal intelligence, and short stature. Birth weight was < 3<sup>rd</sup> % and birth length was between the 10 - 25<sup>th</sup> %. He had neonatal hypotonia and was found to have a 45, XY, der (13;14) (q10; q10) translocation. He required gavage feeding and physical therapy. Gross motor skills were age appropriate at 12 months. His language was at the 20-24 month level at 36 months and speech therapy began. Height and weight at 41 months were < 3<sup>rd</sup> % (50<sup>th</sup> % for 2.3 and 1.45 years respectively) but his bone age was 4.5 years. Head circumference was normal and the only dysmorphic feature noted was short fingers (< 3<sup>rd</sup> % for newborns). Because of language delay, short stature, short fingers and the previous finding of a translocation (13;14), DNA studies were done for MUPD14. Results showed isodisomy of D14S261, 283, 275, 70, 288 and 292, heterodisomy of D14S74 and 280, and D14S 276, 63, 65 and 985 were partially informative. Chromosome 13 was biparentally inherited. The Wechsler Preschool and Primary Scale of Intelligence-Revised (WPPSI-R) (mean = 100; S.D. = 15) indicated verbal and nonverbal intellectual skills at 43 months were in the mid-average range (91 and 97 respectively with a Full Scale IQ of 93). The Vineland Adaptive Behavior Scales (mean = 100; S.D. = 15) suggested communication, daily living, socialization, and motor skills were in the low average to mildly delayed range (84, 83, 76, and 69 respectively). Our findings indicate that: 1) MUPD14 may present with language delay and subtle physical findings, and 2) careful evaluation of physical, chromosomal and developmental phenotypes may identify UPD in children presenting with the common complaint of language delay.

**A further delineation of the paternal uniparental disomy (UPD) 14: The fifth reported liveborn case.** *S. Yano<sup>1</sup>, L. Li<sup>1</sup>, S. Owen<sup>1</sup>, S. Wu<sup>1</sup>, T. Tran<sup>2</sup>.* 1) Div Medical Genetics, Childrens Hosp, Los Angeles and University of Southern California, Los Angeles, CA; 2) University Childrens Genetics Laboratory, ProGene, Inc.

Uniparental disomy (UPD) for chromosome 14 has been reported in more than 14 patients with maternal UPD and in 4 patients with paternal UPD (one additional case diagnosed prenatally and terminated, Cotter et al., 1999). Major clinical feature of maternal UPD 14 consists of premature puberty, developmental delay, hypotonia, short stature, small hands, IUGR, and macrocephaly/ hydrocephalus. At least three out of four patients with paternal UPD 14 had polyhydramnios, blepharophimosis, small ears, small thorax, abnormal ribs, feeding difficulty, digit contractures, and simian creases. We report the fifth liveborn case of paternal UPD 14. The proposita was born to a 16-year old G2P2 Hispanic female and a healthy unrelated Hispanic male. Polyhydramnios was noted prenatally. The proposita was delivered by Caesarian section at 32 weeks. She weighed 2200 grams. Multiple congenital anomalies were noted, which included loose skin, blepharophimosis, low set small ears, micro/ retrognathia, prominent glabella, short webbed neck, narrow small rib cage, abdominal wall hernia, and multiple joint contractures/camptodactyly. She developed a seizure disorder and was treated with phenobarbital. A brain MRI showed generalized hypoplasia and multiple small scattered areas of signal abnormality within the subependymal areas which may represent calcification. Parental chromosome studies showed normal karyotype in her mother and a balanced Robertsonian translocation 45,XY, der(13;14)(q10;q10) in her father. Linkage analysis using microsatellite markers on chromosome 14 (D14S742, D14S587, D14S606, D14S617, D14S129, and D14S267) revealed paternal UPD: analysis with D14S587 and D14S129 revealed uniparental isodisomy. This case provides further evidence of existence of imprinted genes on paternal chromosome 14 by showing common characteristic clinical features in the patients with paternal UPD 14.

**Autosomal dominant isolated cryptophthalmos (Parks-Saal)syndrome - a third family.** *V.M. Siu<sup>1,2,4</sup>, R.B. Orton<sup>3,4</sup>.*  
1) CPRI; 2) Medical Genetics Program, London Health Sciences Centre; 3) Dept. of Ophthalmology; 4) Department of Pediatrics, University of Western Ontario, London, ON, Canada.

Cryptophthalmos is a rare congenital anomaly of the eye, involving various degrees of fusion of the eyelids to the underlying cornea. The most well-known syndrome associated with cryptophthalmos is Fraser syndrome, an autosomal recessive syndrome, associated with mental retardation, syndactyly, and genital anomalies. Only 2 families with a dominant syndrome of cryptophthalmos have been previously reported in 1910 (Parks) and 1992 (Saal).

We present a female infant with bilateral incomplete cryptophthalmos born at term to nonconsanguineous parents - a 38 year old mother and 41 year old father. Eyebrows were well-defined and eyelashes were present around the lateral margin of the eyelids. Upper eyelids were bulging, thickened, and adherent to the underlying corneas, with a distinctive dimpling and horizontal groove in the eyelids, particularly prominent when the baby cried. Lower eyelids were partially separated, with the inferior fornices present. Superior lacrimal puncta were displaced laterally within the upper eyelids. MRI findings revealed a right microphthalmos with probable retinal detachment and normal-sized left eye with optic pit. A perianal skin tag and syringomyelia constitute the only other non-ophthalmological findings. At four months of age, the baby had normal growth and development, and light perception. Chromosome karyotyping was normal, including multitelomere FISH studies. Father has mild strabismus but normal vision.

Our patient's eye anomalies are similar to the 5 cases in 2 previously reported families. There have been no cases of male-to-male transmission, therefore the mode of inheritance may be either autosomal or x-linked dominant. Dimpling of the eyelids, normal eyebrow development, and absence of other major congenital anomalies allow rapid differentiation from Fraser syndrome. Developmental arrest of normal eye development is postulated.

**FAMILIAL IRIDOGONIODYSGENESIS AND SKELETAL ANOMALIES A NEW AUTOSOMAL RECESSIVE DISORDER.** *L.X. Rodriguez-Rojas<sup>1,4</sup>, R. Mendoza-Topete<sup>2</sup>, M.T. Barrios<sup>3</sup>, B. Patiño-Garcia<sup>1,4</sup>, M.G. Lopez-Cardona<sup>1,4</sup>, I. Nuño-Arana<sup>1,4</sup>, J.E. Garcia-Ortiz<sup>1,4</sup>, D. Garcia-Cruz<sup>1,4</sup>.* 1) Division de Genetica, CIBO-IMSS, Guadalajara, Mexico; 2) Hospital de Especialidades, CMNO-IMSS, Guadalajara, Mexico; 3) Hospital de Pediatria, CMNO-IMSS, Guadalajara, Mexico; 4) Doctorado en Genetica Humana, CUCS-UdeG, Guadalajara, Mexico.

Three sibs with congenital glaucoma and skeletal anomalies were studied. At birth enlarged eyes and cornea were present in the proposita and her brother. The younger sib presented blue cornea since birth. The proposita, aged 30 years old and a brother aged 27 years were submitted to several trabeculotomies, the other one aged 22 years developed unilateral buphthalmos. Clinically, they showed wide forehead, thin nasal bridge, broad nose with large tip, prominent eyes, long philtrum, large ears, wide thorax and cubitus valgus. The ophthalmological examination in the proposita revealed glaucoma, megalocornea, wide anterior chambers and concave iris. At gonioscopy, angle grade IV, with abundant fine iridian processes reaching Schwalbes line, minimum pigment and hypoplasia of the iris stroma. There was no evidence of posterior embryotoxon. One sib presented unilateral ptisis bulbi, cornea with grooves in Descemet, iris hypoplasia and corectopia (presenting blindness since 8 years old). The younger brother is blind since birth, he showed unilateral ptisis bulbi, without ocular tissues, contralateral buphthalmos, edematous cornea with central leukoma, whittish keratopathy in lower band. The propositas daughter and her parents were ophthalmologically normal. The radiological examination showed slender long bones with wide metaphyses and thin cortices, cuboid-shaped vertebral bodies, narrow vertebral canal, small pelvis, and generalized osteopenia, more evident at the metaphyseal region. We concluded that these patients present the clinical, ophthalmological and radiological characteristics as the family previously described by Garcia-Cruz et al (*Ophthal Paediat Genet*, 11(1): 35-40, 1990). The purpose of this paper is to describe the second familial case corroborating this new probably autosomal recessive disorder.

**Two cases of Xq28 functional disomy detected using subtelomeric probes screening.** *M.C.de Blois, D. Sanlaville, M. Prieur, J.M. Lapierre, C. Ozilou, P. Gosset, A. Munnich, V. Cormier-Daire, S.P. Romana, M. Vekemans, C. Turleau.* Departement de Genetique, Hopital Necker-Enfants Malades, Paris, France.

We report on two patients with an additional Xq28 segment attached to the long arm of an autosome. The first patient, a boy, was part of a cohort of patients with unexplained mental retardation and a normal karyotype at the 550 bands level. CGH screening showed an enhancement of band Xq28. Further studies with WCP and subtelomeric probes demonstrated that the additional Xq28 segment was translocated onto 10qter. The translocation breakpoint was found distal to the 10q subtelomeric probe which was not deleted. This unbalanced translocation  $der(10)t(X;10)(q28;qter)$  arose de novo. The second patient is a girl for whom a telomeric rearrangement of 4q was suspected on high-resolution karyotypes. Only one hybridization signal was present with the 4q subtelomeric probe. Using a 41-subtelomeric probes set, an additional signal was observed at the 4q end with the Xq probe. This unbalanced translocation  $der(4)t(X;4)$  arose de novo. In both cases, the unbalanced translocation resulted in a functional disomy for Xq28 which may explain the clinical manifestations observed in both patients. Ten boys with duplicated distal Xq segment and functional disomy have been described in the literature, but, to our knowledge, this is the first report of a girl with an unbalanced translocation yielding functional disomy for Xq28. When the phenotypes of both patients are compared to those of the literature, a particular dysmorphism with wide face and microstomia associated to severe mental retardation can be described. It is suggested that this rare rearrangement is presumably underdiagnosed and that subtelomeric probe screening could help to its detection.

**A new X-linked syndrome with similarity to CHARGE association, Toriello-Carey syndrome, and FG syndrome.**

*J.M. Graham Jr<sup>1</sup>, P. Wheeler<sup>2</sup>, A.E. Lin<sup>3</sup>, B.D. Hall<sup>4</sup>, T.C. Cox<sup>5</sup>, C.E. Schwartz<sup>6</sup>.* 1) Medical Genetics Birth Defects, Cedars-Sinai Medical Ctr, Los Angeles, CA; 2) Tufts-New England Medical Center, Boston, MA; 3) Harvard Medical School, Boston, MA; 4) University of Kentucky Medical Center, Lexington, KY; 5) Centre for Molecular Genetics of Development, University of Adelaide, Australia; 6) Greenwood Genetic Center, Greenwood, SC.

We describe 2 brothers with a unique pattern of malformations that includes coloboma (iris, optic nerve), high forehead, severe micrognathia, mental retardation, and agenesis of the corpus callosum (ACC) that was initially thought to be CHARGE association. Both boys have low-set cupped ears with sensorineural hearing loss, normal phallus, pectus excavatum, and short stature. One brother has scoliosis, and the other has choanal atresia and VSD/ASD. The possibility of X-linked CHARGE-like syndrome (MIM # 302905) was considered, but this condition with cleft palate, coloboma, coronal hypospadias, deafness, short stature, and radial-ulnar synostosis with normal IQ was excluded because the latter 2 features were not present. Their facial features resemble an autosomal recessive syndrome described by Temtamy et al. (1996), which consists of ACC, mental retardation, micrognathia, low-set ears, and coloboma; however, the absence of brachydactyly, bulbous thumbs, genu vara, and pes planus differentiates these brothers from Temtamys siblings. Because of the ACC and marked micrognathia, there is some similarity to Toriello-Carey syndrome. Because of ACC and distinctive facial features, FG syndrome was considered and DNA was analyzed for markers linked to the FG locus. Both brothers are concordant for markers spanning the presumed FG region in Xq13-q21, and both have an alteration in the 5'UTR of the Alpha 4 gene. This gene encodes a protein, which interacts with the Opitz syndrome protein, MID1. We are testing this alteration to see if it is a polymorphism and if it has any biological effect, as well as checking other similar patients for changes in this gene.

**A unique case of atypical Rett Syndrome: MECP2 mutation in a 47, XXX female.** *S.A. Hammer, N. Dorrani, N.C. Schanen.* Dept Human Genetics, Univ California, Los Angeles, Los Angeles, CA.

Rett Syndrome (RTT) is a neurodevelopmental disorder of X-linked dominant inheritance, characterized by severe mental retardation, seizures, hypotonia, stereotypic hand movements and absent language. RTT is caused by mutation in MECP2, a gene located on Xq28 and subject to X-inactivation. MECP2 encodes for methyl CpG-binding protein 2, a ubiquitously expressed protein that binds to methylated CpG dinucleotides and recruits transcriptional silencing complexes to promoter regions. Mutations in MECP2 are primarily de novo events in the male germ line and thus lead to an excess of affected females. Here we report the identification of a unique 47, XXX female who presented with features of atypical RTT and who carries a de novo MECP2 mutation, L100V. She exhibits a relatively mild RTT phenotype that is distinct from the 47, XXX phenotype; she had regression in skills at 20 months of age and currently at five years, she has no language and limited use of her hands, but is agile and exceptionally socially engaging. To investigate the source of her mutation, intronic polymorphisms in MECP2 were analyzed in the patient and her parents. Genotyping of several markers on the X chromosome indicate that the supernumerary X chromosome is paternally derived. X-inactivation patterns were determined by analysis of methylation of the androgen receptor locus, and indicated essentially random inactivation of maternally and paternally derived alleles. The co-occurrence of a sex chromosome aneuploidy and MECP2 mutation are likely chance occurrences and unrelated mechanistically. Supported by HD 37874 and T32HD7032.

**Genetic Heterogeneity of X-Linked Recessive Microphthalmia-Anophthalmia with Mental Retardation: Is Lenz syndrome a single disorder?** *D. Ng<sup>1</sup>, D. Hadley<sup>1</sup>, C. Tiff<sup>2, 3</sup>, L. Biesecker<sup>4</sup>*. 1) Medical Genetics Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 2) Childrens National Medical Center, Washington, DC; 3) Genetics of Development and Disease Branch, National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health, Bethesda, MD; 4) Genetic Diseases Research Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD.

We identified an African-American family with six affected males exhibiting variable features of microphthalmia or anophthalmia, microcephaly, mental retardation, renal and urogenital anomalies. This phenotype was inherited in an X-linked recessive pattern. These anomalies are consistent with Lenz microphthalmia syndrome. Lenz microphthalmia syndrome (MAA (microphthalmia with associated anomalies) [MIM 309800]) was credited to Lenz for his description of a family in 1955. The features in that family included mental retardation, microphthalmia, high palate, anteverted ears, dental abnormalities, congenital cardiac defect, skeletal defects of the fingers and clavicles, unilateral renal aplasia, and cryptorchidism. Subsequent to the report by Lenz, fourteen additional case reports have been published. These reports show that anophthalmia and microphthalmia are part of a spectrum of ophthalmic malformations. Importantly, these reports also show that there is a wide range of associated extra-ocular malformations in X-linked syndromic microphthalmia (XLSM), which were assumed to be caused by mutational heterogeneity, but alternative theories have not been tested. Forrester et al.,[2001] have demonstrated suggestive evidence of linkage of MAA to Xq27 (LOD max 1.83). We have performed linkage analysis in this region and excluded it in the family reported here. We conclude that MAA is genetically heterogeneous with at least two loci on the X chromosome.

**Integrating the cytogenetic map with the draft human genome.** *W. Jang<sup>1</sup>, H.-C. Chen<sup>1</sup>, R. Yonescu<sup>2</sup>, V. Cheung<sup>4</sup>, N. Nowak<sup>5</sup>, B.J. Trask<sup>3</sup>, I. Kirsch<sup>2</sup>, T. Ried<sup>2</sup>, G.D. Schuler<sup>1</sup>.* 1) National Center for Biotechnology Information, NIH, Bethesda, MD; 2) National Cancer Institute, NIH, Bethesda, MD; 3) Fred Hutchinson Cancer Research Center, Seattle, WA; 4) Dep. of Pediatrics, Univ. of Pennsylvania, Philadelphia, PA; 5) Rosewell Park Cancer Institute, Buffalo, NY.

For many human genetic diseases, cancers, and developmental disorders, disease phenotypes have been associated with chromosomal regions, most often to a cytogenetic band(s). In these cases, to understand molecular defects associated with the disease phenotype, it becomes important to identify genes in a given cytogenetic band. To this end, we have started integrating the cytogenetic map with the sequence map.

For this cytogenetic to sequence map integration, we are making use of BAC or PAC clones that have been mapped cytogenetically by fluorescent in situ hybridization (FISH) and have sequence tags in the form of end-sequence, insert sequence or STSs. These clones were placed on the sequence map based on the alignment of the sequence tag on the genomic contig sequence, providing cytogenetic band information on a region of sequence contigs. In NCBI's genome build 22, 7266 FISH-mapped clones were placed on genomic sequence contigs, providing data points for integrating cytogenetic and sequence maps. This annotation can be accessed by (1) selecting "Clone" map on the MapViewer; or (2) through cytogenetic resource (<http://www.ncbi.nlm.nih.gov/genome/cyto>); or (3) through the CloneServer (<http://www.ncbi.nlm.nih.gov/genome/clone>).

The Clone map in the MapViewer displays the clone position on the sequence map, FISH data, and their sequence tags. The cytogenetic resource lists all the FISH-mapped clones and one can select clones based on FISH-mapped chr, FISH data source, clone distributor, or sequence tags. The CloneServer contains information about the status of sequencing of a clone, insert accessions, end-sequence accessions, FISH mapping, STS mapping, placement result on the contig, and clone distributors.

Program Nr: 747 from the 2001 ASHG Annual Meeting

**HC Forum®: an international telemedicine program in cytogenetics.** *O. Cohen, M.A. Mermet, J. Demongeot.*  
Genetic Lab/TIMC/UMR CNRS 5525, Grenoble Univ Medical Sch, La Tronche, France.

Familial structural rearrangements of chromosomes represent a risk of imbalance at birth, which could vary in a large range, making genetic counseling difficult. They also represent a powerful tool for increasing knowledge of the genome, particularly by studying breakpoints and viable imbalances of the genome. However their great diversity makes difficult phenotypes-genotypes correlations, since a very large sample is necessary. From a collaborative database, including data on more than 4100 families, we have developed a Web site called HC Forum (<http://HCForum.imag.fr>). It offers cytogeneticists assistance in diagnosis by showing in real time rearranged chromosomes according to the international nomenclature (ISCN 1995). For genetic counselors, it provides an assessment of the risk of imbalance at birth in reciprocal translocations or in pericentric inversions, by using statistical models. For researchers, interfaces exhibit the distribution of chromosomal breakpoints and of the genome regions observed at birth in trisomy or in monosomy. They allow requests making easier the finding of specific papers or biological material of interest. Since the most of data stay unpublished, we have recently developed an application allowing secured data submissions through Internet. The users can select a kind of the anomaly, the chromosomes involved and the breakpoint locations from graphical interfaces. Interactive pedigree drawing is available and karyotypes can be inputted. Individual data can be described from dysmorphological features according to the LDDDB thesaurus and from chromosomal and clinical pictures of the abnormalities. All these data are showed in a unique friendly interface and can be electronically submitted. After their validation they are definitively registered in the database, but each user can find all the files he previously submitted. After two years, more than 900 users from about 47 different countries already exist. HC Forum constitutes a bridge between diagnosis laboratories and genome research centers, and is a powerful toll for genetic counseling, clinical cytogenetics and for research workers. Contact: [Olivier.Cohen@imag.fr](mailto:Olivier.Cohen@imag.fr).

**Chromosomal instability syndrome of total PCS with mosaic variegated aneuploidy: Genetic homogeneity of the two Japanese infants.** *S. Matsuura*<sup>1</sup>, *E. Ito*<sup>1</sup>, *T. Ikeuchi*<sup>2</sup>, *T. Kajii*<sup>3</sup>, *K. Komatsu*<sup>1</sup>. 1) Dept. of Rad. Biol., RIRBM, Hiroshima Univ., Hiroshima, Japan; 2) Div. of Genet., MRI, Tokyo Med. Dent. Univ., Tokyo, Japan; 3) Hachioji, Tokyo, Japan.

We (Kajii, 1998) previously reported a chromosomal instability syndrome in two Japanese infants, characterized by premature separation of chromatids, in all chromosomes, called "total PCS" in >50% of their lymphocytes, and mosaic variegated aneuploidy. Clinical findings included severe pre- and postnatal growth retardation, profound developmental retardation, severe microcephaly, hypodysplasia of the brain, Dandy-Walker anomaly, uncontrollable clonic seizures, and development of Wilms tumor. Recently we analyzed cell cycle of primary skin fibroblasts from another two unrelated Japanese infants with the disease; MY1sk from a male infant and PCS1 from the male infant reported by Kawame et al. (1999), and found that the two infants' cells are insensitive to the colcemid-induced mitotic-spindle checkpoint (Matsuura, 2000). Here we report functional complementation studies of the two infants' cells. We established immortal cell lines; MY1skSVT and PCS1SVT, from the primary skin fibroblasts; MY1sk and PCS1 respectively by use of SV40 transformation and hTERT cDNA transfection. The infants' cell lines both showed abnormal response of mitotic indices after colcemid treatment, that was similar to that of parental primary cells, indicating no phenotypic alteration in mitotic-spindle checkpoint during an immortalization process. After somatic cell fusions, hybrid cells were analyzed for their response in mitotic indices after colcemid treatment. Immortal cell line GM7166VA7C was used as normal control cells. When infants' cells, either MY1skSVT or PCS1SVT, was fused with GM7166VA7C cells, all hybrid clones showed accumulation of mitotic cells in response to colcemid treatment. In contrast, the hybrid clones between MY1skSVT and PCS1SVT showed fewer mitotic cells and no clear peak in mitotic index. These results suggested genetic homogeneity in the two Japanese infants, and also suggested that the cellular phenotype of abnormal mitotic-spindle checkpoint might be autosomal recessive.

**Maria Cristina Terreros will make the presentation instead of G. Padula.**

Program Nr: 749

**PROTEIN CALORIC MALNUTRITION AND CHROMOSOMAL ALTERATIONS: A CASECONTROL STUDY.** *G. Padula*<sup>1, 2</sup>, *M.C. Terreros*<sup>3, 4</sup>, *M. Apestegua*<sup>1, 3</sup>, *S.A. Salceda*<sup>1, 2</sup>. 1) Universidad Nacional de La Plata, Argentina; 2) CONICET; 3) Comision de Investigaciones Cientificas (CIC), Argentina; 4) Department of Biological Sciences, Florida International University, Fl. USA.

The relation between protein-caloric malnutrition (PCM) and genetic damage has been studied in human beings and laboratory animals obtaining contradictory evidences. It has been found that children aged 1-60 months with severe PCM exhibited an increase of chromosomal aberrations (dicentric, gaps, isogaps, breaks) in peripheral lymphocytes and bone marrow cell cultures. These abnormalities persisted even after the children had attained normal height and weight. In order to evaluate the effect of the protein-caloric malnutrition on the chromosomal damage a total of 9 individuals (7 females and 2 males) aged 1-60 were studied. Cytogenetics preparations from peripheral blood cells were made according to routine protocols and fixed according to Islam and Levan (1987). Chromosome spreads were stained for C banding according to Summer (1972). Cytogenetics analysis were performed in coded slides by scoring the frequencies of dicentric chromosomes, gaps, isogaps, breaks and telomeric associations (TAS). Statistical analysis were performed by Epi Info 6.0. The results obtained to date show a statistical significance increase of chromosomal aberrations. This genetic damage as consequence of PCM can be explained by a failure of enzymatic mechanisms of DNA replication and repair.

**The involvement of Fanconi anaemia proteins in homologous genetic recombination.** *M.S. Meyn*<sup>1,2</sup>, *A. D'Andrea*<sup>3</sup>, *M. Grompe*<sup>4</sup>, *W. Wang*<sup>1</sup>. 1) Genetics, Hospital for Sick Children, Toronto, ON, Canada; 2) Molecular and Medical Genetics, University of Toronto, Toronto, ON, Canada; 3) Pediatric Oncology, Dana Faber Cancer Institute, Boston, MA; 4) Molecular and Medical Genetics, OHSU, Portland, OR.

Fanconi anaemia is characterized by pancytopenia, malformations, cancer, genetic instability, and impaired fertility. Its etiology has remained elusive despite the isolation of multiple Fanconi anaemia (*FANCA*) genes. We now report that the *FANCD2* protein associates with recombination proteins on synaptonemal complexes in spermatocytes and that lack of a functional *FANCA* or *FANCC* gene disrupts meiotic chromosome pairing.

By studying surface spreads of mouse spermatocytes we found that *FANCD2* first forms discrete foci along the unsynapsed and synapsed axes of homologous chromosomes in zygotene spermatocytes. The number of *FANCD2* foci peaks in pachynema, the stage when reciprocal recombination occurs. Most *FANCD2* foci are coincident with foci of Rad51 and RPA, components of meiotic recombination nodules.

*FANCC*<sup>-/-</sup> and *FANCA*<sup>-/-</sup> mice are subfertile. We found that *FANCD2* staining is unusually diffuse in many *FANCC*<sup>-/-</sup> and *FANCA*<sup>-/-</sup> spermatocyte nuclei. Meiotic pairing in *FANCC*<sup>-/-</sup> and *FANCA*<sup>-/-</sup> spermatocytes is disturbed, as indicated by a 15-20 fold increase in the frequency of mispaired chromosomes. In addition, *FANCC*<sup>-/-</sup> spermatocytes have elevated frequencies of apoptosis.

Our results provide a direct demonstration of the *in vivo* association of a Fanconi anaemia protein with chromosomal DNA. The colocalization of *FANCD2* with recombination nodules in meiosis I suggests that *FANCD2* may be part of the machinery of homologous recombination. Our findings that both *FANCD2* foci formation and chromosomal synapsis are impaired in the spermatocytes of *FANCC*<sup>-/-</sup> and *FANCA*<sup>-/-</sup> mice suggest that *FANCD2* is required for optimal pairing of homologous chromosomes during meiosis and that *FANCC* and *FANCA* facilitate the functioning of *FANCD2*. Our data argue that dysfunctional recombination may be a fundamental defect in Fanconi anaemia.

**Identification and characterization of a *de novo* translocation t(8;14)(q22.3;q13) associated with Klippel-Trénaunay Syndrome (KTS), a vascular disease.** A.A. Timur<sup>1,2,3</sup>, P. Szafranski<sup>4</sup>, A. Sadgephour<sup>1,2,3</sup>, V. Jurecic<sup>5</sup>, J.K. Cowell<sup>1,6</sup>, A. Baldini<sup>5</sup>, D.J. Driscoll<sup>7</sup>, Q. Wang<sup>1,2,3</sup>. 1) Center for Molecular Genetics; 2) Department of Molecular Cardiology, Lerner Research Institute; 3) Center for Cardiovascular Genetics, Department of Cardiology, The Cleveland Clinic Foundation, Cleveland, OH; 4) Department of Pathology; 5) Department of Pediatrics (Cardiology), Baylor College of Medicine, Houston, TX; 6) Department of Cancer Genetics, Roswell Park Cancer Institute, Buffalo, NY; 7) Division of Pediatric Cardiology, Mayo Clinic, Rochester, MN.

Klippel-Trénaunay syndrome (KTS) is a vascular disease comprised of capillary, lymphatic, and venous malformations associated with limb asymmetry. We report the identification of a balanced translocation involving chromosomes 8q22.3 and 14q13 in a patient with KTS. We demonstrated that translocation t(8;14)(q22.3;q13) arose *de novo* and co-segregates with the disease in the KTS kindred. The identification of a *de novo* translocation associated with KTS strongly supports the hypothesis that genetic factors contribute to the development of KTS. Fluorescence in situ hybridization (FISH) analysis was used to define the breakpoint on chromosome 8q22.3 to a <5-cM interval flanked by markers AFMA082TG9 and GATA25E10, and the 14q13 breakpoint within a 1-cM region between STS WI-6583 and D14S989. Possible candidate genes for KTS were identified from the breakpoint regions through the NCBI GeneMap'98 database. The 8q22.3 breakpoint contains angiopoietin-1 gene encoding an angiogenic factor (*ANGPT1*) that is required for embryonic vascular stabilization, branching morphogenesis, and post-natal angiogenesis. FISH analysis indicated that the *ANGPT1* gene is not disrupted by the 8q22.3 translocation breakpoint. Further definition of the breakpoints may assist in the identification of a pathogenic gene causing KTS.

**Trisomy 15qter Including the IGF1 Receptor Gene and Overgrowth: Report of Two Families and Review of the Literature.** *P. Gosset<sup>1</sup>, L. Faivre<sup>1</sup>, V. Cormier-Daire<sup>1</sup>, I. Guirgea<sup>1</sup>, S. Odent<sup>2</sup>, J. Amiel<sup>1</sup>, MC. Nassogne<sup>3</sup>, A. Munnich<sup>1</sup>, S. Romana<sup>1</sup>, M. Prieur<sup>1</sup>, M. Vekemans<sup>1</sup>, C. Turleau<sup>1</sup>, MC. De Blois<sup>1</sup>.* 1) Dept of Genetics, Hopital Necker-Enfants Malades, Paris, France; 2) Dept of Genetics, Hopital Pontchaillou, Rennes, France; 3) Dept of Metabolic diseases, Hopital Necker-Enfants Malades, Paris, France.

Overgrowth can be part of various syndromes and molecular basis is known in only a few of them. In most of the cases, pathogenesis of overgrowth syndrome remains unknown, mainly when non specific overgrowth is associated with psychomotor delay. Overgrowth is a rare finding in chromosomal syndromes, but their study can give a clue for candidate genes. Here, we report on 3 patients from two unreported families with overgrowth syndrome, macrocephaly and psychomotor delay associated with trisomy 15q26 diagnosed using cytogenetic, molecular and FISH studies. Chromosome analysis of the parent showed a balanced translocation between chromosome 15q26 and the telomeric segment of chromosome 13q in the first family, and the telomeric segment of chromosome 20p in the second family. Interestingly, review of the literature showed that six other patients with terminal trisomy 15q have been reported to date, and 3 of them presented with unclassified overgrowth syndrome and psychomotor delay. The duplicated segment includes the IGF1R gene, suggesting that a dosage effect of this gene might be related to some of the clinical features observed in our patients. The present observations emphasize the importance of chromosome analysis in patients with overgrowth syndromes.

**Somatic cell hybrid analysis identifies unequivocally a case of segmental paternal isodisomy of chromosome 14.**

*K.J. Coveler<sup>1</sup>, S.P. Yang<sup>2</sup>, J.M. Milstein<sup>2</sup>, Y.Q. Wu<sup>1</sup>, C. Knox-Du Bois<sup>1</sup>, L. Beischel<sup>3</sup>, J.P. Johnson<sup>3</sup>, L.G. Shaffer<sup>1</sup>.* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) U.C. Davis Health System, Sacramento, CA; 3) Shodair Children's Hospital, Helena, MT.

Uniparental disomy of chromosome 14 (UPD 14) results in one of two distinct abnormal phenotypes depending upon the parent of origin. The phenotype of maternal disomy 14 is relatively milder than the paternal disomy 14 phenotype. This discordance is thought to result from genomic imprinting of different genes on chromosome 14. We report a case of segmental paternal isodisomy for chromosome 14 with features similar to those reported in other paternal disomy 14 cases. Molecular analysis of genomic DNA from this patient and his parents using 19 microsatellite markers spanning chromosome 14q revealed an apparent recombination event at 14q12 between markers D14S1021 and D14S121. Analysis of 12 markers between 14cen and 14q12 demonstrated biparental inheritance in this region. Data for 7 markers distal to 14q12 indicated inheritance of a single paternal allele. Hemizygosity (deletion) could not be distinguished from homozygosity (UPD). FISH with BACs RPCI-11 29E16 and RPCI-11 14N4, mapping to 14q21.1, showed hybridization to both chromosomes 14, excluding a deletion to account for the microsatellite marker results. Analysis of monochromosomal somatic cell hybrids containing either the paternal or maternal chromosome 14 revealed no deletion of the maternally inherited chromosome 14 and demonstrated unequivocally that both chromosomes contained paternal sequences from D14S121 to the telomere. Thus, the patient has paternal isodisomy for 14q12-14qter. This case likely represents a very early embryologic somatic recombination with loss of the normal cell line and the reciprocal maternal disomic cell line. A cluster of imprinted genes has been localized to 14q32. This region is fully contained within the isodisomic segment. Since the patient showed features associated with paternal disomy 14, this lends support for a single imprinted domain distal to 14q12 and excludes the proximal region of this chromosome.

**The 22q13 microdeletion : Recognise the Ring 22 chromosome phenotype to detect a new microdeletional syndrome.** *M.F. Croquette<sup>1</sup>, L. Vallee<sup>1</sup>, B. Delobel<sup>1</sup>, J.L. Bresson<sup>2</sup>, F. Fellman<sup>2</sup>.* 1) Neuropediatrics, CHRU Lille, Lille, France; 2) Cytogenetics, CHU Besancon, Besancon, France.

We detected 6 patients who had a 22q13 deletion revealed by R High Resolution banding and confirmed by FISH. Clinical evaluation of these children focused on the same physical and behavioral characteristics as 22 ring chromosome phenotype. In addition, we compared 19 new cases of ring chromosome 22. They share a common phenotype: delivery after term; at birth, the cranial circumference is slightly below the norm; facial dysmorphism is only slightly perceptible with dolicocephalia; large and/or dysplastic ears are the only frequent prominent dysmorphic feature; lymphedema with podgy hands and feet. However the whole specificity of the two syndromes lies in neurological and behavioral characteristics. Tonicity is normal at birth but hypotonia with hypertonia of limbs is increasingly frequent in the first months of life. Patients do not walk before reaching 20 months. In addition walking on tiptoes, peculiarities include very frequent falls, instability and ataxia. Neurodevelopmental delay is severe and is accompanied by mental retardation. Some first words are sometimes pronounced but suddenly the children stop speaking and many have no language. They display autistic behavior including very severe sleep disturbances in childhood. They are prone to extreme anger with tantrums. They are very unstable and exhibit obsessive forms of behavior. They are prone to eating any food, regardless of suitability, at any time without masticating. Children and adults suffer from enuresis and encopresis. Autistic traits decrease in adolescents; however some adults regress. In conclusion molecular cytogenetics demands clinical and behavioral information. Ring 22 chromosome is easy to detect but cryptic 22 q13 deletion requires FISH demonstration. According to Prasad[1] we propose that patients with a significantly delayed speech, autistic traits with minor facial dysmorphism ( dolicocephalia, large dysplastic ears ) and a normal karyotype, be screened for this deletion. This new microdeletional syndrome is certainly more frequent than literature reports. [1]PRASAD et al.(2000) Clin.Genet.103.

**A case of double mosaicism of Turner syndrome and trisomy 8.** *K.M. Christensen, P.R. Winter, F.F. Yen, G.C. Gowans, B. Angle, J.H. Hersh.* Genetics Unit, Department of Pediatrics, Weisskopf Center for the Evaluation of Children, University of Louisville, Louisville KY.

Even more rare than the presence of two aneuploidies in one cell line in the same individual, or in two cell lines with one apparently derived from the other, is the presence of two apparently unrelated aneuploid cell lines in the same individual. We report on a 12 year old female who was found on peripheral lymphocyte and fibroblast cultures to be a mosaic of 45,X and 47, XX, + 8. The proportions of Turner karyotype cell lines to Trisomy 8 karyotype cell lines were 16% to 84% in the lymphocytes and 96.5% to 3.5% in the fibroblasts. With growth hormone injections for the last year, she is at the 5th percentile of height, with a short broad neck without webbing, pectus excavatum, lateral displaced nipples, Tanner III breasts, no cardiac anomalies, pubic hair but no axillary hair, an increased carrying angle, bilateral partial 2-3 finger and toe syndactyly, and possible cross-fused ectopia of left pelvic kidney (duplication of left collecting system with blind ending right ureter). We contrast the findings in our patient with the well described findings in mosaic Turner and mosaic chromosome 8 syndromes. We compare the findings in our patient to the findings in the few previous reports of double mosaicism of Turner syndrome and trisomy 8. We discuss the most likely mechanisms underlying the mosaic cell lines.

Program Nr: 756 from the 2001 ASHG Annual Meeting

**Multiple congenital anomalies associated with *de novo* interstitial duplication of chromosome 15q11q13.** *S. Mann, N. Dorrani, D-H. Liu, C. Schanen.* Dept. Human Genetics, UCLA, Los Angeles, CA 90095.

The phenotypic consequences of chromosome 15q duplication are known to include various mild facial dysmorphisms, cognitive deficits including autism, hypotonia and seizures. We present a child with multiple congenital anomalies involving complex gastrointestinal atresias, tracheoesophageal fistula, congenital heart disease, and cloacal malformations with unilateral hydronephrosis who delivered at 30 weeks gestation. An interstitial duplication on chromosome 15 was identified by routine G-banded karyotyping, giving rise to a karyotype designation of 46, XX, dup (15) (q11-q13). FISH data with probes across the proximal long arm of chromosome 15q revealed the duplicated region included material from the Class I through Class III breakpoints. Parental karyotypes indicate that the duplication event was *de novo*. This case indicates that the phenotype associated with proximal 15q duplications may be more complex than previously anticipated. Supported by HD37470.

**FISH mapping of the Down syndrome critical region: a case with tandem duplication involving 21q22.2. R.**

*Kosaki<sup>1</sup>, N. Matsumoto<sup>2</sup>, K. Kosaki<sup>3</sup>, H. Ohashi<sup>1</sup>.* 1) Dept of Genetics, Saitama Children's Medical Cen, Iwatsuki, Saitama, Japan; 2) Dept of Human Genetics, Nagasaki Univ, School of Medicine, Nagasaki, Nagasaki, Japan; 3) Dept of Pediatrics, Keio Univ, School of Medicine, Shinjuku-ku, Tokyo, Japan.

Documentation of rare cases of Down syndrome with partial trisomy of chromosome 21 has lead to the idea that there exists the Down syndrome critical region. We evaluated a patient with a duplication of 21q22 [46,XY,dup(21)(q22.1q22.3)] who had classic features of Down syndrome including flat occiput, flat facies, upslanting palpebral fissures, inner epicanthal folds, low nasal bridge, short neck, open mouth, tetralogy of Fallot, cataract, hypotonia, and mental retardation. The duplication extent of the rearranged chromosome 21 was investigated by fluorescent in-situ hybridization with BAC/PAC clones that have been mapped on the contig of chromosome 21q21~22. The BAC clone 169K17 containing D21S211 gave single signal whereas the PAC clone 307O17 containing D21S394 and the BAC clone 1P3 containing D21S15 gave two signals. Hence the proximal end of the duplicated segment is localised between D21S211 and D21S394 and the duplication spans distally beyond D21S15. The present case gives further credence to the concept that the many of the phenotypic features of Down syndrome map to 21q22.12-qter (Kornberg et al. PNAS 91:4997-5001). Considering that the proximal boundary of the duplicated segment in the present case and four cases of dup(21)(q22.1qter) reported by Kornberg et al. are all within the band 21q22.12, it is possible that genome sequence within the band might have architectural features that are prone to duplication.

**Male infant with low level mosaicism for trisomy 22 serendipitously detected by FISH.** *R.P. Ketterling<sup>1</sup>, H.C. Flynn<sup>1</sup>, G. Vockley<sup>1</sup>, D.T. Costakos<sup>2</sup>, J. Rigby<sup>2</sup>, S.M. Jalal<sup>1</sup>.* 1) Mayo Clinic/Foundation, Rochester, MN; 2) Franciscan Skemp Healthcare, Mayo Health System, La Crosse, WI.

A male infant was born at 38.5 weeks gestation to a G2P1, 35-year-old mother. The pregnancy was a product of donor artificial insemination. The prenatal history was remarkable for decreased fetal movement throughout the pregnancy and oligohydramnios noted in the third trimester. The birth weight was 1.77 kg., length was 41.9 cm. and head circumference was 29.5 cm (all well below the 5th percentile). Neonatal medical evaluation revealed multiple congenital anomalies, including a right cleft lip and palate, hypertelorism, bilateral undescended testes, hypospadias with penoscrotal inversion, absence of the corpus callosum, patent foramen ovale, moderate reflux into the left kidney, and moderately severe limb contractures. Laboratory abnormalities included hyperkalemia, hyponatremia and a single episode of hypoglycemia. Of note, the placenta demonstrated massive perivillous fibrin deposition. Neonatal aneusomy detection by fluorescence in situ hybridization (FISH) was performed and revealed a normal result for chromosomes 13, 18, 21, and XY. Conventional cytogenetic studies were performed which also revealed a normal karyotype in all 20 cells analyzed. A FISH test was performed with TUPLE1 (and ARSA internal control) to rule-out DiGeorge Syndrome (DGS). While no deletion of the DGS critical region was observed, 3 signals were observed for both the Tuple1 and ARSA probes in 32 of 200 (16%) interphase cells and in 4 of 63 (6%) metaphases. Subsequent analysis by G-banding of 33 more metaphases revealed 3 cells with trisomy 22 (total = 3 of 53 or 6%). This case represents one of the lowest reported levels for trisomy 22 mosaicism and the phenotypic features are generally consistent with those previously summarized by Crowe et al. (*AJMG* 71:406-413, 1997). These results suggest that when performing FISH tests, a careful analysis can provide unexpected information from the signal patterns observed.

**Dysmorphic features in two neonates with mosaic ring chromosome syndromes.** *P.R.K. Koduru<sup>1</sup>, S. Orner<sup>1</sup>, A. Yenamandra<sup>1</sup>, J.H. Tepperberg<sup>2</sup>, M.G. Bialer<sup>1</sup>.* 1) Dept of Pathology and Pediatrics, North Shore Univ Hosp/NYU School of Medicine, Manhasset, NY; 2) Dept of Cytogenetics, LabCorp, Research Triangle Park, NC.

Ring chromosomes with phenotypic consequences are usually detected because of a proband with developmental delay or growth retardation. We report 2 neonates with ring chromosomes who were identified mainly because of dysmorphic features. Patient #1 was seen at 29 days of age. He was the 2210g product of a 32 wk gestation pregnancy complicated by PROM for 5 wk. Mother was 36 yr old and had declined amniocentesis. Baby required some ventilatory support for a few days. Dysmorphology exam was noteworthy for bitemporal indentation, large anterior fontanelle, overfolded ear helices, cupping of the right ear, mild micrognathia and 3 transverse creases on the right palm. Chromosome analysis of peripheral blood revealed an extra small ring chromosome about 1/2 the size of a G-group chromosome in 16 of 44 metaphases analyzed. Neither parent carried the ring. FISH with a WCP-5 DNA probe painted the ring chromosome. The karyotype is described as mos 47,XY,+r[16]/46,XY[28].ish r(5)(WCP5+). Patient #2 was seen at 3 days of age. He was the 3580g product of a 39 wk gestation pregnancy born by Caesarean section after failed induction to a 23 year old mother. Baby had some initial respiratory distress which quickly resolved. Dysmorphology exam revealed right bony preaxial polydactyly, microstomia, trismus, telecanthus, hyperconvex fingernails, Sydney line and right 3rd toe held under 4th. Left choanal stenosis was noted. Chromosome analysis of peripheral blood revealed an extra ring chromosome about the size of a G-group chromosome in 6 of 20 metaphases. Neither parent carried the ring. FISH with a WCP-8 DNA probe painted the ring chromosome. The karyotype is described as mos 47,XY,+r[6]/46,XY[14].ish r(8)(WCP8+). Because ring chromosome syndromes are uncommon and their phenotypes are variable, it has been difficult to define specific features for each one. The features presumably vary based on the chromosomal material present in the ring, the percentage mosaicism in various tissues and other factors intrinsic to the host. FISH techniques are helping to define the different ring syndromes.

**Clinical/Molecular Studies of UPD14 and a Diagnostic Reversal.** *P. Papenhausen*<sup>1</sup>, *A. Wylie*<sup>2</sup>, *H. Shah*<sup>3</sup>, *J. Ranells*<sup>4</sup>, *B. Kousseff*<sup>4</sup>, *I. Gadi*<sup>1</sup>. 1) Labcorp, Inc RTP, NC; 2) Duke MC Durham, NC; 3) Nassau County MC, East Meadow, NY; 4) U. South Florida, Tampa, FL.

Recent identification of imprinting genes on the long arm of chromosome 14 have underscored the need for clinical follow-up of known cases and confirmation of imprinting status. We report the clinical reevaluation at age 9 of a girl with rare isoUPD(14)pat and a new case with isoUPD(14)mat. The DLK1 and GTL2 genes, recently shown to be normally imprinted, were studied in both cases, as well as in a clinically normal woman previously reported as isoUPD(14)mat. All three presented with 45,XX,i(14q). The first case was studied due to IUGR and polyhydramnios. Postnatal complications included prematurity, feeding and resp. difficulties requiring tracheostoma and G tube placement. She now has a 55-60 IQ with nl growth parameters, distal pectus excavatum and a mild thoracic kyphosis. Clinical comparison with other cases of UPD14pat reveals common features not reported postnatally, i.e. long philtrum, blepharophimosis, webbed neck and long fingers. Some features have resolved: hairy forehead, micrognathia, laryngomalacia, hypotonia. The female in case 2 was born at 26 wks GA. Birth wt was 1261g, length 35 cm, and HC 25.5 cm. Generalized edema, short neck, sm thorax with wide spaced hypoplastic nipples, depressed nasal bridge, sm dysmorphic ears, mild hydrocephalus, protruding philtrum and short palpebral fissures were noted. Abdominal distension from hepatomegaly and clenched long thick fingers were also seen. The infant had a PDA, was hypotonic and required intubation with ventilation support. She died of renal failure at day 51. Most features of this case have not been previously reported in maternal UPD(14) with the exception of hydrocephalus and hypotonia. Methylation analysis of the imprinted DLK1/ GTL2 region, using bisulfite treated DNA, indicated abnormal imprinting in cases 1&2 consistent with UPDpat and mat, respectively. However, normal methylation patterns were found in case 3 consistent with the normal phenotype. Expansion of the original analysis from 2 to 11 microsatellite loci revealed a non-maternal allele (father N.A.) at 4 loci consistent with biparental inheritance.

**Identifying the candidate sequence for the formation of common Robertsonian translocations.** *R. Bandyopadhyay, L.G. Shaffer.* Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Robertsonian translocations (Rob) are the most common rearrangements in humans. Rob(13q14q) and rob(14q21q) form predominantly during female meiosis and comprise the majority (85%) of all Robs. Previous studies have suggested that these translocations form through a specific mechanism. Our working hypothesis is that they form through homologous recombination through a common sequence shared on chromosomes 13,14, and 21. Recently a YAC based map anchored with STS-markers of the 21p region was published (Wang et al.1999). We used these STS-markers on hybrid cell lines that contained a de novo rob(14q21q), segregated from all other acrocentric chromosomes. By determining the presence or absence of the STSs, the breakpoint region was further narrowed to between two markers, D21S1276 [present] and D21S188 [deleted] on the chromosome 14/21 involved in the Robs. After narrowing the breakpoint, these two markers were used to screen a human BAC library, which identified two BACs. One BAC contains both markers and a second BAC contains only D21S188. The BACs were hybridized to six patient samples with de novo, maternally-derived rob(14q21q). FISH on the available mother's chromosomes (n=5) showed that both BACs are present on chromosomes 13, 14 and 21. The BAC containing only the marker D21S188 was deleted from all the de novo robs, while the other BAC containing both the markers was partially deleted (showed a very reduced hybridization signal, on all the rob in all cases). The presence of these BACs on chromosomes 13,14 and 21 supports the possibility that a homologous sequence shared among these chromosomes is involved in the Robertsonian translocations. Additionally, the FISH data suggest that the breakpoints are contained on one BAC between the two STS markers. Sequencing of the BACs will lead to the identification of the precise region involved in the formation of the common Robertsonian translocations.

**Asynchronous Replication of Allelic Loci in Turner Syndrome.** *R. Gal*<sup>1,3</sup>, *O. Reish*<sup>1,3</sup>, *L. Gaber*<sup>2</sup>, *A. Amiel*<sup>2,3</sup>. 1) Genetics, Assaf Harofeh Medical Center, Zerifin, Israel; 2) Genetics, Meir Medical Center, Kefar Saba, Israel; 3) Sackler School of Medicine, Tel Aviv University, Israel.

**Background :** Most allelic pairs of DNA replicate synchronously during the S phase of the cell cycle. However, some genes normally replicate asynchronously i.e. genes on the X chromosome and imprinted genes. The replication control mechanism is unknown but has been shown to be impaired in malignancies and chromosomal aberrations where the replication pattern is asynchronous. **Objective :** To determine the level of synchronization in replication timing of genes from patients with Turner syndrome (45,X0) and Turner syndrome mosaics (45,X0/46,XX). **Study Design :** The replication pattern in leukocytes obtained from patients with Turner and mosaic Turner was compared to previously karyotyped normal cells. Fluorescence in situ hybridization analysis simultaneously utilizing different probes- RB, P-53, c-myc (all red) and a probe for the X centromere (green) was performed. This enabled comparison between cells with one X (X0) and two X chromosomes (XX) in the same slide in the mosaic cases. Asynchrony was determined by the presence of one single and one set of double dots (red) in the same cell. **Results :** The asynchrony level in cells with a 45,X0 karyotype was significantly higher than in cells with a normal karyotype ( $p < 0.05$ ). Turner mosaics showed that cells with the 45,X0 genotype have a higher asynchrony level than cells with the 46,XX genotype ( $p < 0.05$ ). **Conclusions :** We assume that the loss of the X chromosome in Turner syndrome disturbs the replication and cell cycle control mechanism, leading to an asynchronous replication pattern in allelic pairs which normally replicate synchronously. The effect of this phenomenon on the Turner phenotype is yet to be determined.

**Deletion 4q21.1q23 in a newborn with hypogonadotropic hypogonadism and multiple abnormalities.** C. Guze<sup>1,3</sup>, R. Bruni<sup>1</sup>, K.S. Reddy<sup>2</sup>, R. Hassan<sup>1</sup>, D. Baker<sup>3</sup>. 1) King Drew Medical Center, Los Angeles, CA; 2) Quest Diagnostics, San Juan Capistrano, CA; 3) CSU Dominguez Hills, Carson, CA.

A male with a *de novo* deletion of 4q21.1q23 was born at 34 wks by exam, 39 wks by LMP. Weight 2130 g (50%ile), length 42 cm (10-15%ile), head circumference 34 cm (90%ile). Apgars 6 and 9. Parental chromosomes normal. He presented with significant dysmorphism: large head, wide fontanel, frontal bossing, micrognathia, short limbs, short fingers, empty scrotum, microphallus, heart murmur, significant stridor and respiratory distress requiring mechanical ventilation. Endoscopy showed laryngomalacia. EKG showed dysplastic pulmonary valve, ASD and moderate PDA. Initially diagnosed with gastroesophageal reflux disease, required G-tube at 3 months. Repeated episodes of pulmonary edema, desaturations and excessive oral secretions required oxygen supplementation and meds. No testes by ultrasound. Rarely opens his eyes and spontaneous activity limited and inappropriate. Feeding pattern inadequate; fatigue disproportionate to level of heart disease. EEG mildly abnormal, seizure meds at 2 months. MRI showed mild dilatation of frontal horns of lateral ventricles, hypoplastic vermis. He has truncal hypotonia with distal contractures of hands and feet, clinodactyly with overlapping fingers, abnormal fisting, foot drop. Renal function, calcium level, PTH, ophthalmologic exam, head CT, thyroid function all normal. Others with interstitial deletions in this region have been reported. Features common with those of our patient include developmental delay, macrocephaly, heart defects, micrognathia, general brain abnormalities, cyanosis with feeds, clinodactyly, frontal bossing, hypotonia and pulmonary incompetence. Hypogonadotropic hypogonadism (OMIM 138850) (AR) due to mutations in the gonadotropin-releasing hormone receptor gene (GNRHR) maps to 4q21.1. Males present with cryptorchidism and microphallus. Our patient showed partial hypopituitarism with hyperprolactinemia. At birth LH 1.4; FSH 1.2; testosterone 143; cortisol <0.5. He was responsive to hCG and ACTH stimulation. We propose the deletion/disruption of the GNRHR gene may be a cause for the hypogonadotropic hypogonadism in our patient.

**Prader-Willi syndrome and a deletion/duplication within the 15q11-q13 region.** *M.G. Butler, D.C. Bittel, Z. Talebizadeh.* Children's Mercy Hospital and University of Missouri-Kansas City School of Medicine, Kansas City, MO.

Prader-Willi syndrome (PWS), the most common genetic cause of marked obesity, is due to a paternally derived 15q11-q13 deletion, maternal disomy 15 or an imprinting mutation. There are at least three hot spots for breakage in the 15q11-q13 region [two are centromeric (BP1, BP2) and one is telomeric (BP3)]. Duplications, triplications and tetrasomy of the 15q11-q13 region have been reported with varying degrees of clinical manifestation. Generally, duplications of maternal origin have been associated with developmental delay and autistic behavior, while paternal duplications have no apparent impact on the phenotype. Herein, we describe a PWS subject with a paternally derived deletion at 15q11-q13 occurring at breakpoints BP2 and BP3 and a paternal duplication centromeric to breakpoint BP2. At 17 years of age our subject weighed 98.9 kg (> > 97th %ile) and was 149.9 cm (3rd %ile) tall. She presented with the typical features of PWS including facial appearance, hypotonia, small hands and feet, obesity in early childhood, learning and behavioral problems and skin picking. She had the typical chromosome 15q11-q13 deletion confirmed by FISH using SNRPN, D15S11, and GABRB3 probes. PCR methylation testing was diagnostic for PWS. Microsatellite analysis with PCR using 19 short tandem repeats from the 15q11-q13 region showed a paternally derived deletion of several informative loci (e.g., D15S817, D15S63, D15S210, GABRA5, D15S822) supporting breakage at breakpoints BP2 and BP3. Interestingly, she had three alleles at D15S541, D15S542 and D15S1035 centromeric to breakpoint BP2 within the 15q11-q13 region indicating a duplication of these loci. The duplication was shared by her phenotypically normal father and uncle but not by the proband's two unaffected female siblings. No other individual in the family showed the deletion. Recent reports suggest that certain repetitive DNA sequences within this region may impact on chromosome pairing. Our family further supports that a parent with a genomic duplication in this region (e.g., father) may predispose to unequal crossing over leading to a deletion event within the 15q11-q13 region and therefore PWS.

**A novel alphoid marker of the Y chromosome.** *C. Conde, S. Chheng, J. Wu, M. Santini, C.D. Kashork, S. Ware, F. Scaglia, L.G. Shaffer.* Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Many studies have concluded that alpha-satellite DNA is an integral part of the centromere and important for the normal segregation of chromosomes. However, there is an increasing number of stable human marker chromosomes have been identified that lack detectable a-satellite. Generally these marker chromosomes (called "alphoid") have lost their normal centromere through chromosomal rearrangements, leading to the formation of a new centromere (neocentromere) in a non-centromeric region on the chromosome. We describe an unusual marker of the Y chromosome. A newborn baby with ambiguous genitalia and intrauterine growth retardation was referred to our laboratory for cytogenetic studies. No dysmorphic features were noted on physical exam. Exam of the external genitalia showed a phallus that resembled a clitoris, a perineal urethral orifice, pseudovaginal labioscrotal hypospadias and hyperpigmented labioscrotal folds. Gonads could not be detected on the labioscrotal folds or inguinal canal. Pelvic ultrasound showed no defined gonads, and uterus and vagina were present with mild hydrometrocolpos. From the blood sample, an analysis of 30 G-banded cells and fluorescence in situ hybridization (FISH) analysis of 130 cells showed that the majority of cells were 45,X (85%) and the remaining cells showed a marker chromosome that was SRY positive by FISH. The centromere specific probe for the Y chromosome failed to hybridize at any site on the marker. On further evaluation, a tissue sample was requested and results revealed mosaicism for three cell lines. A monosomy X cell line was seen with conventional banding and by FISH analysis in 85% of cells. Two additional cell lines were noted in low level by conventional banding and seen at higher rates in FISH analysis. The first, seen in 9% of cells, contained an acentric marker that hybridized with one copy of SRY. The second cell line, seen in approximately 6% of cells, contained an acentric marker that hybridized with two copies of SRY. These results have been interpreted as an unstable marker of the distal short arm of the Y chromosome and this marker likely represents the first case of neocentromere formation in Yp.

**The shape and DNA mediated banding pattern of chromosomes in interphase are similar to metaphase**

**chromosomes.** *U. Claussen*<sup>1</sup>, *J. Lemke*<sup>1</sup>, *J. Claussen*<sup>1</sup>, *I. Chudoba*<sup>2</sup>, *V. Trifonov*<sup>3</sup>, *N. Rubtsov*<sup>3</sup>, *A. Heller*<sup>1</sup>, *H. Starke*<sup>1</sup>, *K. Sperling*<sup>4</sup>, *T. Liehr*<sup>1</sup>. 1) Inst Human Gen & Anthropology, Friedrich-Schiller-Univ, Jena, Germany; 2) MetaSystems GmbH, Robert-Bosch-Str. 6, D-68804 Altlussheim, Germany; 3) Institute of Cytology and Genetics SB RAS, 630090 Novosibirsk, Russia; 4) Institute of Human Genetics, Humboldt-University, Augustenburger Platz 1, D-13353 Berlin, Germany.

Interphase chromosomes analysed with currently available techniques do not present any recognizable structures such as bands, centromeres, telomeres, or specific shapes. Microirradiation experiments and molecular cytogenetic investigations with whole chromosome paints and region specific microdissection probes have confirmed a territorial organization of chromosomes in interphase nuclei. Until now, however, their structure is not well understood. Using the high-resolution DNA-based multicolour banding technique (MCB), we have generated a banding pattern and have determined the length of human chromosome 5 in lymphocyte interphase nuclei, and in nuclei of HeLa cells arrested at different phases of the cell cycle. Chromosome 5 in interphase nuclei is bent and folded and shows an MCB pattern similar to that of metaphase chromosome 5 at all stages of the cell cycle. The length of the chromosome axis is comparable to that of a metaphase chromosome at a 700-band resolution. Therefore, the concept of chromosome condensation during mitosis has to be reassessed. Interphase chromosome banding was successfully used to identify chromosome aberrations and opens new fields in cytogenetic analysis.

**45,X due to translocation of the Y chromosome onto the short arm of chromosome 15 in males of a 3-generation family and evidence for somatic instability.** *P.M. Gopinath<sup>1</sup>, C.S. Nagarajappa<sup>1</sup>, N. Chandra<sup>1</sup>, B. Palaniappan<sup>1</sup>, R. Wimmer<sup>2</sup>, I. Hansmann<sup>3</sup>.* 1) Dept. of Genetics, Madras University, Chennai, India; 2) Institut fuer Humangenetik, Freiburg, Germany; 3) Institut fuer Humangenetik und Medizinische Biologie, Halle/Saale, Germany.

45,X results in a female phenotype Turner syndrome but is rarely associated with maleness. In some of these males Y chromosomal material is translocated onto the X or to an autosome. Most often such translocations are de novo events associated at least with infertility or subfertility. We report on a 3-generation family with four 45,X males in which a Y/15 translocation segregated from grandfather to father and to his 2 sons without any apparent effect on fertility and/or phenotype. The propositus, a 11-year-old male, was referred for karyotyping because of small testis and penis and non-erection of phallus. The right testis was only partially descended. Chromosome analysis revealed 45,X including a Y/15 translocation with a prominent heterochromatic block proximal on the short arm creating a pseudodicentric der(15) with apparent inactivation of Y centromere. Breakpoints are tentatively assigned to distal Yq12 and 15p11.2. His younger brother, his father and grandfather also were found to possess 45,X and the same translocation. Chromosome Y paint completely labeled the short arm of der(15). FISH using probes for PAR1 (e.g. SHOX) and PAR2 (e.g. SYBL1) revealed signals at the distal short arm of the X and the der(15) for PAR1 and at the distal Xq for PAR2. No signal for PAR2 was observed within the short arm of der(15) indicating loss of PAR2. Loss of PAR2 has only rarely been observed, e.g. in cases of satellited Y chromosomes (Kuhl H. et al. 2001) and it could be speculated that conservation of PAR2 might be required for the stability/integrity of the Y chromosome. We do have evidence from our propositus with PAR2 deletion that the Y;15 translocation might not be stable mitotically, either in vivo or in vitro. Approx. 20% of cultured lymphocyte metaphases did show an additional Y chromosome besides the der(15). Also by interphase FISH with Y specific probe approx. 13% of nuclei did show two separate Y signals.

**Delineation of phenotypically normal chromosomal duplications: Implications for detection and involvement of repetitive DNA.** *M.D. Graf, E.E. Eichler, A.B. Zinn, S. Schwartz.* Ctr for Human Genetics and Dept of Genetics, Case Western Reserve Univ and Univ Hospitals of Cleveland.

Duplication of chromosomal material can occur as a consequence of various structural rearrangements. Most commonly, duplications result from meiotic malsegregation of balanced chromosomal rearrangements (translocations, inversions, and insertions) from a phenotypically normal carrier. However, a proportion are due to de novo intrachromosomal (i.e. tandem) or interchromosomal rearrangements. Additionally, some intrachromosomal duplications are transmitted directly from a phenotypically normal parent. Over the past 10 years, to better understand the phenotype-karyotype implications of different duplications, we have studied over 100 de novo and directly transmitted duplications (not including those that have been inherited due to malsegregation of parental rearrangements). We have utilized high-resolution chromosomal analysis and fluorescence in situ hybridization, mostly with single copy probes, to characterize the duplicated material. Our studies have revealed that 10-15% of these duplications (mostly intrachromosomal) are directly inherited from a phenotypically normal parent with varying phenotypic consequences. In addition, 5% of the de novo duplications had no associated abnormal phenotype. To better understand these cases, we have developed BAC probes and have shown that most cases involve the duplication of repetitive material.

Based on the findings from these studies we have gained additional insights concerning the implication of duplicated material and can conclude the following: (1) a larger than expected number of cases of tandem duplications were directly inherited, while only one interchromosomal duplication was; (2) several of the duplications were not associated with phenotypic abnormalities, suggesting that the duplication consists of only repetitive and/or paralogous DNA; and (3) by utilizing information from the human genome project, we have developed several probes for the different duplications to confirm that the duplications often involve repetitive, rather than euchromatic, material.

**Subtelomeric assay as a genetic screening tool for MR of unknown etiology.** *A.J. Dawson<sup>1,2,3</sup>, S. Putnam<sup>3</sup>, D. Riordan<sup>3</sup>, A. Mhanni<sup>1,2</sup>, S. Kovnats<sup>1</sup>, S. Seshia<sup>4</sup>, C. Prasad<sup>1,2</sup>.* 1) Department of Pediatrics and Child Health, University of Manitoba; 2) Department of Biochemistry and Medical Genetics, University of Manitoba; 3) Cytogenetics Laboratory, Division of Laboratory Medicine and Pathology, HSC, Winnipeg, Manitoba; 4) Manitoba Clinic, Winnipeg, Manitoba.

The telomeres of human chromosomes are gene rich. Chromosome telomere rearrangements occur with a frequency of 7-10% in children with mild to moderate MR and approximately one half of cases are familial. Clinical investigation for subtelomeric rearrangements is now prompted by FISH analysis using specific DNA probes from all relevant chromosome ends. In our study, 20 children were selected for subtelomeric assay using the Chromophore Multiprobe-T Cytocell device. Inclusion criteria were developmental delay or MR, a normal 550 band G-banded karyotype, FRAXA negative, and at least one other clinical criterion. Exclusion criteria included an identified genetic, environmental, or teratogenic diagnosis. Parents had to consent to cytogenetic subtelomere analysis if necessary. Of the 20 patients analyzed, one (5%) was found to have an unbalanced female karyotype with a derivative chromosome 9 resulting from a translocation between the telomeres of the long arms of chromosomes 5 and 9: 46,XX.ish der(9)t(5;9)(q35.3;q34.3) (D5S2097-,D9S2168+;D5S2097+, D9S2168-)pat. The father was a balanced de novo carrier for this translocation as paternal grandparents had normal karyotypes. The patient's brother was also a balanced carrier. The proband's mother had a history of two miscarriages. At nine months of age, the patient had a weight of 7.6kg (10th-25th%ile), height of 68.5cm (25th-50th%ile) and an OFC of 39.9cm (2nd%ile). She had significant midface hypoplasia with a high, sloped forehead and significant microcephaly. The anterior fontanel was patent and there was no ridging of any cranial sutures. Her DQ was 40. The cranial MRI showed marked deep white matter changes in the posterior half of the brain with generalized atrophy. Our findings support the view that screening for subtelomeric rearrangements is a significant and cost-effective way of making diagnoses in children with unexplained mental retardation.

**Distribution of exchanges in chromosome 15 nondisjunction.** *J.L. Gair, B.D. Kuchinka, W.P. Robinson.*

Dept. Medical Genetics, UBC, Vancouver, BC, Canada.

Nondisjunction (ND) leading to trisomy and other aneuploidies contributes significantly to reproductive difficulties and human genetic disease. Understanding factors affecting ND in humans is necessary if we are ever to develop therapies to reduce its occurrence. Studies of recombination in meiotic ND leading to trisomy 21, suggest that both alterations in the amount and the distribution of recombination along the chromosome are associated with ND. Previous studies of ND for chromosome 15 also show a reduction in recombination in meiosis I (MI) errors. To investigate recombination and chromosome 15 ND further, molecular marker typings from 157 cases of trisomy 15 or UPD15 were used to divide chromosome 15 into 14 intervals. The amount and distribution of crossovers in each interval was then compared to CEPH controls (public and own data). A comparison of genetic and physical maps was also made to test if recombination correlates closer with physical distance with ND, suggesting relaxation of chromatin influences on recombination. As sequence is not complete for this chromosome, physical distance was estimated from radiation hybrid maps. Comparisons of MI and meiosis II (MII) errors with CEPH control females, shows that there does not appear to be an alteration in the distribution of recombination along chromosome 15 in any but the most proximal region from D15S541 to D15S122 (with estimates of 0.96 cM, 10.8cM and 15.59 cM for MI errors, CEPH control females and MII errors, respectively). The distance between double crossovers was also estimated to determine if interference patterns might be altered in ND. Of 56 double crossovers identified among MI errors, most (59-86%) occurred within 50cM. Of these, 8 definitely and 26 possibly, occurred over less than 30cM genetic distance. In contrast, double crossovers within such a short distance were extremely rare among 50 double crossovers identified in CEPH controls. The shortest distance of double crossover was 8-16cM among MI errors and 11-17 cM among CEPH female controls. Further refinement of crossovers and analysis will be necessary to determine if relaxed interference is associated with ND.

**The Importance of Chromosome Analysis for Assessing the Recurrence Risk in Cases of Anencephaly.** *G.S. Frohlich, D.B. Rogers, M. Thangavelu.* Genzyme Genetics, Orange, CA.

The prenatal diagnosis of anencephaly commonly leads to a recurrence risk based on multifactorial inheritance. However, if a chromosome abnormality is detected, the risk for recurrence can lead to vastly different genetic counseling for the patient. The incidence of chromosome abnormalities in anencephalic fetuses is, at best, poorly documented in the literature. We have reviewed the Genzyme Genetics database of cytogenetic analyses performed (n = 292) on pregnancies affected with anencephaly. The indications for analysis and cytogenetic abnormalities were reviewed. Our review revealed chromosome abnormalities consisting of numerical (n = 13, 4.4%) and structural (n = 4, 1.3%) defects, accounting for greater than 5% of the total number of anencephaly cases. Two cases with structural abnormalities had partial duplication of chromosome 2. The recurrence risk following a single occurrence of anencephaly is based on the overall incidence of neural tube defects in a particular population. This may vary from 1-2% in the United States to as high as 5% in other areas of the world where the NTD incidence is much higher. Genetic counseling following the diagnosis of a chromosome abnormality can, in many instances, be more precise and could signal the existence of significant risks for the patient and possibly other members of his/her family. Structural chromosome abnormalities can, depending on whether they are de novo or familial, lead to genetic counseling recommendations varying from minimal risk for recurrence to the offering of prenatal diagnosis to multiple family members. It is our conclusion that, in cases of anencephaly discovered on prenatal ultrasonography, chromosome analysis be offered in order to identify familial rearrangements and to provide the most appropriate genetic counseling for the patient.

**A prospective, double-blind study comparing results of G-banding and SKY methodologies in 89 neonates referred for cytogenetic testing.** *A. Anguiano, V. Sulcova, A. Sbeiti, K. Hoang, S. Wang, A. Fraser, M. Ayad, K. Reddy, B. White.* Cytogenetics Dept, Quest Diag, Nichols Inst, San Juan Capist, CA.

Spectral karyotyping (SKY) has proven very useful for detecting various chromosomal rearrangements not revealed by conventional banding methods. To further assess the utility of SKY, we tested 89 neonates in a prospective, double-blind study that utilized both conventional cytogenetics and SKY methodologies. Cases with common numerical abnormalities were excluded via a preliminary assessment of five G-banded metaphases derived from a 24-hour culture. The non-aneuploid cases were then evaluated by SKY in parallel with G-banding studies. In each case, at least 20 G-banded metaphases were examined during conventional cytogenetic analysis, and a minimum of 3 metaphases were studied using SKY. Emphasis was placed on examination of telomeric regions. Conventional G-banding identified six abnormal cases. SKY revealed the same 6 cases and one additional abnormality, a trisomy 8 mosaicism. On the other hand, G-banding defined a mosaic with two abnormal and one normal cell line, while SKY detected the normal cell line and only the more prevalent abnormal cell line, missing the second abnormal cell line observed in 25% of G-banded metaphases. Thus, SKY did not demonstrate significantly improved sensitivity relative to G-banding. While it was useful to detect the one mosaic case missed by G-banding, cryptic imbalances such as telomeric-region rearrangements or insertions were not revealed by SKY. Possibly larger series will detect such abnormalities. At this point it does not seem justified to routinely recommend SKY for further investigation of phenotypically abnormal neonates showing a normal G-banded karyotype.

**A contiguous gene syndrome in an infant with both cleidocranial dysplasia and CHAR syndrome due to deletion 6p21.2-p11.2.** *Y.S. Choy<sup>1</sup>, S.K Tan<sup>2</sup>, A. Othman<sup>2</sup>.* 1) Cons Gen/Neurologist/Ped, Kuala Lumpur Hosp/Ped Inst, Kuala Lumpur, Malaysia; 2) Cytogenetic Department, Kuala Lumpur Hospital.

The coexistence of two rare Mendelian disorders in an individual is uncommon but can be explained by the deletion of a sequence of adjacent genes. Cleidocranial dysplasia is an autosomal dominant skeletal dysplasia due to mutations in the RUN-related transcription factor 2 gene located at 6p21. An adjacent gene at 6p12, TFAP2B gene, causes CHAR syndrome in a dominant negative manner. Most of the other genes with known functions in the region 6p21.2-p11.2 are inherited in an autosomal recessive manner except for RP7 which causes adult onset retinitis pigmentosa and HMGIIY which is responsible for lipoma. Therefore, haploinsufficiency of the region 6p21.2-p11.2 would result in a contiguous gene syndrome with these disorders. We described a 16-month old Malay boy born to a 28-year-old G1P1 mother and a non-consanguineous father. Multiple birth defects and dysmorphism were noted at birth including widely separated sutures and widely open anterior fontanel with parietal bossing, hypertelorism, flat short nose, long philtrum, thick lips, micronagthia and high arched palate, narrow thorax, short digits, bilateral clinodactyly. Both the clavicles were absent. He had a moderate sized patent ductus arteriosus requiring anti-failure therapy. Karyotype analysis revealed a interstitial deletion of 6p21.1-p11.2. Parental karyotypes were both normal. Subsequently, he had recurrent respiratory distress needed bronchodilator therapy. Bilateral mild conductive deafness was detected. Beside a delay in fontanel closure, there was delay in eruption of deciduous teeth with enamel hypoplasia and malalignment consistent with the natural history of cleidocranial dysplasia. His facies on the other hand became more reminiscent of CHAR syndrome where he has duck-bill like lips associated with flat face and broad flattened nasal tip. renal ultrasound and MRI of the brain were normal, He has a relatively normal milestone thus far. His eyes are normal now but being followed up closely. This case illustrated the correlation of cytogenetic abnormality and phenotype of the deleted region 6p21.2-p11.2.

**Detection of a submicroscopic deletion 1p36.3 in a patient with mosaicism for trisomy 9p resulting from der(1)t(1;9)(p36.3;p13) using a subtelomeric FISH probe.** *N.J. Carpenter<sup>1</sup>, X. Yang<sup>2</sup>, B. Moghaddam<sup>1</sup>, M.E. Floyd<sup>1</sup>, K.S. Reddy<sup>2</sup>.* 1) HA Chapman Institute of Medical Genetics, Tulsa, OK; 2) Quest Diagnostics, Inc., San Juan Capistrano, CA.

Mosaicism involving an apparently normal cell line and an unbalanced autosomal structural aberration that is not a ring or a supernumerary marker chromosome is rare. This report describes an infant with mosaicism for an unbalanced translocation for whom the apparently normal cell line was found to have a submicroscopic deletion. Prenatal diagnosis was performed due to fetal hydrocephalus and IUGR and a 46,XX karyotype was observed. At birth, the infant had patent ductus arteriosus, generalized hypotonia, bilateral optic nerve hypoplasia, clitoromegaly and pes calcaneovalgus. At 6 months of age, she has dysmorphic facies, bitemporal depression, low-set ears, inverted nipples, and significant developmental delay. Cytogenetic and FISH studies of peripheral blood showed a mosaic karyotype, 46,XX,der(1)t(1;9)(p36.3;p13).ish der(1)(wcp9+)/46,XX, resulting in trisomy 9p in 88% of the cells. A retrospective study of the prenatal sample revealed only 4% of the cells had the der(1). Surprisingly, FISH analysis of the blood with a subtelomeric probe for 1p detected a deletion of 1p36.3 in the apparently normal cell line as well as in the der(1) cell line. The mother has a 46,XX karyotype and FISH study is in progress. The father is unavailable. The infant has some features of the del(1p) syndrome, some of the dup(9p) syndrome, and some which are common to both. It is postulated that the del(1p) was present in the zygote as a result of a de novo deletion or a familial cryptic translocation. Exchange of chromatids of chromosomes 1 and 9 during mitosis, loss of one of the translocated chromatids, and segregation resulted in the del(1p) and the der(1)t(1;9) cell lines. The deletion of the 1p telomere may have increased the likelihood of a mitotic exchange involving this chromosome region. The finding of the del(1)(p36.3) in the apparently normal cell line means that the possibility of a familial translocation must be investigated to assess the risk for future pregnancies and for other family members.

**Deletion of distal Yp chromosome resulting from a dicentric chromosome(Y;22) in a child with short stature and no dyschondrosteosis.** C. Borie<sup>1</sup>, J. Leger<sup>2</sup>, O. Dupuy<sup>1</sup>, N. Bondeux<sup>1</sup>, C. Pignal<sup>1</sup>, C. Dupont<sup>1</sup>, P. Czernichow<sup>2</sup>, P. Eydoux<sup>1</sup>. 1) Biologie du Developpement; 2) Endocrinologie, Hospital Robert Debre, Paris, France.

We report a 4 year-old child with short stature, and a dicentric chromosome with a deletion of the distal part of chromosome Yp. The parents were not consanguineous, and did not have any relevant history of genetic disease. The pregnancy was uneventful, until intra-uterine growth retardation was noted. Prenatal karyotyping showed a de novo(Y;22) translocation. No structural fetal abnormality was shown at ultrasound examination, and the pregnancy went to term. A growth retarded boy with an otherwise normal physical examination was delivered at 39 weeks. At age 4, the child had short stature (-3SD) without mental retardation. Radiological examination of the wrist was normal. A blood karyotype confirmed the chromosomal rearrangement seen on amniotic fluid cells. C-banding showed a dicentric chromosome, and FISH with centromeric probes confirmed the presence of both chromosome Y and 22 centromeres on the derivative chromosome. FISH using a TUPLE1 probe did not show any rearrangement at 22q11 or at the ARSA locus. Using a subtelomeric probe, a deletion of the distal Yp region was shown. The karyotype was thus 45,X,der(Y;22)(p11;q11)del(Y)(p11p11). We hypothesise that the chromosomal rearrangement of this patient resulted in the deletion of the distal part of the pseudoautosomal region PAR1, including SHOX but not SRY. Haploinsufficiency of the former gene may result in Leri-Weill dyschondrosteosis, which did not appear to be an obvious diagnosis in this young patient. Further studies are pending to demonstrate the extent of the Yp deletion.

**Non-convulsive status epilepticus and ring chromosome 20: a specific cytogenetics syndrome.** *O. Dupuy<sup>1</sup>, C. Borie<sup>1</sup>, A. Arzimanoglou<sup>2</sup>, N. Collot<sup>1</sup>, A. Thaly<sup>1</sup>, M. Vitu<sup>1</sup>, P. Evrard<sup>2</sup>, P. Eydoux<sup>1</sup>.* 1) Biologie du Developpement; 2) Epilepsy Program, Child Neurology and Metabolic Diseases Dpt., University Hospital Robert Debre, Paris, France.

Our patient, a 14 years old girl, was born after an uneventful pregnancy, from non consanguineous parents with no relevant history of a genetic disease. Physical examination was normal at birth and further development was reported as normal. The first paroxysmal episodes were observed at age 9. They occurred mostly on awakening, and consisted of a prolonged confusional state, slowness of response, wandering, oro-motor automatism and redness of the face. The child could recall the events during periods of mild confusion and exhibited fear, often related to hallucinations involving animals such as spiders or reptiles. Episodes were markedly long, lasting from 15-20 minutes up to one hour. Ictal EEGs showed long-lasting high-voltage slow waves with occasional spikes, with a frontal predominance. The blood karyotype was performed because of this very peculiar type of epilepsy, and showed a ring chromosome 20 in 7 out of 18 cells. One double ring was observed. FISH, using subtelomeric probes, showed the presence of both 20p and 20q signals, thus did not reveal any distal deletion of the chromosome 20 subtelomeric regions, as would be expected in a ring chromosome resulting in phenotypical anomalies. Epilepsy characterized by prolonged episodes of non-convulsive status and associated with spider or reptilian hallucinations is a very specific syndrome and warrants karyotyping. The mechanism resulting in this syndrome is not well understood, since no specific deletion seems to be associated with the ring chromosome. Hypotheses include a deletion very close to the telomere, mosaicism with a heterogeneous population (double ring chromosome, broken ring, chromosome 20 deletion), or a position effect around the subtelomeric region resulting in an abnormal inactivation or activation of gene(s) within this region.

**Genetic study on 231 women affected by premature ovarian failure (POF).** *L. Dalprá<sup>1</sup>, C. Porta<sup>2</sup>, E. Martinoli<sup>2</sup>, A. Patrizi<sup>2</sup>, E. Sala<sup>3</sup>, N. Villa<sup>3</sup>, MG. Tibiletti<sup>4</sup>, M. Taborelli<sup>4</sup>, B. Dossena<sup>4</sup>, E. Ginelli<sup>2</sup>, A. Marozzi<sup>2</sup>.* 1) Dept Experimental and Environmental Medicine and Medical Biotechnology, Univ.Milan-Bicocca, Italy; 2) Dept Biology and Genetics for Medical Sciences, Univ Milan, Italy; 3) Genetic Lab, H.S.Gerardo, Monza, Italy; 4) Dept Clinical and Biological Sciences, Univ. Insubria, Varese, Italy.

The absence of germ cell is associated with a complete ovarian failure, while the decrease number is more likely associated with partial ovarian failure or secondary amenorrhoea. Primary and secondary amenorrhoea are highly heterogeneous and their aetiology is still unknown in most cases, and these conditions may be considered as the different expression of the same disorder. A chromosomal and genetic role is universally recognised in the pathogenesis, but the frequencies and the types of chromosome aberrations and gene mutations are to be determined. A systematic genetic study on 231 (21 primary and 210 secondary amenorrhoea) women affected by POF was performed, including chromosome analysis and FRAXA premutation screening. The inclusion criteria for the study were menopause before of age 40, FSH values > 40 IU/l and normal phenotype. The overall percentage of chromosome anomalies was 7%, including 3 pure autosomal abnormalities, 3 Xq deletions, 1 Xp deletion, 1 psudic(Xp) (the only observed aberration in primary amenorrhoea), 2 translocations involving chromosome X and autosome (1 balanced active and 2 unbalanced completely inactivated), 1 translocation (Xp;Xq), 1 XXX and 4 numerical and structural mosaicisms. For cases in which a single cell with 45,X and/or 47,XXX karyotype were detected, further analysis by means of interphase FISH were carried out. The observation of single or triple signals confirmed the hypothesis that the mosaic situations can be an underestimated event. All these data indicate that both monosomy and triple dosage of X regions are responsible of ovarian failure. Moreover, FRAXA premutation screening on 179 POF women with normal karyotype indicates a premutation status in 9 patients (5%). In conclusion, FRAXA premutation testing and chromosomal analysis must be done in order to identify the cause of ovarian failure.

**Multiple copies of SHOX does not overcompensate for the loss of Yq in a male with short stature and iso Yp.** *L.E. Evans<sup>1</sup>, V. Shashi<sup>1</sup>, A.R. Turner<sup>1</sup>, R. Schwartz<sup>2</sup>, M.J. Pettenati<sup>1</sup>.* 1) Department of Pediatrics/Section on Medical Genetics, Wake Forest University School of Medicine, Winston-Salem, NC; 2) Department of Pediatrics, Wake Forest University School of Medicine, Winston-Salem, NC.

Routine cytogenetic analysis was performed on a 3 2/12 year old male, presenting with short stature, delayed bone age, developmental delay and small testicles. His karyotype revealed a structurally normal X chromosome and an apparent isodicentric Yp chromosome rearrangement. Molecular cytogenetic analysis confirmed that this was an isodicentric Yp chromosome lacking centromeric material and having two copies of the SHOX (Xp22.3) and SRY (Yp11.3) gene on either end of the isochromosome [46,X,rec(Y)i(Y)(p11.1)t(X;Y) (p22.33;p11.32)]. His X chromosome had a single SHOX gene on the Xp. Thus, he was trisomic for SHOX. Parental chromosomes were normal. This rare recombination probably occurred in two stages. The first event most likely was a paternal meiosis I error, involving the translocation of a region on Xp including the SHOX gene to the distal end of Yp, followed by a second event, when the Y chromosome missegregated, resulting in an isochromosome.

The pseudoautosomal short stature homeobox-containing gene (SHOX) is believed to exert a dosage effect in sex chromosome aberrations. Haploinsufficiency of the SHOX gene has been shown to cause short stature and overdosage of the SHOX gene has been implicated in tall stature among females. Overdosage of the SHOX gene specifically in males has not been described. Although the presented male has 3 copies of the SHOX gene, he demonstrates short stature. This phenotype may be best explained by the lack of Yq, which has been associated with short stature and infertility in males. Thus, we suggest that the deletion of Yq is dominant for stature over the overdosage of SHOX.

**Partial trisomy 11q due to a  $\text{ins}(22;11)(q13.3;q14.2q23.3)\text{pat}$ .** A. Cervantes<sup>1</sup>, R. Guevara-Yáñez<sup>2</sup>, J.T. Granados<sup>1</sup>, E. Gálvez<sup>1</sup>, V. Madrid<sup>1</sup>, N. Téllez<sup>1</sup>, M. López<sup>3</sup>, S. Kofman<sup>1</sup>. 1) Genética, Hospital General México/Facultad Medicina, UNAM; 2) UIM Genética Humana, H Pediatría CMN SXXI, IMSS; 3) S Biológicos, UAM-X, México D.F.

Most cases of partial trisomy 11q involve a  $\text{t}(11;22)(q23;q11)$  with a 3:1 meiotic segregation and includes clinical manifestations of trisomy 22. In some cases, trisomy 11q can be linked to a partial monosomy of another chromosome due to adjacent I segregation of a parental reciprocal translocation. Insertions or de novo duplications are found rarely. The breakpoints involved vary from 11q12.1 to 11q23.2 and the severity of manifestations are related to the extent of the implicated segment. The major diagnostic criteria includes development delay, growth retardation, and characteristic facies.

A five-year-old girl with moderate psychomotor retardation and language anomalies is reported. She had low-set ears, divergent strabismus, short and wide nose, anteverted nares, prominent upper lip, high palate, retrognathia, short neck, funnel chest, fifth toe clinodactyly and cutaneous syndactyly 2-3 of toes. Her karyotype with GTG banding revealed a  $46,XX,-22,+der(22)$  complement. The karyotype of her mother was normal and the father and grandfather's karyotypes were  $46,XY,\text{ins}(22;11)(q13.3;q14.2q23.3)$ . Fluorescent in situ hybridization (FISH) was performed in the patient and her father. A chromosome painting cocktail (ONCOR) for chromosome 22 painted only normal and derivative chromosomes 22; telomeric probes for 11p, 11q and 22q (CYTOCELL) were used to confirm the insertion. We discuss the mechanism of formation of der (22) and compare clinical data with different cases of pure trisomy 11q described in the literature.

**Prenatal diagnosis of trisomy 1p36.3 and monosomy10q26.** *S.G. Adhvaryu<sup>1</sup>, L.G. Shaffer<sup>2</sup>, R.C. Lewandowski<sup>1</sup>.* 1) Center for Genetic Services, Corpus Christi, TX 78412; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX 77030.

Amniotic fluid sample from 25 years old (G2P1) was received for chromosome analysis because of elevated risk for fetal Down syndrome based on abnormal maternal serum screen. Chromosome analysis revealed the fetal karyotype as an abnormal female: 46,XX,?del(10)(q26). Parental chromosome analysis showed the father to be a carrier of a balanced translocation involving chromosomes 1 and 10, with the breakpoints at p36.3 and q26.1, respectively. Fluorescence in-situ hybridization (FISH) studies with telomere-region specific probes were pursued for confirmation of the breakpoints. A female infant was born at 32 weeks gestation with a birth weight of 1610 gm. Other clinical findings at birth were respiratory distress syndrome, bilateral clubfeet, abnormal eye movement and low platelets. A detailed physical examination on 21st day revealed a child with dolichocephaly with slight frontal bossing, bilateral epicanthus, blepharophimosis with a concurrent telecanthus, anteverted nares, micrognathia and abnormal ears with folding of the helix bilaterally. FISH studies are an important, integral part of the cytogenetic laboratory in identification of subtle chromosome rearrangements. Few cases of trisomy for the terminal short arm of chromosome 1 (1p36.3) exist in the literature. This infants physical findings are compounded by the double segmental imbalance of concomitant monosomy for the distal long arm of chromosome 10 (10q26). Given the identification of a parental translocation, this family is at significant risk of the same or the reciprocal imbalance in future pregnancies.

**Subtelomeric Chromosome Abnormalities in South Carolina.** *B.R. DuPont, J.S. Collins, J.G. Archie, R.S. Saul, C.E. Schwartz, R.E. Stevenson.* Greenwood Genetics Center, Greenwood, SC.

Fluorescence in situ hybridization (FISH) analysis of chromosome subtelomeric areas has enhanced the search for the underlying etiology in patients with idiopathic mental retardation. Previous studies have shown between 4% and 23% of children with moderate to severe retardation have a subtle chromosome abnormality using subtelomeric FISH probes. The largest study (Knight et al., 1999) found approximately 7% of patients had an unbalanced telomere rearrangement. A subsequent analysis of their data [29 affected, 110 controls] demonstrated that the prenatal onset of growth retardation and a positive family history for mental retardation are good indicators for subtelomeric analysis (STA) (deVries et al., 2001).

The Greenwood Genetic Center Cytogenetics Laboratory initiated STA in 2000. To date, we have analyzed 43 people with developmental delay. We found subtelomeric abnormalities in 6 patients (3M, 3F), 4 Caucasian, 1 African-American, and 1 Indian. They ranged in age at testing from 2 months to 56 years, with 4 below the age of 8 and 2 above the age of 50; birth weights fell into normal ranges. Clinical features and abnormal test results that occurred in more than one of these individuals included facial dysmorphism (6/6), skeletal abnormalities (2/5), CNS abnormalities (3/5), cardiac abnormalities (3/5), vision abnormalities (2/5), cranial image abnormalities (3/4), and other abnormalities (3/5). The chromosome aberrations included der(4)t(4;11), 8p-, 8p+, 9p-, der(13)t(5;13), and der(14)t(7;14). Three of these rearrangements were familial in origin, one was de novo, and results on the others were pending.

In reviewing the causes of mental retardation in 7600 persons in South Carolina, we found 2513 with moderate to severe MR with unknown causation and an additional 324 with MR and a family history. If these two groups are combined, we might expect a retrospective analysis to find as many as 210 STA abnormalities using a 7.4% estimate.

**Pallister-Killian Syndrome Due to a Novel Chromosome Abnormality: A Case of 12p Intrachromosomal**

**Triplication.** *H.M. Bedford*<sup>1</sup>, *S. Unger*<sup>1</sup>, *M. Nowaczyk*<sup>2</sup>, *I. Teshima*<sup>3</sup>. 1) Division of Clinical & Metabolic Genetics, Hospital for Sick Children, Toronto, ON, Canada; 2) Clinical Genetics Services, Hamilton Health Sciences Corporation, Hamilton, ON, Canada; 3) Molecular Diagnostics, Department of Paediatric Laboratory Medicine, Hospital for Sick Children, Toronto, ON, Canada.

Pallister-Killian Syndrome (PKS) is a rare sporadic condition characterized by multiple congenital anomalies, mental retardation and tissue-limited mosaicism for isochromosome 12p (i(12p)). Children with PKS surviving beyond the newborn period typically present with seizures, severe developmental delay, hypo/hyperpigmented streaks of skin, disproportionate shortening of the limbs and characteristic craniofacial features. The mechanism(s) of formation and parental origin of the isochromosome are not well understood. The i(12p) is usually present in fibroblasts but is rarely seen in leukocytes. Selection against the i(12p) chromosome in leukocytes or anaphase lag may explain the lack of abnormal cells in blood. In the majority of cases in which parent of origin was studied, the i(12p) was maternal in origin.

We present an 18-month-old boy with characteristic features of PKS due to a novel chromosome 12 abnormality. Peripheral blood karyotype was normal (46,XY), however chromosome analysis of cultured fibroblasts demonstrated mosaicism for a 12p+ chromosome. This 12p+ chromosome was further characterized by C-banding and molecular cytogenetic techniques including whole chromosome painting and fluorescence in-situ hybridization (FISH) analysis to determine the chromosomal origin of the additional material and to define the breakpoints. The resulting final karyotype was 46,XY, trp(12)(p11.2p13)[113]/46,XY[2]. This is the first case of PKS due to an intrachromosomal triplication of 12p. In addition, this is the first case of an intrachromosomal triplication involving chromosome 12. Intrachromosomal triplications involving chromosomes 2, 5, 7, 9 and 15 have been previously reported. The mechanism(s) of intrachromosomal triplications has been debated. This case provides evidence for a postzygotic event in the generation of some intrachromosomal triplications.

**A mosaic ring chromosome 4 in a fetus with Wolf-Hirschhorn phenotype - breakpoint mapping and histopathology.** *S.U. Endeke<sup>1</sup>, A. Kocks<sup>1</sup>, B. Schroeder<sup>1</sup>, R. Heller<sup>1</sup>, M. Makrigeorgi-Butera<sup>2</sup>, C. Staedtler<sup>3</sup>, H.J. Schaefer<sup>3</sup>, A. Winterpacht<sup>1</sup>.* 1) Inst. of Human Genetics, Hamburg, Germany; 2) Dept. of Neuropathology, University of Hamburg, Germany; 3) Inst. of Pathology, University of Hamburg, Germany.

The molecular basis of Wolf-Hirschhorn syndrom (WHS), also deletion 4p syndrome, has not yet been elucidated. However, based on genotype-phenotype correlation studies and by molecular analysis of chromosomal breakpoints on chromosome 4p, the critical region has been narrowed to an interval of 165 kb between D4S43 and FGFR3. Several candidate genes are being tested for their role in WHS by us and others using cloning techniques and mouse knock-out models. The study of dysmorphological and histopathological features in affected human fetuses with well characterized chromosome 4p deletions is an additional strategy to gain insight into the developmental pathology of WHS. We present the case of an aborted fetus (21st gestational week) with Wolf-Hirschhorn phenotype: pronounced growth deficiency, complex cardiac defect, leftsided diaphragmatic hernia, aplasia of the gallbladder, and typical craniofacial manifestations (bilateral cleft lip and palate, hypertelorism with broad base of nose, low-set ears). Conventional karyotyping revealed a mosaic ring-chromosome 4 with breakpoints tentatively assigned to 4p16 and 4q33. We report on the breakpoint mapping by FISH using probes from subtelomeric regions 4p and 4q, probes for the WHS critical region and for 4q33. An attempt was made to correlate the cytogenetic and molecular data with the histopathological findings. We propose that a thorough work up of human aborted fetuses with WHS is an important strategy to complement data obtained from mouse knock-out models.

**Molecular cytogenetic studies in a family with a half cryptic translocation involving the Wolf-Hirschhorn syndrome critical region.** *S.K. Gogineni<sup>1</sup>, I. Wieting<sup>1</sup>, A. Shanske<sup>2</sup>, R.W. Marion<sup>2</sup>, D. Iacoboni<sup>3</sup>, S.J. Gross<sup>1</sup>, H.M. Nitowsky<sup>1</sup>, S.M. Carter<sup>1</sup>, R. Ehrenpreis<sup>1</sup>, Y. Goldberg<sup>1</sup>, P. Bobby<sup>3</sup>, V.R. Pulijaal<sup>1</sup>.* 1) Genetics Laboratory, Montefiore Medical Ctr, Bronx, NY; 2) Dept of Pediatrics, Montefiore Med Ctr, Bronx, NY; 3) Jacobi Medical Center, Bronx, NY.

The proband is the first born to a 29 yr old mother and 30 yr old father. Maternal complications during the pregnancy includes a positive triple screen and polyhydromnios, and amniocentesis revealed an apparently normal 46,XY chromosome complement. The proband was born at term with moderate hypospadias, mild dysmorphic features and undescended left testicle. High resolution chromosome studies postnatally exhibited an additional band in one of the homologues of chromosome no. 4 in the short arm at the p16.3 band - 46,XY,add(4)(p16.3), in the Wolf-Hirschhorn syndrome (WHS) critical region. Parental chromosome studies revealed that the mother has a similar add(4) chromosome, indicating in that this add(4) may represent a half cryptic balanced translocation. Fluorescence in situ hybridization (FISH) studies using a 4p16.3 locus specific probe for the WHS critical region revealed a deletion of this region in the proband. In the mother there were two signals for 4p16.3 probe, one on chromosome no. 4 and the other is on one of the homologues of chromosome no. 12 at p13.31. These findings were confirmed by whole chromosome painting probes for chromosomes number 4 and 12 which revealed that the proband has a unbalanced karyotype with monosomy for the 4p16.3@ pter region, and trisomy for the 12p13.31@ pter region, i.e. 46,XY,add(4)(p16.3).ish der(4)t(4;12)(p16.3;p13.31)mat(wcp12+,DS496-,D4S174+). The mother has a half cryptic balanced translocation, i.e. 46,XX,add(4)(p16.3).ish der(4)t(4;12)(p16.3;p13.31)(wcp12+,DS496-,DS174+;wcp4+,DS496+). Further molecular studies are in progress seeking genotype-phenotype correlations with the WHS critical region and 12p.

**Analysis of 32 supernumerary marker chromosomes derived from chromosome 15.** *K. Eggermann<sup>1</sup>, U.A. Mau<sup>2</sup>, G. Bujdoso<sup>3</sup>, E. Koltai<sup>3</sup>, T. Eggermann<sup>1</sup>, R. Raff<sup>4</sup>, R. Schubert<sup>4</sup>, G. Schwanzitz<sup>4</sup>.* 1) Institute of Human Genetics, RWTH Aachen, Aachen, Germany; 2) Dept. of Medical Genetics, University of Tuebingen, Germany; 3) Institute of Forensic Medicine, Semmelweis University Budapest, Hungary; 4) Institute of Human Genetics, University of Bonn, Germany.

Among phenotypically normal individuals supernumerary marker chromosomes (SMCs) occur at a frequency of approximately 0.72 per 1,000; in the mentally retarded their frequency may increase to up to 3.27 per 1,000. With an incidence of more than 50 per cent, derivatives of chromosome 15 (der(15)) represent the most common SMCs. The formation mechanism is usually a homologous recombination between two chromosomes 15 leading to a psu dic (15;15) or, more commonly, inv dup(15). We have analysed in detail 32 SMCs derived from chromosome 15; they were either detected pre- or postnatally using conventional cytogenetic and molecular cytogenetic procedures. The following conclusions can be drawn: The vast majority of der(15) were dicentric inv dup(15) with the second centromere being inactive and they were mitotically stable. Presence of euchromatin invariably leads to psychomotor and mental retardation (15q12 syndrome) while exclusively heterochromatic marker chromosomes may be regarded as harmless. However, we experienced a high incidence of heterochromatic der(15) in azoospermic males karyotyped prior to ICSI. In the literature, prevalence of maternal transmission of familial der(15) has been reported. Interestingly, in our cohort paternal inheritance of familial der(15) is more frequent than it would therefore have been expected. To the best of our knowledge, this is the largest number of der(15) examined so far and the results of this study may have implications for genetic counseling.

**Heterochromatic insertion and inactivation of PBGD; a novel etiology for Acute Intermittent Porphyria (AIP).**

*M.A. Fox, R.K. Iyer, Z. Jiang, P.N. Rao.* Univ California Med Ctr, Los Angeles, CA.

Acute intermittent Porphyria (AIP; OMIM 176000) is an AD disorder caused by haploinsufficiency of Porphobilinogen deaminase (PBGD). Very rarely, individuals homozygous for loss of PBGD function (usually compound heterozygotes for defective alleles) have been reported but these are usually fatal early in childhood. Over 130 different mutations have been identified in AIP. Most are single base substitutions resulting in non-conservative amino acid changes, while a smaller number cause splice site defects or premature terminations. A few frameshifting insertions or deletions have also been documented. In this report we describe a now 16-year old male with mental retardation, multiple congenital anomalies, and autism, exhibiting many symptoms suggestive of AIP (constipation, abdominal pain, rust-colored urine, anemia, mild tics and neuropathic changes), with an unusual insertion of heterochromatic material within the chromosomal band 11q23.3 [ins(11;?)(q23.3;?)], the genomic location of PBGD. Molecular cytogenetic analyses showed this material is composed of non-chromosome 11 material (WCP11-), C-band positive but, negative for common alpha-sat. centromeric sequences, and is distal to the MLL gene on 11q23.3. Chromosomal analyses of this proband and other family members revealed that the derivative 11 chromosome is maternally inherited and is also present in the maternal grandfather. However, neither showed any symptoms of AIP. Possible explanations for this include: (1) Heterochromatization of the region, adversely affecting expression of genes in the region, including several potential players in neurodevelopment and/or function; (2) Alteration of the chromatin structure may also have created/alterd local patterns of sex-specific imprinting, and may account for lack of disease in the maternal progenitors; (3) In addition to the 11q23.3 insertion the patient may also contain a deleterious mutation in the paternally inherited PBGD allele; (4) The disease in the patient is the result of a combination of both the effect of the insertion and in utero insults and/or post-natal environmental factors. Mutation analysis of the AIP gene is currently in progress.

**Paternal exposure to cyclophosphamide induces chromosomal damage and differential DNA repair gene expression in mouse zygotes and 2-cell embryos.** *L. Cosentino<sup>1</sup>, F. Marchetti<sup>1</sup>, S. Mabery<sup>1</sup>, J. Bishop<sup>2</sup>, A.J.*

*Wyrobek<sup>1</sup>*. 1) Biology and Biotechnology Research Program, Lawrence Livermore National Laboratory, Livermore, CA; 2) Experimental Carcinogenesis and Mutagenesis Branch, National Institute of Environmental Health Sciences, Research Triangle Park, NC.

The integrity of germ cell DNA is critical for the fate of the offspring, yet little is known of the DNA repair capabilities of these cells. Post-meiotic male germ cells lose the ability to repair their DNA while oocytes are equipped with DNA repair mechanisms throughout their maturation. The survival of the zygote strongly depends on maternal mRNAs and proteins stored in the egg before fertilization. The shift from maternal stored gene products to zygotic expression is poorly understood, especially for the genes involved in DNA repair pathways. Also paternally transmitted chromosomal damage may alter the expression of these genes. The purpose of our research was to determine (a) whether paternal exposure to cyclophosphamide (CP) leads to an induction of chromosomal aberrations in mouse zygotes and 2-cell embryos using PAINT/DAPI, and (b) whether fertilization with mutagenized sperm alters the expression profiles of various DNA repair genes during early mouse embryogenesis using real time TaqMan PCR. When B6C3F1 males were mated with untreated females 10 days after CP treatment (120 mg/kg) a significant increase in the incidence of chromosomal aberrations was detected in zygotes ( $36 \pm 4.1\%$ ) and 2-cell embryos ( $49 \pm 1.3\%$ ) compared to controls. Approximately a 2-fold increase in Ku80 and Rad54 transcripts were detected in zygotes fertilized by mutagenized sperm compared to controls, while no significant difference was seen in embryos. These results suggest that CP-induced chromosomal damage is associated with changes in expression of DNA repair genes. These changes appear to be restricted to the first cell cycle after fertilization, when the egg is attempting to repair sperm DNA damage. This work was conducted under the auspices of the US DOE by the University of California, LLNL under contract W-7405-ENG-48 with support from NIEHS ES09117-02 and DOE KP110202.

**A girl with inversion chromosome 7q22-q11.21: Insights into mechanisms of Williams syndrome and**

**ectrodactyly.** *T.A. Grebe<sup>1</sup>, S.R. Cox<sup>1</sup>, J.A. Hebrick<sup>2</sup>, S.W. Scherer<sup>2</sup>.* 1) Ped, Div Medical/Molec Gen, Univ Arizona, Phoenix, AZ; 2) The Hospital for Sick Children, Toronto, Ontario, Canada.

Williams syndrome (WS) and ectrodactyly, while distinct clinical entities, are both linked to chromosome 7q. WS is caused by a deletion of 7q11.23 and is associated with supravalvular aortic stenosis, typical facies, hypercalcemia, and a specific psychobehavioral profile. Ectrodactyly (split hand/split foot) is a defect in formation of the central ray, due to mutations at the SHFM1 locus on 7q21.3-22.1.

We evaluated a girl who exhibits features of both conditions. She was born at term to a G1P0 mother and was noted at birth to have ectrodactyly of the feet. Her development has been delayed and she has mild mental retardation. The diagnosis of Williams syndrome was not made until age 15 years. On examination her height, weight and head circumference are at the 50th percentile. She has thick hair, mild periorbital fullness, a stellate iris pattern, a wide mouth with full lips and a broad neck with a low posterior hairline. She has 5th digit contractures and ectrodactyly of the feet. She is extremely talkative. An echocardiogram revealed only a patent foramen ovale.

Karyotype showed a paracentric inversion of 7q: 46,XX,inv(7)(q22q11.21). FISH analysis using the ELN probe was, however, negative for a deletion at 7q11.23. Further FISH analysis has shown an inversion of WS critical region, including two flanking duplications. Possible mechanisms for the atypical WS phenotype in this patient include a disruption of a gene near the flanking region or other mutations in that area. Alternatively, the inversion of the WS region may have predisposed her to the paracentric inversion causing her complex phenotype. The ectrodactyly is likely due to a disruption of the SHFM1 locus at the translocation breakpoint.

This case provides insight into mechanisms of WS and illustrates the need to consider chromosome analysis as well as FISH analysis in syndromic patients with atypical findings.

**Inverted low copy repeats and a common 8p23 inversion polymorphism.** *N. Matsumoto*<sup>1,2</sup>, *N. Harada*<sup>1,2,3</sup>, *S. Giglio*<sup>4</sup>, *K. Kuroiwa*<sup>5</sup>, *D.H. Ledbetter*<sup>6</sup>, *N. Niikawa*<sup>1,2</sup>. 1) Human Genetics, Nagasaki Univ Sch of Med, Nagasaki, Nagasaki, Japan; 2) CREST, Japan Science and Technology Corporation, Kawaguchi, Japan; 3) Nagasaki Laboratory, Kyushu Medical Science, Nagasaki, Japan; 4) IRCCS Ospedale San Raffaele, Clinical Molecular Biology and Cytogenetics Laboratory, Milano, Italy; 5) Division of Medical Genetics, Kanagawa Children's Medical Center, Yokohama, Japan; 6) Department of Human Genetics, University of Chicago, Chicago, IL, USA.

In order to characterize a novel, submicroscopic, common inversion polymorphism on 8p23, we constructed a 7-Mb BAC/PAC-based physical map covering the entire 6-Mb inversion and its flanking regions. Low copy repeats (LCRs) with an inverted orientation were identified at both inversion breakpoints. Analysis of two patients with inverted duplication of chromosome 8 [inv dup(8)] showed that the breakpoints of their inv dup(8) were consistent with the 8p23 inversion breakpoints. FISH studies in the general Japanese population revealed that 28 of 50 normal individuals were homozygous for the normal chromosome 8, while 17 and 5 were heterozygous and homozygous for the inversion, respectively. Thus, the allele frequency for the 8p23 inversion in the Japanese was estimated to be 27 %. These findings support the previous hypothesis that the 8p23 inversion is causally related to inv dup(8) chromosomal rearrangement.

**An abnormal phenotype displayed in a proband with an inherited “balanced” t(12;16) translocation.** *L. Mehta<sup>1</sup>, A. Babu<sup>2</sup>, S. Kleyman<sup>2</sup>, S. Sastry<sup>1</sup>, M.J. Macera<sup>2</sup>.* 1) Dept. of Pediatrics, Div. of Medical Genetics, North Shore Univ. Hospital, Manhasset, NY; 2) Department of Molecular Medicine and Genetics, Wyckoff Heights Medical Center, Brooklyn, NY.

A female child was referred for genetic evaluation because of a clinical phenotype consisting of relative microcephaly (head circumference 2%), dysmorphisms consisting of frontal prominence, shallow orbits, flat nasal bridge, downturned mouth, high palate, micrognathia, 5th finger clinodactyly and significant 2/3 toe syndactyly. She had a right multicystic kidney and recurrent left knee dislocation with left hip dysplasia. There were mild fine and gross motor delays with no cognitive issues at age 6 years. The child was known to carry a maternal balanced reciprocal translocation 46,XX, t(12;16)(q22;q22.1). The mother was phenotypically normal with both parents having normal head sizes. High resolution GTG banding was performed on chromosomes from both the mother and proband to determine if any material was missing from the child's chromosomes. No apparent loss of material was detected by cytogenetic analysis. The breakpoint on chromosome 16 at q22.1, is a known fragile site. Wenger et al [1995], have reported six cases where abnormal offspring were determined to have inherited apparently "balanced" translocations from normal carrier parents. The breakpoints in these cases were coincident with chromosomal fragile sites. An association has been implied between chromosomal breakpoints and fragile sites, suggesting predisposition of these fragile sites to breakage and unequal cross over. The products of the unequal crossing over could be submicroscopic deletions and duplications. Thus, an apparently "balanced" inherited translocation may be associated with clinical abnormalities. These cases raise a counseling issue in terms of predictive risk/reassurance when dealing with a pregnancy involving a familial balanced translocation. Additional studies are needed to elucidate whether the breakpoints coincident with known fragile sites have a different risk factor when compared to other translocations.

**Interstitial microdeletion of 21q.** *K.M. May, N. Longo.* Emory University School of Medicine, Department of Pediatrics, Division of Medical Genetics, Atlanta, GA.

Partial monosomy for 21q22 has been associated with microcephaly, IUGR, mental retardation, congenital heart disease, hypertonia, short stature and dysmorphic facial features. There is evidence that deletion within the 21q22.2 band may specifically be responsible for microcephaly and IUGR. We present a child who was evaluated at 20 months of age for microcephaly (head circumference (HC) appropriate for 5 month old), short stature (appropriate for 11 month old), developmental delay and febrile seizures. He was the product of a full term pregnancy with a birth weight of 3.75 kg (75th centile). He had coarse facial features with hirsutism, low set and posteriorly rotated ears, thick lips, widely spaced teeth, high arched palate, micrognathia, and hypotonia alternated to hypertonia. Chromosome analysis at 700 bands was interpreted as normal. At repeat evaluation at 4 years he was non-verbal, his height and weight were appropriate for a 2 year old child, and his HC was appropriate for a 10 month old. Subtelomeric FISH analysis with the Vysis, Inc. ToTelVysion probe panel was performed. All subtelomeric probes showed a normal pattern; however, one 21 was missing a signal for the AML1 control probe in 21q22.2. A second hybridization with the Vysis, Inc. LSI21 probe, specific for loci D21S259, D21S341 and D21S342, showed a normal hybridization pattern. These loci are mapped to band 21q22.2, distal to the AML1 locus. Repeat chromosome analysis at 850 bands revealed a subtle change in the size of band q22.2 on one chromosome 21. Data from FISH analysis confirms the distal breakpoint within q22.2. The proximal break could be within q22.13 or in q22.2 on the basis of chromosome analysis. Parental FISH studies were normal. The patient's phenotype supports the theory that a gene or genes responsible for microcephaly reside in 21q22.2. This is, to our knowledge, the smallest reported interstitial deletion of 21q22, and the fact that the child had a normal birth weight followed by postnatal growth retardation may indicate that his proximal breakpoint lies outside of the region responsible for IUGR.

**Screening for cryptic chromosomal abnormalities using telomere FISH probes** . *B.J. Hulley, M. Hummel, S.L. Wenger.* West Virginia University School of Medicine, Morgantown, WV.

Mental retardation is present in 2-3% of the general population. Chromosomal abnormalities may be detected in up to 35% of patients with mental retardation, depending on patient selection and laboratory techniques. Deletions of 2-3 megabases and larger are usually microscopically visible. Smaller deletions, duplications, or rearrangements have been identified in 7% of individuals with idiopathic mental retardation using telomere probes. Some subtle subtelomeric deletions such as 1pter, 1qter, and 22qter are each associated with a specific phenotype including mental retardation. To date 15 blood samples for patients with mental retardation and facial dysmorphism have been collected and analyzed by G-banded karyotypes and telomere FISH. Of these samples, one was sent out for additional molecular testing and was diagnosed with a single gene defect, and two were found to have chromosomal abnormalities: dup(16)(p11.1 p11.2) de novo and del(17)(p11.2 p11.2). All others were apparently normal by karyotype. The three samples were not included in the idiopathic mental retardation group since the cause for mental retardation and dysmorphism was determined. Therefore, out of the remaining twelve cases, two samples were found to have a subtle telomere abnormality: del(1)(p36.3) and der(1)t(1;8)(p36.3; p23). This resulted in 2/12 or 16.7% of idiopathic mental retardation patients having a subtle telomere deletion or rearrangement. Our results suggest that these patients should be routinely evaluated for subtle chromosomal rearrangements using FISH telomere probes. Also, further studies may identify common telomere regions involved in abnormal cases and may lead to clinical phenotype correlation for the characterization of subtle chromosomal syndromes.

**Mosaicism for two de novo supernumerary markers derived from chromosomes 18 and 13.** *K.N. Nandi<sup>1</sup>, M.T. McDonald<sup>2</sup>, K.K. Rogers<sup>1</sup>, K.W. Rao<sup>1</sup>.* 1) Departments of Pediatrics & Pathology, UNC Hospitals; Chapel Hill, NC; 2) Division of Medical Genetics, Duke University Medical Center; Durham, NC.

We present a 4y4m old female with developmental delay and dysmorphic features who showed mosaicism for two different de novo markers originating from chromosomes 18 and 13, respectively. She was born at term (bw: 6lb 1oz) to a 30y G3 mother following an uncomplicated pregnancy; there were no major neonatal problems. She exhibited slight delay in motor development and more marked delay in speech and language development; at age 4yr, she only had a few single words. Her brain MRI, renal US scan, EEG and hearing tests were normal. She appeared to be a healthy child with average height, weight and head circumference. She had a medial flare to the eyebrows, synophrys, long eyelashes, full cheeks, hyperconvex fingernails, bilateral 5th finger clinodactyly, a large space between the first and second toes, a medially deviated second toe, deep plantar creases between the first and second toe, and prominent calcaneus. Chromosome analysis of blood revealed a mosaic karyotype with two supernumerary markers. The markers appeared to be differently sized ring-chromosomes. The larger marker was about half the size of a G-group chromosome, while the smaller marker was about half the size of the larger marker. Of the 50 metaphase cells studied, 27 had one ring, 16 contained two rings, and the remaining 7 cells were normal. C-banding suggested that both markers contained euchromatic and centromeric material. Cytocell's Multiprobe whole chromosome paint FISH assay showed that the large and small marker were derived from chromosomes 18 and 13 respectively. Whole chromosome paints from Oncor confirmed the chromosomal origin of both markers. The larger marker contained both 18p and 18q material as shown by 18p and 18q partial paint FISH probes from American Laboratory Technologies. This patient is therefore mosaic for partial trisomy 18 and partial trisomy 13. We are aware of only one similar case (Plattner et al., 1993). The patient had two supernumerary markers derived from 18 and 13/21 and multiple congenital abnormalities including cardiac, skeletal, and genital-urinary malformations.

**Trisomy for the 16p telomere: genotype/phenotype correlations.** *C.M. Lese, J.F. Hedrick, J.A. Roseberry, A. Wong, S. Uhrig, D.H. Ledbetter, D. Waggoner.* Univ. of Chicago, Dept. of Human Genetics, Chicago, IL.

It has become increasingly evident that a significant proportion of individuals with idiopathic congenital malformations and mental retardation have subtle rearrangements involving the telomeres of human chromosomes. During the course of genome-wide telomere screening in patients with unexplained mental retardation and normal karyotypes, we identified three cases where the telomere rearrangement resulted in trisomy for the 16p telomere. One case involved an unbalanced translocation between the telomeres of chromosome 7p and 16p while the other two unrelated cases had unbalanced translocations involving the 10q and 16p telomeres. In all three cases, only 16p trisomy was observed; the breakpoint on the second chromosome occurred distal to the telomere probe and did not result in any detectable corresponding monosomy. A fourth case, an unbalanced translocation between 16p and 17p, resulting in trisomy 16p and monosomy 17p, was previously reported by our group. Clinical features common to these four patients include: mental and growth retardation, brain malformations, heart defects, cleft palate, pancreatic insufficiency, genitourinary abnormalities and similar dysmorphic features. The clinical diagnoses of Toriello-Carey and Johanson-Blizzard syndromes were considered in two of the cases, demonstrating that the features of trisomy 16p overlap with other conditions. To compare the extent of trisomy and determine genotype/phenotype correlations for these four cases, we developed a molecular ruler for 16p consisting of BAC/PAC clones spaced at ~1 Mb intervals for use in a FISH assay. The size of the trisomic segment ranged from ~4 Mb to ~10 Mb and correlated with the phenotypic severity. Interestingly, the breakpoint of the two 10q;16p translocations was contained within the same BAC clone, suggesting a common mechanism for their origin. The identification and characterization of such cryptic translocations is important for accurate genetic counseling and recurrence risk assessment. In addition, fine mapping to examine genotype/phenotype correlations can help not only to predict clinical outcomes, but also to identify the genes contributing to the phenotype.

**Use of single-sperm typing to determine the relationship between recombination in the pseudoautosomal region and paternal age.** *R.H. Martin*<sup>1,2</sup>, *Q. Shi*<sup>1,2</sup>, *E. Spriggs*<sup>3</sup>, *A.W. Rademaker*<sup>4</sup>. 1) Medical Genetics Clinic, Alberta Children's Hospital, Calgary, Alberta, Canada; 2) Department of Medical Genetics, University of Calgary, AB, Canada; 3) Department of Clinical Chemistry, Health Sciences Centre, Winnipeg, MB, Canada; 4) Cancer Center Biometry Section, Northwestern University, Chicago, IL.

Recombination between the X and Y chromosome is limited to the pseudoautosomal region and is necessary for proper segregation of the sex chromosomes during spermatogenesis. Failure of the sex chromosomes to disjoin properly during meiosis can result in individuals with a 47,XXY constitution and approximately one-half of these result from paternal nondisjunction at meiosis I. Analysis of these paternally-derived 47,XXY cases have shown that the majority of these males are the result of meiosis wherein the X and Y chromosomes have failed to recombine. Our studies in sperm have demonstrated that aneuploid 24,XY sperm have a decreased recombination frequency compared to normal sperm. Some studies have indicated a relationship between increased paternal age with 47,XXY offspring and with the production of XY disomic sperm, whereas others have failed to find such relationships. To determine if there is a relationship between paternal age and recombination in the pseudoautosomal region, single-sperm typing was performed to measure the frequency of recombination between a sex-specific locus, STS/STS pseudogene, and a pseudoautosomal locus, DXYS15, in young men (<30 yr.) compared to older men (>50 yr.). A total of 1599 sperm were typed by single-sperm PCR analysis in 13 men heterozygous for the DXYS15 locus: 708 sperm from 7 young men and 891 sperm from 6 older men. The mean recombination frequency was 38.7% (SE .00865) in the young men and 37.3% (SE .00738) in the older men. The recombination rates were homogeneous in both groups ( $p > .8$ , chi square test). There was no significant difference in the recombination frequencies in young men compared to older men ( $p = .21$ , two-tailed Z test, adjusting for within person clustering of data), suggesting that there is no effect of paternal age on the recombination frequency in the pseudoautosomal region.

**Ring 21 complex mosaicism: clinical and cytogenetic phenotype.** *J. Kreutzman, L. Dong, R.E. Falk.* Med Gen/Birth Defects Ctr, Cedars-Sinai Medical Center, Los Angeles, CA.

MZ was a 2386 gm, 46 cm, 31 cm OFC product of a 38 week gestation to a healthy 30 year old woman and her unrelated 32 year old partner. Prenatal ultrasound suggested IUGR and intracranial cyst. Delivery was by C-section for failure to progress. He had hypoglycemia, apnea with feeding, and GE reflux requiring medical treatment. MRI of the brain revealed a thin corpus callosum and arachnoid cyst. Ophthalmologic evaluation noted foveal hypoplasia OU. Cytogenetic analysis revealed a complex karyotype: 46,XY,r(21)(p10q22[21]/46,XY,del(21)(q21~22)[cp16]/45,XY,-21[6]/46,XY,r(21)(p10q22p10q22[4]. Hence, he had a cell line with ring chromosome 21, cells in which the ring opened at various breakpoints resulting in different 21q deletions, cells with monosomy 21, and cells with a double ring producing trisomy for most of 21q. At age 3 months, his height of 54 cm and weight of 4.3 Kg were 3 SD below the mean, and OFC of 36.5 cm was 4 SD below the mean. He had microcephaly, prominent forehead, bitemporal narrowing and an occipital shelf. Eyes were deep set with downslanted palpebral fissures and long lashes. Ears were asymmetric and mildly dysmorphic. Nose was short with broad bridge, prominent tip and anteverted nares. He had a long philtrum, normal oral exam and retrognathia. The neck, thorax, heart, lungs, abdomen and genitalia were unremarkable. He had lateral elbow dimples, and clinodactyly V. Skin demonstrated cutis marmorata. Neurologic exam revealed moderate, generalized hypertonia, mild developmental delay, and no focal findings or seizures. Developmental assessment at age 12 months revealed cognitive function at 8.5-10 months, language at 5.5-7 months, motor and social skills at 7-8.5 months. Evaluation at 15 months of age revealed length >3 SD below the mean and severe microcephaly. Facial dysmorphism was unchanged except for obvious asymmetry. The hypertonia had improved. He had chronic otitis media requiring middle ear ventilation but no other surgery or hospitalization. Vision and hearing were clinically normal. Detailed cytogenetic characterization and clinical features of this child will be reviewed and compared to those in published cases of r(21).

**Delineation of a BAC contig in chromosome 11p15.5 and detection of a microduplication associated with Beckwith-Wiedemann syndrome.** *L. Jeng, L. Christ, M. Eichenmiller, S. Schwartz.* CWRU and Univ Hosps of Cleveland, Cleveland, OH.

Beckwith-Wiedemann syndrome (BWS) is a congenital disorder, which has been localized to 11p15.5. Patients may present with the classical triad of abdominal wall defect (eg. omphalocele), macroglossia and overgrowth, but in other cases, part of the triad, hypoglycemia and/or Wilms tumor are present. BWS is genetically heterogeneous, but in many cases the etiology is not known. A chromosomal abnormality is estimated to be present in only 2-3% of BWS cases. The most common chromosomal abnormality in BWS is a duplication of the distal short arm of chromosome 11, but only about 20 cases have been described in the literature. Over the past several years, we have used high-resolution chromosome analysis to study 15 referrals with a clinical diagnosis of BWS. Two of these cases were detected to have a de novo chromosome abnormality; one had a duplication of the entire short arm of chromosome 11, and the other had a very subtle duplication of part of 11p15.5. Both cases had features consistent with BWS.

In the second case, cytogenetic analysis allowed only a tentative diagnosis. Therefore, a BAC/STS map was constructed around the putative duplication using 38 BACs and 11 STSs. BACs from this newly constructed map were then used to study the region in question, and the presence of a subtle duplication was confirmed. These studies not only confirmed the duplication, but demonstrated that it was an inverted tandem duplication with an estimated size of only 2-3 Mb. The results of these studies are important in that: (1) we have constructed a BAC contig around the BWS critical region; (2) the duplication we identified in our case involved only a 2-3 Mb region, the smallest reported in BWS; (3) given the identification of such a small duplication, the number of cytogenetic abnormalities in BWS is likely under ascertained; (4) subtle duplications may be present in patients who were previously classified as having a normal karyotype; and (5) the BACs identified in this study can be utilized to delineate similar microduplications in other patients in order to determine if a higher proportion of cases actually have a chromosomal abnormality.

**A male child with a 46,idic(Y)(q11.2)/45X mosaicism and autistic disorder.** *B. Niederer*<sup>1</sup>, *S. Kleyman*<sup>2</sup>, *A. Babu*<sup>2</sup>, *M.J. Macera*<sup>2</sup>. 1) Queens-Long Island Medical Group, P.C., Ronkonkoma, NY; 2) Department of Molecular Medicine and Genetics, Wyckoff Heights Medical Center, Brooklyn, NY.

The etiologies of autism and the related pervasive developmental disorder (PDD) are unknown, however, the contribution of complex genetic factors are strongly implicated. Involvement of chromosomes 4, 7, 10, 16, 19, 22 and the X with these disorders has been reported. [Vincent et al, 2000, Gillberg 1998] There is also growing evidence for an association with autism, PDD and individuals possessing the 47,XYY karyotype. The additional Y may contribute to abnormal brain development, possibly predisposing these children to learning disorders [Nicolson et. al., 1998]. The isodicentric(Y), may be the genetic equivalent to two Y chromosomes. Blackman et al. [1991] did report a case of autism in a child with an 46,X,idic(Y). An 8 1/2 year old boy was referred for genetic evaluation because of developmental delay with autistic features. He was the product of a normal pregnancy, born at term, to a 33 year old mother and 36 year old father. His infancy and early childhood were unremarkable. His motor milestones were normal. He grew at the 5th percentile for height and weight until age 2 years. From that time, his height remained at the 5th percentile, but his weight increased until at age 6, it reached the 95th percentile. His physical examination was within normal limits and he had normal male genitalia with normal testes. By age 5, he exhibited aggressive behavior and poor attention span and was determined to have markedly delayed speech. At age 7, he was placed in a program for autistic children and has done well. Chromosomal evaluation with GTG banding identified a 46,X,Ynf[95]/45,X[5] mosaicism in his peripheral blood lymphocytes. Molecular analysis with probes specific for the SRY gene, Y centromere and Y satellite I DNA (Vysis Inc.) using the FISH technique, revealed a 46,X,idic(Y)(q11.2).ish Y(SRY++, DYZ3++, DYZ1-)/45,X karyotype. The father had a normal Y chromosome [46,XY.ish Y(SRY+, DYZ3+, DYZ1+)]. It is believed that this proband is the first reported case of mosaic 46,X,idic(Y)/45,X with autism. Additional data may elucidate the role of the idic(Y) chromosome in autism.

**Unstable centromeric fission products of a balanced Robertsonian translocation in a markedly discordant twin.**

*R.V. Lebo<sup>1</sup>, H.E. Wyandt<sup>1</sup>, P.E. Warburton<sup>2</sup>, S. Li<sup>2</sup>, J.M. Milunsky<sup>1</sup>.* 1) Ctr Human Genetics, Boston Univ Sch Medicine, Boston, MA; 2) Department of Human Genetics, Mount Sinai School of Medicine, New York, NY.

Mitotic fission of a dicentric Robertsonian chromosome resulted in an unstable chromosome complement that gave rise to mosaic cells of decreased viability and decreased fetal growth. A woman from southern India conceived twins by intrauterine injection of sperm from a southern Indian donor because her husband is azoospermic. Amniocytes sampled at 16 weeks and again at 18 weeks found Twin A had a normal 46,XX karyotype. Twin B had a 45,XY,dic(13;14)(p11.1;p11.1)[106/128]de novo karyotype in a majority of cells. Centromeric fission of this dicentric chromosome in a progenitor cell and nondisjunction of the unstable derivative chromosomes resulted in cells trisomic for 14q and monosomic for 13q or 14q:mos46,XY,-13,+fis(13)(p11.1),-14,+fis(14)(p11.1)[14/128]/45,XY,-13,-14,+fis(14)(p11.1)[4/128]/45,XY,-13,+fis(13)(p11.1),-14[3/128]/47,XY,-13,+fis(13)(p11.1),-14,+fis(14)(p11.1),+fis(14)(p11.1)[1/128]. Centromeric antibody studies distinguished two active centromeres in 13 dic(13;14) chromosomes and one active centromere in 6. Uniparental disomy for chromosomes 13 or 14 was ruled out in both twins and both had a normal targeted ultrasound. Given the uniqueness of these findings the couple was advised of the uncertain but real risk of abnormality in Twin B, and the risk of selective reduction to Twin A. Considering these risks and options, the couple elected to continue carrying both fetuses. At 32 weeks gestation the mother delivered Twin A who weighed 3 lbs 0 oz and Twin B who weighed 2 lbs 0 oz. No other abnormalities were noted. Term cord blood analysis revealed a 46,XX karyotype in Twin A and a 45,XY,dic(13;14) karyotype in all cells of Twin B. Twin discordance in this study can be explained by the de novo translocation prior to fertilization to produce dic(13;14) in twin B followed by centric fission in an early mitotic progenitor cell and loss of cells with unstable chromosomes. This case illustrates that an unstable chromosome complement may result in discordant fetal growth.

**Case report of a male fetus 46,XY,add(22)(p11.2).ish i(22)(q10)[9]/ish dup(22)(q12q13)[37].** *R. Hassan*<sup>1</sup>, *N. Qin*<sup>2</sup>, *C. Guze*<sup>1,3</sup>, *D. Baker*<sup>3</sup>. 1) Dept of OB/GYN, Genetics Unit, King Drew Medical Center, Los Angeles, CA; 2) Quest Diagnostics at Nichols Institute, San Juan Capistrano, CA; 3) CSU Dominguez Hills, Carson, CA.

A 15-year-old female, G1 P0 Ab0 was referred for amniocentesis counseling because of an abnormal ultrasound at 18 weeks gestation. The ultrasound showed an echogenic bowel, irregular heart beat and a left club foot. The family history revealed that the mother of the fetus also had a left club foot that had been repaired. TORCH titers were negative. CF mutation testing on the mother gave her a carrier risk of 1/198. A fetal echocardiogram done at 21 weeks was normal, no fetal arrhythmia was noted. Amniocentesis was performed at 21 3/7 weeks. The AF-AFP was 0.33 MoM. Cytogenetic analysis found additional genetic material of unknown origin attached to the short arm of one chromosome 22. FISH study using whole chromosome 22 painting probe identified the extra material as chromosome 22 in origin. Subsequent FISH studies using the TUPLE1 probe mapping to the DiGeorge syndrome region (22q11.2) with the ARSA control probe mapping to 22q13 revealed an abnormal mosaic karyotype with two cell lines. Among 46 metaphases examined, 9 (20%) had an isochromosome for the long arm of chromosome 22: i(22)(q10)[9]; the remaining 37 metaphases (80%) showed a duplication of a segment distal to the q11.2 region [dup(22)(q12q13)]. Therefore, the resulting net imbalance is trisomy for the long arm of chromosome 22 (20%) and trisomy for the segment distal to 22q11.2 (80%). Chromosome analysis of the mother of the fetus showed a normal 46,XX karyotype. The father of the fetus is phenotypically normal. However, no chromosome study on him is available at this time. The mother chose to continue the pregnancy. Repeat ultrasound at 25 4/7 weeks revealed polyhydramnios. Follow up ultrasounds are scheduled.

**Report of 6 cases of trisomy 10p resulting from parental pericentric inversion (10).** *R.R. Karimi-Nejad, H. Karimi, H. Miri, N. Nabavi-nia, M. Rahimi, K. Shirneshan, M.H. Karimi-Nejad.* Karimi Nejad Path & Genetics Center 1143 Shahrak Gharb Medical Bldg Shahrak Gharb, Tehran 14667 Iran.

During the past 20 years and among more than 25000 peripheral blood karyotypes, we have detected 6 cases of add(10)(q25). All of these cases were referred between 1-12 months of age with multiple congenital anomalies including: severe growth retardation, congenital dislocation of the hip, bilateral club feet, high bossing forehead, narrow face with sagging cheeks, broad nasal bridge, harelip or cleft palate, small round chin, large posteriorly rotated low set ears, hyperflexed limbs, hypoplastic genitalia and severe hypotonia. One of the families did not participate in the study. In 5 of the cases, their parents' karyotypes were studied and 3 of the fathers and 2 of the mothers had a pericentric inversion in chromosome 10. The inversion involves the short and the long arm with breakpoints at p11 and q25, resulting in a long acrocentric chromosome 10. This identified the karyotype of the children as rec(10)dup(10p)inv(10)(p11q25). Prenatal diagnosis has been performed for two of the families, revealing a normal fetus in one and a trisomy 10p in the other.

**Cytogenetic and molecular characterization in a Turner patient with a complex Y chromosome mosaicism.** S.

*Majore<sup>1</sup>, M. Poscente<sup>1</sup>, B. Boscherini<sup>2</sup>, R. Rinaldi<sup>3</sup>, F. Binni<sup>1</sup>, P. Grammatico<sup>1</sup>.* 1) Medical Genetics, Univ. of Rome "La Sapienza", Italy; 2) Pediatric Clinic, University of Tor Vergata, Rome, Italy; 3) Medical Genetic Service, S. Camillo-Forlanini Hospital, Rome, Italy.

The phenotypic spectrum of mosaic individuals with 45,X/46,XY or 46,X,der(Y)karyotype varies from females with Turner syndrome through intersex conditions to almost normal males. Clinical expression, is believed to be dependent on the level of mosaicism in gonadal tissues but this correlation has not been confirmed in all reported cases. Recently, a missense mutation in the 5 non HMG box region of the SRY gene has been described in two patients with Turner syndrome and Y or der(Y) mosaicism (Canto et al., 2000). It has been proposed that such kind of mutations, associated with the predominance of the 45,X cell line in the embrional gonad, is able to prevent the development of any testicular tissue in at least a number of Turner syndrome patients with 45,X/46,XY or der(Y) mosaicism. We describe a patient with Turner syndrome and a complex sex chromosomes mosaic karyotype, in which we performed cytogenetics and molecular studies of the SRY gene. The girl was referred for genetic evaluation at age 9 years because of her short stature. Her height was cm 114 (under 3rd percentile) while her weight Kg 23 (3rd-10th percentile). Hypertrichosis and areas of hyperpigmentation were present on her back and limbs; her external genitalia were female. Cardiac auscultation showed a 2/6 midsystolic murmur. Pelvic ultrasound demonstrated a hypoplastic uterus and a right gonad recognizable with difficulty, while the left gonad was not evident. Cytogenetics analysis on peripheral blood lymphocytes showed the presence of a mosaic karyotype with 4 different cell lines: 45,X[42]/ 46,X,der(Yq)[32]/46,X,idic(Yp)(q11.23)[24]/47,X,idic(Yp)(q11.23),idic(Yp)(q11.23)[2]. FISH analysis was carried out using DYZ3 Oncor probe, 884b7, 913b1, 908e8 YAC probes and PHU (SRY) BAC probe. Sequencing of the whole coding region of SRY gene didn't reveal any mutation suggesting that SRY gene mutations are not always involved in determining of female phenotype in individuals carrying Y chromosome mosaicism.

**Prenatal diagnosis of a small supernumerary, mosaic XIST-negative, ring X chromosome identified by fluorescence in situ hybridization in an abnormal male fetus.** C. LE CAIGNEC<sup>1</sup>, M. BOCENO<sup>1</sup>, M. JOUBERT<sup>2</sup>, N. WINER<sup>3</sup>, F. AUBRON<sup>4</sup>, J.M. RIVAL<sup>1</sup>. 1) SERVICE DE GENETIQUE, CHU, NANTES, FRANCE; 2) LABORATOIRE D'ANATOMIE PATHOLOGIQUE, CHU, NANTES, FRANCE; 3) SERVICE DE GYNECO-OBSTETRIQUE, CHU, NANTES, FRANCE; 4) CENTRE D'ECHOGRAPHIE DE L'ILE GLORINETTE, NANTES, FRANCE.

Abnormal chromosomes whose origin cannot be unequivocally established are called marker chromosomes. Marker or ring X [r(X)] chromosomes of varying size have been found in 5% of Turner syndrome patients. The phenotype of these patients was variable : some had the typical turner syndrome phenotype, while others had a more severe phenotype including mental retardation, and other abnormalities. The more severe phenotype was usually associated with very small r(X) chromosomes which did not include the X-inactivation (XIST) locus. Presumably, the abnormal phenotype was due to functional disomy for the duplicated X chromosome regions. Small r(X) chromosomes are rare in males and there are only five previous reports of such cases. We report the identification of a small supernumerary chromosome in an abnormal male fetus. A 28-year-old woman, gravida 1 presented for first-trimester chorionic villus sampling because of fetal nuchal translucency thickness (4 mm) at 12 weeks gestation. RTG-banding study showed a karyotype 46,XY[4]/47,XY,+r(X)[10]/48,XY,+r(X),+r(X)[6]. FISH with a probe specific for the X centromere (DXZ1 probe) showed the marker to be of X chromosome origin. Subsequent FISH analysis with an XIST locus probe (Oncor) was negative, indicating that the XIST locus was not present in the ring X chromosome. Parental karyotypes from lymphocyte cultures were normal. A second ultrasound examination was performed at 20 weeks gestation and revealed a Dandy-Walker malformation, an agenesis of corpus callosum and septum pellucidum and a hypoplasia of vermis. After genetic counselling, the family decided to have the pregnancy terminated. Autopsy confirmed brain malformations. To our knowledge, we report the first prenatal diagnosis of a small supernumerary, mosaic XIST-negative, ring X chromosome in an abnormal male fetus.

**A targeted ablation of the Mlh3 locus.** *S.M. LIPKIN<sup>1</sup>, V. WANG<sup>2</sup>, D. SHANMUGARAJAH<sup>2</sup>, J. CHENG<sup>2</sup>, E. PAM<sup>2</sup>, J. THOMAS<sup>2</sup>, E. GREEN<sup>2</sup>, J. TOUCHMAN<sup>2</sup>, F. COLLINS<sup>2</sup>, P. COHEN<sup>3</sup>.* 1) Dept of Medicine, UC IRVINE, IRVINE, CA; 2) NHGRI/NIH, BETHESDA, MD; 3) ALBERT EINSTEIN COLLEGE OF MEDICINE, BRONX, NY.

DNA mismatch repair is of considerable scientific and medical importance because of its essential role in maintaining genomic integrity during meiosis and mitosis, and its association with Hereditary Non-Polyposis Colon Cancer. Our laboratory recently cloned MLH3, the 9th mammalian DNA mismatch repair gene, and demonstrated the existence of somatic mutations in MSI+ colon cancers. In order to understand the biological roles of MLH3, we have sequenced the Mlh3 locus from the C57BL/6 mouse strain, and compared and annotated the genomic organization of this sequence with reference to the finished MLH3 locus sequence. We have used this sequence to create a targeted ablation of Mlh3 in the mouse. Provocatively, both Mlh3 male and female deficient mice are infertile, and demonstrate severe defects in meiosis prophase I, including aneuploidy and a meiotic arrest phenotype in male germ cells that is distinguishable histologically from that observed in other DNA mismatch repair gene targeted ablation studies. These results suggest Mlh3 plays a unique role in mammalian meiosis that cannot be compensated for by other MutL homologues.

**Three Way Translocation confirmed by M-FISH in a Couple with Reproductive Loss.** *N.B. Kardon, T.M. Dunn, K. Hirschhorn, B. Levy.* Human Genetics and Pediatrics, Mount Sinai School of Medicine, New York, NY.

A 28yr old G 0020 presented with a history of two early spontaneous abortions. Her husband was 32 years old. They were referred for chromosome analysis by their obstetrician as part of a routine workup for reproductive loss. Family history was unremarkable. There were no other instances of reproductive loss. Medical history was unremarkable except for a recent diagnosis of cavernous angiomas in the husband. Routine chromosome analysis was performed and revealed a normal 46,XX karyotype in the patient. Her husband presented with a three way translocation described as 46,XY,t(1;4;7)(p35;q32.1;p14). The initial analysis was obtained using G-banded chromosomes and molecular cytogenetic techniques were utilized to confirm the origins of the chromosomes involved in the 3-way translocation. Whole chromosome paints and M-FISH revealed that material from the long arms of chromosome 4 had moved to the short arms of chromosome 1; material from the short arms of chromosome 7 had translocated to the long arms of chromosome 4; and material from the short arms of chromosome 1 was located on the short arms of chromosome 7. During gametogenesis, there are 20 possible combinations of these three chromosomes when considering 3:1 segregation and only 2 of these would be expected to be viable. The first viable combination would comprise chromosomes that are not involved in the translocation and the second would contain the same balanced rearrangement as the father. The predicted risk for an unbalanced offspring would be 90%. However, when the adjacent-1 and adjacent-2 meiotic errors are included, the possibility of having an unbalanced offspring is theoretically closer to 99%. It is common practice to refer patients with more than two spontaneous abortions for chromosome analysis. The yield of finding a chromosome translocation is low by routine cytogenetic techniques, however this case demonstrates the importance of pursuing this line of investigation. With the availability of molecular cytogenetic techniques, it is now possible to identify even more subtle rearrangements that could have the same adverse implications for reproduction.

**Learning difficulties, minor dysmorphic features and interstitial telomeric sequences in a boy with 45,XY and a 5;22 translocation.** A. Krueger, R. Reichl, P. Stankiewicz, I. Hansmann. Institut fuer Humangenetik und Medizinische Biologie, Halle/Saale, Germany.

We report on a 10-year-old boy who was referred for cytogenetic analysis because of moderate learning difficulties, speech problems and attention deficits. As the only dysmorphic features a bulbous nose, low set ears, short philtrum and a short stature (10th percentile) was present. Chromosome analysis of cultured lymphocytes revealed a karyotype of 45,XY,-22 with additional chromosome material on the long arm of chromosome 5 in all metaphases. The karyotype of both parents was normal with 46,XX and 46,XY, respectively. Microscopically there was no evidence for loss of chromosome 5q bands. A chromosome 5 paint labeled the normal 5 and the der(5) with the exception of a distal segment at 5q. A chromosome 22 paint labeled this distal der(5) segment in addition to the normal chromosome 22, indicating a translocation between chromosome 5q and 22q. For narrowing down the translocation breakpoint FISH using probes for the DGS1 locus at 22q11.2 (D22S75) and the control locus (D22S39) was performed. Analysis revealed no signal for the DGSCR at 22q11.2 but signal for the control locus D22S39 at 22q13.3, indicating deletion of the DGSCR. FISH using the all human telomere probe (Oncor) surprisingly identified two sites on the long arm of der(5) chromosome: one at the distal end representing the telomere of chromosome 22q and one interstitial site at a position compatible with the original telomere of the regular chromosome 5q. It is concluded that the mild phenotype associated with the translocation is due to hemizyosity of the DGSCR at 22q11.2. Interstitial telomeric repeats are only rarely observed in the human karyotype. Occasionally they are detected in neoplasia and there in association with jumping translocations. We do not have evidence for instability of the translocation chromosome in cells of our propositus. This could mean that jumping translocations or translocation instability might not be directly related to the existence of interstitial telomeric sites. (P.S. has been supported by DAAD).

**Risk Assessment of Prenatal Double Supernumerary Ring(9) Chromosomes.** *P.N. Mowrey<sup>1</sup>, B. Williford<sup>1</sup>, S. Kratzer<sup>1</sup>, J.H. Tepperberg<sup>1</sup>, I.K. Gadi<sup>1</sup>, K.K. Phillips<sup>1</sup>, J. Canterino<sup>2</sup>, R. Neal<sup>2</sup>, T. Dalaya<sup>2</sup>, P.R. Papenhausen<sup>1</sup>.* 1) Diagnostic Genetics, Laboratory Corp of America, Res Triangle Pk, NC; 2) Jersey Shore Perinatal Institute, Neptune, NJ.

Supernumerary marker chromosomes range in size from tiny dot-like structures to large inverted duplications to complete telomere-telomere rings. Occurrence is ~1/1000 prenatal studies (Hook and Cross, 1987), of which 40% are familial with a typically normal outcome. Approximately 13% of the de novo cases present with an abnormal phenotype (Warburton, 1991). We report a 34 y.o. female referred for AMA, with an obstetric history significant for a previous 35 wk cesarean delivery for oligohydramnios and breech presentation. Ultrasound findings at 17 wks gestation identified a complete placenta previa, but no fetal anomalies were noted. Heart, face and genitalia were not well visualized. Prenatal chromosome analysis revealed the presence of two small supernumerary marker chromosomes in all colonies. Both markers were shown to be completely C-band positive and derived from the chromosome 9. FISH was 1/3 positive for the pericentromeric and 2/3 positive for the heterochromatic regions. There was no hybridization with WCP9, implying absence of euchromatin. The karyotype was 46,XY,ish r(9)x2(D9Z3+, D9Z5+, WCP9-). Maternal chromosome analysis identified a single marker chromosome in 65% of the metaphases analyzed that appeared similar to the small marker chromosome observed in the fetus. UPD studies confirmed biparental inheritance of the normal chromosome 9 homologues. Markers of this type are usually considered not to be clinically significant when inherited from a clinically normal parental carrier. However, this conclusion must be tempered by both the possibility of increased dosage effects from two markers and the non-mosaicism in the fetus. Although this fetus carried about 3X the maternal extra dosage of this material, the risk of congenital anomalies would appear to be low based on the apparent heterochromatic derivation of the marker chromosome. Sparse case reports also support an apparent tendency for chromosome 9 and 16 derived rings to be composed of benign alpha and classical satellite DNA.

**Common chromosomal anomalies detected in mouse embryonic stem cell (ES) cell lines.** *S. Li, F. Bates, J.J. Mulvihill.* Dept Pediatrics, Univ Oklahoma Hlth Sci Ctr, Oklahoma City, OK.

The ability to obtain a germ line is one of the most important steps in the process of developing a transgenic or knockout mouse with the targeted mutated gene of interest. A common problem with this technology is that the ES cells often lack or have a low efficiency of germ line transmission. To find out whether chromosomal anomalies are correlated with a low efficiency of ES cell germ line transmission, we examined 56 ES cell lines with different constructs at different cell passages using conventional cytogenetics analysis as well as fluorescence in situ hybridization (FISH). Chromosomal abnormalities occurred in 31(55%)specimens: 20 had trisomy 8 or mosaic trisomy 8, 8 had partial trisomy 8 resulting from unbalanced translocations, and 3 had other chromosomal anomalies (trisomy 12, translocation between chromosomes 6 and 12, and random loss or gain of chromosomes). ES cell lines with full or partial trisomy 8 can contribute to somatic tissues, but lose the ability to contribute to the germ line. Our data indicate that karyotyping analysis is a very important tool in quality assurance and perhaps improving the yield of gene targeting experiments in mice. Further, the cytogenetics abnormalities may shed light on the mechanisms of fetal wastage and aneuploidy.

**Partial monosomy 4p with no overt phenotype of Wolf-Hirschhorn syndrome and/or Pitt-Rogers-Danks syndrome.** *L.H. Lockhart<sup>1</sup>, J. Hawkins<sup>1</sup>, S. Zhang<sup>1</sup>, V.S. Tonk<sup>2</sup>, G.V.N. Velagaleti<sup>1</sup>.* 1) Dept of Pediatrics, Univ. Texas Medical Branch, Galveston, TX; 2) Dept of Pediatrics, Texas Tech Univ., Lubbock, TX.

Wolf-Hirschhorn syndrome (WHS) and Pitt-Rogers-Danks syndrome (PRDS) are multiple malformation syndromes resulting from a partial deletion of p16 region of chromosome 4 [del(4)(p16)]. There is wide variability in both the range and severity of symptoms. However, the extent and severity of phenotype are correlated with the length of the deleted segment. Here, we report two cases of partial monosomy 4p detected prenatally. In both cases the phenotypic features were not typical of those seen in the WHS or PRDS.

Case 1 involved a 21-year-old, Caucasian woman who underwent amniocentesis because of multiple fetal anomalies observed on ultrasound at 17 weeks gestation. The fetus had cleft lip and palate, increased nuchal thickness, cystic hygroma, cervical hemivertebrae, a small meningomyelocele, left pleural effusion, diaphragmatic hernia, two-vessel cord, ventricular septal defect and clubbed feet; features commonly seen with trisomy 13. Chromosome analysis showed extra material on the terminal short arm of a chromosome 4 [46,XX,add(4)(p16)]. FISH studies with WHS probe showed that the tested locus was deleted. Parental chromosome analysis showed father with a balanced karyotype 46,XY,t(4;13)(q32;p16), which was confirmed by whole chromosome painting. Thus the fetus has partial monosomy 4p16->pter and partial trisomy 13q32->qter [46,XX,der(4)t(4;13)(p16;q32).ish der(4)del(4)(p16.3p16.3)(WHS-).

Case 2 involved a 35-year-old G7P3A3, Hispanic woman who underwent amniocentesis since she was known to carry a balanced translocation with karyotype 46,XX,t(4;12)(p15.3;p13). She had one child with phenotypic features similar to WHS. Chromosome analysis from amniotic fluid showed partial monosomy 4p [46,XX,der(4)t(4;12)(p15.3;p13)]. However, the fetus did not show any abnormalities on ultrasound at 20 weeks gestation except for increased nuchal thickness.

Both couples elected to terminate the pregnancies and refused autopsy or examination of the fetus.

**Chromosome 15 duplicons mediate both Class I and Class II common deletions of Prader-Willi and Angelman syndrome patients.** *S.K. Mewborn<sup>1</sup>, J.A. Fantes<sup>2</sup>, N.L. Miley<sup>1</sup>, R. Brown<sup>1</sup>, S.L. Christian<sup>3</sup>, D.H. Ledbetter<sup>1</sup>.* 1) Dept of Human Genetics, Univ of Chicago, Chicago, IL; 2) Medical Genetics Section, Department of Medical Sciences, University of Edinburgh, Edinburgh, UK; 3) Department of Psychiatry, University of Chicago, Chicago, IL.

Molecular analyses of Prader-Willi and Angelman syndrome patients provided evidence that the breakpoints of the deletions clustered to three locations; one distal location (BP3), and two proximal (BP1 and BP2). These breakpoints create two classes of patients, Class I using BP1 and Class II using BP2. Mapping of these breakpoint regions revealed blocks of duplicated genomic sequences or duplicons of approximately 500 kb at BP2 and BP3 in inverted orientation. Breakpoint 1 was hypothesized to contain duplicon sequences as well. Current genomic sequence and mapping information has enabled the construction *in silico* of a contig from BP2 to BP1, spanning approximately 200 kb. Anchor BAC clones containing unique and duplicon sequences confirm the presence of duplicon sequences at BP1 and connect BP1 to the pericentromeric pseudogene amplicon previously mapped to proximal 15q. Analysis of the sequence of these anchor BACs has provided evidence that BP1 is in the same orientation as BP2, but contains only a partial copy of the duplicon found at BP2 and BP3. In order to confirm the involvement of the duplicon sequences in the deletion events, pulsed field gel electrophoresis (PFGE) analysis has been performed to identify junction fragments in Prader-Willi and Angelman syndrome patients. Seven junction fragments have been identified. These junction fragments are not identical in size, but show some clustering suggesting that within the duplicons there may be hotspots of breakage. *in silico*.

**Mapping of a mosaic deletion of the short arm of chromosome 7 (7p15.3 to 7p21.1).** *J. Mack, M. Nimmakayalu, B. Pober, M.B. Qumsiyeh.* Genetics, Cytogenetics, Yale University Sch Med, New Haven, CT.

A deletion involving the short arm of chromosome 7 has been reported to result in variable phenotypes which may include delayed growth and development, cleft palate and dysmorphic facial features such as epicanthal folds, hypertelorism, high forehead and micrognathia. Some patients also had congenital heart disease and craniosynostosis. We investigated a 6 year old female referred for evaluation of her developmental delay and congenital anomalies. Clinical evaluations revealed pulmonary valvular stenosis, cleft palate, bilateral epicanthal folds, wide palpebral fissures with apparent telecanthus, prominent nose, and smooth philtrum. Cytogenetic analysis revealed seven cells with a 46,XX karyotype and 14 cells containing a possible paracentric inversion of 7p15.3p21.3 *de novo*. YAC hybridization instead showed a deletion in 7p15 to 7p21.1 rather than an inversion. YAC 927-h-6 (1140 kb) was deleted and a more proximal YAC (850-a-1, 830 kb) had reduced signal on the deleted chromosome. High resolution GTW-banding showed that the banding pattern of the short arm in this case could be explained by a deletion rather than an inversion. Previous reports of deletions of 7p suggest that there are two bands associating with craniosynostosis on 7p: 7p13 and 7p21. Our case with a deletion of 7p15.3 to 7p21.1 and no craniosynostosis suggest that this phenotype on 7p21 is likely associated with more distal deletions at 7p21.2 or 7p21.3. A deletion of TWIST gene at 7p21 was reported in association with Saethre-Chotzen syndrome (SCS, acrocephalosyndactyly type III). This patient had little similarity to SCS. The presence of several homeobox and other developmental genes in the deleted area of 7p15.3 likely accounts for the phenotypic features seen in our patient.

**Molecular characterization of microscopically visible deletion of 7q11.23 to q21.11.** *M.A. Nimmakayalu, J. Mack, M.B. Qumsiyeh.* Dept Genetics, Yale Univ, New Haven, CT.

Visible deletions of 7q11.2 region are very rare and the two cases reported earlier were not characterized molecularly. Our patient had heart murmur and non-obstructive hypertrophic cardiomyopathy at birth. Motor delay was noticed around 6 months. He was notable for growth delay, mental retardation, seizures, and weak vocalizations but with absent speech. At clinical examination, the proband had microcephaly, prominent lips, microstomia, macrocytosis of the red cells, ataxic gait, and mild supra-aortic stenosis. Karyotype at 550-600 band level showed a microscopically visible deletion: 46,XY,del(7)(q11.23q21.11)de novo. FISH using a BAC probe that includes Elastin and LIMK1 (Vysis Inc.) confirmed a deletion. To further characterize the breakpoints in this visible deletion, YACs were picked from two contigs in the area of the deletion. Of the seven YACs we mapped in this patient's sample, one (771A1) was deleted, three mapped proximal, and three mapped distal to the deletion. Our molecular characterization suggests a large deletion of more than 3 Mb. The patient's phenotype represents an extension of the Williams syndrome phenotype. The involvement of mental retardation, absence of speech, seizures, and red blood cell abnormalities are likely due to hemizygosity for genes outside the classical Williams syndrome region. Erythropoietin loss (7q21) may be critical in the red cell macrocytosis.

**Analysis of Genetic Sex Reversal by Comparative Genomic Hybridization.** *B. Levy*<sup>1</sup>, *M. Huang*<sup>1</sup>, *K. McElreavey*<sup>2</sup>, *H. Ostrer*<sup>3</sup>. 1) Mount Sinai School of Medicine, New York, NY; 2) Institut Pasteur, Paris, France; 3) New York University School of Medicine, New York, NY.

Genetic sex reversal occurs with a frequency of 1 in 20,000 individuals. The associated phenotypes are either 46,XY pure or mixed gonadal dysgenesis, 46,XX maleness or 46,XX true hermaphroditism. In approximately 2/3 of cases, the genetic basis is unknown. We hypothesized that some of these cases may arise from chromosomal imbalances (gains or losses) that could be detected by comparative genomic hybridization (CGH). First, we calibrated the technique by analyzing cases of sex reversal with known cytogenetic abnormalities and confirmed 9p and 11p deletions in two cases of 46,XY gonadal dysgenesis. Among several cases with 46,XY gonadal dysgenesis, we observed duplications of the distal short arm of chromosome 9, not seen by conventional cytogenetics, including one case previously reported as a 9p deletion. In a case of 46,XX campomelic dysplasia, we observed an inverted duplication of distal 17p in the region of the SOX20 gene, not seen by conventional cytogenetics. This was confirmed by fluorescence in situ hybridization. In two cases of 46,XX true hermaphroditism, we observed the presence of a Y-bearing cell line, confirming our previous observations that such cases may arise from mosaicism or chimerism. These findings suggest that chromosomal imbalances are an important cause of sex reversal affecting dosage for sex-determining genes. The range of such dosage-sensitive genes extends beyond DAX1, SOX9, and WNT4 and may include genes in the DMRT family. Thus, CGH offers an important new tool for mapping sex-determining genes.

**Unusual X inactivation: an active ring(X).** *M. Shago*<sup>1</sup>, *D. Antinucci*<sup>1</sup>, *P. Chakraborty*<sup>2</sup>, *M. Sgro*<sup>3</sup>, *T. Barozzino*<sup>3</sup>, *D. Chitayat*<sup>2</sup>, *I. Teshima*<sup>1</sup>. 1) Cytogenetics Laboratory, Department of Pediatric Laboratory Medicine, Hospital for Sick Children; 2) Clinical Genetics, Hospital for Sick Children, 555 University Avenue; 3) Division of Pediatrics, Mount Sinai Hospital, 600 University Avenue, Toronto, Canada.

A newborn female with birth parameters (length, weight, and head circumference) of less than the third percentile presented with facial dysmorphism including flattened mid face, a prominent forehead, a small chin, and low set posteriorly rotated ears. Physical assessment revealed short limbs and small hands and feet. Mild pulmonary stenosis was detected and an eye examination indicated Rieger's anomaly. Cytogenetic analysis of cultured lymphocytes revealed a karyotype of 47,X,r(X)(p?q?),der(Y)rea(X;Y)[49]/46,X,der(Y)rea(X;Y)[3] by GTG banding, FISH, C-banding and spectral karyotyping. The mitotic instability of the ring chromosome was evident by its absence in 3/52 cells and the presence of a double ring in 2/52 metaphases examined. The derivative Y appears to be a complex rearrangement of chromosomes X and Y. By FISH, the *SRY* gene determining region is not present on the derivative Y while the *XIST* gene (within the X inactivation locus) is present on both the normal X and the r(X) but not on the der(Y). Replication studies suggest that the normal X is late replicating (inactive) and the r(X) is early replicating (active) in 50/50 cells examined. In normal females, X inactivation is a random event occurring early in embryogenesis. Abnormal Xs lacking *XIST* cannot undergo inactivation. Most abnormal X chromosomes that contain *XIST*, although they are randomly inactivated, are late replicating and inactive as a result of secondary cell selection. The unusual skew of activation towards the r(X) in this case presumably results in the least amount of functional disomy of X-linked genes in the cells of this patient. By FISH, this child has an Xp terminal deletion. Mutations in the *SHOX* gene, which localizes to the pseudoautosomal region of Xp, lead to short stature and mesomelic limb shortening. FISH analysis using probes from the *SHOX* genomic region revealed that this child has haploinsufficiency of the *SHOX* gene.

**Deletion of chromosome 15 centromere and short arm sequences in a patient with features of Prader-Willi syndrome (PWS).** *C.M. Tuck-Muller<sup>1</sup>, J.E. Martinez<sup>1</sup>, G. Lu<sup>2</sup>, E.R. Rowley<sup>1</sup>, A.K. Lee<sup>1</sup>, W. Wertelecki<sup>1</sup>, T.J. Chen<sup>1</sup>.* 1) Dept Medical Genetics, Univ South Alabama, Mobile, AL 36688; 2) Dept Obstetrics and Gynecology, Univ South Carolina, Columbia, SC 29203.

About 70% of PWS patients have deletions in chromosome 15q which include the SNRPN gene. We report a female with some features of PWS and deletion of chromosome 15 centromere and proximal short arm sequences. Examination at age 9 years revealed tall stature, obesity, hypotonia, distally tapered fingers, almond shaped eyes, narrow bifrontal diameter, micrognathia, large ears with fleshy lobes and mental retardation. She had a normal DNA methylation pattern at the SNRPN locus, suggesting that she is not a typical PWS patient. The patient's mother, who was unavailable for examination, is also obese and is said to be "slow". No abnormalities were detected in either the patient or her mother by high resolution chromosome analysis. The FISH probes SNRPN, specific for the PWS region (15q11-q13), and PML (15q22) hybridized to both copies of chromosome 15, while the probes D15Z4, specific for the centromere, and D15Z1, specific for the proximal short arm (15p11.2), failed to hybridize to one copy of chromosome 15 in both the patient and her mother. To rule out a translocation between this chromosome 15 and a non-homologous chromosome as the reason for the failure of hybridization, we used individual centromeric probes specific for all chromosome pairs (Cytocell Chromoprobe Multiprobe system). Two hybridization signals were seen with each probe, except for the chromosome 15 probe where only one signal was seen and the probes for chromosomes 13 and 21 and chromosomes 14 and 22 where cross-hybridization produced 4 signals. These results provide no evidence of a translocation. We conclude that the failure of hybridization with centromeric and short probes is probably due to deletion of repetitive DNA sequences in the unusual chromosome 15, which may represent a normal chromosome variant. However, if the deletion extends into the proximal long arm, it may be associated with the abnormal phenotype in the patient and her mother.

**Phenotypic effects of tetrasomy 20p.** *M. Thangavelu*<sup>1</sup>, *I.N. Zeibarth*<sup>2</sup>, *S. Bhatt*<sup>1</sup>. 1) Genzyme Genetics, Orange, CA; 2) Kapiolani Medical Center for Women and Children, Honolulu, HI.

Structurally abnormal chromosome 20, resulting in partial trisomy 20 has been observed both as derivatives and as markers. We present a case of mosaic tetrasomy 20p diagnosed prenatally. Amniocentesis and cytogenetic studies were performed on a 43 year old because of advanced maternal age and abnormal maternal serum screen indicating an increased risk for trisomy 21. An extra marker chromosome of de novo origin, identified as an idic(20)(q11.2) (isodicentric for the short arm of chromosome 20) by conventional cytogenetics and FISH, was observed in 11 of 15 colonies. At 33 weeks, because of decreased fetal movement and heart deceleration the baby was delivered by emergency C-section. During a three month hospitalization, the patient was found to have bilateral inguinal hernia, bilateral cryptorchidism, left pelvic kidney, gastrointestinal reflux and mild dysmorphic features (rotated ears, long philtrum, micrognathia, and prominent occiput). To our knowledge this is the first case of tetrasomy for 20p. As in previously reported cases of abnormalities resulting in mosaicism for increased dosage of chromosome 20 material as the sole abnormality, the phenotypic abnormalities appear to be minimal. Although there is anecdotal evidence to suggest a probable relationship between chromosome 20 aneuploidy and abnormalities involving the kidney and gastrointestinal system, additional studies are required at the epidemiological as well as biological level.

**Screening cryptic telomeric rearrangements in children with idiopathic mental retardation using an automated fluorescent genotyping strategy.** *M. RIO<sup>1</sup>, S. HEUERTZ<sup>1</sup>, F. MOLINARI<sup>1</sup>, V. PIGNOT<sup>1</sup>, C. TURLEAU<sup>1</sup>, MC. de BLOIS<sup>2</sup>, O. RAOULT<sup>2</sup>, M. PRIEUR<sup>2</sup>, S. ROMANA<sup>2</sup>, A. VEKEMANS<sup>2</sup>, A. MUNNICH<sup>1</sup>, L. COLLEAUX<sup>1</sup>.* 1) INSERM U393, Hopital NECKER-ENFANTS MALADES, PARIS, FRANCE; 2) Service de Cytogenetique, Hopital NECKER-ENFANTS MALADES, PARIS, FRANCE.

Mental retardation is a common condition that affects largely 2 % of the general population. However, its origin remains poorly understood. Recent studies have demonstrated that cryptic unbalanced subtelomeric rearrangements contribute to a significant proportion of idiopathic mental retardation cases. Because of the limited sensitivity of routine analyses, we developed a novel strategy based upon automated fluorescent genotyping to search for non-Mendelian segregation of telomeric markers. The results of a pilot study suggested that fluorescent genotyping is a sensitive and cost-effective method to detect telomeric rearrangements and that the microsatellite technique provides the unique opportunity to detect uniparental disomies. Here we report a larger study including 110 children. This study resulted in the characterization of twelve telomeric rearrangements and two uniparental disomies, confirming the efficiency of this strategy to detect subtelomeric abnormalities in children with severe mental retardation. Our results also provide evidence for the prevalence of the paternal origin of the rearrangements. They illustrate the potential difficulty in demonstrating the pathogenicity of previously undocumented small telomeric rearrangements. Finally our data emphasize the phenotypic variability of these subtelomeric rearrangements.

**An adjacent-2 segregation in a balanced familial t(9;15)(q32;q13) with a large centric segment.** *J. Xu, T. Heshka, M.J.M. Nowaczyk.* Dept. of Pathology & Molecular Medicine, Hamilton Regional Laboratory Medicine Program, Hamilton Health Sciences and McMaster Univ., Hamilton, ON., Canada.

Adjacent-2 segregation is rather uncommon among familial balanced translocations. It usually occurs in translocations involving the chromosomes with small short arms; mostly chromosome 9 and acrocentrics. Both centric segments are characteristically small. We report adjacent-2 segregation in a familial balanced t(9;15)(q32;q13) with a large centric segment in the derivative chromosome 9 and a small centric segment in the derivative chromosome 15. The proband is a 22-year-old mother with a maternally inherited translocation, 46,XX,t(9;15)(q32;q13). The grandmother had a history of pregnancy with an unbalanced karyotype 47,XY,+der(15)t(9;15). Our patient has had three recognized pregnancies. The first pregnancy was lost at 12 weeks gestation. Analysis of products of conception indicated the fetus had a karyotype of 46,XY,+der(9)t(9;15)mat,-15. The second pregnancy was lost at 12 weeks gestation, but was not cytogenetically investigated. The third pregnancy was terminated at 20 weeks gestation because the fetus was found by amniocentesis to also have a karyotype of 46,XX,+der(9)t(9;15)mat,-15. This karyotype was unbalanced, with trisomy for 9pter-q32 and monosomy for 15pter-q13. The abnormal karyotype was probably a result of adjacent-2 segregation. This finding indicates that this adjacent-2 segregation product is compatible with fetal life to at least mid-gestation. This is hardly surprising, considering that a full-blown trisomy of entire chromosome 9 has been documented in liveborn cases. The deficiency of the centric segment 15 is unlikely to be lethal in fetal development, because of its small genetic content. Based on the grandmother's history of pregnancy with 47,XY,+der(15), it is also possible that the abnormal pregnancies in our patient might have resulted from the loss of the der(15) from an original trisomy gamete with der(9) plus der(15), originating from a 3:1 segregation. Accumulation of more cases and further molecular investigations should help us to better understand the mode of segregation for this (or similar) translocation and its clinical implications.

**Non-acrocentric satellited chromosomes. A review.** *C. Sarri, J. Gyftodimou, M. Grigoriadou, E. Pandelia, S. Kalogirou, A. Stefanidou, M.B. Petersen.* Dept Genetics, Inst of Child Health, Athens, Greece.

Translocations involving satellites with or without the nucleolar organiser region (NOR) and the terminal region of a non-acrocentric chromosome arm result in satellited non-acrocentric chromosomes. In our Department, we have found only three cases with non-acrocentric satellited chromosomes in a total of about 7,000 karyotypes (0.04%). The three cases were 2qs, 4ps and 10qs.

Several such reports exist in the literature. These unique chromosomes presumably occur secondary to a translocation with an acrocentric chromosome. Generally, balanced carriers of such translocations are not affected, but individuals with unbalanced segregation products exhibit diverse symptoms because of partial trisomy or monosomy. Males with a Yqs chromosome generally are not affected by the secondary deletion of Yq13 (13 cases at least), because this region of the Y does not appear to contain expressed genes. There are many additional reports of satellited non-acrocentrics, i.e. 1p (two cases), 1q (two cases), 2p (one case), 2q (seven cases), 3q (one case), 4p (one case), 4q (7 cases), 9p (one case), 9q (one case), 10q (one case), 12p (one case), 18p (one case), Yp (3 cases), and Yq (at least 13 cases), in which carriers are not adversely affected even though the reciprocal translocation chromosome is absent. In other reports the carriers of a satellited non-acrocentric chromosome are affected because of proved or possible loss of genetic material. Such cases have been described concerning chromosomes 1p (two cases), 1q (one case), 4p (four cases), 4q (two cases), 5p (one case), 6q (one case), 9q (one case), 10p (one case), Xp (one case), and Yq (one case). There are some other reports of satellited non-acrocentric chromosomes of unknown phenotype involving chromosomes 1q (two cases), 2q (one case), 7q (one case), 9q (one case), and 12q (one case).

In situ hybridization with subtelomeric probes and molecular analysis are necessary to clarify the molecular event in order to give a proper genetic counseling to the families.

**Polymorphisms in genes involved in folate metabolism are not maternal risk factors for Down syndrome.** *M.B. Petersen<sup>1</sup>, M. Grigoriadou<sup>1</sup>, M. Mikkelsen<sup>2</sup>*. 1) Genetics Dept, Inst Child Hlth, Athens, Greece; 2) Dept Med Genet, J.F. Kennedy Inst, Glostrup, Denmark.

Trisomy 21 is the most common chromosome abnormality in liveborns and is usually the result of nondisjunction of chromosome 21 in meiosis in oogenesis. There is still a lack of understanding of the cellular and molecular mechanisms underlying nondisjunction. Two recent studies suggested that abnormal folate metabolism and polymorphisms in genes involved in folate metabolism may be maternal risk factors for DS (*Am J Clin Nutr* 1999;70:495-501 and *Am J Hum Genet* 2000;67:623-30). Significantly higher frequencies of the 677C>T polymorphism in the methylenetetrahydrofolate reductase (MTHFR) gene and the 66A>G polymorphism in the methionine synthase reductase (MTRR) gene were found in mothers of children with DS than in control mothers. The studies suggested potential opportunities to improve public health strategies for the primary prevention of DS. We therefore analyzed the MTHFR 677C>T and MTRR 66A>G polymorphisms in a population-based study of DS in Denmark, where the origin of nondisjunction was determined by DNA microsatellite analysis. The material consisted of 181 mothers of children with DS (non-mosaic free trisomy 21) with origin of nondisjunction in maternal meiosis I or II. The frequency of the 677T allele in the DS mothers (27.7%) was not significantly different from the frequency in the fathers (29.8%) and not significantly different from the frequency in Danish controls (29.0%, n=1,084). There was no significant difference in the frequency of the 66G allele between mothers (55.3%) and fathers (53.7%). Also, there was no significant difference in the frequency of the two mutant alleles between mothers with meiosis I errors (n=126) and mothers with meiosis II errors (n=55). Furthermore, the frequency of combined MTHFR and MTRR homozygous mutant genotypes in the mothers (2/174) was not significantly different from the frequency in the fathers (3/171). We conclude that the common MTHFR 677C>T and MTRR 66A>G mutations are not likely to be maternal risk factors for DS and that the previously published findings were probably due to bias caused by population admixture.

**Centromere specific multicolor-color FISH (cenM-FISH) is a versatile method for the characterization of small SMC - case report.** *H. Starke<sup>1</sup>, A. Nietzel<sup>1</sup>, F. v. Eggeling<sup>1</sup>, A. Heller<sup>1</sup>, M. Rocchi<sup>2</sup>, B. Mitulla<sup>3</sup>, V. Beensen<sup>1</sup>, U. Claussen<sup>1</sup>, T. Liehr<sup>1</sup>.* 1) Inst. of Human Genetics and Anthropology, Jena, Germany; 2) Inst. of Genetics, Bari, Italy; 3) Central Clinic, Genetic Counselling, Suhl, Germany.

Stable small supernumerary marker chromosomes (SMC) often present without molecular cytogenetically detectable euchromatin and are uneasy to characterize in standard cytogenetic approaches. Microdissection and reverse painting could be used for their characterization. However, this technique is used more reasonably for larger markers with more euchromatin. Recently, we developed a probe set using all human centromeric probes labeled in different colors, allowing the simultaneous characterization and identification of all chromosomes by their centromeric region (Nietzel et al., *Hum Genet* 2001, 108:199-204). The technique, called cenM-FISH has been applied in the following case: Cytogenetic diagnostic was done in a newborn boy who presented with typical features of Down syndrome like hypertelorism, simian crease and hypomotility. The suspicion Down syndrome was confirmed in cytogenetics as a free trisomy 21. Additionally a small SMC was detected in 28/35 analyzed metaphase spreads (karyotype: 48,XY,+21,+mar). CenM-FISH revealed, that the small SMC was a derivative chromosome 4. As it was not stained by a whole chromosome painting probe for chromosome 4 it was described as a der(4)(p11q11). The karyotypes of the parents were inconspicuous, thus, two de novo events must have taken place to lead to the detected numerical aberrations. Uniparental disomy (UPD) 4 of the inconspicuous chromosomes 4 has been excluded for whole chromosome 4 apart from a small region in 4pter. In summary, the cenM-FISH technique is a very useful approach for the one step identification of all human chromosomes by their centromeres. Molecular genetic studies to exclude UPD should always be done after determination of SMC's origin. Acknowledgments: This work was supported by the Herbert Quandt Stiftung der VARTA AG, the Madeleine Schickedanz-Kinderkrebs-Stiftung, the EU (ICA2-Ct-2000-10012 and QLRT-1999-31590) and the Wilhelm Sander-Stiftung.

**A prospective (three years) cytogenetical study of 114 children with congenital anomalies submitted to necropsy died between 0 to 14 years old.** *J.M. Pina-Neto<sup>1</sup>, D. Ortolan<sup>1</sup>, H.H.L Fernandez<sup>1</sup>, L.F. Mazzucatto<sup>1</sup>, L.C. Peres<sup>2</sup>.* 1) Dept Genetics, Fac Medicine Ribeirao Preto, Sao Paulo, Brazil; 2) Dept Pathology, Fac Medicine Ribeirao Preto, Sao Paulo, Brazil.

The objectives of this study were to establish an adequate cytogenetics methodology for necropsy studies and to determine the frequency and characteristics of chromosomal aberrations in children with congenital anomalies, who died in pediatric ages (0 to 14 years). In the period of the present study (November, 1996 to November, 1999) 832 pediatric necropsies were made at University Hospital. From them, 229 children (27.5%) had congenital anomalies and 144 had indications for a karyotype study. Culture success was obtained in 79.2% (114) of these cases. Chromosomal anomalies were observed in 29 children, which represents 3.5% of total sample (29/832), 12.6% among anomalous children (29/229) and 25.4% of the children karyotyped (29/114). From the 29 chromosomally abnormal children, 27 died within the first year (25% were stillbirth). After a complete clinical-genetic evaluation of the children with congenital anomalies, it was possible to detect 8 children with multiple congenital anomalies without a cytogenetic study, in which only in one of them was made a hypothesis of chromosomal disorder. The 29 cases of chromosomal disorder represented 20.1% within the etiologic factors involved in this sample. It was detected trisomy 18 (10 cases), trisomy 21 (9 cases), trisomy 13 (4 cases), trisomy 9 (1 case), triploidy 69,XXX (1 case) and 4 cases of structural aberrations (1 with Robertsonian balanced translocation 14;21; 1 with a monosomy 5p; 1 with a partial monosomy 21 and 1 with a double partial trisomy 9pter-q2 and distal 16q). The higher culture successes were obtained with fascia of abdominal rectus muscle (75.5%), followed by skin (69.5%), blood (58.7%) and kidney (33.3%). There was a clear effect of time between death and beginning of culture in the culture success rate.

**Complex Behavioural disorder in a patient with ring chromosome 10(p15;q26).** *P. Strisciuglio<sup>1</sup>, M.A. Iembo<sup>1</sup>, R. Marotta<sup>3</sup>, M.T. Moricca<sup>1</sup>, E. Rossi<sup>2</sup>, D. Concolino<sup>1</sup>.* 1) Dept Pediatrics, Univ Catanzaro, Catanzaro, Italy; 2) Dept of Biology and Medical Genetics Univ Pavia, ITALY; 3) Dept of Psychiatry, Univ Catanzaro, Italy.

Ring chromosomes have been described and are usually associated with growth and mental retardation when autosomes are involved. Only few patients with ring chromosome 10 have been reported. According to many studies that have reported association between chromosome deletion syndromes and neuropsychiatric disorders, we describe a patient with ring and deletion of chromosome 10 presenting severe psychiatric and behavioural problems. The patient, a male, was the fifth child of healthy and unrelated parents. The family history, the pregnancy and the delivery were unremarkable. During childhood there were severe feeding difficulties with progressive growth retardation. Psychomotor delay associated with comportamental abnormalities were referred during the infancy. Bilateral cryptorchidism was surgically corrected at 13 years of age. Physical examination at the age of 32 years demonstrated a low weight, a short stature, microcephaly, triangular face, pectus excavatum, micropenis normal sexual development. The neuropsychiatric examination showed mental retardation and mood disorders, moderate anxiety and personality problems. Plasma ammonia levels and acido-base status, plasma and urinary aminoacid evaluation were normal. Brain axial computerized tomography, ophthalmologic examination, echocardiography and abdominal ecography were normal. Chromosome analysis was performed on QFQ and GTG banded metaphases from synchronised peripheral lymphocyte cultures using standard procedure. Proband's karyotype was interpreted as 46,XY,ring 10(p15q26) Ring breakpoints were defined at YAC level by fluorescent in situ hybridization (FISH). The clinical features of our patient have been described in other cases of monosomy 10qter. According to the recent evidences suggesting a greater incidence of psychiatric and behavioural problems in children and adults with chromosome deletions, we suggest that the complex behavioural disturbances in our patient may be a primary feature of this chromosomal abnormality.

**Interstitial deletion of chromosome 21q.** *S. Sastry*<sup>1</sup>, *I.K. Gadi*<sup>2</sup>, *P. Papenhausen*<sup>2</sup>, *L. Mehta*<sup>1</sup>. 1) Dept. of Pediatrics, Div. of Medical Genetics, North Shore University Hospital, Manhasset, NY; 2) Laboratory Corporation of America.

Partial monosomy 21q is reported in association with unbalanced chromosome translocations, ring chromosome 21 and chromosome 21 deletions. We report a 3.5 yr. old girl evaluated for moderate developmental delays. Growth parameters were normal. Dysmorphic features consisted of flat nasal bridge, small nose, short palpebral fissures, mild hypertelorism, thin upper lip, posteriorly rotated ears with small lobules, abnormal palmar creases and overlapping toes. She had a history of infantile colic and poor weight gain. She was nearsighted and had astigmatism. Hearing, EEG and head imaging were normal. Cardiac evaluation and renal sonogram were normal. Blood chromosome analysis showed a chromosome 21 deletion, 46,XX,del(21)(q11.2-q22.1). A FISH whole chromosome 21 DNA probe study painted both homologues completely with no evidence of a balancing insertion. Parental chromosomes were normal. Interstitial deletions of 21q are rare; only 7 reports have been ascertained where the abnormality was not associated with other chromosome imbalance. Most cases were reported without FISH or molecular studies. Dysmorphic features and developmental delays are non-specific in these patients. The phenotype can be mild and one patient with normal intelligence was reported (Korenberg,1991). A possible critical region for growth and mental retardation, heart defects, facial dysmorphisms, arthrogyriposis and hypertonia has been suggested between bands 21q21-21q22.1 (genes APP to SOD1)(Chettouh,1995). Holoprosencephaly was present in one patient with del 21q22.3(Estabrooks,1990).It is suggested that deletions distal to 21q22.2 generally result in more severe abnormalities. Our patient presents with a fairly mild phenotype and a deletion proximal to the q22.2 band. Further molecular studies in such cases can provide more precise phenotype/genotype correlations.

**Duplication of chromosome 15q14q15 associated with short stature, mental retardation, speech problems and atypical body fat distribution.** *M. Weickert, M. Adamowicz, C. Baldermann, H. Thiele, U. Hehr, I. Hansmann.* Institut fuer Humangenetik und Medizinische Biologie, Halle/Saale, Germany.

Duplications of the proximal segment of maternal chromosome 15 including PWS/AS critical region has been described in several probands with a complex phenotype including developmental delay, speech and learning difficulties as well as autistic behaviour. Here we present a unique patient with a maternal duplication for 15q. The propositus is the only child of clinically normal unrelated parents. Pregnancy was complicated by placental insufficiency and IUGR. Two days after spontaneous delivery a VSD was observed. At the age of 7 1/2 years the boy revealed short stature below the 3rd percentile, developmental delay, dysmorphic facial features, feeding, speech and behavioral problems and a female-like body fat distribution. Karyotyping revealed additional bands within 18q. Analysis of the mother identified her as a carrier of a translocation 46,XX,ins(15;18)(q1?q15;q11.2). Painting for maternal chromosome 15 labeled both chromosomes 15 and a proximal 18q segment. A chromosome 18 paint labeled only the normal 18 and the der(18), respectively. No signal was present on the der(15), confirming an insertion of chromosome 15 segment into chromosome 18. FISH using SNRP (15q11.2) and PML (15q22) probe (Vysis) placed the proximal breakpoint telomeric to PWS/AS and the distal breakpoint centromeric to PWL locus. Analysis of 8 microsatellite markers representing segment 15q13-q15 revealed no evidence for duplication of any maternal allele. To further narrow down the duplication FISH was performed to metaphases of the proband using 8 YACs. According to signals obtained at the normal chromosome 15 and the der(18) the proximal boundary of the duplication is flanked by YAC 879f03 and the distal boundary by YAC 900d8. Two YACs, i.e. 850d6 and 876c4 are located within the duplication. Due to a significantly reduced signal of YAC 876c4 (approx. 890kb) on the der(18) chromosome we assume that the telomeric breakpoint maps within the template for that YAC at 15q15. A maternal dosage effect of duplicated genes within 15q14q15 is considered to be responsible for the phenotype.

**Prenatal diagnosis of an unusual translocation.** *G.S. Sekhon<sup>1</sup>, S. Jalal<sup>2</sup>, A. Salvador<sup>3</sup>, K. Thompson<sup>1</sup>, E. Johnson<sup>1</sup>, C. Corsi<sup>1</sup>.* 1) Div Clinical Gen, Waisman Ctr, Univ Wisconsin, Madison, WI; 2) Cytogenetics Lab, Mayo Clinic, Rochester, MN; 3) St. Johns Mercy Medical Center, St. Louis, MO.

Cytogenetic analysis of amniocytes obtained at 15.3 weeks of gestation revealed a female karyotype with an abnormal banding pattern of 19p terminus. There seemed to be extra euchromatic material on the short arm of chromosome 19 and it was thought that the extra material was either from 7q or 5q by G-banded analysis. Parental cytogenetic studies revealed a similar anomaly in the phenotypically normal father. To clarify this, FISH studies were performed. The individual chromosome painting probes and M FISH did not reveal the origin of the extra material on 19p terminus. FISH analysis on the amniotic fluid and on the father using Vysis subtelomeric probes 7 and 19 consisting of p and q terminal probes, showed only a signal on the p arm of one chromosome 7, with the 7q signal relocated distal to the 19p subtelomere signal on the derivative 19 chromosome. The 19p subtelomeric unique sequence DNA was retained on the derivative 19 chromosome, indicating a more distal breakpoint. Further analysis with BAC FISH is in progress to delineate the extent of the submicroscopic translocation. These findings demonstrate 1) The size of genomic material translocated from the chromosome 7 homologue was too small to be detected by chromosome painting probe or M FISH, 2) subtelomeric FISH analysis is important in delineating structural rearrangements when prometaphase analysis is questionable, but subtelomeric translocations may occur that will be undetected by subtelomeric specific FISH probes, 3) there is a need for knowing the gap size between subtelomere clones and the distal sequences, and 4) despite new technologies counseling dilemmas persist.

**Molecular cytogenetic characterization of a pericentric inversion, inv(22)(p13q13.1).** *G.V.N. Velagaleti<sup>1</sup>, C.A. Jesurun<sup>2</sup>, L.H. Lockhart<sup>1</sup>, V.S. Tonk<sup>3</sup>*. 1) Department of Pediatrics, University of Texas Medical Branch, Galveston, TX; 2) Department of Pediatrics, Texas Tech University, El Paso, TX; 3) Department of Pediatrics, Texas Tech University, Lubbock, TX.

Pericentric inversions occur at a frequency of 0.12-0.7% in humans. Although chromosome 22 has been suggested to be preferentially involved in structural rearrangements, pericentric inversions of chromosome 22 are rare. Here we report for the first time a pericentric inversion of chromosome 22; the resulting recombinant chromosome and the phenotypic features associated with this recombinant chromosome.

A newborn infant was referred because of multiple congenital anomalies. He is the first child of a 25-year-old mother with unremarkable pregnancy history. At birth his height, weight and OFC were below the 5<sup>th</sup> percentile. He had hypertelorism, depressed nasal bridge, right cleft lip, bilateral cleft palate and small, low-set and malformed ears. Chromosome analysis showed a structurally rearranged chromosome 22 with additional material on 22p. Suspecting a duplication, parental chromosome analysis was requested. The proband's mother showed a rearranged chromosome 22 that is morphologically different from the child. C- and AgNOR banding studies showed a positional shift in both centromeric heterochromatin and satellite stalks. Studies with a series of FISH probes confirmed the pericentric inversion in the mother [karyotype 46,XX,inv(22)(p13q13.1)] and showed that the proband has a recombinant chromosome 22 resulting in partial duplication of the distal 22q13.2-qter region [karyotype 46,XY,rec(22)dup(22q)inv(22)(p13q13.1)].

Our proband with distal 22q13 duplication has several features common in patients with larger duplications extending to proximal 13q and patients with complete trisomy 22. Thus, it appears that the distal trisomy for 22q13.2->qter region is sufficient to result in complete trisomy 22 phenotype. Our case illustrates the efficacy of molecular cytogenetics in delineating subtle chromosome rearrangements which would not have been accurately characterized using conventional methods.

**Cytogenetic and molecular studies on an unusual partial trisomy 13 recombinant resulting from a maternal rearranged chromosome 13.** *N. Qin<sup>1</sup>, A. Fujimoto<sup>2</sup>, A. Anguiano<sup>1</sup>, Q. Xiao<sup>1</sup>, J.-J. Chen<sup>3</sup>, Y. Wang<sup>4</sup>, C. Tuck-Muller<sup>4</sup>, T.-J. Chen<sup>4</sup>.* 1) Dept of Cytogenetics, Quest Diagnostics' Nicholes Institute, San Juan Capistrano, CA; 2) Keck School of Medicine, University of South California, Los Angeles, CA; 3) Dept. of Medicine, University of Michigan, Ann Arbor, MI; 4) Dept. of Medical Genetics, University of South Alabama, Mobile, AL.

We describe an 11 month-old boy born at 39-week gestation to a 22 year-old gravida 2 para I phenotypically normal mother. At birth, he weighed 2420 gm (3-10th centile) and had a broad nasal bridge, micrognathia, neonatal teeth and cryptorchidism. No abnormality was found in the brain, heart and kidneys by ultrasound examinations. At 11 months, he weighed 7.7 kg (<5th centile), and measured 72 cm in length (10th centile) and 44 cm in OFC (<5th centile). He had social smiles at 3 months and rolled over at 9 months. Karyotype of peripheral blood lymphocytes showed an additional genetic material attached to the short arm of one of the chromosome 13. FISH assays for chromosome 13 (whole chromosome paint, centromere, RB-1 mapping to 13q14, and D13S585 at 13q32q33) identified it as an unusual partially duplicated chromosome 13. FISH results also indicated that there was a duplication of the RB-1 locus, but only a single D13S585 locus on the derivative chromosome 13. Father's karyotype was normal, while the mother had an apparently balanced, complex abnormality of chromosome 13 with a rearrangement of the centromere, RB-1, and D13S585 loci. CGH and high density (5-cm resolution) short tandem repeat (STR) genotyping are in progress to elucidate the location and size of the duplication on the derived chromosome 13 of the proband. In summary, we identified a rare duplication that resulted in nearly complete trisomy 13, but without a typical trisomy 13 phenotype. The mechanism of rearrangement and the segregation pattern during meiosis have been studied. The correlation of genotype and phenotype will be also discussed.

**A complex rearrangement in a mother simplified into a single balanced translocation in her fetus.** *F. Tihy<sup>1</sup>, N. Lemieux<sup>2</sup>, E. Lemyre<sup>1</sup>*. 1) Dept Genetics, Hosp Ste-Justine, Montreal, PQ., Canada; 2) Dept Pathology, Hosp Ste-Justine, Montreal, PQ., Canada.

An amniocentesis was performed for advanced maternal age on a woman with mild mental retardation, short stature, facial dysmorphism, and hydronephrosis. A sample of the mother's blood was taken at the same time for karyotyping. The fetal chromosomes showed an abnormal short arm of chromosome 20, which was analyzed by FISH. Subtelomeric probes from chromosome 20 showed a balanced translocation  $t(16;20)(q23;p11.2)$ . FISH with the subtelomeric probes of chromosome 16 confirmed this result.

Surprisingly, the mother's karyotype showed a complex chromosomal rearrangement (CCR):  $46,XX,t(5;16)(q11.2;q12),t(16;20)(q23;p11.2)$ . The derivative chromosome 5 was composed of short arm and pericentromeric region on the long arm of 5, proximal long arm of chromosome 16 and distal short arm of chromosome 20.

The transmission to the fetus of a simpler balanced rearrangement involving half of the rearrangements seen on the mother  $der(5)$  is the first reported to our knowledge. Such a phenomenon can be explained by two hypotheses. Meiotic recombination between the normal 16 and  $der(5)$  would result into a recombinant chromosome containing chromosome 16 and part of chromosome 20p as seen in the fetus. The second hypothesis involves germline mosaicism in the mother for  $46,XX,t(16;20)/46,XX,t(5;16),t(16;20)$ . However, all the lymphocytes analyzed showed the complex rearrangement.

The baby was born at 33 weeks with intra-uterine growth retardation, facial dysmorphism and hydronephrosis.

**Partial 4p and 5p inverted duplications are constantly associated with cryptic terminal deletions.** *M. Zollino<sup>1</sup>, M. Petersen<sup>2</sup>, L. Bortotto<sup>4</sup>, L. Memo<sup>3</sup>, G. Zampino<sup>5</sup>, Y. Gyftodimou<sup>2</sup>, C. Sarri<sup>2</sup>, G. Neri<sup>1</sup>.* 1) Genetica Medica, Univ Cattolica, Rome, Rome, Italy; 2) Institute of Child health "Aghia Sophia" Children's Hospital Athens, Grecia; 3) Patologia Neonatale ospedale Regionale Treviso, Treviso, Italy; 4) Genetica Medica Az. Ospedaliera S.Maria della Misericordia Udine, Italy; 5) Istituto di Pediatria, Univ Cattolica Rome, Rome, Italy.

A partial 4p duplication was detected by conventional chromosome analysis in three patients presenting with a Wolf-Hirschhorn syndrome (WHS) phenotype. One of these patients was already reported (Zollino et al, 1999). By FISH, the duplication was demonstrated to be inverted. On clinical evidence, a concomitant 4p deletion, encompassing the WHS critical region, was detected by FISH in each occasion. A different size of both the duplication and the deletion was observed both cytogenetically and molecularly in the three patients, the proximal breakpoint of the duplication being at bands p15.1, p15.2 and p16.1, the duplication-deletion boundary being at bands p16.2, p16.1 and p16.3. respectively. Clinical manifestations were only consistent with a WHS phenotype, and were according to the size of the deletion. The only sign consistent with the phenotype of partial 4p trisomy syndrome was hypoplastic corpus callosum, that was associated with the larger duplications (two patients). A similar rearrangement, consisting of inverted partial duplication on 5p and cryptic deletion encompassing the cri du chat syndrome locus, was diagnosed in a newborn with multiple congenital malformations/ dysmorphisms, including the cri du chat syndrome clinical manifestations. From these observations, we can infer that 1) inverted duplications affecting the distal half of 4p and 5p chromosome arms are always associated with a terminal deletion, as a consequence of a common meiotic rearrangement; 2) the presence of an undiagnosed deletion is likely to be responsible for some phenotypic inconsistencies so far observed among apparently pure partial 4p trisomies; 3) such double chromosome imbalance identify a specific subset of WHS and cri du chat syndrome patients.

**Complex chromosomal rearrangements - 7 new cases and a new classification system based on mechanism during cell division.** *S.M. Zneimer, J.C. Kelly, S.D. Stewart.* Cytogenetics Laboratory, Quest Diagnostics, Van Nuys, CA.

We report 7 cases of complex chromosomal rearrangements (CCRs) in a series of 6000 post-natal chromosome studies: Case 1: 46,XX,der(2)t(2;3)(p15;q27)inv(2)(q14q23) Case 2: 46,XY,der(12)inv(12)(q21.3q24.1)t(1;12)(q42.3;q24.3) Case 3: 46,XX,der(5)inv(5)(p13p15.1)t(5;8)(q23.2;q22.1)/46,XX Case 4: 46,XY,der(7)t(7;13)(p11.2;q14.3)t(7;21)(q11.2;q22.3) Case 5: 46,XY,t(1;7;14)(q32.3;p21.2;q21.2) Case 6: 46,X,ins(X;8)(p22.1;p23.1p23.3) Case 7: 46,XY,der(18) inv(18)(p11.2q12.2) t(15;18)(q21.2;p11.32) Four of these cases are of phenotypically normal individuals with reproductive problems, and 3 of these cases are children with phenotypic problems. Four of these cases required fluorescence in situ hybridization to define the breakpoints involved. There are various classifications of CCRs described in the literature; however, none of the classifications help define the cases of CCRs reported here. Along with a description of the genotype of these cases and their correlation with phenotype, we propose a new classification system to better define CCRs. It is the underlying mechanism occurring during cell division that defines the structure of chromosomes and this classification system reflects those differences. The classification is divided into 3 categories differentiating the number of breaks per chromosome that ultimately give rise to specific types of chromosome aberrations: 1) At least three breaks in a single chromosome with at least one break in a second chromosome (e.g. at least one chromosome with an inversion and a translocation event that involves at least a second chromosome). 2) Two breaks in a single chromosome with a single break in a second chromosome (e.g. an insertion of genetic material from one chromosome into a second chromosome). 3) A single break in three or more chromosomes (e.g. three or more chromosomes involved in a related translocation event, or 2 or more unrelated translocation events involving at least 3 chromosomes). This is the first classification system based on mechanisms during cell division and may be helpful in defining differences between complex cytogenetic aberrations.

**Identification of the sex determining region (SRY) gene in 46,XX males.** *J.G. Pappas<sup>1</sup>, M.J. Macera<sup>2</sup>, V. Mizhiritskaya<sup>2</sup>, A. Babu<sup>2</sup>.* 1) Clinical Genetic Services, New York University, School of Medicine, NY., NY; 2) Dept. of Molecular Medicine and Genetics, Wyckoff Heights Medical Center, Brooklyn, NY.

The sex determining region (SRY) gene, located at Yp11.2, regulates the expression of male specific genes by changing chromatin structure and creating new binding sites for other transcription factors [Giese et al 1992]. Cases of sex reversal 46,XX males, generally are discovered because of infertility; with the exception of sterility, there are generally no phenotypic differences with 46,XY males. The X and Y chromosomes pair and recombine briefly during male meiosis in two homologous regions the pseudoautosomal regions (PAR) located at the distal p and q arms of the X and Y. Abnormal exchanges of the X-Y can lead to transfer of Y material, including the SRY gene, to the p arm of the X chromosome. Receipt of this chromosome by a 46,XX individual will confer a male phenotype. To date, 80% of the 46,XX males investigated are positive for the presence of the SRY gene. The PRKY and PRKY are two homologous genes on the Y and X chromosomes respectively. The PRKY gene is located within an inversion polymorphism on the p arm of the Y chromosome. Sixty percent of normal 46,XY males showed the inversion polymorphism in one orientation, where as less than 10 percent of 46,XX SRY+ males showed the same orientation, suggesting illegitimate recombination between these two homologous genes as a possible cause for the formation of 46,XX, SRY+ males [Tar et al 1995, Aleck et al 1999, McElreavey and Fellous 1999]. We were referred two phenotypically normal males due to infertility. The clinical examination was normal except for micro-orchidism, which has been described [Margarit et al 1998]. Chromosomal analysis with GTG banding revealed a 46,XX karyotype in both cases. FISH analysis with a cocktail probe for the SRY gene and the X centromere (Vysis) identified the presence of the SRY gene in both cases. The karyotypes were revised to 46,XX.ish t(X;Y)(p22.3;p11.3)(DXZ1+,SRY+). Studies are under way to determine the orientation of the inversion polymorphism in the paternal Y chromosomes. It is through such studies that a clearer understanding of sex determination can be obtained.

**Two Cases with Xp Deletions: Characterization Using Subtelomeric FISH Probes.** *D.I. Quigley, K.A. Kaiser-Rogers, M.I. Roche, C.M. Powell.* Depts of Pathology and Pediatrics, Univ North Carolina, Chapel Hill, NC.

Chromosome specific subtelomeric FISH probes are useful in the ascertainment of cryptic rearrangements involving chromosome ends. These probes may also be beneficial for identification of complex rearrangements that appear, by G-banding, to be simple cytogenetic aberrations. We report two cases in which subtelomeric FISH probes (Vysis ToTelVysion) identified a cryptic deletion and a complex rearrangement of the X chromosome, respectively. The first case is a female patient with mild mental retardation and multiple minor anomalies who was approximately 14 weeks pregnant at the time of her referral. Karyotype analysis, fragile X testing and FISH for DiGeorge syndrome yielded normal results. A subtelomeric FISH assay revealed a deletion of the Xp subtelomeric region. Additional FISH studies indicated no deletion of the steroid sulfatase (STS) or Kallmann genes. Thus the Xp deletion identified in this patient lies distal to the STS gene and is cryptic. Since the Xp subtelomeric region is reportedly polymorphic, we do not know if the deletion in this patient represents a polymorphism without clinical significance. Parental karyotypes have been requested. The second case is a female who was referred for short stature, hypothyroidism, renal problems and a history of failure to thrive. Cytogenetic analysis revealed a large Xp deletion, 46,X,del(X)(p11.2?3). FISH for subtelomeric sequences was performed to determine if the deleted X chromosome contains material from another chromosome. FISH analysis revealed hybridization of the Xq, rather than the Xp, subtelomeric probe to the p-arm of the deleted X chromosome. None of the subtelomeric probes hybridized to the q-arm of the deleted X chromosome. This result suggests that the abnormal X chromosome observed in this patient carries a terminal deletion of the p-arm as well as a large pericentric inversion. Our studies underscore the versatility and value of the subtelomeric FISH probes. These probes are not only useful in indentifying cryptic rearrangements, but also in characterizing seemingly simple cytogenetic aberrations.

**Delineation of phenotype resulting from an unbalanced complex chromosomal rearrangement t(6;15;7)**

**(p11.2;q26.1;p15.3).** *S.Kim. Tan<sup>1</sup>, Y.S. Choy<sup>1</sup>, A. Othman<sup>1</sup>, S.K. Ten<sup>2</sup>, M.Z. Norzila<sup>1</sup>.* 1) Cytogenetics, Kuala Lumpur Hospital, Kuala Lumpur, Malaysia; 2) Cytogenetics, Institute of Medical Research, Kuala Lumpur, Malaysia.

Complex chromosomal rearrangements (CCR) resulting from three way translocation are rare. Most of the three way CCRs are usually familial and transmitted through the mother. Here we describe two siblings with unbalanced karyotype inherited from a 28 year old G4P2A2 mother who has an apparently balanced three way translocation 46,XX,t(6;15;7)(p11.2;q26.1;p15.3) and relatively normal phenotype except for preauricular pits. The CCR were identified using high resolution karyotyping and fluorescence in situ hybridization/whole chromosomal painting. Both the siblings had partial trisomy 7pter-15.3 and a deletion of 15q26.1-qter. Both of them have proportionate short stature and dysmorphic facies characterized by macrocephaly and prominent forehead, large anterior fontanel with delay closure, hypertelorism, strabismus, short palpebral fissure, preauricular ear pits with low set ears, micrognathia and short neck. There were prominent fetal pads of the finger tips. Both had umbilical hernia and single café au lait spot. One of them had patent ductus arteriosus and pulmonary stenosis while the other had hyperactive airway disease. Both had moderate degree of global developmental delay, generalized tonic-clonic epilepsy, central hypotonia and incoordination. MRI of the brain revealed dysgenetic corpus callosum with septum pellucidum, increase extra-axial space and slightly hypoplastic cerebellum. Similar features were found in one of their uncle and one of their cousin brothers on maternal side of family, the mother of whom also had preauricular ear pits.

**Chromosomal instability in a family with a paternal  $der(1)inv(1)(q25.1q31.1)inv(1)(q32.3q42.3)$ .** *D.J. Tomkins, N.J. Leonard.* Medical Genetics, University of Alberta and Stollery Children's Health Centre Edmonton, Alberta, Canada.

A family with unusual chromosomal instability was identified through a proband with global developmental delay, failure to thrive and mild dysmorphism. She was found to have an abnormal chromosome 16 with extra chromosomal material in the long arm. Her mother, who had mild dysmorphism and learning difficulties, carried the same chromosomal rearrangement, but it was not found in either of the mother's parents. However, the mother's father had an abnormal chromosome 1 which appeared to be balanced. He passed this chromosome on to a phenotypically normal daughter, but another daughter had an abnormal chromosome 1 with extra chromosomal material in the long arm which she passed on to two sons. These three individuals had minor dysmorphic features and developmental delay. All of the individuals with normal karyotypes had normal phenotypes.

FISH with a multiprobe device for all whole chromosome paints (Cytocell OctoChrome) showed that the unbalanced rearrangement of chromosome 1 was a duplication of chromosome 1 material. The paternal chromosome 1 was also entirely painted with a whole chromosome 1 paint. Therefore, the balanced paternal chromosome 1 rearrangement was interpreted as a derived chromosome 1 with two inversions in the long arm:  $der(1)inv(1)(q25.1q31.1)inv(1)(q32.3q42.3)$ . The abnormal karyotype in his daughter and two grandsons was an inverted duplication of chromosome 1 q32.3 to q42.3. The chromosome 16 rearrangement was also an inverted duplication, of chromosome 16 q12.1 to q21. The phenotype-karyotype correlations confirmed the interpretations of the unbalanced chromosomes as duplication chromosomes.

The occurrence of different inverted duplications in two offspring of a carrier of a balanced chromosomal rearrangement is unusual. The duplication 1q cannot be explained by simple recombination, but could have arisen by an abnormal recombination event at the site of an inversion loop formation. The duplication 16q could also have occurred by an abnormal recombination event. It is possible that an abnormality in recombination or repair led to the chromosomal instability observed in this family.

**Y chromosome abnormalities in two patients with congenital diaphragmatic hernia.** *C.M. Powell<sup>1</sup>, K.W. Rao<sup>1,2</sup>*. 1) Div Genetics & Metabolism, Department of Pediatrics, UNC-Chapel Hill, Chapel Hill, NC; 2) Department of Pathology, UNC-Chapel Hill.

Congenital diaphragmatic hernia (CDH) is a developmental field defect with causal heterogeneity. It has an incidence of 1/3500 births and approximately 1000 infants are born with it each year in the U.S. It comprises 8% of all major congenital anomalies. There is a high rate of morbidity and mortality with reported survival rates ranging from 25-83% (average 60%). Chromosomal syndromes with CDH include trisomy 13, 18 and 21, tetrasomy 12p, monosomy 1q32-42, and monosomy 15q24-26. There have been rare reports of patients with Turner syndrome and diaphragmatic hernia. Abnormalities of the Y chromosome have not been reported. We report two unrelated patients with CDH and sex chromosome mosaicism with cell lines containing a structurally abnormal Y chromosome. Patient 1 is a phenotypic male with 45,X/46,X ring Y mosaicism found in amniocytes and peripheral blood. FISH revealed the presence of SRY and DYZ2 on the ring. In addition to a left CDH, the patient had a jejunal stricture and atrial flutter. Growth and development at age 12 months were normal. Patient 2 had a left CDH, coarctation of the aorta, genital abnormality with enlarged labia majora and clitoris, a unilateral multicystic dysplastic kidney and pedal edema. Chromosome analysis of peripheral blood revealed 45,X in 103/105 cells. Two cells had 46 chromosomes with an isodicentric Y chromosome confirmed by FISH analysis using SRY. This chromosome consists of 2 copies of the Y short arm, 2 centromeres, and 2 copies of the Y proximal long arm. At age 6 months she has symmetric growth retardation, microcephaly, and global developmental delay.

Deletions of Yp or Yq are not typically associated with congenital anomalies. A structurally abnormal Y chromosome may increase the risk for CDH when combined with a 45,X cell line. Due to the risk of gonadoblastoma it is important to search for a Y chromosome in patients with 45,X, but the presence of CDH should prompt a more extensive search including FISH analysis of interphase cells to look for low-level mosaicism.

**Unexpected positioning of subtelomeric DNA probes in balanced chromosome anomalies: potential effects on chromosome pairing and clinical consequences.** *P.N. Rao<sup>1</sup>, M.J. Pettenati<sup>2</sup>, P. Mowrey<sup>3</sup>, K.M. May<sup>4</sup>*. 1) Univ California at Los Angeles,CA; 2) Wake Forest Univ School of Medicine,NC; 3) Laboratory Corporation of America,NC; 4) Emory Univ School of Medicine,GA.

Molecular cytogenetic analyses with subtelomeric DNA probes provide a finer examination of cryptic chromosome rearrangements. Balanced anomalies generally have no direct clinical implications. Routine FISH analyses using subtelomeric probes identified unexpected results in 4 of 6 normal individuals with apparently balanced chromosome anomalies and a history of miscarriages and/or abnormal outcomes. The breakpoints in one chromosome occurred at or near the telomere. Three cases were reciprocal translocations: t(9;11)(q12;q25); t(4;15)(q21;q26.3);t(11;16)(p15.5;q22); and one a paracentric inversion :inv(4)(q33q35.2). In Case 1, FISH with chromosomes 9 and 11 dual-color subtelomere probes (VYSIS) showed both 11q and 9q specific probes on the long arm of the rearranged 11. There was no evidence of the 11q probe at 9q12. Similarly, in Case 2, the rearranged 15q had both 15q and 4q subtelomere probes, while the reciprocal chromosome 4 had no subtelomere signals at 4q21. In Case 3, the rearranged 11p had signals from both 11p and 16q subtelomeric probes. In each of these cases, one of the involved chromosomes lacked a subtelomere. In the paracentric inversion case, the subtelomeric 4q probe was identified within the q-arm at 4q33. Thus while the rearrangements were apparently balanced and present in normal individuals the FISH results were unexpected. Whole chromosome paint probes failed to detect this apparent imbalance. Chromosomal terminal regions are unique, rich in genes, show relatively elevated meiotic recombination, and are the first regions to pair at the onset of meiosis. So the relocation and hence chromosomal loss of a subtelomeric region could possibly disrupt chromosome pairing and have an effect on gamete production. Our serendipitous finding of an unusual relocation of subtelomeric probes in 4 cases with terminal band chromosome rearrangement regions and abnormal reproductive histories may suggest that such individuals may be at an increased risk for miscarriages and/or abnormal outcomes.

**Subtelomeric Testing: "Don't Leave Clinic Without It".** *E.H. Zackai, I.D. Krantz, J.E. Ming, K.W. Gripp, P. Kaplan, L. Bason, L. Celle, K.L. Russell, D.M. McDonald-McGinn, N.B. Spinner.* Division of Human Genetics and Molecular Biology, The Children's Hospital of Philadelphia, Philadelphia, PA.

From a multi-center study in the UK, deVries et al. (J Med Genet 38:145, 2001) identified 29 patients with a submicroscopic subtelomeric rearrangement (SSR). They suggested that significant preselection criteria for SSR studies include: IUGR and a family history of mental retardation (MR). However, 35% of their patients would have been missed if only those indicators were used for selection. They then suggested a five category scoring system to guide the selection of cases: 1) IUGR, 2) a family history of MR, 3) post-natal growth differences, 4) facial dysmorphism, and 5) congenital anomalies (with a maximum of 2 points for each category and a maximum total of 10 points). Using a minimum score of 3, all of their cases of SSR would have been pre-selected and 20% of cases with MR could have been excluded from testing. Based on these studies, we performed a retrospective review of our own SSR cases (12) at The Children's Hospital of Philadelphia utilizing the deVries checklist. The rearrangements included the following subtelomeric deletions: 1p (4), 6p, 9q, 10p, 11q (2), and 20q; and duplications of 16p and 5q. After diagnosing two patients with 1p deletion, another with a similar phenotype was targeted for 1p studies. Of note, only 1 patient had IUGR and 3 had a positive family history of MR. Utilizing the two significant preselection parameters of deVries, two-thirds of our cases would have been missed. On the deVries checklist, using a minimum score of 3, 4 of our 12 cases would have been missed. Based on these findings, it is our impression that a patient whose findings prompt a high-resolution karyotype also deserves one that rules out SSR. We advise using no preselection criteria for patients with a "chromosomal phenotype". Furthermore, as additional cases are identified and reported, specific phenotypes may emerge which could potentially lead to targeted SSR studies.

**Clinical Frequency of Chromosomal Abnormalities Observed in a Consecutive Series of Patients with Autistic Disorder.** *C.M. Wolpert<sup>1</sup>, S.L. Donnelly<sup>1</sup>, H.L. Abel<sup>1</sup>, S.A. Ravan<sup>2</sup>, H.H. Wright<sup>2</sup>, R.K. Abramson<sup>2</sup>, G.R. DeLong<sup>2</sup>, M.L. Cuccaro<sup>2</sup>, M.A. Pericak-Vance<sup>1</sup>.* 1) Dept Medicine, Duke Univ Medical Ctr, Durham, N.C; 2) University of South Carolina Columbia, S.C. 29208.

Numerous reports cite the co-occurrence of AutD with various chromosome anomalies suggesting the potential of a causal relationship in a subset of cases. We examined the frequency of chromosome anomalies in 333 AutD patients consecutively ascertained for a genetic research study. These 333 AutD patients came from 99 multiplex and 127 singleton families. All the research participants had their diagnosis confirmed using the Autism Diagnostic Interview-Revised (ADI-R) and were included in this analysis if they met the strict diagnostic criteria for AutD. 32% (N=106) of the AutD individuals had had chromosome analysis done as part of their medical evaluation. Seven different chromosomal anomalies were observed in 7 independent families. The anomalies included: 18q- (3 patients); de novo, partial duplication of 7p, familial paracentric inversion of 7q, inv (7q) (q22.1-q31.2); XO; 2q- (1 patient); familial 13;14 Robertsonian translocation; and isodicentric chromosome 15 anomalies (5 patients). In one family, 4 members carried the chromosomal anomaly inv (7q) (q22.1-q31.2), but only the two male children met strict diagnostic criteria for AutD. In a second family, the Robertsonian translocation was maternally transmitted with only the son being affected. The remaining chromosomal anomalies, observed only in singleton families, were de novo occurrences in the affected individual. Here we report the clinical, developmental, and cytogenetic results of these individuals and compare them with the remaining AutD patients who had no chromosomal anomaly identified.

**A Case Report of a Complex Chromosomal Rearrangement Consisting of a Four-Way Non-Reciprocal Balanced Translocation.** *T.L. Prosen, U. Surti, W.A. Hogge.* Dept Genetics, Magee Womens Hosp, Pittsburgh, PA.

We report a case of a phenotypically normal patient with a de novo complex chromosomal rearrangement consisting of a four-way non-reciprocal balanced translocation. This 33-year old patient presented to our institution for prenatal care in her second pregnancy. Her first pregnancy had ended in an early spontaneous abortion. Her prenatal course had been uncomplicated until a routine ultrasound at 21 weeks gestation noted a fetal omphalocele. Multiple marker screening had been declined. Amniocentesis was performed and revealed an unbalanced translocation resulting in a partial trisomy 18. 46,XY,der(21)t(18;21)(q21.1;p11.2). The couple opted to terminate the pregnancy and underwent labor induction at 22 weeks gestation. The stillborn male fetus had an omphalocele, but no other gross structural abnormalities. Autopsy was declined. Maternal karyotype revealed a complex chromosomal rearrangement consisting of a four-way non-reciprocal balanced translocation. 46,XX,t(4;15;18;21)(q12;q11.2;q21.1;p11.1). Karyotypes were obtained on the parents of the patient and were found to be normal. Since that time, the patient has had two pregnancies that have both resulted in spontaneous abortion. The first of these pregnancies spontaneously aborted at 6 weeks gestation. No tissue was available for karyotyping. The second was a missed abortion identified at 9 weeks 0 days gestation. An ultrasound showed a crown rump length consistent with 7 weeks 5 days gestation without cardiac activity. Dilation and curettage was performed and tissue was sent for fetal karyotype but grew very poorly. A single cell was able to be analyzed but there was significant overlap of the chromosomes. A Y chromosome was visualized. Only one of each of the translocated chromosomes could be identified.

**Identification of a familial interstitial 13q deletion passed from an unaffected father to a daughter with cardiac malformations.** *J. Winters*<sup>1</sup>, *K. Brookhyser*<sup>2</sup>, *M. Lipson*<sup>2</sup>. 1) Genetics Department, Kaiser Permanente Northern California, San Jose; 2) Sacramento.

Deletions and duplications of euchromatic material in humans are almost always associated with anatomic and phenotypic abnormalities, developmental delays, and even reduced lifespan. However, there are reports of various gains and losses of genetic material from several chromosomes which are familial and whose carriers have no apparent problems related to the extra or missing material.

We describe a female infant delivered prematurely to a 32-year-old G5P2SAB2TAB1 woman with pregnancy-induced hypertension. The baby was intubated due to meconium and, other than fused eyelids, appeared normal at birth. On day three, she was noted to have a murmur and was diagnosed to have patent ductus arteriosus, ventricular septal defect, and atrial septal defect. Blood chromosome analysis was performed, but the chromosome morphology was extremely poor. A deletion within the long arm of chromosome 13 was suspected, and a repeat analysis confirmed it. The karyotype was determined to be 46,XX,del(13)(q21.2q22). Studies of parental blood chromosomes revealed that the 24-year-old father had an identical-appearing deletion. FISH was performed with a whole chromosome painting probe (Vysis, Inc.) for chromosome 13 to rule out an interchromosomal rearrangement. No other chromosome was found to contain chromosome 13 material, confirming the interstitial nature of this deletion. He is reportedly normal, although he carries the diagnosis of attention deficit hyperactivity disorder. The proband underwent surgery to repair her heart defects at 3 months of age and died shortly after surgery due to respiratory failure.

Cases such as this one cloud the prognosis of an individual in whom a deletion or duplication has been found. Even confirming the familial nature of the rearrangement may not assure the absence of structural anomalies or developmental delays. Possible explanations for the inconsistencies observed in this father and daughter and a review of the literature will be presented.

**Evaluation of MAPH for the determination of subtelomeric deletions.** *E.A. Sistermans<sup>1</sup>, W.M. Nillesen<sup>1</sup>, C. Van Ravenswaaij<sup>1</sup>, D. Smeets<sup>1</sup>, H.G. Brunner<sup>1</sup>, E. Hollox<sup>2</sup>, J.A.L. Armour<sup>2</sup>.* 1) Dept Human Genetics, Univ Medical Centre Nijmegen, Nijmegen, Netherlands; 2) Institute of Genetics, University of Nottingham, Queen's Medical Centre, Nottingham, United Kingdom.

Sub-telomeric deletions are a frequent cause of mental retardation. Fluorescent in situ hybridization (FISH) is currently the most widely used technique for the detection of these deletions. Unfortunately, even when all probes are tested in parallel, this technique is time-consuming and does not allow a cost-effective analysis of the large numbers of patients that are generally sent in for routine analysis to a diagnostic service. Multiplex amplifiable probe hybridization (MAPH) is a new technique for the determination of locus copy number that does allow the analysis of large numbers of patients for tens of loci at the same time. Patient DNA is first hybridized with a set of amplifiable probes, followed by amplification of all probes using common flanking primers. Analysis of the resulting peaks, which differ in length for each probe, allows the detection of deletions and duplications. To establish the reliability of MAPH for the detection of sub-telomeric deletions, we tested the technique on a panel with 30 patients with chromosomal abnormalities that included sub-telomeric regions. First results on a limited number of patients show that all abnormalities were correctly identified. Most strikingly, a very small deletion of 17q was identified in a patient with a known duplication of this chromosome arm as detected by FISH analysis, demonstrating the presence of a deletion/duplication event.

**Small interstitial 4q21 deletion that appears to create hemizyosity for PKD2 gene (polycystic kidney disease, type II).** *M.T. Velinov<sup>1,2</sup>, J. Kupferman<sup>1</sup>, S. Barrett<sup>1</sup>, D. Rosa<sup>1</sup>, M.J. Macera<sup>3</sup>, A. Babu<sup>3</sup>, G. Kupchik<sup>1</sup>*. 1) Department of Pediatrics, Maimonides Medical Center, Brooklyn, NY; 2) Department of Cytogenetics, NYS Institute for Basic Research, Staten Island, NY; 3) Department of Molecular Medicine and Genetics, Wyckoff Heights Medical Center, Brooklyn, NY.

We report a 3-year-old boy with severe development delay and dysmorphic features: hypertelorism, large head with frontal bossing, broad flat nasal bridge, up-slanting palpebral fissures, simple external ears. The patient also had short and mildly contracted fingers with mild interdigital webbing. He was born post term, with perinatal hypoxia. The birth weight was 5 lbs and 13oz. The family history was unremarkable. He had motor and cognitive developmental delay since birth. This patient was found to have large complex cyst in his right kidney and multiple small cysts bilaterally. He underwent surgical excision of the large renal cyst. He also presented with neurological abnormalities: arachnoid cyst, muscle hypotonia and increased DTR. He had two episodes of bowel obstruction for which surgical intervention was necessary. His ophthalmological exam was unremarkable. G-banding chromosome analysis revealed an abnormal karyotype with a small interstitial deletion of the long arm of chromosome 4 with most likely breakpoints at 4q21.1 and 4q21.3 - karyotype 46,XY,del(4)(q21.1q21.3). Our patient presented with dysmorphic features, similar to the ones observed in previously reported cases with 4q21-q23 chromosomal deletions (Nowaczyk et al. Am J Med Gen, 69:400, 1997). Other previously reported phenotypic associations, with proximal 4q deletions, absent in our case include Rieger anomaly (associated with more distal deletions) and piebaldism (probably result of more proximal deletions). In contrast our patient had kidney abnormalities consistent with Adult Polycystic Kidney Disease. The gene for Adult Polycystic Kidney Disease PKD2, has been mapped to chromosome region 4q21-4q23 (MIM#173910). We suggest that our patient's hemizyosity for PKD2 explains his renal findings. We are planning further molecular studies to better define the extent of this microdeletion.

**Molecular characterization of a satellited chromosome 22 in a patient with mental retardation and no dysmorphic features.** *V.R. Pulijaal<sup>1</sup>, S.K. Gogineni<sup>1</sup>, S.J. Gross<sup>1</sup>, D. Iacoboni<sup>2</sup>, R.W. Marion<sup>3</sup>, A. Shanske<sup>3</sup>.* 1) Dept OB/GYN, Albert Einstein Col Medicine, Bronx, NY; 2) Jacobi Medical Center, Bronx, NY; 3) Dept. of Pediatrics, Montefiore Med Ctr, Bronx, NY.

Satellited nonacrocentric chromosomes are derived from the translocation of the nucleolus organizer region( NOR ) of acrocentric chromosomes and are generally considered to be of no clinical significance but there are some reported cases with variable phenotypes and reproductive outcomes. We report a 20-year-old male with hypotonia, seizures, ear anomalies, mental retardation and delay in expressive speech. High resolution chromosome studies revealed a 46,XY,22qs karyotype . Molecular characterization of satellited chromosome 22 revealed a subtelomeric deletion of 22q telomere using a 22q subtelomeric probe i.e., 46,XY,22qs.ish del(22)(q13.33)(pVYS207M-). The mother has a normal 46,XX.ish 22q13.33(pVYS207x2) chromosome complement and the father was not available for testing. Further molecular studies are in progress to investigate any genotype/phenotype correlations of the 22q subtelomeric deletion in this patient, and also to verify a possible causal role of the ribosomal gene position effects in the 22q13 region.

**Comparison of whole chromosome painting probes and telomeric region probes in identifying *de novo* chromosomal duplication.** C.W. Yu<sup>1</sup>, H-G. Bock<sup>1</sup>, F.G. Megason<sup>2</sup>, M.H. LeBlanc<sup>2</sup>, P.G. Rhodes<sup>2</sup>. 1) Dept Preventive Medicine; 2) Dept Pediatrics, Univ Mississippi Medical Ctr, Jackson, MS.

The addition chromosomal material of unknown origin, especially in the *de novo* cases, provides challenges for cytogenetic diagnosis. Identifying the extra chromosomal material would add valuable information for genetic counseling and patient treatment. We present here three cases of *de novo* chromosome duplication and compare the diagnostic value between the whole chromosome painting (wcp) probes and the telomeric (telo) region probes. **Case 1.** SM, a female newborn, referred for chromosome study because of clinical features of flat nasal bridge, unilateral hernia and signs of Down syndrome. Cytogenetic study revealed an abnormal 9 with extra chromosomal material on the short arm. WCP probe indicated that the extra material was from chromosome 9. Telo region probe identified the duplication as an inverted terminal duplication. Karyotype is 46,XY, dup(9)(p24p13). **Case 2.** BN, a male newborn, referred for chromosomal study because of MCA. Clinical features include unilateral cleft lip, cleft palate, brachycephaly, and clubfoot. G- and C-banding revealed that this patient had an extra dicentric marker chromosome. WCP probe revealed that this marker was derived from chromosome 9. Telo region probes identified the marker as an iso-9p. Karyotype is 47,XY,+idic(9)(q12). **Case 3.** KD, a 2.5-year-old girl, referred for chromosome study because of mild dysmorphism and developmental delay. Clinical features include upward slanting palpebral fissures, flat nasal bridge, short philtrum and capped teeth. G banding revealed an abnormal X chromosome with additional material on the long arm. WCP probe demonstrated the extra material was from an X chromosome. Telo region and locus specific probes revealed a duplication of Xp11.23 to Xpter and a deletion of Xq27.1 to Xqter.

For the study of *de novo* chromosome duplication, the telomeric probes seem to provide more information than the wcp probes towards chromosome identification. With the addition of proper unisequence DNA probe(s), the *de novo* duplicated segment can be properly identified.

**Pure Partial Trisomy of Chromosome 2q22-q23 Secondary to a Paternally Inherited Direct Insertion.** A. Sajoo, M.D. Speevak, S.A. Farrell. Genetics, The Credit Valley Hospital, ON, Canada.

We report the smallest duplication of 2q to date resulting in pure partial trisomy in a male infant who presented at 2 weeks with minor congenital anomalies and facial dysmorphism. BW was 50<sup>th</sup> centile, height and OFC were below the 10<sup>th</sup>. The infant had hypospadias and right foot post-axial polydactyly. Tone was normal. Developmental delay was apparent by 5 months. Echocardiogram, renal and head ultrasounds were normal. Family history was unremarkable. The infant's G-banded chromosomes showed 46,XY,der(5)ins(5;2)(q22;q22q23). This karyotype was paternally derived. Maternal chromosomes were normal. Commercially available microdissected band-specific FISH probes confirmed the direct insertion of bands 2q22-q23. Three other individuals with pure partial trisomy 2q encompassing this region have been reported, none of whom survived. All three were larger *de novo* duplications causing structural CNS and renal anomalies, and a variety of dysmorphic facial features including a prominent forehead. Complex congenital cardiac anomalies and either polydactyly or abnormal toes were noted in two cases of dup(2)(q21q33), but not in the case of dup(2)(q21q31). Common to all were low set ears and hypoplastic genitalia or hypospadias. Our case can be differentiated from the other reports by its viability, the absence of structural CNS, cardiac, and renal anomalies and the presence of a receding forehead. Ascertainment of this small insertion was through a liveborn with anomalies, which implies the recurrence risk for other carriers in this family could be up to 50% (Gardner & Sutherland, 1996). The duplicated segment in our case comprised only 0.61% of total HAL (haploid autosomal length), suggesting equal segregation ratios for balanced and unbalanced progeny. A private segregation analysis could be provide if paternal relatives are found to have this rearrangement.

**Use of M FISH, painting probes, and subtelomeric probes in refined Cytogenetic diagnosis.** *A. Salvador<sup>1</sup>, G. Sekhon<sup>2</sup>, S. Jalal<sup>3</sup>, K. Thompson<sup>2</sup>, D. Wargowski<sup>2</sup>.* 1) Dept. of Ob/Gyn, St. Johns Mercy Medical Center, St. Louis, MO; 2) Div Clinical Genetics, Waisman Center, University of Wisconsin, Madison, WI; 3) Cytogenetics Lab, Mayo Clinic, Rochester, MN.

We have utilized M FISH and subtelomeric probes along with conventional cytogenetic analysis to improve the ability of cytogenetic diagnosis. Five patients were initially detected using prometaphase G banding analysis. The first case had additional material on the short arm of chromosome 20, the second case had a duplication of the short arm of chromosome 8, the third case had additional material on the short arm of chromosome 4, the fourth case had a possible duplication or insertion in the long arm of chromosome 1, and the fifth case had a supernumerary marker chromosome. In the first case, M FISH showed that the extra euchromatic material on 20p was from chromosome 8. In the second case, M FISH showed that the duplicated material was from chromosome 8. Further analysis with subtelomeric probes showed that the 8pter probe was absent. In the third case, painting probes showed that the extra material was from chromosome 4. The fourth case by painting probe revealed a duplication of part of the long arm of chromosome 1 and the maternal karyotype showed a direct within-arm intra chromosomal insertion in chromosome 1. The fifth case of supernumerary marker chromosome was from a prenatal diagnosis. The M FISH was uninformative since the marker had no euchromatic material and this would be expected. The use of alpha and beta satellite probes showed that the marker was derived from 14 or 22. The results contributed to the counseling and the parents chose to continue the pregnancy. These strategies are particularly useful in characterization of de novo rearrangements or in cases where parental studies are not possible. These studies indicate that molecular cytogenetic studies applied in a systematic fashion can aid in the cytogenetic diagnosis and clinical management.

**Subtelomere Analysis of 270 Cases Referred for Nonspecific Idiopathic MR and/or Nonspecific Mild Dysmorphic Features.** *J.H. Tepperberg, I.K. Gadi, P.N. Mowrey, K.K. Phillips, P.F. Stone, S.K. Griffin, C.J. Bullen, P.R. Papenhausen.* Dept Cytogenetics, Laboratory Corp of America, Res Triangle Pk, NC.

Subtle subtelomere chromosome alterations are reported to occur in 7.4% of children with moderate to severe MR (Knight et al., 1999). Our center received 270 cases for subtelomere FISH testing with the majority of patients referred for nonspecific idiopathic MR and/or nonspecific mild dysmorphic features. G-band analysis was performed concurrently with or prior to the FISH analysis. Fourteen patients were found to have a terminal rearrangement (14/270 = 5.2%). Three of the 14 cases were found to have a 2qter deletion, which in all cases were shown to be familial chromosome variants. This essentially reduces the yield to 4.1% (11/270). Eight of the 11 patients had apparent terminal deletions (no extra subtelomere signal) for chromosomes 4p, 10q, 13q, 22q, 22q, 22q, Yq, and Yq. Absence of a non-homologous subtelomere signal on the deleted chromosome is likely to correlate with a de novo deletion, but translocations of a reciprocal site distal to the subtelomere probe site would have a significant recurrence risk and can only be detected by parental studies. Two of the 11 patients inherited unbalanced derivative translocation chromosomes, der(18)t(4;18) and der(10)t(8;10) (2/11 = 18.1%). One of the 11 cases, referred for subtelomere analysis only, showed two X and two Y chromosomes consistent with a follow-up 48,XXYY karyotype. In reviewing the G-banded chromosomes, 7 cases, the der(18), the der(10), the three 22qter's, and the two Yqter's could be described as truly "cryptic". Three cases had apparent deletions; 4p-, 13q- and 10q-. It is unclear at this time whether the deletion Yq's are significant. The 4.1% of cases with a subtelomere alteration is lower than the figures reported by Knight et al., and Slavotinek et al., (7.5% J Med Genet 1999) and closer to the 4.9% figure reported by Lamb et al. (Abst ACMG 2001). Removing those cases which we describe as visibly identifiable, we calculate a lower percentage of cases with a "cryptic" subtelomeric alteration (6/270 = 2.2%), although a focused analysis could alter what is considered visible.

**Cryptic terminal deletions: Are they precursors to chromosome rearrangements?** *K.S. Reddy, X. Yang.* Dept Cytogenetics, Quest Diagnostics, Inc, San Juan Capist, CA.

For the first time we report two cases with chromosome rearrangements probably subsequent to a submicroscopic terminal deletion. The first case had a 46,XX,der(1)t(1;9)(p36.3;p13).ish der(1)(wcp9+)[88]/46,XX[12] karyotype. Mother has normal chromosomes the father is not available. A FISH scrutiny using wcp9, 1ptel and pan telomeric probes found a subtelomeric 1ptel deletion on the der(1) and on a chromosome 1 in the apparently normal cell line. The telomere (TTAGGG)<sub>n</sub>, however, was present on both copies of chromosome 1 in the apparently normal and abnormal cell lines. The unexpected subtle terminal deletion was detected by FISH when the abnormality was teased apart to draw a genotype to phenotype correlation. The second case had a de novo 46,X,der(X)t(X;22)(p23;q11.2),inv dup(22)(q11.2)[85]/45,X,der(X)t(X;22)(p23;q11.2),-inv dup(22)[15] karyotype. The complex rearrangement was further assessed using FISH paint probes for chromosomes X and 22, TUPLE-1/ARSA, BCR/ABL, Xptel, pan telomere, STS and KAL probes. The unexpected finding was a terminal deletion of Xpter distal to the KAL gene. The mechanism involved in the generation of these two rearrangements is probably initiated by a pre-zygotic terminal deletion. Case 1: a deletion of chromosome 1p36.3 in the zygote was followed by a somatic telomere healing of one deleted chromatid and a recombination between the other deleted 1p36 and 9p chromatids. The only two lines that survived were the original subtelomeric deletion of chromosome 1 cell line and the der(1) cell line. Case 2: Possibly during meiosis, a terminal deletion of Xp23 was stabilized by a recombination between X and chromosome 22. The inv dup(22) was formed by an U-type exchange. A second cell line was derived by a post-zygotic loss of the inv dup(22). These two cases suggest that terminal deletions are prone to recombination with another chromosome/chromatid if they do not heal with a telomere (TTAGGG)<sub>n</sub> cap.

**A novel method to detect parental origin of rea(21q21q).** *B.B. Wang<sup>1,2</sup>, W.L. CHEN<sup>1</sup>, H.C. LU<sup>1</sup>, L.J. HSIEH<sup>1</sup>, M.H. LEE<sup>1</sup>, C.J. GUO<sup>1</sup>.* 1) Department of Medical Research and Education, Changhua Christian Hosp, Changhua, Taiwan; 2) Department of Laboratory Medicine, Changhua Christian Hosp, Changhua, Taiwan.

Historically, homologous rearrangements of 21q have been termed Robertsonian translocations. This implies a translocation between two different chromosomes. Traditional cytogenetic methods can not distinguish between a true Robertsonian translocation and an isochromosome involving 21q. However, using molecular polymorphisms and Southern blotting hybridization, the majority of rea(21q21q) have been recently shown to be isochromosomes, of which parental origins were equally divided between two parents (Shaffer et al, 1993). In this study, we developed a novel non-radioisotope labeling method and successfully identified the parental origin of rea(21q21q) in a patient with Down syndrome. We used a panel of 8 highly polymorphic microsatellite markers for chromosome 21 and 8 internally labeled primer sets for non-isotopic amplification and detection. Unlabeled primer sets of DNA markers were extended briefly in the presence of infrared dye (IRD700) -labeled dATP prior to PCR amplification. Without further purification, the amplified products were applied directly to the denaturing sequencing gel, then detected and analyzed with a Li-Cor Model 4200L automatic DNA sequencer. The results revealed that two out of the 8 markers were informative and parental origin of the rea(21q21q) chromosome was maternal. This non-isotopic detection system has proven to be effective and straightforward in determining parental origin of homologous arrangements of 21q.

**Serendipitous detection of low-level somatic mosaicism in the mother of a child with deletion 5p14.2: limitation of "limited studies" in relatives of cytogenetically abnormal individuals.** *P. Van Tuinen<sup>1</sup>, J. Grignon<sup>2</sup>, P. Miller<sup>2</sup>, P. Schalk<sup>2</sup>, M. Emery<sup>2</sup>, C. Brooks<sup>2</sup>, L. Weik<sup>3</sup>.* 1) Medical College of Wisconsin, Milwaukee; 2) Dynacare Laboratories, Milwaukee; 3) Children's Hospital of Wisconsin, Milwaukee.

A child with dysmorphic features and hyperactivity was found to have a deletion 5p14.2. Although this is among the larger deletions seen in Cri-du-Chat syndrome, the child's features were considered surprisingly mild compared to most children with this syndrome. As in our standard work-ups in all such cases of structural rearrangement, a recommendation was made to consider peripheral blood studies of the parents to rule them out as carriers of a balanced rearrangement that may predispose them to bear further abnormal offspring. Several months later the mother was again pregnant, and both parents elected to be tested. For relatives of a bearer of a cytogenetic abnormality, our analysis, as in many cytogenetics labs, is a "limited study" consisting of five metaphase cells, since it is focused on the presence or absence of a known abnormality. The father's study was normal in five cells. In the mother five metaphases chosen randomly for the study were normal. However, the technologist evaluating G-banding had noted deletion 5p, initially considering it a spurious finding in light of the apparently "normal" result. Further searching quickly revealed a second deletion 5p. Nevertheless, in an extended study of 90 metaphases, only 4 were found to bear the deletion. The detection of what proved to be a low level of mosaicism was considered to be opportune and serendipitous. Obviously the probability of detection would have been nearer a certainty in a full standard study of 20 metaphases. While limited studies are valid for working horizontally or downward in a pedigree, our use of limited studies when working upward in a pedigree was brought into serious question with this case.

**Genetic variation in meiotic recombination in the male mouse.** *K.E. Koehler, J.P. Cherry, A. Lynn, J.H. Nadeau, T.J. Hassold.* Department of Genetics, Case Western Reserve Univ, Cleveland, OH.

Studies from model organisms such as *Drosophila* have shown that the frequency of meiotic exchange varies among different genetic backgrounds. Such effects are obviously more difficult to demonstrate in humans, and in mammalian model organisms (e.g., the mouse), conventional linkage analyses cannot be performed in inbred strains. However, recently developed immunofluorescence methodology, involving direct analysis of recombination-associated proteins in pachytene stage meiocytes, now makes it possible to circumvent these obstacles. Specifically, substantial evidence suggests that the mismatch repair protein MLH1 is a component of the late recombination nodule, and the number and distribution of MLH1 foci precisely mimic meiotic exchange patterns. Here we employ this technology to assess recombination patterns in male mice.

We find that among four different inbred strains - SPRET/Ei, C57BL/6, A/J, and CAST/Ei - the mean numbers of autosomal MLH1 foci per cell are significantly different. These means range from a high of 24.9 in SPRET/Ei to a low of 21.5 in CAST/Ei; therefore, in CAST/Ei males, most homologous chromosomes or bivalents are held together by only the single "obligate" crossover rather than multiple exchanges. From our observations of over 10,000 autosomal synaptonemal complexes, we conclude that non-exchange bivalents only rarely arise in the male mouse. We also present evidence suggesting that with advanced age the meiotic process in male mice may begin to break down, resulting in decreasing interference and more variability.

Although genetic background effects have long been suspected, this study provides the first direct, systematic demonstration of genetic variation in meiotic recombination between inbred strains of the laboratory mouse.

**Molecular cytogenetic studies of synapsis and recombination in infertile males.** *S. Mehra*<sup>1,2</sup>, *S. Schwartz*<sup>1,2</sup>, *A. Seftel*<sup>1,2</sup>, *L. Judis*<sup>1</sup>, *E. Chan*<sup>1</sup>, *T. Hassold*<sup>1,2</sup>. 1) Genetics, Case Western Reserve Univ, Cleveland, OH; 2) Univ Hospitals of Cleveland, Cleveland OH.

Application of immunofluorescence methodology to mammalian pachytene preparations now makes it possible to visualize expression of meiotic recombination pathway proteins. This methodology also has potential clinical significance: it seems likely that abnormalities in the recombination machinery are a contributor to infertility. To test this, we have begun to examine pachytene preparations from infertile males. Meiotic preparations from men undergoing testicular biopsies for azoospermia/oligospermia were processed using CREST antiserum to identify kinetochores, and antibodies against SCP3 to identify synaptonemal complexes (SCs) and MLH1 to identify late recombination nodules, the sites of crossing-over. To date, we have analyzed 11 individuals with obstructive azoospermia but with normal spermatogenesis on histology ("Controls") and 5 individuals with non-obstructive azoospermia/oligospermia ("Cases"); individuals were pre-screened to rule out constitutional abnormalities or Yq microdeletions. For most individuals, 50 or more cells were analyzed. There were no obvious abnormalities in pairing/synapsis in any of the 11 controls. However, in 1 of the 5 cases, the normal complement of 23 SCs was replaced by 46 unpaired axial elements, resulting in complete meiotic arrest. This may reflect defects in proteins such as SCP1 that comprise the central portion of the SC; tests are now underway to test this. There were no obvious defects in the remaining 4 cases. However, the mean number of meiotic exchanges per cell, determined by counting MLH1 foci, was slightly but significantly lower than controls. Possibly, disturbances in recombination are a feature of any perturbation of spermatogenesis. Our results suggest that this approach will be useful in characterizing specific meiotic "phenotypes" in infertile males, thus providing an entree to mutation detection analyses. Further, the observation of reduced recombination in some infertile males may provide a reason for the increased rate of aneuploidy frequently seen in sperm of these individuals.

**High resolution mapping of centromeric satellite DNA families** . Y.C. Li<sup>1,3</sup>, C. Lee<sup>2</sup>, T.H. Hseu<sup>3</sup>, S.Y. Li<sup>1</sup>, C.C. Lin<sup>1,4</sup>. 1) Dept Life Sci, Chung Shan Medical/Dental Col, Taichung, Taiwan; 2) Dept. Obstetrics and Gynecology, Brigham and Women's Hospital, Harvard Medical School, Boston, USA; 3) Department of Life Sciences, National Tsing Hwa University, Hsinchu, Taiwan; 4) Dept Laboratory Medicine and Pathology, University of Alberta, Edmonton, Canada.

Centromere is an important domain responsible for proper segregation and transmission of chromosome during mitosis and meiosis. Higher eukaryotic centromeres including those of human comprise of mainly megabases of tandem repeated satellite DNA families. Some of these sequences have been implicated in centromere structure and/or function, but their genomic organizations at large remain uncharacterized due to the repetitive nature and complexity. We have applied multiple color FISH and fiber FISH to analyze the organization of three newly isolated cervid satellite DNA families (cervid sat.I, II, and III) in the centromeric/pericentromeric regions of Chinese water deer (*H. inermis*) chromosomes. Satellite II and satellite I were found to be located at the primary constriction and pericentric region respectively in most of the chromosomes of the complement. Satellite III usually was observed in the acrocentric chromosomes and was located toward to the short arm. The order of these three satellite DNA families appeared as pter - Sat.III - Satellite II - satellite I - qter. These satellite DNAs formed contiguous arrays with satellite I and satellite II juxtaposed to each other. The length of each satellite DNA array in a given centromeric region was also estimated based on the extended chromatin fiber preparation of ~10 kb/mm.

**Toward an analysis of the chromatin structure of the X-inactivation center.** *N. MISE, P. AVNER.* Mouse Molecular Genetics Unit, Institut Pasteur, Paris, FRANCE.

X chromosome inactivation is a chromosome wide phenomenon controlled by a cis-acting element called the *Xic* (X-inactivation center). Recent analysis has suggested that dynamic structural changes in chromatin structure contribute to the action of the *Xic*. To analyze the protein components and the structural change of the *Xic* chromatin during X-inactivation, we are establishing a native *Xic* chromatin isolation protocol from mouse embryonic stem (ES) cells carrying an *Xic* transgene.

As starting material for chromatin isolation, we have established a male BAC based transgenic ES cell line having a functional multicopy arrayed *Xic* transgene. The BAC clone used for the transgenesis covers the reported *Xic* region including the *Xist/Tsix* locus. Because the BAC contains a loxP site in the vector region, tandem arrayed transgenes can be excised in circular form by Cre recombinase. The BAC has been modified to contain a Neo resistant gene cassette allowing stable maintenance in ES cells and was tagged with a lac operator tandem repeat, so that the chromatin of the *Xic* transgene could be purified using a lac repressor protein affinity column taking advantage of the strong and specific binding between the lac operator and lac repressor protein. We have also constructed Cre expression vectors for inducible expression system in ES cells. The pANMerCreMer construct encodes a fusion protein MerCreMer which consists of Cre linked to two mutant mouse estrogen receptor ligand binding domains (Mer). Whilst this fusion protein has no recombinase activity in normal culture condition, the Cre is activated in the presence of the estrogen analogue OH-TAM (hydroxy-tamoxifen). Using this construct, we can synchronously excise *Xic* chromatin in vivo. The excised *Xic* chromatin is extracted from nuclei and is purified from the nuclear extract. Because the nuclear extract will contain many contaminated proteins unrelated to the *Xic* chromatin, a lac repressor protein affinity column has been used for purifying the lac operator tagged *Xic* chromatin. A progress report on our experimental approach will be presented.

**Conservation of FRA3B and FRAXB in the great apes.** *A.M. Loeb, M.F. Arlt, T.A. Morrish, T.W. Glover.*

Department of Human Genetics, University of Michigan, Ann Arbor, MI.

Common fragile sites are loci characterized by gaps or breaks on metaphase chromosomes from cells grown under conditions that inhibit DNA replication. Such conditions have been observed to induce fragile sites in several mammalian species, including dog, cat, pig, horse, cow, Indian mole rat, deer mouse and laboratory mouse. Some fragile sites in these species appear to be at sites homologous to human loci containing common fragile sites, but few direct tests of fragile site homology have been performed. It has been proposed that common fragile sites could play a role in chromosome evolution, as these sites are characteristically unstable after induction, showing increased rates of translocation, deletion and sister chromatid exchange, and are preferred sites for plasmid integration. FRA3B and FRAXB are two extensively studied fragile sites that each span hundreds of kilobases. FRA3B lies within the *FHIT* gene at 3p14.2, and it is known that *FHIT*/FRA3B is frequently deleted and translocated in tumors. FRAXB spans across the *STS* and *GSI* genes at Xp22.3 and is also unstable in some tumors. We have studied expression of FRA3B and FRAXB in several primate cell lines by FISH analysis with YACs known to span these fragile sites in humans. The YAC probes for both FRA3B and FRAXB were observed to cross their respective homologous fragile sites in the three great apes studied, chimpanzee, orangutan and bonobo, as well as in baboon, an old world monkey. Thus, both FRA3B and FRAXB appear to be conserved in these primates. In gibbon, a lesser ape, YAC probes for FRAXB were observed to cross a fragile site; however, probes for FRA3B were not observed to cross a fragile site. RT-PCR analysis indicates that the *FHIT* ortholog is expressed in this gibbon cell line, indicating that the gene is not extensively rearranged. These studies thus show that fragile sites are highly conserved in great apes but suggest that FRA3B may diverge in gibbons or the lesser apes. Furthermore, comparison of the FRA3B region between gibbon and species expressing this fragile site may allow insight into the mechanism of instability.

**A large intragenomic duplication homologous to human chromosome 3p21-24 during hominoid evolution.** *E. Zend-Ajusch, F. Gruetzner, U. Haensel, R. Sudbrack, H.H. Ropers, T. Haaf.* Max Planck Institute for Molecular Genetics, Berlin, Germany.

By hybridizing >80 YACs which are evenly spaced on human (HSA) chromosome 3 to chromosomes of orangutan (*Pongo pygmaeus*, PPY), gibbon (*Hylobates syndactylus*, HSY), Old World monkey (*Presbytis cristata*, PCR), and New World monkey (*Callithrix geoffreyi*, CGE), we have reconstructed the hypothetical ancestral chromosome, which is most similar to PCR 1. Two pericentric inversions each are required to derive HSA 3 and Borneo PPY 2 from this ancestral chromosome. An additional pericentric inversion separates the Sumatra PPY 2 from Borneo PPY 2. HSA 3 and Borneo PPY 2 share four large segments of conserved chromosomal synteny. Two smaller (1-3 Mb) segments have changed their chromosomal position by transposition. Evidently, chromosomal phylogeny is much more complex than suggested by classical chromosome banding and painting studies. We have identified YACs/PACs containing evolutionary breakpoints in HSA 3p25, 3p24.3, 3p13, and 3q21. These regions are also frequently involved in pathological chromosome rearrangements. Two of the evolutionary breakpoints are very close to olfactory receptor genes, which may promote illegitimate recombination between distant regions. Segments homologous to HSA 3 are found on two New World monkey chromosomes, CGE 17 and CGE 19, and on four gibbon chromosomes, HSY 1, HSY 10, HSY 17, and HSY 21. The series of derived chromosome rearrangements (translocations) in gibbon led to a duplication of a large (approximately 20 Mb) segment on HSY 1 and HSY 10. The duplicated segment is homologous to HSA 3p21-24 and contains approximately 100 genes. Smaller segmental duplications comprising only sequences of one YAC from HSA 3p21-24 are found on HSA 1q, PPY 1q and PCR 6q. There is no detectable duplication in the New World monkey. Our results suggest that large intragenomic duplications have occurred during recent primate evolution. Unique segmental duplication of a large number of genes and subsequent divergent mutations may be an important mechanism for acquiring genetic diversity and, thus, drive species evolution.

**A study on the relationship between chromosome polymorphism and reproduction abnormality.** *D.S. Tang<sup>1</sup>, Y.B. Tian<sup>1</sup>, L.H. He<sup>1</sup>, S.Q. Zeng<sup>1</sup>, X.J. Li<sup>2</sup>, W.P. Liu<sup>2</sup>, G. Yang<sup>2</sup>, Z.H. Chen<sup>3</sup>, X.L. Guo<sup>3</sup>.* 1) Dept Animal Sci, Foshan Univ, Foshan, Guangdong People's Republic of China; 2) The First Hospital of Foshan Foshan, Guangdong People's Republic of China; 3) The Women and Children Hospital of Foshan Foshan, Guangdong People's Republic of China.

The relationship between chromosome polymorphism and reproduction abnormality was investigated by comparing chromosome polymorphism group to normal karyotype group. Methods: Blood samples of health examination people with normal phenotype were collected, cell cultured and G-band analyzed. Karyotypes of some samples were analyzed by high-resolution banding. 158 people with chromosome polymorphism were regarded as test group. Control group of 206 people was sampled from other people with normal karyotype. The rates of reproduction abnormality of two groups were compared. The reproduction abnormality included abortion, infertile and baby abnormality, etc. Results: There was 46.8% (74/158) people with reproduction abnormality in polymorphism group and 23.3% (48/206) people with reproduction abnormality in control group. 29.1% (46/158) people had spontaneous abortion in polymorphism group and 15.5% (32/206) people had spontaneous abortion in control group. There was a significant difference between two groups ( $P < 0.01$ ). Half of abortion people had abortion in 2 month pregnancy in polymorphism group, compared to 25% in control group. Discussion: Studies of other groups didn't show the relationship between chromosome polymorphism and reproduction abnormality or cancer. But many doctors found some people with chromosome polymorphism had reproduction abnormality. Having reviewed some studies in other papers, we found these studies compared the rate of polymorphism in abnormal phenotype group with normal phenotype group. The two rates were too low to be compared. We compared the rate of abnormal phenotype in polymorphism group with the rate in normal karyotype group. The results showed that there was a relationship between chromosome polymorphism and reproduction abnormality. The chromosome polymorphism maybe resulted in reproduction abnormality.

**Molecular and cytogenetic characterization of translocations involving 22q11.** *E. Spiteri<sup>1</sup>, R. Goldberg<sup>1</sup>, L. Edelmann<sup>2</sup>, S.W. Gogineni<sup>1</sup>, V.R. Pulijaal<sup>1</sup>, A. Shanske<sup>1</sup>, K. Wakut<sup>3</sup>, C.D. Kashork<sup>3</sup>, L.G. Shaffer<sup>3</sup>, B.E. Morrow<sup>1</sup>.* 1) Albert Einstein College of Medicine/Montefiore Medical Center, Bronx, NY; 2) Mount Sinai School of Medicine, NYC, NY; 3) Baylor College of Medicine, Houston, TX.

Chromosome 22q11 is susceptible to recurrent constitutional rearrangements associated with congenital anomaly disorders. Velo-cardio-facial syndrome/DiGeorge syndrome (VCFS/DGS) is associated with a partial monosomy of 22q11. Offspring of carriers of the constitutional t(11;22) translocation are susceptible to derivative (22) syndrome. These patients carry a supernumerary der(22) chromosome resulting in a trisomy of proximal 22q and distal 11q. Breakpoints for these disorders are clustered in three regions of 22q11 coinciding with low copy repeats (LCR22s) 200 kb in size. Homologous recombination events between LCR22s mediate the 1.5 and 3 Mb VCFS/DGS deletion. The t(11;22) translocation is mediated by AT-rich palindromes in one of the LCR22s (LCR22-3a). Non-recurrent translocations also occur in the 22q11 region associated with congenital anomalies. We have ascertained two such patients, one has a t(1;22) and the second has a t(18;22) whose translocation breakpoints occurred in LCR22-3a, suggesting a common mechanism. To investigate this possibility or to identify other hot spots in the 22q11 region, we are defining the translocation breakpoints in 13 other unrelated translocations by STS and FISH mapping approaches. Identifying the breakpoints will lead to a better understanding of the mechanism of translocation formation and define hotspots for chromosomal breakage leading to rearrangements. In addition, LCR22-3a has not been completely cloned, perhaps due to the presence of the AT-rich palindrome. We are currently mapping this region in non-human primates to determine the evolutionary origin of this unstable region in the genome.

**CGH IN THE EVALUATION OF THE PLACENTA IN ABNORMAL PREGNANCIES.** A. Amiel<sup>1,2</sup>, N. Bouaron<sup>2</sup>, M. Fejgin<sup>1,2</sup>, E. Gaber<sup>1</sup>, R. Sharony<sup>1,2</sup>. 1) Genetic Institute, Meir General Hosp, Kfar-Saba; 2) Sackler School of Medicine, Tel-Aviv University, Israel.

Comparative genomic hybridization (CGH) is a FISH related technique used to assess global chromosomal aberrations in variety of human tumors. Recently CGH has been utilized for cytogenetic analysis of fresh, frozen and paraffin embedded feto-placental tissues. We applied CGH technique to samples taken from various sites of placentas originating from abnormal pregnancies (IUGRs, fetal malformations, toxemia, hydrocephalus, ante-partum fetal death and undetectable MSAFP) and controls. Among the four IUGR cases, one placenta was with trisomy 13 in one of the sites and one placenta with 47,XXY in all sites and trisomy 8 in one site. In the case with MSAFP=0, monosomy 16 was detected in two sites. In the control cases (7 normal and 5 with aneuploidy) CGH results concurred with the known karyotype. Our result demonstrate the usefulness of CGH technique in the genetic evaluation of the placenta of problematic pregnancies even if its morphology is normal.

**No accelerated telomere shortening on the Y chromosome with age.** *L. Chavez<sup>1</sup>, E. Rajcan-Separovic<sup>2</sup>, P. Lansdorp<sup>1</sup>*. 1) Terry Fox Laboratory, BC Cancer Research Centre, Vancouver, Canada; 2) Cytogenetics Laboratory, BC Children's Hospital, Vancouver, Canada.

It has recently been shown that telomere shortening with age does not affect all the chromosomes equally. Surralles et al (*Am. J. Hum. Genet*, 1999, 65:1617-1622) measured the length of the inactive X chromosome telomeres in young and older females and showed that telomere repeats are lost from the inactive X chromosome at an accelerated rate. These authors proposed that accelerated telomere shortening renders the inactive chromosome unstable relatively early in life and that this may have a role in the observed phenomenon of chromosome X aneuploidy in the peripheral blood of elderly females.

A similar, age-related loss of the Y chromosome is observed in hematopoietic cells in the bone marrow of elderly males. This finding frequently represents an interpretational dilemma since it is hard to distinguish between the age-related loss of the Y chromosome and a neoplastic change. We have used quantitative FISH to evaluate the rate of telomere loss at the Y chromosome relative to other chromosome ends in normal bone marrow cells from children and elderly males. We found no significant difference in the rate of telomere shortening in the Yq and Yp telomere compared to that in all autosomal telomeres (young males 2-17 yrs: average Yp= 8.78 TFU, average Yq=5.9 TFU, average autosome p=6.35 TFU; old males 54-71 yrs: average Yp= 6.65 TFU; average Yq=3.35 TFU; average autosome p= 4.15 TFU). These results suggest that other mechanisms than accelerated telomere shortening are responsible for the loss of the Y chromosomes with age. Interestingly, significantly longer Yp telomeres were found in cells from 6/8 individuals from both age groups, indicating that Yp telomeres are typically among the longer telomeres in the genome.

**A rec(7)dup(7q)inv(7)(p22q23.2) derived from an inverted maternal chromosome 7, inv(7)(p22q31.2) in a new born.** A. Babu, T. Shlovsky, S. Kleyman, V. Mizhiritskaya, M.J. Macera. Dept Mol Medicine & Genetics, Wyckoff Heights Med Ctr, Brooklyn, NY.

Chromosomal analysis of peripheral lymphocytes from a new born revealed an abnormal 46,XY,rec(7)dup(7q)inv(7)(p22q31.2) karyotype. Follow-up analysis of maternal blood revealed an abnormal 46,XX,inv(7)(p22q31.2) karyotype. The recombinant chromosome was further characterized using directly labeled probes, Elastin located at 7q11.23, and D7S486 and D7S522 located at 7q31.3 on both proband and maternal chromosomes. In the mother, the inv(7) had elastin signal located in the proximal short arm, opposite to the centromere from D7S486,D7S522 at 7q21.3, while a normal pattern was seen on the 7 homologue. In the proband, the recombinant 7 had two sets of signals corresponding to D7S486,D7S522, one on each side of the centromere with only a single signal for the elastin locus. This confirms the breakpoint in the inv(7) at q31.2 and establishes the presence of two copies of band 7q(7q31.3 -> qter) in the proband. The entire rec(7) is positively labeled by wcp 7. The final karyotype of the proband is 46,XY,rec(7)dup(7q)inv(7)(p22q31.2)mat .ish rec(7)(wcp+, Elastin+, D7S486, D7S522+,+). The recombinant chromosome 7 originated during maternal meiosis I, owing to a cross over between the inv(7) and the normal 7 homologue within the inverted region. The product of the crossing over gave rise to the rec(7)dup(7q)inv(7)(p22q31.2), which has a very small monosomy for the 7p terminal region (7p22->pter) and a trisomy for the 7q terminal region (7q31.2->qter). It is interesting that the location of the breakpoint in this case, is at 7q31.2. There is strong evidence showing genes that contribute to both autism and specific developmental disorders of speech and language (SDDSL) are located on chromosome 7 band 3q. [Vincent et al 2000, Lai et al 2000, Warburton et al 2000, Ashley Koch et al 1999, Folstein and Maknoski 2000]. Due to the duplication of the critical region 7q31.2, the proband is being followed, and additional molecular characterization of the recombinant chromosome is underway.

**Microdeletions and cryptic translocations detected by FISH with multiple subtelomeric probes and spectral karyotyping in idiopathic mental retardation.** *Y.S. Fan<sup>1</sup>, Y. Zhang<sup>1</sup>, M. Speevak<sup>2</sup>, S. Farrell<sup>2</sup>, J.H. Jung<sup>1</sup>, V.M. Siu<sup>1</sup>.*  
1) London Health Sciences Ctr, London, ON., Canada; 2) The Credit Valley Hospital, Mississauga, ON., Canada.

Genomic alterations in the subtelomeric regions appear to be a frequent cause of mental retardation and developmental disabilities. However, the reported frequency of subtelomeric abnormalities in this population has been inconsistent. We have performed FISH testing using the Cytocell Multiprobe-T system on 149 patients selected based on the criteria: 1) mental retardation (IQ<70) or developmental delay with dysmorphic features; 2) a normal karyotype at the level of resolution of 450-500 bands; and 3) exclusion of other possible etiologies by a full genetic assessment and relevant tests. Abnormal findings were confirmed by spectral karyotyping (SKY) and Vysis probes, and family studies were carried out to determine inheritance. Clinically significant aberrations were detected in 6 proband patients (4%) including 1p36 deletion in two cases and unbalanced cryptic translocations in 4 cases, while deletion of the 2q subtelomeric region detected by probe D2S2986 appeared to be a common variant (6%). All the cryptic translocations were also identified by SKY. These results have demonstrated that both FISH with multiple subtelomeric probes and SKY are valuable clinical tests for establishing a definitive diagnosis for patients with idiopathic mental retardation / developmental disorders.

**Delineation of mosaic constitutional marker chromosomes using CGH, m-FISH and DNA analysis.** *B.L. Lomax<sup>1</sup>, O. Ludkovski<sup>2</sup>, S. Masui<sup>1</sup>, C. Brown<sup>3</sup>, DK. Kalousek<sup>1,2</sup>, E. Rajcan-Separovic<sup>1,2</sup>.* 1) Dept of Pathology, Women's and Children's Health Centre, Vancouver, BC; 2) Dept of Pathology, UBC, Vancouver BC; 3) Dept of Medical Genetics, UBC, Vancouver BC.

Supernumerary marker chromosomes are a heterogeneous group and precise characterization is necessary to establish their potential clinical significance. We have studied two patients who presented with behavioral problems but no dysmorphic features (Case 1) and dysmorphic features and learning problems (Case 2). In both cases, conventional cytogenetic analysis demonstrated the presence of a variable number (1-3) of small marker chromosomes in <50% of cells. C-banding suggested an euchromatic (C-band negative) component in both cases.

Multicolor FISH analysis (m-FISH) showed that in Case 1 both markers originate from chromosome 8, while in Case 2, 1 out of 3 markers showed chromosome X specific painting. The remaining 2 markers in Case 2 were not painted by m-FISH. CGH showed a slight gain at chromosome 8p11.1-q13 in case 1, and at the X chromosome centromere in case 2. Conventional FISH analysis confirmed that both markers in Case 1 hybridize with chromosome 8 paint, while only one hybridized with chromosome 8 a satellite. In Case 2, only one of the markers hybridized with the X chromosome a satellite and both the Xp and Xq arm-specific paints. Co-hybridization of chromosome X a satellite and the arm-specific probes showed co-localization of the two colors on one marker chromosome reflecting the presence of centromeric repeats in the microdissected arm-specific probes and precluding further cytogenetic characterization. Pericentromeric DNA markers will be used in an attempt to establish presence of euchromatin in this marker.

We can conclude that although the chromosomal origin can be suggested or confirmed by CGH and m-FISH, determining the euchromatic component of small marker chromosomes will remain a challenge due to the unavailability of FISH probes solely for euchromatic regions. The elucidation of small markers not painted by m-FISH will be facilitated in the future with the development of centromere specific m-FISH (cenM-FISH).

**The Association of Subtelomeric Deletions and Severe Mental Retardation.** *J.H. Hersh<sup>1</sup>, M.J Barch<sup>1</sup>, F.F. Yen<sup>1</sup>, J.A. Axelrod<sup>1</sup>, G. Gowans<sup>1</sup>, L. Sears<sup>1</sup>, A. Parsian<sup>2</sup>.* 1) Weisskopf Center for the Evaluation of Children/Dept Pediatrics, Univ Louisville, Louisville, KY; 2) School of Dentistry, Univ of Louisville, Louisville, KY.

Mental retardation occurs in about 3 percent of the general population. Although the likelihood of determining its etiology increases with the severity of the cognitive deficits, the cause remains unknown in up to 40 percent of cases with moderate to severe mental retardation. Recently, it has been demonstrated that cytogenetically invisible chromosomal rearrangements involving the subtelomeric regions represent an important cause of mental retardation. Knight et al reported the presence of subtle chromosomal abnormalities in 7.4 percent of children with moderate to severe unexplained mental retardation identified by a multiprobe telomere FISH protocol. Using the same approach with a ToTel Vysion probe panel (Vysis cat.33-270000), we have completed studies on 44 children with severe developmental delay/mental retardation of undetermined etiology. In 3 (6.8 percent) cases, a subtelomeric deletion was identified involving 1p, 1q and 2q. In 2 (4.5 percent) patients, parental telomere studies were normal, and in the third, results are pending. Our findings are similar to those previously reported, and support the notion that subtelomeric rearrangements represent an important cause of unexplained severe mental retardation. Therefore, a search for subtelomeric deletions using a multiprobe FISH protocol should be included in the diagnostic evaluation, when the etiology of the mental retardation is not readily apparent in this patient population.

**Sequential M-FISH and Rx-FISH in delineating the origin of ambiguous chromosome regions / fragments. C.**

*Lee<sup>1,5</sup>, M.F. Murray<sup>2,5</sup>, P.M. Miron<sup>3,5</sup>, M. Irons<sup>4,5</sup>, L.E. Wilkins-Haug<sup>1,5</sup>, C.C. Morton<sup>1,3,5</sup>.* 1) Department of Obstetrics and Gynecology, Brigham and Women's Hospital, Boston, MA; 2) Partners Center for Human Genetics, Boston, MA; 3) Department of Pathology, Brigham and Women's Hospital, Boston, MA; 4) Division of Genetics, Children's Hospital, Boston, MA; 5) Harvard Medical School, Boston, MA, USA.

Elucidating the origin of de novo marker chromosomes or ambiguous chromosome regions may be clinically significant and provides valuable data on phenotypic and aneuploidy relationships. However, in the clinical cytogenetics laboratory, determining the origin of these chromosome regions can be difficult and laborious when relying on conventional banding techniques, individual chromosome paints and/or locus-specific probes. Multicolor karyotyping systems are ideal technologies for rapidly identifying the composition of these markers / derivative chromosomes. Multiplex (M-) FISH and spectral karyotyping (SKY) in humans use a probe set containing differentially-labeled, chromosome-specific human paints to simultaneously identify each of the 24 non-homologous chromosomes with a unique spectral profile (color). Rx-FISH uses differentially-labeled chromosome-specific gibbon chromosomes which when hybridized to human chromosomes, produces a specific banding pattern on human chromosomes. Here, we illustrate the value of sequential M-FISH and Rx-FISH in a clinical case: Chromosome studies from a chorionic villus sample revealed a fetal karyotype of 46,XY,add(9)(p24) by GTG-banding. Chromosome analysis by GTG-banding on peripheral blood lymphocytes was normal for both parents. The pregnancy was continued and led to the birth of a full term, dysmorphic male infant. Subsequent peripheral blood karyotyping by GTG-banding confirmed the previous CVS chromosome results. M-FISH on the peripheral blood chromosome sample revealed that the additional chromosome material came from chromosome 2. Rx-FISH more specifically identified the additional material as originating from the distal short arm of chromosome 2. Together with a review of the G-banded chromosomes, the revised karyotype was 46,XY,add(9)(p24)*de novo*.ish der(9)t(2;9)(p21;p24)(wcp2±,wcp9±).

**Partial Trisomies and Deletions Identified by FISH, M-FISH, and Subtelomeric Probes.** *C.B. Lozzio, T. Ryan, E. Bamberger, E. Ralston, E. Holland, W. Carter, C. Worthington, K. Harmon.* University of Tennessee Department of Medical Genetics, Knoxville, TN.

Examples of chromosome rearrangements identified by molecular cytogenetic techniques are reported. One case of partial trisomy 14q and monosomy 18p was found in a 6 years old Hispanic male with severe growth and mental retardation, mild dysmorphic features, and history of duodenal atresia. The initial karyotype showed a "de novo" add(18)(p11.2) and the FISH studies with Vysis ToTelVysion Probe Panel for subtelomeric probes demonstrated a der(18)t(18;14)(q32.1;p11.2). Monosomy 8p and partial trisomy 13q with karyotype 46,XY,der(8)t(9;13)(p23;q22) was also identified using the Vysis subtelomeric probes in a 14 month old white male with craniofacial asymmetry, mild dysmorphic features and severe developmental delay. Telomeric deletions 2q37 have been frequently found as polymorphic familial variants using the Cytocell Multiprobe-T. We observed a true telomeric deletion 2q37.3 visible at the 600 band level by cytogenetic analyses and confirmed with the Vysis 2q telomeric probe in a 2 years old white female with brachycephaly, dysmorphic features and developmental delay. Mosaicism for partial trisomy 5 due to the presence of a small marker chromosome was observed in two cases. The origin of the marker chromosome was determined by Multicolor FISH studies (M-FISH) using the Multicolor Spectra Vysion from Vysis and the Applied Imaging Cytovision version 4.1 for UNIX with software for M-FISH. This finding was confirmed with the whole chromosome 5 and centromeric probes. One case was a 2 years old black male with tall stature, relative microcephaly and severe developmental delay. The other was initially found in an amniocentesis and confirmed by cytogenetic analyses of peripheral blood after delivery. At 1 month of age this baby had normal development and did not show dysmorphic features. The first case had the extra marker in 54% of the cells and the second case showed the extra marker in 71% of the cells. Both cases appear to be trisomic for the same pericentric region of chromosome 5, however the clinical findings were severe in one case and very mild or absent in the other.

**The origin of abnormalities in recurrent aneuploidy.** *W.P. Robinson<sup>1</sup>, D.E. McFadden<sup>1,2</sup>, M.S. Stephenson<sup>3</sup>*. 1) Dept of Medical Genetics, Univ British Columbia, Vancouver, BC., BC, Canada; 2) Dept. of Pathology; 3) Dept. of ObGyn.

Recurrent miscarriage due to sporadic aneuploidies may simply be a consequence of the dramatic increase of trisomic conceptions with maternal age. However, it is possible that some couples are at increased risk as a result of gonadal mosaicism, factors affecting chromosome structure or segregation, or increased sperm abnormalities in the male partner. We report cytogenetic and molecular findings from 111 spontaneous abortions (SAs) from 49 couples ascertained as having two or more documented aneuploid or polyploid SAs. The mean number of SAs per couple was 4 and mean maternal age at time of loss was 37.8 (range 19-46) yrs. The distribution of abnormalities was compared to 210 chromosomally abnormal SAs diagnosed at the same center but without documented recurrent aneuploidy/polyploidy (although most were from women with other non-karyotyped SAs); Mean maternal age was 35.3 (range 21-47) yrs for the control group. Although recurrence of the same trisomy occurred in 6 families, this was not more often than expected by chance, indicating that gonadal mosaicism is rarely the explanation for recurrence. The origin of the trisomy was determined in 33 SAs from 22 of the couples in the study. A maternal meiotic origin was concluded for 28 cases, possible somatic (mat) for 2 cases, and a paternal meiotic origin in 3 cases. These results are consistent with data from sporadic trisomies and suggest a similar etiology (e.g. maternal ovarian aging). The distribution of abnormalities among the recurrent aneuploidy group was similar to that for the controls, although both groups showed more trisomy 15 as compared to previous reports. The proportion of trisomic SAs (as compared to monosomy or polyploidy) was significantly higher in the recurrent aneuploidy group overall (84% vs. 67%;  $P=.0005$ ) and, when stratified by age, was significant among mothers <32 (83% vs. 40%;  $P=.05$ ) and 32-35 years of age (75% vs. 50%;  $P=.05$ ), suggesting possible premature ovarian aging in younger women experiencing recurrent trisomy. Further studies are needed to confirm an increased predisposition to trisomy in these women and determine if some specific trisomies are over-represented.

**A familial 14Mb interstitial deletion of 21q11-q21.3 confirmed by FISH using subregional-specific DNA clones.**

*K. Wakui<sup>1</sup>, A. Toyoda<sup>2</sup>, M. Hattori<sup>2</sup>, T. Kubota<sup>1,3</sup>, E. Hidaka<sup>4</sup>, M. Ishikawa<sup>4</sup>, T. Katsuyama<sup>4</sup>, Y. Sakaki<sup>2</sup>, Y.*

*Fukushima<sup>1</sup>.* 1) Dept Hygiene & Med Genetics, Shinshu Univ Sch Medicine, Nagano, Japan; 2) Genomic Sciences Center, RIKEN, Japan; 3) National Institute of Neuroscience, NCNP, Japan; 4) Dept Lab Med, Shinshu Univ Sch Medicine, Matsumoto, Japan.

We previously reported a family with an interstitial deletion of 21q11-q21 including a mother and two children (ASHG meeting, 1999). Although the mother was phenotypically and mentally normal, and the first affected child had deafness and moderate mental retardation and the second affected child had only mild mental retardation. We report here the precise breakpoints of the deletion confirmed by FISH using subregional-specific DNA clones. Recently, the human draft genome sequence had been reported. The availability of the mapped and sequenced clones allows for accurate diagnosis of chromosomal abnormalities associated with various phenotypes. Forty-five different subregional-specific DNA clones (Nature, 2000) were used as FISH probes, and we proved that the proximal breakpoint of the deletion of 21q of three family members was located between P16C2 and P879G12 (~0.8 Mb region) and the distal breakpoint was located between RP11-45O19 and RP11-666H8 (~14.8 Mb region). Thus, this family has a 14Mb deletion within 21q11-q21.3. It is interesting that the phenotype of these family members are variable. As the mother is entirely normal, the dark band 21q21 perhaps is lower in gene content. However, it is possible that some recessive genes responsible for mental retardation or deafness exists within 21q11-q21.3. The children with the same deletion are affected with mental retardation and/or deafness and thus may represent an unmasking of a deleterious gene on the fathers chromosome.

**Molecular Cytogenetic delineation of a rearrangement involving the TSHR gene region at 14q31-32 resulting in a rare occurrence of Graves' Disease in early childhood.** *L.R. Shapiro<sup>1,2</sup>, T.F. Davies<sup>3</sup>, M.B. Damore<sup>2</sup>, D.L. St.*

*Germain<sup>4</sup>, J.P. Park<sup>4</sup>, H.G. Taska<sup>1</sup>, A.N. Lamb<sup>5</sup>.* 1) Regional Medical Genetics, Westchester Med Ctr, Hawthorne, NY; 2) Department of Pediatrics, New York Medical College, Valhalla, NY; 3) The Mount Sinai School of Medicine, New York, NY; 4) Dartmouth Medical School, Lebanon, NH; 5) Genzyme Genetics, Santa Fe, NM.

Graves' Disease is an autoimmune hyperthyroid disorder of adulthood resulting in thyrotoxicosis, exophthalmos, goiter and elevated T4 and T3, low TSH and elevated Thyroid Stimulating Antibody (TSHR-Ab). The occurrence of Graves' Disease during childhood is rare. The 14q31 region is the location of the genes for Graves' Disease, Thyroid stimulating hormone receptor (TSHR) and Congenital Hyperthyroidism without an autoimmune component.

A 4 year female old child with developmental delay was diagnosed with hyperthyroidism because of rapid heart rate and muscle weakness and found to have elevated T3 and T4 with low TSH and elevated TSHR-Ab, indicative of Graves' Disease. She was referred for genetic evaluation because of dysmorphic features and manneristic behavior and found to have exophthalmos consistent with Graves' Disease. Chromosome analysis revealed an apparently balanced de novo translocation [46, XX, t(4;14)(q23;q32)]. Comparative genomic hybridization was confirmatory. Because the products of the type 3 iodothyronine deiodinase (DI03) and TSHR genes at 14q31-32 are involved in thyroid function, FISH analysis using the D3 probe was done and revealed an intact FISH signal on the derivative 4q; therefore, the break point was proximal to 14q32 and the DI03 gene. In view of a likely 14q31 breakpoint and the clinical picture of Graves' Disease, a position effect on the TSHR gene or a disruption of the gene at the break point became a possibility. In order to determine if the TSHR gene is intact, a FISH probe was prepared from thyrotropin receptor cDNA, but the initial FISH attempt was unsuccessful. The TSHR FISH will be repeated, and depending on the results, a sequential FISH strategy and/or sequencing of the region will be considered.

**Deletion of the proteolipid protein gene (PLP) in a patient with Pelizaeus-Merzbacher disease.** *V.C. Thurston<sup>1</sup>, T.A. Gobbett<sup>1</sup>, L.R. Smith<sup>1</sup>, Q. Gao<sup>1</sup>, K. Inoue<sup>2</sup>, J.R. Lupski<sup>2</sup>, S.R. Dlouhy<sup>1</sup>, J.T.R. Clarke<sup>3</sup>, M.E. Hodes<sup>1</sup>, G.H. Vance<sup>1</sup>.*  
1) Dept Medical & Molecular Gen, Indiana Univ, Indianapolis, IN; 2) Dept Molecular & Human Genetics, Baylor College of Med, Houston, TX; 3) Dept Genetics, Hospital for Sick Children, Toronto, ONT.

Pelizaeus-Merzbacher disease (PMD) is an X-linked neurologic disorder characterized by dysmyelination in the central nervous system. Duplications of the proteolipid protein (PLP) gene located at Xq22 are estimated to cause 60% of cases of PMD, while point mutations in exons account for another 10-15%. We report here the second case of a deletion of the PLP gene observed in PMD. Peripheral blood was obtained from a patient referred for a diagnosis of PMD, presenting with developmental delay, spastic diplegia and an abnormal MRI. To determine whether he carried a duplication of the PLP gene, FISH studies were performed on interphase cells with a cosmid probe for the PLP gene and two control probes. Two hundred interphase cells were analyzed and all were deleted at the PLP locus. Cytogenetic analysis was normal. PCR analysis with primers for exon 4 of the PLP gene was negative for the PLP locus. FISH and haplotype analysis was also performed on the proband's mother and maternal grandparents. FISH analysis detected the deletion only in the patient's mother. Haplotypes of the proband and the grandfather were identical. This suggests the genomic recombination event that results in the PLP deletion may have occurred in the grandfather's meiosis. To determine the extent of the deletion in the proband, three overlapping BACs were hybridized to cells from the patient. One BAC that mapped to the telomeric side of the PLP gene was also deleted. Preliminary evidence indicates the size of the deletion is at least 73 kb. In the other report of a patient with a deletion of PLP, it was estimated that the deletion spanned at least 29 kb of genomic DNA. That patient had clinical features of PMD similar to patients with a duplication of PLP, and peripheral neuropathy. Further mapping of the deletion in our patient will be performed to determine more precisely the extent of the deletion and whether other genes in the area are also deleted.

**Molecular cytogenetic screening in CHARGE association.** *D. Sanlaville<sup>1</sup>, J.M. Lapierre<sup>1</sup>, D. Genevieve<sup>2</sup>, C. Ozilou<sup>1</sup>, M. Le Lorc'h<sup>1</sup>, S. Brisset<sup>1</sup>, P. Gosset<sup>1</sup>, C. Baumann<sup>3</sup>, J. Amiel<sup>2</sup>, S. Lyonnet<sup>2</sup>, C. Turleau<sup>1</sup>, M. Vekemans<sup>1</sup>, S.P. Romana<sup>1</sup>.*  
1) Laboratoire de cytogenetique, hopital Necker Enfants Malades, PARIS, FRANCE; 2) genetique clinique hopital Necker Enfants Malades, PARIS, FRANCE; 3) genetique clinique hopital Robert Debre, PARIS, FRANCE.

CHARGE association is a non random occurrence of congenital malformations including coloboma, heart disease, choanal atresia, retarded growth and/or retarded development, genital hypoplasia, ear anomalies and/or deafness. The cause of this association remains unknown. Various genetic mechanisms were proposed, including, a subtle chromosome anomaly involving an unknown gene. To date individuals with CHARGE association phenotype and a visible cytogenetic anomaly have not provided any localization. To address this question, we decided to study 27 patients with CHARGE association and a normal standard karyotype with CGH and FISH using 41-subtelomeric probes. We found 2 chromosomal anomalies not yet described in CHARGE association: a der(9)t(9;13) derived from a parental translocation and a der(6)t(4;6) of unknown origin. Other observed anomalies were a dim(9p) observed using CGH in five patients and an unusual insertion of a small segment of 3p into 22q arm, inherited from the mother. We are currently trying to confirm the del(9p) using a YAC contig. Two regions (9p and 22q) are therefore potentially interesting to investigate by molecular tools in CHARGE association patients. Our results confirmed that chromosome anomalies might mimic CHARGE association and that more precise clinical criteria are needed. It is likely that the new diagnostic criteria of the CHARGE association proposed by Blake and al.(1998) could define a homogeneous-group of patients for which a single genetic cause might be identified. In conclusion a patient with CHARGE association must be tested with classical and molecular cytogenetic studies. Only a biological marker would allow the identification of a distinct clinical entity.

**Partial 9p monosomy in a child with a der(9)t(9;11)(p24;p15.4) identified by chromosome microdissection. D.**

*Wattendorf<sup>1</sup>, D. Krasnewich<sup>1</sup>, A. Smith<sup>1</sup>, J. Meck<sup>2</sup>, J. Trent<sup>3</sup>, T. Dennis<sup>3</sup>.* 1) Medical Genetics Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 2) Dept of Obstetrics and Gynecology, Georgetown University Medical Center, Washington, DC; 3) Cancer Genetics Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD.

We report a 4 year old male with a partial monosomy for the regions 9p24 ® pter and a partial trisomy for the region 11p15.4 ® pter as a result of a de novo translocation; der(9)t(9;11)(p24;p15.4). The child was evaluated for severe developmental delay, failure to thrive and dysmorphic features including triangular facies, prominent forehead and wide nasal bridge. Other features included pectus excavatum and scoliosis. Chromosomal evaluation prior to his visit to the National Institutes of Health revealed a derivative 9 chromosome. High resolution G-banding failed to identify the unknown chromosomal material. Spectral karyotyping (SKY) was employed and was unsuccessful in identifying this chromosome material. Microdissection of the region spanning the presumed breakpoint identified the undetermined chromosomal material on 9p as 11p15.4 ® pter. This region was technically large enough for resolution with SKY; however, the involved combination of fluorors utilized for identifying chromosomes 9 and 11 were too similar for reliable detection. The critical region for the 9p-deletion syndrome has been mapped to 9p22-p23. While the proband shared features consistent with the 9p-deletion syndrome, his deletion is more terminal and excluded the critical region for the 9p-deletion syndrome. Chromosome microdissection may be used to delineate complex chromosomal rearrangements not identified by high resolution banding or spectral karyotyping.

**Prenatal interphase FISH analysis: Five year experience and unusual cases.** *G.D. Wenger, J. Labanowska, M. Millard, J.M. Gastier.* Children's Hospital Dept. of Laboratory Medicine and Ohio State University Dept. of Pathology, Columbus, OH.

FISH analysis for prenatal screening for aneuploidy involving chromosomes 13, 18, 21, X, and Y is becoming increasingly common. This testing, generally requested due to ultrasound abnormality, late gestational age, or abnormal maternal serum screening results, provides a rapid (24-48 hr) preliminary result to physicians and patients awaiting results of metaphase chromosome analysis. Currently, approximately 17% of amniocentesis samples in our lab are accompanied by a request for FISH analysis. Since participating in the clinical trial that led to FDA approval for the AneuVysion-TM probe panel in 1997, our experience with 477 cases indicates 100% concordance between FISH and conventional cytogenetics for the aneuploidies that the AneuVysion assay is designed to detect. 2.1% of tests (10 cases) were non-informative due to maternal cell contamination or insufficient volume/cells. Aneuploidies were detected in 14% of cases: 27 cases +21, 19 cases +18, 7 cases +13, 6 cases monosomy X, 6 cases triploidy, 2 cases with other sex chromosome abnormalities. Our experience includes a case with abnormal AneuVysion result (3 signals CEP18 probe) and an unusual karyotype: 46,XX,dic(15;18)(q24;q11.2),+18.ish dic(15;18)(D18Z1+)de novo. Our experience also includes 12 cases with no abnormalities detected by the AneuVysion screen but with an abnormal karyotype (3 derivative chromosomes, 3 inversions, 2 recombinant chromosomes, 2 deletions, 2 ring chromosomes) and 3 cases with abnormalities or rearrangements in addition to those detected by AneuVysion (dicentric or supernumerary chromosomes). 2.5% of cases thus had chromosome rearrangements that were not detected by the screening test, but these represent abnormalities not designed to be detected by the probe panel. Overall for this time period, 16.3% of AneuVysion tests performed had an abnormal result. This testing, accompanied by clear, thoughtful communication and counseling between laboratory, physician, and patient, represents an accurate, sensitive method for rapid detection of the most common aneuploidies in high risk pregnancies.

**FISH (Fluorescent in situ Hybridization) Confirming a Mosaic Trisomy 14 in a Newborn.** *J. Burns, M. Arsham, L. Adomaitis, J. Christian, R. Ligi, S. Kazimi.* Cytogenetics Lab, Danbury Hosp, Danbury, CT.

Newborn blood for chromosome analysis was received to rule out or confirm a suspected mosaicism for trisomy 14. Mosaics are individuals with two or more genetically different cell populations. Amniocentesis performed by two separate labs had found extra copies of chromosome 14 in some cells. Since these trisomic cells were found in more than one culture vessel, this mosaicism was considered to represent a true mosaicism, not an artifact of in vitro culturing. Physical findings at birth included organomegaly, short proximal limbs, a right auricular pit, and abnormal pinnae. The patient was transferred to a tertiary institution where she was later discharged home. Cytogenetics of peripheral blood revealed a karyotype of mos 47,XX,+14[5]/46,XX[95]. FISH studies confirmed this finding with 5/117 cells (1 metaphase and 4 interphase nuclei) having 3 signals for the telomere of chromosome 14. Placental tissue was also cultured and showed this mosaicism. The ISCN (1995) cytogenetic and FISH results are as follows: mos 47,XX,+14[49]/46,XX[74].ish 14(D14S308x3)[12] nuc ish 14(D14S308x3)[174]. This pregnancy most probably started as a trisomy 14 and rescue occurred when a daughter cell lost one copy of chromosome 14. As the pregnancy progressed, placental tissue continued to have the highest percentage of trisomic cells, followed by extraembryonic membranes (amnion and chorion), and finally the peripheral blood. Uniparental disomy (UPD) is a problem which can complicate this type of cell rescue from a trisomic to a diploid cell line. With UPD, both copies of the chromosome in question will have originated from one parent, while the lost chromosome will have been the only one contributed by the second parent. Since UPD for chromosome 14 has recently been shown to be associated with an abnormal phenotype, studies for this are being planned by the other institution, which is caring for this child. Hopefully the results will determine if the observed phenotypic anomalies seen are the result of mosaicism for trisomy 14, UPD, or a combination of both.

**47,XX,+8/47,XX,+13 karyotype in a newborn with multiple congenital anomalies.** *I.M. Amir<sup>1</sup>, B. Abolaimoun<sup>2</sup>, M. Al-Hathal<sup>2</sup>, K. Al-Hathlol<sup>2</sup>, W. Al-Eyaid<sup>2</sup>, S. Sultan<sup>3</sup>, M. Al-Balwi<sup>1</sup>, N. Al-Atwi<sup>1</sup>, K. Al-Tawi<sup>2</sup>.* 1) Dept Pathology, King Fahad National Guard Hosp, Riyadh, Saudi Arabia; 2) Dept Pediatrics, King Fahad National Guard Hosp, Riyadh, Saudi Arabia; 3) Dept Obstetrics and Gynecology, King Fahad National Guard Hosp, Riyadh, Saudi Arabia.

Cases with double autosomal aneuploidies are rare. We report the first case of its kind of a grossly abnormal baby girl with two separate cell lines, one with trisomy 8 and one with trisomy 13. Ultrasound examination of the fetus at 31 weeks gestation revealed hydrocephalus, Dandy-Walker malformation, absent corpus callosum, bilateral dilated renal pelvises, overlapping fingers and bilateral club feet with rocker-bottom. Chromosome analysis on a cordocentesis specimen showed trisomy 8 (65% of cells) and trisomy 13 (35% of cells). Examination of the baby after birth confirmed the antenatal findings and revealed other multiple organ anomalies that were features from trisomy 8 and trisomy 13 syndromes. The trisomy 8 and trisomy 13 cell lines were also demonstrated in skin fibroblasts. The baby was supported actively for two weeks and then was put on no code and died from heart failure.

**Case Report: De novo t(1;6) translocation with partial anodontia and speech delay.** *A.B. Decker, A. Asamoah, D.L. Van Dyke.* Department of Medical Genetics, Henry Ford Hospital, Detroit, MI.

We report on a 6.5-year-old girl with a balanced translocation between the short arms of chromosomes 1 and 6. She was referred for evaluation because of speech delay, and congenital absence of several deciduous and permanent teeth. She was reportedly very sensitive to noise (hyperacusis), had poor growth of the hair and nails, had decreased sweating and becomes red with high fever. When we saw her, she had microcephaly (head circumference at the second percentile; weight and height were at the 25th percentile), short palpebral fissures, epicanthal folds, sparse eyelashes, large ears, partial anodontia, short finger and toenails, and dry skin. She has mild developmental delay. Family history is significant for learning problems in two paternal uncles, one paternal aunt and several paternal cousins. Thyroid studies, calcium, phosphorus and alkaline phosphatase levels were within normal limits. Her karyotype was 46,XX,t(1;6)(p22;p22) and parental karyotypes were normal. This apparently balanced rearrangement might have resulted in either a submicroscopic loss of genetic material or loss of function of a gene that causes ectodermal dysplasia. There is no reported case of ectodermal dysplasia associated with this chromosome rearrangement. Further studies might help determine whether there is a gene locus for ectodermal dysplasia at or near either of the translocation breakpoints.

**Duplication 6q11-q15.** *L.M. Dellefave, C.B. Whitley, B. Hirsch.* Institute of Human Genetics and University of Minnesota Medical School, University of Minnesota, Minneapolis, MN.

We describe a patient with a small duplication within the long arm of one chromosome 6. The proband was referred to a Clinical Geneticist at Fairview University Medical Center at 5 yrs. of age for evaluation of developmental delay and a history of neurological problems including failure to thrive due to feeding difficulties, and at 3 yrs. of age, stumbling and an abnormal EEG. Evaluation at that time with the Bayley Mental scale showed functioning in the moderate range of mental retardation with an IQ of 46. Physical exam at 5 yrs. revealed OFC below the 5th percentile, height below 5th percentile, weight at 25th percentile, with developmental and speech delay. Craniofacial dysmorphism included hypertelorism, small mouth, and micrognathia. Gait abnormality, equinovarus, and flatfooted feet while standing were present. Neurological exam showed slightly increased ankle reflexes with normal deep tendon reflexes, strength, and tone. Chromosome analysis of peripheral blood lymphocytes revealed a duplication within the long arm of one chromosome 6 extending from band q11 to q15. Parental studies were performed and revealed mosaicism for the duplication of bands 6q11 to 6q15 present in one cell out of 50 in one parent.

Of the 26 reported cases of partial trisomy 6q, the majority involve duplications distal to band 6q15. Only one of the published cases had apparently the same 6q11 and 6q15 breakpoints as the present case (Giardino et al., 1994). However, many of the features of the proximal duplication are the same as those described for the more distal duplications. Unlike the situation with chromosome 21 where partial duplications have yielded information about critical regions for specific phenotypic findings, such fine mapping of the phenotype of 6q duplications may not be feasible. Furthermore, the present study highlights the importance of ruling out mosaicism in a parent of such an affected child, even for an abnormality that one would have presumed, a-priori, to have arisen de-novo.

**Analysis by telomere specific FISH probes of 191 karyotypically normal patients with nonspecific dysmorphic features or developmental delay, or history of multiple miscarriages.** *S.M. Jalal<sup>1</sup>, A.R. Harwood<sup>1</sup>, M.H. Anderson<sup>1</sup>, G.S. Sekhon<sup>2</sup>, R.P. Ketterling<sup>1</sup>, V.V. Michels<sup>1</sup>.* 1) Cytogenetics Laboratory, Mayo Clinic, Rochester, MN; 2) Division of Clinical Genetics, Waisman Ctr., University of Wisconsin, Madison, WI.

Complete sets of telomere specific FISH probes except the acrocentric p-arms were used from two commercial companies. Analysis was based on 147 karyotypically normal patients with non-specific dysmorphic features and/or mental retardation (NDF/MR) and 44 patients with multiple miscarriages (MM). In addition, some of these probes were also used to define breakpoint boundaries in 17 patients with abnormal karyotypes. To maintain a high mitotic index cell suspensions were dropped in a Thermotron drying chamber. At least three metaphases were analyzed by FISH for each of the 41 telomeric sites for every specimen. Among the 147 NDF/MR patients, cryptic deletions were observed in 10 (6.8%) involving 3p, 4p, 7q, 8p, 10q, 22q and Xp. An abnormality rate of 6.8% in NDF/MR patients is similar to earlier reports. Parents were available for analysis in 4/10 abnormal cases. Of these, 2/4 (50%) had a balanced translocation in one parent. No telomere region abnormality was observed by FISH in 44 individuals with MM. However, a normal polymorphic variant involving del(2)(q37.3)(D2S2986-) was observed in 9.4% of MM cases using only Cytocell™ probe set. These same patients were normal by Vysis™ probe set strongly suggesting a cryptic polymorphism of this locus. A more rare polymorphic variant involving del(7)(p22.3)(G31341-) was observed in two cases (<1%), one of whom was phenotypically normal, using both Vysis™ and Cytocell™ probes. Use of telomere specific FISH probes is effective in determination of cryptic anomalies of the telomere regions, especially for patients with NDF/MR. Individual telomere specific probes are also useful in defining breakpoint boundaries near the telomeric regions.

**Identification of two copies of large inv dup(15) chromosomes in an infant.** *B. Huang*<sup>1</sup>, *J. Bartley*<sup>2</sup>. 1) Genzyme Genetics, Orange, CA; 2) Loma Linda University, Loma Linda, CA.

Marker chromosomes originated from chromosome 15, often referred to as inv dup(15), is the most common marker chromosome found in humans. The large marker 15 that contains the Prader Willi(PWS)/Angelman syndrome(AS) chromosome region is usually associated with an abnormal phenotype of moderate to severe mental retardation, seizures, poor motor coordination, behavioral problems, and mild dysmorphic features. We report here an infant boy with two copies of the large inv dup(15).

A 10-day-old infant was found to have infantile spasm, hypotonia, lethargy and marked developmental delay. He had no distinctive dysmorphic features at time of examination. Lymphocyte chromosome analysis revealed a 48,XY,+marx2 karyotype. Fluorescence in situ hybridization with probes rRNA, D15Z, D15S11,GABRB3 showed hybridization of each probe to two locations on both marker chromosomes, demonstrating that both markers are inv dup(15) that contain PWS/AS chromosome region. Therefore, this patient has 6 copies of the PWS/AS region. To our knowledge, this is the first case reported in liveborn with two copies of the large inv dup(15). The phenotype in this patient does not appear to be significantly more severe than patients with one copy of the large inv dup(15). However, some features may not have manifested in this age and follow-up evaluation is necessary.

**Paracentric inversion of chromosome 2 [inv(2)(q21q35)] in a family with Cutis Laxa.** *M.A. Micale*<sup>1,2</sup>, *T.W. Kurczynski*<sup>1,2</sup>, *W. Curtin*<sup>3</sup>, *L. Myers*<sup>3</sup>, *M. Marcotte*<sup>3</sup>. 1) Dept Pathology; 2) Dept Pediatrics; 3) Dept Obstetrics/Gynecology, Medical Col Ohio, Toledo, OH.

Cutis laxa (CL), a connective tissue disorder involving elastin depletion or fragmentation, is characterized by an inappropriate and symmetrical looseness of skin which presents as inelastic redundant folds often involving the face, eyelids, ears, earlobes, dorsum of the hands, chest, and abdomen. The disorder may also present systemic abnormalities of the lungs, vasculature, and urinary tract, as well as prenatal and postnatal growth deficiency. CL has been shown to segregate as an autosomal dominant, autosomal recessive, or X-linked disorder. Mutations in the *ELN* gene (dominant form) at 7q11 which codes for elastin and the *ATP7A* gene (X-linked form) at Xq12-q13 have been identified. We report a multigenerational family ascertained through an amniotic fluid chromosome study performed because of an elevated MSAFP (3.4 MOM). This study revealed a paracentric inversion involving the long arm of chromosome 2 [inv(2)(q21q35)], which was subsequently found to be paternally inherited. The family history was remarkable for short stature, premature aging, and a "skin disorder" present in multiple family members. The father of the baby was diagnosed upon genetic evaluation as having CL, and the pedigree revealed that three of his four siblings (two sisters and one brother) as well as his father had short stature and a similar skin disorder. Chromosome studies performed on the unaffected six-year-old daughter revealed a 46,XX normal female karyotype while an affected sister demonstrated the inv(2q). The pregnancy was followed by serial ultrasound examinations that demonstrated generalized subcutaneous edema, an enlarged fetal abdominal circumference, and a shortened femur length. At birth, short lower extremities and loose skin at the neck, shoulders, and upper extremities were noted. The baby has had recurrent pulmonary problems requiring several admissions. Given the concordance of the abnormal phenotype and the inv(2q) in this family, it is reasonable to speculate that a gene responsible for the phenotype lies at one of the breakpoints identified in the inversion (2q21 or 2q35).

**Alternate clinical phenotypes involving deletions of HPEIII and the cri-du-chat critical region subsequent to adjacent-1 segregation of a t(5;7)(p13.3;q32.3)pat.** S.K. Manhas<sup>1,2</sup>, A. Dawson<sup>1</sup>, D. Riordan<sup>1</sup>, D. Tucker<sup>1</sup>, S. Bal<sup>1</sup>, A. Prasad<sup>2</sup>, S. Marles<sup>1,2</sup>, S.M. Nikkel<sup>1,2</sup>, C. Prasad<sup>1,2</sup>. 1) Department of Biochemistry and Medical Genetics; 2) Department of Pediatrics and Child Health, University of Manitoba, Winnipeg, Manitoba, Canada.

We present a male Cree infant born at 36 weeks gestational age with dysmorphic features to non-consanguineous parents following a normal pregnancy and normal maternal serum triple screen. Growth parameters were: birth weight 25%ile, length <3%ile, and head circumference 50%ile. Multiple anomalies noted in the infant included: hypertelorism, preauricular skin tags, tag on right cheek, short palpebral fissures, small upturned nose, Pierre-Robin Sequence, broad forehead, single palmer creases, clenched hands, short sternum, 11 ribs, cryptorchidism, small penis, right ureteral hydronephrosis, generalized hypotonia and an unusual cry. ECHO demonstrated a large ASD with poor left ventricular function. Atrial flutter with 2:1 block was present. Cranial imaging revealed agenesis of the corpus callosum and cerebellar hypoplasia. The father, with a different unrelated partner, has had three fetuses with holoprosencephaly and multiple congenital anomalies. Chromosomal analysis of this newborn revealed an unbalanced male karyotype with a derivative chromosome 5 resulting from a balanced paternal translocation. The child's karyotype was interpreted as: 46,XY,der(5)t(5;7)(p13.3;q32.3)pat. The net genetic imbalance resulting from the der(5) is monosomy and trisomy for the distal portions of chromosomes 5p and 7q respectively. The monosomy of chromosome 5p13.3@pter necessarily includes deletion of the critical region of the cri-du-chat syndrome (mapped to 5p15.2). It is likely that the first three pregnancies resulted in fetuses with holoprosencephaly subsequent to inheritance of the der(7). The net genetic imbalance resulting from the der(7) is monosomy and trisomy of chromosomes 7q and 5p respectively. Monosomy for 7q32.3@qter includes deletion of the HPEIII gene for holoprosencephaly mapped to 7q36. The clinical features of the offspring are discussed in relation to their chromosomal deletions and duplications.

**Segregation of inherited Robertsonian translocations as assessed through prenatal diagnoses.** *S. Langlois<sup>1</sup>, R.D. Wilson<sup>1,2</sup>, H. Bruyere<sup>3</sup>*. 1) Dept Medical Genetics; 2) Dept. of Obstetrics and Gynecology; 3) Dept. of Pathology, University of British Columbia, Vancouver, Canada.

**INTRODUCTION:** Robertsonian (Rob) translocations are the most common structural rearrangements seen in humans. The normal progeny of carriers of Rob translocations can either have a normal karyotype or be carriers of the Rob translocation seen in the parent. A recent publication by Pardo-Manuel de Villena et al. concluded that the inheritance of ROB chromosomes in the balanced progeny of heterozygous carriers does not conform to Mendelian ratios. Their study was based on a review of previously reported segregation data from published families and one published prenatal diagnosis study. To determine if the findings could be due to reporting bias, we analyzed the segregation of ROB translocations in our prenatal diagnosis population. Patients included in the study were all patients seen in the Medical Genetics Department for prenatal diagnosis because one of the parent was a known carrier of a non-homologous Rob translocation. Cases of Rob translocations identified at amniocentesis done for advanced maternal age or other indications were excluded from the study. **RESULTS:** A total of 31 couples were seen for prenatal diagnosis in 53 pregnancies which resulted in a normal/balanced progeny. In 37 cases, the mother was the carrier of the Rob translocation and in 16 cases the father was the carrier. 33 cases were 13;14 translocations and 10 cases were 14;21. There were two cases of 13;22, 14;15, 15;21 and 15;22. There was 1 case of 14;21 and 1 of 14;22. The segregation ratio was analyzed according to the sex of the carrier parent. Offspring of female carriers were found to inherit the balanced Rob translocation in 59% of cases whereas offspring of male carriers inherited the translocation in 50% of cases. **CONCLUSION:** Our results support the findings of Pardo-Manuel de Villena et al. and indicate that in female transmission the segregation of the Rob translocation does not conform to Mendelian ratios and is in favour of the transmission of the Rob translocation to the offspring. This results in an increased proportion of at risk individuals amongst the progeny of female carriers.

**Developmental Genome Anatomy Project: Breakpoint localization updates.** *A.W. Higgins<sup>1,6</sup>, E. Lemyre<sup>4,7</sup>, G.A.P. Bruns<sup>3,6</sup>, C. Farra<sup>1,6</sup>, J.F. Gusella<sup>2,6</sup>, B.R. Korf<sup>1,2,6</sup>, S.R. Herrick<sup>1</sup>, A.H. Ligon<sup>1,6</sup>, J. Lewis<sup>1</sup>, R.L. Maas<sup>1,6</sup>, M.E. MacDonald<sup>2,6</sup>, A.M. Michelson<sup>1,5,6</sup>, B.J. Quade<sup>1,6</sup>, C. Rooryck<sup>4,7</sup>, F. Tihy<sup>4,7</sup>, C.C. Morton<sup>1,6</sup>.* 1) Brigham & Women's Hospital, Boston, MA; 2) Massachusetts General Hospital, Boston, MA; 3) Children's Hospital, Boston, MA; 4) Hôpital Ste. Justine, Montreal, QUE; 5) Howard Hughes Medical Institute; 6) Harvard Medical School, Boston, MA; 7) University of Montreal, Montreal, QUE.

The goal of the Developmental Genome Anatomy Project (DGAP) is to identify and study genes critical in human development by analyzing samples from patients with balanced chromosomal rearrangements and at least one congenital anomaly. We hypothesize that in a substantial proportion of these patients a developmentally important gene will be disrupted or dysregulated by the breakpoint and be etiologic in the abnormal phenotype. DGAP involves three steps: FISH mapping of the breakpoints using BACs at ~1 Mb intervals; sequence analysis and candidate gene identification in the region of the breakpoints; and functional analysis of candidate genes in model organisms (mouse and *Drosophila*). We have established a growing network of collaborators among clinical cytogeneticists, clinical geneticists and genetic counselors around the U.S. and abroad and now have over 90 cases in our database from patients with a variety of developmental defects and apparently balanced rearrangements. According to a prioritization scheme, we have FISH-mapped 10 breakpoints at the highest resolution possible using a genomic BAC map with BACs FISH mapped at ~1 Mb intervals. Two of these 10 breakpoints have been localized to single BACs, RP11-781L3 and CTD-3193O13, and narrowed to ~40 kb and ~20 kb intervals within these clones, respectively. These cases are now undergoing detailed molecular analyses. Three additional breakpoints have been mapped between 2 genomic BAC clones within intervals of ~90 kb, ~100 kb, and ~200kb. These FISH data along with clinical and cytogenetic data for each case can be found at the DGAP website (<http://dgap.harvard.edu>). As DGAP expands and progresses, we believe this will be a powerful resource for scientists in the genetics and developmental biology communities.

**Prenatal diagnosis of a de novo marker chromosome using FISH and CGH.** A. Zaslav<sup>1</sup>, B. Levy<sup>2</sup>, J. Jacob<sup>1</sup>, D. Blumenthal<sup>3</sup>, E. Valdarrama<sup>3</sup>, J.E. Fox<sup>3</sup>. 1) Department of Pathology, Long Island Jewish Medical Center, The Long Island Campus of the Albert Einstein College of Medicine, New Hyde Park, NY; 2) Departments of Human Genetics & Pediatrics, Mount Sinai School of Medicine, New York, NY; 3) Department of Pediatrics, Schneider Childrens Hospital, Long Island Jewish Medical Center, The Long Island Campus of the Albert Einstein College of Medicine, New Hyde Park, NY.

Prenatal cases with de novo marker chromosomes are problematic because of the sparsity of information regarding the phenotypic consequences to the fetus. We report a prenatal case of mosaicism for a marker chromosome that was characterized using FISH and Comparative Genomic Hybridization (CGH). Amniocentesis was performed on a 43 year old, white female for AMA. The karyotype was 47,XY,+mar[13]/46,XY[21]. Chromosome analysis of 100 cells from each of the parents revealed normal chromosomes. A high-resolution ultrasound at 16.6 weeks revealed that the fetus had clenched fists. The AneuVysion TM Probe set (Vysis, Inc, Downers Grove, IL) encompassing the centromeric regions of chromosomes 13, 18, 21, X, and Y was used. The marker chromosome demonstrated a positive signal for chromosome 18. CGH was also performed to more accurately characterize the size and breakpoints of the marker chromosome. CGH demonstrated a gain of the pericentric region of chromosome 18 from q10 to q12. Thus, the fetus was partially trisomic for chromosome 18 and the revised karyotype was 47,XY,+mar(18)[13]/46,XY[21].rev ish enh(18)(q10q12). Based on these findings the patient terminated the pregnancy. Autopsy performed on fragmented placenta and fetal parts revealed only a high arched palate. Follow-up cytogenetic studies on fetal tissue confirmed the above findings. This report illustrates the importance of using molecular cytogenetic techniques to determine the origin and also the size and breakpoints of de novo prenatally diagnosed marker chromosomes. This information, together with the clinical data, is important for genetic counseling issues. In addition, it provides insight into phenotype/genotype correlations.

**Phenotypic and cytogenetic analysis of a liveborn infant with prenatally detected trisomy 9p and partial trisomy 8p resulting from 3:1 malsegregation of a maternal reciprocal translocation.** *R. Smith<sup>1</sup>, H.E. Wyandt<sup>2</sup>, J.M.*

*Milunsky<sup>2</sup>*. 1) Div Genetics, Dept Pediatrics, New England Medical Ctr, Boston, MA; 2) Center for Human Genetics and Dept Pediatrics, Boston Univ School of Medicine, Boston, MA.

Tertiary or double trisomy, is a rare occurrence, produced by 3:1 malsegregation of a reciprocal translocation. We present an infant with trisomy 9p and partial trisomy 8p as a result of such an event. Our patient was born to a 37 y.o. G4P0 mother with a history of 3 previous losses. Maternal karyotyping revealed a 46,XX,t(8;9)(p22;q12) balanced translocation. Prenatal ultrasound revealed a VSD and a small aortic root, a unilateral CPC, and a slightly small cerebellum. Amnio confirmed a 47,XX,+der(9),t(8;9)(p22;q12) unbalanced karyotype.

The infant was born AGA at 35 4/7 wks due to PROM. Features noted on exam included: broad and prominent nasal bridge, short distinct philtrum, prominent upper lip with downturned corners of the mouth, overfolded helices with prominent antihelix, redundant nuchal skin, close set nipples, and digital anomalies consisting of nail hypoplasia with distal thumb hypoplasia and 5th finger clinodactyly. An echocardiogram revealed complex congenital heart disease consisting of pre-ductal coarctation of the aorta, two VSDs, small secundum ASD, and dysplastic aortic and pulmonic valves. Head MRI showed mild prominence of the temporal horn of the left ventricle and a slightly small cerebellar vermis. The infant also had 3rd degree heart block. Support was electively withdrawn at 1 week of life.

Our patient's features appear to primarily resemble those of trisomy 9p, although congenital heart defects can also be seen in partial trisomy 8p. Tertiary trisomies, typically of maternal origin, most frequently occur with translocations involving acrocentrics or chromosome 9, where the partial trisomies of the chromosome segment(s) are small enough to be viable. Our case supports this finding and illustrates the need to consider the phenotypic consequences of all possible segregation products when counseling couples where the mother carries a reciprocal translocation involving chromosome 9.

**Deletion Mapping in a Normal Father and a Normal Child Reveals Suspected Chromosome Instability at**

**21q11.2.** *H. Tinkel<sup>1</sup>, S. Finkernagel<sup>1</sup>, F. Desposito<sup>2</sup>, C. Pittore<sup>3</sup>, K. Reynolds<sup>1</sup>, L. Sciorra<sup>1</sup>.* 1) Department of Obstetrics and Gynecology, RWJUH, UMDNJ, New Brunswick, NJ; 2) Department of Pediatrics, New Jersey Medical School, UMDNJ, Newark NJ; 3) Division of Genetics, Mercer Medical Center, Trenton, NJ.

We present a child with speech delay and an otherwise normal phenotype with a deletion of chromosome 21q11.2 to 21q21. The child's father, who has a normal phenotype, was found to have a smaller deletion on 21q11.2 in 50% of his cells with the remaining cells normal.

The patient, a two year and eight month old girl, is the second child of healthy, unrelated parents. Testing has shown mostly age-appropriate milestones. However, she has delayed speech and began to speak beginning at two years of age. The patient is thought to have apraxia with a discrepancy between receptive language, which is judged to be four months above her chronological age, and expressive language. Physical examination is normal revealing no dysmorphism.

Metaphase spreads were analyzed via FISH with YAC DNA inserts spanning chromosome 21q11.1 to 21q21. The YACs in order from proximal to distal are 831b6, 52h5, 849b10, 949b9, 881d2, 746b10, 937e2, 940e2, 916h7, 925h10, and 799g3. The subjects were also analyzed with marker D21S13 located approximately on YAC 881D2.

The child was shown to be deleted in all cells for YACs 881d2, 746b10, 937e12, 940e2, 916h7 and 925h10. The father was found to be deleted in 50% of his cells only for marker D21S13.

These findings support previous work showing that proximal chromosome 21q does not include genes that are responsible for severe clinical defects. This pattern of inheritance also suggests a region of instability in chromosome 21q. We postulate that the region of deleted material in the father's chromosome created structural difficulties in the alignment of the chromosome 21s during meiosis resulting in the further loss of genetic material seen in the daughter. To our knowledge, this is the only report of such a pattern.

**Cytogenetics studies including FISH for 15q11.2/17p12 duplications and subtelomeric rearrangements in children with autistic spectrum disorder.** *R.T. Zori<sup>1</sup>, B. Gray<sup>1</sup>, K. Keller<sup>1</sup>, P. Wharton<sup>2</sup>, A. Bent-Williams<sup>1</sup>, A. Ward<sup>1</sup>, H. Stalker<sup>1</sup>, M. Paulk<sup>2</sup>, C.A. Williams<sup>1</sup>. 1) R.C. Philips Unit, Division of Genetics, Department of Pediatrics, University of Florida, Gainesville, FL; 2) Jacksonville Center for Autism and Related Disabilities, Department of Pediatrics, University of Florida, Gainesville, FL.*

To assess the frequency of chromosome aberrations 50 children with an autistic spectrum disorder were identified. Age range of the children was 2.6 to 20.0 years (av=8.3). M:F ratio was 2.6:1. Diagnoses included classic infantile autism (39%), pervasive developmental disorder, not otherwise specified (48%) and Asperger syndrome (14%). All 50 children were studied for chromosome abnormalities by routine G-banded blood chromosome analyses and by FISH analyses for 15q11.2 duplications, 17p11.2 duplications, and subtelomeric rearrangements. A maternally inherited chromosome 5 short arm duplication was detected in one child by routine chromosome analysis and an interstitial duplication of the Prader-Willi and Angelman syndrome critical region of chromosome 15 was detected by FISH analysis in another child. No instances of 17p11.2 duplication or of any chromosomal subtelomeric rearrangements were observed. Detection of these two cases underscores the importance of obtaining routine chromosome analyses and 15q11.2 FISH analyses in children with autistic spectrum disorder. Although subtelomeric FISH studies may be useful in the diagnostic assessment of certain subgroups of children with mental retardation syndrome, our results do not support their routine use in the diagnostic assessment of children with autism.

**Interphase FISH defines characteristic chromosomal abnormalities in diffuse large B-cell lymphomas. D.**

*Pickering, B. Dave, W. Sanger.* Human Genetics Laboratory, Univ Nebraska Medical Ctr, Omaha, NE.

Complex karyotypic alterations are characteristic of Diffuse Large B-Cell Lymphomas (DLBCL), the most common subtype of non-Hodgkin's Lymphomas (NHL). Using Multicolor-Fluorescence in situ Hybridization (M-FISH) we resolved complex chromosomal changes and delineated specific regions that were recurrently involved in rearrangements. These included 1p36, 3p21, 3p24, 3q27, 6q21, 8q24, 14q32, 17p13, and 18q21. To determine possible alterations in these regions specifically among cases without cytogenetic studies on their diagnostic specimen, we examined whole nuclei extracted from paraffin embedded tissue cores using interphase FISH studies with cosmid, YAC, and/or BAC probes. Twenty-nine (88%) of the 33 DLBCL cases analyzed were abnormal as determined by interphase FISH and 13 (40%) of these exhibited disruptions of IgH. Rearrangements of bcl2, including fusion with IgH and amplification were observed in 8 (24%) cases; the bcl6 alterations and c-myc amplification were found in 3 cases each (9%). Loss of heterozygosity of p53 (17p13) and p58 (1p36) were observed in 9 (27%) and 6 (18%) cases, respectively; while loss of 3p24 and 3p21 were observed in 8 (24%) and 5 (15%), respectively. Nine (27%) cases exhibited complex abnormalities involving 2 or more abnormal clones frequently with increasing ploidy. Seventeen (51%) cases contained the rearrangements of bcl2, bcl6, c-myc and/or IgH. Ten (30%) of these showed multiple copies of fusion signals or amplification of bcl2, bcl6 or c-myc. Fourteen (42%) cases revealed the loss of one or more regions investigated, with 7 of them showing loss of multiple regions. Nine of these 14 cases showed no rearrangement of the bcl2, bcl6, c-myc or IgH, indicating the possible presence of a primary abnormality other than that investigated. Interphase FISH using a panel of probes has been a valuable tool to assess chromosomal abnormalities of interest and has demonstrated that various combinations of the primary and secondary abnormalities may be present in DLBCL, each resulting in a distinct subset of this histological subtype of lymphoma.

**The Common and Often Cryptic 1p36 Deletion.** *K.K. Phillips, J.H. Tepperberg, P. Stone, D.J. Holliday, I.K. Gadi, P.N. Mowrey, P.R. Papenhausen.* Dept Cytogenetics, Lab Corp of America, Res Triangle Pk, NC.

Monosomy 1p36 is reported to have an incidence of ~1 in 10,000. The breakpoint within the p36 band (i.e., the size of the deletion) varies, and this generally correlates with phenotypic variability, such that patients with larger deletions are more severely affected. Severe phenotypic features include failure to thrive, seizures, heart malformations, dysmorphic facies, and development of mild to severe mental retardation. Milder features can be limited to generalized muscular hypotonia. In our laboratory, we routinely follow up apparent de novo 1p36 deletion cases with FISH subtelomere probe analysis (Vysis, Inc.), both to verify deletion status and to allow resolution of possible cryptic reciprocal translocations. Until it became commercially unavailable, we also used the more proximal p58 FISH probe (Oncor, Inc.) to permit estimation of the size of the deletion. We have identified 8 patients (3 prenatal and 5 postnatal) in the last ten months with isolated deletion of 1p36. An additional prenatal case, referred for maternal serum DS risk without ultrasound abnormalities, was initially reported as deletion 1p36 but was later found to be a cryptic balanced translocation. Follow up FISH analysis on this prenatal case, using 1p subtelomere probe, showed signal on distal chromosome 19p. Parental G-band analysis revealed that the translocation was maternal in origin, and therefore, of negligible risk to the fetus. Without the FISH data and parental analysis follow up, the case would have been initially reported incorrectly. These data indicate that 1) the incidence of monosomy 1p36 may be higher than previously reported, and 2) parental karyotype analysis and utilization of FISH should be routinely employed as precautionary follow up procedures in cases with apparent de novo 1p deletion.

**Cell lineage confined mosaicism in specimens of spontaneous abortion.** *D.K. Kalousek<sup>1,2</sup>, T.A. Loukianova<sup>1</sup>, S.S. Tang<sup>1</sup>, T. Philipp<sup>3</sup>.* 1) Dept Path/Lab Med, Univ of BC, Vancouver, BC, Canada; 2) Dept Path, Women's and Children's Health Center of BC, Vancouver, BC, Canada; 3) Clinical Obstetrics and Gynecology Donauespital im SMZ-Ost, Vienna, Austria.

High incidence of chromosomal mosaicism is described in preimplantation embryos, while the frequency of fetal mosaicism detected by amniotic fluid culture is less than 0.5%. Confined placental mosaicism (CPM) is recorded in 1-2 % of pregnancies examined by CVS at 10-12 weeks of gestation. The mechanism by which the high levels of preimplantation mosaicism are reduced during the first trimester are not understood and the role of mosaicism in early pregnancy loss has been questioned. Previous studies of spontaneous abortions (SAs) using tissue culture and traditional cytogenetic techniques describe the frequency of mosaicism at around 10 % (Warburton et al, 1978). We have used comparative genomic hybridization (CGH) analyses for detection of cell lineage confined mosaicism in 78 specimens from first and second trimester SAs. CGH analysis of trophoblast, chorionic stroma and amnion revealed 11 specimens with cell lineage confined mosaicism from the first trimester (11 out of 43) and one from the second trimester (1 out of 25). The most common mosaicism (6 cases) involved the detection of aneuploidy (trisomy 3, trisomy 15, trisomy 16, monosomy X x3) in trophoblast and chorionic stroma but a normal diploid karyotype in amnion. In two cases, triploidy was found in all cell lineages, but in amnion the additional sex chromosome duplication was presented (70,XXXYY). Three sex chromosome aneuploidies confined to trophoblast (monosomy X x2; 47,XXY) in otherwise diploid conception were diagnosed. The CGH analysis of all cases was complemented with either flow cytometry, traditional cytogenetic analysis or fluorescence in situ analysis. This study of 43 first trimester SA specimens showed a 25% frequency of mosaicism confined to a specific cell lineage. This result suggests a significant role for chromosomal mosaicism in early pregnancy loss.

**Paternal UPD14 is responsible for a distinctive malformation complex.** *K. Kurosawa<sup>1</sup>, H. Sasaki<sup>2</sup>, Y. Sato<sup>1</sup>, M. Yamanaka<sup>1</sup>, M. Shimizu<sup>3</sup>, Y. Ito<sup>4</sup>, T. Okuyama<sup>4</sup>, M. Matsuo<sup>1</sup>, K. Imaizumi<sup>1</sup>, Y. Kuroki<sup>1</sup>, G. Nishimura<sup>5</sup>.* 1) Kanagawa Children's Med Ctr, Yokohama, Japan; 2) Department of Human Genetics, National Institute of Genetics, Japan; 3) Tokyo Metropolitan Bokuto Hospital, Japan; 4) National Childrens Hospital, Japan; 5) Division of Radiology, Nasu-chuo Hospital, Japan.

In humans, uniparental disomy (UPD) is known as the cause of several malformation syndromes. To date, 23 cases with maternal UPD14 (matUPD14) and 4 cases with paternal UPD14 (patUPD14) have been reported. Most cases with matUPD14 and all cases with patUPD14 had translocated ch14. MatUPD14 cases did not compile a distinctive pattern of malformations, but patUPD14 cases may have constituted a distinctive malformation syndrome. We report three additional patUPD14 cases, all of which shared common manifestations with those of previously reported cases, which unequivocally established that patUPD14 gives rise to a distinctive malformation syndrome. Moreover, two of 3 cases, unlike previously reported cases, had a normal karyotype, which may suggest that patUPD14 is more common than previously thought and the majority of cases have gone unrecognized. The constellation of thoracic hypoplasia with short, wavy ribs, diastasis recti, and minor facial dysmorphism. A total of 15 highly polymorphic microsatellite markers spanning the entire long arm revealed patUPD14 for all patients. Human ch14 has a large region homologous to mouse ch12. Mouse embryos with patUPD12 display skeletal defects, all of which are consistent with the phenotype of human patUPD14. It is therefore likely that the malformations common to human patUPD14 and mouse patUPD12 result from an evolutionarily conserved imprinted gene(s). Recently, two imprinted genes, *Gtl2* and *Dlk1*, have been identified in the distal regions of mouse ch12 and their orthologues on human ch14. These genes may be candidates for the patUPD14 phenotype. In addition, the sheep callipyge (CLPG) phenotype shows hereditary muscular hypertrophy with an unusual parent-of-origin effect, and the gene is mapped to the *Gtl2/Dlk1* locus. The complex roles of the CLPG mutation raises the assumption of the important role of *Gtl2/Dlk1* locus in the development of the patUPD14 and matUPD14 phenotypes.

**Chromosome 22q11.2 Deletion Syndrome: FISH Study of 71 Cases.** *S.J. Abulhasan, S.A. Al-Awadi.* Kuwait Medical Genetics Centre, Maternity Hospital, P.O. Box 31121, Sulaibikhat 80901, Kuwait.

Chromosome 22q11.2 deletion syndrome, which includes DiGeorge (DGS), velocardiofacial (VCFS), conotruncal anomaly face (CTF), and recently Kenny Caffey (KCS) syndrome is the most common microdeletion syndrome. It has been estimated that deletion at 22q11.2 occur in 1:4000 newborns and in up to 90% of patients with DGS and VCFS. The majority of deleted patients share a common 3 Mb hemizygous deletion of 22q11.2. This study reports FISH results of 71 cases presented clinically with a spectrum covering the above mentioned syndromes. FISH technique applied to blood lymphocyte metaphase spreads and interphase nuclei using dual color DNA probe specific for DiGeorge critical region (DGCR) on chromosome 22q11.2 and to the band 22q13 as a control region (Vysis) and probe D22S75 (Oncor), revealed 22 q11.2 haploinsufficiency in 19 cases (27%). Seven cases (37 %) inherited the deletion from either parent (maternal in 5 and paternal in 2). Five parents had translocation involving chromosome 22q and other non-homologous chromosome. Two maternal deletions were in the mosaic form so pointing out to the possibility of gonadal mosaicism as a cause of 22q11.2 deletion in the affected offspring. The 7 parents with the deletion were phenotypically normal except one who had congenital heart disease and 22q11.2 deletion. Parents with 22q11.2 deletion who have a 50% risk of transmitting the deletion to their offspring have to perform amniocentesis for prenatal diagnosis and preimplantation genetic diagnosis using FISH technique whenever possible.

**Rapid sequence-based definition of chromosomal abnormalities.** *P.M. Cazcarro, P.K. Rogan, J.H.M. Knoll.* Medical Genetics & Mol Medicine, Children's Mercy Hospital, Kansas City, MO.

Chromosomal rearrangements are generally delineated by in situ hybridization using large recombinant DNA probes. The sequences of these probes are often not precisely determined, and their size precludes detection of small deletions, duplications or cryptic abnormalities within corresponding or closely related genomic sequences. Nevertheless, they have been useful in demonstrating heterogeneous breakpoints and shortest regions of overlap in disease states, which has led to assignment of chromosomal intervals to specific phenotypes in many disorders. We developed custom single copy (sc) probes from the draft genome sequence for fluorescence in situ hybridization (scFISH; *Genome Res.* 11:1086, 2001), and now use this approach to precisely delineate chromosome abnormalities at a resolution equivalent to genomic Southern analysis. Probes, 1.5 - 10 kb in length, have been designed, produced by long PCR, visualized and validated rapidly as this approach does not require cloning. We have validated 75 probes from 23 chromosomal disease intervals. We demonstrate the versatility and sensitivity of this approach by presenting examples of (A) deletion breakpoint definition in Smith-Magenis syndrome on chromosome 17p11.2 (eg. for the *FLII* gene: probes from IVS9-IVS12, IVS12-IVS14, and IVS15-Ex21; for *MFAP4*: IVS2-3UTR; for *SHMT1*: IVS1; for *LLGL*: promoter-exon 2, and promoter-IVS1; and for *ADORA2B*: Promoter-IVS1 and IVS1), (B) microdeletion detection at or near the chromosome 15q11.2 imprinting centers in Prader-Willi and Angelman syndromes (eg. for *IC/SNRPN*: IVS3'-exon u1B\*, and exon u5-IVS3'; for *SNRPN*, promoter-IVS1; and for *UBE3A*: IVS8-IVS9), and (C) translocation 9;22 breakpoint delineation in chronic myelogenous leukemia (eg. for *ABL1*: exon 1B-IVS1B, IVS3[3], IVS4-IVS6[2], exon 11-IVS11; for *BCR*: proximal of M-BCR[2] and IVS8). By combining sequence-based probe design with FISH, nearly any euchromatic abnormality can be readily characterized. scFISH will facilitate and refine cytogenetic studies, such as phenotype-genotype correlation, mechanisms of formation, and analyses of chromatin structure.

**Application of the complete human multicolor banding (MCB) set in cancer and clinical cytogenetics.** *T. Liehr<sup>1</sup>, A. Heller<sup>1</sup>, H. Starke<sup>1</sup>, A. Weise<sup>1</sup>, K. Mrasek<sup>1</sup>, V. Trifonov<sup>2</sup>, N. Rubtsov<sup>2</sup>, U. Claussen<sup>1</sup>.* 1) Inst. of Human Genetics and Anthropology, Jena, Germany; 2) Inst. of Cytology and Genetics, Novosibirsk, Russia.

The multicolor-banding (MCB) technique allows the differentiation of chromosome (chr) region specific areas at the band and sub-band level and is based on regionspecific microdissection libraries producing changing fluorescence intensity ratios along the chrs. The latter are used to assign different pseudocolors to specific chromosomal regions. We present for the first time the complete set of 138 regionspecific microdissection libraries for the entire human genome and the resulting MCB patterns for all human chrs at the 400 band level. More than 120 cases with congenital or acquired complex chromosomal rearrangements involving different chrs have been analyzed up to now using this DNA-based high resolution banding technique. In most of the studied cases neither GTG-banding nor 24-color-FISH could resolve the complex changes, e.g. interstitial deletions, insertions or inverted insertion. Additionally, Zoo-FISH experiments on Gorilla gorilla (GGO) and Hylobates lar (HLA) have been done using the complete human MCB probe set. In GGO no paracentric inversion was found on GGO 14, and no pericentric inversions could be demonstrated on GGO 16 or 17. In HLA the position of centromeres, the breakpoints and the up to now unknown orientation of small "rearranged" chromosomal regions could be determined. Moreover, interphase analysis using the MCB-probe sets for chr 2 and 5 showed, that interphase chrs present with a banding pattern similar to that of metaphase chrs at any stage of the cell cycle. In summary, the MCB-technique is a high resolution alternative to other M-FISH based banding approaches and suited to clarify within one single FISH experiment, which changes appeared in complex rearrangements, to study in detail the architecture of the interphase nucleus and to do high-resolution comparative ZOO-FISH studies. Acknowledgments: Supported in parts by the Herbert Quandt Stiftung der VARTA AG, the Madeleine Schickedanz-Kinderkrebs-Stiftung, the DAAD, the DFG, the EU and the Wilhelm Sander-Stiftung.

**Human multicolor banding (MCB) probes applied for ZOO-FISH in Gorilla gorilla and Hylobates lar.** A. Heller<sup>1</sup>, K. Mrasek<sup>1</sup>, M. Rocchi<sup>2</sup>, V. Trifonov<sup>3</sup>, N. Rubtsov<sup>3</sup>, H. Starke<sup>1</sup>, U. Claussen<sup>1</sup>, T. Liehr<sup>1</sup>. 1) Inst. of Human Genetics and Anthropology, Jena, Germany; 2) Institute of Genetics, Bari, Italy; 3) Inst. of Cytology and Genetics, Novosibirsk, Russia.

The origin of human and ape chromosomes has been studied by comparative chromosome-banding analysis and more recently by fluorescence in situ hybridization (FISH) studies using human whole chromosome painting (wcp) probes. Using these techniques, however, it is not always possible to determine the exact breakpoints or orientation of specific DNA-regions which have been distributed on different chromosomes in apes compared to human. To overcome that problem, in the present study the recently developed multicolor banding (MCB) probe set for all human (HSA) chromosomes has been applied to reanalyze the chromosomes of Gorilla gorilla (GGO) and Hylobates lar (HLA). These two species have been chosen, as karyotype of the first one is very similar to the human and the second one is known to be highly rearranged with respect to the human one. The MCB results for GGO agree with those of most previous banding and FISH studies, however, the breakpoints for the pericentric inversion on GGO 3 were defined more precisely, no paracentric inversion was found on GGO 14, and no pericentric inversions could be demonstrated on GGO 16 or 17. Former FISH studies using human wcp probes clarified, which HLA chromosomes are homologue to which human ones. Nevertheless, using MCB it could e.g. be shown that material of HSA 8 is present not only on HLA 7 and 9 but also on 5 and 12. The orientation of chromosomal subregions in HLA have been unclear up to present. Using MCB it could e.g. be shown that HLA 19 is homologous to 1q44-1q31::1p31.1-1p34.2::1q32-1q44. We could demonstrate, that MCB leads to complete information about all kinds of rearrangements which appear during primate chromosomal evolution. **Singlet/doublet FISH patterns point out allele-specific differences, but not necessarily asynchronous replication.**

*O.A. Haas, A. Slany, S. Strehl. CCRI, St Anna Children's Hosp, Vienna, Austria (o.a.haas@magnet.at).*

Asynchronous replication is considered a distinct feature of particular genes and is commonly associated with allele-specific methylation and monoallelic expression. In imprinted genes, this difference is fixed in a parent of origin specific fashion, whereas in X-linked and certain immune system-associated, growth factor, and receptor genes, doublets and singlets are originally randomly distributed. Allelic exclusion and clonal expansion may eventually lead to a seemingly nonrandom distribution. The asynchronous replication behavior of such genes is usually analyzed with FISH by determining the singlet/doublet ratio of the two alleles. Such studies are based on the assumption that unreplicated loci generate single hybridization signals, whereas replicated ones produce doublets. Of interest, however, the absolute numbers of cell with asynchronous FISH patterns do not differ significantly in S- and non-S phase cell fractions. To investigate this issue further, we therefore generated dual-color labeled RNA FISH probes from the imprinted Prader-Willi region that bind to nonoverlapping solitary DNA strands. By that, we clearly distinguish between doublets in replicated (two chromatids with two dual-colored signals) and in nonreplicated regions (one chromatid with two mono-colored signals). The results of our experiments prove that the vast majority of doublets actually do not represent replicated DNA. Differences in the compaction and utilization of the two nonreplicated alleles may lead to a better separation of the DNA strands of the allele with two mono-colored signals. In case this notion is true, this FISH pattern should be strongly influenced by the respective preparation and denaturation methods. Indeed, we found that the number of asynchronous pattern significantly increases in halo preparations of unstimulated G0 mononuclear cells, whereas this is not the case in those of PHA-stimulated cells.

**A case with persistent low mosaicism of trisomy 18 detected by interphase FISH: an artifact or true mosaicism?**

*X. Li<sup>1</sup>, B. Burt<sup>2</sup>, J. Winters<sup>1</sup>, K. Nguyen<sup>1</sup>, A. Grix<sup>2</sup>.* 1) Genetics Department, Kaiser Permanente Northern California, San Jose, CA; 2) Genetics Department, Kaiser Permanente Northern California, Sacramento, CA.

Prenatal diagnosis using interphase fluorescence in situ hybridization (FISH) on uncultured amniotic fluid cells is generally considered accurate and reliable. However, detection of mosaic chromosome aneuploidy, in particular at a low level without confirmation by standard cytogenetics, can be problematic for result interpretation and genetic counseling. We report here prenatal detection by interphase FISH and postnatal follow up of a case with mosaic trisomy 18. Amniocentesis and interphase FISH were performed for a 34-year-old G3P1->2 woman at 22.6 weeks gestation. U/S showed 3mm unilateral choroid plexus cyst. Cytogenetic study demonstrated a normal male karyotype (46,XY) in 27 colonies. Interphase FISH (AneuVysion, Vysis, Inc.) revealed an X and a Y and three signals for chromosome 18 in 12% (12/100) of cells. Probes for chromosomes 13 and 21 showed a normal pattern. The FISH result was reported as inconclusive. The patient decided to continue the pregnancy. A foreskin biopsy sample was obtained after a normal delivery. Cytogenetic analysis showed a normal male karyotype in 20 cells examined. Interphase FISH using the same chromosome 18 probe revealed three signals in 6% (6/100) and 11% (11/100) of cells from two independent touch preps. FISH on the cultured cells showed a similar result: 5% (10/200) of cells with three signals for 18. The FISH results raise a concern for a low mosaicism of trisomy 18. Further evaluation of a buccal smear and a urine sample by interphase FISH showed 17% (17/100) of buccal cells and 12% (19/165) of urine cells with three signals for chromosome 18. Clinical evaluation at 6 weeks of age revealed normal development with no dysmorphic features and no significant congenital anomalies. The persistent presence of an abnormal signal pattern for chromosome 18 in various tissues is highly suggestive of a true mosaic trisomy 18. However, without confirmation by standard cytogenetics, a rare artifact or polymorphism cannot be totally ruled out.

**Referral trends for FISH analysis on blood samples in a regional cytogenetics laboratory over a 9 year period.** *E. Mak-Tam, A. Mar-Wah, P. Wyatt.* Dept. Genetics, North York General Hospital, North York, ON, Canada.

The Cytogenetics database was reviewed to look at the requests for blood FISH analysis over a 9 year period from 1992 to 2000. This regional laboratory accepts samples from a wide geographic region and from associate clinics. The percentage of bloods referred for FISH analysis increased from 1.5% in 1992 to an average of 10.5% in the last 5 years. Of the total bloods with FISH analysis, over 80% were for microdeletion probes. The most frequent referrals were for the William and DiGeorge/Velocardiofacial probes. Other microdeletion probes included Smith-Magenis, Prader Willi/Angelman and STS probes. The positive (detection) rate interestingly, decreased from a high of 25% to an average of 6.5%, which has been stable for the last 5 years. The initial high detection rate confirmed appropriate referrals from our own geneticists during the time when microdeletion probes were first introduced. FISH tests can now be ordered by any clinician. With increased availability of new probes, the clinician can make a diagnosis previously not possible with routine classical cytogenetics. However, added laboratory costs and patient follow up are real concerns. Monitoring detection rates and referral patterns can be important components of an effective laboratory quality assurance program.

**Visualization of multiple peptide nucleic acid (PNA) probes by combinatorial multicolor fluorescence in situ hybridization.** *K.L. Taneja<sup>1</sup>, B. Williams<sup>1</sup>, E.A. Chavez<sup>2</sup>, J. Coull<sup>1</sup>, R.H. Singer<sup>3</sup>, P.M. Lansdorp<sup>2</sup>*. 1) Boston Probes, Inc, Bedford, MA; 2) Terry Fox Laboratory, British Columbia Cancer Agency, Vancouver, BC, Canada; 3) Departments of Anatomy, Albert Einstein College of Medicine, Bronx, New York 10461.

Combinatorial labeling of probes (i.e., with two or more different reporters) increases the number of target sequences that can be detected simultaneously by fluorescence in situ hybridization. We have designed and developed directly labeled PNA probes to distinguish up to  $2^n - 1$  probes ( $n$  is the number of different fluorochromes) using an epifluorescence microscope equipped with a digital imaging camera and computer software for pseudocoloring and merging images. Peptide nucleic acids (PNA) are synthetic mimics of DNA in which the phosphodiester backbone has been replaced with 2-aminoethyl glycine linkages, but maintaining the four natural nucleobases. PNA probes bind to the complementary DNA sequence obeying Watson-Crick base pairing, however the neutral backbone of the PNA molecule allows for the PNA/DNA binding to occur more rapidly and more tightly than DNA/DNA binding. Chromosome specific composite PNA probe sets were generated from the human satellite sequences, in which the different fluorochromes were incorporated. The technique has been used to delineate the centromeres or satellite regions of different human chromosomes, on both 4',6-diamidino-2-phenylindole-stained metaphase spreads and interphase nuclei in a single hybridization experiment and to detect and to enumerate chromosomes. Our data suggest that multiplex fluorescence in situ hybridization (M-FISH) could have wide clinical utility, particularly in detection and enumeration of chromosomes in a given sample. Multi-parameter hybridization analysis should facilitate the study in molecular cytogenetics and probe-based diagnosis of pathogens.

**Duplicated genes and markers in 17q11.2 detected by high resolution FISH and involvement of repeated regions in NF1 microdeletion breakpoints.** *P. Riva<sup>1</sup>, C. Gervasini<sup>1</sup>, M. Venturin<sup>1</sup>, A. Bentivegna<sup>1</sup>, L. Corrado<sup>1</sup>, M. Stabile<sup>2</sup>, M. Clementi<sup>3</sup>, R. Tenconi<sup>3</sup>, L. Larizza<sup>1</sup>.* 1) Dept Biol & Genetics, Univ Milan, Milan, Italy; 2) Medical Genetic Service, Cardarelli Hospital, Naples, Italy; 3) Dept. of Pediatrics, University of Padua, Italy.

Evidence links duplicons flanking the NF1 gene in 17q11.2 to the breakpoints of NF1 microdeletion syndrome. Physical mapping and structural definition of duplicated regions is often precluded by using conventional approaches, thus the sequence ready map of 17q11.2 and numerous other pericentromeric regions is still a draft. Recently by using an alternative physical mapping approach based on high resolution FISH on stretched chromosomes and DNA fibers, we detected and mapped duplications of BLMH and GOS28 genes and SHGC30113 transcript in 17q11.2. We found further duplications involving ESTs AN2, 41099, M79255 and IB518, anchored to 41c23, not reported as duplicated in 17q11.2 physical maps. To disclose the genomic organization of duplicated loci we mapped, directly by fiber FISH, 41c23 in respect to other genomic clones establishing their reciprocal order: cen-41c23-977d19-1015j22-gap-977d19-1015j22-41c23-tel. A parallel study aimed at verifying the involvement of repeated sequences in the deletion bkp of NF1 patients is also in progress. We used cell lines from 5 NF1 deleted patients (pts) from a group of 25 pts previously characterized by conventional FISH. In all cases we identified a centromeric bkp flanking D17S1317, while the telomeric bkp flanks ACCN1 gene in 50% of pts. By using FISH with selected PACs, targeting the regions adjacent at the centromeric and telomeric bkps, overlapping signals were detected on stretched deleted chromosomes. FISH on DNA fiber from three pts allowed to observe that signals given by PACs anchored to D1S1317 and to MCP-3 in one pt, as well as D1S1317 and ACCN1 in two pts, were partially overlapping indicating the presence of common sequences located 1-3 Mb apart on the normal chromosome 17. Use of high resolution FISH is a powerful tool of mapping duplicated regions. Data disclosing 17q11.2 genome organization will allow to clarify NF1 microdeletion syndrome pathogenetic mechanism.

**mRad54 is a key protein in the maternal repair of ionizing radiation-induced sperm lesions.** *F. Marchetti<sup>1</sup>, J. Essers<sup>2</sup>, R. Kanaar<sup>2</sup>, A.J. Wyrobek<sup>1</sup>*. 1) BBRP, Lawrence Livermore National Laboratory, Livermore, CA; 2) Erasmus University, Rotterdam, The Netherlands.

The repair of sperm DNA lesions is essential for genomic integrity of the zygote and proper embryonic development and is thought to be controlled by maternal mRNAs and proteins stored in the egg before fertilization. We investigated the role of mRad54 in the repair of ionizing radiation (IR)-induced sperm DNA lesions using female mice carrying a knockout mutation of this gene. B6C3F1 males were treated with 0 or 4 Gy gamma irradiation and were mated with either B6C3F1 or mRad54 null females seven days after exposure. First-cleavage (1-C1) zygote metaphases were analyzed for the presence of chromosomal aberrations using chromosome painting. The baseline frequencies of fertilized eggs (fertilization rate), 1-C1 metaphases (zygotic development) and chromosomal aberrations were not different between B6C3F1 and mRad54 null females. Paternal exposure to IR did not reduce the fertilization rate and zygotic development among B6C3F1 females. Among mRad54 null females, the fertilization rate was also unaffected, however, there was a significant reduction in the number of 1-C1 metaphases (75% vs 55%,  $P=0.02$ ). As expected, paternal exposure to IR increased the frequencies of zygotes with chromosomal aberrations in both B6C3F1 and mRad54 null females ( $P<0.001$ ). However, in mRad54 null females there was a 24% increase in the frequencies of zygotes with chromosomal aberrations with respect to B6C3F1 females. Additionally, there was a significant 2-fold increase ( $P=0.004$ ) in the total number of chromosomal aberrations per metaphase analyzed. This was mostly due to a 7-fold increase in the frequencies of chromatid-type aberrations. These results suggest that mRad54 is a key protein in the biochemical processing and repair of IR-induced sperm DNA lesions during the first cell cycle of mouse development. Work performed under the auspices of the U.S. DOE by the University of California, Lawrence Livermore National Laboratory under contract W-7405-ENG-48 with funding support from NIH ES 09117-03.

**A new class of fluorescent dyes: Alexa Fluor 555 and Alexa Fluor 647 dyes are spectrally identical to Cy3 and Cy5 dyes, yet produce much brighter DNA probes.** *W.G. Cox, M.P. Beaudet, C. Ying, S. Yue, X. Chen, V.L. Singer, J.M. Beechem, R.P. Haugland.* Molecular Probes, Eugene, OR.

DNA labeling based on enzymatic incorporation of aminoallyl-dUTP (AA-dUTP), followed by reaction with a succinimidyl ester dye, is a reliable labeling method that eliminates the intrinsic dye-to-dye variability associated with incorporation of pairs of fluorophore-labeled nucleotides. Unlike fluorophore-labeled nucleotides, AA-dUTP is efficiently incorporated by DNA polymerase I and reverse transcriptase, and we have developed conditions under which the AA-dUTP:dTTP ratio used in the reaction mixture dictates the resulting degree of substitution in the labeled DNA molecule. In theory, the brightness of the labeled DNA should increase linearly with the number of primary amines introduced into the DNA. We found, however, that the brightness of labeled DNA varied in a non-linear manner when those amines were labeled with either Cy3 or Cy5 dyes. To solve this problem, we invented two new fluorophores, Alexa Fluor 555 and Alexa Fluor 647 dyes, which are spectrally similar to Cy3 and Cy5 dyes, yet do not show this anomalous behavior when attached to DNA. In characterizing this phenomenon, we found that DNA labeled with Cy3 and Cy5 dyes exhibited a change in absorbance spectra that occurred as a function of increased dye labeling. We found a progressive shift in the absorbance spectra of these labeled DNA molecules, from their initial long wavelength absorbance maxima to blue-shifted maxima that are completely non-fluorescent. This effect is especially pronounced for DNA labeled with Cy5 dye. The spectral shifts and associated reduction in fluorescence were eliminated by nuclease digestion of the labeled DNA, indicating that it is the interaction of the bound dyes with one another on the DNA that is problematic. We found that the use of Alexa Fluor 555 and Alexa Fluor 647 dyes greatly minimizes this effect, and yields labeled DNA that is much brighter than DNA labeled with Cy3 or Cy5 dyes at equivalent degrees of labeling. We are evaluating the relative performance of DNA labeled with Alexa Fluor dyes and Cy dyes, in a variety of applications, including microarrays and FISH.

**Novel features of genome organization revealed by single copy FISH.** *P.K. Rogan, P.M. Cazcarro, J.H.M. Knoll.* Med Genetics & Mol Medicine, Children's Mercy Hospital, Kansas City, MO.

Some highly-conserved paralogs are misaligned and reiterated intervals are underrepresented in the human genome reference sequence due to incorrect positioning of the respective contigs (Genome Res. 11:1005, 2001). While using repeat-masked sequences to design short 1.5-10 kb probes for FISH studies (scFISH; Genome Res. 11:1086, 2001) of clinically-significant chromosomal regions, we detected unexpected hybridization, consistent with misassembly and misclassification of single/low copy sequences. Probes from 3 of 24 regions studied to date, ie. the chromosome 21q22.2 Down Syndrome critical region (20, 30, and 39 kb upstream, respectively, of the DSCR4 gene, which themselves are embedded in a >100 kb segmental duplicon) and chromosomal regions disrupted in acute myelogenous leukemia-M4 (20 and 60 kb downstream of PM5 in 16p13; exon 6 and exon7-IVS7 of ATBF1 in 16q22), detected repetitive sequence families with localized, clustered distributions on the short arms of acrocentric chromosomes - in addition to their respective locations on chromosomes 21 and 16. These probe sequences are unrelated to the ribosomal RNA cistron, which colocalizes to the acrocentric short arms. Hybridization to the acrocentric short arms was eliminated either by suppression with C<sub>0</sub>t1 DNA or by high-stringency post-hybridization washes. We also found that members of a paralogous family of sequences near PM5, all of which were presumed distal and »1.3 mb telomeric of the 16p13 breakpoint in AML-M4, unexpectedly also mapped proximal to this breakpoint, based on their chromosomal locations in patients with this disorder. Sequence gaps are more dense and there is less redundant coverage in this region, consistent with lower reliability of ordering of these sequences. scFISH is likely to be useful in detecting other misassembled regions and other unrecognized repetitive sequence families. By differential labeling of flanking probes, scFISH may also be useful in verifying the existence and lengths of sequence gaps.

**Molecular cytogenetic characterization of a new case of partial trisomy 16q24.1-qter: literature review and phenotype-genotype correlations.** *S. Brisset<sup>1</sup>, G. Joly<sup>2</sup>, C. Ozilou<sup>1</sup>, J.M. Lapierre<sup>1</sup>, P. Gosset<sup>1</sup>, M. Le Lorc'h<sup>1</sup>, O. Raoul<sup>1</sup>, C. Turleau<sup>1</sup>, M. Vekemans<sup>1</sup>, S.P. Romana<sup>1</sup>.* 1) Department of Genetics, Hopital Necker-Enfants Malades, Paris, France; 2) Cytogenetics, CHU Charles Nicolle, Rouen, France.

We describe a 3 1/2-year-old girl with psychomotor and mental retardation, dysmorphic features including high forehead with bitemporal narrowing, a broad nasal bridge and a broadened nose, antimongoloid slant of palpebral fissures, abnormal ears, vertebral abnormalities, cardiac defect, genital hypoplasia and anorectal abnormalities. The karyotype of our patient (550 bands) was normal. Molecular cytogenetics techniques including comparative genomic hybridization (CGH) and FISH revealed that this girl was carrier of a de novo derivative chromosome 7 arising from a cryptic t(7;16)(p22.3;q24.1) translocation generating a trisomy 16q24.1-qter and a 7p22.3-pter deletion. FISH with a series of specific chromosome 7p and 16q probes permitted us to delineate the chromosome 7 breakpoint distal to YAC855A6 (WI-6692) and the chromosome 16 breakpoint between BAC457K7 (D42O53) and BAC442O1 (SGC30711). The comparison of the clinical features of our patient and those of 2 cases of pure terminal 7p deletion and 28 cases of trisomy 16q reported in the literature allowed us to establish the following phenotype-genotype correlations for trisomy of the long arm of chromosome 16: profound and severe mental retardation to band 16q12.1-13, intestinal abnormalities to 16q13 band, feet deformity (club feet) to 16q22 region, flexion/contractures of joints to 16q23 band, and dysmorphic features (high/prominent forehead, bitemporal narrowing, periorbital edema in the neonatal period), vertebral abnormalities, anorectal anomalies and low birth weight to band 16q24.

**Characterization of breakpoints in 67 Prader-Willi and Angelman syndrome deletion patients.** *M.C. Varela, C.P. Koiffmann.* Dept Biol, Univ Sao Paulo, Sao Paulo, Brazil.

Prader-Willi (PWS) and Angelman syndromes (AS) are distinct neurobehavioral disorders resulting from molecular defects in an imprinted cluster in chromosome 15q11-q13. PWS results from the loss of paternal gene expression, whereas AS is caused by loss of expression of a maternal gene (UBE3A). The chromosome segment 15q11-q13 is meiotically unstable with an unusual variety of cytogenetic rearrangements, including a common 4Mb deletion that occurs in 75% of PWS/AS patients. Here we present results on breakpoint analysis of 67 PWS/AS deletion patients (36 PWS; 31 AS), which strongly supports evidence indicating the presence of 3 specific breakpoint clusters in 15q (BP1-BP3). The patients were diagnosed by DNA methylation at SNURF-SNRPN exon 1, with the deletion extent detected by microsatellite analysis of 6 markers within and outside the critical region as well as 5 markers flanking BP1-3. No significant differences in the deletion breakpoint locations were observed between paternally or maternally derived deletions in PWS or AS, respectively. Of 63 patients analyzed for the proximal BP1-2 region markers D15SS541/D15S542, 54 were informative for at least one of two markers. Overall, 28% (15/54) were deleted for S541/542, indicating the deletion breakpoint being proximal to these loci (BP1). The other 72% (39/54) were heterozygous at S541/542, and of 34 patients were tested for D15SS543, all 12 informative cases showed deletion, while 22 uninformative cases had only one allele shared by both parents, indicating that the majority or all these cases had a proximal breakpoint at BP2. At the distal end of the deletions, all 36 informative cases were deleted for D15S1002 (none of the other 24 patients were heterozygous). In contrast, 0/39 informative cases were deleted for D15S1048. These results suggest a single major PWS/AS breakpoint cluster in the distal region of 15q11-q13 (BP3), between S1002 and S1048. In summary, we found only 3 breakpoint regions in PWS/AS deletion patients (BP1-BP3). Ongoing molecular studies will determine whether the PWS/AS breakpoints occur in HERC2- or other duplicons in these regions. Support: FAPESP, CEPID, PRONEX.

**Real-time PCR to detect a chromosome 1p36 deletion: A novel screening strategy for submicroscopic subtelomeric deletions.** *R.L. Touraine<sup>1</sup>, V. Adouard<sup>1</sup>, B. de Fréminville<sup>1</sup>, S. Pestre<sup>1</sup>, M. Till<sup>2</sup>, F. Prieur<sup>1</sup>, B. Lauras<sup>1</sup>.* 1) Genetique, CHU-Hopital Nord, Saint Etienne, France; 2) Genetique, CHU-Hopital Debrousse, Lyon, France.

Submicroscopic subtelomeric chromosome rearrangements are considered to be found in 5-10% of children with moderate to severe mental retardation and in 0.5-1% of children with mild mental retardation. Two principal techniques are used to detect these anomalies, namely FISH detection and microsatellite markers analysis. The utilization of the multitelomeric FISH analysis is limited by its cost. Microsatellites analysis is less informative and further requires the parents' DNA, making it expensive too. We decided to use a different approach based on locus quantification using real-time PCR. We first tested this method on a patient harboring a chromosome 1p36 deletion.

The patient was a young adult male with mild to moderate mental retardation and few dysmorphic features (large hands with short fifth fingers, small palpebral fissures, deep-set eyes, flat nasal bridge and pointed chin). De novo chromosome 1p36 was diagnosed on high resolution karyotyping and confirmed by FISH analysis. Real-time PCR was performed on a LightCycler (Roche) using either SYBR Green or hybridization probes. Loci for quantitative-PCR analysis were chosen in subtelomeric clones of chromosome 1pter and 1qter, according to the available databases.

We were able to show 1pter haploinsufficiency in our patient, together with a normal 1qter dosage. We found the opposite results in a control patient having a chromosome 1qter deletion.

This study established the feasibility of real-time PCR analysis for the screening of subtelomeric aneuploidies. We will discuss the respective advantages of SYBR Green and hybridization probes for the detection of haploinsufficiency with the LightCycler system. This new strategy represents a quicker and cheaper alternative to the multitelomeric FISH analysis.

**Cul1 and Skp1 complexes inactivation leads to defective chromosome segregation, genetic instability and neoplastic transformation.** *J. Liu, R. Piva, R. Chiarle, A. Podda, M. Pagano, G. Inghirami.* Pathology, NYU School of Medicine, 31st E.River Drive, NY, NY.

The ubiquitin dependent proteolysis involves a cascade of enzymatic reactions catalyzed by the E1 ubiquitin-activating enzyme, the E2 ubiquitin-conjugating enzymes, and the E3 ubiquitin-protein ligases. The substrate specificity of the ubiquitin pathway is conferred by the E3s. One such E3 is a multimeric protein complex designated SCF composed of Skp1, Cullin, F-box-containing proteins, and Rbx1/Roc1. The SCF complex promotes cell cycle transitions through degradation of multiple cell cycle regulators. To block SCF- and other Skp1-dependent activities, we generated Cul1 dominant-negative mutants (D-Cul1) capable of binding Skp1 but not Rbx1. As a proof of principle, D-Cul1 over-expression induced the accumulation of p27, b-catenin, cyclin E and p21, all targets for SCF-mediated ubiquitination. The expression of high levels of D-Cul1 resulted in hyperdiploid and multinucleated cells, with a concurrent number of centrosomes. Impaired chromosome segregation and chromosomal instability was strikingly seen in D-Cul1 expressing cells. Accordingly, FISH analysis confirmed that D-Cul1 cells underwent random and uneven chromosomal segregation resulting in cell growth defects. Over time, however, D-Cul1 expressing NIH-3T3 cells could overcome this proliferative block and generate tumors in nude mice. Transgenic (Tg) mice expressing D-Cul1 in the T-cell lineage showed hypocellularity in the thymus and peripheral lymphoid organs. Starting at week sixteen, D-Cul1 Tg mice displayed a high incidence (>80%) of CD4-CD8 double positive thymic lymphomas. Moreover, DCul1 Tg lymphomas and derived cell lines were aneuploid (85-90%) with widespread karyotype heterogeneity. Both depleted and neoplastic phenotypes in D-Cul1 Tg mice were partially rescued crossing D-Cul1 with Skp1 Tg mice, confirming the specificity of these findings and the crucial role of Skp1. Overall, our data demonstrate that Cul1 and possibly other Skp1 complexes are instrumental in the maintenance of chromosomal stability.

**Chromosome analysis of endometrial biopsy from a female IVF-candidate with 45X/46,XX mosaicism. H.E. Wyandt, S. Phansey-Chauhan, J.M. Milunsky.** Center for Human Genetics, Boston Univ Sch Medicine, Boston, MA.

A 26 year-old woman had a history of two IUI pregnancies that miscarried at 5 and 10 weeks. Her husband has a normal karyotype. The woman has 45,X in 43% of cells and 46,XX in 67% of cells from peripheral blood. One cell was 47,XXX. She has no major health problems. Menarche was at age 13 and she has had regular menses. She has normal hearing and vision and no known learning problems. Her weight is in the 10th centile, height in the 3rd centile and head circumference in the 90th centile. She has a prominent chin, posteriorly rotated ears, malocclusion, cubitus valgus, slightly hyperconvex nails, mild scoliosis and multiple nevi and freckles. Due to a planned IVF, an endometrial biopsy was obtained for hormonal assessment and concurrently submitted for chromosome studies. Three sites were cultured: site 1 had 45,X in 10/11 cells, site 2 in 9/20 cells and site 3 in 8/20 cells. Overall, 51% of cells were 45,X and 49% were 46,XX. No cells had 47,XXX. Two % of women with Turner syndrome (TS) reportedly have pregnancies (more likely, if they are mosaic or have a structurally abnormal X). A high rate of pregnancies miscarry or end in perinatal death, malformations and chromosome abnormalities. IVF is a proposed solution for TS patients, especially those who are mosaic. A few IVF pregnancies are reported, with a low rate of embryos transferred. Reasons cited are poor embryo quality and a high frequency of chromosome abnormalities in the embryos. We would like to suggest an additional possible impediment to successful IVF -namely problems in implantation due to mosaicism within the uterine lining. Because endometrium is replaced at each menses, it is conceivable the degree of mosaicism could vary in each pregnancy. To our knowledge, this idea is untested. Whether such mosaicism is significant in IVF success or not will require additional chromosome studies of pre-IVF endometrial biopsies and of pregnancy outcomes. The option of IVF is increasingly offered to high-risk infertility patients including those with TS. Chromosome study of an endometrial biopsy in TS patients is worth considering as a routine part of IVF work-up.

**The use of X-chromosome inactivation to determine the mechanism of UPD15.** *C. Fridman, C.P. Koiffmann.* Dept Biology, Univ Sao Paulo, Sao Paulo, Brazil.

Prader-Willi (PWS) and Angelman syndrome (AS) are neurobehavioral disorders resulting from the loss of expression of imprinted genes in the paternal or maternal chromosome 15, respectively, and can result from 15q11q13 deletion, uniparental disomy (UPD), imprinting mutation or UBE3A mutations in AS. Maternal (mat) or paternal (pat) UPD may arise through gamete complementation (GC), trisomic rescue (TR) or compensatory UPD (C). GC involves pat and mat meiotic errors, while TR and C involve a meiotic error and a postzygotic loss or gain of a chromosome, respectively. To identify the mechanism of UPD, X-inactivation (XCI) studies were used as an indirect test of trisomic rescue versus the other two mechanisms. Both mat and pat X chromosomes are active in pre-implantation embryos and random XCI occurs around the time of implantation in the fetal precursor cells. If matUPD arises from zygotic rescue, this chromosome loss can occur either early in development before XCI, which would be associated with random XCI, or shortly after XCI and in the latter case the presence of non-random XCI would be detected. Similarly, patUPD is a rare event and the embryonic timing of the gain of a chromosome 15 can be determined by the degree of XCI. We performed X-inactivation studies (DXS225) in 7 matUPD15 and 3 patUPD15 females, and defined non-random XCI as more than 90% inactivation of one X. Two cases (1PWS,1AS) were uninformative. Two patUPD15 showed random XCI; one was known to be due to meiotic II nondisjunction, but the hypothesis of TR could not be confirmed. Only one matUPD15 showed extremely skewed XCI (100%), while 5 cases showed random XCI (3 between 50-69%, one has 70% and one 80% skewing). In one case, trisomy 15 was detected by CVS testing followed by a normal karyotype in amniocentesis, and the matUPD15 was detected when the child was diagnosed with PWS, confirming the TR. The degree of skewing was 66:34, suggesting the loss of one chromosome 15 before XCI in the embryo proper. The data are consistent with most cases of matUPD15 and patUPD15 arising from an early TR or C mechanism, respectively, but a larger dataset is needed to accurately establish correlations between XCI and the mechanisms that generate UPD. Support: FAPESP, CEPID.

**Uniparental disomy: UK Collaborative Study.** *K.K. Smith<sup>1</sup>, T.A. Boyle<sup>2</sup>, D.L. Morgan<sup>1</sup>, C.A. Parkin<sup>3</sup>.* 1) Cytogenetics, Addenbrooke's NHS Trust, Cambridge, England; 2) Cytogenetics, Salisbury NHS Trust, Salisbury, England; 3) Cytogenetics, City Hospital NHS Trust, Nottingham, England.

An Association of Clinical Cytogeneticists Collaborative Study collected data from eighteen UK laboratories on prenatal and postnatal uniparental disomy (UPD) investigations.

**PRENATAL:** Fetal UPD 15 was confirmed in two cases of trisomy 15 confined to the placenta (CPM) and one case of apparent trisomy 15 pseudomosaicism in amniotic fluid. Fourteen cases with a supernumerary marker derived from 15 and 12 cases with a parent carrier of a Robertsonian translocation involving 15 were investigated and all showed biparental inheritance. Fifty prenatal cases where one parent carried a Robertsonian translocation involving chromosome 14 (24 cases maternal and 26 cases paternal) showed biparental inheritance. There were no cases of UPD7 or UPD6 detected. UPD16 was confirmed in two cases of trisomy 16 CPM.

**POSTNATAL:** UPD14 was confirmed in a female with precocious puberty, a phenotypically abnormal carrier of a balanced Robertsonian translocation involving 14 and in conjunction with trisomy 14 mosaicism. Four referrals for Silver-Russell syndrome/short stature showed UPD7 and one case of transient neonatal diabetes mellitus showed UPD6. UPD was found associated with either structural rearrangements or mosaicism for chromosomes 2, 6, 7 and 9.

**Towards an X inactivation profile of the mouse X chromosome.** *L.H. Chadwick, A. Cottle, H.F. Willard.* Genetics, Case Western Reserve University and University Hospitals of Cleveland, Cleveland, OH.

While the majority of genes on the inactive X chromosome (Xi) are silenced by X inactivation, a subset of genes has been identified that escape from inactivation and are biallelically expressed. In a recent survey of 224 human X-linked transcripts, approximately 15% were found to escape inactivation in somatic cell hybrids (PNAS 96(25):14440-4). In contrast, the X inactivation profile of the mouse X chromosome is far less well defined. The few genes that have been tested are mainly restricted to the homologues of genes that escape inactivation in humans. Only five genes have been identified thus far that escape inactivation in mice. It is unclear whether this discrepancy between humans and mice reflects a difference in the regulation of X inactivation between these two species or merely a sampling bias. To address this question generally, we are conducting an ongoing survey of the X inactivation status of genes on the mouse X chromosome using RT-PCR and allele-specific restriction enzyme digestion. To generate informative polymorphisms for our assays, we used *M. domesticus* x *M. castaneus* F1 mice carrying Searles translocation (T16H), which show non-random inactivation of the normal X. Polymorphisms that distinguish these two alleles have been identified for twenty X-linked genes. Thus far, we have designed assays for seven of these genes; all seven showed monoallelic expression from the T16H chromosome, indicating that they are subject to inactivation. In addition, we are analyzing the relative levels of escape from inactivation of genes on the mouse X. Previous work has shown that *Smcx* expression from the Xi is roughly half that of the *Xa*, with some variability between individual mice. Using a quantitative allele-specific expression assay, we have confirmed these data and have determined the relative level of escape for *Utx*. On average, we have found *Utx* expression from the Xi to be nearly 80% of the active X expression, significantly higher than what has been demonstrated for *Smcx*. These data indicate that the local chromatin environment may vary across the Xi, determining the likelihood of escape from inactivation and/or the degree of silencing.

**Variability in DNA methylation assays of X chromosome inactivation (XCI).** *C.L. Beever, R.H. Jiang, C.J. Brown, W.P. Robinson.* Department of Medical Genetics, University of British Columbia, Vancouver, B.C., Canada.

Skewed XCI is currently used as a biological marker for clonality and carrier status of certain X-linked diseases as well as for research into various biological processes and disorders. With the broad use of XCI assays, unbiased measurement of the degree of XCI skewing is necessary. XCI assays generally involve amplification by PCR of an X-linked locus which is both differentially methylated, allowing distinction of the inactive and active X via digestion with a methylation-sensitive enzyme (HpaII), and polymorphic, allowing discrimination of alleles of the locus. To test the reproducibility of such assays, we examined the effect of the following on XCI results: 1) locus (androgen receptor (AR) vs. FMR-1); 2) the use of a secondary cutter (RsaI) during digestion with HpaII; and 3) quantification methods (densitometry of silver-stained gels vs. automated fluorescent analysis (AFA) using an ABI 310). The mean difference in percent inactivation of one allele in 12 samples tested with both AR and FMR-1 was  $10.7\% \pm 2.0\%$  (mean  $\pm$  SE) with a range of 0-26. One case was 99% skewed with FMR-1 and 75% skewed with AR. Further analysis of this sample with a third locus, DXS6673E, was consistent with the AR results, suggesting additional influences upon FMR-1 methylation make this assay less reliable. Using the AR locus, the mean difference among 77 samples assayed with and without a secondary cutter was  $6.4\% \pm 0.7\%$  with a range of 0 to 35. Overall, a slight tendency to greater skewing was seen when a secondary cutter was used, perhaps reflecting reduced secondary structure formation that could impede digestion by HpaII or amplification. Although results from densitometry and AFA were highly correlated for 18 samples tested by both methods, within sample reproducibility was higher with AFA. In conclusion, we recommend using the AR locus with a secondary cutter and AFA. With this methodology we observed a mean difference in 45 replicated samples of only  $2.9\% \pm 0.7\%$ . Additional studies, including comparisons to expression based assays, would validate the accuracy of measuring XCI skewing based on DNA methylation at a single locus.

**Identification of autoimmune sera that target the Barr body.** *W.H. Brooks<sup>1</sup>, B. Hong<sup>1</sup>, M. Satoh<sup>2</sup>, W.H. Reeves<sup>2</sup>, P. Reeves<sup>3</sup>, B. Panning<sup>3</sup>, T.P. Yang<sup>1</sup>.* 1) Dept. of Biochem. & Mol. Biol., Univ. of Florida, Gainesville, FL; 2) Dept. of Rheumat. & Clin. Immunol., Univ. of Florida, Gainesville, FL; 3) Dept. of Biochem. & Biophys., Univ. of California at San Francisco, San Francisco, CA.

Early in mammalian embryogenesis, one of the two X chromosomes in female somatic cells is transcriptionally inactivated to achieve dosage compensation of X-linked genes in males and females. The resulting inactive X chromosome appears as a dense, peripheral, heterochromatic structure in the nucleus, termed the Barr body. Little is known about the structure and molecular composition of the Barr body. Because sera from autoimmune patients commonly contain antibodies against a variety of nuclear structures, we used indirect immunofluorescence to screen sera from 440 autoimmune patients for antibodies against the Barr body as an initial step to investigate the composition of the Barr body. Autoimmune diseases represented by the patients included systemic lupus erythematosus (SLE), scleroderma, mixed connective tissue disease, discoid lupus and others. Each serum was applied to XY male and XXX female human fibroblasts grown on slides, and examined for preferential immunostaining of the Barr body. Two sera were identified that stained a distinct nuclear structure consistent in size, location, and number with the Barr body. Immunostaining of female fibroblasts by the first serum demonstrated co-localization with *XIST* RNA. This serum also stained all human metaphase chromosomes and a nuclear structure consistent with the inactive X in female mouse fibroblasts. Staining of metaphase chromosomes did not show preferential staining of centromeres, indicating the antigen(s) is unlikely to be a general heterochromatin-associated protein. Immunostaining of cells from E7.5 mouse embryos did not show co-localization with *Xist* RNA, suggesting the antigen(s) is unlikely to be associated with initiation of X inactivation. Analysis of the second serum, from a female SLE patient, is currently in progress. These sera provide a novel strategy for investigating the composition and dynamics of the Barr body and demonstrate that one or more components of the Barr body are autoantigens in some autoimmune diseases.

**Skewed X-inactivation in extraembryonic tissues and early embryonic lethality in humans.** *V.N. Evdokimova*<sup>1, 2</sup>, *S.A. Nazarenko*<sup>2</sup>. 1) Dept Biological Sci, Florida Intl Univ, Miami, FL; 2) Institute of Medical Genetics, RAMS, Tomsk, Russia.

Genetic inactivation of one X-chromosome appears in early embryonic development of mammals and leads to a monoallelic expression of X-linked genes in the somatic cells. Repression of one of X-chromosomes inherited from either mother or father in 100% of the cells can create uniparental expression pattern even in the normal 46,XX females without uniparental disomy by X. Most mammal species have imprinted paternal X-inactivation in the extraembryonic cell lines. In terms of evolution the distribution of imprinted paternal X-inactivation tends to decrease from whole organism (in marsupials) to the restricted cell lines (in mice). The patterns of preferential X-inactivation in humans is not completely clear. The goal of present study was to show the patterns of X-inactivation in extraembryonic tissues in spontaneous and induced abortions during the first trimester of development with normal 46,XX karyotype. The DNA samples that were extracted from extraembryonic tissues dissected from spontaneous (52) and induced (37) abortuses with normal female karyotype - 46,XX and DNA samples from their parents were investigated. The karyotypes were obtained by cytogenetic analysis and verified by PCR analysis with a set of chromosome-specific STR-markers. Skewed X-inactivation was determined using the AR model. PCR amplification was performed with TET-labeled primers. The PCR products were separated by automated capillary electrophoresis in an ABI PRISM 310 Genetic Analyzer. The size and ratio of AR alleles are calculated automatically using GeneScan Software (Perkin Elmer). Two types of X-inactivation were found in spontaneous abortions (SA) and induced abortions (IA): stochastic and skewed. Stochastic X-inactivation was in 53.2% of SA and in 40.0% of IA. However, the comparative analysis of the distribution of X-inactivation patterns in the different morphological groups of the spontaneous abortions (blind ovums, missed abortuses, spontaneous abortuses) indicated the tendency to increasing asymmetrical X-inactivation depends on the severity of damage in the embryonic development.

**Mouse *Prophet of Pit1 (Prop1)* gene knockout.** I. Nasonkin, S. Camper. Human Genetics, University of Michigan, Ann Arbor, MI.

*Prophet of Pit1 (Prop1)* is one of several homeodomain transcription factors that are required for the development of the hormone producing cell types of the anterior pituitary gland. During embryogenesis *Prop1* regulates the expression of other homeobox genes, extinguishing *Hesx1* and activating *Pit1*. Ames dwarf mice have a Ser83Pro mutation in the homeodomain of *Prop1* that causes a partial loss of function and leads to profound pituitary hypoplasia. The *Pit1* lineage fails to develop, resulting in GH, TSH and PRL deficiency. Gonadotropins are also reduced, but corticotropes appear unaffected. *Prop1* is usually extinguished by embryonic day 16. Persistent expression of *Prop1* interferes with gonadotrope differentiation and thyrotrope function, and increases the incidence of pituitary adenomas. Thus, regulation of *Prop1* expression is important for normal pituitary development and function. Eleven different mutations in *PROP1* have been described in human patients with Combined Pituitary Hormone Deficiency (CPHD), with an A301G302 deletion being the most common. The age of onset, effect on pituitary size and number of hormone deficiencies is variable, but patients generally lack GH, TSH, PRL, LH and FSH. ACTH deficiency occurs rarely. There is no obvious genotype-phenotype correlation, suggesting that other genes may influence the severity of the endocrine deficiency. In order to understand the role of *PROP1* in pituitary development we created a null allele by gene targeting. Mice homozygous for the *Prop1* null allele exhibit differentiation of corticotropes and gonadotropes, but the hypoplasia of the anterior lobe is more severe than in the Ames dwarf. In addition, 50% of the homozygous null mice die before weaning, while Ames dwarf mice are viable. This null allele will be a valuable tool for dissecting the role of *Prop1* in corticotrope and gonadotrope function.

**AP-2a Transcription Factor Mutation Demonstrates the Power of ENU.** *N. Ahituv*<sup>1</sup>, *A. Erven*<sup>2</sup>, *H. Fuchs*<sup>3</sup>, *R. Balling*<sup>3</sup>, *M. Hrabe de Angelis*<sup>3</sup>, *K.P. Steel*<sup>2</sup>, *K.B. Avraham*<sup>1</sup>. 1) Department of Human Genetics & Molecular Medicine, Sackler School of Medicine, Tel-Aviv University, Israel; 2) MRC Institute of Hearing Research, University Park, Nottingham, UK; 3) GSF Center of Environment & Health Institute of Experimental Genetics, Neuherberg, Germany.

Mice serve a vital role as a model for studying human genetic hearing loss. Due to the similarities between mouse and human genomes, auditory and vestibular function and morphology, mice are being used both for isolating genes and characterizing the inner ear. Using N-ethyl-N-nitrosourea (ENU), a chemical mutagen, we are generating deaf and vestibular mouse models to search and study the function of different genes and proteins in the auditory and vestibular system. One of the advantages of using ENU is that it mutates genes randomly, causing single nucleotide changes, and provides the possibility of learning more about protein site-specific functions. Several dominant ENU induced deaf and vestibular malfunction mouse mutants have been characterized on a phenotypic level, and were mapped to chromosomal regions.

Doarad (*Dor*), a dominant ENU-derived mutant, has a misshapen incus and mildly-abnormal malleus and stapes, leading to deafness. *Dor* was found to map to a 5.5 cM region on mouse chromosome 13. This region contains AP-2a, a member of a family of transcription factors found to function as regulators in a large spectrum of important biological functions, including cell-cycle control, apoptosis and vertebrate development. AP-2a homozygous knockout mice exhibit failure of cranial neural-tube closure at embryonic day 9, which leads to skeletal defects and anencephaly; mice die perinatally due to severe congenital defects. Our candidate gene analysis of *Dor* revealed a C®T missense mutation in AP-2a that changes a highly conserved proline, located in the PY motif of the activation domain, to leucine. No live homozygotes were detected in a total of 4 litters (n=18), suggesting that the *Dor* mutation in a homozygous state is lethal. This is the first report of a mutation in a gene specifically causing middle ear abnormalities, leading to conductive hearing loss.

**Genetic Modifier of Mouse Eya1BOR Mutation**<sup>BOR</sup>. *D.A. Gold*<sup>1,2</sup>, *D. Concepcion*<sup>2</sup>, *X. Wang*<sup>2</sup>, *E.M. Keithley*<sup>2</sup>, *A.F. Ryan*<sup>1,2</sup>, *B.A. Hamilton*<sup>1,2</sup>. 1) Biomedical Sciences, UC San Diego, San Diego, CA; 2) School of Medicine, UC San Diego, San Diego, CA.

Mutations in the EYA1 gene cause dominant branchio-oto-renal syndrome (BOR) in humans. A spontaneous mouse mutation, Eya1<sup>BOR</sup>, causes similar phenotypes in inner ear and kidneys with recessive inheritance. Each Eya1<sup>BOR</sup> allele expresses approximately 50% normal RNA levels due to insertion of an endogenous retrovirus. We have observed strong variation in Eya1<sup>BOR</sup> homozygous phenotypes on a mixed genetic background. Using histology, auditory-evoked brainstem responses (ABR) and northern blot analysis, we see variation of the Eya1<sup>BOR</sup> phenotype at morphological, physiological, and molecular levels. Our preliminary data suggests that this effect maps near the Mvb1 locus, which has similar effects on the mouse vibrator mutation.

**Definition of co-ordinately regulated gene clusters in muscle regeneration.** *P. Zhao*<sup>1,2</sup>, *Y-W. Chen*<sup>1</sup>, *D. Dressman*<sup>1</sup>, *E.P. Hoffman*<sup>1</sup>. 1) Research Center for Genetic Medicine, Children's National Medical Center, Washington, DC; 2) Genetics Program, George Washington University, Washington, DC.

Muscle regeneration is important in inherited muscle disease, and slowly fails in the progressive dystrophies. Muscle regeneration is important to development geneticists as it is believed to recapitulate embryonic muscle development. Here, we report the first use of expression profiling in tissue regeneration *in vivo*. We present the identification of co-ordinately regulated gene clusters in staged skeletal muscle degeneration/regeneration induced by cardiotoxin. Mouse gastronemius muscles at 6 time points (duplicate muscles at 0, 12h, 1 day, 2 day, 4 day and 10 day) after cardiotoxin or PBS injection were profiled using Affymetrix murine genome U74A chips (10,000 genes/ESTs). Gene expression patterns were temporally clustered using GeneSpring. We nucleated gene clusters using known muscle regeneration markers (myogenin, MyoD, myf5, M-cadherin, N-cadherin, acetylcholine receptors). We identified a large number of novel genes involved in muscle regeneration, including transcription factors (Sox11, Slug), signaling pathway proteins (Calpain6, WISP-1, Peg3, Ulip), and extracellular matrix proteins (matrilin-2, osteoglycin, Col15a1, Col8a1). We further tested the hypothesis that temporal clustering is able to lead to identification of novel downstream targets of the myogenic regulatory factor, MyoD. We used a known MyoD downstream target to nucleate a temporal cluster. We found MyoD binding site (E-box) in the putative promoter region of several novel cluster members. We then verified some of these as regulated by MyoD by promoter gel shift assay. Our results show that genome-wide expression profiling method can be utilized in an *in vivo* model of muscle regeneration. Moreover, we show that *in vivo* temporal clustering is an effective approach to identify novel downstream targets of myogenic transcription factors.

**REDUCTED LEVEL OF DYTROPHIN Dp71 INHIBITS NEURONAL DIFFERENTIATION OF PC12 CELLS.**

*R. Acosta-Salinas*<sup>1</sup>, *C. Montañez*<sup>1</sup>, *P. Gómez*<sup>1</sup>, *J. Luna*<sup>2</sup>, *B. Cisneros*<sup>1</sup>. 1) Genetic and Molecular Biology, CINVESTAV, Mexico DF, Mexico; 2) Physiology, Biophysic and Neurosciences, CINVESTAV, Mexico DF, Mexico.

Duchenne muscular dystrophy (DMD) is caused by mutations in the DMD gene. DMD gene produces at least seven different dystrophin isoforms and the smallest one, Dp71 has a unique N-terminus of seven amino acids but shares the cystein-rich and C-terminal domains with all other dystrophins. Dp71 is the most abundant dystrophin in the nervous system and its expression has been correlated with stages of terminal neuronal differentiation. Likewise, it is thought the Dp71 is involved in the DMD-associated mental retardation present in 30% of the patients. In order to ascertain the function of the Dp71 in neuronal cells we have adopted the PC12 cells as a study model. These cells respond to the nerve growth factor and differentiate into cells morphologically and biochemically similar to sympathetic neurons. Previously we found that two different splicing isoforms of Dp71 are expressed in PC12 cells, and interestingly, splicing isoform, which lacks exon 78, augments, its expression during neuronal differentiation. If Dp71 has an important role in neuronal differentiation, it could be expected that its absence affect the mentioned cellular process. Therefore, we decide to inhibit the expression to Dp71 in PC12 cells by antisense treatment. Vectors, expressing sense and antisense Dp71 RNAs, were constructed and stable transfectans clones were isolated by neomycin resistance. To select clones with reduced levels of Dp71, western blot and immunofluorescence assays, using anti-Dp71 antibodies, we performed. Selected Dp71-deficient clones present a marked inhibition of neurite outgrowth, after NGFA treatment. Confocal microscopy analysis of proteins belonging to the dystrophin associated proteins complex showed that these proteins are affected by the reduction of Dp71. Results suggest that Dp71 and its associated proteins play an important role during neuronal differentiation.

**Lateralized expression of sex chromosome genes in a gynandromorphic finch does not predict masculine brain phenotype.** *R.J. Agate*<sup>1</sup>, *S. Mann*<sup>2</sup>, *C. Schanen*<sup>2</sup>, *A. Palotie*<sup>2, 3</sup>, *A. Arnold*<sup>1</sup>. 1) Physiological Science, UCLA, Los Angeles, CA; 2) Human Genetics, UCLA, Los Angeles, CA; 3) Pathology, UCLA, Los Angeles, CA.

A prominent question regarding sexual differentiation of the neural song system in zebra finches is whether this difference is induced by sex-specific action of gonadal steroid hormones, by direct sex-specific action of sex chromosome genes expressed in the brain, or by some combination of these mechanisms. We have analyzed the brain/behavior of a zebra finch bilateral gynandromorph to shed light on this question. The plumage color was male on the right, female on the left. Its behavior was completely masculine in that it sang a masculine song, courted females successfully and copulated as a male. The amount of DNA per blood cell was in the diploid range. The gonads were lateralized, with a testis on the right and mostly ovarian tissue on the left. The neural circuit for song was masculine on both sides.

In birds males are the homogametic sex (ZZ) and females the heterogametic sex (ZW). The W chromosome is small and heterochromatic like the Y chromosome in mammals. In this bird, W-specific genomic DNA encoding CHDW was found predominantly on the left side in brain and feather pulp by PCR. The mRNA encoding the W-linked gene ASW, expressed only in genetically female brains, was expressed at high levels on the left side of the brain but was low or absent on the right. These results indicate that the bilateral masculine neural phenotype does not correlate with expression/distribution of two W-chromosome genes, compatible with a theory of hormonal induction of sex differences in brain. A direct role for genetic factors cannot be completely excluded by the available data because, for example, side-specific rearrangement of the sex chromosomes could have resulted in the lateralized expression of some genes regulating sexual differentiation of gonads and plumage but not brain. Supported by: NIH DC00217

**HOX-B1 allelic variants in hindbrain malformations.** *V. Capra<sup>1</sup>, A. Moroni<sup>1</sup>, P. De Marco<sup>1</sup>, E. Merello<sup>1</sup>, L. Arata<sup>1</sup>, M. Crippa<sup>2</sup>, F. Blasi<sup>2</sup>, A. Cama<sup>1</sup>.* 1) Lab Servizio Di Neurochirurgia, Inst Scientifico G Gaslini, Genova, Italy; 2) Laboratorio di Genetica molecolare, DIBIT-HSR, Milan-Italy.

Hindbrain malformations are a group of congenital developmental anomalies involving cerebellum, brain-stem, 4th ventricle, and cervical spinal cord. Chiari complex is the most frequent form and is characterized by caudal cerebellar herniation, sometimes associated with lower brainstem dysmorphism, skull base and vertebral anomalies. In vertebral hindbrain, generation of regional diversity is achieved through a segmentational process that leads to the formation of 7 rhombomeres. Hox genes display a key role in controlling, regulating neuronal migration and maintaining cellular segmental identity. Hoxb-1 gene is the first, in addition to Hoxa-1 gene, to be activated in CNS; moreover its expression domain is selectively restricted to rhombomere 4 and neural crest cells that from r4 migrate in the second branchial arch. Mutant mouse analysis and expression studies has shown that Hoxb1 gene is the first, in addition to Hoxa1, to be activated in CNS and it is the only one to show a regionally restricted expression domain (r4). We performed, by means of SSCP analysis, a mutational screening of the homologous HOX-B1 gene in 64 patients and 198 control individuals. Sequencing of abnormal SSCP conformomers revealed the existence of three allelic variants characterized by the presence of several in cis associated mutations, at the NH2 terminal region of the gene. The a1 haplotype, distributed according the Hardy-Weinberg equilibrium, is due to a 9-bp tandem duplication (CCCACAGCG) at position 80 associated to two synonymous transitions (C237T and G450A) and one missense mutation (A309T). The a1A allele, that differs from a1 for the absence of the A309T and the G450A was identified in 2 unrelated patients, while the a2 haplotype, showing three silent substitutions (G114A, C213T and G246A) and the C167T missense mutation, was isolated in three additional patients. Since a1A and a2 haplotypes were present in five healthy parents, but not in the control population, we can't directly correlate these mutations to the disorder but they could be predisposing factors to this complex malformation.

**Down syndrome cell adhesion molecule (DSCAM): a role in spinal cord differentiation and cortical plasticity?**

*G.M. Barlow<sup>1</sup>, G.E. Lyons<sup>2</sup>, J.R. Korenberg<sup>1</sup>*. 1) Medical Genetics Birth Defects Center, Cedars-Sinai Medical Ctr, Los Angeles, CA; 2) Dept. Anatomy, U. Wisconsin Medical School, Madison, WI.

Molecules involved in axon guidance play central roles in the development and plasticity of the human central and peripheral nervous systems (CNS and PNS) through their effects on neurite outgrowth, differentiation and synaptic transmission. In Down syndrome, brain characteristics include defective cortical lamination, cerebral and cerebellar hypoplasia and abnormalities of the dendritic tree. We have previously described DSCAM (Down Syndrome Cell Adhesion Molecule), an axon guidance molecule that is expressed in CNS and PNS neurons from the time of neurite differentiation and which maps to chromosome 21q22 in a region associated with DS mental retardation. We now report evidence supporting a role for DSCAM in cortical plasticity and in spinal cord differentiation. To evaluate the role of DSCAM in morphogenetic and cognitive processes, we examined DSCAM expression in the adult mouse brain using tissue in situ hybridisation (TISH) at three, six, nine and twenty-one months of age. The results indicate that DSCAM is widely expressed in the mouse brain throughout adult life with highest levels in the hippocampus, the midlayers of the cortex, the olfactory bulb and the purkinje cells of the cerebellum. These are regions which display continued neurogenesis and synaptic plasticity, supporting a role for DSCAM in prenatal CNS defects and learning and memory in DS. We further report the identification of a novel homolog, DSCAM2, whose predicted protein product has the same domain structure and over 55% amino acid identity to DSCAM (hereafter DSCAM1). Comparisons of DSCAM1 and DSCAM2 expression using TISH demonstrate complementary patterns of expression in the spinal cord during fetal development and distinct patterns in the adult mouse brain. We propose that DSCAM1 and DSCAM2 play different roles both in the developing CNS and in adult synaptic plasticity, and that their over- or underexpression contributes to the neurocognitive defects of DS.

**Sim1 haploinsufficiency causes hyperphagia, obesity and reduction of the paraventricular nucleus of the hypothalamus.** *J.L. Michaud<sup>1</sup>, F. Boucher<sup>1</sup>, A. Melnyk<sup>2</sup>, F. Gauthier<sup>1</sup>, E. Goshu<sup>3</sup>, E. Levy<sup>1</sup>, G.A. Mitchell<sup>1</sup>, J. Himms-Hagen<sup>2</sup>, C.M. Fan<sup>3</sup>.* 1) Research Center, Hopital Sainte-Justine, Montreal, QC; 2) Department of Biochemistry, Microbiology & Immunology, University of Ottawa, Ottawa, ON; 3) Department of Embryology, Carnegie Institution of Washington, Baltimore, MD.

The bHLH-PAS transcription factor SIM1 is required for the development of the paraventricular nucleus (PVN) of the hypothalamus. Mice homozygous for a null allele of *Sim1* (*Sim1*<sup>-</sup>) lack a PVN and die perinatally. In contrast, we show that *Sim1*<sup>+/-</sup> mice are viable but display increased weight gain beginning at 4 weeks of age. By 24 weeks of age, the weight of *Sim1*<sup>+/-</sup> males and females is 33% and 40% higher than that of controls, respectively. This obesity is associated with increased linear growth, white fat hyperplasia and brown fat hypertrophy. *Sim1*<sup>+/-</sup> mice are normoglycemic but develop hyperinsulinemia and hyperleptinemia with increasing weight. Hyperphagia is observed in these mice beginning at 4 weeks of age, before the onset of obesity, and is sustained as 35-week-old *Sim1*<sup>+/-</sup> males and females eat 39% and 30% more than controls, respectively. In contrast to other mouse models of early-onset obesity, such as *McR4*<sup>+/-</sup> and *ob/ob* mice, oxygen consumption and pair-feeding experiments showed that their energy expenditure is not decreased. Quantitative histological comparison with normal littermates revealed that the PVN of *Sim1*<sup>+/-</sup> mice is smaller (+/+ : 8.6x10<sup>5</sup> mM + 2.7x10<sup>4</sup>; +/- : 7.1x10<sup>5</sup> mM + 2.3x10<sup>4</sup>, p<0.002) and contains on average 31% fewer cells as shown by nuclear profile counts (+/+ : 5823 + 259; 4431 + 168; p<0.005) and measurements of area occupied by nuclei (+/+ : 2.8x10<sup>5</sup> mM + 1.0x10<sup>3</sup>; +/- : 2.1x10<sup>5</sup> mM + 7.4x10<sup>3</sup>; p<0.005). Marker analysis did not show a selective loss of any identifiable major cell type. Since acquired lesions in the PVN also induce increased appetite without a decrease in energy expenditure, we propose that abnormalities of PVN development cause the isolated hyperphagia of *Sim1*<sup>+/-</sup> mice. Severe obesity has been described in a patient with a balanced translocation disrupting SIM1. Pathways controlling the development of the PVN thus have the potential to cause obesity in both mice and humans.

**Expression of sex chromosome genes in mouse brain.** *J. Xu*<sup>1</sup>, *P. Burgoyne*<sup>2</sup>, *A.P. Arnold*<sup>1</sup>. 1) Dept. of Physiological Science, UCLA, Los Angeles, CA; 2) Div. Developmental Genetics, MRC National Inst. For Medical Research, Mill Hill, London UK.

A major question is whether genes encoded on the sex chromosomes act directly in non-gonadal tissues to cause sex differences in development or function, or whether all sex differences in somatic tissues are induced by gonadal secretions. We use the brain, a sexually dimorphic tissue, as a model system to explore this question of sex-linked genes vs. hormones. The sex chromosomes could directly influence sexual differentiation via several mechanisms including sex differences in the expression of genes on the non-recombining portion Y (NRY) chromosome or because of the presence of sex differences in dose of X genes. Based upon the following results, both factors may attribute to sex differences of the brain.

We performed RT-PCR analysis to determine the neural expression of mouse NRY genes at three developmental stages, 13.5 days post coitus (13.5 dpc), postnatal day 1 (P1) and adult. Ubiquitously expressed Y genes *Smcy*, *Eif2s3y*, *Uty* and *Dby* were detected in brain at all three ages examined. Y genes *Ube1y*, *Usp9y* and *Ssty* have been thought to be expressed only in testis, but we detected authentic transcripts from these genes in brain at one or more ages. *Zfy* and *Rbmy* were not detected in the brain at any age.

We also detected transcripts of the X homologues *Smcx*, *Eif2s3x*, *Utx*, *Dbx*, *Ube1x* and *Usp9x* in the brains of both sexes at all three ages. These X-linked homologues of the NRY genes were not always expressed in parallel with the NRY genes, suggesting differences in regulation of the two forms. In adulthood, Northern blot analysis indicated that the expression of all six of these X genes is higher in adult female brain than adult male brain, irrespective of their X-inactivation status. The higher expression in female brain is not a general feature of all X genes, because no sex difference was found in the expression of *Hprt*.

**Insights into the regulation of hedgehog signalling from subcellular localisation studies.** *C.A Wicking<sup>1</sup>, T. Evans<sup>1</sup>, B. Wainwright<sup>1</sup>, R. Parton<sup>1,2</sup>.* 1) Inst for Molecular Bioscience, Univ Queensland, Brisbane, Australia; 2) Department of Physiology and Pharmacology, Univ of Queensland, Brisbane, Australia.

Dysregulation of the hedgehog signalling pathway is the major determinant of the most common form of cancer, basal cell carcinoma (BCC). In addition this highly conserved pathway is pivotal to the normal development of a mammalian embryo, with alterations in several key members resulting in developmental disorders. In particular, mutations in the hedgehog receptor molecule patched are responsible for both inherited and sporadic forms of BCC, as well as the developmental anomalies associated with the autosomal dominant disorder Gorlin syndrome. The current model of hedgehog signalling predicts that the patched protein acts as a receptor for the hedgehog ligand in a preformed complex with the smoothed molecule. Despite this role for patched in the cell surface reception of hedgehog, several studies have reported an absence of protein at the cell surface at any given time. We sought to clarify the subcellular localisation of both patched and smoothed in an attempt to more fully understand the cellular processes involved in hedgehog signalling. Using a combination of immunofluorescent and immunoelectron microscopy we show that patched localises primarily to the endocytic pathway of mammalian cells, with very little evidence of staining at the cell surface. Most notably we show that patched exists in recycling endosomes, and to a lesser extent in endocytic carrier vesicles and late endosomes. In contrast, transiently transfected smoothed was shown by immunoelectron microscopy to reside in the endoplasmic reticulum. We also show that patched and smoothed in transfected cells associate with detergent resistant membranes or lipid rafts which are rich in cholesterol. This finding is significant since several factors have implicated a major role for cholesterol in hedgehog signalling and in development in general. Combined with recent data from the *Drosophila* system, the results from this work support a shift in how we view the cellular and molecular processes involved in the regulation of hedgehog signalling.

**Hypoglycemia and abnormal metabolism associated with failure-to-thrive of neonatal Prader-Willi syndrome**

**mice.** *J.L. Knepper<sup>1</sup>, R.S. Ahima<sup>1</sup>, H.R. Patel<sup>1</sup>, T. Ohta<sup>1</sup>, E.M. Rinchik<sup>2</sup>, S. Bogdanovich<sup>1</sup>, T.S. Khurana<sup>1</sup>, R.D. Nicholls<sup>1</sup>.* 1) University of Pennsylvania, Philadelphia, PA; 2) Oak Ridge National Laboratory, Oak Ridge, TN.

Prader-Willi syndrome (PWS) infants have hypotonia and failure-to-thrive, with onset of hyperphagia and obesity after ~2 years of age, abnormal fat and muscle distribution, short stature with growth hormone deficiency, hypogonadism, and abnormal behavior. The underlying genetic defect is a loss of paternal imprinted expression in chromosome 15q11-q13, with PWS commonly ascribed to a hypothalamic deficiency. PWS mouse models have failure-to-thrive and hypotonia, and survive only ~1 wk. Analyses of body weight in postnatal ~1 day old (P1) PWS vs. wildtype (WT) mice showed growth retardation in the former (1.45±0.10 vs. 1.79±0.17 g., n=17-22; p<0.0001), with similar results at P3.5 (1.3±0.10 vs. 2.69±0.24 g., n=4-8; p<0.0001). At P5, PWS pups are severely hypoglycemic (22±1.8 vs. WT, 129 mg/dl; n=4, p<0.0001), and had low insulin levels (0.26 vs. 2.19 ng/ml). Oxygen consumption (VO<sub>2</sub>) and heat, measured by indirect calorimetry (ambient temperature 22°C), were markedly reduced in PWS (768 ml/kg/hr and 0.02 kcal/h) vs. WT mice (3981 and 0.234 kcal; p<0.0001). Carcass analysis showed that PWS and WT pups did not differ in water (68% vs. 63%, p=0.47) or protein (32% vs. 29%, p=0.4) content, but differed significantly in triglyceride content (4.3% vs. 0%). Our data suggest that neonatal mortality in PWS is likely as a result of severe hypoglycemia and impaired thermogenesis. Studies are underway to further characterize feeding behavior, plasma hormones, muscle and liver metabolism and gene expression in PWS and WT mice, as well as rare escaper PWS mice that survive into adulthood.

**Paired interstitial duplications and deletions: a novel cause of ocular developmental abnormalities and glaucoma.**

*O.J. Lehmann*<sup>1</sup>, *N. Ebenezer*<sup>1</sup>, *T.L. Jordan*<sup>2</sup>, *R. Ekong*<sup>3</sup>, *R.A. Hitchings*<sup>4</sup>, *P.T. Khaw*<sup>4</sup>, *J. Sowden*<sup>5</sup>, *S. Povey*<sup>3</sup>, *M.A. Walter*<sup>6</sup>, *S.S. Bhattacharya*<sup>1</sup>. 1) Institute of Ophthalmology, London; 2) Southampton General Hospital, Southampton; 3) MRC Human Biochemical Genetics Unit, London; 4) Moorfields Eye Hospital, London; 5) Institute of Child Health, London; 6) University of Alberta, Edmonton, Canada.

Mutations in the forkhead transcription factor gene *FOXC1* cause a range of ocular developmental abnormalities associated with the development of glaucoma. However mutations are not present in all pedigrees which map to the vicinity of the 6p25 forkhead gene cluster. Our identification of comparably sized interstitial duplications in two families and an interstitial deletion (encompassing *FOXC1* and neither *FOXF2/FOXQ1*) in a Rieger syndrome pedigree, supports the concept that a common mechanism, presumed to be homologous recombination, is responsible for these 6p25 rearrangements and ocular developmental abnormalities. These findings represent the first example of both interstitial duplications and deletions causing a developmental phenotype attributable to altered transcription factor dosage and extend the limited number of disorders in which pairs of interstitial cytogenetic abnormalities have been observed. The interstitial duplications cause a contiguous gene syndrome, suggest that such cytogenetic rearrangements result in more extreme phenotypes than *FOXC1* coding mutations and provide additional evidence for the pathogenicity of altered *FOXC1* dosage.

**HOXD13 GENE ANALYSIS IN SUBJECTS WITH COMPLEX DIGITAL ANOMALIES.** *A. Perez-Cabrera, J.C. Zenteno, S. Kofman-Alfaro.* Department of Genetics, Hospital General de Mexico, Mexico City, DF, Mexico.

Homeodomain-containing homeotic genes (Hox) have been remarkably well conserved during animal evolution and are essential for the appropriate organization of the body plan during development. Several studies on the expression patterns and mutant phenotypes of these genes have indicated that the proper development of digits (number and size) in tetrapods requires the activity of several genes of the HOXA and HOXD complexes, particularly those belonging to posterior (5' located) groups 11, 12 and 13. disruption of the Hoxd13 gene in mice produced a limb malformation pattern characterized by reduction in the length of some bony elements, loss of phalanges, bone fusions and the presence of an extra element. In addition, synpolydactyly, a condition consisting of 3/4 syndactyly in the hands, 4/5 syndactyly in the feet and digit duplication in the syndactylous web, is due to expansions of an amino-terminal polyalanine tract or partial deletions in HOXD13. As HOXD13 might be implicated in other congenital digital anomalies, we search for molecular alterations of this gene in individuals with complex digital malformations. We included in the study a four member family with triphalangeal thumb-brachyectrodactyly syndrome and two unrelated subjects with a digital malformative pattern characterized by polydactyly, syndactyly and brachydactyly in hands and feet. We perform PCR amplification of the complete coding region of HOXD13 and automated sequence analysis of PCR products. After sequencing the two exons and the intron/exon boundaries of HOXD13 we were not able to detect any deleterious mutation in these subjects. We identified a previously undescribed silent polymorphism at nucleotide position 291 in exon 1 (GCA to GCG without changing the encoded alanine). Our data excludes that mutations in HOXD13 are a common cause of complex digital anomalies.

**Relative Difference Analysis of Cell Lines Stably Expressing the C-terminal Isoforms of the Receptor Tyrosine Kinase RET.** *L. Mulligan, S. Myers.* Dept Pathology, Queen's Univ, Kingston, ON, Canada.

The receptor tyrosine kinase RET is essential for early development of the kidney and the enteric nervous system. A number of splice variants of the *RET* transcript have been identified that result in proteins varying in the number of C-terminal amino acids, specifically encoding 9, 43 or 51 unique amino acids (RET9, RET43, RET51). In vitro studies have indicated that the RET9 isoform may contribute to cell growth while the RET51 isoform may be involved in both cell growth and cell differentiation. In agreement with this, we have previously reported differential expression of these isoforms of RET in the developing human kidney. In order to determine the differences in the downstream signals caused by these isoforms, we have developed cell lines stably expressing either RET9 or RET51 to compare the expression patterns of downstream target genes. Relative difference analysis was performed on RNA isolated from these cell lines, where cDNA from the RET9 expressing cells was limiting (tester) and cDNA from the RET51 cells was in excess (driver), to identify genes overexpressed in response to RET9. In preliminary analyses, we identified 6 differentially represented transcripts. Two of these genes have been independently confirmed by northern analyses (*ADAMTS1* and *HSGLUCOII*). The remaining 4 genes (*ILF2*, *GNB2*, *TAXREB107* and *DDB1*) are currently being investigated. Relevance of these genes to the different roles of these RET isoforms is being investigated.

**Detection of Genes Regulated by the Proto-oncogene *RET* Using Microarray Analysis.** *S.M. Myers*<sup>1</sup>, *G.C. Hui*<sup>1</sup>, *H.E. Feilotter*<sup>1,2</sup>, *L.M. Mulligan*<sup>1</sup>. 1) Dept Pathology, Queen's Univ, Kingston, ON, Canada; 2) Queen's University Microarray Centre, Kingston, ON, Canada.

The proto-oncogene *RET* codes for a receptor tyrosine kinase (RET) that plays an integral part in the development of the kidney and enteric nervous system. Splice variants of the *RET* transcript result in proteins with C-termini varying in the number of distinct amino acids; 9, 43 or 51 (RET9, RET43, RET51). These isoforms of RET are differentially expressed in the developing kidney and have been shown to be functionally different in *in vitro* assays. In order to determine if different genes are up or down regulated in response to the presence of these isoforms, we developed *RET* expression constructs for each of the RET isoforms and used these to generate cell lines stably expressing RET9 or RET51. Multiple independent RNA preparations from these cell lines were used to generate cDNAs labeled with either Cy3 or Cy5. Comparisons of gene expression in cells expressing RET9 versus RET51 or to RET9 versus untransfected cells were performed using microarrays containing both 1700 and 19,000 human cDNA clones. We selected genes with a two-fold difference in expression level for further study. Using this criterion, we have identified 14 genes differentially expressed between RET9 and RET51 expressing cells and 110 genes differentially expressed between RET9 and untransfected cells, including *RET* itself. We are presently verifying these results using more precise methods for comparison of gene expression. Our data suggest that a broad array of genes may be differentially expressed in response to RET activation. Relevance of up or downregulation of specific genes by RET is being investigated.

**Conditionally transformed human growth plate chondrocytes: A model system for the *in vitro* study of human chondrocyte biology.** *E.B. Mougey, J. Wang, R.C. Olney.* Dept Research, Nemours Children's Clinic, Jacksonville, FL.

The difficulty in obtaining and expanding human long bone growth plate chondrocytes to sufficient number to allow meaningful experiments, has hampered *in vitro* analysis of the mechanisms that regulate human chondrocyte proliferation and differentiation. While much has been learned about chondrocyte biology from numerous animal model systems, the more subtle aspects of human growth plate chondrocyte regulatory mechanisms await elucidation. One possible solution to the paucity of human cells would be a conditionally transformed cell line, which ideally would allow expansion and then reversion to the untransformed state. Indeed numerous primary human cell types have been successfully conditionally transformed; human costochondral chondrocyte and human osteoblast cell lines being the two most recent and relevant to this study. Therefore we sought to develop a conditionally transformed human long bone chondrocyte cell line. Human long bone growth plate cartilage was recovered from patients undergoing epiphysodesis after receiving informed consent. Chondrocytes were isolated by collagenase and hyaluronidase digestion and percoll gradient fractionation. The recovered chondrocytes were pooled, expanded and infected with adenovirus-*ori* SV40 *tsA* 209. This virus contains a temperature sensitive large T antigen mutant. Clones were obtained and expanded at 34°C and were verified as belonging to the chondrocyte lineage by assaying for collagen I, II, III, X, XI, and XII mRNA by RT-PCR. One clone (hGPC IV1B) exhibiting a doubling time of ~48 hr at permissive temperature and no growth at 40°C was selected for further study. The expression patterns of chondrocyte hypertrophy markers in monolayer and pellet cultures of this cell line suggest that it will be useful in studies of chondrocyte differentiation.

**Identification of human SRY-interacting factors.** *L. Salas-Cortes*<sup>1</sup>, *N. Hanley*<sup>2</sup>, *M. Fellous*<sup>1</sup>, *K. McElreavey*<sup>1</sup>. 1) Immunogenetique Humaine, Institut Pasteur, Paris; 2) 2Division of Human Genetics, University of Southampton, Southampton General Hospital, Southampton, U.K.

A number of human genes involved in sex determination have been identified in recent years including, SOX9, DAX1, FGF9 etc. However the vast majority of human cases of sex reversal (46,XY females with gonadal dysgenesis and 46,XX males) do not harbour mutations in these genes. Mutations involving the SRY gene occur in 15 % of cases of 46,XY females with complete gonadal dysgenesis and in about 1% of cases of 46,XY females with partial gonadal dysgenesis. This suggests that other, as yet unidentified genes, are involved in human sex determination. To identify coregulatory molecules that participate in transcriptional control by SRY, we applied a far-Western expression cloning strategy to identify transcripts encoding proteins that bind SRY. Initially a monoclonal antibody was raised against human SRY and immunohistochemistry demonstrated the presence of SRY protein in both Sertoli cells and germ cells. Extracts were prepared from human testis and, in a series of far-Western experiments using the human SRY protein as a probe and the antibody to detect interactions, we identified 6 nuclear proteins that specifically bind SRY. A lambda<sub>gt</sub>11 expression library from human adult testis was screened by far-Western blotting using recombinant SRY as a probe. 6 proteins were identified that bind SRY. A direct interaction between one of these factors and SRY was confirmed by co-immunoprecipitation experiments. This factor was demonstrated to be expressed in the human genital ridge at the moment of sex determination (48 days post-conception) by immunohistochemistry in pre-Sertoli cells and furthermore was expressed in the nuclei of Sertoli cells during fetal development and in adult testis.

**Position-specific expression of HOX genes along adult gastrointestinal tract in humans.** *N. Yahagi<sup>1</sup>, T. Suzuki<sup>1</sup>, T. Mitsuhashi<sup>1</sup>, R. Kosaki<sup>2</sup>, T. Takahashi<sup>1</sup>, K. Kosaki<sup>1</sup>.* 1) Dept of Pediatrics, Keio Univ, Tokyo, Japan; 2) Dept of Med Genetics, Saitama Children's Med Ctr, Iwatsuki, Japan.

Key molecules that control region-specific cellular renewal of the adult gut epithelium are yet to be delineated. We hypothesized that the 39 HOX genes, highly conserved transcriptional factors clustered on 4 separate chromosome loci, may represent plausible candidates because they are expressed in a segmental fashion along the gastrointestinal tract during embryonic period. HOX genes in each cluster are arranged in tandem and genes that are progressively more 5' within the clusters show progressively more anterior domains of expression in a Russian doll pattern. The purpose of the present study was to systematically investigate the expression pattern of the human HOX genes in tissues along the adult gastrointestinal tract: esophagus-stomach-duodenum-jejunum-ileum-ileocecum-cecum-ascending colon-transverse colon-descending colon-distally to rectum. A panel of cDNA derived from each tissue was amplified using primer pairs specific for each HOX gene. Monitoring of fluorescence from intercalating dye during the log-linear phase of the PCR reaction allowed quantification of relative expression level. We demonstrated the following: 1) HOXC genes were expressed at very low level. 2) Peak expression level of HOXA13, HOXA11, HOXA9, and HOXA6 were at descending colon, ascending colon, cecum, and jejunum, respectively. 3) Peak expression level of HOXB13, HOXB9, and HOXB7 were at rectum, descending colon, cecum, and jejunum, respectively. 4) Peak expression level of HOXD13 and HOXD10 were at rectum and cecum, respectively. Hence there is a correspondence between the physical location of the genes within the cluster and the relative expression along the anterior-posterior axis of the adult gut. This spatially co-linear expression pattern of the HOX genes was reminiscent of that during embryogenesis. We infer HOX genes may well play critical roles in position-specific differentiation of the adult gut epithelial precursor cells. Overlap of the expression domain indicates that HOXA, HOXB, and HOXD paralogues may have redundant functions in the regional specification of the gut.

***Prop1* and *Lhx4* interact in stimulating cell specification and expansion of the pituitary primordia.** *L.T. Raetzman, S.A. Camper.* Department of Human Genetics, University of Michigan Medical School, Ann Arbor, MI. 48109-0638.

Mutations in *PROPI*, *POUIF1* (*PIT1*) and *LHX3* (OMIM 601538, 173110, 600577) cause combined pituitary hormone deficiency (CPHD) in humans and mice. Most cases are associated with severe anterior pituitary hypoplasia due to differentiation failure of many cell types. Mice deficient in LIM homeobox transcription factor *Lhx4*, also have a hypoplastic anterior pituitary lobe, although no mutations in humans have been described to date (OMIM 602146). In the absence of *Lhx4* the somatotropes, thyrotropes and gonadotropes undergo initial specification, but fail in lineage specific proliferation. Little is known about the mechanism through which these homeobox genes promote the cytodifferentiation of specialized anterior pituitary cells. *LHX4* is expressed in many tissues during murine development, suggesting that it interacts with lineage specific factors to promote proliferation specifically in the pituitary. One likely candidate for this interaction is *PROP1*, a homeodomain transcription factor that has only been detected in the pituitary gland. To determine if *Lhx4* and *Prop1* have a complimentary role in lineage proliferation, we generated *Lhx4*<sup>-/-</sup>, *Prop1*<sup>df/df</sup> mice and analyzed the appearance of differentiated cells in the anterior pituitary. In the absence of both of these genes, the pituitary phenotype is more severe and the development is arrested earlier than in the single mutants. Rathke's pouch forms, yet there is no evidence of cell differentiation. Analysis of pituitary marker gene expression confirms the increase in severity of the double vs. single mutants. The  $\alpha$  subunit (CGA) and ACTH appear at e10.5-e12.5 and are the first hormone markers detectable in normal pituitaries and in the single mutants. In the double mutants the appearance of corticotropes is delayed until e16.5, at which point only a few differentiated cells are present. No other hormone producing cells are detected. These data indicate that both *Prop1* and *Lhx4* together are necessary for expansion of all anterior pituitary cell types. This suggests that interactions between *PROP1* and *LHX4* could contribute to endocrine abnormalities in humans.

**Mutational and functional analysis of *HESX1* within Septo-Optic Dysplasia (SOD).** D. McNay, K. Woods, J. Turton, D. Dattani. Institute of Child Health, London, UK.

Septo-Optic Dysplasia(SOD) is a variable developmental abnormality of the midline structures of the brain, classically resulting in hypoplasia of the optic nerves, the septum pellucidum and the corpus callosum in addition to dysgenesis of the pituitary gland. The homeobox gene *Hesx1* is a transcriptional repressor expressed at gastrulation within the anterior midline visceral endoderm, with subsequent expression in the prosencephalon and Rathke's pouch. *Hesx1* null mutant mice manifest a phenotype similar to SOD in man. This led to the successful search for causative *HESX1* mutations in patients with SOD. Here we report the findings of a follow up study of 574 patients with SOD. The cohort was screened for sequence variations within the coding region of *HESX1* using SSCP and HPLC heteroduplex analysis. A heterozygous S170L mutation was identified in a sib pair, both of whom demonstrate growth hormone deficiency(GHD) but only one of whom shows optic nerve hypoplasia, and also in an unrelated child with GHD and an ectopic posterior pituitary(EPP). The mutation occurs within a highly conserved motif and shows a dominant mode of inheritance with incomplete penetrance. *In-vitro* analysis demonstrates a 7-fold reduction in DNA binding, while *in-vivo* studies revealed no effect on repression. A heterozygous E149K mutation was identified in a child with GHD, EPP and anterior pituitary hypoplasia. The E149K variant lies at position 42 of the homeodomain, at the first residue of the third helix. This residue is highly conserved and we are currently investigating the function of this mutation. A N125S substitution has been identified in 5 Afro-Caribbean individuals with SOD. This substitution, at position 18 of the homeodomain, occurs at Hardy-Weinburg equilibrium within the Afro-Caribbean population, but has not been documented in Caucasian controls. N125S is associated with an altered conformation in *in-vitro* EMSA studies, with an increased affinity for the P3 consensus site, whilst repression is unaffected *in-vivo*. To conclude, coding region mutations of *HESX1* in association with SOD are rare but lead to valuable insights into the role of *HESX1* in normal development.

**Loss-of-function mutation in the CFC domain of TDGF-1 is associated with human forebrain defects.** *J.M. dela Cruz*<sup>1</sup>, *E. Roessler*<sup>1</sup>, *R.N. Bamford*<sup>1</sup>, *R.D. Burdine*<sup>2</sup>, *D. Donnai*<sup>3</sup>, *A.F. Schier*<sup>2</sup>, *M. Muenke*<sup>1</sup>. 1) Medical Genetics Branch, NHGRI/NIH, Bethesda, MD; 2) Skirball Institute of Biomolecular Medicine, NYU, New York, NY; 3) Regional Genetic Service, St. Mary's Hospital (SM2), Manchester, UK.

Nodal signalling has been implicated in vertebral development of the midline, forebrain, and left-right axis asymmetry. At the onset of gastrulation, the TGF- $\beta$  ligand Nodal is expressed in dorsal mesoderm progenitors and, subsequently, in the left lateral plate mesoderm. Based on mouse models, mice null for Nodal lack a primitive streak, most mesoderm and die early in development. Transheterozygotes for Nodal and Smad2 survive gestation but succumb early to severe anterior midline and laterality defects. Importantly, Nodal signalling depends on the extracellular EGF-CFC family of proteins that by an unknown mechanism acts as an obligate cofactor for Nodal.

Members of the EGF-CFC family are characterized by an N-terminal signal sequence, an EGF-like motif, and a novel cysteine-rich region known as the CFC domain. Based on animal models, mutations in genes within this family create developmental anomalies that include defects affecting the orientation of the anterior-posterior axis, germ layer formation, and laterality. As a member of the EGF-CFC family, *Tdgf-1/Cripto* is implicated in embryonic development as well as in carcinogenesis. Previous mouse studies demonstrated that *Cripto* homozygous mutants generate a mispositioned anterior-posterior axis and lack also a primitive streak, node, and embryonic mesoderm.

Human *TDGF-1* has been evaluated for its potential role in forebrain development by SSCP and denaturing HPLC. Two unique missense mutations in *TDGF-1* have been identified in patients with sporadic holoprosencephaly that were not found in over 200 normal control chromosomes. Here we identify a mutation in the conserved CFC domain of TDGF-1 in a patient with midline anomalies of the forebrain. The mutant protein is inactive in a zebrafish rescue assay, indicating a role for *TDGF-1* in human midline and forebrain development.

**Aquaporin gene expression in craniofacial tissues.** *W. Wang<sup>1</sup>, X. Lu<sup>1</sup>, P.S. Hart<sup>2</sup>, N.P. Piesco<sup>1</sup>, M.C. Gorry<sup>1</sup>, T.C. Hart<sup>1,2</sup>.* 1) Oral Medicine, University of Pittsburgh, Pittsburgh, PA; 2) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, PA.

The aquaporins (AQP) family of membrane channel proteins serve as selective pores through which water crosses the plasma membranes of many tissue and cell types. To date, 10 members of this transporter family have been cloned, designated AQP0-9. AQPs have different structures, which give them specific or selective function to be permeated by water, glycerol, and other small solutes. There are 2 subgroups of AQPs: water-selective channels (orthodox aquaporins) and channels permeated by water, glycerol, and other small molecules (aquaglyceroporins). The AQPs have distinct tissue distributions and different functions during water metabolism. We screened for all 10 AQPs in human gingiva (HG), fetal meckel cartilage (FMC) and fetal mandibular bone (FMB) by RT-PCR. Primers were designed to amplify specific AQPs and distinguish genomic and cDNA. RESULTS: AQP3 and AQP7 were expressed in HG; AQP1, AQP3, AQP4, AQP5 and AQP6 were expressed in FMC. Surprisingly, no AQPs were expressed in the FMB. AQPs have different permeabilities. AQP3 and AQP7 are aquaglyceroporins permeable to both glycerol and water. AQP3 is also permeable to urea. AQP1, AQP4, AQP5 and AQP6 are orthodox aquaporins. The expression of many AQPs in cartilage may reflect a high metabolic rate. As AQPs are expressed in a developmentally regulated fashion, it may be that at the particular stage we examined, no AQPs were expressed but at a different stage or after birth, they are expressed. While it is possible AQPs play no role in water transport in FMB, novel AQPs may be involved or other tissues may support water transport in FMB. Meckel cartilage is important for mandibular bone development and mineralization is part of this process. Lipid synthesis is reported to play a very important role during bone mineralization. AQP3 was expressed in Meckel cartilage. Thus, it may be involved in lipid metabolism and be important for bone mineralization. Further studies are needed to determine the developmental expression of the AQPs in both gingival and Meckel cartilage and also to determine their location in these tissues.

**Localization of *FOXC1* transcripts in normal adult human eye and optic nerve by *in situ* hybridization. R.**

Swiderski<sup>1</sup>, J. Ross<sup>2</sup>, D. Nishimura<sup>1</sup>, C. Searby<sup>1</sup>, A. Clark<sup>4</sup>, W. Alward<sup>3</sup>, E. Stone<sup>3</sup>, V. Sheffield<sup>1</sup>. 1) Dept Pediatrics and The Howard Hughes Medical Institute, Univ Iowa, Iowa City, IA; 2) Central Microscopy Research Facility, Univ IA, Iowa City, IA; 3) Dept Ophthalmology, Univ IA, Iowa City, IA; 4) Alcon Research, Ltd., Ft. Worth, TX.

Mutations in the forkhead/winged helix family member *FOXC1* cause a spectrum of anterior segment eye defects that are related to the development of congenital glaucoma associated with chromosome 6p25, most notably Axenfeld-Rieger Anomaly. We have recently used an optimized donor eye preservation method and tissue RNA isolation procedure and demonstrated *FOXC1* expression in the trabecular meshwork and optic nerve head as well as other normal adult eye tissues by RT-PCR analysis. In this study, we used *in situ* hybridization to further refine the analysis of *FOXC1* expression in specific ocular tissues associated with glaucoma pathogenesis. In the anterior segment of the normal adult human eye, *FOXC1* expression was noted in the trabecular meshwork, ciliary muscle, and corneal epithelium. In the optic nerve head and optic nerve, *FOXC1* transcripts were abundantly expressed in the dura mater and arachnoid layers of the meningeal sheath; and, to a lesser extent, in optic nerve axons. *FOXC1* expression in the trabecular meshwork, ciliary body and optic nerve suggest that *FOXC1*, a gene known to be associated with developmental glaucoma, may have an important role in the adult eye.

**Specific decrease in fibrillin-1 and fibrillin-2 expression following antisense targeting in chick embryos. M.**

*Godfrey<sup>1</sup>, S. Plaza<sup>1</sup>, S.V. Vinogradov<sup>2</sup>, J.M. Valasek<sup>1</sup>, S. Belleh<sup>1</sup>, A.V. Kabanov<sup>2</sup>.* 1) Center for Human Molecular Genetics; 2) Dept Pharmaceutical Sciences, University of Nebraska Medical Ctr, Omaha, NE.

Mutations in fibrillin-1 and fibrillin-2, microfibrillar glycoproteins with unique and overlapping distributions, are known to cause the Marfan syndrome (MFS) and congenital contractural arachnodactyly (CCA), respectively. Given the pathophysiology of these disorders, it has been hypothesized that fibrillin-1 plays primarily a "load bearing" function in the extracellular matrix while the function of fibrillin-2 may be more as a director of elastogenesis. Importantly, both fibrillins are expressed in the early developing embryo where "load bearing" is probably not critical.

We have successfully used phosphorothioate antisense oligonucleotides bound to cationic block copolymers of polyethyleneglycol and polyethylenimine to enter efficiently into early chick embryos. Embryos have been successfully inoculated in vitro and in ovo from 24 to 120 hours of fertilization. Sense controls were included in all experiments.

Inoculation with both antisense to fibrillin-1 and fibrillin-2 causes a delay in embryonic development. While this delay is variable, in all cases, there is a significant decrease in the size of the vascular net. In addition, the morphology of the blood vessels in the vascular net is abnormal. This may contribute to the delay in development of the embryos.

To examine the specificity of the targeting we used immunostaining with antibodies to chick fibrillin-1 (gift of Dr. R. Burke) and fibrillin-2 (gift of Dr. C. Little). When antisense to fibrillin-1 was inoculated into the embryos we observed a decrease in expression of fibrillin-1, but normal fibrillin-2 immunostaining. The converse was observed following inoculation of antisense to fibrillin-2. These studies highlight our ability to deliver antisense oligonucleotides with good specificity. In addition, they suggest a possible antiangiogenic affect on the vascular net of the chick embryo.

**In search of placenta-specific genes and promoter elements.** *C. Galaviz-Hernandez, T. Tanaka, M. Ko, M. Uda, D. Schlessinger, R. Nagaraja.* Laboratory of Genetics, National Institute on Aging, Baltimore, MD.

Responsible for gas and nutrient exchange between mother and fetus, the placenta is thus indispensable for proper development. Some genes have been detected that are critical for placental function, based on gene disruption studies in mice and differential gene expression studies in choriocarcinoma cells. We have extended the search for placental-specific genes in two ways. In one, based on genomic sequence, we found PLAC1, distal to HPRT in Xq26, and specifically expressed in placenta in 7.5 to 14.5 dpc in ectoplacental cone, giant cells, and labyrinthine trophoblasts. To try to understand the specificity of expression in the placenta, we have cloned fragments of genomic DNA upstream of PLAC1. Constructs have been made that place putative promoter fragments 5' of a reporter luciferase gene, and they are being tested in the JEG-3 and BeWo cell lines (which show endogenous expression of placental genes) along with HeLa cells as a negative control. A TATA box found at 30 bp and a PEBP2/CREBdelta binding site at 647 nucleotides are the only transcription elements found thus far, but they, in the context of 3.6 kb of DNA upstream of exon 1 of the gene, are insufficient to give specific expression. Longer fragments are now being tested. In a second approach, we have used RNA isolated from 12 dpc placenta as a probe on microarrays containing the NIA mouse 15K cDNA set. For a group of 6 cDNAs, an expression pattern suggesting placental specificity was confirmed by Northern blot and in situ hybridization experiments, and two of the cDNAs have been characterized in detail. Comparative sequence analysis of possible promoter elements shared with PLAC1, however, awaits the availability of the corresponding genomic regions.

**Vax2 inactivation in mouse determines alteration of the eye dorsal-ventral axis, misrouting of the optic fibers and eye coloboma.** *S. Banfi<sup>1</sup>, A.M. Barbieri<sup>1</sup>, V. Broccoli<sup>1</sup>, P. Bovolenta<sup>2</sup>, G. Alfano<sup>1</sup>, A. Marchitello<sup>1</sup>, A. Ballabio<sup>1</sup>.* 1) Telethon Institute of Genetics and Medicine (TIGEM), Naples, Italy; 2) Departamento de Neurobiología del Desarrollo, Instituto Cajal, CSIC, Madrid, Spain.

Vax2 is a homeobox gene whose expression is confined to the ventral portion of the prospective neural retina. Overexpression of this gene at early stages of development in *Xenopus* and in chicken embryos determines a ventralization of the retina, thus suggesting its role in the molecular pathway underlying eye development. Here, we describe the generation and characterization of a mouse with a targeted null mutation of the Vax2 gene. Vax2 homozygous mutant mice display incomplete closure of the optic fissure that leads to eye coloboma. This phenotype is not fully penetrant suggesting that additional, non-genetic factors contribute to its generation. Vax2 inactivation determines dorsalization of the expression of mid-late (EphB2 and ephrin-B2) but not early (Pax2 and Tbx5) markers of dorsal-ventral polarity in the developing retina. Finally, Vax2 mutant mice exhibit abnormal projections of ventral retinal ganglion cells. In particular, we observed the almost complete absence of ipsilaterally projecting retinal ganglion cells axons in the optic chiasm and alteration of the retinocollicular projections. All these findings indicate that Vax2 is required for the proper closure of the optic fissure, for the establishment of a physiological asymmetry on the dorsal-ventral axis of the eye and for the formation of appropriate retinocollicular connections.

**Dissection of the regulatory elements that control the *Chx10* pathway of eye development.** R. Abboud<sup>1</sup>, A. Sertié<sup>1</sup>, S. Basu<sup>2</sup>, B.E. Snow<sup>1</sup>, D.J. Horsford<sup>1</sup>, M. Burmeister<sup>2</sup>, R.R. McInnes<sup>1</sup>. 1) Program in Developmental Biology, Research Institute, Hospital for Sick Children, Toronto, ON, Canada; 2) Mental Health Research Inst., Depts. of Psychiatry and Human Genetics, Univ. of Michigan, Ann Arbor, MI.

The *Chx10* gene encodes a homeodomain transcription factor essential for eye development. In mouse, *Chx10* expression is first detected in retinal progenitor cells, but is later restricted to the inner nuclear layer of the adult retina. *Chx10* is also expressed in the hindbrain, suggesting that it may be regulated by several enhancers. To identify the regulatory elements that control *Chx10* retinal expression, we are using two complementary strategies. First, we established, by PFGE analysis, that one *Chx10* mutant allele, *or<sup>2J</sup>*, is due to a 75-100 kb rearrangement located 10-20 kb upstream of the *Chx10* transcription unit; this unit is intact in *or<sup>2J</sup>*, as shown by Southern blots, SSCP analysis and DNA sequencing. By *in situ* hybridization, we found that the *or<sup>2J</sup>* allele ablates the expression of *Chx10* in retinal progenitors from E9.5-E12.5, whereas hindbrain expression is unaffected. Using transgenic mice, we also found that 5.3 kb of sequence immediately 5' of the *Chx10* transcription unit allows normal *Chx10* expression in hindbrain but not in retina, at E10.5. Second, to identify putative regulatory elements in the DNA sequences ~100 kb upstream of *Chx10/CHX10*, we aligned these sequences from mouse and human and identified 31 shared elements larger than 100 bp and with more than 80% identity. Initial studies show that one element (#510) identifies abnormal bands in blots of *or<sup>2J</sup>* DNA, and cannot be amplified from *or<sup>2J</sup>* DNA using some primer pairs. We conclude that i) the *or<sup>2J</sup>* allele appears to contain a rearrangement that disrupts the element(s) controlling *Chx10* developmental retinal expression; ii) the retinal regulatory element(s) may be found in the set of 31 conserved sequences upstream of the gene; iii) element #510 may be disrupted in the *or<sup>2J</sup>* allele; iv) the regulatory elements that direct *Chx10* hindbrain expression are distinct from those for the retina and are contained in 5.3 kb 5' to the transcription unit.

**Developmental patterns of altered gene expression in the lungs of a glucocorticoid receptor knockout mouse:**

**Altered expression of the retinoic acid responsive growth factor midkine.** *F. Kaplan<sup>1</sup>, J. Comber<sup>1</sup>, T. MacRae<sup>1</sup>, R. Sladek<sup>2</sup>, T. Hudson<sup>2</sup>, N.B. Swezey<sup>3</sup>.* 1) Dept Human Genetics/Pediatrics, McGill U / McGill U Health Centre Montreal, QC; 2) Montreal Genome Centre; 3) Hospital for Sick Children Toronto, ON.

Deficiency of lung maturation due to premature birth is a leading cause of neonatal morbidity (respiratory distress syndrome, RDS.) Normal maturation of the lung is dependent on glucocorticoid (GC) stimulation. We are investigating intermediary mechanisms that link GC stimulation to the timely achievement of a mature lung in a GC receptor (GR) knockout mouse. Seventy-five percent of mice homozygous for a hypomorphic disruption in the GR gene ( $GR^{hypo}$ ) die shortly after birth of respiratory failure. Surviving  $GR^{hypo}$  mice are normal and fertile. We used cDNA microarrays and northern analysis to identify genes that are differentially expressed in the lung at fetal day 18 ( $GR^{hypo-18}$ ) and postnatal day 1 in  $GR^{WT}$  vs  $GR^{hypo}$  mice. Neonatal animals were divided into survivors ( $GR^{hypo/surv}$ ) and non-survivors ( $GR^{hypo/nsurv}$ ). Multiple alterations in gene expression were observed in the 3 groups of  $GR^{hypo}$  vs  $GR^{WT}$  mice. The retinoic acid responsive gene Midkine (MK), was among 8 genes identified with similar patterns of altered gene expression in all 3 groups. MK is upregulated in the lungs of  $GR^{hypo-18}$ ,  $GR^{hypo/nsurv}$  and  $GR^{hypo/surv}$  mice. By contrast, MK is downregulated in  $GR^{hypo}$  mice at fetal day 16.5. In rat lung cell culture, MK expression is enriched in epithelium compared to mesenchyme from fetal day 16.5-21. GC treatment downregulated rat lung epithelial MK expression at day 21. MK, a secreted heparin binding growth factor, is expressed at high levels in mid-gestation and is associated with epithelial-mesenchymal interactions in the developing lung. MK is important in angiogenesis and tissue remodeling. MK is not detected in adult rat lung but is expressed in lung tumours. Our findings suggest that absence of a functional GR is associated with inhibition of the downregulation of MK by GC in late gestation. Overexpression of MK in late gestation, in turn, is associated with deficient terminal differentiation of the fetal lung.

**LGL1, a developmentally and glucocorticoid regulated gene, modulates airway branching morphogenesis. L.**

*Oyewumi<sup>1</sup>, F. Kaplan<sup>2</sup>, S. Gagnon<sup>1</sup>, N.B. Swezey<sup>1</sup>.* 1) Lung Biology Research, Hosp Sick Children, Toronto, ON; 2) Dept Human Genetics/Peds, McGill U Health Centre, Montreal QC.

We recently reported (*Am J Physiol.* 1999 Jun; 276(6 Pt 1): L1027-36) a novel gene, late gestation lung 1 (LGL1). LGL1, a member of the CRISP family of cysteine-rich secreted proteins, is glucocorticoid inducible, developmentally regulated, and expressed in the mesenchyme, but not epithelium, of fetal rodent and human lung. Here we report mapping of LGL1 to human chromosome 16q24 by FISH. We investigated LGL1 subcellular localization and function in fetal lung development. LGL1 mRNA is detectable from gestational day 12 through to maximal expression on gestational day 21 (term = d 22). Lgl1 protein expression is maximal in late gestation (days 18 - 21). Consistent with the postulate that lgl1 protein is secreted, lgl1 fused with green fluorescent protein was localized by confocal microscopy to the cytoplasm, but not the nuclei, of fetal rat lung adjacent fibroblasts. Expression of LGL1 mRNA (by in situ hybridization) and lgl1 protein (by immunohistochemistry) is evident in mesenchymal cells during the pseudoglandular stage of lung development, when branching morphogenesis begins. To test the hypothesis that lgl1 modulates airway branching morphogenesis, fetal rat day 13 lung explants were treated for 24 and 48 hr with LGL1 antisense oligodeoxynucleotides. The number of terminal airway buds ( $p < 0.001$ ), and the levels of LGL1 mRNA and lgl1 protein ( $p < 0.01$ ), were significantly reduced in the antisense treated explants when compared to sense, missense and untreated controls in a dose and time dependent fashion. Our findings implicate lgl1 in mesenchymal-epithelial interactions that regulate airway branching. Furthermore, the timing of maximal lgl1 protein expression during active alveolarization leads us to speculate that lgl1 may also promote alveolar formation. This work was supported by the Canadian Institutes of Health Research.

**DIFFERENTIAL GENE EXPRESSION IN NASCENT AND MATURE MOUSE OVARY ASSESSED BY 15K cDNA MICROARRAY.** *L.M. Herrera, M.S.H. Ko, D. Schlessinger.* Laboratory of Genetics, National Institute on Aging, National Institutes of Health, Baltimore, MD.

Reproductive lifespan is set by the development of the ovary, with all of the eggs and follicles that a woman will have in adult life already formed at the time of her birth. The progressive utilization of follicles, particularly after puberty, leads to menopause at an average age of 51; but in about 1% of women the rate of attrition of oocytes and follicles in utero is too great, leading to premature ovarian failure. To analyze the basis for the number of follicles, one approach aims to discover the genes and regulatory networks involved in ovarian and follicle development. The mouse provides a particularly good model system, because the phases of oocyte, follicle, and ovary development are discretely phased. We have used cohorts of cDNAs recovered from every mouse embryonic cleavage stages, selected fetal tissues and organs, and newborn ovary. In particular, 7,000 ESTs from newborn ovary have been sequenced and analyzed for the frequency of representation of individual genes. Single members of each gene observed (3,892) have been included in an initial group of 15,000 distinct genes in the NIA15K cDNA microarray. Using the NIA15K cDNA microarray we have compared gene expression in newborn (nascent) and adult (mature) ovary, and have extended the comparison to 12.5 dpc placenta, 12.5 dpc embryo, and adult testis, to find ovary-specific genes and germ cell-specific genes. Results were verified for sampled genes by Northern analysis and real-time PCR, and several genes were shown to have specific follicular or germ cell localization, as confirmed by in situ hybridization. Both nascent and mature ovary show very high expression of synthetic metabolic genes, including those encoding energy-yielding and protein synthetic machinery. In addition, there were also differentially expressed genes, notably including several transcription factors.

**Expression of Three Proneural basic Helix-Loop-Helix Transcription Factors in Extravillous Trophoblasts suggests Role in Trophoblast Differentiation and Invasion.** *C.B.M. Oudejans, B.A. Westerman, A. Poutsma, I.J. van Wijk.* Clinical Chem, 'Vrije Universiteit' Medical Center, Amsterdam, the Netherlands.

Trophoblasts form the outermost region of the developing embryo and contact the uterus during implantation. The contact between the maternal cells of the uterus and trophoblast cells is further established when differentiated trophoblasts invade interstitially into the uterus, a process which occurs in humans, but not in rodents. In human placentation, villi are formed from week 4 to 20. On the top of the anchoring villi, proliferative stem cells downregulate proliferation, leave the villous tip and adopt an extravillous phenotype. These extravillous trophoblast cells (ETCs) invade into the maternal decidua and myometrium. This invasion has similarities to invasion by cancer cells. However, trophoblast invasion is restricted in time and place, in contrast to tumor invasion. Since differentiation of trophoblasts is controlled genetically by basic Helix-Loop-Helix (bHLH) transcription factors, we are using invasive placenta cells to study bHLH regulated differentiation, and use this as a model system to investigate the process of tumor invasion. We constructed a unique cDNA library of placental bed tissue obtained during week 10 of gestation enriched for ETCs in different stages of invasion. A subset of proneural genes (i.e. NEUROD1, NEUROD2, ATH2) was found to be activated in extravillous trophoblast cells, as is the Achaete Scute member ASCL2 (HASH2). Other (pro)neural genes of the Achaete Scute and Atonal family (all genes currently known were tested) were found not to be expressed in placental bed tissue. Thus, out of 9 proneural genes tested, 3 genes, all belonging to the same subfamily, are transcribed in placental bed tissue. This suggests the use of a differentiation cascade by trophoblast analogous to the cascade used by neuroectoderm involving Mash1. So far, the only other tissue besides neuroectoderm in which transcription of proneural bHLH genes has been found to be essential is the pancreas. Current experiments are being performed to see whether subpopulations of cells can be identified with differential (co)expression of these 3 bHLH genes in invasive cells.

**Refinement of Lif-Stat-3 Pathway Using Microarray Analysis.** *S.A. Jaradat<sup>1</sup>, T. Yokota<sup>2</sup>, M.S.H Ko<sup>1</sup>*. 1) Lab Genetics, NIH/NIA, Baltimore, MD; 2) Institute of Medical Science, The University of Tokyo, Minatoku, Tokyo 108-8639, Japan.

Mouse embryonic stem (ES) cells are pluripotent and can differentiate into many different cell types in vitro. The ES cells can be propagated in an undifferentiated state in vitro in the presence of leukemia inhibitory factor (LIF). Although it is well established that LIF exerts its function by activating a Stat3 transcription factor, its downstream targets are largely unknown. To identify such genes, we have employed cDNA microarray technology. First, the STAT3ER construct was made by fusing the entire coding region of Stat3 with the ligand-binding domain of the estrogen receptor. Then the construct was stably transfected into ES cells. STAT3ER is conditionally active in the presence of the synthetic ligand 4-hydroxytamoxifen (4HT), and maintains ES cells in an undifferentiated state. ES cells were cultured in the presence or the absence of 4HT for up to 6 days. Total RNAs were extracted from these cells and utilized for NIA 15K cDNA microarrays hybridization. Student's t-test was applied to hybridization results done in triplicate. 500 genes showed statistically significant differences in expression between ES cells (4HT+) and ES cells (4HT-). Functionally these genes can be organized into five categories. The first category contains genes involved in cell cycle progression and DNA repair, including MutS, Chek1 and Cyclin D1. Genes in the second category include Igf-Bp3 and Caspase-8, known to function in apoptosis. Genes in the third category include p300/CBP acetyltransferases and Sfm1b Polycomb, which are known to function as global activators or repressors of transcription. Genes in the fourth category include Mef2 and Cytokeratin type II, which are tissue or lineage specific factors. The last category includes over 100 newly identified genes. Further analysis of these groups of genes should define further the role of Stat3 in the pluripotency and self-renewal of ES cells.

**Identification and Characterization of DAZ Function at Two Critical Stages in Germ Cell Development.** *F.L. Moore, J. Jaruzelska, M. Castillo, R.A. Reijo-Pera.* OB/Gyn/RS, UC San Francisco, 513 Parnassus ave., bldg HSW, rm. 1475 San Francisco, CA. 94143.

The identification of the DAZ (Deleted in Azoospermia) gene, the most genetically defined cause of infertility in males, has enhanced the possibility of understanding human germ cell development at the molecular level. The expression pattern of DAZ is restricted to germ cells in the testis and the protein sequence contains a RRM motif, which belongs to a family of RNA binding proteins. We are further characterizing the function of the DAZ gene by understanding what proteins interact with it. Seven interacting protein candidates have been identified using the yeast two-hybrid approach. Co-immunoprecipitation in yeast has verified an *in vitro* protein interaction between DAZ and Pumilio proteins and DAZ and BOL proteins. The Pumilio protein has been shown in *Drosophila* to function as a translational repressor. The Pumilio protein contains eight Puf (Pumilio Fbf) repeats that are used to bind RNA, and binds to the 3' UTR region of various transcripts to repress translation. The Pumilio protein has multiple roles during development and interestingly is essential for the maintenance of germ line stem cells in *Drosophila* oogenesis. The BOL gene, which is a new member of the DAZ gene family has been characterized in *Drosophila* as a translational activator and functions as a meiotic regulator in male germ cells. The DAZ and Pumilio proteins localize to the nucleus in spermatogonia and relocate to the cytoplasm in spermatocytes. The BOL protein is expressed at meiosis and localizes with the DAZ protein to the cytoplasm of spermatocytes. We believe that the DAZ protein has two functions during germ cell development. It plays a role in the maintenance of germ cells and is also required as a meiotic regulator. Further characterization of the DAZ protein and interacting proteins will lead to a better understanding the function of the DAZ gene family in germ cell development.

**The Kallmann syndrome gene homologue in *C. elegans* is involved in epidermal morphogenesis and neurite branching.** *E.I. Rugarli<sup>1</sup>, E. Di Schiavi<sup>2</sup>, M. Hilliard<sup>2</sup>, S. Arbucci<sup>2</sup>, C. Ghezzi<sup>1</sup>, A. Facciolli<sup>2</sup>, A. Ballabio<sup>1</sup>, P. Bazzicalupo<sup>2</sup>.* 1) TIGEM, Naples, Italy; 2) IIGB, Naples, Italy.

Kallmann syndrome (KS) is an inherited disorder defined by the association of anosmia and hypogonadism and is due to impaired targeting and migration of olfactory axons and of gonadotropin-releasing hormone secreting neurons. The gene responsible for the X-linked form of Kallmann syndrome (KAL) has been identified and encodes a secreted protein of still elusive function. It has been proposed that KAL might be involved either in olfactory axon target recognition and/or invasion or in olfactory bulb morphogenesis. Functional characterization of KAL has been hampered so far by the failure to clone a mouse homologue. We now describe the isolation of the KAL homologue in *Caenorhabditis elegans*. By analyzing loss of function and hypermorph mutants of the *C. elegans* *kal-1* gene, we provide evidence that CeKAL-1 is involved in neurite extension/branching and in epidermal morphogenesis during ventral enclosure and male tail formation. Since *kal-1* reporters are expressed in neuronal cells while the cells most affected by mutants are epithelial cells undergoing active morphogenesis, we propose that CeKAL-1 acts non-cell-autonomously to modulate the adhesion of cells and growth cones to the matrix and to other cells, in concert with other molecules. Likely candidates are components of the Eph-Receptor/ephrin and/or semaphorin pathways. We also demonstrate that overexpression of worm and human KAL cDNAs in the nematode result in the same phenotypes, indicating functional conservation across species and establishing the nematode as a powerful model to investigate the mechanism of action of the KAL protein and to identify interacting partners. These results provide the first *in vivo* evidence of the function of KAL gene and open new perspectives on the pathogenesis of KS. Furthermore our data contribute to the emerging knowledge that the same set of molecules underlies both morphogenesis and axonal-neuronal navigation in vertebrates and invertebrates.

**Deficiency of *Zic3* causes defects in gastrulation and left-right patterning.** *S.M. Ware, S. Purandare, B. Casey, J.W. Belmont.* Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

X-linked heterotaxy (HTX1) is a rare developmental disorder characterized by disturbances in laterality and other midline developmental field defects. HTX1 results from mutations in *ZIC3*, a member of the *GLI* transcription factor superfamily, which is expressed in the primitive streak, dorsal central nervous system (CNS), tailbud and developing limb. A targeted deletion of the murine *Zic3* locus has been created in order to investigate its function and to determine how it interacts with other molecular components of the left-right axis pathway. The phenotype of these mice closely models the defects seen in human HTX1 with malformations in liveborn null mice including complex congenital heart disease, pulmonary reversal or isomerism, CNS defects and vertebral and rib anomalies. Embryonic lethality is seen in approximately 50% of null mice with an additional 30% lethality in the perinatal period. Analyses of embryos at 7.5-9.5 days post coitum show varying degrees of gastrulation defects. The most severely affected embryos have no obvious node by both gross morphologic examination and analyses with molecular markers. Less severely affected embryos show defective mesoderm development including notochord abnormalities and degeneration and failure of somitogenesis. Failure of neural tube closure is found in a subset of embryos and it is unclear whether this represents a primary failure or is secondary to abnormal mesodermal inductive signals. A third category of embryos include those in which gastrulation occurs but left-right axis development is disrupted. Examination of these null embryos shows defects in embryonic turning, cardiac morphogenesis and positioning, and pulmonary and abdominal situs. Investigation of *nodal* expression in *Zic3* deficient mice indicates that although *nodal* is initially expressed symmetrically at the node, there is failure to maintain expression and to shift to asymmetric expression. Taken together, these results suggest that *Zic3* is required for maintenance of the node and that its expression plays a critical role both in gastrulation and left-right patterning.

**Microarray transcriptional profiling of DNA repair-related genes in mammalian oocytes.** *A.J. Wyrobek<sup>1</sup>, M.A. Coleman<sup>1</sup>, S. Mabery<sup>1</sup>, B.J. Marsh<sup>1</sup>, R. Raja<sup>2</sup>, T.B. Taylor<sup>2</sup>, F. Marchetti<sup>1</sup>.* 1) Biology and Biotechnology Research Program, Lawrence Livermore National Laboratory, Livermore, CA; 2) Arcturus, Mountain View, CA.

Maintenance of genomic integrity at fertilization and during early development relies on maternally stored gene products until the time of genomic activation. Expression microarray technology provides a genomic approach to characterizing the initial storage pool and subsequent changes in transcript levels after fertilization. However, the low amount of mRNA in oocytes has remained a serious obstacle. Using the mouse model, we have improved the technology for obtaining RNA and preparing antisense RNA (aRNA) from oocytes for microarray evaluation. We utilized custom-built cDNA microarrays containing over 800 genes involved in DNA damage recognition, DNA repair, cell-cycle control, stress response and various related functions. Oocytes free of contaminating cumulus cells were collected from superovulated B6C3F1 females 16 hr after induction of ovulation. RNA was isolated and amplified by a new in vitro linear amplification process (RiboAmp<sup>TM</sup> RNA Amplification Kit, Arcturus). An initial pool of 84 oocytes containing ~35 ng of total RNA yielded ~11 mg of aRNA. Five mg aliquots of aRNA were labeled and hybridized to our array. Approximately 150 genes, including *Cyclin A*, *Cenp B*, *Cdc2*, *Nbs1* and *Bax*, showed significant intensities above the confidence intervals for negative reference genes. The microarray findings for selected DNA-repair-related genes were confirmed by RT-PCR and/or TaqMan (e.g., *Ku80*, *Rad51*, *Rad54*, *Dna-pkcs*, *Xpa*, *Ape1*). Nineteen transcripts that represented unannotated ESTs from developmental libraries were also detected on our microarrays: four of these encode putative proteins that have human and *C. elegans* homologies. These microarray protocols are being optimized to require lower amounts of RNA from fewer oocytes and to characterize the expression profiles during early development. [This work was conducted under the auspices of DOE by the University of California, LLNL under contract W-7405-ENG-48 with support from NIH ES09117-03, DOE KP110202 and TRDRP 7RT-0073.].

**Microarray transcriptional profiling of mammalian male meiosis.** *L.M. Tomascik-Cheeseman*<sup>1,2</sup>, *F. Marchetti*<sup>1</sup>, *M.A. Coleman*<sup>1</sup>, *E. Yin*<sup>1</sup>, *K. Rankin*<sup>1</sup>, *J. Nath*<sup>2</sup>, *A.J. Wyrobek*<sup>1</sup>. 1) Biology & Biotechnology Research Program, Lawrence Livermore National Laboratory, Livermore, CA; 2) Genetics and Developmental Biology Program, West Virginia University, Morgantown, WV.

The first wave of spermatogenesis in the prepubertal mouse provides a unique model for investigating the kinetics of gene expression during mammalian spermatogenesis. The purpose of this research was to characterize the patterns of gene expression at the onset and during the progression of male meiosis. Testes were evaluated at specific postnatal days when the leading edge of the first wave of spermatogenesis was in the preleptotene (day 9) and pachytene (day 14) stages, respectively. Total RNA was isolated from seminiferous tubules, fluorescently labeled and hybridized onto oligonucleotide microarrays. Hundreds of genes were significantly and/or differentially expressed across meiosis. Several distinct expression patterns were observed: (a) genes known to be essential for normal spermatogenesis were differentially expressed between the preleptotene and pachytene stages [e.g., *Mdes* was down-regulated and *Dazl* was up-regulated]; (b) genes with no previously known role in spermatogenesis, meiosis or fertility were differentially expressed at the two stages [e.g., *Crkol* and *Peg3* were down-regulated; *Grp78* and *Tcf20* were up-regulated]; and (c) genes that did not have detectable levels of expression at the onset of meiosis were significantly expressed during the pachytene stage (e.g., *Tcte3*, *Pem* and *Rzf*). These findings provide important insights into the kinetics of gene expression during spermatogenesis, identify novel meiosis-specific and meiosis-enriched genes, and assign new putative functions to known genes. This research enhances our understanding of the mechanisms of meiosis and the genetic causes of male infertility. [Work was conducted under the auspices of U.S. DOE by the University of California, LLNL under contract W-7405-ENG-48 with support from NIH ES09117-02, NIEHS Superfund P4ZES04705, DOE KP110202 and West Virginia University.].

***NNAT* resides in a micro-imprinted domain on human chromosome 20q11.2.** *H.K. Evans*<sup>1,2</sup>, *A.A. Wylie*<sup>1</sup>, *S.K. Murphy*<sup>1</sup>, *R.L. Jirtle*<sup>1</sup>. 1) Department of Radiation Oncology, Duke University, Durham, NC; 2) University Program in Genetics, Duke University, Durham, NC.

A small proportion of the genome consists of imprinted genes - genes expressed exclusively from one parental allele. Imprinted genes are involved in the etiology of a variety of clinical diseases including Prader-Willi, Angelman, and Beckwith-Wiedemann syndromes. In addition, they have been implicated in several complex disorders such as diabetes and autism. Yet despite the clinical significance of imprinted genes, the precise regulatory mechanism for this phenomenon remains undefined. Therefore, our laboratory was interested in identifying novel imprinted genes in humans that could be used as models to further study and understand imprinting. This study focuses on characterizing the imprinting at one specific locus - *Peg5/NNAT*. While previous research has confirmed imprinting of mouse *Nnat*, the imprinting status of human *NNAT* has not been addressed. Using gene-specific polymorphisms to determine biallelic versus monoallelic expression of *NNAT* in human fetal tissues, we demonstrate that *NNAT* is imprinted in humans. Since differential methylation of CpG islands near or within imprinted genes has been demonstrated to play a role in the imprinting mechanism, we used bioinformatics in combination with bisulfite treatment and subsequent sequencing of genomic DNA to perform an in-depth methylation analysis of the *NNAT* locus. We identified a large CpG island at the *NNAT* promoter that exhibits consistent differential methylation in all tissues examined and hypothesize that this island may be a component of an imprint control region for the *NNAT* domain. Furthermore, we show that *NNAT* lies within the singular 8.5 kb intron of a second gene, *BLCAP*, which is not imprinted. Therefore, *NNAT* lies in an imprinted micro-domain, making it uniquely suited for investigating mechanisms of localized imprint regulation.

**Fibroblast Growth Factor Receptor 1 signalling during limb and sternum development.** *M.D. Lalioti<sup>1</sup>, A.O.M. Wilkie<sup>2</sup>, J.K. Heath<sup>1</sup>*. 1) Sch Biosciences, Univ Birmingham, Birmingham, UK; 2) Weatherall Institute of Molecular Medicine, University of Oxford, The John Radcliffe, UK.

The fibroblast growth factor receptors (FGFRs1-4) are a family of related transmembrane tyrosine kinases, which, upon binding of the fibroblast growth factors (FGFs), dimerize, autophosphorylate, and initiate intercellular signaling. A Pro252Arg on the ligand-binding domain of R1, and the same alteration in R2 cause Pfeiffer and Apert syndromes, respectively. Ser252Phe and Ser252Trp in R2 also cause Aperts, while Ser252Phe/Pro253Ser cause Pfeiffer syndrome. Both syndromes are characterized by various degrees of craniosynostosis and limb abnormalities. Taking into consideration the complex pattern of alternative splicing of FGFR1-3 and the autosomal dominant mode of inheritance of the syndromes, we created mouse models by introducing FgfR1 BAC transgenes harboring specific point mutations. A mouse containing a wt BAC was normal, showing that overexpression of FgfR1 is not responsible for the disease. Mice containing the Ser251Phe/Pro252Ser show limb, skull, sternum and tail deformities. Smaller body size, preaxial polydactyly and/or triphalangial big toe occur in 100 % of the animals. This is consistent with the big toe defect of the Pfeiffer patients due to Pro252Arg. Other defects include fusion of sternebrae and rib misalignment, shorter digits, kinked tails, and forelimb autopod abnormalities. The phenotype is copy number dependent. The defects likely to be due to a gain of function of the mutant receptor, presumably due to increased affinity for specific Fgf ligands, as it has been previously shown in vitro. Our models provide a powerful system for dissecting the role of Fgfr1 during development of the limbs, skull and sternum, their affinity for Fgfs and their signalling to downstream morphogens.

**Analysis of *Dmrt1* in *Ellobius lutescens*: Evidence for the exclusion of a testis inducing function.** A.C. Baumstark<sup>1</sup>, W. Vogel<sup>1</sup>, A. Schulze<sup>1</sup>, M. Akhverdyan<sup>3</sup>, I. Reiser<sup>2</sup>, W. Just<sup>1</sup>. 1) Dept Human Genetics, Univ of Ulm, Ulm, Germany; 2) Dept Anatomy and Cellular Biology, Univ of Ulm, Ulm, Germany; 3) Dept Conservation Biology and Genetics, Uppsala Univ, Uppsala, Sweden.

Mammalian sex determination is a complex event involving various genes. Animal models are a suitable tool to investigate these genes. In the mole vole *Ellobius lutescens* both sexes show the identical karyotype 17,X. Cytogenetic analyses of a polymorphism in different *E. l.* families revealed sex specific segregation of chromosome 1 indicating the localization of a sex determining gene. The absence of *SRY*, initiating testis differentiation in other mammals has been shown. Thus it is hypothesized that another gene from the sex determination cascade is mutated and has taken over testis determining function. *SOX9*, for which a testis determining function in the absence of *SRY* has been shown, has been excluded from being the testis initiating factor in *E. l.* Another candidate gene for the induction of testis development is *DMRT1*. *DMRT1* shows testis specific expression in all vertebrate species examined to date. Because of its localization on the Z chromosome in birds it is considered a candidate gene for the postulated dosage dependent avian sex determination. A comparable mechanism, based on two *DMRT1* alleles differing in expression levels, could also exist in *E. l.* To investigate the role of *Dmrt1* in testis determination of *E. l.* we isolated and sequenced phage clones containing part of the gene. One of these clones was used to localize *Dmrt1* on distal 1p outside the candidate sex determining region on 1q by FISH. Intronic sequences were screened for polymorphic markers by an enzymatic mutation detection system. Analysis of the distribution of alleles of isolated markers showed no association of alleles with the sex of the tested animals. Because of the expected extensive linkage disequilibrium in the investigated subpopulation and the close linkage between tested markers and *Dmrt1* an association between *Dmrt1* alleles and sex and thus a testis determining function of *Dmrt1* can also be excluded. This study was supported by grant Re 413/6-1 from the Deutsche Forschungsgemeinschaft.

**Identification of two *Drosophila* homologs of *Chx10*, a homeobox gene essential for eye development.** *T. Erclik*<sup>1</sup>, *G. Sheng*<sup>2</sup>, *K. Duecker*<sup>3</sup>, *C. Desplan*<sup>2</sup>, *E. Hafen*<sup>3</sup>, *H. Lipshitz*<sup>1</sup>, *R.R. McInnes*<sup>1</sup>. 1) Program in Developmental Biology, Research Institute, Hospital for Sick Children, Toronto, Ontario, Canada; 2) Department of Biology, New York University, New York, N.Y., USA; 3) Zoologisches Institut, Universitat Zurich, Zurich, Switzerland.

*Chx10* encodes a homeodomain (HD) protein and is an essential component of a genetic pathway that regulates mammalian eye development. In humans and mice, homozygous *Chx10* null alleles are associated with impaired proliferation of retinal progenitors, absent bipolar cells, microphthalmia and blindness. Because regulators of eye development are highly conserved between invertebrates and mammals (e.g. *Pax6*), we are using the powerful genetics of *Drosophila* to facilitate the dissection of the mammalian *Chx10* regulatory pathway. We have identified two *Drosophila* homologs of *Chx10*, *dChx1* and *dChx3*. Both homologs are >75% identical to *Chx10* in the HD and CVC domain. *dChx1* and *dChx3* map to polytene region 5A3-6 on the X chromosome where they are located 33 kb apart. *dChx1* is expressed in the procephalic region and certain sensory neuron precursor cells in the embryo (like *Chx10*) while *dChx3* is not embryonically expressed. In third instar larvae, both *dChx1* and *dChx3* are expressed in the dorsal and ventral regions of the eye-antennal discs. *wingless*, a *Drosophila* *Wnt* homolog, is expressed in similar regions of eye-antennal discs where it functions to define the boundaries of the retinal field. Ectopic expression of *wingless* in the eye disc leads to ectopic expression of both *dChx1* and *dChx3* indicating that expression of the *dChx*'s may be activated in response to *wingless* signaling. Ectopic expression of *Chx10* or *dChx1* in the developing eye disc leads to a loss of photoreceptor cell types. This phenotype is consistent with the *dChx*'s functioning downstream of *wingless* to repress retinal cell fate at the boundary of the retinal field. Genetic screens to generate loss of function *dChx* phenotypes by P-element mediated mutagenesis are underway. The identification of *dChx* regulatory pathways is likely to lead to the recognition of homologous upstream and downstream components of the mammalian *Chx10* developmental network.

**Generation of mouse models of human congenital malformation syndromes using ENU mutagenesis. B.J.**

*Herron*<sup>1</sup>, *C. Rao*<sup>1</sup>, *H. Peters*<sup>1</sup>, *W. Lu*<sup>1</sup>, *S. Liu*<sup>1</sup>, *R.T. Bronson*<sup>2</sup>, *M.J. Justice*<sup>3</sup>, *J.D. McDonald*<sup>4</sup>, *D.R. Beier*<sup>1</sup>. 1) Genetics Division, Brigham & Womens Hospital, Harvard Medical School, Boston, MA; 2) Tufts University School of Veterinary Medicine, North Grafton, MA; 3) Baylor College of Medicine, Houston TX; 4) Wichita State University, Wichita, KS.

Mouse models of congenital malformation syndromes can be useful both for understanding mammalian development and for determining the molecular basis of birth defects. We are screening embryos derived from mice mutagenized with N-ethyl-N-nitrosourea (ENU) for recessive phenotypes similar to human congenital defects. 3rd generation progeny are evaluated for developmental anomalies at embryonic d18.5; we thus identify defects in organogenesis that are consistent with survival *in utero* to late gestation, but which may cause post-natal lethality. Affected progeny are used directly for genetic mapping utilizing our previously described method of interval haplotype analysis. With this strategy we are able to localize the mutation to a single linkage group by genotyping 8-10 mice.

The main component of the mutation screen is an inspection of major organs after embryo dissection, followed by a more detailed analysis for craniofacial, kidney, brain and skeletal abnormalities. In our first study we identified 15 monogenic mutants in 54 families. The addition of a mapping component has proven extremely useful in prioritizing our analyses and expediting characterization. We have mapped 7 loci, identified the causal gene for 2 of the mutants obtained, and demonstrated by exclusion that a number of the unmapped mutations are not new alleles of known mutants with similar phenotypes. The spectrum of abnormalities found to date is remarkably varied, and many of these disorders are similar to human malformation syndromes. For example, we have generated models of asphyxiating thoracic dystrophy, Robin sequence, congenital diaphragmatic defect, non-syndromic cleft palate, polycystic kidney disease, and congenital heart defects. Our results demonstrate that a recessive screen can be extremely productive for the purpose of generating abnormal developmental phenotypes and can be readily managed even in a small laboratory.

**Single tube gene-specific expression analysis by high primer density multiplex reverse transcription.** *R.C. Clipsham, E.R.B. McCabe.* Dept Pediatrics, UCLA Sch Med, Los Angeles, CA.

Molecular genetics is rapidly moving from simple identification of a gene of interest to characterization of gene products as components in complex networks. Critical tools for gene product analysis require a rapid method for evaluation of contextual expression. Here, we describe a robust, high primer density, multiplex reverse transcription (RT)-polymerase chain reaction (PCR) technique capable of analyzing for the presence of numerous transcripts in a single tube. This assay substantially increases the total number of different cDNAs for amplification beyond previously published techniques. Our approach simultaneously eliminates RNA quality control issues for samples run in parallel while improving efficiency in the use of time and materials. This assay is designed for broad applicability, employs modifications of commercially available components and allows more than 25 independently selected gene-specific primers to be used simultaneously. Our protocol allows multiplexed primers to behave similarly to uniplex RT reactions, while avoiding potential interference between gene-specific and /or nonspecific primers during annealing and reverse transcription. Expression of putatively networked homologous transcripts was analyzed in multiple cell lines and tissues from mouse and human to validate the technique.

**Regulation of *Cbfa1/Runx2* action during osteoblast development by a *cbfa1*-interacting protein, *Cip*.** G. Zhou, P. Hermanns, Y. Chen, B. Lee. Molecular & Human Genetics, Baylor College of Medicine, Houston, TX.

CBFA1/RUNX2 is one of three vertebrate runt family transcription factors which have in common amino acid motif that mediates both DNA binding and protein-protein interaction. In transfection studies, *Cbfa1* can directly activate transcription of several bone-specific genes. *Cbfa1* null mice have complete absence of osteoblast and bone but an intact cartilagenous skeleton. CBFA1's requirement for osteoblast differentiation is supported by the finding of loss of function mutations in the human skeletal dysplasia-cleidocranial dysplasia (CCD). While *Cbfa1* is essential for osteoblast differentiation, additional factors are likely required to maintain the differentiation program. To identify potential CBFA1-interacting proteins, we screened a human osteosarcoma cDNA library using a yeast two-hybrid approach and isolated a 500-bp partial cDNA which we named CIP. Sequence analysis revealed homology to several anonymous human and mouse ESTs and Northern analysis and in situ hybridization on mouse E15.5 embryos revealed ubiquitous expression. The full-length cDNA was obtained by RT-PCR. It encodes a 297 amino acid polypeptide with no homology to known proteins. It has a multidomain structure with several protein-protein interaction domains and a nuclear localization signal. In transient transfections CIP down-regulated target gene transactivation by CBFA1 by 50%. FISH and radiation hybrid mapping showed that CIP localizes to chromosome 8q22 syntenic with a hypothesized second CCD-like locus. CIP mutation analysis in patients with CCD-like phenotypes who do not have mutations in CBFA1 revealed several potential polymorphism in its regulatory elements. We would predict that upregulation of *Cip*, a putative repressor of *Cbfa1*, would cause loss of *Cbfa1* transactivation and hence a CCD-like phenotype. To elucidate the potential in vivo effect of *Cip* on skeletogenesis, we are generating *Cip* null mice and transgenic mice overexpressing *Cip* in osteoblasts.

**A search for down-regulated genes in a DiGeorge syndrome mouse model.** *T. Pramparo, A. Baldini, E. Lindsay.* Pediatrics/cardiology, Baylor College of Medicine, Houston, TX.

Df1/+ mice carry a 1 Mb heterozygous chromosome deletion, which includes most of the murine homologs of genes deleted in DiGeorge syndrome. The deletion is associated with cardiovascular, thymic and parathyroid abnormalities. Our goal is to identify genes that are down-regulated in this model, as they may be downstream effectors of the haploinsufficient gene, *Tbx1*. To achieve this goal, we have used a commercially available cDNA subtraction kit (Clontech). The kit is based around a technique of subtractive hybridization that allows one to compare two different mRNA populations, in this case Df1/+ and wildtype, and thereby to obtain cDNA clones that represent genes that are expressed in one population but not in the other. At E10.5, *Tbx1* is highly expressed in the pharyngeal arch region, we therefore used as starting material for the cDNA subtraction, RNA that was extracted from segments of embryos encompassing the entire pharyngeal arch region and the heart. Following cDNA subtraction, we obtained 25 clones that were confirmed to be down-regulated in Df1/+ embryos. Sequencing of these clones revealed that two were transcription factors of the Forkhead and Sox families and a third clone that was a Rho family member. Of the remaining 22 clones, 7 were enzymes, 11 were other non-enzyme proteins and 4 were unknown sequences. We are currently confirming down-regulation of the transcription and Rho-related clones by in situ hybridization on Df1/+ and wild-type embryos. Moreover, we approached this goal by screening an oligonucleotide array (Affymetrix) of 6,000 full-length mouse genes, plus 6,000 clustered ESTs using cRNA probes made from the same starting material of the cDNA subtraction. This analysis identified several differentially expressed genes of interest that may be involved in the *Tbx1* pathway. Overall, our results demonstrate the feasibility of cDNA subtraction as a means to identify down-regulated genes in a haploinsufficiency model. Our preliminary results show that some candidate downstream targets of *Tbx1* may be transcription factors involved in the mesenchymal specification and differentiation. **Developmental candidates for ocular colobomas: VAX1, VAX2 and SHH.** *L.A. Schimmenti<sup>1</sup>, J.D. Karkera<sup>2</sup>, J. dela Cruz<sup>2</sup>, H. Tran<sup>1</sup>, G.S. Manligas<sup>1</sup>, E. Roessler<sup>2</sup>, M. Muenke<sup>2</sup>.* 1) Dept Human Genetics, Pediatrics and the Mental Retardation Research Center, UCLA School of Medicine, Los Angeles, CA; 2) Medical Genetics Branch, NIH/NHGRI, Bethesda, MD.

Ocular colobomas represent a heterogeneous phenotype caused by maldevelopment of the optic cup and stalk. It is estimated that 10% of childhood blindness is caused by colobomatous eye malformations. Ocular colobomas may present as abnormalities of the iris, retina or optic nerve and may include severe phenotypes such as microphthalmia and anophthalmia. We have previously demonstrated that autosomal dominant mutations in *PAX2*, a transcription factor expressed in the developing optic cup and stalk, cause optic nerve colobomas as part of the renal-coloboma syndrome. As most individuals with colobomas are not part of large kindreds, but rather isolated probands, we could not perform linkage analysis. We therefore hypothesized that genes expressed in the developing optic cup and stalk or genes that control *PAX2* expression would represent developmental candidate genes for ocular colobomas. *VAX1* is a transcription factor expressed in the optic cup and stalk in a spatial and temporal pattern similar to *PAX2*. *Vax1* knockout mice exhibit colobomas. *VAX2*, a related transcription factor, is expressed primarily in the optic cup along the optic fissure. *SHH*, a secreted factor, controls *PAX2* expression in the developing eye. Patients with holoprosencephaly (HPE) have been described with coloboma and coloboma has been observed in family members of HPE patients. We therefore analyzed *VAX1*, *VAX2* and *SHH* genes for mutations in genomic DNA isolated from 52 probands with ocular colobomas. The majority of patients carried the diagnosis of non-syndromic colobomas and microphthalmia. CHARGE syndrome was diagnosed in 4 individuals. We performed single stranded conformational polymorphism analysis, dHPLC or direct sequencing on amplimers of the coding exons of *VAX1*, *VAX2* and *SHH*. Screening of *VAX1* and *VAX2* has not identified causative mutations in patients with ocular colobomas. *SHH* analysis is still in progress.

**Further Characterization of the X-linked Dominant, Male Lethal Bare Patches Mutation.** *G.E. Herman<sup>1</sup>, X. Wang<sup>1</sup>, M. Lucas<sup>1</sup>, Q. Ma<sup>1</sup>, J. Peters<sup>2</sup>, B. Cattanach<sup>2</sup>, C. Pierson<sup>3</sup>, M. Bard<sup>3</sup>, R.I. Kelley<sup>4</sup>*. 1) Dept of Pediatrics, Children's Research Inst., Columbus, OH; 2) Mammalian Genetics Unit, Harwell, UK; 3) Dept of Biology, Indiana-Purdue University, Indianapolis, IN; 4) Kennedy Krieger Inst., Baltimore, MD.

The X-linked mouse mutation bare patches (Bpa) and most cases of human CHILD syndrome result from mutations in *Nsdhl* (for NADH steroid dehydrogenase-like). *Nsdhl* is involved in the removal of C-4 methyl groups in the cholesterol biosynthetic pathway. While the features in surviving affected human and murine females have many similarities, the striking unilateral skin and skeletal phenotype found in CHILD syndrome is not seen in the mouse. We have now detected missense mutations V53D and A94T in conserved amino acids in two additional Bpa alleles. Functional complementation assays of these mutations in yeast demonstrate their significance. The latter mutation is identical to one identified in 2 unrelated CHILD patients (*Amer. J. Med. Genet.* 90:339-346, 2000). Differences in the phenotype between Bpa mice and CHILD syndrome are unlikely to be explained on the basis of different types or sites of mutations. Male embryos for several Bpa alleles die during midgestation, and cholesterol levels in affected male embryos at the time of death are normal. Placentas from affected male embryos at day 10.5 are smaller than those of normal littermates ( $p < 0.001$ ) and the labyrinthine layer of the placenta appears thinner and disorganized. There are also statistically significant differences in placental thickness between affected male and affected female placentas. Most cells in the female rodent placenta undergo preferential inactivation of the paternal X Chr. We believe that mesodermally derived cells that undergo random X-inactivation are responsible for the male lethality. Finally, we have been unsuccessful in attempts to generate transgenic mice that overexpress *Nsdhl*. Preliminary data from experiments in which a tyrosinase minigene was coinjected with an *Nsdhl* cDNA suggest that such overexpression may be lethal during embryogenesis. A possible explanation is abnormal feedback regulation of isoprenoid synthesis.

**X-linked gene expression and methylation in Rett syndrome: role of MeCP2 in epigenetic control of X chromosome inactivation.** *L. Carrel, B.P. Chadwick, K.C. Trevarthen.* Dept. Genetics, Case Western Reserve Univ., Cleveland, OH.

Rett syndrome (RTT) is caused by mutations in the X-linked gene MECP2 that encodes a methyl-cytosine binding protein involved in transcriptional repression via a histone deacetylase complex. This suggests that the RTT phenotype results from at least partial derepression of normally silenced genes. Target genes remain unknown, but plausible candidates in RTT females include any of the several thousand genes on the X that are normally epigenetically silenced by X inactivation. X inactivation patterns in most RTT females are random, establishing that MeCP2 is not essential for X inactivation. However, multiple methyl-binding proteins have been identified and, therefore, MeCP2 may be necessary for silencing only a subset of X-linked genes.

To determine whether X-linked gene expression or other epigenetic features of X inactivation are altered in RTT individuals, lymphoblast or fibroblast cell lines from 5 RTT females were subcloned to isolate lines that carry the mutant MECP2 allele on the active X. In each case, clonality was established by monoallelic expression of a transcribed XIST polymorphism and/or by methylation analysis at the Androgen Receptor (AR) locus. Additionally, correct clones exclusively expressed the mutant MECP2 transcript. The XIST gene, normally expressed only from the inactive X, and 10 X-linked genes normally silenced on the inactive X were then tested using transcribed polymorphisms to distinguish active and inactive X expression. All 28 informative loci analyzed (3-8 genes/cell line) showed complete monoallelic expression, indicating that their expression is not altered in the RTT lines. Intriguingly, one of three RTT lymphoblasts tested showed aberrant methylation; 5 subclones from this line were completely unmethylated at AR on both the active and inactive X. These results suggest that MeCP2 likely has a role in X inactivation, yet because of functional redundancy, proper inactivation for X-linked genes can occur in the absence of MeCP2. Additionally, these data caution that methylation-based assays may not accurately predict X inactivation ratios in all RTT females.

**DsRNAi and overexpression of the *C.elegans* orthologue of MADSO1, a novel HC21 gene, suggest an important role in embryonic development and adult morphogenesis.** *O. Menzel*<sup>1</sup>, *T. Vellai*<sup>2</sup>, *K. Takacs-Vellai*<sup>2</sup>, *A. Reymond*<sup>1</sup>, *F. Mueller*<sup>2</sup>, *S.E Antonarakis*<sup>1</sup>, *M. Guipponi*<sup>1</sup>. 1) Division of Medical Genetics, University of Geneva, CMU, Switzerland; 2) University of Fribourg, Institute of Zoology, Perolles, Switzerland.

Down syndrome (DS), the most common cause of mental retardation, is caused by the presence of an extra copy of some but certainly not all the approximately 220 genes on human chromosome 21 (HC21). In order to identify those genes, we isolated a new transcript, MADSO1. This gene contains 9 exons and spans 24kb of genomic sequence on 21q22.3 between ADARB1 and COL18A1. Two ubiquitous mRNAs of 3.3 and 5kb respectively and a brain-specific transcript of 2.7kb are expressed. Transfection of tagged-MADSO1 protein revealed a perinuclear localization. Colocalization experiments showed a probable localization for MADSO1 protein within the Golgi apparatus. The human protein is highly conserved in *C.elegans* and in *Drosophila* (52% and 35% identical, respectively) and contains a MADS box domain. To investigate the function of MADSO1, we isolated the *C. elegans* orthologue and performed dsRNAi and overexpression experiments. DsRNAi was used to decrease the endogenous level of CeMADSO1 protein. 5-7 % of the progeny (F1) of the adults nematodes microinjected or fed (F0) with CeMADSO1 dsRNA showed embryonic arrest mainly after gastrulation and around morphogenesis. The majority of F1 adults exhibited a partial Egl phenotype (Egg-laying defective) and approximately 2% became extremely malformed with a highly deformed vulva region and gonadal structure. Overexpression analysis was used to determine the effect of an excess of CeMADSO1 protein. CeMADSO1 was ectopically overexpressed under the control of a *C.elegans* heat-shock promotor in all the tissues of adult *C.elegans*. Embryonic lethality was observed. These results indicate that CeMADSO1 is essential for the development and the morphogenesis of *C. elegans*. This study provides the first example of the use of *C. elegans* as a model to study the effects of silencing and overexpression of genes on HC21 that might be involved in Down syndrome.

**Microarray gene expression analyses in cells transfected with sense and antisense sequences of a novel activator of cyclin-dependent kinase (ACDK4).** *H. Zhao, C. Wang, P. Yang, C. Collins, S. Eckenrode, Q. Ruan, R. McIndoe, J. She.* Dept. of Pathology, Immunology and Laboratory Medicine, University of Florida, Gainesville, FL.

ACDK (activators of cyclin-dependent kinases) is a newly identified gene family encoding four individual proteins. Our functional study revealed that ACDK is a novel group of cell cycle regulatory proteins which can promote cell cycle progression by activating CDKs (cyclin-dependent kinases) to phosphorylate the retinoblastoma protein (pRB). In the present study, we established stable cell lines with both sense and antisense constructs in a pBIG2i inducible tet-on vector using ACDK4 coding sequence in HeLa cells. Genes with differential expressions between sense and antisense clones were analyzed by cDNA microarray technology. A total of 12288 human cDNA clones (from Research Genetics HTVV library) were analyzed in our study. RNAs from untransfected cells, sense and antisense cell clones were mixed as reference for normalization. Cy-dye labeled cDNA probes from 6 sense and 6 antisense clones (after induced 48hrs) were hybridized with the human cDNA clones. Discriminant and hierarchical clustering analyses showed that 37 genes were up-regulated in sense clones, and 58 genes were up-regulated in antisense clones. Database search revealed ten out of 37 genes are known genes for the sense clones, most of them are cell cycle related proteins, e.g. CCNK, PTMA, NEB, TGR, and PRP18 etc, which suggests that these genes are probably regulated by the ACDK proteins. While only four out of 58 genes are known genes for the antisense clones, most of them are ion channel proteins.

**Identification of proteins that interact with human diaphanous, DFNA1.** *A.B.S. Giersch<sup>1</sup>, C.L. Beattie<sup>2</sup>, P.L. Welch<sup>2</sup>, M-C. King<sup>2</sup>.* 1) Department of Pathology, Brigham and Women's Hospital, Boston, MA; 2) Departments of Medicine and Genomic Sciences, University of Washington, Seattle, WA.

DFNA1 is responsible for nonsyndromic sensorineural progressive hearing loss in a large Costa Rican kindred. Mutant DFNA1 is truncated 32 aa from the C-terminus of the 1251-aa wildtype protein. DFNA1 is a human homolog of *Drosophila* diaphanous, an essential mitotic gene and effector of the small GTPase Rho. Rho regulates actin cytoskeleton by shuttling between the GDP-bound inactive form and the GTP-bound active form. The active form causes reorganization of active stress fibers while inactivation leads to dissolution of these structures. As a formin homology (FH) protein, diaphanous contains the Rho-binding domain and three FH regions. Its FH1 domain interacts with profilin to induce actin polymerization. Also, the diaphanous C-terminus interacts with its N-terminal Rho-binding domain. Thus GTP-bound Rho may interact with diaphanous to expose FH domains and activate actin polymerization. Given that actin is the major component of the cytoskeleton of hair cells of the inner ear, we postulated that mutant diaphanous may disrupt Rho-mediated regulation of actin polymerization. In a yeast two-hybrid screen we identified three proteins that interact specifically with the C-terminus of human diaphanous: estrogen-related receptor alpha (ESRRA); ATP-binding cassette, sub-family D, member 4 (ABCD4); and protein phosphatase 2, regulatory subunit B (B56), alpha (PPP2R5A). ESRRA (11q12) is an orphan nuclear receptor homologous to the estrogen receptor that binds similar DNA target sites. However, ESRRA is not activated by classic estrogens and its target genes are not yet known. ABCD4 (14q24.3) is a novel human ABC-half-transporter. PP2A is a heterodimeric serine/threonine protein phosphatase implicated in cell growth and division, muscle contraction, and transcription, whose alpha subunit gene (1q41) encodes a cytoplasmic phosphoprotein. To determine if these proteins may play a role in hearing, we are testing their interaction with the human mutant DFNA1 in the two-hybrid system.

**Inner ear localization of mRNA and protein products of *COCH*, mutated in the sensorineural deafness and vestibular disorder, DFNA9.** *N.G. Robertson*<sup>1</sup>, *B.L. Resendes*<sup>1,3</sup>, *J.S. Lin*<sup>1</sup>, *C. Lee*<sup>1,3</sup>, *J.C. Aster*<sup>1,3</sup>, *J.C. Adams*<sup>3,4</sup>, *C.C. Morton*<sup>1,2,3</sup>. 1) Dept Pathology, Brigham & Women's Hosp, Boston, MA; 2) Dept Ob/Gyn, Brigham & Women's Hosp, Boston, MA; 3) Harvard Medical School, Boston, MA; 4) Dept Otology and Laryngology, Mass Eye and Ear Infirmary, Boston, MA.

Missense mutations in the *COCH* gene, which is expressed at high levels and preferentially in the inner ear, cause the autosomal dominant sensorineural deafness and vestibular disorder at the DFNA9 locus. By *in situ* hybridization of mouse and human inner ear sections, we find high-level expression of *COCH* mRNA in the fibrocytes of the spiral limbus and of the spiral ligament in the cochlea, and in the fibrocytes of the connective tissue stroma underlying the sensory epithelium of the crista ampullaris of the semicircular canals.

We also developed a polyclonal antibody against the human *COCH* protein product, cochlin. The antibody was raised against the N-terminal 135 amino acid residues of cochlin, corresponding to the *Limulus* factor C-homology (cochFCH) domain, which harbors all five known point mutations in DFNA9. On Western blots, anti-cochlin reacts with bacterially-expressed cochlin constructs and not with another control protein expressed in the same bacterial strain. Western blots also reveal high levels and different isoforms of cochlin in extracts of human fetal cochlea.

Immunohistochemistry performed with anti-cochlin shows staining predominantly in the regions of the fibrocytes of the spiral limbus and of the spiral ligament in mouse and human fetal and adult tissue sections. These sites correspond to those that express *COCH* mRNA as determined by *in situ* hybridization, and to the regions of the inner ear which show histological abnormalities in DFNA9. The fibrocytes expressing mRNA and protein products of *COCH* are the very cell types which are markedly absent in temporal bone sections of individuals affected with DFNA9, which also show a striking accumulation of a homogeneous eosinophilic acellular material replacing the normal fibrocytes.

**A single amino acid substitution in the FMR protein (I304N) results in reduced phosphorylation and an altered conformation.** *S.S. Ceman*<sup>1,2</sup>, *S. DiMarco*<sup>3</sup>, *S.T. Warren*<sup>1,2</sup>. 1) Howard Hughes Medical Institute; 2) Dept Genetics, Emory Univ, Atlanta, GA; 3) Boston University.

Fragile X syndrome is caused by the absence of the protein product of the FMR1 locus. An exception has been found in a severely affected individual who has normal levels of FMRP but with a single amino acid substitution at position 304 (I304N). The I304N protein has been extensively characterized and has many features distinguishing it from the wild type protein: it is not found associated with polysomes, forms a smaller mRNP particle, has altered RNA binding, shuttles more rapidly through the nucleus and is unable to form homodimers. We show here that unlike normal FMRP, which is serine-phosphorylated in a number of different cell lines labeled with [32P] ortho-phosphate and isolated by immunoprecipitation, the I304N protein is poorly phosphorylated. Phosphorylation of wild type FMRP is inhibited by 5,6 dichloro 1-B-D ribofuranosyl benzimidazole, which inhibits a limited number of kinases, including CK2. CK2 does co-immunoprecipitate with FMRP suggesting that it may be a substrate. In addition, we found that the I304N protein is not recognized efficiently by a newly developed monoclonal antibody, 6G2, which readily recognizes wild type FMRP. The epitope recognized by mAb 6G2 is N-terminal to amino acid 304 at peptide 131-142. Because this peptide contains no serines, the loss of reactivity of 6G2 may be due to an altered conformation of the I304N protein.

**Intracellular distribution of lysosomal sialidase is controlled by the internalization signal in its cytoplasmic tail.**

*A. Pshzhetsky<sup>1</sup>, K.E. Lukong<sup>1</sup>, K. Landry<sup>1</sup>, S. Trudel<sup>1</sup>, V. Seyrantep<sup>1</sup>, A. Ahmad<sup>1</sup>, W.A. Gahl<sup>3</sup>, S. Lefrancois<sup>2</sup>, C.R. Morales<sup>2</sup>.* 1) Department of Medical Genetics, Ste-Justine Hospital, Montreal, Quebec, Canada; 2) Department of Anatomy and Cell Biology, McGill University, Montreal, Quebec, Canada; 3) Heritable Disorders Branch, NICHD, National Institutes of Health, Bethesda, Maryland, USA.

Sialidase (neuraminidase), encoded by the *neu-1* gene in the MHC locus catalyzes the intralysosomal degradation of sialylated glycoconjugates. Inherited deficiency of sialidase results in sialidosis or galactosialidosis, both severe metabolic disorders associated with lysosomal storage of oligosaccharides and glycopeptides. Sialidase also plays an important role in cellular signalling and is specifically required for the production of cytokine IL-4 by activated T lymphocytes. In these cells, *neu-1*-encoded sialidase activity is increased on the cell surface, suggesting that a specific mechanism regulates sorting of this enzyme to the plasma membrane. We investigated that mechanism by first showing that sialidase contains the internalization signal found in lysosomal membrane proteins targeted to endosomes via clathrin-coated pits. The signal consists of a C-terminal tetrapeptide 412YGTL415, with Tyr412 and Leu415 essential for endocytosis of the enzyme. We further demonstrated that redistribution of sialidase from lysosomes to the cell surface of activated lymphocytes is accompanied by increased reactivity of the enzyme with anti-phosphotyrosine antibodies. We speculate that phosphorylation of Tyr412 results in inhibition of sialidase internalization in activated lymphocytes.

**Protein tyrosine phosphatase families resulted from gene duplication, fusion, horizontal transfer and circular permutation.** *J.-F. Huang, C.-Q. Liu.* Lab. Cell. & Mol. Evol., Kunming Institute of Zoology, Kunming, Yunnan, P. R. China.

Protein tyrosine phosphatases (PTPs) play a key role during cell signal transduction, which contain three families, low-molecular-weight phosphotyrosine phosphatases (lmwPTPs), higher-molecular-weight phosphotyrosine phosphatases (hmwPTPs) and dual specificity phosphatases (DSPs), and lmwPTP family is considered as an example of convergent evolution with hmwPTP and DSP families in early studies. In this work, we have searched 98 genomes/NR database and compared PTP sequences, structures and functions, the results indicate that PTP gene copies in these three families are increased from archaeotes/virus to eubacteria and to eukaryotes, and the gene encoding lmwPTP can be found in archaeotes, virus, eubacteria, and eukaryotes; but those encoding hmwPTP and DSP are not found in archaeotes. Sequence analysis and structure/function comparison show that these three families have similar structure, function, catalytic mechanism and a common functional motif, but low sequence identities, a different order of active site in sequence (or circular permutation) between lmwPTP and hmwPTP/DSP families, and the difference in substrate specificity between lmwPTP and DSP. On the other hand, the part of N-terminal in mRNA capping enzyme is a domain with similar DSP function, which cannot be found in bacteria, but in virus and eukaryotes. Thus, the results suggest that hmwPTP and DSP families are evolved from lmwPTP gene, the circular permutation in sequence of PTPs is resulted from the ancestral lmwPTP gene duplication, fusion and different reading, and which could be one of the reasons caused the different substrate specificities between lmwPTPs and DSPs. The DSP-like domain in mRNA capping enzyme might come from DSP in virus by horizontal gene transfer.

**Interspecific Comparisons of 35 Nuclear Receptor Superfamily Members Show the *NROB* Subfamily to be Permissive for Sequence Variability.** *M. Patel*<sup>1</sup>, *G.B. Golding*<sup>2</sup>, *A.P. Arnold*<sup>1</sup>, *J.S. Sinsheimer*<sup>3,4</sup>, *E.R.B. McCabe*<sup>5</sup>. 1) Dept. of Physiological Sciences, UCLA, Los Angeles, CA; 2) Dept. of Biology, McMaster University, Hamilton, ON, Canada; 3) Dept. of Biomathematics, UCLA, Los Angeles, CA; 4) Dept. of Human Genetics, UCLA, Los Angeles, CA; 5) Dept. of Pediatrics, Mattel Children's Hospital, UCLA School of Medicine, Los Angeles, CA.

We have previously shown that in closely related primate species the X-linked gene, *NROB1* encoding the nuclear receptor (NR) superfamily member DAX1, is predisposed to amino acid-changing substitutions similarly to *SRY* and greater than *SOX9*. The purpose of the current investigation was to compare *NROB1* sequence changes during evolution with 34 other members of the NR superfamily from all seven subfamilies, including the other *NROB* subfamily member, *NROB2*, which codes for SHP. We compared the coding sequences of these genes in human and mouse. The number of non-synonymous substitutions per non-synonymous site (Ka) and synonymous substitutions per synonymous site (Ks) were calculated in pairwise comparisons for genes between species. Codon usage and GC content at silent sites of synonymous codons (GC3s) were compared. We also performed correspondence analysis on codon usage for these genes in human and mouse. We found that codon usage correlated with GC3 content, superfamily, subfamily and ligand binding group. Among the genes we compared between human and mouse, *NROB1* and *NROB2* had the highest Ka values ( $0.221 \pm 0.016$  and  $0.117 \pm 0.015$ , respectively) and Ka/Ks ratios (32.03 and 18.88, respectively). We conclude that the *NROB* subfamily is permissive for sequence variability. We speculate that the sequence variability of the *NROB* subfamily members may reflect their evolutionary history as well as functional properties of their protein products.

**A novel human MOB gene encodes a member of novel family of transmembrane proteins.** *I.P. Vladychenskaya, L.V. Dergunova, S.A. Limborska.* Dept Molecular Basis, Inst Molecular Genetics, Moscow, Russia.

As the result of the differential hybridization of the human medulla oblongata cDNA library the 1,6 kb brainspecific clone Hmob33 was obtained (Acc. No. Y14155). Hmob33 sequence was searched with BLAST against the human cDNA and genomic sequences. The data revealed the highest similarity between 5'-end of Hmob33 and 3'-end of AK026683, which is a 2,2 kb anonymous cDNA clone from the human lung. These overlapping clones were used for constructing the 3,2 kb HMOB33 contig. HMOB33 contig has appeared to include the coding region flanked with the untranslated regions. It probably represents one of the mRNA transcription variants of some unknown gene named MOB gene. The results of the Northern blot analysis confirmed the predicted size and brainspecific expression pattern of the corresponding transcript. BLAST analysis of the human genomic sequences revealed the high similarity of the whole HMOB33 contig with two different genomic clones of the human chromosome 10. The alignment of HMOB33 contig relative to these clones breaks the contig into the fragments which have the identical patterns of distribution along both genomic clones thus representing the presumed exon-intron structure (7 exons and 6 introns spanning the region more than 155,5 kb) for the proposed MOB gene. The hypothetical product of MOB gene is assigned to be a five pass transmembrane protein of 413 amino acids with its N-terminus oriented into the cytoplasm and bearing the protein-protein interaction module. BLAST-analysis has revealed a number of anonymous putative proteins similar to the Mob protein coming from mouse, fruit fly and nematoda. The proposed exon-intron structure of two genes encoding two proteins from mouse is identical for that for the human MOB gene. BLAST search of the corresponding mouse mRNA sequences through the human genomic sequences database proposed the existence of the human gene related to MOB gene on the human chromosome 4. All the putative proteins coming from the named organisms are predicted to be the transmembrane molecules. These data argues for the existing of thus far unknown gene family of transmembrane proteins.

**Genomic organization and alternative transcription of a novel human SAM-dependent methyltransferase gene on chromosome 2p21-p22.** *Y. Zhang<sup>1</sup>, M.C. Gorry<sup>1</sup>, P.S. Hart<sup>2</sup>, M.J. Pettenati<sup>3</sup>, X. Lu<sup>1</sup>, L. Wang<sup>1</sup>, J.J. Marks<sup>1</sup>, B. Suppe<sup>1</sup>, T.C. Hart<sup>1,2</sup>.* 1) Oral Biol & Medicine, Univ Pittsburgh Sch Dental Med, Pittsburgh, PA; 2) Genetics, Univ Pittsburgh Sch Public Health; 3) Pediatrics, Wake Forest University Sch Medicine.

Gene identification and characterization of genomic structure in the post-genome-era increasingly involves the integration of bioinformational and laboratory methodologies. Using this strategy, we have identified a novel human methyltransferase gene (288L6 methyltransferase - 288L6 MTase). This gene contains the highly conserved methyltransferase domain characteristic of SAM-dependent methyltransferases. We localized this gene to chromosome 2p21-p22 by FISH, and sublocalized to BAC288L6 by homologous search. Computational analysis of aligned ESTs identified 11 exons in the hypothetical 288L6 MTase gene spanning 46 kb sequences. Results of RACE analysis in placenta suggest there are multiple transcripts, with three predominant forms of transcript I, II, and III. Two alternative polyadenylation sites are present in this gene. Sequencing of these three cognate transcripts demonstrates heterogeneity at the 5' untranslated region. Alternative transcription and tissue specific expression of this gene are detected by Northern blot analysis. The 288L6 MTase gene is expressed in a variety of tissues including brain, heart, colon, thymus, spleen, kidney, liver, small intestine, placenta, and lung. Open reading frame analyses of the three alternative transcripts identified a shared coding region spanning exons 7-11. This ORF consists of 732 nucleotides encoding a putative 244 amino acid protein. Bioinformational searches of both the 288L6 MTase DNA and the putative protein product identified three methyltransferase motifs conserved across many prokaryotic and eukaryotic species. The genomic structure and alternative transcripts of 288L6 MTase gene were determined. Since enzymatic methylation is important in cellular processes, including differentiation, growth, gene regulation, embryonic development, and oncogenesis, it will be important to functionally characterize the 288L6 MTase. (supported in part by NIDCR R01-DE12771).

**Identification of Human FEM1A, the homologue of a *C. elegans* sex-differentiation gene.** *D. Krakow*<sup>1,2</sup>, *E. Sebald*<sup>2</sup>, *L.M. King*<sup>2</sup>, *D.H. Cohn*<sup>2,3,4</sup>. 1) Dept OB/GYN Cedars-Sinai Medical Ctr and UCLA School of Medicine; 2) Medical Genetics-Birth Defects Center/Ahmanson Dept of Pediatrics; 3) Dept of Human Genetics, UCLA School of Medicine; 4) Dept of Pediatrics, UCLA School of Medicine, LA CA.

We report the isolation, genomic structure, chromosomal location, and expression pattern of the FEM1A gene, the human homolog of the *C.elegans* fem-1 and mouse Fem1a genes. The coding sequence is 1851 bp and encodes a 617 amino acid protein. The human FEM1A protein has 65% identity with the mouse Fem1a protein and 34% identity with the *C.elegans* fem-1 protein, indicating conservation of this gene. The N-terminal region of the encoded protein contains 6 ANK repeat elements, a motif found in signaling and transcriptional regulatory molecules such as Notch and glp1. The gene was highly expressed in human skeletal muscle and cardiac tissue, and was expressed at lower levels in multiple tissues, including cartilage. FEM1A was localized to chromosome 5q23.1, a region of conserved synteny with a portion of mouse chromosome 17 that contains Fem1a. In *C.elegans*, fem-1 is involved in a pathway necessary for sex-determination. The identification of a human homolog of this conserved gene suggests a potential role for this sex-determining molecule in humans.

**Isolation and characterization of the ALX4 promotor region.** *W. Wuyts, W. Van Hul.* Department of Medical Genetics, University of Antwerp, Antwerp, Belgium.

The Alx4 gene is a homeodomain transcription factor related to the *Drosophila aristaless* gene. Expression studies have shown that Alx4 is expressed in mesenchymal cells at several sites in the embryo, including the craniofacial mesenchyme. Alx4 KO mouse show preaxial polydactyly, ventral body wall defects and a delay in the formation of the parietal bone of the skull. Previously, we isolated the human ALX4 gene out of a region which is deleted in patients suffering from the Proximal 11p Deletion Syndrome (P11pDS) and showed that in humans inactivating mutations in ALX4 cause skull ossification defects (Foramina Parietalia Per magna; FPP). To identify potential regulators of ALX4 expression we isolated and analyzed the 5' region flanking the ALX4 gene. By reverse transcriptase mapping the ALX4 transcription start site (TSS) was mapped in a region located approximately 700 bp from the start codon and further fine mapping of the TSS was obtained by 5' RACE experiments. Several fragments surrounding the TSS were generated by PCR and exonuclease/S1 treatment and cloned in the pGL3 Luciferase vector. By a dual Luciferase reporter assay, promotor activity of the various constructs was analyzed in two osteosarcoma cell lines to identify the minimal promotor sequences and potential positive and negative regulating regions.

**Promoter analysis of Kv8.1 revealed the essential element for Kv8.1 expression.** *M. Ebihara, H. Ohba, T. Yoshikawa.* Lab Molec Psychiatry, Brain Sci Inst, Riken, Saitama, Japan.

It has been reported that there are more than seventy potassium channel genes in human. Some of these are associated with human diseases, such as long QT syndrome, episodic ataxia and epilepsy. It has been suggested that mutations of KCNQ channel genes cause benign familial neonatal convulsions (BFNC) and other epilepsies are strongly associated with channel proteins, i.e. potassium channel, sodium channel and nicotinic cholinergic receptor. In 1991, Yasuda et al. have reported benign adult familial myoclonic epilepsy (BAFME) among Japanese population. Mikami et al. have reported the gene responsible for BAFME is mapped on the distal portion of 8q (8q23.3-24.11). We have isolated and determined whole genomic structure of Kv8.1 potassium channel gene that is mapped on human chromosome 8q23-24. In the previous report, it has been reported that Kv8.1 has 3 exons, but our analysis of genomic structure has revealed the Kv8.1 has 4 exons indicating the existence of an additional 5' exon has been found. We also detected its promoter elements in upstream region. Series of deleted promoter mutants were constructed to determine the minimum region of Kv8.1 promoter. Luciferase assay showed that 130 bp upstream region is required for full activation of Kv8.1 expression. Two sp1 elements and some other elements have been found in this region suggesting they are essential for Kv8.1 expression. Here we show Kv8.1 genomic structure and its promoter region as a candidate gene for BAFME.

**Different mutations in the spastin gene result in distinct electrophysiological phenotypes in patients with hereditary spastic paraplegia type 4 (SPG4).** *D. Boensch<sup>1,2</sup>, A. Schwindt<sup>1,3</sup>, P. Navratil<sup>1,3</sup>, D. Palm<sup>3</sup>, S. Klimpe<sup>1</sup>, J. Hazan<sup>4</sup>, C. Weiller<sup>5</sup>, T. Deufel<sup>1</sup>, J. Liepert<sup>5</sup>.* 1) Institut fuer Klinische Chemie, Friedrich-Schiller Universitaet, Jena, Germany; 2) Klinik fr Neurologie, Friedrich-Schiller Universitaet, Jena, Germany; 3) Abteilung fr Neuropaediatric, Kinderklinik der Universitaet Muenster; 4) Genoscope, 2 rue Gaston Cremieux, 91000 Evry; 5) Klinik fr Neurologie, Universitaet Hamburg.

Hereditary spastic paraparesis (HSP) denotes a heterogeneous group of inherited neurological disorders with progressive lower limb spasticity; pedigrees have been described with autosomal dominant, autosomal recessive and X-linked inheritance. Pure and complicated forms of HSP exist. Even in patients within the same pedigree, however, clinical presentation may vary to a large degree; similarly, electrophysiological tests show variable results: transcranial magnetic stimulation (TMS) studies have demonstrated that central motor conduction times (CMCT) to lower extremities are delayed in a majority but not all patients; CMCTs to upper extremities are usually normal. A large proportion of autosomal dominant cases of HSP have been found to belong to HSP type 4 on chromosome 2; the gene, spastin, was recently cloned and a variety of mutations have been identified in different pedigrees. We report on 2 families with pure HSP caused by different mutations in the spastin gene. Clinically, affected members in both pedigrees present with a disease that is very similar with respect to age of onset, progression and severity of symptoms. With the aim to reveal subtle phenotypic differences that might reflect different molecular changes in the two pedigrees, the motor system of both clinically affected and clinically unaffected subjects was evaluated using transcranial magnetic stimulation. Our results show differences in several categories depending on the type of mutation present; this finding provides, for the first time, a phenotypic correlate of a given genetic change in this gene with its, so far, largely unknown function.

Program Nr: 979 from the 2001 ASHG Annual Meeting

**A Resource for Models of Human Disease.** *J.M. Fuller, S.F. Rockwood, L.E. Mobraaten, M.T. Davisson.* Induced Mutant Resource, The Jackson Laboratory, Bar Harbor, ME.

Mouse models have become a principle tool for use in dissecting disease pathways and target drug development. The recent availability of mouse and human genome sequence information will only promote the use of the mouse models in a wide range of human disease-related applications. In an effort to support this trend, the Induced Mutant Resource (IMR) at The Jackson Laboratory makes available over 600 genetically engineered mouse models. Created in 1992, the IMR serves as a centralized facility to collect, cryopreserve and distribute induced mutant mice to the scientific community. Since its inception, the IMR has accepted over 800 different induced mutant mouse strains, distributing over 100,000 mice a year to the scientific community. Current growth in the IMR collection is approximately 70-80 new strains each year, offering new mouse models in many areas including cancer, diabetes, neurobiology, development and immunology. Included in the resource collection are recently accepted models for mucopolysaccharidosis type I (MPS I), thrombosis, von Hippel-Lindau (VHL) disease and Batten Disease (juvenile neuronal ceroid lipofuscinoses-JNCL). An on-line resource is available allowing researchers to retrieve information related to the mutant strains maintained in the IMR. Mutant strain records in the IMR database include brief phenotype descriptions, strain construction and husbandry information and a list of related references. Researchers wishing to have mutant strains considered for inclusion in the IMR collection may submit their strains using the form available at the IMR web site. The IMR database can be accessed at URL: <http://www.jax.org/resources/documents/imr/>. The Induced Mutant Resource is supported by the National Center for Research Resources (RR09781), The National Institute for Allergy and Infectious Disease and The Howard Hughes Medical Institute.

**Direct analysis of MECP2 inactivation status in patients with Rett syndrome.** *I. Kondo<sup>1</sup>, R. Morishita<sup>1</sup>, T. Matsuishi<sup>2</sup>, Y. Yamashita<sup>2</sup>, T. Fukuda<sup>1</sup>, H. Yamagata<sup>1</sup>.* 1) Dept. of Hygiene, Ehime Univ. School of Med., Ehime, Japan; 2) Dept. of Pediatrics, Kurume Univ. School of Med., Fukuoka, Japan.

Rett syndrome (RTT) is an X-linked dominant disorder characterized by impaired neurodevelopmental system. Most patients with RTT have DNA mutations in a gene for methyl-CpG binding protein 2 (MECP2) mapped to Xq28. Over 120 mutations in MECP2 have been reported in patients with RTT and the genotype-phenotype correlation has been studied, but not established, because clinical phenotypes might be modified by the X-chromosome inactivation status. Most patients with RTT had random X-chromosome inactivation pattern using an androgen receptor (AR) polymorphism, but their healthy mothers with the same mutations had skewed X-chromosome inactivation. The X-chromosome inactivation has not always influenced on clinical severity in sporadic patients with RTT. The reason might be that the X inactivation status has been studied by AR polymorphism. We have detected a parental origin of DNA mutations of MECP2 in 50 sporadic patients with RTT and paternal MECP2 mutations were observed in 45 cases (90%). Then, to establish the genotype-phenotype correlation in RTT patients, we have directly analyzed MECP2 inactivation status by PCR amplification of HpaII digested DNA using allele specific primers and restriction enzymes. Most sporadic patients with RTT have random MECP2 inactivation patterns. However, a patient with the skewed expression of P152R mutation allele (80%) was more severely affected compared to patients with the random inactivation patterns of P152R mutations. On the other hand, a patient with R133C who had less expression of mutated allele had milder clinical phenotype. Then, the direct inactivation analysis of MECP2 is very useful to study the skewed gene expression status in patients with RTT.

**The novel association of SMN protein with a ribonucleoprotein complex containing two major nucleolar proteins is altered in Spinal Muscular Atrophy.** *S. Lefebvre, P. Burlet, L. Viollet, S. Bertrand, C. Huber, C. Belser, E. Vial, A. Munnich.* INSERM U-393, Hopital des Enfants Malades, Paris, France.

Spinal muscular atrophy (SMA) is caused by the loss of functional survival motor neuron (SMN) protein. This protein is part of a multifunctional complex involved in the assembly/regeneration of spliceosomal small nuclear ribonucleoproteins (snRNPs) and in the assembly of the RNA polymerase II machinery. Yet, which SMN-dependent function is responsible for the disease remains unclear. The SMN protein complex is detected in the cytoplasm and in the nuclear gems colocalized with coiled bodies often found at the periphery of the nucleolus. Here, we show that the SMA frameshift 472del5 mutation encodes a mutant SMN protein found into the nucleolus and/or the nucleoplasm of transfected COS cell cultures. It is the first SMA mutant to display an intranucleolar distribution. Co-immunoprecipitation studies carried out on untransfected cell nuclear extracts reveal that the normal SMN protein is associated with RNP complexes containing two major non-ribosomal nucleolar proteins and the association is mediated, at least, by RNA moieties. Most interestingly, the association is disrupted in fibroblast cell culture derived from an SMA type I patient (with an homozygous SMN1 gene deletion), showing a close correlation between the marked reduction of SMN protein level and defects in RNP complex assembly and/or stability. Our findings support the view that SMN protein is involved in different aspects of RNA processing and the identification of proteins in SMN-associated RNPs should help in understanding the pathogenesis of SMA.

**Identification of the proteins in neuroblastoma that were affected by overexpression of parkin.** *T. Kawamura*<sup>1</sup>, *A. Takayanagi*<sup>1</sup>, *S. Asakawa*<sup>1</sup>, *S. Minoshima*<sup>1</sup>, *Y. Mizuno*<sup>2</sup>, *N. Shimizu*<sup>1</sup>. 1) Department of Molecular Biology, Keio University School of Medicine, Shinjuku-ku, Tokyo, Japan; 2) Department of Neurology, Juntendo University School of Medicine, Bunkyo-ku, Tokyo, Japan.

*PARKIN* was discovered as a pathogenic gene of the autosomal recessive juvenile parkinsonism (AR-JP). The parkin protein possesses ubiquitin-like domain and ring-finger motif as well as several phosphorylation sites. Recently, we found parkin is involved in protein degradation pathway by playing a role as an ubiquitin-protein ligase in the dopaminergic cells in substantia nigra. We postulated the substrate(s) for parkin may be accumulated in the pathogenesis of AR-JP. Patients of AR-JP lack Lewy body, the characteristic protein aggregates seen in sporadic Parkinsons disease. Parkin was found in Lewy body in substantia nigra of sporadic Parkinsons disease. Here, we attempted to identify parkin-associated proteins by comparing the expression patterns of cellular proteins in dopaminergic neuroblastoma cell line SH-SY5Y with and without infection of recombinant Adenovirus with parkin cDNA. Effects of a proteasome inhibitor and a differentiating agent were also assessed. Identification of the proteins was performed by two-dimensional polyacrylamide gel electrophoresis followed by tandem mass spectrometry (MS/MS). Several proteins changed in their expression levels and molecular weights. Some proteins were down-regulated or ubiquitinated by parkin over-expression while other proteins were up-regulated by proteasome inhibitor. Characteristics of these parkin-associated proteins will be presented.

**Microscopic aggregations of  $\alpha$ 1A-calcium channel subunit and polyglutamine-containing protein are present mainly in the cytoplasm of the Purkinje cell in SCA6 brain.** *K. Ishikawa<sup>1</sup>, H. Fujigasaki<sup>1</sup>, N. Ohkoshi<sup>2</sup>, T.*

*Makifuchi<sup>3</sup>, T. Arai<sup>4</sup>, K. Hasegawa<sup>5</sup>, T. Kato<sup>6</sup>, S. Shoji<sup>2</sup>, H. Mizusawa<sup>1</sup>.* 1) Dept. Neurology and Neurological Science, Graduate School, Tokyo Medical & Dental Univ, Tokyo, Japan; 2) Dept. of Neurology, Inst. of Clinical Medicine, The University of Tsukuba, Ibaraki, Japan; 3) Dept. of Neuropathology, Saigata National Hospital, Niigata, Japan; 4) Dept. of Applied Biol. Science, Science Univ. of Tokyo, Noda, Chiba, Japan; 5) Dept. of Neurology, National Sagamihara Hospital, Sagamihara, Kanagawa, Japan; 6) 3rd Dept. of Internal Medicine, Yamagata Univ. School of Medicine, Yamagata, Japan.

SCA6 is a dominantly-inherited ataxia caused by an expansion of trinucleotide CAG repeat that code polyglutamine tract in the  $\alpha$ 1A (P/Q-type)-voltage-dependent calcium channel gene. To clarify the site of accumulation of mutant protein and polyglutamine-containing protein in SCA6, we underwent immunohistochemical analysis in 5 SCA6 brains. The  $\alpha$ 1A-calcium channel protein was detected with polyclonal antibody against C-terminal polypeptide of the channel protein, whereas polyglutamine was detected with mouse monoclonal antibody, 1C2. Microscopic aggregation of  $\alpha$ 1A-calcium channel subunit was seen exclusively in the cytoplasm of Purkinje cells, while it was not seen either in the cytoplasm or in the nucleus of any other neurons in SCA6 brains. Numerous 1C2-immunoreactive aggregates were seen in the cytoplasm of SCA6 Purkinje cells, but occasionally smaller 1C2-immunoreactive aggregates were also seen in the nucleus. However, diffuse nuclear staining with 1C2 seen in affected neurons of Machado-Joseph disease (MJD) and dentatorubral-pallidolusian atrophy (DRPLA) were not seen in any Purkinje cells of SCA6 brains. Furthermore, transcription factors TAFII130 or CREB which are positive in nuclear inclusions in MJD, DRPLA and Huntington's disease, were not stained in SCA6 Purkinje cells. The present data suggest that protein aggregation is mainly present, not in the nucleus, but in the cytoplasm of SCA6 Purkinje cells. Therefore, the pathogenic mechanism underlying in SCA6 may be different from that in other polyglutamine diseases.

**Toxicity associated with overexpression of FANCD2 exons 11-13 requires nuclear localization.** *J.A. Hejna, D.A. Bruun, R.E. Moses.* Molec & Med Genetics, L103, Oregon Health Sciences Univ, Portland, OR.

Fanconi Anemia (FA) is a cancer predisposition disorder associated with bone marrow failure, developmental abnormalities and chromosomal instability. Cells from Fanconi anemia patients are hypersensitive to DNA crosslinking agents such as mitomycin C, and also show varying degrees of hypersensitivity to ionizing radiation. Functional complementation of the cellular phenotype by cDNAs has been demonstrated for all of the *FANC* genes cloned to date; however, functional complementation of *FANCD2* cells has only been possible with retroviral constructs because overexpression of *FANCD2* from transfected plasmids is toxic to cells. We have developed an enhanced green fluorescent protein (EGFP) assay to monitor the toxicity of *FANCD2* subclones. Electroporation of CMV-driven *FANCD2*-EGFP fusion constructs into immortalized fibroblast GM639 cells leads to rounding up and cell death within 24 hr. Control electroporations with the pEGFP-N1 vector alone typically achieved greater than 60% transfection efficiency, with uniform fluorescence within 24 hr. Using this assay, we have identified a region of approximately 95 aa, encoded by exons 11-13, that is toxic when transfected into GM639 cells. Furthermore, this region is only toxic when coupled to a nuclear localization signal (NLS), suggesting that the toxicity is mediated by nuclear overexpression of *FANCD2* exons 11-13. The *FANCD2* NLS alone is not toxic in the same assay. Similar results were obtained with a pIRESpuro2 assay, scoring viable colonies after selection on puromycin relative to control transfections. *FANCD2* exon 12 contains a consensus ATM phosphorylation site. We speculate that this site may be required for the toxicity associated with overexpression of *FANCD2*.

**Transcript profiling in Nijmegen breakage syndrome: identification of transcripts induced by ionizing radiation.**

*J.A. Wright, K.M. Cerosaletti, P. Concannon.* Molecular Genetics, Virginia Mason Research Center, Seattle, WA.

Two rare recessive disorders in humans, ataxia-telangiectasia (A-T) and Nijmegen breakage syndrome (NBS) are characterized by a specific sensitivity to the cell-killing effects of ionizing radiation. Milder forms of radiosensitivity are not uncommonly observed among cancer patients undergoing radiotherapy. A rapid test for radiosensitivity could protect these genetically radiosensitive individuals while allowing potentially larger and more efficacious dosages to be delivered to the remaining population. We are exploring the utility of transcript profiling as a tool to identify radiosensitive individuals. As a test system we are using cell lines from NBS patients, and subclones of these lines that have been restored to normal radiosensitivity through the introduction of a functional copy of the NBS1 gene. Microarray hybridization and differential screening of subtracted cDNA libraries from these cell lines have been used to identify transcripts whose expression levels are modulated in response to ionizing radiation exposure. Identified transcripts are then profiled by quantitative PCR over a range of radiation doses and times following radiation exposure. By measuring transcript levels in cells derived from patients with defined DNA damage response defects, such as NBS and A-T, we can categorize transcripts according to the biochemical pathways to which they respond. In NBS cells, we find that genes such as p21 and GADD45 that are regulated normally by p53 are not induced upon irradiation, consistent with a defect in activation of the cellular G1 checkpoint. Similar results were obtained for several S phase inducible transcripts. Unirradiated NBS cells were found to express constitutively high (>10X) levels of several transcripts such as the human homologue of the *Drosophila* smoothed gene that decline to normal levels upon irradiation. Our results define a panel of novel radiation-regulated transcripts that may be of utility in screening patients for radiosensitivity. Their profiling in NBS cells provides new insights into the nature of the DNA damage response defect in this disorder.

**Microarray based expression analysis of mouse cells that lack or overexpress menin.** *N.B. Prasad<sup>1</sup>, E.A. Novotny<sup>1</sup>, J.S. Crabtree<sup>1</sup>, A.G. Elkahoun<sup>1</sup>, S.J. Marx<sup>2</sup>, A.M. Spiegel<sup>2</sup>, F.S. Collins<sup>1</sup>, S.C. Chandrasekharappa<sup>1</sup>.* 1) National Human Genome Research Institute, NIH, Bethesda, MD; 2) National Institute of Diabetes and Digestive and Kidney Diseases, NIH, Bethesda, MD.

Mutations in *MEN1* lead to multiple endocrine neoplasia type 1 (MEN1), a familial cancer syndrome with endocrine tumors primarily of the parathyroid, anterior pituitary and entero-pancreatic tissues. Other endocrine (foregut carcinoids) and non-endocrine (lipoma, angiofibroma, collagenoma, and ependymoma) tumors are also often associated with MEN1. The 610 amino acid *MEN1*-encoded protein, menin, resides primarily in the nucleus, and is known to interact with the transcription factor JunD. Menin appears to be a typical tumor suppressor, as its inactivation or absence leads to tumors. However, its precise role in tumorigenesis is not yet clear. Here we report our efforts to identify gene expression changes in mouse cells that do not express menin. Since homozygous loss of *Men1* in mice leads to embryonic lethality, we established mouse embryo fibroblast cell lines (MEFs) from 9.5 day embryos with wildtype (wt), heterozygous and null genotypes. The null cells do not express menin as measured by both western and immunofluorescence analysis using menin specific antibodies. RNA isolated from two null and a wt MEF cell lines were used for global expression analysis utilizing mouse cDNA microarrays consisting of 9,000 transcripts. Limiting to a minimum of 3-fold change, we identified 17 transcripts that were up, and 43 that were down, in both the null cell lines compared to wt. We have also established several independent NIH-3T3 mouse fibroblast cell lines that stably overexpress menin up to 8 fold over the endogenous level. RNA from these menin-overexpressing cell lines was also used to generate gene expression profiles using cDNA arrays. Fifteen of the transcripts showing altered expression in menin-overexpressing NIH-3T3 cells were found to be in common with the list of most significant results from the null cells, albeit in the opposite direction, as anticipated. The importance of these transcripts in mapping out the pathway of menin biology can now be explored.

**Transcriptional Analysis of Murine Cardiac Hypertrophy.** *T.D. Gallardo<sup>1</sup>, X. Zhao<sup>1</sup>, G. Esposito<sup>2</sup>, H.A. Rockman<sup>2</sup>, R.V. Shohet<sup>1</sup>.* 1) Internal Medicine, University of Texas Southwestern Medical Ctr, Dallas, TX; 2) Internal Medicine, Duke University Medical Center, Durham, NC.

We have created a cardiac-specific murine cDNA microarray to investigate the transcriptional response during the development of cardiac hypertrophy. We generated a library from adult mouse heart, removed redundancy by a cross-hybridization strategy, and identified the remaining 2500 clones by sequencing. We also removed redundancy from commercially available adult and fetal libraries and spotted all clones, a total of 9100, onto lysine-coated microscope slides using a robotic spotter. RNA was prepared from the left ventricle of mice having similar aortic gradients at 1, 4 and 8 weeks after aortic banding. Pooled samples from 3 mice were compared to hearts from untreated animals. After normalization two main expression trends were recognized. At week one of banding there were 94 cDNAs >3-fold up-regulated and 56 >3-fold down-regulated. By the 4th week only 49 of these up-regulated genes were still regulated to the same degree and by 8 weeks only 30. Interestingly, none of the down-regulated genes were even 1.5-fold down-regulated by week 4. There was a separate group of 16 genes that were not modified at week 1 but were >3-fold up-regulated at 4 weeks. Up-regulation persisted for 7 of these genes at 8 weeks.

We have identified, using a highly representative microarray, two waves of transcriptional regulation that occur after aortic banding. In addition, down-regulation of gene expression appears to rapidly remit during chronic aortic banding despite progressive hypertrophy. Among both sets of regulated genes are novel ESTs. We expect that characterization of these genes and their products will generate new hypotheses about the mechanisms of cardiac hypertrophy as well as targets for analysis of genetic variation in human subjects.

Program Nr: 988 from the 2001 ASHG Annual Meeting

**Identification of eight novel 5-exons in cerebral capillary malformation gene-1 (*CCM1*) encoding KRIT1.** B.A.S. McIntyre, I. Eerola, M. Vikkula. Lab. of Human Molec. Genetics, Christian de Duve Institute, Univ. catholique de Louvain, Brussels, Belgium.

Cerebral capillary malformations (CCM), also known as cerebral cavernomas, are vascular malformations of the brain. These malformations are usually multiple and consist of dilated capillary-venous channels, which tend to grow in size. The average age of clinical presentation is 33 years and the most common symptoms include headache, seizures and cerebral haemorrhage. CCMs often show familial aggregation and genetic linkage has been established to three chromosomal loci, 7q21-22 (CCM1), 7p13-15 (CCM2) and 3q25.2-27 (CCM3).

Identification of mutations in the *CCM1* gene encoding KRIT1 (Krev-1 Interaction Trapped 1) has provided the first clue to the molecular mechanisms causing CCM. In addition, we showed that vascular defects caused by *CCM1* mutations are not restricted to cerebral vasculature, but can also cause cutaneous lesions defined as hyperkeratotic capillary-venous malformations. However, *CCM1* mutations have not been identified in all the families linked to *CCM1*. Here we demonstrate that the *CCM1* gene contains eight additional exons, which may thus encompass missing mutations. (vikkula@bchm.ucl.ac.be).

**A transgenic mouse model for the ANT1 gene.** *V. Tiranti*<sup>1</sup>, *A. Limongelli*<sup>1</sup>, *F. Altruda*<sup>2</sup>, *M. Morbin*<sup>3</sup>, *S. Iussich*<sup>3</sup>, *M. Zeviani*<sup>1</sup>. 1) Divisione di Neurogenetica Molecolare, Istituto Nazionale Neurologico, Milano, Italy; 2) Dipartimento di Genetica, Università di Torino, Torino, Italy; 3) Divisione di Neuropatologia, Istituto Nazionale Neurologico, Milano, Italy.

Heterozygous mutations of ANT1, the heart/muscle isoform of the ADP/ATP translocator, cause autosomal dominant progressive external ophthalmoplegia and multiple mtDNA deletions in the affected tissues. So far, only three ANT1 mutations have been identified, A114P, V289M, and a novel one, L98P. The expression of the A114P substitution in AAC2, the yeast ortholog of ANT1, is associated with reduced or absent growth in glycerol medium. In addition, a KO ANT1<sup>-/-</sup> mouse has been shown to develop combined myopathy and cardiomyopathy with the typical hallmarks of a mitochondrial disease. We have generated a transgenic mouse expressing the A114P mutation in the murine protein, under the control of the heart-specific alpha-myosin heavy chain promoter. The transgenic mice developed an unusual cardiomyopathy, characterized by enormous dilation of the left atrium, hypertrophy of the septum, and profound disorganization of the cardiac syncytium. No defect of the respiratory chain complexes was detected in transgenic hearts. However, a tremendous increase of abnormal mitochondria was observed by both light and electron microscopy. The severity of the cardiac pathology did correlate with the level of expression of the transgene, evaluated by RT-PCR on heart RNA. PCR-based analysis of mtDNA disclosed the presence of multiple rearrangements in transgenic hearts, but not in age-matched control hearts. The mitochondrial cardiomyopathy observed in our model has peculiar features, similar to those found in extremely aged mice. Whether this phenotype is the consequence of the mutation carried by the ANT1 extra-allele, or of an overall increase of ANT1 expression, is currently under investigation.

**Elucidation of the genomic organisation of the bovine Plakoglobin gene and evaluation of its role in a bovine model of arrhythmogenic right ventricular cardiomyopathy (ARVC), associated with woolly haircoat.** *M.A. Simpson<sup>1</sup>, B. Davies<sup>1</sup>, R. Cook<sup>2</sup>, O. Abubaker<sup>1</sup>, M.A. Patton<sup>1</sup>, A.H. Crosby<sup>1</sup>.* 1) Dept Medical Genetics, St Georges Hosp, London, England; 2) NWS Agriculture, Camden, NSW, Australia.

Arrhythmogenic right ventricular cardiomyopathy (ARVC) is a heart muscle disorder characterised by fibrofatty replacement of cardiomyocytes and extracellular matrix with a marked predilection for the right ventricle. The disorder increases the risk of electrical instability leading to ventricular arrhythmias and sudden death. Naxos disease is an autosomal recessive form of ARVC associated with non-epidermolytic palmoplantar keratoderma and woolly hair. We previously mapped the disorder to 17q21 and disease causing mutations were subsequently identified in the plakoglobin gene. The plakoglobin gene encodes a member of the armadillo protein family and is a constituent protein in adherens and desmosomal junctions, with adhesive and signalling functions. An autosomal recessive bovine disorder characterised by ARVC, very similar to that seen in human Naxos disease, has been discovered amongst Australian Poll Herefords. Affected animals also have a woolly haircoat, suggesting that this may represent the first large animal model of Naxos disease and ARVC. In the current study we have identified the bovine homologue of the plakoglobin gene, elucidated its genomic organisation and screened for disease causing mutations in affected cattle.

**Proteomic analysis of vascular smooth muscle cells defines genes involved in the inhibition of apoptosis. V.**

*Seyrantepe*<sup>1</sup>, *S. Taurin*<sup>2</sup>, *S.N. Orlov*<sup>2</sup>, *P. Hamet*<sup>2</sup>, *A.V. Pshezhetsky*<sup>1</sup>. 1) Centre de recherche de l'hôpital Sainte Justine, Montreal, PQ., Canada; 2) CHUM-Hotel Dieu, Centre de recherche Montreal, PQ., Canada.

Apoptosis of vascular smooth muscle cells (VSMC) plays an important role in vascular remodelling, which is one of the major determinants of long-term blood pressure elevation and independent risk factor for cardiovascular morbidity and mortality. Recently we have found that apoptosis in VSMC can be inhibited by inversion of the intracellular Na<sup>+</sup>/K<sup>+</sup> ratio after the sustained blockage of the Na-K-ATPase. Using the proteomic approach we have performed a comparative analysis of protein expression patterns of control VSMC and of those with Na-K-ATPase inhibited by ouabain. Soluble, membrane bound, and cytoskeleton proteins of VSMC separated by the detergent extraction, were resolved by two-dimensional electrophoresis. We found that ouabain treatment led to overexpression of nearly 100 soluble and 15 membrane-bound proteins. Among proteins, which showed the highest level of expression we identified several members of the heat shock protein superfamily HSP70 which suggests that these proteins may participate in a direct or indirect inhibition of apoptosis. This hypothesis was confirmed by the transient expression of cDNA coding for HSP70 protein, which caused inhibition of apoptosis in VSMC triggered by their deprivation from growth factors.

**Differences of intracellular localization and molecular size indicate that posttranslational modification of overexpressed BIPs is different from native BIPs.** *W. Ju<sup>1</sup>, R. Kascsak<sup>2</sup>, W.T. Brown<sup>1</sup>, N. Zhong<sup>1,3</sup>.* 1) Dept. Human Genetics, New York State Inst Basic Res, Staten Island, NY; 2) Laboratory of Monoclonal Core2, NYS Inst Basic Res, Staten Island, NY; 3) Dept. Neurology, SUNY-Health Science Center at Brooklyn, Brooklyn, NY.

BIPs, a protein with one transmembrane domain, which we previously identified and cloned, shows a slow interaction with CLN3-encoded protein Battenin. Battenin is deficient in Batten disease, the juvenile form of neuronal ceroid lipofuscinoses (JNCL) and characterized by lysosomal lipofuscin storage. Overexpressing BIPs by fusing BIPs N-termini with 6 x Histidines in plasmid pcDNA 6 transformed into human neuron precursor cells NT2, and into Cos-7 cells showed that BIPs could be detected as a cellular membrane protein with two forms, ~52-kDa and ~60-kDa, by anti-His antibody. However, using antibodies generated against two peptides selected from the N-terminal region of BIPs, we found that both protein localization and molecular size for native BIPs are quite different from the overexpressed and fused BIPs. Immunostaining signals for native BIPs were cytoplasmic, as well as peri-nuclear, in a punctate vesicular fashion. Two protein bands, with molecular sizes of ~89-kDa and ~105-kDa, were detected on western blots. Our results are similar to the immunochemical studies of Battenin, for which the native protein is localized at mitochondria but the overexpressed protein was found in lysosome, ER, and Golgi bodies. These results indicate that the overexpressed protein has a different posttranslational modification than the native protein, which results in protein mislocalization.

**Identification of genes differentially expressed in the fragile X syndrome.** *I. Gantois, E. Reyniers, R.F. Kooy.*

Department of Medical Genetics, University of Antwerp, Antwerp, Belgium.

The fragile X syndrome is caused by the absence of the FMR1 protein, FMRP. FMRP is expressed in most cell types but shows highest expression in neurons and Sertoli cells. In the cell FMRP may shuttle between nucleus and cytoplasm, perhaps transporting a specific subset of brain mRNAs to the actively translating ribosomes near the synaps in neurons. To study the function of the protein, a fragile X knockout mouse was created several years ago. This mouse model shows some characteristics compatible with the symptoms of human patients, including macroorchidism, spatial learning deficit and dendritic spine abnormalities.

To increase our understanding how absence of FMRP leads to mental retardation, sequences differentially expressed between fragile X knockout mouse and control mouse were isolated using the differential display technique. This method allows comparison of the expression levels of >95% of all neuronal genes between the two genotypes. Using differential display, we isolated 143 sequences underexpressed in knockout and 81 overexpressed in knockout with a length between 200-1100 bp. Differential expression of some of the sequences was verified using micro arrays. These partial cDNAs were sequenced, and we searched for homologies of these sequences in EST and gene databases. For some sequences, homologies with known genes in the database were found.

A study of the function of these differentially expressed genes may help us understand how absence of FMRP relates to the clinical symptoms of the fragile X syndrome.

**Hirschsprung disease, microcephaly, mental retardation, and dysmorphic facial features caused by loss-of-function mutations in SIP1 (Smad Interacting Protein 1).** V. CACHEUX<sup>1</sup>, F. DASTOT-LE MOAL<sup>1</sup>, H.

KAARIAINEN<sup>2</sup>, N. BONDURAND<sup>1</sup>, R. RINTALA<sup>3</sup>, B. BOISSIER<sup>1</sup>, O. CAMAND<sup>4</sup>, G. BASSEZ<sup>1</sup>, M. ABITBOL<sup>4</sup>, M. WILSON<sup>5</sup>, D. MOWAT<sup>6</sup>, M. GOOSSENS<sup>1</sup>. 1) INSERM U468 et AP-HP, Hopital Henri Mondor, Creteil, France; 2) Department of Medical Genetics, The Family Federation of Finland, Helsinki, Finland; 3) Helsinki University Children's Hospital, Helsinki, Finland; 4) CERTO, Faculte de Medecine de Necker, 75015 Paris, France; 5) Department of Clinical Genetics, The Children's Hospital at Westmead, Sydney, Australia; 6) Department of Medical Genetics, Sydney Children's Hospital, Randwick, and School of Paediatrics, University of New South Wales, Sydney, Australia.

Hirschsprung disease (HD), or aganglionic megacolon is a relatively common disorder resulting from the failure of normal neural crest cells development. The genetic aetiology of this neurocristopathy is complex all the more because HD is associated with a variety of other congenital disorders. In particular, HD has been described in association with microcephaly, mental retardation and characteristic facial features, delineating a syndromic form of HD. Taking advantage of a de novo translocation breakpoint at 2q22, we identified SIP1 (Smad interacting protein 1), a two-handed zinc finger/homeodomain transcription factor, as the gene disrupted by the chromosomal rearrangement. Here, we report on 6 unrelated patients with the same phenotype, which bear heterozygous frameshift mutations of SIP1 gene causing early truncation of the protein. Most of the SIP1 mutations described in this syndrome lie in exon 8, delineating a hot spot region for mutations. Preliminary expression studies show that SIP1 mRNA is detected in almost all adult human tissues tested (heart, brain, placenta, lung, liver). To help unravel its physiological role during development, we studied SIP1 gene expression in embryonic and fetal mouse and human tissues by in situ hybridization. These experiments allowed to precisely map SIP1 early expression in fetal brain, a finding relevant to the phenotypic features that constitute this syndrome.

**Satellite 2 methylation patterns in normal and ICF syndrome cells and association of hypomethylation with advanced replication.** *K.M.A. Hassan*<sup>1</sup>, *T. Norwood*<sup>2</sup>, *G. Gimelli*<sup>3</sup>, *S.M. Gartler*<sup>1</sup>, *R.S. Hansen*<sup>1</sup>. 1) Medicine, University of Washington, Seattle, WA; 2) Pathology, University of Washington, Seattle, WA; 3) Laboratorio de Citogenetica, Istituto G. Gaslini, Genova, Italy.

Mutation in the *DNMT3B* DNA methyltransferase gene is a common cause of the ICF immunodeficiency syndrome and leads to hypomethylation of satellites 2 and 3 in pericentric heterochromatin. This hypomethylation is associated with centromeric decondensation and chromosomal rearrangements, suggesting that these satellite repeats have an important structural role. In addition, the satellite regions may have functional roles in modifying gene expression. The extent of satellite hypomethylation in ICF cells is unknown because methylation status has only been determined with restriction enzymes that cut infrequently at these loci. We, therefore, developed a bisulfite conversion-based method to determine the detailed cytosine methylation patterns at satellite 2 sequences in a quantitative manner for normal and ICF samples. From our sequence analysis of unmodified DNA, the internal repeat region analyzed for methylation contains an average of 17 CpG sites. The average level of methylation in normal lymphoblasts and fibroblasts is 69% compared to 20% in such cells from ICF patients with *DNMT3B* mutations, and 29% in normal sperm. Although the mean satellite 2 methylation values for these groups do not overlap, there is considerable overlap at the level of individual DNA strands. Our analysis also revealed a pattern of methylation specificity, suggesting that some CpGs in the repeat are more prone to methylation than other sites. Variation in satellite 2 methylation among lymphoblasts from different ICF patients prompted us to determine the frequency of cytogenetic abnormalities in these cells. Although our data suggest that some degree of hypomethylation is necessary for pericentromeric decondensation, factors other than DNA methylation appear to play a major role in this phenomenon. Another such factor may be altered replication timing because we discovered that the hypomethylation of satellite 2 in ICF cultures is associated with advanced replication time.

**A necdin-like gene (*NDNL2*) in the chromosome 15 autism susceptibility region: expression, imprinting, and mapping of the human and mouse orthologues.** R. Wevrick, J.M. Bischof, T.K. Chibuk. Dept Medical Genetics, Univ Alberta, Edmonton, AB., Canada.

Human chromosome 15q is prone to cytogenetic rearrangements, in part due to repetitive elements located therein. Prader-Willi syndrome (PWS) and Angelman syndrome (AS) are two neurodevelopmental disorders caused by deletions of 15q11-q13, and neurodevelopmental abnormalities are associated with supernumerary chromosomes derived from inverted duplications of 15q. In addition, an autistic disorder susceptibility locus has been localized to proximal 15q by linkage and association studies. While AS is strongly associated with *UBE3A* mutations, multiple candidate genes for PWS have emerged and are likely to have an additive effect in causing this disorder. In particular, two members of the *NDN/MAGE* gene family, *NDN* and *MAGEL2*, are located in the PWS deletion region and are not expressed in individuals with PWS. *NDN* and *MAGEL2* may be implicated in the PWS phenotype as they are expressed in the developing nervous system. We have therefore investigated the possibility that other *NDN/MAGE* genes may also be present on proximal 15q and may be involved in neurodevelopmental disorders. Indeed, a novel necdin-related gene, *NDNL2*, is found on proximal 15q within the critical region for autistic disorder susceptibility. We have examined the expression of *NDNL2* and its murine orthologue, and placed the murine gene on mouse chromosome 7 in the region of conserved synteny with other PWS region genes. The proximal region of chromosome 15 is subject to genomic imprinting, the expression of a gene from only one allele depending on parent-of-origin. Furthermore, the maternal derivation of chromosomal abnormalities seen in individuals with autistic disorder suggests a parent-of origin effect. We have also analyzed the imprinting of human and mouse *NDNL2/Ndnl2*. In summary, we have identified a candidate gene for the neurodevelopmental abnormalities associated with proximal human chromosome 15.

**3-Hydroxyisobutyrate dehydrogenase gene: characterization of the cDNA, structural organization, mapping of the locus to 7p15, and mutation analysis.** *K. Yuji<sup>1</sup>, S. Ogawa<sup>1</sup>, A. Hangaishi<sup>1</sup>, H. Ueno<sup>1</sup>, M. Gibson<sup>2</sup>, W. Nyhan<sup>3</sup>, S. Yamaguchi<sup>4</sup>, M. Kimura<sup>4</sup>, M. Sasaki<sup>5</sup>, S. Ikawa<sup>6</sup>, H. Hirai<sup>1</sup>.* 1) Dept. of Hematology, Graduate School of Medicine, Univ. of Tokyo, Tokyo, Japan; 2) Biochemical Genetics Laboratory, Oregon Health Sciences Univ., Portland, OR; 3) Division of Biochemical Genetics, UCSD School of Medicine, La Jolla, CA; 4) Dept. of Pediatrics, Shimane Medical University, Shimane, Japan; 5) Dept. of Child Neurology, National Center of Neurology and Psychiatry, Tokyo, Japan; 6) Dept. of Cell Biology, IDAC, Tohoku Univ., Miyagi, Japan.

3-Hydroxyisobutyrate dehydrogenase (3HIBADH, 3-hydroxy-2-methylpropanoate: NAD<sup>+</sup> oxidoreductase, EC 1.1.1.31) catalyzes an NAD<sup>+</sup>-dependent, reversible oxidation of 3-hydroxyisobutyrate to methylmalonate semialdehyde in the pathway of L-valine. To date, ten cases of human 3HIBADH deficiency (3-hydroxyisobutyric aciduria, 3HiB uria, [MIM 236795]) have been reported. By screening testis cDNA library, we isolated and characterized a 1.9kb human HIBADH cDNA with a 1008bp (336-amino acid) open reading frame showing 91% amino acid identity to rat 3HIBADH. Determination of the gene structure reveals that the human 3HIBADH gene spans about 137kb with 8 exons and 7 introns, and maps to chromosome 7p15. Northern blot analysis showed a ubiquitous expression of 3HIBADH in all adult tissues. Four patients with 3HiB uria were analyzed for sequence variations, but we could not find any mutations in the human 3HIBADH gene. Functional investigation of the 3HIBADH gene and its potential involvement in 3HIBADH deficiency are in progress.

**Spidey: An mRNA-to-genomic alignment program.** *S.J. Wheelan<sup>1,2</sup>, D.M. Church<sup>1</sup>, J.M. Ostell<sup>1</sup>.* 1) National Center for Biotechnology Information, National Library of Medicine, National Institutes of Health, Bethesda, MD 20894; 2) Department of Molecular Biology and Genetics, The Johns Hopkins University School of Medicine, Baltimore, MD 21205.

Expressed sequences are an incredible resource, but even more information can be gained by locating their genomic sources. By aligning an expressed sequence to its parent genomic sequence, a researcher can locate a genes position, can identify potential regulatory elements, and can study paralogs or pseudogenes. These alignments are not trivial; sequence polymorphisms and repeats (especially at the ends of exons) make the problem more difficult, even after the correct genomic sequence has been found amid all the distracting sequences.

Cross-species spliced alignments are also quite useful, especially from a medical or developmental perspective. Many tissues representing many developmental stages are available from experimental organisms and not from humans, and these tissues may harbor uniquely informative expressed sequences. Evolutionary divergence increases the difficulty of achieving correct and useful cross-species spliced alignments.

We have developed a spliced alignment program, Spidey, that can quickly produce reliable mRNA-to-genomic alignments. Spidey can also compute cross-species comparisons.

We first tested Spidey's accuracy and ability to ignore nearby related sequences by aligning mRNAs from gene clusters back to the genomic sequence. We then took mRNAs derived from annotations and aligned them back to their genomic sequences. We also wanted to test Spidey's ability to perform interspecies alignments accurately; to this end, we aligned mouse orthologs to human genomic sequence. In an effort to test Spidey's efficacy using real data, we took a set of 11,000 sequences from LocusLink and aligned them to the NCBI human genome assembly based on the December 7 data freeze.

Spidey is available as a web service and an executable at <http://www.ncbi.nlm.nih.gov/spidey>.

**Analysis of differential gene expression during development of cardiac hypertrophy.** *T. Hahn, I. Hansmann, M. Schlicker.* Institut für Humangenetik, Martin-Luther-Universität, Halle, Germany.

The spontaneously hypertensive rat (SHR) is a well-known model for the study of hypertension and heart failure. Diverse quantitative trait loci (QTLs) for hypertension and cardiac hypertrophy indicate that different chromosomal areas account for the development of the two diseases. While the development of the clinical symptoms the SHR passes through distinct phenotypic stages. Up to four weeks after birth the animals are normotensive, and then males firstly evolve hypertension (12 weeks) and afteron hypertrophy of the left heart ventricle (26 weeks). To identify candidate genes that contribute to the initiation or the progression of cardiac hypertrophy we screened the hearts of these SHRs for differentially expressed genes. To use a high-resolution method we established a subtractive hybridization system based on cDNA selection and suppression PCR. The subtractive hybridizations from the 4- to the 12- and to the 26-weeks stages resulted in 145 different cDNA clones. The following differential screening suggested 56 cDNAs to be candidates for differentially expressed genes. Northern blot analyses of meanwhile 42 cDNAs identified 16 genes which are upregulated at their expression level in comparison to the wild type Wistar-Kyoto rat. According to homology searches in electronic databases we identified so far 8 novel genes that are differentially expressed in hypertrophic growing SHR hearts. The parallel identification of known genes which are discussed to be involved in cardiomyopathy (g-sarcoglycan) or cardiac hypertrophy (acyl coenzyme A dehydrogenase) points to the efficiacy of the chosen method. Next, we will check the chromosomal localization of these genes in respect to known QTLs for cardiac hypertrophy by FISH analysis and analyze the expression and integrity of the novel identified genes in animals with cardiac hypertrophy.

**Identification of a novel mammalian DM-domain containing gene, candidate for premature ovarian failure.** C. Ottolenghi<sup>1</sup>, R. Brauner<sup>2</sup>, E. Thibaud<sup>2</sup>, K. McElreavey<sup>1</sup>. 1) Immunogenetique Humaine, Institut Pasteur, Paris, France; 2) Pediatric Endocrinology, Necker Hospital, Paris, France.

Premature ovarian failure (POF), defined as a condition causing amenorrhea, hypoestrogenism and elevated gonadotropins before the age of 40, is estimated to have an incidence of 2-3%. In approximately 60% of all POF patients the underlying cause cannot be identified and these cases are classified as idiopathic. Recent epidemiological studies suggest that up to 30% of cases may be familial. POF, primary amenorrhoea and ovarian dysgenesis can occur within the same family indicating that although they represent a spectrum of phenotypes, a common genetic cause is suspected. Deletions of the long arm of the X chromosome are associated with both primary amenorrhea and POF. Three regions have been defined associated with ovarian failure, i.e. Xq13-21 (POF2), Xq22-25 (POF1) and Xq26.2-28 (POF3). The *Drosophila* doublesex (*dsx*) and *Caenorhabditis elegans* *mab-3* gene products perform several related regulatory sex-specific functions, which are at least partially interchangeable in vivo. A unique DNA-binding domain (the DM domain) is shared by Doublesex and Mab-3. Vertebrate DM genes have likewise been identified and, remarkably, one of them is associated with anomalies of early testis differentiation. In *Drosophila* sexual differentiation is controlled by alternative splicing of doublesex mRNA resulting in male and female specific isoforms which direct sexual differentiation. We describe the characterisation of a novel mammalian DM-domain containing gene, DMRTC1, which may be structurally and functionally related to the female-specific isoform of doublesex. This gene is expressed in the human ovary and localised in Xq13. We propose that DMRTC1 is a positional and evolutionary candidate for the POF2 condition.

**Human GH Transcripts are Alternatively Spliced in Different Tissues of Transgenic Mice.** *C.T. Moseley<sup>1</sup>, M.A. Prince<sup>1</sup>, L.K. Hedges<sup>1</sup>, R.C. Ryther<sup>1</sup>, J.G. Patton<sup>1</sup>, W.G. Beamer<sup>2</sup>, J.A. Phillips III<sup>1</sup>.* 1) Dept Pediatrics, Division of Medical Genetics, Vanderbilt Univ, Nashville, TN; 2) The Jackson Laboratory, Bar Harbor, ME.

Human growth hormone (GH) is produced by pituitary somatotroph cells. GH enhances tissue proliferation and maturation and exerts a variety of metabolic effects. GH mRNA is alternatively spliced to yield different isoforms that encode 22, 20, 17.5 and 11.3 kDa translation products. Mature (22 kDa) GH is translated from the mRNA isoform that includes exons 1-5. The 20 and 17.5 kDa isoforms have deletions of the first 15 or all codons of exon 3, respectively, and the 11.3 kDa isoform has exons 3 and 4 deleted. We have discovered a series of GH gene mutations that cause GH deficiency because they perturb intron (ISE) or exon (ESE) splicing enhancers and derange alternative splicing. We hypothesize that alternative splicing of GH transcripts is regulated in a tissue-specific manner. We determined the patterns of GH alternative splicing by quantitative RT-PCR analysis of human GH transcripts in different tissues from transgenic mice. RNA was isolated from frozen tissues, and human GH specific primers in exons 1 and 5 were used to PCR amplify cDNAs. The amounts of isoforms were quantitated by comparison of peak locations and areas on an ABI 310 using a FAM labeled primer. Relative amounts of 22, 20, 17.5 and 11.3 kDa transcripts were determined to be 83, 11, 5 and 1%; 88, 10, trace amounts (TA) and 1%; and 87, 12%, TA, and TA; in pituitary, liver and kidney, respectively. Our data indicate that: 1) consistent, tissue specific patterns of alternative splicing of human GH transcripts occurs in a transgenic mouse model and 2) the resulting transcripts could result in different GH proteome patterns for each tissue. Our results suggest that: 1) the tissue specific patterns of alternative splicing may result from tissue specific variations in the amounts of serine/arginine (SR) rich or other proteins or factors that promote alternative splicing, and 2) many of the estimated 22-34% of all human genes that are alternatively spliced may have tissue specific regulation.

**Heterogeneously reduced expression of calcium receptor, vitamin D receptor and parathyroid hormone mRNAs in parathyroid glands of secondary hyperparathyroidism.** *S.V. Valimaki<sup>1</sup>, F. Farnebo<sup>1</sup>, L. Forsberg<sup>1</sup>, C. Larsson<sup>1</sup>, L.O. Farnebo<sup>2</sup>.* 1) Molecular Medicine, Endocrine Tumor Unit, Stockholm, Sweden; 2) Department of Surgery, Karolinska Hospital, stockholm, Sweden.

Secondary hyperparathyroidism (2HPT) arises in patients with chronic renal failure and is characterized by inappropriate control of parathyroid hormone (PTH) secretion and asymmetric hyperplasia of the parathyroid glands. Receptors for calcium and vitamin D are involved in the control of secretion as well as parathyroid cell proliferation. Defective receptor mechanisms may therefore play a role in the pathogenesis of 2HPT. Previous reports have shown decreased expression levels of expression of calcium receptor (CaR), calcium sensing receptor (CAS) and vitamin D receptor (VDR) protein and mRNA in hyperplastic parathyroid glands of 2HPT when compared with normal parathyroid glands whereas the expression pattern between and within different glands remains unknown. **Methods.** In order to investigate the expression of CaR, CAS, VDR and PTH mRNAs we analyzed 36 hyperplastic glands from 18 patients with 2HPT with *in situ* hybridization. In nine nodular parathyroid glands, it was possible to make a comparison between the expression of these mRNAs in nodular and internodular areas. **Results.** The level of CaR was similar in the hyperplastic glands as in the biopsies of normal parathyroid, while the levels of CAS, VDR and PTH were clearly reduced in the hyperplastic glands. There was a positive correlation between the expression of CaR and CAS ( $p=0.02$ ). Otherwise, no correlations between CaR, CAS, VDR and PTH mRNAs were found. The expression of all four genes was highly variable as well between different glands as within individual glands. **Conclusion.** This study demonstrates a heterogeneously decreased expression of four receptor mRNAs that are of importance in the control of PTH secretion and parathyroid cell proliferation in parathyroid glands of 2HPT. The expression pattern corroborates earlier studies in which it has been assumed that each nodule in secondary HPT is of monoclonal origin, but that the monoclonal origin of each nodule is independent.

**AF-1 specific coactivators of steroid hormone receptors.** *L.B. Tovar y Romo, E. Langley, A. Leon Del Rio.*  
Department of Molecular Biology and Biotechnology, Universidad Nacional Autonoma de Mexico, Mexico, DF, Mexico.

Steroid hormone receptors are ligand dependent transcriptional regulators capable of controlling gene expression in many biological processes. Transcriptional activity is mediated through two transcriptional activation functions, AF-1 and AF-2, in the amino and carboxyl regions of the receptor, respectively. These transcriptional activation functions are modulated by transcriptional coregulators which can enhance or repress transactivation. However, very few have been reported to interact specifically to the AF-1 region of nuclear receptors. We utilized the yeast two hybrid system to identify proteins which interact with the AF-1 of the estrogen receptor (ER). We have begun the characterization of two proteins which interact with this region: SRY-interacting protein (SIP-1) and Myc associated zinc finger protein (MAZ). Transcriptional activation studies show that SIP-1 functions as a coactivator, not only for the ER, in a number of cell types, but for the androgen and progesterone receptors as well. SIP-1 increases transactivation by the estrogen receptor by up to 200% in MCF-7 cells. In CV-1 cells, SIP-1 increases transactivation by the androgen and progesterone receptors by up to 600%. In contrast, MAZ seems to act as a corepressor for these receptors. The AF-1 region of ER is involved not only in the estrogenic response of target genes, but is also required for inhibition of ER activity by tamoxifen (TOT). TOT is the most common treatment for patients with ER-positive breast cancer. However, although treatment with TOT is highly effective, eventually there is an acquired resistance to this compound and, in many cases, TOT can now act as an ER agonist. Identification of proteins involved in AF-1 activation could lead to a further understanding of the mechanisms by which TOT can have differential activities in different tissues and in different stages of breast cancer.

**Dose-dependent Shift from Repressor to Activator in a DAX1 Variant from a Female with Adrenal Hypoplasia Congenita.** *J.J. Wilson<sup>1</sup>, B.D. Bowling<sup>1</sup>, J. Phelan<sup>2</sup>, Y.H. Zhang<sup>2</sup>, B.L. Huang<sup>2</sup>, E.R.B. McCabe<sup>2</sup>, E. Vilain<sup>1, 2</sup>.* 1) Human Genetics, UCLA, Los Angeles, CA; 2) Pediatrics, UCLA, Los Angeles, CA.

Mutations in the nuclear receptor DAX1 are responsible for both X-linked adrenal hypoplasia congenita (AHC) and male-to-female XY sex reversal. All missense mutations discovered to date alter DAX1 repression of SF1 activity, another orphan nuclear receptor, and have been limited to the C-terminal hydrophobic core of the putative ligand binding domain (LBD). We identified a family in which an unaffected father and his daughter with AHC both harbor a DAX1 sequence variation: cysteine-200 changed to tryptophan (C200W). The sequence variant was not found in over 100 X chromosomes analyzed within an ethnically mixed population. C200W is the first missense mutation to be localized upstream of the classic nuclear receptor LBD, within a region that harbors novel sequence repeats that display RNA-binding capability *in vitro*. Three sequential consensus SF1 response elements were utilized upstream of a luciferase reporter construct in order to demonstrate the classic DAX1-mediated silencing of SF1 trans-activation. Upon co-transfection of equimolar concentrations of the C200W DAX1 mutant with SF1 in embryonic kidney cell culture (293T), a complete wild-type repression of reporter expression was found. However, as the C200W concentration was incrementally increased, a concomitant loss of silencing function became apparent. High concentrations of C200W enhanced luciferase expression to levels exceeding those seen with SF1 activation alone. In summary, the unique C200W variant, associated with a normal and an AHC phenotype, converts DAX1 activity from antagonist to agonist. Since the father carries the variant and does not exhibit AHC, this mutant may be acting through variable co-factor complexes represented within the different genetic backgrounds. Our studies on this mutant suggest a repressor role for DAX1 in a complex and robust network critical for the developing reproductive axis. This work supports the emerging theme in biology that normal development is shaped by powerful inhibitory forces and molded by transient surges of relief from this silencing repression.

**Functional delineation of the COOH-terminal tail of the human cystic fibrosis transmembrane conductance regulator (CFTR) using a combined analysis.** *C. Ferec, J.M. Chen.* INSERM-EMI 01 15, Etablissement Français du Sang-Bretagne, Université de Bretagne Occidentale, and Centre Hospitalier Universitaire, 46 rue Félix Le Dantec, 29275 Brest, France.

Since the cystic fibrosis transmembrane conductance regulator (CFTR) gene was cloned in 1989 (Riordan et al.), an enormous wealth of knowledge about its encoded 1480 amino acid protein, including evolutionary, mutational, functional, and structural data, has been accumulated. These data, evaluated together, have recently enabled us to define a "functional R domain" (Chen, Scotet, and Ferec 2000). Importantly, this new definition not only agrees well with that derived from a concurrent functional approach (Csanady et al. 2000), but also appears to concur with the regulatory role of this unique domain (Baldursson, Berger, and Welsh 2000). Here, we extend to refine the COOH-terminal tail (C-tail) of the CFTR protein by exploiting the same approach. Taking into accounts the current available evolutionary data, clinical observations and functional studies, we could confidently assign residue E1418 as the NH<sub>2</sub> boundary of the C-tail, which is 31 amino acid downstream the original definition (T1387). This new definition can best delineate the C-tail's functional role in the CFTR. On the one hand, the newly defined C-tail is "non-essential", as the effects on the biogenesis, processing and stability of the CFTR previously assigned to the original C-tail have now been re-located to the preceding sequence. On the other hand, the newly defined C-tail does appear to be "essential", as the well conserved motif involving the final three amino acids (T1478-R1479-L1480) represents a PDZ-interacting domain which is required for the polarization of CFTR to the apical plasma membrane in epithelial cells. Nevertheless, the new defined C-tail as a whole would play a minor role in the pathogenesis of CF disease. Indeed, neither the S1455X nor the Q1476X caused a severe CF phenotype; and none of the three missense mutations (R1422W, D1445N and R1453W) identified in this region can be confidently assigned as causal for CF disease. The usefulness of this basic approach may be further exploited in the NBD1 and NBD2 domains.

**Beta-defensin 1 gene variability among non-human Primates.** *S. CROVELLA*<sup>1</sup>, *M. BONIOTTO*<sup>1</sup>, *M. DEL PERO*<sup>2</sup>, *A. AMOROSO*<sup>1</sup>. 1) Molecular Genetics Unit. Department of Sciences of Biology and Reproduction . University of Trieste. Italy; 2) Department of Animal Biology, University of Turin. Italy.

Defensins are a family of peptides that play an important role in innate immunity. Defensins exhibit a broad spectrum of antimicrobial activities against bacteria and fungi. Two families have been identified so far in mammals, a-defensins and b-defensins, presumably derived from a common ancestral defensin. A long term study on the evolution of these multigene families among primates has been undertaken to investigate i) the degree of interspecific differentiation; ii) the genetic mechanisms responsible for the variability of these molecules; and iii) the possible role of different environmental factors in their evolution. In this study we sequenced the coding regions of the b-defensin 1 gene in 16 primate species. Nucleotide sequences have been obtained from apes, several African and Asian catarrhine monkeys and one New World monkey. A comparison of rates of synonymous and nonsynonymous nucleotide substitution indicates that the primate b-defensin 1 gene evolved under a pattern of random nucleotide substitution as predicted by the neutral theory of molecular evolution. These results are not consistent with the hypothesis that defensins have diversified in response to changes in the microbial species to which a given host is exposed. Analyses of the gene's interspecific variability have yielded some insights about the pattern of molecular evolution of the gene among primates. Humans and apes present high levels of sequence similarity, differing in only one amino acid residue in the mature peptide. Compared with these taxa, hylobatids and cercopithecids exhibit 3-4 amino acid substitutions, which increase the net charge of the active molecule.

**Molecular Evolution of MC1R Gene in human and non-human Primates.** *X-M. Lu, Y-P. Zhang.* Lab. Cellular & Molec. Evol., Kunming Inst. Zool., Chinese Academy of Sciences, Kunming, Yunnan 650223, People's Republic of China.

It is widely assumed that genes that influence variation in skin and hair pigmentation are under selection. The melanocortin receptor 1 (MC1R) plays a central role in regulation of eumelanin (brown/black melanins) and pheomelanin (red/yellow melanins) synthesis in the mammalian melanocyte. Many substitutions have been observed in human MC1R gene, a few of which may associate with variation of skin and hair color. To understand the sequence variation pattern of MC1R gene in human population and to study the evolution of this gene, we sequenced the MC1R gene from 25 nonhuman primates: 4 in Hominoidea, 17 in Cercopithecidae (Old world monkey), 3 in Cebodae (New world monkey) and one in Loridea. Based on these nucleotide and amino acid sequences and the published sequences from humans and other primates, the phylogenetic trees were constructed using parsimony and maximum likelihood methods. The evolutionary rate was estimated and then neutral selection hypothesis was tested. Our results indicated that: (1) nearly neutral selection was showed in Hominoid and the Old World monkeys, but not in the New World monkeys; and (2) the evolutionary rate in the Hominoid is significantly higher than that in the Old World monkeys, which conflicted with the Hominoid slowdown hypothesis.

**SCA7 locus information drives trinucleotide repeat instability in transgenic mice.** *R.T. Libby<sup>1</sup>, R. Lau<sup>2</sup>, D.D. Einum<sup>3</sup>, K. Nichol<sup>2</sup>, L.J. Ptacek<sup>3,4</sup>, Y.H. Fu<sup>5</sup>, C.E. Pearson<sup>2</sup>, A.R. La Spada<sup>1</sup>.* 1) Dept Lab Medicine, Univ Washington, Seattle, WA; 2) Dept Genet, Hosp for Sick Children, Toronto, Ont, CA; 3) Dept Human Genet, Univ Utah, Salt Lake City, UT; 4) HHMI, Univ Utah, Salt Lake City, UT; 5) Dept Neurobiol & Anat, Univ Utah, Salt Lake City, UT.

Spinocerebellar ataxia type 7 (SCA7) is caused by a trinucleotide repeat expansion, a class of mutations characterized by intergenerational and somatic genetic instability. Of the CAG repeat disorders, SCA7 shows the most extreme degree of anticipation. To understand the molecular basis of CAG repeat instability, we chose to model the ataxin-7 repeat in mice by generating two types of transgenic constructs. The first construct (RL-) consisted of a 13.5 kb Sal I-Spe I genomic fragment from the human ataxin-7 gene, while the second construct placed the coding region of the human ataxin-7 cDNA into an expression cassette (PrP-). In both cases, an expanded SCA7 allele with 92 CAG repeats was used. We compared intergenerational and somatic instability in 5 independent lines of mice (2 RL-SCA7-92Q lines & 3 PrP-SCA7-c92Q lines) by capillary and polyacrylamide gel electrophoresis of PCR-amplified repeats. Although we observed marked intergenerational instability in RL-SCA7-92Q mice with 87% of parent-offspring transmissions showing alterations, the PrP-SCA7-c92Q mice showed limited instability with changes in just 14% of transmissions ( $p < .001$ ). While the length shifts were modest in the PrP-SCA7-c92Q mice {mean length change = -0.2; range = -4 to +5} and there was a slight tendency toward contractions {expansion:contraction = 2:3}, the RL-SCA7-92Q mice showed a marked expansion tendency with 90% of size shifts being expansions {mean length change = +2.8; range = -4 to +11}. The differences in instability between the two constructs were also observed somatically, with the RL-SCA7-92Q lines showing more instability in testes and liver. Based on these results, we conclude that SCA7 genomic context explains the significantly greater repeat instability. Furthermore, there must be cis-acting information within the genomic fragment used to generate the RL-SCA7-92Q mice that is responsible for this difference in repeat instability.

**Fiber-FISH analysis of gene organization and rearrangements at the Rhesus blood group locus.** *Y. Suto*<sup>1</sup>, *Y. Ishikawa*<sup>2</sup>, *H. Hyodo*<sup>2</sup>, *M. Uchikawa*<sup>2</sup>, *M. Hirai*<sup>3</sup>, *T. Juji*<sup>2</sup>. 1) Department of Biological Sciences, Graduate School of Science, The University of Tokyo, Tokyo; 2) Department of Research, the Japanese Red Cross Central Blood Center, Tokyo; 3) Department of Integrated Biosciences, Graduate School of Frontier Sciences, The University of Tokyo, Tokyo.

Multicolor fluorescence *in situ* hybridization on released chromatin DNA fibers (fiber-FISH) is a powerful tool for visual examination of the overall gene structure and arrangement at a single cell level. Using two DNA probes corresponding to introns 3 and 7 of a human *RH* gene in the analysis of the *RH* locus in healthy humans, we revealed the first evidence that the Rhesus (Rh) blood group locus of typical Rh-positive individuals is composed of two *RH* genes in a tail-to-tail arrangement [telomere - *RHCE* (5'→3') - *RHD* (3'→5') - centromere] within a region of less than 200 kb on chromosome 1p36.1, while typical Rh-negative individuals have a single *RHCE* gene (Suto *et al.*, 2000). When these probes were used in the analysis of the *RH* locus in five chimpanzees, it was found to be homozygous for either two or four *RH* genes. In this study, we further examined the *RH* locus of nine healthy Japanese donors who were serologically Rh-negative but *RHD*-positive by polymerase chain reaction with sequence-specific priming (PCR-SSP assay) on exons 7 and 10, and intron 4. They were shown to have different genomic organizations including partial deletion, duplication, recombination and mosaicism within the *RH* locus, which were likely to be responsible for RhD-negative expression but not necessarily dependent on their serological phenotype. As the frequency of each serological phenotype varies among different races or populations, a subsequent study on other Asian and African populations is underway.

**Towards understanding the functional role of the laforin protein in Progressive Myoclonus Epilepsy.** *L. Ianzano, X.C. Zhao, E. Chan, E.J. Young, D.M. Andrade, B.A. Minassian, S.W. Scherer.* Dept Genetics, Hosp Sick Children, Toronto, ON, Canada.

Lafora disease is an autosomal recessive form of adolescent progressive myoclonus epilepsy (PME) characterized by myoclonias, decreasing mental function, and death within 10 years of onset. The diagnosis of Lafora disease is based on detection of periodic acid Schiff-positive polyglucosan inclusions (Lafora bodies), which are present in various tissues including brain, suggesting LD might be a generalized storage disease. The EPM2A gene at chromosome 6q24 has been shown to be involved in Lafora disease and it encodes a novel dual-specificity phosphatase (DSP) named laforin. Immunofluorescence and electron microscopic studies on laforin expressed in Cos cells revealed its association with the rough endoplasmic reticulum. To gain insight into the possible role of laforin in the pathology of the disease we are working to identify interacting proteins using yeast two-hybrid screens, immunoprecipitation and GST pull-down experiments. The full-length EPM2A cloned into a pGBKT7 vector was used as a bait to screen a human brain cDNA library. Seventeen clones positive using the beta-gal assay were further confirmed when cotransformed with pGBKT7/EPM2A and with pGBKT7 alone. Immunoprecipitation experiments are being performed to prove the in vivo interaction is specific. Since it has been shown that Cys-Ser mutation in the active site of other DSPs can trap the substrate such that the complex can be isolated by immunoprecipitation, we decided to perform our experiments using transfected Cos-cells with pcDNA3mycEPM2A and its Cys-Ser mutant. The cell lysate was immunoprecipitated using myc antibody and three bands of 40, 80 and 180KDa appeared in the wild-type and mutant but not in the vector alone. They are now being subjected to Mass Spectrometry. For GST pull-down experiments Cos-lysates were incubated with GST/EPM2A and the mutant GST/EPM2A Cys-Ser bound to the beads. After washing they were analyzed by SDS-PAGE. Four extra bands of 40, 80, 100, 120KDa were found only in the mutant GST/EPM2A C-S. A large scale experiment is underway to obtain a larger amount of protein for analysis.

**Direct Interactions of Fanconi Anemia Proteins in the Yeast Two Hybrid System.** *M.E. Matkovic, A.F. Foliás, A.M. Ward, J.A. Hejna, R.E. Moses.* Molecular and Medical Genetics, Oregon Health Sciences Univ., Portland, OR.

We used the yeast two-hybrid system to test for interactions between the Fanconi Anemia proteins FANCA, FANCC, FANCD2, FANCE, FANCF, and FANCG as well as FAZ-F. All proteins tested were expressed as fusions to the DNA-binding domain and/or activation domain of GAL4. Co-expression of two interacting proteins in this system leads to the transcriptional activation of three separate reporter genes: *HIS3*, *ADE2*, *lacZ*. We were able to confirm the known interactions between FANCG/FANCF, FANCG/FANCA, and FANCE/FANCC. We also uncovered a novel interaction between FANCG and FAZ-F. The interactions above have also been confirmed by co-immunoprecipitation of *in vitro* translated proteins. To date we have not found an interaction between FANCD2 and any of the Fanconi anemia (FA) proteins; nor did FANCD2 interact with itself. This is consistent with a role for FANCD2 downstream of the other FA proteins. Alternatively, an interaction between FANCD2 and other FA proteins may require either modification of FANCD2 or a third adapter protein.

**Identification of protein binding partners for the Prader-Willi syndrome candidate *necdin*.** *E.L. Organ, J.L. McCauley, J.S. Sutcliffe.* Program in Human Genetics, Department of Molecular Physiology & Biophysics, Vanderbilt University, Nashville, TN.

Prader-Willi syndrome (PWS) is a genomic disorder associated with paternal-specific deficiencies caused by interstitial deletions, unipaternal disomy or imprinting defects affecting human chromosome 15q11-q13. A candidate region of ~1.5 Mb containing multiple imprinted, paternally-expressed genes has been described in the proximal third of the larger deletion interval. One of the imprinted genes mapping to this region, *necdin* (*NDN*), has been suggested to encode a DNA binding protein that functions as part of a complex to mediate neural cell growth arrest. In order to further elucidate *NDN* function, we have sought to identify additional binding partners in brain. A full length *NDN* construct was employed to screen a mouse brain cDNA library in a yeast two-hybrid system that allows for rigorous suppression of background false positives induced by the native DNA binding activity of *NDN*. A regulator of G-protein signaling, a microtubule motor protein, a carboxypeptidase and a RING zinc finger protein were all identified from multiple clones in independent library screenings. Additional putative binding partners were identified; these include CDP-diacylglycerol synthase and a methyl-CpG binding protein. Ongoing studies seek to confirm the interactions between *NDN* and its putative binding partners in a mammalian cell culture system.

**Length Polymorphism of Thymidylate Synthase Enhancer Region is higher in human than in non-human Primates.** *Y-P. Zhang, H-R. Luo.* Lab. Cellular & Molec. Evol., Kunming Inst. Zool., CAS, Kunming, Yunnan 650223, People's Republic of China.

Thymidylate synthase (TYMS; TS; N5, N10-methylenetetrahydrofolate; dUMP C-methyltransferase; EC2.1.1.45) is an essential enzyme for the survival of cell proliferating. It has been reported that TS enhancer region (TSER) contains two, three, four, five or nine tandemly repeated copies of 28bp sequence in human. To understand the pattern of this length polymorphism in human, we sequenced 26 species of nonhuman primates and two monkey populations, including 32 samples of *Macaca mulatta* (*M.mul*) and 30 samples of *Rhinopithecus roxellanae* (*R.rox*). The TSER gene tree had been constructed using Neighbor-joining method with the *Mus musculus* TSER as outgroup. The phylogenetic relationship of these primates consisted with that of generally acknowledged. Length polymorphisms have also been found in the nonhuman primates, but at lower level. Most of the species had the homozygous length with 2 or 3 repeats of 28bp sequence (2/2 or 3/3) except for 4/4 in the *Macaca thibetana* and *Macaca assamensis*, and 2/3 in the *Presbytis phayrei* and *Mandrillus leucophaecus*. Contrary to the high polymorphism in human population, the 28bp repeat allele is conservative in *R.rox* population with genotype 2/2, and in the *M.mul* population with genotype 3/3. No nucleotide variation had been found between the TSER alleles in human except for the difference of the repeat number. Comparison of the repeats in each of the human TSER allele, the last one repeat of them contains a 2-bp insertion (CC) and a single base substitution (G®C), whereas the other repeats have identical 28-bp segment. However, the *Pan troglodytes* and *Gorilla gorilla* show nucleotide variation besides the length polymorphism both in the TSER and in the flanking region. Especially, the last repeat in the apes TSER contains a 7-bp (GCTCGCC) insertion in addition to the 2-base insertion, but it has no G/C substitution.

**Functional analysis of single-minded 2 (SIM2) gene located on human chromosome 21q22.2.** *Y. Shimizu<sup>1</sup>, A. Yamaki<sup>1</sup>, J. Kudoh<sup>2</sup>, S. Minoshima<sup>2</sup>, N. Shimizu<sup>2</sup>.* 1) Dept Medical Genetics, Kyorin Univ Sch of Health Sci, Hachioji, Tokyo, Japan; 2) Dept Mol Biol, Keio Univ Sch of Medicine, Tokyo, Japan.

Human SIM2 gene encodes a PAS family transcription factor and it has been postulated to be a candidate gene for the pathogenesis of mental retardation in Down syndrome. To understand the molecular mechanism of SIM2 gene expression, we have analyzed the promoter region using series of deletion constructs and point mutants fused with luciferase reporter gene and gel retardation assay. we found that c-myb like transcription factor appears to regulate the transcription of human SIM2 gene. Furthermore, we found another region to have a promoter activity located between nt-878 and -835 that is 454bp downstream from the cis-element for c-myb. To determine the nuclear translocation signal of SIM2 protein, we have generated fusion genes of full-length cDNA and deletion mutants of SIM2 with the green fluorescent protein (GFP). Transient expression analysis in HeLa cells revealed that bHLH-PAS and HST domains are not necessary and the region of codon 348 to 399 is sufficient for the nuclear localization of SIM2 protein. We have made a series of point mutants between codon367 and 382 where 8 basic amino acids exist. We found the most important amino acid moiety for nuclear translocalization is arginine of codon 367.

**Expression of the *slc26a3*, *slc9a3*, and *cftr* genes in rat intestine show response to glucocorticoid.** *S.P. Mäkelä<sup>1</sup>, K. Kaunisto<sup>2</sup>, P. Höglund<sup>1</sup>, J. Kere<sup>1,3</sup>*. 1) Dept Medical Genetics, Univ of Helsinki, Finland; 2) Dept Anat and Cell Biol, Univ of Oulu, Finland; 3) Finnish Genome Center, Univ of Helsinki, Finland.

The SLC26A3 gene (alias CLD or DRA) encodes an intestinal epithelial Cl/HCO<sub>3</sub> exchanger that is defective in autosomally recessively inherited congenital chloride diarrhea (CLD, OMIM 214700). The major clinical feature of CLD is severe watery diarrhea with a high concentration of chloride. On the basis of diarrheal phenotype occurring in CLD patients who lack the functional gene, SLC26A3 has been suggested to be the major Cl/HCO<sub>3</sub> exchanger involved in coupled electronegative NaCl absorption in colon. The major exchanger involved in Na<sup>+</sup> absorption has been proposed to be the Na/H exchanger SLC9A3 (alias NHE3), causing diarrheal phenotype in mice if defective. In colon, the major secretor of Cl<sup>-</sup> to intestinal lumen is CFTR that has also been shown to regulate other ion transporters. We have used real-time quantitative RT-PCR using Taqman to investigate the expression profiles of these three intestinal transport genes in different segments of rat intestine. Because glucocorticoid treatment has been shown to reduce diarrhea in a variety of diarrheal states, we have also investigated the effect of glucocorticoid stimulation on the levels of these transcripts in vivo.

As expected, the basal mRNA expression levels of both *slc26a3* and *slc9a3* increased in the distal intestine and were highest in proximal colon. While the expression of *slc26a3* remained high also in distal colon, the expression of *slc9a3* decreased. The basal expression of *cftr* was constant in all regions of intestine studied. The main effect of glucocorticoid stimulation was observed in proximal colon where marked increase in the expression of all three genes was detected. *Cftr* showed response to glucocorticoid in all segments of intestine studied, whereas no clear effect could be detected with *slc26a3* and *slc9a3* in jejunum or with *slc9a3* in distal colon. This study clarifies further the intestinal electrolyte transport physiology and the molecular pathology of CLD. It also elucidates molecular mechanisms by which glucocorticoids regulate fluid and electrolyte homeostasis.

**From Diseases of Anion Transport to New Members of the SLC26 Anion Transporter Family.** *M.M. Kujala<sup>1</sup>, H. Lohi<sup>1</sup>, S.P. Mäkelä<sup>1</sup>, E. Lehtonen<sup>2</sup>, J. Kere<sup>1,3</sup>.* 1) Department of Medical Genetics, University of Helsinki, Finland; 2) Department of Pathology, University of Helsinki, Finland; 3) Finnish Genome Center, University of Helsinki, Finland.

The previous sulfate transporter gene family has recently been newly delineated in human as a second distinct family of anion transporters, SLC26, in addition to the classical SLC4 (or AE) family. The three first known human SLC26 genes are all associated with dissimilar recessively inherited diseases. The diastrophic dysplasia sulfate transporter (DTDST) gene (SLC26A2) causes diseases of the bones and cartilage when mutated. Defects in the down regulated in adenoma (DRA) gene (SLC26A3) produce congenital chloride diarrhea (CLD). Pendred syndrome (childhood deafness and goiter) is caused by mutations in the Pendrin (PDS) gene (SLC26A4). Members of the SLC26 family are structurally well conserved and can transport with different specificities at least the chloride, iodine, bicarbonate, hydroxyl, sulfate and oxalate anions.

We report the expansion of the human SLC26 family with seven new members (SLC26A1 and SLC26A6-A11) in chromosomes 1, 3, 4, 6, 8, 12 and 17. The new proteins are structurally highly homologous to the previous anion transporters, suggesting that they as well function as anion transporters. The new members of the SLC26 family are expressed in variety of different tissues, most of them in a highly tissue-specific manner. We are in the process of characterizing their tissue and cell type distributions in detail. For example, SLC26A8 is expressed specifically in male germ cells in the testis, suggesting that specific anion exchange may be important for these cells. The functional characterization of the novel members of this tissue-specific gene family may provide new insights to anion transport physiology in different organs.

**A new retinal gene, RP1L1, which encodes a protein similar to RP1 and which has unusual polymorphic variation.** *L.S. Sullivan<sup>1</sup>, S.J. Bowne<sup>1</sup>, K.A. Malone<sup>1</sup>, J.R. Heckenlively<sup>2</sup>, S.P. Daiger<sup>1</sup> and The RP1 Consortium.* 1) Human Genetics Ctr, Univ Texas, Houston, TX; 2) Jules Stein Eye Institute, UCLA, Los Angeles, CA.

The RP1 gene causes approximately 6-10% of autosomal dominant retinitis pigmentosa cases. The protein localizes to the connecting cilia of rod and cone photoreceptors and may be involved in protein transport to the outer segment. The doublecortin domain of RP1 probably interacts with microtubules of the cilium but the function of the rest of the protein remains to be determined.

We have identified a novel retinal gene, RP1L1, with a very similar genomic structure and significant sequence similarity to RP1. This gene codes for a protein 2,414 amino acids in length (compared to 2,156 aa for RP1) and has 32% identity and 53% similarity to RP1 over the first 350 amino acids. This region of similarity includes and extends beyond the doublecortin domain and suggests that RP1L1 is RP1's closest protein relative. Preliminary evidence suggests that RP1L1 expression is limited to the retina. The presence of a conserved doublecortin domain implies that RP1L1 may be another microtubule associated protein and might perform a parallel function to RP1. There is also some weak sequence similarity to RPGR, the gene responsible for the RP3 form of retinitis pigmentosa. RPGR has also been recently localized to the photoreceptor connecting cilia.

The middle of the putative RP1L1 protein is highly repetitive and contains a tandemly repeated 16 aa sequence which appears to be polymorphic. We have identified at least three RP1L1 alleles which contain 0-4 of these repeats, embedded within a run of imperfect repeats. The only other reported occurrence of this kind of tandemly repeated polymorphic sequence (within a gene) is in the dopamine D4 receptor.

Because of the similarity of RP1L1 to RP1 we are investigating the possibility that RP1L1 might cause inherited retinal degeneration. Additionally, it might be involved in a parallel pathway which could potentially compensate for the loss of RP1 in patients with the RP1 form of adRP.

**Structure and localization of the *GFRA4* locus and investigation of the gene in human thyroid cancer.** *J.B. Vanhorne, K.J. Harrison, B. Thomas, S.A.M. Taylor, L.M. Mulligan.* Department Pathology, Queen's University, Kingston, ON, Canada.

Glial cell line-derived neurotrophic factor (GDNF) family receptors a (GFRas) are cell surface bound co-receptors required for activation of the RET receptor tyrosine kinase by members of the GDNF family. GFRa family members have strong sequence and structural homology. We have shown that their gene structures are also conserved. The recently identified GFRa-4 is the primary co-receptor for binding of persephin to RET. GFRa-4 differs structurally from other GFRa family members, lacking one of 3 cysteine rich domains thought to confer secondary structure. To understand the relationship of GFRa-4 and other GFRa family members, we investigated the structure and localization of the *GFRA4* gene. We mapped the *GFRA4* locus by FISH to chromosome 20p13. Comparison of *GFRA4* cDNA and genomic sequences for this region indicated that *GFRA4* contains 6 coding exons spanning approximately 4 kb of genomic DNA. Consistent with previously reported protein structure differences, *GFRA4* has an interstitial deletion relative to other members of the *GFRA* gene family, resulting in absence of at least 2 exons conserved in all other family members. GFRa-4 is strongly expressed in thyroid and has been predicted to act as the primary RET co-receptor in this tissue. As activating mutations of *RET* are associated with familial thyroid tumors in multiple endocrine neoplasia type 2 (MEN 2) and are found in a subset of sporadic medullary thyroid carcinoma (MTC), we postulated that mutations or variants of *GFRA4* could alter the level of RET activation occurring in these cells and might also contribute to this disease phenotype. We have investigated a group of MEN 2 cases without detectable *RET* mutations and a panel of individuals with apparently sporadic MTC for mutations or variants of *GFRA4*. We identified polymorphic variants in exons 1, 2, 5 and 6 of *GFRA4* in both normal controls and patient samples. We did not detect any difference in frequency of these variants between our populations. Our data suggest that mutations of *GFRA4* are not a common contributing factor to heritable or sporadic thyroid neoplasia.

**Spatial and temporal control of the human ADH gene complexes in BAC transgenic mice.** *J.S. Su<sup>1</sup>, K.M. Chao<sup>2</sup>, S.F. Tsai<sup>1,3</sup>, T.F. Tsai<sup>1,2</sup>.* 1) Institute of genetics, National Yang-Ming University, Taipei, Taiwan, ROC; 2) Department of Life Science, National Yang-Ming University, Taipei, Taiwan, ROC; 3) Division of Molecular and Genomic Medicine, National Health Research Institutes, Taipei, Taiwan, ROC.

Human 4q21-24 region was previously shown to bear a tumor suppressor gene for human liver cancer. We have conducted genomic sequencing for this region and the syntenic mouse chromosome 3 region. Seven human ADH genes and four mouse Adh genes were identified from the compiled sequences. The PipMaker program (Schwartz, et al., 2000) predicted several conserved noncoding sequences (CNS) for the human and mouse alcohol dehydrogenase (ADH) gene complexes. To identify functional significance of these conserved sequences, in terms of spatial and temporal control of ADH gene expression, we have prepared BAC transgenic mice using sequenced BAC DNA encompassing different region of the CNS. Human ADH gene expression was analyzed in fetal and adult transgenic mouse livers to demonstrate tissue and developmental specificity. The results indicate that, despite the difference in Class I ADH gene numbers, three class I human ADH genes were expressed in a manner similar to the patterns observed in human tissues. Thus, a critical segment regulating the entire class I ADH gene expression is mapped to the conserved noncoding sequences between human ADH3 and ADH7.

**Characterization of a novel gene within the Smith-Magenis syndrome critical interval.** *R.E. Lucas*<sup>1</sup>, *C.N. Vlangos*<sup>1</sup>, *T. Newton*<sup>2</sup>, *S.H. Elsea*<sup>1,2,3</sup>. 1) Genetics Graduate Program, Michigan State University, East Lansing, MI 48824; 2) Department of Zoology, Michigan State University, East Lansing, MI 48824; 3) Department of Pediatrics/Human Development, Michigan State University, East Lansing, MI 48824.

Smith-Magenis syndrome (SMS) is a multiple congenital anomalies/mental retardation syndrome and possible contiguous gene deletion syndrome associated with an interstitial deletion of human chromosome 17p11.2. SMS has a characteristic behavioral and physical phenotype and is estimated to occur in approximately 1 in every 25,000 births. Towards a greater understanding of the molecular basis of SMS, we recently generated an overlapping and contiguous transcription map of the SMS critical interval, linking the proximal 17p11.2 region near the SMS-REPM and the distal region near D17S740. Within the SMS critical interval, we identified 16 known genes, 12 ESTs, and 6 genomic markers. In this study, we have focused on EST DKFZp434A139Q2, which represents the 3' end of the novel gene, retinoic acid induced 1 (*RAII*). Northern analysis reveals that *RAII* is expressed in all adult and fetal tissues studied. Through hybridization to digested BACs and PACs within the SMS critical interval transcription map and human genome project sequencing analysis, we determined that *RAII* maps to the central region of the SMS critical interval, adjacent to *SREBF1*. A gene or genes in this region of the SMS critical interval may play an important role in craniofacial development. In order to gain a greater understanding of the cellular role of *RAII*, we isolated a full-length cDNA clone to create a full-length cDNA-green fluorescent protein construct which will be transfected into mammalian cell lines and used to determine the cellular localization of the novel *RAII* protein. We have also identified mouse and human genomic clone for *RAII* and determined putative intron/exon boundaries. A mouse knockout construct will be developed so that we may gain information about the biochemical processes in which this novel protein may be involved and ascertain the effect of haploinsufficiency.

**Molecular cloning of a novel putative murine mitochondrial transporter.** *F.Y. Li<sup>1</sup>, B. Leibiger<sup>2</sup>, I. Leibiger<sup>2</sup>, C. Larsson<sup>1</sup>*. 1) Department of Molecular Medicine, CMM, L8:01, Karolinska Hospital, SE-171 76 Stockholm, Sweden; 2) Department of Molecular Medicine, The Rolf Luft Center for Diabetes Research L3, Karolinska Hospital, SE-171 76, Stockholm, Sweden.

We report here a novel murine gene, *Mrs3/4*, encoding a putative mitochondrial transporter homologous to the yeast mitochondrial RNA splicing protein 3 and 4 (yMRS3&4) and its human counterpart hMRS3/4. By analyses of radiation hybrids *Mrs3/4* was mapped to mouse chromosome 19, in a region which is syntenic to human chromosome 10q24 where the human gene is located. Structural analysis shows that these proteins belong to the mitochondrial carrier family (MCF), which is characterized by three repeats with two transmembrane domains in each repeat. The murine *Mrs3/4* gene has two splicing forms similar to the human homologue. The long form corresponds to the 341-amino acids (aa) protein with six transmembrane domains and the short form to the 177-aa protein with three transmembrane domains. Both forms have well-conserved signature sequences of MCF. Targeting experiments showed that both forms have mitochondrial localization. Northern blot analyses showed that *Mrs3/4* is ubiquitously expressed as a 1.8 kb transcript with a relative abundance in heart, liver, kidney and testis. In conclusion, the reported *Mrs3/4* gene shows a strong conservation, mitochondrial protein localization and a ubiquitous expression which suggest that it has an important role in mammalian cells most likely as an ion transporter across the mitochondrial inner membrane.

**The Mammalian Fem1c Genes: New Members of the Fem1 Gene Family.** *J.F. Maher, T. Ventura-Holman, S. Xiaohong.* Dept. of Medicine, University of Mississippi Medical Center and G.V.(Sonny) Montgomery Veterans Affairs Medical Center, Jackson, MS.

In the nematode *Caenorhabditis elegans* the fem-1 gene is in a genetic pathway that controls sex-determination. The product of this gene, FEM-1, appears to be involved in signal transduction between an extracellular signal, HER-1, and a transcription factor, TRA-1. Our laboratory has reported two homologs in the mouse, Fem1a and Fem1b. These two genes have highly related homologs in humans, designated FEM1A and FEM1B, respectively. We report here the characterization of a third member of this gene family, highly conserved between mouse and humans and designated Fem1c and FEM1C, respectively. At the protein level, mouse Fem1c and human FEM1C show > 99 % amino acid identity. FEM1C is most highly related to FEM1A. For example, with the encoded amino acid sequences, human FEM1C is 70% identical to human FEM1A, and 41% identical to human FEM1B (by comparison, human FEM1A and FEM1B share 37% amino acid identity). We have mapped the human FEM1C gene to chromosome 5 by FISH analysis, and this has now been verified by available Human Genome Project sequencing data. Northern Blot analysis shows some conservation of expression pattern in adult tissues between mouse and human genes, with message most abundant in testis in both organisms. The gene is also expressed in a mouse embryo Northern Blot of day 7 through day 17. Efforts are now underway to ascertain the biological functions of the human and mouse FEM1C genes. We present evidence that there is a Fem1c homolog in Teleost fish, suggesting a very ancient origin of its divergence from the Fem1a / Fem1b family members.

***hOAT1*, a novel organic anion transporter in kidney.** D. Prawitt<sup>1</sup>, A. Bahn<sup>2</sup>, T. Enklaar<sup>1</sup>, S. Fees<sup>1</sup>, H. Hauser<sup>1</sup>, L. Brixel<sup>1</sup>, C. Spangenberg<sup>1</sup>, F. Quondamatteo<sup>2</sup>, A. Hillemann<sup>2</sup>, R. Herken<sup>2</sup>, G. Burckhardt<sup>2</sup>, B.U. Zabel<sup>1</sup>. 1) Molecular Genetics Lab, Children's Hosp/ Univ Mainz, Mainz, Germany; 2) Center for Physiology and Pathophysiology, Goettingen, Germany.

The recently cloned organic anion transporter 1 (OAT1) belongs to the OAT subfamily of sugar porter proteins which all display remarkable structural homologies. They are expressed in the proximal tubule cells of the kidney and mediate the excretion of a variety of structurally unrelated substances including PAH, many drugs and xenobiotics. To elucidate the genomic structure we isolated a genomic *hOAT1* PAC clone and determined the exon-intron organization of the *hOAT1* gene. It encodes a 12 transmembrane protein with a large extracellular loop between the first two transmembrane domains. RT-PCR analysis on human kidney samples led to the detection of two new splice variants (*hOAT1-3* and *hOAT1-4*) with a 132 bp inframe deletion of the ORF as part of exon 9. Gene mapping experiments placed the *hOAT1* gene on chromosomal region 11q13.1-q13.2. Further elucidation of the OAT1 function and its implication in cellular processes was performed with the human gene (*hOAT1*) and the rabbit orthologue (*rbOAT1*). Transcription was not only observed in kidney and liver, but also in non secreting tissues like muscle and eye. In situ hybridization of rabbit eye sections with the renal *rbOAT1* as a probe revealed positive signals in the endothelium of inner blood vessels, the ganglion cells and several neurons in the bipolar cell layer of the retina. This is the first description of an organic anion transporter in neuron cells and it is tempting to speculate about *hOAT1* playing a role in transport processes of neurotransmitter metabolites in the visual system. *hOAT1* might therefore be involved in diseases where accumulation of these substances in the central nervous system is of critical importance.

**Functional studies of a recurrent mutation in Notch3 in CADASIL.** *T. Haritunians<sup>1</sup>, T. Chow<sup>2</sup>, R. P.J. De Lange<sup>3</sup>, N. Dorrani<sup>1</sup>, D. M. St. Clair<sup>3</sup>, N.C. Schanen<sup>1</sup>.* 1) Dept Human Genetics, Univ California, Los Angeles, Los Angeles, CA; 2) Dept Neurology, Univ California, Los Angeles, Los Angeles, CA; 3) Dept Mental Health, Univ Aberdeen, Aberdeen, UK.

CADASIL (Cerebral Autosomal Dominant Arteriopathy with Subcortical Infarcts and Leukoencephalopathy) is an inherited vascular dementia, characterized pathologically by a loss of vascular smooth muscle cells in the tunica media of small penetrating arterioles in the brain. The ultimate destruction of these vessels leads to recurrent ischemic strokes in the deep white matter, resulting in progressive dementia and neurological deficits in relatively young adults that lack the common risk factors for stroke. It has been identified that most CADASIL patients carry missense mutations in the NOTCH3 gene. Notch3 is part of a larger gene family of evolutionarily conserved cell surface receptors that plays a role in cell fate determination during development. Here, we have identified a new CADASIL family that carries a C185R mutation in exon 4 of the NOTCH3 gene, which results in a Cysteine substitution in the fourth epidermal growth factor (EGF)-like repeat of the extracellular domain. The EGF-like repeats have been proposed to be important for receptor binding to cell surface bound ligands, Delta and Jagged. Using site-directed mutagenesis, we have created the analogous mutation (C187R) in rat Notch3. To assess the effect of this mutation on Notch3 function, the mutant protein was transiently expressed in 293T cells. Cell surface expression of the protein was confirmed and its ability to bind a novel soluble ligand, Delta-1-Fc, was characterized by immunofluorescence, in comparison to wild type Notch3. These studies will evaluate whether the CADASIL mutations interfere with ligand binding or with downstream signal transduction. Supported by AHA 9950030N.

**Late Fifth Instar Larval Stage U1 and U2 snRNA Isoforms from the Silk gland of the silkworm, *Bombyx mori*.**

*J.M. Sierra-Montes, R.J. Herrera.* Dept Biological Sciences, Florida International Univ, Miami, FL.

U1 and U2 snRNA isoforms have been isolated and sequenced from U-specific cDNA libraries generated from the silk gland of the late fifth instar larval stage of the silkworm *Bombyx mori*. Due to the highly specialized nature of the silk gland and its 200,000-fold increase in DNA, it is an ideal candidate for gene expression studies. RT-PCR, cloning, automated sequencing (ABI 377) and secondary structure computer modeling analysis (Mike Zukers RNAdraw program) were utilized to examine the nucleic acid sequence of the full-length U-snRNAs. Five U1 and seven U2 snRNA variants were obtained from screening over 200 clones from their respective cDNA libraries. These isoforms exhibit 1) compensatory base changes (transitions/transversions), 2) conservation of secondary structure, 3) highly conserved protein binding sites (e.g. U1 70K, U2A and Sm binding site), 4) changes in localized regions in moderately conserved sites (e.g. base of loops) and 5) base-pairing generating more stable hairpin structures. The U1 and U2 snRNA sequences are highly conserved across species. Small nuclear RNA molecules have also been shown to be developmentally linked (i.e. mouse U1-specific fetal and adult forms) but none have been correlated to the insect larval stage. The focus of current studies is the examination of U-specific cDNA libraries generated from the silk gland of early and middle fifth instar larval stages.

**Autosomal Dominant Polycystic Kidney Disease Type I: Genes and Pseudogenes.** *J. Horst<sup>1</sup>, A. Markoff<sup>2</sup>, B. Dworniczak<sup>1</sup>, N. Bogdanova<sup>1</sup>*. 1) Inst Human Genetics, WWU Muenster, Muenster, Germany; 2) Institut fr Medizinische Biochemie, Univ. Mnster; Mnster, Germany.

One of the most common monogenic inherited disorders in men, the autosomal dominant polycystic kidney disease (ADPKD), with an incidence of approximately 1 in 1000, is mainly characterized by development of fluid-filled cysts in both kidneys, resulting in most cases in kidney failure. In affected individuals of European descent, mutations in the PKD1 gene, located on 16p13.3 are the most common cause for the disease and account for up to 85% of the cases. The PKD1 gene extends over ~52 kb of genomic DNA and contains 46 exons encoded by a 14 kb transcript. A large part of the gene, extending from exon 1 to the first 87 bp of exon 33, is duplicated in at least three homologous genes (HG), which are located on chromosome 16p13.1 and share approximately 95-97% homology with the PKD1 gene, thus heavily obstructing the mutation analysis of PKD1. Two of these genes have been recently covered in a large sequencing work on chromosome 16. It has been however not known for years if homologous to PKD1 genes code for functional polypeptides. We have identified four more homologues to PKD1 which are different from the previously published sequence by employing PCR screening of a bacterial artificial chromosome (BAC) DNA library and BLAST homology searches in publicly available data bases. Deciphering the structural differences between HG and PKD1 allows for differential analysis of those genes. Assaying their transcripts in the model cell line T98G shows that HG are not translated. Taken together with the sequence information about the genes, these data show that homologues to PKD1 are pseudogenes. This is the first work on PKD1 homologous genes to demonstrate that HG belong to a PKD1 pseudogene family, the members of which emerged at about the same time in the course of molecular evolution. In addition, the precise structural characterization of the PKD1 homologues allows to create better reagents for conventional mutation analysis of the duplicated part of the PKD1 gene and to review the mutation data of the duplicated part of the gene obtained by others.

**Lack of copies of the DAZ gene cluster in normal and infertile males without apparent Yq microdeletions. L.**

*Stuppia*<sup>1, 2</sup>, *AR. Gaspari*<sup>1</sup>, *V. Gatta*<sup>1</sup>, *E. Morizio*<sup>1,3</sup>, *D. Fantasia*<sup>1,3</sup>, *R. Mingarelli*<sup>4</sup>, *G. Calabrese*<sup>1,3</sup>, *G. Palka*<sup>1,3</sup>. 1) Dept di Science/Biomed, Univ G D Annunzio, Chieti, Italy; 2) Institute of Normal and Phatological Citomorphology, CNR, Chieti, Italy; 3) Servizio di Genetica Umana, Ospedale Civile di Pescara; 4) CSS Mendel Institute, Roma, Italy.

About 10% of infertile men show microdeletions of the Y chromosome long arm (Yq) involving three different loci, AZFa, AZFb, AZFc. Deleted in Azoospermia (DAZ) gene is the major candidate for male infertility, being involved in about 60-70% of all microdeletions, and nearly in 100% of deletions involving AZFc. This gene maps within subinterval 6D of the Y chromosome with multiple copies. The typical PCR approach for the detection of Yq microdeletions is able to disclose only deletions removing all the DAZ copies, but not those leaving as few as one copy of the gene. Thus, it is not known whether or not partial deletions of DAZ can be related to male infertility. Based on the presence of intronic single base changes, four copies of DAZ (DAZ1-4) are detectable by PCR amplification of 3 intragenic STSs followed by specific endonuclease digestion. Using this approach, we analyzed 42 infertile patients without apparent microdeletion of the Y chromosome, and 67 fertile controls. Three STS of the DAZ gene (sY581, sY586, SY587) were amplified by PCR and digested with *Sau3A*, *Taq I*, and *Dra I*, respectively. Absence of the band corresponding to the DAZ2 gene was detected in 13 infertile patients (30.9%) and in 10 controls (14.9%). Thus, the absence of this copy of the DAZ cluster appear compatible with normal fertility, being present in about 15% of controls. However, the incidence of this condition in infertile patients was two times higher than in controls. This could mean that subjects lacking this copy of DAZ could be more prone to other genetic and environmental factor in turn responsible of the infertility. On the other hand, simultaneous absence of DAZ1 and DAZ4 were detected in two infertile patients (4.7%), and other two had absence of DAZ2 and DAZ3. No control subject showed this condition, suggesting that this feature could be a cause of male infertility in patients not showing apparent Yq deletions.

**Identification of a novel human cytokine gene in the interleukin gene cluster on chromosome 2q12-14. J.T.**

*Bensen*<sup>1</sup>, *P.A. Dawson*<sup>2</sup>, *J.C. Mychaleckyj*<sup>2,3,4</sup>, *D.W. Bowden*<sup>5,6</sup>. 1) Program in Molecular Medicine; 2) Department of Internal Medicine; 3) Department of Physiology and Pharmacology; 4) Department of Public Health Science; 5) Department of Biochemistry; 6) The Center for Human Genomics, Wake Forest University School of Medicine, Winston-Salem, NC.

Genes residing in the interleukin cluster on chromosome 2q12-14, including interleukin-1 alpha (IL1A), interleukin-1 beta (IL1B) and interleukin-1 receptor antagonist (gene symbol IL1RN and protein symbol IL1Ra), are members of a family of IL-1 cytokines that play an important role in mediating the inflammatory response. We have identified a novel IL-1 like gene, designated IL1F10. Initially BLAST searches of GENBANK's high throughput genome sequence using known cytokine amino acid sequence identified 2 possible exons. Extensive cDNA cloning including 5' and 3' RACE was needed to identify the entire IL1F10 gene encoded by 5 exons spanning over 7.8 kb of genomic DNA. The 1008 bp IL1F10 cDNA encodes a 152 amino acid protein that shares 41 and 43% amino acid identity with human IL1Ra and FIL1 delta (Smith et al., J. Biol. Chem. 275:1169-1175 (2000)), respectively. IL1F10 maps to human chromosome 2, between FIL1 delta and the IL1RN. In addition to a TATA box, this gene contains a putative C/EBPb transcription factor binding site (-120 to -107) within the promoter similar to the promoter of the secreted form of IL1Ra. IL1F10 shares sequence characteristics of the IL1Ra family including, key amino acid consensus sequences and a similar genomic structure. Pairwise global alignment and calculation of evolutionary relatedness suggests that IL1F10 is a common ancestor from which other "IL-1 receptor antagonist-like" homologs arose through gene duplication. In multi-tissue cDNA panels, low-level expression was evident in non-immune tissues such as human heart and placenta. Consistent with a possible immunological role, this novel transcript was present in highest levels in fetal liver, spleen, thymus and tonsil (listed in level of expression from lowest to highest). The expression in a variety of immune tissues and similarity to IL1Ra suggest a role of IL1F10 in the inflammatory response.

**Analysis of the LMX1B promoter in human fibroblasts.** *J.A. Dunston, J.D. Hamlington, I. McIntosh.* McKusick Nathans Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD.

Nail Patella Syndrome (NPS) is the result of heterozygous loss of function mutations in the LMX1B gene. This gene encodes a LIM-homeodomain transcription factor that is required for development of the limbs, eyes, kidneys and portions of the CNS. In this study, we identified the transcription start site and localized promoter elements using a luciferase assay reporter system. The transcription start site was mapped using primer extension and 5' RACE with RNA from HEK-293 cells as template. A 3.5 kb fragment containing the transcription start site was cloned from BAC 265A2, sequenced, and inserted into the luciferase vector (pGL3 basic). This fragment, which contains 2.7 kb of 5' flanking sequence and 0.8 kb of 5'UTR sequence, had significant promoter activity in human fibroblasts. Deletion of 5' sequence to -442 had little effect on reporter activity. Additional deletion to -379 caused a significant increase in reporter activity suggesting the presence of a repressor between -442 and -379. Deletion of 3' sequence to +460 caused a decrease in reporter activity indicating that sequence elements within the 5'UTR are capable of increasing the level of transcription.

**Two genes that map to the STSL locus cause sitosterolemia: genomic structure and spectrum of mutations involving sterolin-1 and sterolin-2 encoded by ABCG5 and ABCG8 respectively.** *K. Lu<sup>1</sup>, M.H Lee<sup>1</sup>, S. Hazard<sup>2</sup>, A. Brooks-Wilson<sup>3</sup>, G. Salen<sup>4</sup>, M. Dean<sup>5</sup>, A. Srivastava<sup>6</sup>, S.B. Patel<sup>1</sup>.* 1) Division of Endocrinology, Diabetes and Medical Genetics, Medical University of South Carolina, Charleston, SC; 2) BioMolecular Computing Resource, Medical University of South Carolina, Charleston, SC; 3) Xenon Genetics Inc., Suite 100, 2387 East Mall, Vancouver, BC, V6T 1Z3 Canada; 4) Division of Gastroenterology, University of Medicine and Dentistry New Jersey, Newark, NJ 07018; 5) Laboratory of Genomic Diversity, National Cancer Institute-Frederick, Frederick, MD 21702; 6) J. C. Self Research Institute of Human Genetics, Greenwood Genetics Center, Greenwood, SC 29646.

Sitosterolemia (MIM 210250) is a rare autosomal recessive disorder, characterized by intestinal hyperabsorption of all sterols, including cholesterol, plant and shellfish sterols and an impaired ability to excrete sterols into bile. Patients with this disease have expanded body pools of cholesterol, very elevated plasma plant sterol species and frequently develop tendon and tuberous xanthomas, accelerated atherosclerosis, and premature coronary artery disease. We previously mapped the STSL locus to human chromosome 2p21. Recently, we reported that a novel member of the ABC transporter family, named sterolin-1 and encoded by ABCG5, is mutated in 9 unrelated sitosterolemia families. In the remaining 25 families, no mutations in sterolin-1 could be identified. We identified another ABC transporter, located less than 400 bp upstream of sterolin-1, in the opposite orientation. Mutational analyses revealed that this highly homologous protein, termed sterolin-2, encoded by ABCG8, is mutated in the remaining pedigrees. Thus, two highly homologous genes, located in a head-to-head configuration on chromosome 2p21, are involved in causing sitosterolemia. These studies indicate that both sterolin-1 and sterolin-2 are indispensable for the regulation of sterol absorption and excretion. Identification of sterolin-1 and sterolin-2 as critical players in the regulation of dietary sterol absorption and excretion identifies a new pathway of sterol transport.

**Genomic structure of the human p22 dynactin light chain (DCTN3) and comparative mapping to rat**

**chromosome 5.** *D.R. Mills<sup>1</sup>, J. Pepperell<sup>2</sup>, U. Tantravahi<sup>2</sup>, M. Shiozawa<sup>3</sup>, A. Matsuzaki<sup>3</sup>, A.E. Kwitek-Black<sup>3</sup>, H.J.*

*Jacob<sup>3</sup>, C.L. Jackson<sup>1</sup>.* 1) Pathology, Rhode Island Hospital, Brown University, Providence, RI; 2) Pathology, Women and Infants' Hospital, Brown University, Providence, RI; 3) Medical College of Wisconsin, Milwaukee, WI.

The gene for the p22 dynactin light chain (DCTN3) was identified using positional cloning methods and localized to human 9p13 by radiation hybrid mapping. The DCTN3 protein has been demonstrated by other investigators to interact with the dynein microtubulebased motor complex, localize to kinetochores, and participate in cell cycle progression and cytokinesis. Human BAC clones were identified that contained the DCTN3 gene. Fluorescence in situ hybridization mapping confirmed that DCTN3 localized to human chromosome 9p13. The genomic organization of DCTN3 was characterized by sequencing longrange interexon PCR products using primers derived from the DCTN3 mRNA (GenBank accession number AF082513). The DCTN3 gene consists of 7 exons and 6 introns and spans approximately 6.9 kb. Introns 1, 5 and 6 are in phase 0, and introns 2, 3 and 4 are in phase 1. A neutral (CT) single nucleotide polymorphism (SNP) was identified at nucleotide position 34 of exon 1. Single strand conformation polymorphism (SSCP) screening of 100 random individuals demonstrated a low 2% frequency for this SNP. While comparative synteny is well established between human 9p13 and mouse 4, the relationship between human and rat is less well characterized. Human DCTN3 is flanked by the genes for GALT and CNTFR. We have localized the rat homologs of these three genes to a common region of rat chromosome 5 by fluorescence in situ hybridization mapping.

**Identification of New Genes from the Pericentromeric 7.4-Mb Region of Human Chromosome 22.** *T. Sasaki, A. Shiohama, K. Hosono, Y. Matsushita, S. Minoshima, A. Asakawa, J. Kudoh, A. Shintani, K. Shibuya, N. Aoki, S. Mitsuyama, K. Kawasaki, N. Shimizu.* Dept. Mol. Biol., Keio Univ., Tokyo, Japan.

The chromosome 22 sequencing consortium including us finished genomic sequencing of chromosome 22q (33.4 Mb) as the first human chromosome (*Nature* **402**:489-495, 1999), in which 545 genes (including 298 related and predicted gene) were reported. Since then, we have been carrying out further analysis of the pericentromeric 7.4-Mb sequence in combination of the manual evaluation of the computer output and experimental isolation of cDNAs. The analyzed regions include: the CES (cat eye syndrome) region (2.2 Mb), the DGS (DiGeorge syndrome) region (1.5 Mb), the BCRL2-GNAZ region (2 Mb), and the BCR-IGLL region (1.7 Mb). As a result, we have found 11 new genes including CESK1 from the CES region, C22ORF12 from the DGS region, LUK1 and LUK2 from the BCRL2-GNAZ region, C22ORF13, C22ORF14, SLC2A11 (GLUT11), ZNFLL1, C22ORF15, C22ORF16, and PNEC9 from the BCR-IGLL region. Here, we report the initial characterization of some of these new genes. CESK1 is an active gene located at the most centromeric on 22q and it consists of single exon. The isolated cDNA of CESK1 is 2.4-kb long, and has 1674-bp coding sequence encoding a protein of 557 amino acids. The deduced amino acid sequence showed a significant homology to human T-complex protein-1 theta (32% identity and 56% homology), which is known to have a chaperon-like activity. Northern blot analysis showed the CESK1 expression is limited in testis. However, PCR analysis using various tissue derived cDNAs showed amplified products in fetal brain as well as testis. GLUT11 (SLC2A11) has a significant homology (51%;) to a known glucose transporter GLUT5. It consists of 12 exons spanning 25-kb long genomic sequence and locates between SMARCB1 and MIF. The comparison with the other members of GLUT family showed that GLUT11 conserves the GRR/K motif located at right after transmembrane helices 2 and 8. The cDNA cloning results indicated the presence of three distinct exon-1s. PCR analysis using multi tissue-derived cDNA panels (MTC) confirmed the differential expression from each exon 1. Characterization of other genes will be presented.

**Characterization of complete methylenetetrahydrofolate reductase (*MTHFR*) genomic region identifies clusters of transcriptional start sites and translation start sites of two protein isoforms.** P. Tran, D. Leclerc, M. Chan, A. Pai, P. Goyette, F. Hiou-Tim, Q. Wu, R. Milos, C. Artigas, R. Rozen. Human Gen, Biol, Pediatrics, McGill Univ, Montreal, PQ., Canada.

MTHFR is a folate-metabolizing enzyme that links folate interconversion with homocysteine metabolism and the methylation cycle. MTHFR converts 5, 10-methylenetetrahydrofolate to 5-methyltetrahydrofolate, a major carbon donor in homocysteine remethylation to methionine. Two polymorphisms cause mild MTHFR deficiency, a condition shown to occur in approximately 35% of North Americans and Europeans. This deficiency may alter risk for neural tube defects, vascular disease, pregnancy complications and certain cancers. While these factors underscore the importance of understanding how *MTHFR* is regulated, molecular studies have been limited to a 2.2kb human partial cDNA that encodes a 70kD isoform of MTHFR. Observed transcript sizes of approximately 7.5kb and 9.5kb and a major protein isoform of 77kD suggest that additional cDNA sequences remain to be identified. Using library screening, PCR-based strategies and homology searches with the NCBI databases, the 5' and 3' UTRs of *MTHFR* were characterized in human and in mouse. In both species, exon 1 was redefined to approximately 4.0kb in length and is alternatively spliced. Expression studies demonstrated that an important splicing event within exon 1 gives rise to a novel coding region that encodes the predominant peptide of 77kD. Using ribonuclease protection assay, clusters of transcriptional start sites were detected, alluding to the presence of multiple promoters. Multiple polyadenylation sites were located which create 3'UTR lengths of 0.2kb-5.0kb and of 0.6kb-4.0kb for human and for mouse mRNAs, respectively. Finally, the 5' and 3' termini of the *MTHFR* cDNA were found to overlap with the 5' terminus of a chloride ion channel gene (*CLCN-6*) and with the 3' terminus of a thus far unidentified gene, respectively, mapping *MTHFR* more finely on chromosome 1p36. These results suggest that *MTHFR* is intricately regulated at several levels. Studies of the promoters and functional analyses of the different protein isoforms are in progress and will be presented.

**Fibroblast Growth Factor Receptor 2 (FGFR2) genomic sequence and variations.** *W.A. Paznekas, R. Ingersoll, A. KieuNgoc Tran, S. Rowe, L. Kasch, A.F. Scott, E.W. Jabs.* Institute of Genetic Medicine, Johns Hopkins University School of Medicine.

Fibroblast growth factor receptors (FGFRs) play a role in morphogenesis, development, angiogenesis, wound healing, and tumorigenesis. Mutations in FGFR2 cause more than five craniosynostosis syndromes. The FGFR2 genomic structure is the largest of the FGFR family. We have refined and extended the genomic organization of the FGFR2 gene by sequencing more than 119 kb of PACs, cosmids, and PCR products and assembling a region of approximately 175 kb from electronic databases. Although the gene structure has been reported to include only 20 exons, we have verified the presence of at least 22 exons, some of which are alternatively spliced. The sizes of six exons differ from those reported previously. The sequence of 20 of the 21 introns has been completed. Interspersed repeat DNA families are relatively enriched in intron 4, but are clustered in intron 2 preventing completion of its sequencing. The nucleotide sequence 5' to the start codon in exon 2 has two regions of 97 percent identity to the mouse promoter region. Comparison of our sequence and those in the NCBI database detected more than 300 potential single nucleotide polymorphisms (SNPs). However, sequencing regions containing 52 of these potential SNPs verified only 14 in PCR products generated from 20 CEPH alleles. In contrast, direct sequencing of the CEPH DNAs revealed 21 other polymorphisms. Only one SNP was found in the 2,926 bp of coding sequence. Twenty-seven SNPs, two insertion polymorphisms and five microsatellite polymorphisms are contained in approximately 18 kb of non-coding sequence. This gives an average of one SNP for every 700 bp of non-coding sequence examined. This collection of SNP, insertion and repeat polymorphisms will aid future association studies between the FGFR2 gene and human disease and will enhance mutation detection.

**A shorter MMP-9 promoter characterizes a mouse strain susceptible to glomerulosclerosis.** *A. Fornoni, O. Lenz, Y. Wang, M. Potier, L.J. Striker, G.E. Striker.* Vascular Biology Institute, Univ Miami, Miami, FL.

The genetic background plays an important role in the development of human glomerulosclerosis (GS). We have developed mouse strains that are glomerulosclerosis-prone (ROP) or resistant (C57). GS results from an imbalance between extracellular matrix (ECM) synthesis and degradation, MMP-9 being one of the major enzymes involved in the regulation of ECM degradation. We have previously shown that mesangial cells (MC) from ROP mice express very low levels of MMP-9 in comparison to C57 MC. The aim of this study were to examine whether the MMP-9 promoter structure is responsible for the differences in MMP-9 expression between ROP and C57 MC, and whether those findings are applicable to humans.

DNA extracted from ROP and C57 MC as well as from kidney cortex and tails was analyzed by SSLP analysis of the d(CA)<sub>n</sub> repetitive region (-142 to -90). In addition, the MMP-9 promoter region between -1167 and +90 was sequenced. Both ROP and C57 MMP-9 promoters were cloned into a pGL3 basic vector and transfection experiments in both MC and in COS7 cells were performed before and after stimulation of protein kinase C (PKC) by PMA. SSLP analysis of the MMP-9 promoter was also performed on DNA of MC from patients with and without GS.

We found that the smaller number of d(CA) repeats in ROP MC (20 vs 24 in the C57 strain) was at least partially responsible for a lower MMP-9 expression. SSLP analysis from tails and kidney cortex confirmed the strain difference in MMP-9 promoter length. The shorter ROP MMP-9 promoter appeared to be functional, i.e. responsive to PKC stimulation, although MMP-9 expression in ROP MC never reached the level observed in C57 MC. MC isolated from a patient with GS had a shorter MMP-9 promoter than MC from a patient without GS.

In conclusion we found that the ROP strain is characterized by a decreased number of d(CA) repeats in the MMP-9 promoter that influences MMP-9 gene expression. Furthermore, the shorter MMP-9 promoter in MC isolated from a patient with GS suggests that the length of d(CA) repeats in the MMP-9 promoter may be a marker of susceptibility to GS.

**Most missense mutations in neural cell adhesion molecule L1 affect intracellular trafficking or ligand binding. E.**

*De Angelis*<sup>1</sup>, *A. Watkins*<sup>1</sup>, *T. Brümmendorf*<sup>2</sup>, *S. Kenwrick*<sup>1</sup>. 1) WTCMMD, Univ. Cambridge Dept. Medicine, Cambridge CB2 2XY, U.K; 2) Max Delbrück Center for Molecular Medicine, 13092 Berlin, Germany.

Mutations in the gene for neural cell adhesion molecule L1 underlie an X-linked neurological disorder that includes hydrocephalus, mental retardation, adducted thumbs and spasticity. About 40% of mutations described in families are missense. These are mostly unique and affect residues that are distributed primarily across the extracellular domains required for ligand binding. Assigning pathogenicity to missense mutations is only possible when functional effects are demonstrated. We have therefore examined the effects of 26 different missense mutations, affecting the extracellular domains of L1, on binding to homophilic (L1) and heterophilic (TAX-1) ligands as well as on intracellular trafficking. 23 out of 26 mutations result in a significant reduction in binding to one or more ligands or ability to reach the cell surface. For mutations that retard protein movement to the cell surface, peri-nuclear accumulation and retention within the endoplasmic reticulum is found. A correlation between morbidity and type of mutation is emerging, with mutations that affect key structural amino acids more likely (44%) to result in death under 1yr than those that affect surface properties of the molecule (13%). This may be due to the fact that key-residue mutations are more often found to affect intracellular processing and/or ligand binding.

**Clustering of ATM mutations in A-T patients with intermediate radiosensitivity.** *X. Sun<sup>1</sup>, M. Mitui<sup>1</sup>, H. Chun<sup>1</sup>, B. Crandall<sup>2</sup>, R.A. Gatti<sup>1</sup>.* 1) Department of Pathology, UCLA School of Medicine, Los Angeles, CA90095-1732; 2) Department of Pediatrics, UCLA School of Medicine, Los Angeles, CA.

One of the unique characteristics of cells from patients with ataxia-telangiectasia (A-T) is hypersensitivity to ionizing radiation. To date, more than 400 mutations have been identified in the ATM (A-T mutated) gene [<http://www.vwresearch.org/atm.htm>]. We report here a clustering of mutations in 10 patients (13 mutations) with an intermediate response in the colony survival assay (CSA) for radiosensitivity, as compared to the random distribution of ATM mutations in 102 A-T patients with characteristic radiosensitivity. The mean survival fraction (SF $\pm$ 1SD) for patients with A-T was 13.4 $\pm$ 7.8%, as compared to 50.1 $\pm$ 13.5% for normals. The response of these 10 A-T patients, who were typical in all other ways, fell within an intermediate, non-diagnostic range (SF=21-36%). Their ATM mutations tended to cluster within either the p53-binding domain, the RAD3 homology region, or the PI-3 kinase domain of the ATM gene. This observation invites speculation as to how such a genotype/phenotype correlation could arise when most A-T patients have little or no detectable ATM protein by western blotting. We hypothesize those small amounts of ATM protein may escape detection by conventional methods while still playing a significant role in the response to ionizing radiation.

**Characterization of PITX2 Rieger syndrome mutations in *C. elegans*.** R. Toro<sup>1</sup>, I. Saadi<sup>1</sup>, Y. Jin<sup>3</sup>, B.G. Condie<sup>4</sup>, A.F. Russo<sup>1,2</sup>. 1) Genetics Program; 2) Department of Physiology and Biophysics, University of Iowa, Iowa City, IA; 3) Department of Biology, University of California Santa Cruz, Santa Cruz, CA 95064; 4) Developmental Biology Program, Medical College of Georgia, Augusta, GA 30912.

Mutations in the PITX2 gene have been established to play a role in the autosomal dominant Rieger syndrome. In the nematode *C. elegans*, the PITX2 homologue unc30 has been shown to regulate the glutamic acid decarboxylase gene unc25. Glutamic acid decarboxylase (GAD) catalyzes the production of the neurotransmitter GABA. *C. elegans* mutants that lack unc30 have a 'shrinker' behavioral phenotype that is characterized by an abnormal response to head touch stimulus. Interestingly, mouse Pitx2 can rescue this phenotype. We have shown that unc30/unc25 relationship extends to mammals; PITX2 can regulate the glutamic acid decarboxylase (Gad1) promoter. PITX2 shows a 5-8 fold activation of a reporter gene driven by the Gad1 promoter in various cell culture lines. Testing the functional consequences of the PITX2 Rieger syndrome mutations, such as the W133Stop truncation and the dominant-negative K88E, yielded unexpected cell-specific results in co-transfection experiments. For instance, the W133Stop protein shows both activation and inhibition depending on the cell line. We plan to test these mutations in *C. elegans* in order to extend these results to an in vivo system. The effects of the Rieger mutations will be assayed by scoring both the behavioral phenotype and expression of an unc25 driven GFP reporter in both wild type and unc30 mutant worms.

**Cloning and characterization of a novel apoptosis-associated gene expressed during erythroid cell differentiation.**

*W. Aerbajinai, J.L. Miller.* Laboratory of Chemical Biology, NIDDK/NIH, Bethesda, MD.

In recent years, we have taken a genomics approach toward understanding the transcriptional basis of human erythropoiesis (<http://hembase.niddk.nih.gov/>). We report here the molecular cloning and characterization of a novel erythroid differentiation-related gene called EDRG9 that is located on the short arm of chromosome twelve. The primary transcript, EDRG9-L, was cloned from two expressed sequence tags catalogued within our genomic database. The EDRG9-L mRNA encodes a putative protein of 1078 amino acids with a C1q-like globular domain at the COOH terminus. We also characterized an alternative transcript lacking exon 5 (EDRG9-S) that encodes a significantly smaller protein lacking the C1q domain. Northern blotting revealed expression of EDRG9 in multiple human tissues with strong signals found only in bone marrow and the fetal liver. RT-PCR analyses of mRNA obtained from primary erythroid cells at defined developmental stages were performed to determine the transcriptional profile of EDRG9 during erythropoiesis. Increased expression was noted among cells undergoing the proerythroblast-basophilic normoblast transition associated with global nuclear condensation and reduced cell proliferation during terminal differentiation. This expression pattern was shared by both EDRG9 isoforms and is similar to the erythroid transcriptional profile of genes associated with regulation and exit from the cell cycle. Plasmids encoding green fluorescent protein (GFP) tagged EDRG9 were also constructed and transfected into CHO cells for cell localization and functional assays. Expression of the GFP-tagged EDRG9-L transcript was localized to the cytoplasmic compartment, and no specific changes in the cellular phenotype have been identified to date. In contrast, overexpression of GFP-tagged EDRG9-S resulted in apoptosis of transfected CHO cells within 24-48 hours confirmed by TUNEL assay. Fluorescence microscopy studies demonstrated GFP-EDRG9-S localized with aggregating mitochondria. We propose that expression of the EDRG9 gene may be important in regulating proliferation and apoptosis during terminal erythroid differentiation.

**A novel retinoic acid-sensitive gene isolated by an induction gene trap approach.** *M. Schlicker<sup>1</sup>, O. Batista<sup>1</sup>, W. Wurst<sup>2</sup>, I. Hansmann<sup>1</sup>.* 1) Institut für Humangenetik, Martin-Luther-Universität, Halle, Germany; 2) Molekulare Neurogenetik, GSF-Forschungszentrum für Umwelt und Gesundheit, Neuherberg, Germany.

In man and mammals prenatal exposure to the teratogens retinoic acid (RA) and/or retinoids (RX) results in characteristic congenital anomalies including cardiac and craniofacial malformations. Incidence and pattern of the malformations apparently depends on dose and stage of exposure. Yet, the respective molecular mechanisms as well as the genes involved are more or less unknown. RA/RX signalling is mediated by nuclear receptors that activate target genes containing RA-binding elements (RAREs). Based on a retinoic acid-induced gene trap approach (Forrester et al., 1996) we set up a strategy to identify RA/RX downstream genes of mouse and human development that are possible candidate genes involved in the generation of congenital malformations. By RACE-PCR of trapped ES clones we identified a novel gene that is expressed in embryonic stages of mouse (8 d p.c. >>) and in different tissues of adult mouse and man. In northern analyses a cDNA fragment of the gene identifies a 2.5 kb transcript in mouse tissues and two transcripts of 2.7 kb and 3.0 kb in tissues of adult humans. By screening of mouse and human Marathon-cDNA libraries and analyzing homologous ESTs we identified the corresponding cDNAs including the various 3'UTRs. The mouse and human sequences of the gene share an identical ORF of 1512 bp and are homologous in 90 % of their nucleotide sequence and in 94 % of their amino acid sequence. Using mouse P1 and human BAC clones we characterized the genomic structure of the gene. Transcription factor scanning identified RA-responsive and RA-related orphan receptor-binding elements in the promoter region. The FISH analysis based on the human BAC located the gene within the chromosomal region 3q24-26. We expect, that the detailed analysis of the promoter region will unravel the retinoic acid responsive control mechanism for the gene and that a refined chromosomal mapping will help to correlate the identified gene with disorders mapped to the chromosomal region 3q24-26. (Supported by DAAD and DFG).

**The Mouse Homolog of Pyrin, the FMF Protein, Regulates Cytokine Production and Apoptosis.** *J.J. Chae<sup>1</sup>, H. Komarow<sup>1</sup>, G. Wood<sup>1</sup>, P.P. Liu<sup>2</sup>, D.L. Kastner<sup>1</sup>*. 1) Inflammatory Biology Section, Rheumatic Disease Genetics and Genomics Branch, NIAMS; 2) Oncogenesis and Development Section, Genetics and Molecular Biology Branch, NHGRI, NIH, Bethesda, MD.

We recently identified the gene for familial Mediterranean fever (FMF), a recessive disorder of inflammation. This gene, denoted *MEFV*, is highly expressed in granulocytes and activated monocytes, but the function of its protein product, pyrin, is unknown. To investigate pyrin's function, we cloned *Mefv*, the mouse homolog of *MEFV*, and generated *Mefv* knockout (KO) mice. *Mefv* transcripts are detected primarily in peripheral blood granulocytes and monocytes, and the predicted protein shares most, but not all, of the motifs found in human pyrin. Using an antibody to N-terminal mouse pyrin, we analyzed protein from in vitro-stimulated peritoneal monocytes. In wild-type mice, pyrin was highly induced by the anti-inflammatory cytokines IL-4 and IL-10, by proinflammatory agents lipopolysaccharide (LPS) and TNF- $\alpha$  at lower levels, and at highest levels by IL-4 and LPS together. Pyrin expression was not induced by TNF- $\alpha$  in TNFR1-KO mice, by IL-4 or IL-10 in JAK3-KO mice, or by any stimuli in NF- $\kappa$ B-KO or LPS-desensitized C3H/HeNHsd mice. Transient transfection of *Mefv* into the mouse monocytic cell line RAW264.7, which does not ordinarily produce pyrin, led to DNA fragmentation characteristic of apoptosis. When treated with LPS/IL-4, transfected cells produced substantially less IL-1 transcript and protein relative to nontransfected controls. We also examined the induction of apoptosis by IL-4/LPS in peritoneal monocytes from *Mefv* C-terminal KO mice, and found that cells from homozygous KO mice exhibited reduced DNA fragmentation relative to wild-type controls. These results suggest that pyrin acts as an anti-inflammatory molecule by inhibiting IL-1 synthesis and inducing monocyte apoptosis.

**Genotypic diagnosis of T<sup>B</sup><sup>+</sup> SCID by functional assay.** A.P. Hsu<sup>1</sup>, S.M. Anderson<sup>1</sup>, R. Buckley<sup>2</sup>, F. Candotti<sup>1</sup>, G. Uzel<sup>1</sup>, J.M. Puck<sup>1</sup>. 1) NHGRI/GMIBB, NIH, Bethesda, MD; 2) Duke Univ Med Center, Durham, NC.

Severe combined immune deficiency (SCID) is a group of disorders affecting both cellular and humoral immunity. Affected patients die of recurrent infections unless immunity is restored by bone marrow transplant or gene therapy. Most SCID cases are T<sup>B</sup><sup>+</sup>, predominantly due to X-linked mutations in *IL2RG*. However autosomal recessive phenocopies include Janus kinase 3 (*JAK3*) and Interleukin 7 receptor  $\alpha$  (*IL7RA*) deficiency. Determination of the genetic defect is crucial for accurate genetic counseling, carrier and prenatal diagnosis and gene therapy. *IL2RG* encodes the common gamma chain (gc) of cytokine receptor complexes for IL2, 4, 7, 9 and 15. Signaling is through heteromeric receptors to JAK proteins and signal transducers and activators of transcription (STATs). Determining the genetic basis of T<sup>B</sup><sup>+</sup> SCID involves ruling out mutations in *IL2RG* and performing laborious IP/western blots for JAK3 and IL7Ra. We have developed a flow cytometric assay to distinguish among *IL2RG*, *JAK3* and *IL7RA* mutations. IL2 or IL7 activate the gc/JAK3/STAT5 pathway in lymphocytes resulting in phosphorylated STAT5 (pSTAT5). In control B-cell lines fluorescence index (FI), ratio of geometric mean of pSTAT fluorescence in stimulated vs unstimulated samples, increases two-fold after IL2 or IL7 stimulation. Cells with gc or JAK3 defects fail to phosphorylate STAT5 resulting in a FI of 1.0. IL4 utilizes gc in its receptor but signals through JAK1 to STAT6. After IL4 stimulation, control cells have a FI near 3.0. *IL2RG* deficient cells, lacking a complete receptor, have a FI of 1.0. *JAK3* deficient cells have an intermediate FI of 1.6. Comparison of the FI of STAT5 and STAT6 after IL2, IL4 or IL7 stimulation makes possible the identification of specific blocks in activation due to mutations in gc, JAK3 or IL7Ra. Targeted sequencing of the appropriate gene then leads to mutation detection. Genotype/phenotype correlation and functional consequences of amino acid substitutions can be evaluated utilizing this signal transduction assay. Appropriate counseling and testing for relatives of T<sup>B</sup><sup>+</sup> SCID patients can be provided and gene therapy for patients can be considered.

**Histone Acetylation and Methylation Patterns of the Human Imprinted *NDN* Gene.** *J.C.Y. Lau, M.L. Hanel, R. Wevrick.* Dept Medical Genetics, Univ Alberta, Edmonton, AB., Alberta, Canada.

A subset of mammalian genes display imprinted expression where monoallelic silencing is observed that is dependent on the parent of origin of the alleles. This differential marking of the parental genomes occurs in gametogenesis, and is switched when passing through the germ line of the opposite gender. The allele-specific expression is initiated by an unknown epigenetic mark and can be propagated through development to direct expression in adult tissues. The mechanism by which imprinted genes are marked has not been fully elucidated. Evidence suggests involvement of allele specific DNA methylation and differential histone acetylation. The imprinted domain on 15q11-q13 contains a cluster of co-ordinately regulated maternally and paternally expressed genes, as well as several biallelically expressed genes. Some of these genes have been implicated in the human genetic disorders Prader-Willi Syndrome (PWS) and Angelman Syndrome (AS). The imprinted genes in the region are under control of a cis acting Imprinting Centre (IC) located at the 5' end of the *SNRPN* gene. The IC has been reported to be associated with allele specific DNA methylation and local histone acetylation differences. As these differences can have significance in *SNRPN* regulation and/or IC function, we studied an imprinted gene not co-localizing with the IC. To this end, we have characterized DNA methylation and histone acetylation patterns in the *NDN* gene, encoding neudin, an imprinted target ~1 Mb proximal to the IC. Differential methylation and histone acetylation was found to be associated with *NDN*. Comparison of methylation states in expressing and non-expressing tissues indicate DNA hypomethylation is associated with the paternal allele regardless of expression in different cell types. Hyperacetylation in expressing cells have correlated with hypomethylation. Our results suggest DNA methylation and histone acetylation may mark paternal and maternal alleles differentially even in the absence of transcription. The IC may therefore direct allelic transcriptional potential and other cell specific factors are required for transcription.

**Identification and characterization of an antisense transcript to the *MEST* gene on 7q32 as a candidate imprinted**

**locus.** *K. Nakabayashi*<sup>1</sup>, *K. Mitsuya*<sup>2</sup>, *M. Meguro*<sup>2</sup>, *M. Oshimura*<sup>2</sup>, *S.W. Scherer*<sup>1</sup>. 1) Dept Genetics, Hospital for Sick Children, Toronto, ON, Canada; 2) Dept. of Molecular and Cell Genetics, Faculty of Medicine, Tottori University, Yonago, Tottori, Japan.

Genomic imprinting is an unusual mode of gene regulation causing the nonequivalent representation of the maternal and paternal genomes. This phenomena can influence mammalian development, growth, and behavior. Imprinted gene(s) on human chromosome 7 are thought to be involved in Russell-Silver syndrome (RSS) based on the fact that 10% of patients shows maternal uniparental disomy of chromosome 7. Although chromosome 7 contains three known imprinting loci, *GRB10* on 7p12, *PEG10* on 7q21 and *MEST* at 7q32, an involvement of the known imprinted genes in RSS has yet to be established. To screen systematically for novel imprinted genes, we have established somatic hybrid cell lines containing a paternal or maternal human chromosome 7 (in which the imprinting of *MEST* is maintained). Because imprinted genes are often clustered, thirty transcripts located between D7S530 and D7S649 (an interval of approximately 1.0 Mb encompassing *MEST*) were subjected to RT-PCR analysis using the somatic cell hybrids. Several transcripts showed allelic expression bias. These transcripts are being subjected to allelic expression analysis using human tissue material to evaluate the imprinting status in vivo. One transcript reproducibly showed paternal-specific expression in the somatic cell hybrid assay. This transcript is located in an intron of one isoform of *MEST* but is transcribed in the opposite direction to the gene. Based on these features, we tentatively named this antisense transcript *MEST-AS*. Northern blot analysis detected a 3.7 kb signal in RNA from paternal but not maternal hybrids. The expression of *MEST-AS* was detected in brain and testis among 12 human tissues tested by RT-PCR. Analysis of the mRNA sequence also revealed (i) the transcript is composed of at least two exons and (ii) that it does not contain any significant open reading frame suggesting the transcript may not encode a protein. We hypothesize *MEST-AS* may be involved in tissue-specific regulation of *MEST* gene.

***In vivo* DNaseI sensitivity studies reveal parent-of-origin-dependent differential chromatin structure in a 47 kb region containing the *Snurf-Snrpn* locus.** *J.R. Khadake*<sup>1</sup>, *R.D. Nicholls*<sup>2</sup>, *D.J. Driscoll*<sup>3</sup>, *T.P. Yang*<sup>1</sup>. 1) Department of Biochem. & Mol. Biol., Univ. Florida, Gainesville, FL; 2) Dept. of Psychiatry, Univ. Pennsylvania, Philadelphia, PA; 3) Dept. of Pediatric Genet., Univ. Florida, Gainesville, FL.

Mouse chr. 7C contains a cluster of imprinted genes spanning a region of 2 Mb which, is orthologous with the imprinted human Prader-Willi/Angelman syndrome (PWS/AS) region on chr. 15q11-q13. Microdeletions in PWS patients and deletion studies in mice have revealed the importance of the 5' region of the *SNURF-SNRPN* gene in regulating imprinted gene expression across these imprinted domains. PWS deletions in this region are associated with the loss of paternal gene expression and differential methylation of the entire imprinted gene cluster. To understand these long-range effects and to map potential *cis*-acting regulatory elements involved, we have analyzed the chromatin structure of 47 kb of the *Snurf-Snrpn* locus in mouse brain cells for DNaseI hypersensitive sites on the paternally and maternally-inherited alleles. Allele specificity of the hypersensitive sites was studied using transgenic PWS and AS insertion-deletion mice that carried either the maternally or paternally-inherited genes, respectively. We found that the major transcription initiation site of *Snurf-Snrpn* is flanked on either sides by hypersensitive sites that are most prominent on the paternal allele. Our studies also identified sites of weaker hypersensitivity that are present on both the maternal and paternal alleles. Weak hypersensitive sites were detected on the maternal allele upstream and downstream of the hypersensitive sites in the promoter region. Accessibility of the maternal and paternal alleles to DNaseI is also being studied to determine the state of chromatin in this region. The differential parent-of-origin-specific chromatin structure revealed by DNaseI hypersensitivity is likely to reflect regions that interact with *trans*-acting factors. These regions are likely to be involved in regulation of *Snurf-Snrpn* gene transcription and/or play a role in control of imprinted gene expression from the paternal mouse chr. 7C region.

**Cloning and characterization of novel members of the TRP superfamily in man and mouse: the MCOLN gene family.** *J.L. Falardeau*<sup>1,2</sup>, *J.C. Kennedy*<sup>1,2</sup>, *J.S. Acierno jr*<sup>1,2</sup>, *S.A. Slaugenhaupt*<sup>1,2</sup>. 1) Molecular Neurogenetics Unit, Massachusetts General Hospital, Boston, MA; 2) Harvard Institute of Human Genetics, Boston, MA.

Mucopolipidosis type IV (MLIV) is an autosomal recessive lysosomal storage disorder characterized by neurologic and ophthalmologic abnormalities. The gene responsible for this disorder, *MCOLN1*, has been cloned and shown to be defective in all MLIV patients. We have cloned the mouse homologue, *Mcoln1*, which shows 90% amino acid and 85% nucleotide identity to *MCOLN1*. *Mcoln1* maps to mouse chromosome 8 and contains an open reading frame of 580 amino acids. The mouse *Mcoln1* gene encodes two transcripts of 2.4 and 4.4 kb, while a single 2.4 kb transcript is seen in humans. Characterization of the larger *Mcoln1* transcript led to the discovery of a novel splice variant that encodes a 611 aa protein that differs in the c-terminal cytoplasmic tail. The identification of the mouse homologue is crucial to the development of mouse models for MLIV, and further investigation of the disorder.

Two additional members of the MCOLN gene family have been identified along with their mouse homologues. *MCOLN2* and *MCOLN3* both show a high degree of similarity to *MCOLN1*. Structural analysis of the amino acid sequences of the MCOLN gene family members predicts a protein motif consistent with the Transient Receptor Potential (TRP) family of proteins. All TRPs contain 6 transmembrane domains and are putative cation channels. The highest degree of synteny among the MCOLN family members occurs at the region of the 3rd through 6th transmembrane domains, including the putative cation pore. *MCOLN1* has been classified into its own TRP subfamily, TRPML. We propose that *MCOLN2* and *MCOLN3* are also members of the TRPML family. The identification of mutations in *MCOLN1* represents the first example of a neurological disease caused by a TRP-related channel.

**Complex organization and transcription profiles in the hyaluronidase gene region of mouse chromosome 9.** *T.L. Shuttleworth*<sup>1</sup>, *B.A. Wicklow*<sup>1</sup>, *M.D. Wilson*<sup>2</sup>, *B.L. Triggs-Raine*<sup>1</sup>. 1) Dept. of Biochemistry and Medical Genetics, University of Manitoba, Winnipeg, Manitoba, Canada; 2) Dept. of Biology, University of Victoria, Victoria, British Columbia, Canada.

Hyaluronidases are required for the breakdown of hyaluronan, an extracellular matrix glycosaminoglycan that is important in many cellular processes involving cellular proliferation and differentiation. Our laboratory has shown that mutations in the gene encoding human hyaluronidase 1, *HYAL1*, result in a mild lysosomal storage disorder, Mucopolysaccharidosis IX. The mild nature of the disorder led to the recognition of a family of three hyaluronidases located in tandem on human chromosome 3p21.3. We characterized a corresponding region of about 18 Kb on mouse chromosome 9 that contained, in order, *Hyal2*, *Hyal1*, and *Hyal3*. *Hyal1* and *Hyal3* were shown by molecular approaches to contain four exons and three introns. Another gene, *Fus2*, encoding an N-acetyltransferase, was partially located within intron 1 of *Hyal3*. Bioinformatic analyses and comparison of the human and mouse genomic sequences in this region confirmed the organization of the mouse genes and suggested a slightly different genomic organization in humans, with the entire *FUS2* gene located within the first intron of *HYAL3*. Northern blot analysis of adult mouse tissues revealed tissue expression profiles for *Hyal1* and *Hyal3* similar to their human counterparts but with more complexity in the number of transcripts representing the genes. Some larger transcripts were shown by Northern blot and RT-PCR to result from the co-transcription of *Hyal1* and *Fus2*; similar analyses demonstrated a cotranscript containing *Hyal1* and *Hyal3*. Our Northern analyses also showed that *Fus2*, whose expression is limited largely to the testis in humans, has acquired an expression profile similar to *Hyal1* in mouse. Transcripts containing *Hyal1* and *Fus2* are abundant, and have the potential to encode novel proteins. Further studies are needed to determine if the larger transcripts containing *Hyal1* and *Fus2* are translatable. This will allow the design of appropriate targeting vectors for mouse knockout models. Funded by CIHR (BTR) and an MHRC studentship (TLS).

**Functional Human Arylsulfatase A Expression in Insect cells.** *Y. Wang, M. Wang, X. Qi and Human Genetics.*  
Human Genetics, Children's Hospital , Cincinnati, OH.

Arylsulfatase A (ASA) is a lysosomal enzyme that catalyzes the hydrolysis of cerebroside sulfate and a variety of sulfate esters. Deficiency of ASA causes metachromatic leukodystrophy (MLD) through the abnormal accumulation of sulfatide. To study the structure-function relationship in ASA we expressed the recombinant human arylsulfatase A (rhASA) in Sf9 insect cells using a baculovirus system with full length hASA cDNA cloned into Bac-N-Blue vector. A high level of rhASA was secreted into the medium with the yield of rhASA in the serum-free medium up to 0.2 mg/ml. The culture medium was collected after the Sf9 insect cells were transfected (concentration:  $1-2.5 \times 10^6$  cells/ml and MOI: 15-35 virus/cell) by recombinant virus stock solution (activity  $8.9 \times 10^9$  pfu/ml). rhASA activity was assayed using artificial chromogenic substrate 4-nitrocatechol sulfate. The specific activity of the rhASA was 85% of native ASA in human brain fibroblast cells as evaluated by the cross-reacting immunologic material (CRIM)-specific activity assay. The expressed rhASA was purified and displayed a single band on an SDS-PAGE gel. Western blot analysis showed a 62 KDa rhASA molecule using rabbit anti-human ASA polyclonal antibody . This antibody had no cross-reactivity with arylsulfatases B and C. An enzymatic deglycosylation assay indicated that the purified rhASA was slightly glycosylated. Additionally, an MS based ASA activity assay was established using the native substrate, palmitoyl sulfatide. ASA activity stimulated by saposin B was measured with a detergent-free system. A number of rhASA mutant proteins were generated by site-directed mutagenesis to study post translational modification and metal binding functions. The present study provides a useful system for investigating the function - structure relationship of human ASA. .

**Impaired conditioned fear and enhanced long-term potentiation in Fmr2 knockout mice.** *Y. Gu<sup>1</sup>, K.L. McILwain<sup>1</sup>, E.J. Weeber<sup>2</sup>, T. Yamagata<sup>1</sup>, B. Xu<sup>1</sup>, B.A. Antalffy<sup>3</sup>, D. Armstrong<sup>3</sup>, C. Reye<sup>3</sup>, H. Zoghbi<sup>1,4,5</sup>, J.D. Sweatt<sup>2</sup>, R.E. Paylor<sup>1,2</sup>, D.L. Nelson<sup>1</sup>.* 1) Molecular and human genetics, Baylor College of Medicine, Houston, TX; 2) Division of neuroscience, Baylor College of Medicine; 3) Department of Pathology, Baylor College of Medicine; 4) Department of Pediatrics, Baylor College of Medicine; 5) Howard Hughes Medical Institute.

FRAAXE mental retardation (MR) results from expansion and methylation of a CCG trinucleotide repeat located in exon 1 of the X-linked FMR2 gene, which results in transcriptional silencing. The product of FMR2 is a member of a family of proteins rich in serine and proline, members of which have been associated with transcriptional activation. We have developed a murine Fmr2 gene knockout model by replacing a fragment containing parts of exon 1 and intron 1 with the *E. coli* lacZ gene, placing lacZ under control of the Fmr2 promoter. Expression of lacZ in the knockout animals indicates that Fmr2 is expressed in several tissues, including brain, bone, cartilage, hair follicles, lung, tongue, tendons, salivary glands, and major blood vessels. In the central nervous system, Fmr2 expression begins at the time that cells in the neuroepithelium differentiate into neuroblasts. Mice lacking Fmr2 showed impairment of both contextual and cued conditioning in the conditioned fear paradigm. Long-term potentiation (LTP) was found to be enhanced in hippocampal slices of Fmr2 KO compared to WT littermates. To our knowledge, this mouse knockout is the first example of an animal model of human mental retardation with impaired learning and memory performance and increased LTP. Thus, while a number of studies have suggested that diminished LTP is associated with memory impairment, our data suggest that increased LTP may be a mechanism that leads to impaired cognitive processing as well.

***MECP2* mutations in Rett syndrome negatively affect lymphocyte growth but do not affect imprinted expression in blood or brain.** *D. Balmer*<sup>1</sup>, *R.C. Samaco*<sup>1</sup>, *H.Y. Zoghbi*<sup>2</sup>, *J.M. LaSalle*<sup>1</sup>. 1) Med Micro & Immuno, UC Davis Sch Med, Davis, CA; 2) Med & Hum Genet & HHMI, Baylor Col Med, Houston, TX.

Rett Syndrome (RTT) is an X-linked dominant neurodevelopmental disorder caused by mutations in *MECP2*, encoding methyl-CpG-binding protein 2 (MeCP2). Due to random X-inactivation, female somatic cells are mosaic for expression of mutant *MECP2*. We therefore performed single cell cloning of T lymphocytes from four RTT patients with known *MECP2* mutations to isolate cells expressing mutant or wild-type *MECP2*. The frequency of *MECP2* mutant-expressing clones was compared to the percentage of mutant allele expression by RT-PCR on RNA derived from bulk lymphocytes. Mutant-expressing clones were present at a significantly lower frequency ( $P < 0.0001$ ) than expected. These results demonstrate that although *MECP2* is not essential for lymphocyte growth, expression of the *MECP2* mutation causes a growth disadvantage *in vitro*. Since MeCP2 is thought to silence transcription of methylated genes by recruiting Sin3A and histone deacetylase (HDAC), we hypothesized that MeCP2 may be required for silencing imprinted or methylated gene expression. The allelic expression of three different imprinted genes (*SNRPN*, *IPW* and *IGF2*) was examined by RT-PCR and RFLP analysis and demonstrated normal monoallelic expression of all RTT clones. To test the possibility that MeCP2 could regulate imprinted gene expression exclusively in brain, we examined the expression of 5 imprinted genes (*SNRPN*, *IPW*, *NECDIN*, *H19* and *IGF2*) in 4 RTT brain samples and also observed monoallelic expression. In addition, RTT lymphocyte clones were tested for expression of *IFNG*, a nonimprinted but methylated gene differentially expressed in T cell clones. *IFNG*-expressing and nonexpressing clones were observed independent of *MECP2* allelic expression, suggesting that *MECP2* mutations do not reverse methylation-induced silencing of this tissue-specific gene. Although the HDAC inhibitor Trichostatin A did not alter *SNRPN* expression, *IFNG* was induced in a previously *IFNG*-nonexpressing *MECP2*-mutant-expressing clone. In conclusion, our results do not support an essential role for either MeCP2 or HDAC in the silencing of imprinted genes.

**Identification of altered gene expressions on specific chromosomes in ICF syndrome cells using oligonucleotide microarrays.** *P. Jin, M.D. Kaytor, S.T. Warren.* Howard Hughes Medical Institute and Department of Genetics, Emory University School of Medicine, Atlanta, GA.

ICF syndrome is a rare autosomal recessive disease characterized by immunodeficiency, centromeric decondensation and facial anomalies, caused by mutations in the putative *de novo* DNA methyltransferase 3B (DNMT3B) gene. In ICF syndrome, the classical satellite II and III regions of chromosomes 1, 9 and 16 are hypomethylated, which leads to chromosomal instability. Despite these cytogenetic abnormalities, how the mutations in DNMT3B affect gene expression remains unclear. Here, using oligonucleotide microarrays we investigated changes in gene expression in ICF syndrome cells. Two B cell lines from ICF syndrome patients and three controls were used. Of 12,000 genes interrogated, over one hundred genes showed consistent changes in the two ICF cells compared to all control cells. Interestingly, one third of these genes are located on chromosome 1 and 6, but not on chromosome 9 and 16. Among the genes altered in ICF cells, several genes including SCHIP-1, RBPMS, PTPRK and UBD, are expressed only in ICF cells but not in any control cell. Since ICF syndrome is caused by the defects in DNA methylation, it is likely that the mutation in DNMT3B leads to demethylation and subsequent activation of these genes in ICF cells, which are transcriptionally repressed in control cells. The methylation status of these genes promoters is being evaluated. These studies will help us understand not only the molecular basis of ICF syndrome but also the roles of DNA methylation in human diseases.

**A canine model for Lafora's progressive myoclonus epilepsy.** *B.A. Minassian<sup>1</sup>, S.N. Fitzmaurice<sup>2</sup>, C. Rusbridge<sup>3</sup>, R.J.M. Franklin<sup>4</sup>, E. Young<sup>1</sup>, L. Ianzano<sup>1</sup>, G.D. Shelton<sup>5</sup>, S.W. Scherer<sup>1</sup>.* 1) Hosp Sick Children, Toronto, Canada; 2) Wey Referrals, Woking, UK; 3) Atkinson Morley's Hosp, Wimbledon, UK; 4) U of Cambridge, UK; 5) U of California, San Diego.

Lafora's disease (LD) is a severe autosomal recessive progressive myoclonus epilepsy. Myoclonic and photically induced seizures begin between ages 6 and 15 years in previously normal children and continue until death. Pathognomonic accumulations of an abnormal glucose polymer (polyglucosans; Lafora bodies) are found in most tissues including the perikarya of neurons. Mutations in at least two genes cause LD. One gene, EPM2A, encodes a rough endoplasmic reticulum-associated dual-specificity phosphatase. The locus for the other, much rarer, form(s) is unknown. LD has been documented in autopsies of several animals including parakeets, foxes, cats, dogs and cows. However, there is presently no natural or genetically engineered animal model for the disease. Because of the relatively frequent reporting of LD in animals, we sought to identify a natural animal model. We studied several dog breeds with autosomal recessive epilepsies. In the miniature wirehaired dachshunds (MWHD), affected individuals exhibited myoclonic and photoconvulsive seizures starting between ages 6 and 13 years and progressively worsening with time. Muscle biopsy showed polyglucosan accumulations, and brain at autopsy revealed typical Lafora bodies in neuronal perikarya. In order to determine the mutation in these animals, we screened a canine bacterial artificial chromosome library with each of the four exons of the human EPM2A gene and identified overlapping clones containing the corresponding dog *epm2a* exons. Sequencing of these exons and surrounding introns is in progress (90% complete). So far we have measured 95% identity between dog and human at the translated amino acid level. Interestingly, we also detected ~61% identity in the 5'UTR and intronic sequences (this was not observed in human and mouse comparisons). The affected MHWD belong to an extended pedigree with multiple affected members. This breed will serve as a model for the EPM2A form of LD, or will facilitate mapping of the other LD gene(s).

**mRNA may carry spatial genetic information-the topological configuration of mRNA affect the initial structure of nascent polypeptides.** *C.Q. Liu, S.Q. Liu.* Laboratory of cellular and molecular evolution, Kunming Institute of Zoology, Chinese Academy of Sciences, Kunming YN, 650223, P. R. China.

The hypothesis of "Three-dimensional genetic information flow" put forward by us describes that mRNA's structure can affect protein's folding, it indicates mRNA carries three-dimensional genetic information. The nonuniform of translational rate exert a phenotypic effect on the folding of encoded protein. We explored the factors that can affect translational rate through modeling structure of single-stranded mRNA (PDB ID is 1ILI) and ribosomal model, Some significant information was obtained: i. After mRNA hairpin is unfolded, the conformation of the single stranded mRNA is close relative to that of the corresponding mRNA hairpin structure, and it is helical region alternating with extended or coiled region when it is read by ribosome, such conformation of single stranded mRNA affect the translational speed. ii. we constructed the models that showed how the tRNA-mRNA interacted and orientated on ribosome. iii. Based on the model of ribosomal functional center and the novel structural information we gained, a new ribosomal model was built. iv. From the model of interaction between mRNA and tRNA, we observed that through the anticodon of relative rigid tRNA pairing with the codon of mRNA the distance between mRNA and CCA end of tRNA keep relative constant, and the shape of the connection line of the CCA ends was analogous to that of mRNA, it suggest that there exists relationship between the conformation of mRNA and that of nascent polypeptide. Our results imply that mRNA not only carry one-dimensional linear genetic information, but also possibly carry three-dimensional genetic information. The conformation of single stranded mRNA unfolded from hairpin of template mRNA can affect translational rate and initial structure of nascent polypeptide. Such brand-new translation mechanism has important biological significance for understanding the process of genetic information transferring from mRNA to protein.

**Development and characterization of a conditional M6p/Igf2r knockout mouse.** *S.K. Murphy<sup>1</sup>, A.A. Wylie<sup>1</sup>, A.J. McVie-Wylie<sup>2</sup>, D. Pulford<sup>1</sup>, C.M. Nolan<sup>1</sup>, T.C. Orton<sup>3</sup>, R.L. Jirtle<sup>1</sup>.* 1) Radiation Oncology; 2) Medical Genetics, Duke University Medical Center, Durham, NC; 3) Molecular Toxicology, AstraZeneca, UK.

The mannose-6-phosphate/Insulin-like growth factor 2 receptor (M6p/Igf2r) encodes for a multifunctional protein involved in lysosomal enzyme trafficking, tumor suppression and T-cell mediated immunity. M6p/Igf2r is also imprinted in mice with exclusive expression from the maternal allele. Previous M6p/Igf2r knockout studies resulted in neonatal lethality thus preventing any further analysis on the multifunctional role of the M6p/Igf2r during adulthood. To help elucidate the role of this gene in adult mice, we have generated conditional M6p/Igf2r knockout mice using the cre/loxP system. A transgenic line was produced in which M6p/Igf2r exon 10 was flanked by two loxP sites.

Concomitant expression of cre recombinase in cells with a floxed M6p/Igf2r exon 10 resulted in the creation of a null allele through the excision of exon 10 sequence and the introduction of a premature stop codon in exon 11. Germline inheritance of a maternal allele lacking exon 10 sequence due to cre-mediated excision resulted in a neonatal lethal phenotype identical to that observed in the original knockout study. Subsequently, tissue-specific knockout mice were produced harboring a null maternal M6p/Igf2r allele in either the liver or cardiac/skeletal muscle. Both knockout lines of mice are viable and the absence of M6p/Igf2r in the tissues of interest was confirmed by western blot analysis. Comparison of either the liver-specific or muscle-specific M6p/Igf2r knockout animals with wild-type littermates at 3 months and 12 months of age revealed no significant phenotypic or histological differences. M6p/Igf2r expression does not therefore appear to be critical to the normal function and maintenance of adult liver or muscle, however, the mechanistic role M6p/Igf2r plays in response to cellular stress remains to be determined. The successful creation of viable, tissue specific, M6p/Igf2r knockout mouse models will now allow detailed analysis of M6p/Igf2r function in a number of cellular processes including carcinogenesis, lysosomal trafficking and T-cell mediated immunity.

**Targeted disruption of the Nijmegen breakage syndrome gene NBS1 leads to early embryonic lethality in mice.**

*C. Vissinga*<sup>1,2</sup>, *D. Willerford*<sup>2</sup>, *P. Concannon*<sup>1,2</sup>. 1) Molecular Genetics, Virginia Mason Research Center, Seattle, WA; 2) University of Washington School of Medicine, Seattle, WA.

Nijmegen breakage syndrome (NBS) is a rare human autosomal recessive disorder characterized by microcephaly, immunodeficiency, and a significantly increased incidence in cancer. Phenotypically, NBS cells display chromosome instability, radiation sensitivity, and impaired cell cycle checkpoint control in response to ionizing radiation. We and others identified NBS1, the gene mutated in NBS patients as well as Nbn, the murine homologue of NBS1. Approximately 90% of NBS patients are homozygous for the 657del5 mutation of NBS1 that causes premature termination at codon 219. Since it is unknown whether the 657del5 mutation in NBS patients is a hypomorphic or null mutation, it is possible that complete inactivation of NBS1 might reveal novel functions for this protein. We therefore targeted the 5' region of the Nbn gene to produce a null allele. From Nbn<sup>+/-</sup> targeted ES cell clones chimeric mice were generated that transmitted the germline Nbn mutation to offspring. Nbn<sup>+/-</sup> mice were viable and healthy and grew normally. Nbn<sup>+/-</sup> mice did not display immune defects, as measured by flow cytometric analysis using a variety of T cell (lineage) markers and B cell (lineage) markers. Nbn<sup>+/-</sup> mice were fertile, but when interbred, homozygous mutants for the targeted Nbn allele were not found among the 98 offspring ( $p < 0.0001$ ) analyzed from one founder line. Thus it appears that Nbn, and by extension NBS1 is essential for growth of early embryonic cells. We determined the onset of lethality at embryonic day 6.5 (e6.5) and found several resorbed embryos at e7.5-e9.5. The timing of this apparent developmental block in Nbn<sup>-/-</sup> embryos is similar to that for knockouts of Rad50 and Mre11, whose products complex with nibrin. The results suggest that the observed phenotypes in NBS patients may not result from a complete inactivation of NBS1 but rather from hypomorphic truncation mutations that are compatible with cell viability. To test this hypothesis we are using full length NBS1 and various mutant forms to rescue the embryonic lethality of the Nbn<sup>-/-</sup> mice.

**The MJD1 homologue in *C. elegans* is expressed ubiquitously and is essential for egg laying and hatching.** *C. Santos*<sup>1</sup>, *M. Ailion*<sup>4</sup>, *J. Thomas*<sup>4</sup>, *J. Sequeiros*<sup>1,2</sup>, *P. Maciel*<sup>1,2,3</sup>. 1) UnIGENE, IBMC, Univ Porto; 2) ICBAS, Univ Porto; 3) ISCS-Norte, Paredes, Portugal; 4) Dept Genetics, Univ Washington, Seattle.

Machado-Joseph disease (MJD) is a neurodegenerative disorder caused by the expansion of a CAG/polyglutamine repeat within the coding region of the MJD1 gene. The function of the MJD1 gene product, ataxin-3, remains unknown.

We have identified a *C. elegans* gene encoding a protein with a high degree of homology to human ataxin-3, presenting 38 % identity and 56% similarity at the aminoacid level, suggesting evolutionary conservation. The *C. elegans* gene consists of 4 exons, encoding a protein with 317 aminoacids, which does not contain a glutamine tract.

In order to study the expression pattern of this MJD1-like gene in *C. elegans* we constructed a fusion protein using the genomic sequence of the gene, including the endogenous promoter region, and a GFP (green fluorescent protein) expression vector. The worm line obtained after injection of this construct showed a strong fluorescence during all stages of postnatal development. In the adult hermaphrodite, expression could be seen in many tissues like hypodermis, gut, neurons in the head and tail, spermatheca and coelomocytes.

Silencing of the gene expression using bacterial-mediated RNAi, originated morphological abnormalities in the adult hermaphrodite, with swelling and distortion of internal body structure due to accumulation of eggs. These were arranged in a disorganized manner, quite different from the regular disposition in the wild-type animal. Movement of the worms was slightly slower than usual. A small percentage of the animals showed protrusion of the vulva, and in another subgroup the eggs hatched inside the mother ("bag-of-worms" phenotype), leading to death of the animal.

Further analysis is needed to clarify in more detail the role of this gene in development and to confirm that it is the worm orthologue of the MJD1 gene.

**Interaction analyses elucidate the pathophysiology of HCM-causing missense mutations in cardiac myosin binding protein-C.** *J. Moolman-Smook<sup>1</sup>, L. Korkie<sup>1</sup>, T. DeLange<sup>1</sup>, C. Redwood<sup>2</sup>, H. Watkins<sup>2</sup>, V. Corfield<sup>1</sup>.* 1) US/MRC Centre for Molecular and Cellular Biology, University of Stellenbosch Health Sciences Faculty, SA; 2) Dept Cardiovascular Medicine, University of Oxford, UK.

Despite its identification as an integral thick filament protein ~30 years ago, the function of cardiac myosin binding protein-C (cMyBPC) has only become clear recently, while its sarcomeric arrangement is still speculative. Yet, understanding both facets is crucial due to its role in hypertrophic cardiomyopathy (HCM), a common genetic cardiomyopathy. The pathophysiology of HCM-causing truncation mutations in cMyBPC relate to loss of the thick filament-binding sites; however, the pathophysiology of missense mutations in domains of the protein with as-yet undefined interactions is unknown. C5 is one such domain, in which two HCM-causing missense mutations have been described.

We used the yeast two-hybrid system to screen a cardiac cDNA library for the ligand of domain C5, and investigated the effect of the HCM-causing R654H and N755K mutations on this interaction with quantitative B-galactosidase assays.

When more than  $7 \times 10^6$  clones were screened, domain C5 preferentially bound to clones encoding other domains of cMyBPC. The interaction was narrowed to domain C8 by deletion mapping. This interaction was significantly strengthened by the R654H mutation, and more so by the N755K mutation ( $p < 0.0001$ ).

Our data are consistent with a model for the sarcomeric arrangement of cMyBPC in which consecutive cMyBPC molecules trimerize into a tight collar around the thick filament, with overlaps of domains C5-C7 of one cMyBPC with domains C8-C10 of the next, with conservation of protein orientation. This interaction is likely to be dynamically formed and released during the phosphorylation cycle of cMyBPC, a process which is hindered by the tighter bonds introduced by the R654H and N755K mutations. This model synthesizes data from previous biochemical and structural studies, and for the first time, sheds light on the pathophysiology of HCM-causing missense mutations in cMyBPC.

**Ataxin-1 Binds a Brain-Specific RNA.** *H.G. Serra<sup>1</sup>, L.A. Duwick<sup>1</sup>, C.E. Byam<sup>1</sup>, H.Y. Zoghbi<sup>2</sup>, H.T. Orr<sup>1</sup>.* 1) Lab Medicine & Pathology, Univ Minnesota, Minneapolis, MN; 2) H. Hughes Medical Institute, Baylor College of Medicine, Houston, TX.

Spinocerebellar ataxia type 1 (SCA1) is an autosomal dominant neurodegenerative disease caused by the expansion of a polyglutamine repeat within ataxin-1. Recently, we demonstrated that ataxin-1 binds to RNA in vitro with decreasing affinity as the length of the polyglutamine repeat increases. As an approach to isolate and characterize in vivo RNA targets of ataxin-1, we synthesized biotinylated ataxin-1 that was further coupled to avidin resin making an affinity column. Nuclear extract from FVB mouse cerebellum was incubated with the affinity resin and the bound RNA population was isolated. The subpopulation of RNA specifically bound to ataxin-1 was then amplified by differential display RT-PCR and analyzed on a denaturing gel. Bands specifically bound by ataxin-1 were excised from the gel, reamplified, cloned and sequenced. We isolated a 7kb specific ataxin-1 bound mRNA (ABR-14) that is expressed only in brain and shows differential levels of expression among our different transgenic mouse lines. ABR-14 is downregulated in the affected ataxin-1 mutant mice that carry an SCA-1 allele with 82 CAG repeats (BO5). The gene is also downregulated in ataxin-1 knockout mice (SCA1<sup>-/-</sup>). In addition, this mRNA is upregulated in two other non-ataxic SCA-1 transgenic mouse lines. One of these lines expresses a wild type SCA-1 allele with 30 CAG repeats (AO2), the other contains 82 repeats and only expresses the SCA1 gene in the cytoplasm due to a point mutation in the nuclear localization signal (K772T). ABR-14 is presently being sequenced to determine the protein encoded by this mRNA. Subsequent studies will examine its role in SCA1.

**Transfection of MEFV, the gene causing Familial Mediterranean Fever, induces alterations in arachidonate lipoxygenation.** *Y. Torosyan, G. Wood, N. Raben, E. Mansfield, D.L. Kastner.* NIAMS/NIH, Bethesda, MD.

Familial Mediterranean fever (FMF) is an autoinflammatory disorder characterized by self-limited recurrent episodes of fever and aseptic leukocyte-mediated polyserositis. The causative gene, MEFV, was recently identified by positional cloning, and is expressed predominantly in granulocytes and activated monocytes. In the present study we examined the relationship between MEFV expression and the expression of two enzymes in the arachidonate pathway, 5-lipoxygenase (5-LOX) and 15-lipoxygenase (15-LOX). 5-LOX expression is restricted to myeloid cells and leads to the production of proinflammatory leukotrienes, while the more widely expressed, reciprocally regulated 15-LOX synthesizes antiinflammatory lipoxins. Since leukotriene levels are increased in the serum of FMF patients, we utilized multiplex RT-PCR to analyze 5- and 15-LOX gene expression as a possible function of MEFV expression. MEFV and 5-LOX demonstrated concordant expression profiles in monocytic cell lines: low levels in immature U937 cells and high levels in the more mature THP-1 cell line. HeLa cells (a fibroblast-like cervical carcinoma line) demonstrated low endogenous levels of MEFV and 5-LOX, which were upregulated by IL-4 (but not IL-13). Transient transfection of HeLa cells with wild-type MEFV upregulated 5-LOX expression to levels characteristic of leukocytes, and this effect was blocked by colchicine, the drug of choice in FMF. In addition, MEFV transfection altered the response of HeLa cells to cytokines. In transfected, but not untransfected, HeLa cells, both IL-4 and IL-13 induced 15-LOX expression, as is characteristic of monocytic cells. Interferon-gamma induced 15-LOX expression in untransfected, but not transfected, cells. MEFV transfection led to altered LOX expression patterns and cell survival (based on apoptotic rates by APO/BRDU) in HeLa cells in response to the proapoptotic agents CD95, staurosporine, NDGA, and colchicine. Thus, MEFV expression leads to changes in lipoxygenase gene expression, which probably play a role in both inflammation and apoptosis. cDNA microarray experiments are in progress to delineate more global effects of MEFV on gene expression profiles. *MEFV*.

**A novel FLNC interacting protein.** *I. Dalkilic*<sup>1</sup>, *T.G. Thompson*<sup>1</sup>, *M.A. Brosius*<sup>1</sup>, *A.A. Puca*<sup>1</sup>, *F. Muntoni*<sup>2</sup>, *L.M. Kunkel*<sup>1</sup>. 1) Department of Genetics, Children's Hospital, Boston, MA; 2) Neuromuscular Unit, Division of Pediatrics, Obstetrics, and Gynaecology, Imperial College School of Medicine, Hammersmith Hospital, London.

Mutations in genes encoding for the sarcoglycans (a-, b-, d-, g-) produce a limb-girdle muscular dystrophy phenotype; however, the precise role of this group of proteins in skeletal muscle is not known. We have recently identified a skeletal muscle specific form of filamin (FLNC or g-filamin) as a d- and g-sarcoglycan interacting protein. We have previously shown that FLNC localizes to both the sarcolemmal membrane and the Z-line in the contractile apparatus. Interestingly, in patients with sarcoglycanopathies or in mdx mice the percentage of FLNC in the membrane is greatly increased.

In order to better understand the role of FLNC in skeletal muscle we have also performed a yeast two-hybrid assay in the hope of finding novel interacting partners. One of the clones we isolated is a novel gene whose homolog in *C.elegans* gives an uncoordinated phenotype when mutated. This new gene maps to chromosome 1. It has been recently reported that two families with congenital muscular dystrophy (CMD1B) are genetically linked to a region in chromosome 1 containing this new clone. We have determined the genomic organization for this gene and currently analyzing DNA from these patients to determine if they have a disease causing mutation. We have also confirmed interaction of this protein with FLNC *in vitro* and are currently studying this interaction *in vivo*.

**Integrin is a compensatory transmembrane linkage to sarcoglycan in muscle.** *M. Allikian*<sup>1</sup>, *A.A. Hack*<sup>1</sup>, *S. Mewborn*<sup>1</sup>, *U. Meyer*<sup>2</sup>, *E.M. McNally*<sup>1</sup>. 1) Dept Medicine, University of Chicago, Chicago, IL., USA; 2) Wellcome Trust Centre for Cell-Matrix Research, Manchester UK.

Mutations in g-sarcoglycan cause autosomal recessive muscular dystrophy in humans and mice. In muscle, the sarcoglycan complex includes transmembrane proteins that normally associate with dystrophin and are secondarily reduced when dystrophin is mutated. Additionally, mutations in any single sarcoglycan gene produce instability of the entire sarcoglycan complex. Integrin  $\alpha 7$  is a transmembrane protein expressed mainly in skeletal and cardiac muscle that, like sarcoglycan, provides linkage between cytoskeletal elements and the extracellular matrix. Integrin  $\alpha 7$ , together with integrin  $\beta 1$ , constitute the major integrin type in mature skeletal muscle. Moreover, mice lacking integrin  $\alpha 7$  (Mayer et al. Nat. Gen. 1997) show muscle degeneration similar, but less severe, than those lacking g-sarcoglycan (Hack et al. J. Cell Biol. 1998). We found that integrin  $\alpha 7$  protein is upregulated at the plasma membrane in g-sarcoglycan null mice. To ascertain whether upregulation of integrin  $\alpha 7$  compensates for the loss of the transmembrane sarcoglycan linkage in sarcoglycan and dystrophin-deficient muscle, we bred mice lacking integrin  $\alpha 7$  with mice lacking g-sarcoglycan (*gxi*). These *gxi* mice exhibit profound rapid muscle degeneration leading to death at an average of 21-25 days of age. Histopathologic examination suggests pronounced and diffuse muscle degeneration as seen by Evans Blue dye uptake. Embryonic myosin heavy chain immunostaining of *gxi* muscle, together with normal in vitro fusion properties of *gxi* myoblasts indicates that *gxi* myotubes have normal regenerative capacity. Therefore, upregulation of integrin where sarcoglycan is absent reflects a compensatory transmembrane linkage for muscle cell attachment to the extracellular matrix. Furthermore, this argues that the function of sarcoglycan, like that of integrin, is as a mechanosignaling complex that integrates extracellular matrix signals for the growth and maintenance of myotubes.

**Gene expression analysis of muscle from Duchenne muscular dystrophy patients.** *J.N. Haslett, D. Sanoudou, S.A. Greenberg, H.G.W. Lidov, I.S. Kohane, A.H. Beggs, L.M. Kunkel.* Genetics Division, Children's Hospital, Harvard Medical School, Boston, MA.

Muscular dystrophy (MD) refers to a clinically and genetically heterogeneous group of myopathies defined by progressive degeneration of skeletal muscle fibers, leading to loss of muscle function. Mutations in the dystrophin gene were identified as causative of the most common muscular dystrophy, Duchenne MD. Dystrophin is linked to a group of integral membrane proteins, forming the dystrophin-associated protein complex (DAPC). To examine the DMD pathogenic pathways and identify new or modifying factors involved in muscular dystrophy we used Affymetrix oligonucleotide arrays to analyze the expression patterns of 12,600 genes in 12 DMD patients. The DMD data were compared to data from 10 normal skeletal muscle samples and to data obtained from other myopathic samples. Conventional statistical and fold-ratio comparisons and automated classification and clustering techniques were used to analyze the data, allowing identification of both disease-specific changes and changes due to the non-specific response of diseased muscle. This will enable additional analysis of DMD pathophysiological mechanisms and those of skeletal muscle more generally. When compared to other datasets, the DMD samples show a distinctive clustering pattern, presumed to reflect differences in the pathogenic pathways. Fold-ratio analysis suggests approximately 80 of the genes examined differ significantly in expression level between normal and DMD muscle. More genes were found to be overexpressed than underexpressed in DMD, potentially reflecting an increase in protein turnover, probably due to the degenerative and regenerative nature of the disease. As expected dystrophin was found to be substantially underexpressed in DMD muscle. In contrast, a number of other muscle genes (myosin, troponinT, alpha- and beta-tubulin, alpha-actinin) were found to be overexpressed in DMD muscle. The observed changes are being subjected to further statistical analysis and classification, in addition to experimental verification, to provide insight into the molecular mechanisms behind the DMD pathogenic pathways.

**Myne-1, a spectrin repeat protein of the myocyte inner nuclear membrane, interacts with A-type lamins.** *J.M.K. Mislow*<sup>1,2</sup>, *M.S. Kim*<sup>2</sup>, *E.M. McNally*<sup>2</sup>. 1) Department of Pathology, University of Chicago, Chicago, IL; 2) Department of Medicine, University of Chicago, Chicago, IL.

Mutations in the genes encoding the inner nuclear membrane proteins lamin A/C and emerin produce cardiomyopathy and muscular dystrophy in humans and mice. The mechanism by which these broadly expressed gene products result in tissue specific dysfunction is unknown. We have identified a protein of the inner nuclear membrane that is highly expressed in striated and smooth muscle. The primary sequence of myne-1 (myocyte nuclear envelope) predicts seven spectrin repeats, a serine-rich domain, and a single transmembrane domain at its carboxyl terminus. Between spectrin repeats five and six is an interrupted "LEM domain" so named for its presence in the nuclear envelope proteins MAN-1, emerin, and LAP2. The LEM domain of emerin has been shown to directly bind BAF, a protein shown to bridge and organize double-stranded DNA (dsDNA). Therefore myne-1 may play a role not only in structural integrity of the nuclear envelope through spectrin repeats, as spectrin does in erythrocyte membranes, but may also serve to localize dsDNA to the inner nuclear membrane. We found that myne-1 is expressed upon muscle differentiation in intranuclear foci concomitant with lamin A/C expression. In mature muscle, myne-1 and lamin A/C are perfectly colocalized, while colocalization with emerin is only partial. Moreover, we show that myne-1 and lamin A/C co-immunoprecipitate from differentiated muscle in vitro. Myne-1 maps to chromosomal 6q25, near the marker D6S420, placing it near two genetically mapped regions associated with cardiomyopathy. The muscle-specific inner nuclear envelope expression of myne-1, in conjunction with its interaction with lamin A/C, indicates this gene is a potential mediator of cardiomyopathy and muscular dystrophy.

**Homeobox Gene BP1 Expression Strongly Correlates with ER Expression in Human Breast Cancer.** *S. Fu<sup>1</sup>, A. Schwartz<sup>2</sup>, H. Stevenson<sup>1</sup>, G. Davenport<sup>1</sup>, P.E. Berg<sup>1</sup>.* 1) Dept Biochemistry & Molecular Biology, George Washington Univ Med Ctr, Washington, DC; 2) Dept Pathology, George Washington Univ Med Ctr, Washington, DC.

Homeobox genes are transcription factors that regulate a variety of genes involved in development and malignant transformation. In humans, we now report a newly identified divergent homeobox gene called Beta Protein 1 (BP1), functioning as a potential oncogene in human breast cancer. Previous studies in our laboratory demonstrated that BP1 is overexpressed in 47% of adult acute myeloid leukemia (AML) patients and 81% of pediatric AML patients, and that it is normally expressed in early hematopoietic progenitors. Overexpression of BP1 leads to increased growth and decreased erythroid differentiation in K562 leukemia cells, while reducing BP1 expression using antisense strategies leads to apoptosis. These data implicate BP1 as a survival factor and suggest a possible general mechanism by which BP1 could function as an oncogene. We demonstrated that BP1 is overexpressed in human breast cancer cell lines and tissues compared to normal epithelial cells and normal tissues by RT-PCR. Interestingly, BP1 overexpression strongly correlates with the tumorigenic potential in the cell lines examined. In tissues from 15 newly diagnosed breast cancer patients, we found that 73% expressed high levels of BP1 mRNA, whereas BP1 mRNA was undetectable in the remaining 27%. In contrast, BP1 was expressed (at a very low level) in only one of six normal breast tissues examined. BP1 expression was seen in 100% of the high grade, estrogen receptor (ER) negative, progesterone receptor (PR) negative tumor tissues and in 43% of ER positive, PR positive tumors. Additional breast tumors, as well as normal breast tissues, are being examined. These data suggest that BP1 may be a new marker in breast cancer for poor prognosis tumors and that it is a potential molecular target for therapy.

**Carboxylesterase 2 pharmacogenetics: intron/exon boundaries and polymorphism analysis.** *S. Marsh*<sup>1</sup>, *S.C. Pritchard*<sup>1</sup>, *C.M. Rose*<sup>1</sup>, *R. Donaldson*<sup>2</sup>, *P. Kwok*<sup>2</sup>, *H.L. McLeod*<sup>1,2,3</sup>. 1) Department of Medicine; 2) Department of Genetics; 3) Department of Molecular Biology and Pharmacology, Washington University School of Medicine, St Louis, MO.

Carboxylesterase enzymes are found in several animal species and play an important role in drug metabolism and as a physiologic barrier to environmental toxins. There are carboxylesterases in a range of human tissues including placenta, brain and liver. Liver carboxylesterases 1 and 2 (CES1 and CES2) are involved in the conversion of the anticancer drug CPT-11 to its active form SN-38, a topoisomerase I poison. It has been recently shown that CES2 has a 12.5 fold higher affinity for CPT-11 compared to CES1. Differences in CES2 activity in patients receiving CPT-11 could have serious implications for drug efficacy and toxicity. The genomic structure of the CES1 gene has previously been characterized, with 14 exons and a gene size of 30kb. Currently little is known about the CES2 gene structure. Using *in silico* analysis and direct sequencing, CES2 was localized to 16q13-22.1 between markers D16S3031 and D16S3139, approximately 11.1cM telomeric from CES1. CES2 contains 12 exons ranging from 43 to 296bp and 11 introns ranging from 81 to 2335bp. The genomic sequence spans 1546bp, with an 8460bp cDNA sequence. CES2 shares 73% nucleotide homology with CES1. Variations in drug metabolizing enzymes can contribute to toxicity and/or altered sensitivity/resistance to drug treatment. SNP mining by *in silico* methods identified an a1242t polymorphism in exon 9 causing a Glu392Val substitution and a synonymous c1714t polymorphism in exon 12. SNP a1242t was not detected using TDI in 95 Caucasians. PCR-RFLP analysis for c1714t observed an allele frequency of 1% in 95 Caucasians, 0% in 71 Chinese, and 4.9% in 92 Ghanaians (p=0.002). This data highlights the importance of studying world populations when assessing DNA variations. CES2 SNP analysis is now being integrated into a polygenic pharmacogenetic approach for prediction of CPT-11 toxicity and efficacy in patients with cancer.

**Regulation of the tissue specific expression of the nephrin gene.** *O. Beltcheva*<sup>1</sup>, *S. Kontusaari*<sup>2</sup>, *H. Putaala*<sup>1</sup>, *K. Tryggvason*<sup>1</sup>. 1) Div. Matrix biology, MBB, Karolinska Inst., Stockholm, Sweden; 2) Biocenter and Dept. of Biochemistry, University of Oulu, Oulu, Finland.

The gene for nephrin, a key component of the kidney filter was recently cloned in our laboratory. Using *in situ* hybridization and performing detailed analyses of nephrin knockout mice Putaala *et al.* showed that the gene is expressed in kidney, brain and the pancreas. In kidney the nephrin expression is restricted to podocytes. While nephrin protein is proposed to have a major role for the urine filtration in kidney, its functions in brain and pancreas remain unknown. Studies of the regulatory mechanisms of the nephrin gene may help to clarify aspects of podocyte differentiation and biology and they may also allow us to better understand the extrarenal functions of nephrin.

In order to identify the nephrin promoter sequence and to distinguish between the transcription elements involved in its tissue specific expression we cloned 5 different segments of the 5' upstream region of nephrin in front of b-galactosidase as a reporter gene. The constructs were then used to generate transgenic mouse lines. Tissue expression of LacZ in the different mouse lines was studied by histochemistry. We also performed analyses of the nephrin mRNA in brain and kidney. The results from our experiments show that differential expression of nephrin is controlled by both alternative splicing in the 5' end of the gene and existence of tissue specific elements in the promoter.

**Characterization of a new SOX10 target gene in the glial lineage.** *M. Girard, N. Bondurand, V. Pingault, N. Lemort, M. Goossens.* INSERM U468, et Laboratoire de Biochimie et Genetique Moleculaire, AP-HP, Hopital Henri Mondor, Creteil, FRANCE.

The identification of the mammalian testis determination factor SRY led to the description of the SOX gene family, a new class of genes coding for transcription factors. The SOX genes are highly conserved through evolution and appear to govern cell fate during embryogenesis. Among them, SOX10 was identified as an essential factor in the enteric nervous system (ENS), melanocytes and glial cells development. Mutations in the SOX10 gene have been described in several cases of Shah-Waardenburg syndrome, a neurocristopathy characterized by the association of Hirschsprung disease (intestinal aganglionosis) and Waardenburg syndrome (pigmentation defects and sensorineural deafness). Some patients also present with myelination defects of the central and peripheral nervous system. In accordance, it has been shown that SOX10 controls expression of MPZ, MITF and RET, which play important roles during glial cells, melanocytes and ENS development, respectively. Nevertheless, it is likely that SOX10 regulates other genes, some of them involved in glial cells development. To test this hypothesis, we sought the possible involvement of SOX10 in the regulation of expression of several candidate genes, including MBP, PMP22 and GJB1 (Connexin32). Here we show that SOX10 strongly activates GJB1 expression in transfection assays by binding directly to the proximal region of the GJB1 promoter, while SOX10 mutant proteins fail to transactivate this promoter. Moreover, SOX10 is known to modulate the function of other transcription factors such as PAX3, EGR2 and POU3F1. We demonstrate in our in vitro system that these factors act in synergy with SOX10 on the GJB1 promoter. Overall, our results provide insights into the regulation of Connexin32 expression, and underline the potential importance of SOX10 during the myelination process. Our study may also improve our understanding of molecular mechanisms involved in the phenotypic features of some peripheral neuropathies.

***In vivo* DNase I footprint analysis of the kinin B1 receptor gene promoter shows footprints specific to cell types.**

*M. Angers*<sup>1</sup>, *I. Paradis*<sup>1</sup>, *M. Bachvarova*<sup>2</sup>, *F. Marceau*<sup>2</sup>, *D.R. Bachvarov*<sup>2</sup>, *R. Drouin*<sup>1</sup>. 1) Dep. of Med. Biol., Faculty of Med., URGHM, Hopital St-François d'Assise, CHUQ, Univ. Laval, Québec, Québec, Canada; 2) Dep. of Med., Faculty of Med., URGHM, Hopital l'Hôtel-Dieu de Québec, CHUQ, Univ. Laval, Québec, Québec, Canada.

Nearly absent in healthy tissues under normal physiological conditions, the kinin B1 receptor (B1R) gene product is strongly and quickly upregulated following tissue injury and inflammation. Beside the participation of interleukin-1 beta (IL-1b), the molecular mechanisms implicated in this upregulation are not clearly defined. Gene promoters are best studied in their natural state in living cells and LMPCR (Ligation-Mediated Polymerase Chain Reaction) is the best approach to efficiently analyze DNA from living cells. *In vivo* DNA footprinting analysis of the B1R gene promoter region using dimethylsulfate and UVC was conducted on four human cell types: IMR-90, HEK-293, smooth muscle cells (SMC) and peripheral blood lymphocytes (PBL). The analysis revealed no difference between the footprinting patterns of the four cell types studied. Moreover, no additional change of the *in vivo* footprinting pattern was observed upon cell treatment with IL-1b. The footprinted sequences were analyzed using a transcription factor database and putative transcription factors were identified. In contrast to previous *in vitro* studies, no footprinted NF-kB site was found *in vivo*. To further characterize the promoter, *in vivo* DNase I footprinting analysis of the B1R gene promoter region was conducted on SMC and PCL. Although, no additional change of the *in vivo* footprinting patterns was found upon cell treatment with IL-1b, additional DNA sequences were footprinted upstream from the core promoter region. Interestingly, footprint differences were seen between PBL (cell expressing a non-functional B1R) and SMC (cell expressing a functional B1R). With over 1.4 kb of DNA analyzed in the promoter region, we can reasonably speculate that specific regulatory sequences are constitutively bound by transcription factors to ensure basal transcription and upregulation must be driven by protein cofactors, undetectable by *in vivo* DNA analysis.

**Characterisation of an erythroid-specific domain of histone acetylation across the  $\alpha$ -globin locus.** *C.A. Johnson<sup>1, 3</sup>, E. Anguita<sup>2</sup>, D.R. Higgs<sup>2</sup>, B.M. Turner<sup>1</sup>*. 1) Chromatin and Gene Expression Group, Anatomy Department, University of Birmingham Medical School, Birmingham, B15 2TT, UK; 2) Molecular Haematology Unit, Institute of Molecular Medicine, John Radcliffe Hospital, Oxford, OX3 9DS, UK; 3) Medical and Molecular Genetics, Birmingham Womens Hospital, Birmingham, B15 2TG, UK.

An important current issue in transcriptional regulation is the relationship between epigenetic phenomena, disease pathogenesis and the establishment, maintenance and inheritance of patterns of gene expression. Epigenetic control can be mediated by several types of chromatin modification and remodelling events that alter the structure of chromatin. Specifically, transcriptional activation and maintenance of an euchromatic state has a general correlation with post-translational acetylation of specific lysine residues in histone proteins.

To investigate the molecular events that link gene expression and the establishment of histone acetylation patterns, we have used the terminal 300kb of the short arm of human chromosome 16 (16p13.3) as a model system. This is a GC-rich telomeric region that contains a high density of unmethylated CpG-rich islands and widely-expressed genes, in addition to the  $\alpha$ -globin cluster. The embryonic and fetal/adult  $\alpha$ -like genes in this cluster are expressed in a defined tissue- and developmental stage-specific manner. To analyse patterns of histone acetylation at these genes and their regulatory elements, we have used the technique of chromatin immunoprecipitation (ChIP). In non-erythroid cells, there are moderate levels of all acetylated H4 histones across the  $\alpha$ -globin cluster, with low levels at heterochromatic and telomeric sequences. However, in erythroid cells there is a dramatic enrichment of the most highly acetylated histones (assayed with an antibody against histone H4 acetylated at lysine 5) in 100kb of chromatin that contains the  $\alpha$ -globin cluster and its regulatory element. This broad region of acetylation has sharp boundaries that may demarcate a complete chromosomal domain. Such domains are thought to be an important feature of genome organisation in eukaryotic chromosomes.

**Transcriptional regulation of murine matrix metalloproteinase 9 (MMP-9).** *E.E Hjörleifsdóttir*<sup>1</sup>, *S. Kontusaari*<sup>2</sup>, *K. Tryggvason*<sup>1</sup>. 1) MBB, Matrix biology, Karolinska Institute, Stockholm, Sweden; 2) Biocenter and Dept. of Biochemistry, University of Oulu, Oulu, Finland.

The aim of this project is to characterize the mechanisms that regulate tissue-specific expression of the MMP-9 gene. MMP-9 belongs to a large family of enzymes that are capable of degrading components of the extracellular matrix. These enzymes play a crucial role in many important biological processes, like embryonic development, bone remodeling, wound healing, and formation of blood vessels. Furthermore, MMPs are involved in tissue turnover in many pathological conditions; e.g. arthritis, tumor metastasis and tumor associated blood vessel growth. Prior to this study we have shown that a 5 kb long sequence upstream of the MMP-9 gene in mouse contains the regulatory elements necessary for tissue-specific expression in osteoclasts and migrating keratinocytes. In order to close in on the regulatory sequences, DNA-constructs containing different parts of the 5 kb sequence in front of a LacZ reporter gene, have been used to make transgenic mouse lines. So far four different mouse lines have been generated and the analysis of the reporter gene expression is ongoing. The whole region has been sequenced and the sequence analyzed both by searching databases for potential transcription factor binding sites and comparing the mouse sequence to the recently available human sequence. This computer analysis of the sequence gives further clues on where the regulatory elements may reside. The next step in the project will be to map the protein binding sites with direct methods, using methods like gel mobility shift assay, DNaseI hypersensitivity and Chromatin Immuno precipitation.

**Reduced expression of b<sub>2</sub>-glycoprotein I (apolipoprotein H) associated with a transcriptional initiation site mutation (-1C®A) that also disrupts the binding of hepatic nuclear factors.** *H. Mehdi, P. Desai, X. Wang, R. Zarnegar, S. Strom, M.I. Kamboh.* University of Pittsburgh, Pittsburgh, PA.

Human b<sub>2</sub>-glycoprotein I (b<sub>2</sub>GPI), also known as apolipoprotein H (apoH), is a subject of intense investigation, because it plays a central role in the production of antiphospholipid antibodies in the sera of patients with primary antiphospholipid syndrome and lupus. There is a wide range of interindividual variation in b<sub>2</sub>GPI plasma levels (<1 mg/dl to 35 mg/dl), and individuals with low b<sub>2</sub>GPI plasma levels are considered to be prone to thrombosis. The wide interindividual variation in b<sub>2</sub>GPI plasma levels is thought to be under genetic control, but its molecular basis is unknown. We have previously demonstrated that two polymorphisms in the coding region, Cys306Gly and Trp316Ser, are significant determinant of variation in b<sub>2</sub>GPI plasma levels. However, our *in vitro* mutagenesis and expression studies revealed that these mutations are not causative, but are in linkage disequilibrium with yet to be determined functional mutations. Therefore, we hypothesize that the 5' flanking region of b<sub>2</sub>GPI harbors functional mutations that determine interindividual variation in b<sub>2</sub>GPI plasma levels. To test our hypothesis, we screened 600 nucleotide region upstream of the transcriptional initiation site for mutation detection by D-HPLC. We identified a functional mutation at the transcriptional initiation site (-1C®A), which is associated with low b<sub>2</sub>GPI plasma and mRNA levels. We also found that the -1C®A mutation is associated with two-fold decrease in the luciferase reporter gene expression and it disrupts the binding of crude hepatic nuclear extracts as well as purified TFIID on electrophoretic gel mobility shift assay (EMSA). Screening of the b<sub>2</sub>GPI-deficient samples revealed that although the -1C®A mutation was associated with extremely low b<sub>2</sub>GPI plasma and mRNA levels, not all deficient samples had this mutation. Therefore, we conclude that the -1C®A mutation is one of the causative mutations and additional functional mutations may exist in the promoter region of b<sub>2</sub>GPI, which affect gene expression and ultimately plasma levels of b<sub>2</sub>GPI.

**Transcriptional regulation of the *GFRA1* gene.** *J.R. Hansford, S.L. Samson, D. Naumovski, J.B. Vanhorne, L.M. Mulligan.* Department of Pathology, Queen's University, Kingston, Ontario, Canada.

The glial cell line-derived neurotrophic factor receptor alpha-1 (GFRa-1) is an extracellular, non-signaling co-receptor for the RET receptor tyrosine kinase. GFRa-1 binds members of the glial cell line-derived neurotrophic factor (GDNF) family of ligands and presents them to RET. GFRa-1 has been shown to be expressed in cells of the central and peripheral nervous systems and in the kidney in a tissue-specific, developmentally regulated pattern. Mouse knock-out models have demonstrated that GFRa-1 is the RET co-receptor required for enteric neurogenesis and kidney development. In order to understand the mechanisms regulating the complex pattern of GFRa-1 expression observed in normal growth and development, we have studied the 5' upstream region of the gene, identified promoter(s) and transcriptional start sites and characterized tissue-specific transcriptional regulation of *GFRA1* expression. We have generated a sequence contig for the *GFRA1* 5' region and used this material to characterize the gene structure. Using a combination of 5' RACE and RT-PCR with total RNA from kidney and neuroendocrine cell types, we have identified three putative transcription start sites within our sequence contig. In order to confirm transcription from these sites, we generated a series of subclones from our contig, using the pGL3 luciferase based reporter system, and compared the relative luciferase expression associated with each construct in transient transfections. Our analyses suggest that *GFRA1* may have multiple distinct upstream regulatory sequences or promoters. In preliminary studies, we have identified the minimal promoter region required for transcription from each of our transcription start sites and have compared their activity in several cell types. Our data suggest that regulation of *GFRA1* transcription is complex and may require both common and cell-type specific regulatory elements. Continued investigation of the regulatory regions of *GFRA1* may help determine its role in development, growth and disease.

**Transcriptional regulation of the microsomal triglyceride transfer protein (MTP) gene by dietary cholesterol.** *J.*

*Lamb*<sup>1</sup>, *H.M. Sims*<sup>2</sup>, *A.M. Salter*<sup>2</sup>, *D.A. White*<sup>1</sup>, *A.J. Bennett*<sup>1</sup>, *M.A. Billett*<sup>1</sup>. 1) University of Nottingham Medical School, Nottingham, UK; 2) School of Bioscience, University of Nottingham, Nottingham, UK.

Microsomal triglyceride transfer protein (MTP) catalyses the transfer of lipids to apoprotein B in the assembly and secretion of triglyceride rich lipoproteins. The central role of MTP in lipoprotein assembly suggests that modulation of MTP activity may lead to changes in plasma levels of low-density lipoprotein (LDL), an important determinant for atherogenic risk. We have investigated the response of the human MTP gene promoter to dietary cholesterol. Truncated MTP promoter constructs linked to a luciferase reporter gene have been introduced by transient transfection into primary hepatocytes isolated from Syrian hamsters fed 0.24% cholesterol supplemented diets for 14 days prior to hepatocyte preparation. Expression from the MTP promoter was stimulated 3-4 fold in these cells compared with hepatocytes from control fed animals. It has been suggested that the response of MTP to cholesterol is mediated via two sterol response elements (SREs). Constructs deleting all previously identified transcription factor binding sites including both SREs show a 50% reduction in expression when compared to expression of the intact promoter in control cells. A 4-fold increase in expression, however, is maintained with cholesterol loading despite also deleting sites for hepatic nuclear factor (HNF)-1, activator protein-1 and HNF-4. We have identified two direct repeat elements with similarity to HNF-4 binding sites in the proximal MTP promoter. Co-transfection of an HNF-4 expression vector replicated the cholesterol response in both the intact MTP promoter and a construct containing only the two putative HNF-4 sites. Cholesterol loaded hepatocytes showed a greater increase in promoter activity with HNF-4 over-expression, implying that cholesterol facilitates the action of HNF-4. Expression of a dominant negative HNF-4 mutant reduced MTP expression in the presence and absence of over-expressed wild type HNF-4, suggesting that endogenous HNF-4 is normally required for MTP expression. Binding activities and the interaction of the HNF-4 sites in the MTP promoter are currently under study.

**Optimization of the cell membrane permeabilization for in vivo DNaseI footprint analysis.** *S. Ouellet, N. Dallaire, R. Drouin.* Med Biol, Faculty of Medicine, Hosp. St-Francois d'Assise, Quebec, Quebec, Canada.

Gene promoters are best studied in their natural state in the living cell and, thus, it is not surprising that in vivo DNA footprinting is one of the most accurate predictors of the state of transcriptional activity of genes. Ligation-Mediated Polymerase Chain Reaction (LMPCR) is the method of choice for in vivo footprinting and DNA structure studies because it can be used to investigate complex genomes, such as the human genome. In essence, LMPCR can be combined with a variety of modifying agents used for probing chromatin structure in vivo, including DNaseI. Compared to dimethylsulfate and UV, DNase I is less base selective, is more efficient at detecting minor groove DNA-protein contacts, provides more information on chromatin structure, displays larger and clearer footprints, and better delimits the boundaries of DNA-protein interactions. In vivo DNaseI footprint analysis is technically difficult to carry out because DNaseI cannot penetrate cells without previous cell membrane permeabilization. The membrane permeabilization presents problems of reproducibility. Furthermore, the permeabilization conditions may influence the ability of DNase I to detect DNA-protein interactions and special DNA structures. The purpose of our work was the optimization of the membrane permeabilization using either lysolecithin or Nonidet P40 to make it more reproducible without losing any DNA-protein interactions. We investigated the effect of the temperature (from 4C to 37C) and the duration (from 15 sec to 360 sec) of the treatment on permeabilization of human fibroblasts and lymphoblasts using either lysolecithin or Nonidet P40. We have found that the temperature had no significant effect on permeabilization of fibroblasts and lymphoblasts independently of the agent used. On the other hand, the permeabilization duration is very critical for fibroblasts whereas it does not affect the permeabilization efficiency of lymphoblasts. The permeabilization treatments with both agents did not produce any losses of DNA-protein interactions, independently of the temperature and duration of the treatments.

**Alterations in the SRY-box transcription factor *SOX1* in Cataract Patients.** *H.M. Prior*<sup>1</sup>, *R. Clarke*<sup>2</sup>, *E. Héon*<sup>3</sup>, *M.A. Walter*<sup>2</sup>. 1) Dept Biol, The King's University College, Edmonton, AB, Canada; 2) Depts. Ophthalmology and Medical Genetics, University of Alberta, Edmonton, AB, Canada; 3) Eye Research Institute of Canada, Department of Ophthalmology, University of Toronto, Toronto, ON, Canada.

Members of the SOX family of transcription factors contain a conserved DNA-binding domain, the SRY-box, which was originally identified in the product of the Sex-determining Region on the Y chromosome (SRY) gene. Human genetic disorders such as XY sex reversal, campomelic dysplasia, and Waardenburg-Hirschsprung disease are associated with mutations in various SOX genes. SOX1 function has been linked to proper expression of crystallin genes in the developing lens by studies done on chick and mouse eyes. In mouse, SOX1 deletion animals have small eyes and cataracts. We have therefore screened a panel of cataract patients for alterations in SOX1 coding sequence. Several polymorphisms were identified in patients and controls, including a six basepair duplication creating a glycine-valine duplication in the putative protein. A thymine to cytosine transition near the 3' end of the gene, generating a tyrosine to histidine substitution, was identified in affected members of a family with zonular cataracts that was not found in a panel of 120 control chromosomes. This substitution in the SOX1 coding sequence may be associated with cataract formation in this family. The functional consequences of this alteration are currently being investigated.

**Hes-1, a known transcriptional repressor, functions as a transcriptional activator for the human acid a-glucosidase gene in human fibroblast cells.** *B. Yan, N. Raben, P. Plotz.* Arthritis/Rheumat Br, Clin Ctr, NIAMS/NIH, Bethesda, MD.

Transcription factor Hes-1 is one of a family of basic helix-loop-helix proteins which play important role in myogenesis, neurogenesis, hematopoiesis, and sex determination. It has been demonstrated that Hes-1 is a transcriptional repressor for a number of known genes. We have previously shown that Hes-1 acts as a repressor that binds to a silencer element within intron 1 of the human acid a-glucosidase gene, which encodes a lysosomal enzyme for glycogen-breakdown. Deficiency of the enzyme results in Glycogen Storage Disease type II (Pompe syndrome), an inherited progressive muscle disease. In this study, we have determined its transcription activity in normal human fibroblast cells with same reporter gene system. Using constructs containing the DNA element that demonstrates repressor activity in Hep G2 cells, we found that this element functioned as an enhancer in human fibroblast cells. Electrophoretic mobility shift assay and super-shift assays with specific antibodies revealed that binding pattern of transcription factors Hes-1 and YY1 to the element in fibroblast cells is the same as in Hep G2 cells. Site-directed mutagenesis analysis showed that Hes-1 alone functioned as a transcriptional activator. Furthermore, co-transfection experiments with expression plasmid for Hes-1 significantly enhanced the activating effect of Hes-1. Thus, these data demonstrate for the first time that Hes-1, a known transcriptional repressor, can work as a transcriptional activator - on the acid a-glucosidase gene in human fibroblast cells. The finding expands the complexity of our understanding of Hes-1 and related basic helix-loop-helix proteins.

**Mutations of *QRX*, a Novel Retinal Homeobox Gene, Are Associated with Retinal Degeneration.** *Q. Wang*<sup>1</sup>, *S. Chen*<sup>2</sup>, *N. Esumi*<sup>1</sup>, *P. Swain*<sup>3</sup>, *H. Haines*<sup>4</sup>, *P. Mathers*<sup>5</sup>, *J. Heckenlively*<sup>6</sup>, *S. Jacobson*<sup>7</sup>, *E. Stone*<sup>4</sup>, *A. Swaroop*<sup>3</sup>, *D. Zack*<sup>1</sup>. 1) Johns Hopkins University, Baltimore, MD. 21287; 2) Washington University School of Medicine, St. Louis, MO. 63110; 3) University of Michigan, Ann Arbor, MI. 48105; 4) University of Iowa College of Medicine, Iowa City, IA. 52242; 5) West Virginia University School of Medicine, Morgantown, WV. 26506; 6) University of California-Los Angeles School of Medicine, Los Angeles, CA. 90095; 7) University of Pennsylvania, Philadelphia, PA. 19104.

**Purpose:** To identify transcription factors involved in regulating photoreceptor-specific gene expression. **Methods:** Yeast one-hybrid assays, Northern blot analysis, In situ hybridization, radiation hybrid mapping, EMSA, DNaseI footprinting, cell transfections, sequencing and sequence analysis. **Results:** Yeast one-hybrid screens of a bovine retina cDNA-Gal4 fusion library using elements (Ret-1 and BAT-1) from bovine rhodopsin promoter as baits yielded a number of putative positive clones. Among them was one encoding a novel paired-like homeobox gene, designated as *Qrx*. *Qrx* is highly and preferentially expressed in multiple retinal cell types. Bovine and human *QRX* share 91% identity at amino acid level. The homeodomain of human *QRX* is 93% identical to that of *RX/RAX*, a factor that has previously been shown to be essential for eye development. Although the in vitro target sites for *QRX* and *RX/RAX* are identical, namely the Ret-1 and BAT-1 sites, in transient transfection assays *QRX* and *Rx/Rax* preferentially transactivate Ret-1 and BAT-1 sites, respectively. *QRX* specifically increases the effect of *CRX* and *NRL* on Ret-1 by more than 10 fold. Human *QRX* consists of 3 exons and maps to chromosome 19. Three putative heterozygous mutations have been found in *QRX*, 2 in cone-rod dystrophy patients and 1 in an age-related macular degeneration patient, but not in normal controls. **Conclusion:** As a novel member of the transcription factor network operating in the retina, *QRX* appears to be important in maintaining normal retinal function.

**Tal1 binding to centromeric satellite DNA: A new role for Tal1 in transcription repression.** *J. wen*<sup>1</sup>, *T. Noguchi*<sup>1</sup>, *K. shigematsu*<sup>2</sup>. 1) LCB,NIDDK, NIH, BETHESDA , MD; 2) Department of cell and molecular biology, Lawrence Berkeley National laboratory, Cyclotron Road,Berkeley CA.

Tal1 is a bHLH transcription factor that plays a role in blood development, and is aberrantly expressed in T-ALL. Although Tal1 can function as an activator or repressor of transcription during hematopoiesis via its E-box binding motif and by interacting with transcription factor, GATA-1, and other coactivators or corepressors, few target genes for Tal1 have been identified. To elucidate target sites for Tal1 interaction, we use immunoprecipitation of genomic fragments bound to Tal1 in K562 erythroleukemia cell nuclear extracts. We found two Tal1 binding fragments consisting of multiple E-boxes overlapping a binding site for SATB1 (special AT-rich sequence-binding protein 1), that binds to the matrix attachment regions (MARs) of DNA and can act as a repressor. One of these fragments, EEGS, contained two E-boxes, CATTG and CATCTG, and a GATA binding site, specific for GATA-1 and GATA-2, within the SATB1 site. Chromatin immunoprecipitation confirmed that EEGS bound Tal1 in the chromatin of K562 cells. The EEGS core sequence with the two E-boxes, GATA motif, and SATB1 binding site, exhibited intrinsic Tal-1 dependent repression in reporter gene assays in K562 cells, but not in HeLa cells. Repression increased with increased expression of Tal1 and required the intact E-boxes and GATA motif for maximal affect. The EEGS sequence shares up to 98% homology with select satellite DNA (localizing particularly to 1q12 and 1q11), repetitive elements localizing to the centromere region of the chromosome. In addition to SATB1 binding to EEGS, we determined a direct interaction between Tal1 and SATB1, and overexpressing SATB1 in K562 cells can augment the transcriptional repression produced by the EEGS, both raising the possibility that Tal1 may recruit or stabilize SATB1 binding to selected satellite DNA to involve in the formation of heterochromatin in this region to maintain the repressed state of centromeric associated DNA. These data identify a subset of centromeric satellite DNA with Tal1 binding in erythroid cells, and suggests a new role for Tal1 in transcription repression.

**FMR1 expression in multiple tissues: post-mortem study of a male carrier of a premutation.** *F. Tassone<sup>1</sup>, R.J. Hagerman<sup>2</sup>, C. Greco<sup>3</sup>, E. Spector<sup>4</sup>, P.J. Hagerman<sup>1</sup>*. 1) Dept Biological Chemistry, University of California at Davis, Davis, CA; 2) M.I.N.D. Institute, University of California Davis Medical Center, Sacramento, California; 3) Department of Pathology, UC Davis Medical Center, Sacramento, California; 4) Department of Pediatrics, UCHSC, Denver, Colorado.

To understand the possible significance of inter-tissue heterogeneity to clinical involvement in fragile X syndrome, we have determined the CGG repeat size and FMR1 expression levels in multiple tissues from a 70 year old male carrier of a fragile X premutation. The proband, with a premutation of 135 CGG repeats in peripheral blood leukocytes, was debilitated by a neurodegenerative condition prior to his death. Our analysis of the CGG repeat in various tissues found no variation in repeat size. The lack of inter-tissue heterogeneity is supportive of somatic stability for premutation alleles. We have also analyzed the tissue-specific distribution of FMR1 mRNA in 13 different brain regions and in peripheral blood leukocytes. The range of FMR1 mRNA in various tissues was quite broad, with the highest expression levels found in superior temporal gyrus, hippocampus, frontal cortex and amygdala. FMR1 mRNA in peripheral blood leukocytes was 3.8 ( $\pm 0.13$ )-fold higher than normal, in agreement with previous observations for individuals with a premutation of  $>100$  CGG repeats. Immunocytochemistry revealed a deficit in FMRP expression, with 62 percent FMRP-positive lymphocytes, indicating post-transcriptional deficit. Neuropathologic examination showed the presence of discrete, eosinophilic intranuclear inclusions in neuronal and glial cells throughout the brain. The origin and composition of these inclusions are currently under investigation.>>.

**ID4 is both a transcriptional target of BRCA1 and a negative regulator of BRCA1 expression.** *P.L. Welch, R.M.G. Hernandez, M-C. King.* Departments of Genomic Sciences and Medicine, University of Washington, Seattle, WA.

In many sporadic breast and ovarian tumors, expression of BRCA1 protein is reduced. Identification of genes that regulate BRCA1 expression may elucidate the role of BRCA1 in sporadic tumorigenesis. ID4 (inhibitor of DNA binding 4) is a helix-loop-helix protein that functions as a dominant negative regulator of basic helix-loop-helix transcriptional regulators. ID4 is a negative regulator of BRCA1 expression. Modulation of ID4 expression resulted in inversely regulated BRCA1 expression; increased expression of ID4 was associated with anchorage-independent growth (PNAS 98:130, 2001). We analyzed genes regulated by BRCA1 in epithelial cell lines in which levels of BRCA1 were controlled by induction via ecdysone. We selected lines in which BRCA1 was modestly induced (~8-fold) over endogenous message, because gross over-expression of BRCA1 induces apoptosis. RNA from induced and uninduced cells was isolated and hybridized to Affymetrix expression arrays. In three independent experiments, expression of ID4 was consistently increased in response to BRCA1 induction ( $P=0.0025$ ). If in normal cells BRCA1 expression is regulated by ID4, which in turn regulates BRCA1, then loss of BRCA1 could result in loss of ID4. To determine if this regulatory loop is relevant to breast tumorigenesis, we stained primary breast tumors with antibodies to both ID4 and BRCA1 proteins. Normal breast epithelium stained positive for both BRCA1 and ID4. BRCA1 protein expression was reduced or absent in 46 of 79 primary tumors (58%). ID4 expression was dramatically reduced in 33 of these 46 BRCA1-deficient tumors, but in only 7 of 33 tumors with normal BRCA1 expression. Loss of BRCA1 and ID4 protein expression were highly correlated in the breast tumors ( $r^2=0.65$ ).

**DNAH3: characterisation of the full length gene and mutation search in patients with Primary Ciliary**

**Dyskinesia.** *J.-L.C. Blouin<sup>1</sup>, C. Gehrig<sup>1</sup>, D. Jeganathan<sup>2</sup>, L. Bartoloni<sup>1</sup>, C. Rossier<sup>1</sup>, G. Duriaux-Sail<sup>1</sup>, N. Scamuffa<sup>1</sup>, H.M. Mitchison<sup>2</sup>, C.D. DeLozier-Blanchet<sup>1</sup>, S.E. Antonarakis<sup>1</sup>.* 1) Division of Medical Genetics, University Cantonal Hospital and School of Medicine, Geneva, Switzerland; 2) Department of Paediatrics and Child Health, Royal Free and University College Medical School, University College London, United Kingdom.

Primary Ciliary Dyskinesia (PCD), or Immotile Cilia Syndrome, is an autosomal recessive disorder with an incidence of 1/20,000 characterized by dysmotility to complete immobility of cilia/flagella with ultrastructural defects in most patients. In addition to upper respiratory tract infections, bronchiectasis and male subfertility, 50% of cases show situs inversus (Kartagener syndrome). We have previously performed a genome-wide linkage analysis (Blouin et al. *Eur J Hum Genet* 2000 8:109-118) showing extensive genetic locus heterogeneity, as suggested by the variety of ciliary ultrastructural defects. However, we proposed several potential loci on chromosomes 3p, 5p, 8q, 11p, 15q, 16p, 17q and 19q, most of them colocalizing with genes coding for dyneins, the major structural proteins of dynein arms defective in 50% of PCD families and therefore strong candidates for the disease. Since then, mutations in dynein genes DNAI1 and DNAH11 have been detected in patients. Our most suggestive/almost significant linkage interval on chromosome 16p near marker D16S748 (NPL score =2.96 on families with dynein arm deficiency) contains the gene for axonemal dynein heavy chain DNAH3. We report here full length sequence characterisation of DNAH3 gene and mutation search in patients with PCD. Genomic and transcript organisation of the gene were determined using cDNA isolated by RT-PCR and searches of genomic sequences and ESTs. The DNAH3 gene spans 200 Kb of genomic DNA and is composed of approximately 60 exons coding for a protein of 4400 amino acids, highly homologous to known dynein heavy chain paralogues and orthologues. Mutation search, currently under progress, is performed in selected patients, with the double occurrence of allele sharing among affected sibs using a polymorphic marker close to the gene and ultrastructure defects of dynein arms.

Program Nr: 1082 from the 2001 ASHG Annual Meeting

**The alternative splicing of DMPK is affected *in cis* by the CTG expansion of Myotonic Dystrophy Type-1..** A.J. Gibb, M.G. Hamshere. School of Life & Env. Sciences, University of Nottingham, Nottingham, Nottinghamshire, UK.

Myotonic Dystrophy Type-1 (DM1) is the most common muscular dystrophy affecting 1/8000 live births in Western European and North American populations. The condition is characteristically multisystemic with symptoms including myotonia, progressive muscle weakness, cardiac conduction defects, cataracts, frontal balding in males, testicular atrophy, diabetes, hypersomnia and mental retardation. The condition segregates in an autosomal dominant manner and is caused by a CTG triple-repeat expansion found in the 3'UTR of the gene for a serine-threonine protein kinase, DMPK.

*DMPK* has several alternative splice forms. The frequency of their use and the nature of any effect mediated by the repeat, either *in cis* or *in trans*, has not yet been fully investigated. Using affected and control fibroblasts heterozygous for a SNP in Exon 10 of *DMPK*, we have been able to develop a fluorescence based quantitative RT-PCR method in order to discriminate between transcripts derived from the affected and unaffected chromosomes. By a combination of fluorescence and size discrimination, we have established that the profile of alternative splicing is affected *in cis* by the myotonic dystrophy triplet repeat expansion.

**Identification of alternatively spliced messengers for IL-12p35 and IL-12Rb2 genes.** *H. Elloumi Zghal, S. Abdelhak, M.R. Barbouche, K. Dellagi.* Immunology Dept, Institut Pasteur, Tunis, Tunisia.

Interleukin 12 is a disulfide heterodimeric glycoprotein comprised of two subunits designated p35 and p40. This pleiotropic cytokine is produced primarily by antigen-presenting cells. IL-12 plays a pivotal role in promoting cell mediated immunity against intracellular pathogens as it is a dominant factor in directing the development of Th1 cells producing high levels of IFN-g. These immune responses are mediated through its interaction with a high affinity cell surface receptor (IL-12R) on activated T and NK cells composed of at least two subunits termed b1 and b2. In the present study, we have identified alternatively spliced mRNA variants for IL-12p35 and IL-12Rb2 genes. For IL-12p35 gene, three transcripts including the normal one have been identified. One alternative transcript corresponds to exon 2 skipping generating a premature stop codon at position 300-302. The other messenger shows an in-frame deletion of exon 3 resulting in an isoform deleted for 38 amino acids. For IL-12Rb2 gene, subcloning of RT-PCR products allowed the identification of a normal as well as an alternatively spliced transcript missing exons 4 to 7. Furthermore, the latter is sometimes associated to an insertion of 102bp between exons 8 and 9. This inserted sequence corresponds to the use of cryptic splice sites within intron 8 and shows a homology of 91% with Alu Sx subfamily. These isoforms deleted for the cytokine receptor-homologous region (CHR) may correspond to a diminished ligand binding capacity. Our findings may suggest that the identified alternatively spliced transcripts of IL-12p35 and IL-12Rb2 genes correspond to regulatory forms that diminish the ligand-receptor interaction. Such post transcriptional mechanism may contribute to the host protection against the deleterious effects of IL-12 over-production.

**A 16-bp duplication of splice-acceptor site results in silencing of the downstream copy of the splice-acceptor site.**

**How are duplicated splice-acceptor sites selected in pre-mRNA splicing?** *K. Ohno<sup>1</sup>, A. Tsujino<sup>1</sup>, B. Anlar<sup>2</sup>, A.G. Engel<sup>1</sup>*. 1) Dept Neurology, Mayo Clinic, Rochester, MN; 2) Hacettepe University, Ankara, Turkey.

Congenital myasthenic syndromes (CMS) are caused by genetic defects in presynaptic, synaptic, or postsynaptic molecules. In a CMS patient, we identified a homozygous 16-bp duplication of the splice-acceptor site at the intron 10/exon 11 boundary of the acetylcholine receptor  $\epsilon$  subunit gene (eIVS10-9ins16). The duplication consists of 8 nucleotides at 3' end of intron 10 ('cccgccag', introns are shown in lower case letters) and 8 nucleotides at 5' end of exon 11 ('CTGCCTTC', exons in capital letters).

Wild type: ctgccaggggggaggctcctaaggcccaccccggtgtttccccgccagCTGCCTTC

eIVS10-9ins16: tcctaaggcccaccccggtgtttcccgcagCTGCCTTCcccgccagCTGCCTTC

To test which of the duplicated splice-acceptor sites is activated in pre-mRNA splicing, we constructed a minigene that spans exons 9 to 12 of the acetylcholine receptor  $\epsilon$  subunit gene and introduced it in COS cells. RT-PCR analysis of cytoplasmic RNA of transfected COS cells revealed that only the upstream copy of the splice-acceptor site is active. Although the duplication disrupts the polypyrimidine tract of the downstream copy of splice-acceptor site, the pyrimidines-to-purine ratio remains unchanged in the polypyrimidine tract. However, a 'tttt' stretch at positions -13 to -10 of the upstream copy is changed to 'cctt' for the downstream copy. As a stretch of t's is more efficient than c's in the polypyrimidine tract, we mutated 'cctt' to 'ttt', but the downstream copy still remained inactive. To test a hypothesis that a distance between the branch point sequence and the 'ag' dinucleotide is important, we moved the invariant 'a' in the 'tcctaag' branch point sequence 15 bp downstream to make a new branch point sequence of 'cggtgat' in both wild-type and mutant minigenes. These mutations, however, had no effect on splicing. Further mutagenesis studies are in progress to identify essential *cis*-acting elements that govern selection of the duplicated splice-acceptor sites.

**Human L1 ORF2 is translated in an unconventional manner.** *R.S. Alisch, J.V. Moran.* Human Genetics & Internal Med., Univ. of Michigan, Ann Arbor, MI.

LINES (L1s) are the most abundant retrotransposons in the human genome. Retrotransposition-competent L1s are 6.0 kb and contain a 5' untranslated region (UTR), two non-overlapping open reading frames (ORF1 and ORF2), and a 3' UTR that ends in a polyadenylic acid tail. It previously was demonstrated that certain L1s could retrotranspose in cultured human cells and that mutations in conserved domains of the ORF1- and ORF2-encoded proteins (ORF1p and ORF2p) block retrotransposition. To identify cis-acting sequences in L1 RNA important for ORF2 translation, we performed site-directed mutagenesis to alter conserved bases in the vicinity of the putative ORF2 initiation codon. Frameshift mutations positioned upstream of the initiation codon had virtually no effect on retrotransposition, whereas the introduction of a stop codon (L11X) near the presumptive amino terminus of ORF2p completely abolished retrotransposition. Remarkably, missense mutations in the putative initiation codon (AUG to AUA; AUG to CCC) only slightly reduced retrotransposition (to ~30% of wild-type levels). To prove that endogenous sources of reverse transcriptase (RT) were not promoting the retrotransposition of these constructs, we created a double mutant that contains the AUG to CCC mutation as well as a point mutation in the RT domain of L1 ORF2. This double mutant cannot retrotranspose, indicating that the ORF2p is synthesized in the original mutants. To further demonstrate that ORF2p was synthesized in our full-length L1 constructs, we fused a luciferase reporter gene to ORF2. Luciferase activity was detected in HeLa cells transfected with retrotransposition-competent constructs (~10-fold above background levels). By contrast, cells transfected with retrotransposition-defective mutants (e.g., L11X) exhibited only background levels of activity. Because there is no evidence for splicing of L1 mRNA, and there are no other candidate initiation codons (AUG, GUG, CUG) near the presumptive amino terminus of L1 ORF2, our data suggest that L1 ORF2 translation may be initiated from an unconventional (non-AUG) codon.

**Human KPNA2 regulation of cell cycle and tumorigenesis pathways.** *B.A. Fullmer, K. Lieuallen.* Research and Development, Gene Logic Inc., Gaithersburg, MD.

Karyopherin alpha 2 (KPNA2) belongs to a family of importins that are receptors for nuclear localization signals implicated in nuclear transport systems. Importins are responsible for the initial docking at the nuclear pore complex and are also associated with the interactions that occur within the pore complex during translocation. KPNA2 has been associated with cellular functions ranging from proliferation to viral susceptibility. To determine the specific pathways associated with KPNA2, transfection studies were performed with KPNA2-specific antisense oligonucleotides (ASOs) on human umbilical vein endothelial cells (HUVEC). Cells were treated with either KPNA2-specific ASO, a control missense ASO, or the transfection reagent alone (vehicle control). Total RNA from each cell line was hybridized over the Affymetrix known gene array (12,000 known genes, HU 60K sub A), to assess global transcriptional changes as a result of loss of KPNA2 mRNA expression. Genes that were regulated in both sets of transfection assays were examined and assigned to biochemical/physiological pathways. A total of 268 genes out of 12626 genes showed significant differences in expression levels between cells treated with the ASO and vehicle control. Of these genes, 39 showed a significant difference with a p value of less than or equal to 0.01 in the antisense oligo versus the missense and vehicle control. Seven of these genes are known to participate in the cell cycle while four are known to be implicated in tumorigenesis.

**Isolation, expression, and subcellular localization of the mouse *Tmprss3*.** *M. Guipponi*<sup>1</sup>, *K. Shibuya*<sup>2</sup>, *M. Vasquez*<sup>3</sup>, *L. Dougherty*<sup>4</sup>, *N. Scamuffa*<sup>1</sup>, *E. Guida*<sup>5</sup>, *M. Okui*<sup>2</sup>, *C. Rossier*<sup>1</sup>, *P.L. Marzella*<sup>5</sup>, *N. Shimizu*<sup>2</sup>, *H.S. Scott*<sup>4</sup>, *S.E. Antonarakis*<sup>1</sup>. 1) Div Medical Genetics, University of Geneva Medical School, Switzerland; 2) Dpt of Molecular Biology, Keio University School of Medicine, Tokyo, Japan; 3) Dpt of Morphology, University of Geneva Medical School, Switzerland; 4) Genetics and Bioinformatics group, The WEHI, Royal Melbourne Hospital, Australia; 5) Department of Otolaryngology, The University of Melbourne, Australia.

Recently, we have found that the human *TMPRSS3* gene is responsible for two previously defined non-syndromic autosomal recessive deafness located on human chromosome 21q22.3, DFNB8 and DFNB10 (Scott et al Nat Genet 27:59, 2001). *TMPRSS3* encodes a putative protein that contains 4 recognizable domains: transmembrane-LDLRA-SRCR-Serine protease. Several loss-of-function mutations have been identified in families with these forms of deafness. In order to investigate the expression profile and the function of the *TMPRSS3* protein, we isolated the mouse homologue (*Tmprss3*), and determined its expression profile and subcellular localization. The mouse *Tmprss3* gene is split into 13 exons over 20 kb of genomic sequence on chromosome 17 and encodes a predicted protein that shows 95% identity with the human protein. *Tmprss3* expression was detected by RT-PCR in rat modiolus, stria vascularis, organ of Corti and cultured spiral ganglion cells. RNA in situ hybridization on mouse embryos ranging from 8.5 to 10.5 dpc, and on inner ear sections derived from 5-day postnatal mice showed *Tmprss3* expression in the supporting cells the organ of Corti and in the spiral ganglion. The subcellular localization of EGFP-*TMPRSS3* fusion protein in transfected HeLa cells was found diffuse in the cytoplasm; colocalization experiments suggested that *TMPRSS3* is an endoplasmic reticulum protein. These data provide first insights toward the definition of the precise role of *TMPRSS3* in the function of the inner ear. The generation of a mouse with targeted disruption of the *Tmprss3* gene is in progress; this will provide an animal model for the elucidation of the molecular pathophysiology of DFNB8/10.

**Analysis of mutations in Survival of Motor Neuron (*SMN1*) gene through model systems.** *N. Owen*<sup>1</sup>, *S.E. Squire*<sup>1</sup>, *U.R. Monani*<sup>2</sup>, *M. Sendtner*<sup>3</sup>, *A.H.M. Burghes*<sup>2,4</sup>, *K.E. Davies*<sup>1</sup>. 1) Dept of Human Anatomy & Genetics, University of Oxford, Oxford, England, UK; 2) Dept of Neurology, College of Biological Sciences, Ohio State University, Columbus, OH; 3) Dept of Neurology, University of Würzburg, Josef-Schneider Strasse 11, Würzburg, Germany; 4) Dept of Molecular Genetics, College of Biological Sciences, Ohio State University, Columbus, OH.

Childhood onset Spinal Muscular Atrophy (SMA) is a common autosomal recessive disorder characterised by the loss of a motor neurons. The Survival Motor Neuron (*SMN1*) gene, present in two almost identical copies on chromosome 5, is mutated in the majority of patients. Both *SMN* genes undergo varying degrees of alternative splicing, with *SMN1* producing mainly full length transcript, as compared to *SMN2* whose expression results in predominately alternatively spliced transcripts. Therefore, in patients the amount of full length SMN protein is markedly reduced. *SMN2* copy number correlates strongly with disease severity; more copies resulting in increased SMN protein and a milder phenotype. To further understand the effect of patient *SMN1* mutations and alternative splicing of *SMN2* we have characterised mutant SMN proteins. To specifically investigate loss of exon 5 we have generated transgenic mice expressing *SMN2D5*. A second transgene utilises the E134K patient mutation known to alter interaction of SMN with Sm proteins. The ability of each transgene to rescue the lethality of the null mouse has been investigated. Up-regulation of *SMN2* may act as a potential therapeutic route, therefore the effects of increasing spliced *SMN* isoforms needs to be investigated.

Previously, analysis of our model system in *S.pombe* has lead to the identification of a lethal missense mutation in a conserved region of the SMN protein. This conserved domain is in human exon 5. Proteins known to interact with this region of SMN are profilins. *In vitro* assays have been carried out to investigate the effect of mutation this domain on binding to PFNs. The generation of transgenic models utilising *SMN* mutations and binding assays will provide further insight into the pathogenesis of SMA.

**Characterization, tissue expression, and chromosomal assignment of the human RAB22A gene belonging to Rab small GTPases.** *S. Kussmann, S. Worch, A. Hehr, I. Hansmann, D. Schlote.* Institut fuer Humangenetik und Medizinische Biologie; Halle, Germany.

The mouse chromosome 2 segment (MMU2) corresponding to human chromosome 20 (HSA20) is known to be involved in both, maternal as well as paternal noncomplementation (genomic imprinting). Uniparental disomies for distinct regions of MMU2 result in different neonatal lethalties with opposite anomalous phenotypes, strongly suggesting the presence of imprinted genes in this region. These chromosomal regions show a conserved synteny of gene loci to human 20q13 segment, predicting the presence of imprinted genes in this syntenic human chromosomal region. We have identified a new gene in this region of interest which is located on a BAC RPCIB753L051096 proximal to GNAS1 on HSA 20q13. Cloning and sequencing the full-length cDNA revealed a novel isoform of the human RAB22 subfamily of small GTP-binding proteins located in distinct intracellular compartments and playing an important role in the regulation of vesicular trafficking. Based on the EST WI-12997 this new isoform was isolated containing 2242 nucleotides and is designated RAB22A. Structurally, the RAB22A encodes a polypeptide of 194 amino acids which has 97% identity to the canine rab22. Northern blot analysis revealed ubiquitous expression slightly increased in heart. The genomic structure was completed by database analysis and sequencing of the isolated BAC clone RPCIB753L051096. The gene consists of 7 exons spanning about 50 kb of genomic sequence. Physical and FISH mapping revealed that RAB22A is located on a BAC RPCIB753L051096 proximal to GNAS1 but downstream of PCK1 on human chromosome 20q13. Supported by a grant of the DHGP.

**PITX2 homeodomain protein forms a dimer: Insights from natural and synthetic mutations.** A. Kuburas<sup>1</sup>, I. Saadi<sup>2</sup>, A.F. Russo<sup>1,2</sup>. 1) Department of Physiology and Biophysics; 2) Genetics Program, University of Iowa, Iowa City, IA.

Rieger syndrome is an autosomal-dominant human disorder characterized by glaucoma, mild craniofacial dysmorphism, umbilical stump abnormalities, and occasional growth abnormalities. Knockout studies have shown that mouse *Pitx2* is required for development of multiple organs, including the pituitary. We have previously described a mutation in a Rieger syndrome patient that changes a key lysine at position 50 of the homeodomain to a glutamic acid (K88E). This mutation yields a dominant negative protein and this phenotype is most prominent in the presence of the pituitary transcription factor Pit-1. We now provide evidence that this dominant negative effect is mediated by dimerization of K88E with wildtype PITX2 in the yeast two-hybrid assay. The significance of this dimerization is supported by the finding that a different Rieger homeodomain mutant (T68P) that is not dominant negative showed much weaker dimerization activity. The K88E mutant may possibly interact with portions of PITX2 to a greater extent than the wildtype interaction. These results suggest that the position 50 residue in the PITX2 homeodomain may play a role in facilitating PITX2 dimerization and the subsequent dominant negative phenotype of the K88E Rieger mutation.

**Genomic characterisation of the human PRNP/PRND locus.** *E. Makrinou*<sup>1</sup>, *J. Collinge*<sup>1</sup>, *M. Antoniou*<sup>2</sup>. 1) MRC Prion/Neurogenetics Unit, Imperial College School of Medicine, London, England; 2) Division of Medical and Molecular Genetics, GKT Medical and Dental School, Kings College, London, England.

Chromatin domains can consist of a mixture of genes, with some been ubiquitously expressed and others been tissue specific. Although the PRNP gene is found to be ubiquitously expressed, the levels of expression in a given tissue can vary markedly, with highest amounts observed in neurons and lymphocytes. In addition, Northern blot analysis of two genes laying within close distance, PRND and a second novel gene downstream of PRND, showed that they are both tissue specific. Here we report the genomic characterisation and expression profile of these two genes. Regulatory elements within the same domain may be shared with genes of similar or divergent characteristics, like PRNP and PRND. These findings may provide a new insight, regarding the presence and further study of any regulatory elements and/or a Locus Control Region (LCR), within the domain.

**Mutations Generating a Premature Stop Codon in the Protein S Gene (*PROSI*) Lead to Nonsense-Mediated mRNA Decay and Protein S Deficiency *PROSI*.** X. Munyoz, Y. Espinosa-Parrilla, N. Sala. Medical.Molecular Genetic Center, IRO, L'Hospitalet de Llobregat, Barcelona, Spain.

The purpose of this study was to analyse the effect at the mRNA level of different nonsense and frameshift mutations in the protein S gene (*PROSI*) that segregate with quantitative protein S (PS) deficiency in Spanish families with thrombophilia. **Methods:** Platelet *PROSI* mRNA was obtained from healthy controls and from 9 PS deficient patients who were heterozygotes for a missense mutation (M599T) and for 8 mutations postulated to generate a premature stop codon. Four of these are nonsense (Q238X, S293X, R410X, W465X), two are short frameshift deletions (333,334delTG and 1877delT), one alters the splice site (1302+5G->A) and one is a missense and a splice site mutation (404,405AG->GT). *PROSI* cDNA fragments covering *PROSI* exons 1 to 15 were obtained by RT-PCR and directly sequenced. The results obtained were confirmed by analysis of transcribed polymorphisms for which the patients were heterozygotes. **Results:** Electrophoretic analysis of the amplified cDNA fragments revealed the presence of normal-sized fragments in all cases, thus excluding splicing alterations. cDNA corresponding to both the normal and the mutated alleles was only observed from the M599T missense mutation in exon 15 and from the 333,334delTG mutation in exon 2. In the other 7 mutations analysed, the amplified cDNA sequence corresponded to that of the normal allele, indicating the absence (or presence in inappreciable quantities) of transcripts from the mutated allele. **Conclusion:** From these results we concluded that nonsense-mediated mRNA decay, rather than the synthesis of a truncated protein, is the main cause of quantitative PS deficiency associated to mutations which generate a premature stop codon.

We thank DGICYT (PB94/1233) and FIS (98/0645) for grants.

**A candidate gene for FSHD within each of the 3.3 kb repeated elements of the 4q35 locus.** C. Mattéotti<sup>1</sup>, J. Gabriëls<sup>2</sup>, J.M. Saint-Remy<sup>2</sup>, R.R. Frants<sup>3</sup>, G. Padberg<sup>4</sup>, D. Collen<sup>2</sup>, F. Coppée<sup>1</sup>, A. Belayew<sup>1,2</sup>. 1) Lab. Molecular Biology, University of Mons-Hainaut, Mons, Belgium; 2) CMVB, University of Leuven, Leuven, Belgium; 3) MGC Dept Human Genetics, Leiden University Medical Center, Leiden, The Netherlands; 4) Dept Neurology, University of Nijmegen, Nijmegen, The Netherlands.

Facioscapulohumeral muscular dystrophy (FSHD) is linked to partial deletions of a tandem 3.3 kb repeat array in the heterochromatic D4Z4 locus: the repeat copy number decreases from 10-100 in non-affected individuals down to 1-8 in patients. We have identified a putative double homeobox gene (*DUX4*) in each of the two 3.3 kb repeats left in the rearranged D4Z4 locus of a patient (Gabriëls et al, 1999, Gene 236: 25-32). Functionality of this gene was questioned because the TATAA box is mutated to TACAA, and it lacks intron and a polyadenylation signal. We tested *DUX4* activity *in vivo* by injecting a plasmid with the 13.5 kb *EcoRI* DNA fragment of the patient locus into a mouse leg muscle. An active gene would express a human protein, triggering synthesis of antibodies in the mouse. Indeed, a strong immunoreactivity was detected in the sera of the 6 injected mice by ELISA using plates coated with part of *DUX4* expressed in *E. coli* as an MBP fusion. A much weaker response was found against MBP alone or in the preimmune sera.

A northern blot identified a 2.5- and a 1.3-kb *DUX4* RNA in total RNA extracted from mouse C2C12 cells transfected with this plasmid. The protein intracellular location was studied in cells transfected with a CMV-*DUX4* expression vector: a rabbit serum directed against the homeodomains detected the *DUX4* protein at the nuclear envelope, partially overlapping with lamin B and emerin.

In conclusion, we think *DUX4* is a new candidate gene for FSHD. We hypothesize that in non-affected individuals, the *DUX4* genes are in a repressive heterochromatin. The deletion linked to FSHD would open this chromatin and allow expression of the *DUX4* genes present in the few repeats left, producing a nuclear envelope protein toxic to muscles. (Supported by the AFM-France, the FSH Society, the MDA, and the G. Shaw family).

**Aggregation of misfolded proteins is a selective and sequence-specific process that determines the composition and cellular distribution of aggregates.** *M.I. Milewski<sup>1</sup>, J.E. Mickle<sup>1</sup>, J.K. Forrest<sup>1</sup>, B.A. Stanton<sup>2</sup>, G.R. Cutting<sup>1</sup>.* 1) Inst Genetic Medicine, JHU Sch Med, Baltimore, MD; 2) Dept Physiol, Dartmouth Med Sch, Hanover, NH.

Abnormal protein aggregation is associated with growing number of inherited and sporadic genetic diseases. However, little is known about relationship between the sequence of aggregating peptides and the process of intracellular accumulation. To test the specificity of protein aggregation, we examined the cellular localization and composition of aggregates formed by different aggregation-prone proteins. We show that CFTR- and huntingtin-derived constructs accumulate in separate aggregates when co-expressed in the same cell, which indicates that aggregation of misfolded proteins is a selective process. We also demonstrate that fusion to a reporter protein considerably alters the distribution of aggregating peptide. When fused to green fluorescent protein (GFP), the peptide containing amino acids 1370-1480 of CFTR accumulates in large perinuclear or nuclear aggregates. The same CFTR fragment devoid of GFP localizes predominantly to discrete accumulations associated with mitochondria. Importantly, both types of accumulation are dependent on the presence of the same two amino acids within the CFTR sequence. The inability of different misfolded proteins to co-aggregate or form a specific type of aggregates is accompanied by differences in association with molecular chaperones, which suggests a possible role for chaperones in regulating the pattern of protein accumulation. Together, our results contradict the common view that protein aggregates are non-specific associations of misfolded molecules. Instead, we propose that sequence- and structure-specific interactions are critical for protein aggregation, thus suggesting potential avenues for preventing aggregate formation in disease states.

Program Nr: 1095 from the 2001 ASHG Annual Meeting

**Targeted Disruption of the *Pcyt1b* Gene by Homologous Recombination.** *M.A. Karim, J. Wang, S. Jackowski.*  
Protein Science Division, Department of Infectious Diseases, St. Jude Children's Res Hosp, Memphis, TN.

The mouse *Pcyt1b* gene encodes two isoforms, CCTb1 and CCTb2, of the second CTP:phosphocholine cytidylyltransferase, a key regulator of phosphatidylcholine biosynthesis in mammals. We cloned a 9-kb genomic *Pcyt1b* gene fragment by screening a mouse 129/SvE library in IEMBL3 with a homologous human 5' *PCYT1B* cDNA probe. The isolated genomic clone contained the entire exon 1 plus flanking regions. The *Pcyt1b* gene is located on the X-chromosome and we disrupted the gene in male (XY) embryonic stem cells W9.5, resulting in a (-/0) genotype. Four individual stem cell clones with bona fide karyotypes were injected into blastocysts and clone #25 gave rise to chimeric males with germline expression of the disrupted allele. Agouti male offspring from the clone #25 chimeras did not carry the disrupted allele, as expected, whereas female agouti mice were heterozygous. CCTb-deficiency apparently did not alter male reproductive function, despite high-level expression in the testes of the wild-type allele. Heterozygous females will be mated with wild-type C57Bl6 males to obtain male mice hemizygous for the disrupted allele, which will be analyzed for the CCTb-deficient phenotype and also will be mated with heterozygous females to obtain (-/-) female mice. The availability of the *Pcyt1b* (-/0) and (-/-) mice will be useful for the investigation of the role of this gene in phospholipid metabolism, particularly X-linked disorders. (Supported by NIH GM45737, ALSAC and Cancer Center CORE grant to St. Jude Children's Research Hospital.).

**Two apparently unrelated proteins encoded by three related mRNAs having monocistronic and dicistronic structures.** *M. Takagi*<sup>1,2</sup>, *R. Sakaguchi*<sup>1</sup>, *Y. Tohyama*<sup>2</sup>, *J. Yamada*<sup>1</sup>, *T. Watanabe*<sup>1</sup>, *T. Kurihara*<sup>2</sup>, *T. Suga*<sup>1</sup>. 1) Dept. of Clinical Biochemistry, Tokyo University of Pharmacy and Life Science, Tokyo, Japan; 2) Institute of Life Science, Soka University, Tokyo, Japan.

We isolated three related cDNAs, C184L (2.5 kb), C184M (1.2 kb), and C184S (0.7 kb) from a developing mouse brain cDNA library. C184S is the 5'-end portion and C184M is the 3'-end portion, respectively, of C184L. C184S and C184M are monocistronic structures having open reading frames of 199 amino acids (ORF1) and 189 amino acids (ORF2), respectively; C184L has both ORF1 and ORF2 (dicistronic structure). Although the corresponding mRNAs were expressed ubiquitously in the tissues examined, C184L and C184M mRNA expressions were relatively high in the embryonic brain. Southern blot analysis suggests that all of the three related mRNAs are transcribed from the same single gene. The intervening region of C184L cDNA between ORF1 and ORF2 contained a promoter sequence for C184M mRNA, which is transcribed from the corresponding genomic sequence. Our results indicate that the mRNAs encoding these apparently unrelated proteins are transcribed within an adjacent or overlapping area on the genome, suggesting the same origin of the two transcription units. A cDNA (Sjögren's syndrome/scleroderma autoantigen 1, human autoantigen p27) encoding human homologue of ORF1 was isolated by immunoscreening using autoimmune antiserum from a patient with anti-centromere antibodies; a cDNA encoding a different mouse isoform of ORF2 was cloned as a novel mammary tumor virus receptor. The normal functions of both ORF proteins remain unclear. Cloning, genomic structure, and expression analysis of the human counterparts are ongoing, and could be an important step to understand their physiological functions and potential association with Sjögren's syndrome and scleroderma.

**Characterization of brain acyl-CoA hydrolase (BACH) gene.** *J. Yamada, Y. Kuramochi, R. Sakaguchi, T. Watanabe, M. Takagi, T. Suga.* Dept. of Clinical Biochemistry, Tokyo University of Pharmacy and Life Science, Tokyo, Japan.

Acyl-CoA hydrolases cleave acyl-CoA thioesters to free fatty acids and coenzyme A. The potency of this enzyme may be a mechanism that modulates cellular concentrations of acyl-CoAs to regulate various cellular events, including fatty acid metabolism and gene expression, for which only limited evidence is available. To better understand the physiological function of this enzyme, we characterized the brain acyl-CoA hydrolase (BACH) gene. Human BACH gene (1p36.31-p36.11) spanned about 130 kb and comprised 13 exons, generating several isoforms through a mechanism of alternative use of exons. Four first exons (1a-1d) can alternatively be used and three patterns of splicing occur at an exon X located between exons 7 and 8 that contains an internal 3'-splice acceptor site. There were motives for mitochondrial targeting sequence encoded in exons 1b and 1c, and a nuclear localization signal in exon 9. Real-time quantitative RT-PCR revealed that among the isoforms, BACHa with a sequence corresponding to exon 1a is exclusively expressed in the human brain, with or without 73- or 165-bp inserts derived from exon X that create premature stop codons. Similar results were obtained for mouse homolog of BACH gene, with respect to the genomic organization and the isoform expressed in the brain. Mouse BACHa cDNA encoded a 338-amino acid polypeptide with 96% identity to human BACHa, indicating that the BACH gene is highly conserved beyond the species. While palmitoyl-CoA hydrolase activity was widely distributed in mouse tissues, it was marked in the brain, consistent with BACH almost exclusively found there, where >80% of the enzyme activity was explained by BACH present in the cytosol. Immunohistochemistry demonstrated neuronal localization of BACH both in the central and peripheral nervous systems. A 50-kDa polypeptide along with the major 43-kDa polypeptide seemed to be translated from the BACHa mRNA using differential in-frame ATG triplets as the initiation codon. These findings will make a large contribution to the functional analysis of BACH gene including genetic studies.

**Identification and characterization of a novel Strongly Expected Brain Specific Transcript (SEBS1) as candidate for imprinting.** *S. Worch, S. Kussmann, A. Hehr, I. Hansmann, D. Schlote.* Institut fuer Humangenetik und Medizinische Biologie; Halle, Germany.

Uniparental disomies for distinct regions of mouse chromosome 2 result in opposite anomalous phenotypes, strongly suggesting the presence of imprinted genes in this region. These chromosomal regions show a conserved synteny of gene loci to human chromosome 20q13 segment, predicting the presence of imprinted genes in this syntenic human chromosomal region. Starting out from the human EST marker A005Z17 we have identified a novel transcript within the candidate region which is strongly expected to be brain specific as Northern hybridisation revealed expression of a 3,2 kb transcript in brain only. The corresponding cDNA contains a 1680 bp ORF encoding 559 amino acids. The genomic structure was determined by database analysis and sequencing of the isolated BAC clone RPCIB753A07289. The gene consists of 13 exons spanning a genomic region of approximately 250 kb. Analysing possible gene function, database search using the translated gene product revealed homology to 3 hypothetical human proteins of yet unknown function sharing a striking homology of 120 aa at the C-terminal end suggesting the existence of a shared domain. This homology seems to be evolutionary conserved down to *D. melanogaster* and *C. elegans*. Recently, mouse cDNA clones have been isolated which will serve to verify the physical localisation in the distal region of MMU2 and the mouse gene will be the basis to investigate monoallelic expression using a translocation mouse model. This work was supported by a grant of the DHGP.

**Molecular characterization of a Rieger syndrome nonsense mutation in PITX2.** I. Saadi<sup>1</sup>, A. Kuburas<sup>2</sup>, A.F. Russo<sup>1,2</sup>. 1) Genetics Program; 2) Department of Physiology and Biophysics, University of Iowa, Iowa City, IA.

Rieger syndrome is an autosomal-dominant developmental disorder characterized by ocular anterior chamber anomalies, dental hypoplasia, mild craniofacial dysmorphism, and umbilical stump formation in humans. Mutations in the PITX2 bicoid-type homeodomain protein have been found in Rieger syndrome patients. The C-terminal tail of PITX2 has been shown to contain a DNA binding inhibitory domain and to be involved in protein-protein interaction with Pit-1. Here we report the characterization of a nonsense mutation (W133Stop) originally described by Semina *et al.* (1996) that truncated the C-terminal 139 amino acids of PITX2. We have performed electrophoretic mobility shift assays (EMSAs) using the W133Stop truncated protein to show greater binding than the wildtype protein to the bicoid site (TAATCC). Consistent with the greater DNA binding, the truncated protein also showed greater activation of the *Prolactin* and *Gad1* promoter-reporter constructs in CHO (Chinese hamster ovary) cells. However, co-transfection of wildtype PITX2 with W133Stop mutant resulted in suppression of the increased W133Stop activity in CHO cells. We are currently repeating these experiments in N2a (neuroblastoma) and LS8 (dental epithelium) cells. Preliminary results have shown that W133Stop poorly transactivated *Prolactin* and *Gad1* promoters in N2a cells, contrary to CHO cells. We are also examining the ability of W133Stop to dimerize with wildtype PITX2 using a yeast two-hybrid assay. Finally, we are testing the effect of W133Stop mutant following injection of mutant RNA into *Xenopus* embryos.

**The FMF Protein, Pyrin, Specifically Interacts with the SH3 Domain of the Cytoskeletal Protein PSTPIP1.** *N.G. Shoham, E. Mansfield, G. Wood, M. Centola, D.L. Kastner.* Inflammatory Biology Section, Rheumatic Disease Genetics and Genomics Branch, NIAMS,NIH, Bethesda, MD 20892.

Familial Mediterranean fever (FMF) is a recessive disorder characterized by episodes of fever and inflammation. Recently we identified the FMF gene (*MEFV*) by positional cloning; it is expressed at high levels in granulocytes and monocytes, and the protein product, pyrin, is associated with microtubules and actin filaments. Using the yeast two-hybrid system, we identified proteins that specifically interact with pyrin. One group of clones encodes the cytoskeletal protein, proline serine threonine phosphatase-interacting protein (PSTPIP1). PSTPIP1 is a CDC15p homolog that is known also to associate with the actin cytoskeleton and the Wiskott-Aldrich syndrome protein (WASP). We investigated the interaction domains of pyrin and PSTPIP1 as well as the influence of FMF-associated mutations on the interactions. Deletion and domain interaction analysis showed that the B-box and coiled-coil domains of pyrin are involved in the binding of pyrin to PSTPIP1. Fluorescence microscopy confirmed the binding by colocalization of full length pyrin or the B-box and coiled-coil domain with PSTPIP1 in transfected HeLa cells. Moreover, disease-associated mutations in pyrin altered the binding in the yeast two-hybrid system and changed the localization of PSTPIP1 in transfected cells. In the yeast two-hybrid system, analysis of PSTPIP1 interaction domains revealed that deletion of the SH3 domain completely abolished the binding to pyrin. Substitution of tyrosine 367 (found in the SH3 domain) to aspartate resulted in a loss of pyrin binding. These results suggest that the PSTPIP1 and pyrin interaction may be regulated by tyrosine phosphorylation of the PSTPIP1 SH3 domain, and that pyrin may regulate inflammatory responses at the level of cytoskeletal organization. FMF-associated mutations in pyrin appear to interfere with this interaction.

**Relative Rates of Disease Causing Missense Substitution are Predicted by the Level of Evolutionary**

**Conservation in *F9*.** W.A. Scaringe<sup>1</sup>, E.C. Thorland<sup>2</sup>, R.K. Pruthi<sup>2</sup>, D. Ricke<sup>2</sup>, K.A. Hill<sup>1</sup>, S.S. Sommer<sup>1</sup>. 1) Department of Molecular Genetics, City of Hope National Medical Center and Beckman Research Institute, Duarte, California, USA; 2) Department of Biochemistry, Mayo Clinic/Foundation, Rochester, Minnesota, USA.

The *in-vivo* effects of a missense substitution are typically variable even when truncating mutations to the gene are known to be devastating. The degree to which an amino acid is conserved through evolution has been demonstrated to be a useful indicator of its functional importance and may be viewed as the most direct measure of the *in-vivo* functional importance of the amino acid to reproductive fitness. The degree of cross species conservation was analyzed in detail in the factor IX gene family (*F9*, MIM No. 306900) and correlated with the spectrum of *F9* missense mutations observed in patients with hemophilia B which is caused with varying severity by different *F9* mutations. Members of the factor IX gene family were sequenced in non-mammalian vertebrates to supplement the existing database. By comparing more than 500 different missense changes known to cause hemophilia B in humans with the sequence variation among wildtype members of the factor IX gene family, the amino acids in the protein were classified into five levels of evolutionary conservation. The frequency of ascertained hemophilia B causing missense mutation was found to increase with the degree of evolutionary conservation. In addition, the observed disease causing variants were biased towards chemically dissimilar amino acids. These results further validate the utility of evolutionary conservation for predicting the impact of missense mutations and provides an approach for quantifying the likelihood that a missense change in a given candidate gene will be of functional significance. By helping to predict the likelihood that a missense change will be deleterious or neutral, evolutionary conservation analysis may be a cost-effective way to allocate resources for candidate gene analyses of complex disease.

**Expression of DAZAP1, a protein that interacts with the fertility factors DAZL and DAZ.** *Y. Vera*<sup>1</sup>, *T. Dai*<sup>1</sup>, *E. Salido*<sup>3</sup>, *T. Guo*<sup>2</sup>, *A. Sinha Hikim*<sup>2</sup>, *P. Yen*<sup>1</sup>. 1) Pediatrics, Harbor-UCLA Medical Center, Torrance, CA; 2) Medicine, Harbor-UCLA Medical Center, Torrance, CA; 3) Pathology, University of La Laguna, Spain.

DAZAP1 (DAZ Associated Protein 1) was originally identified through its interaction with two closely-related germ-cell specific proteins, DAZL and DAZ, that are required for germ cell development. DAZAP1 is a 407-amino-acid protein containing two RNA-binding domains and a proline-rich C-terminal portion. It is expressed most abundantly in testes. Its amino acid sequence is 83% identical to that of the *Xenopus* Prp protein which binds to the localization element in the 3' UTR of *Xenopus Vgl* mRNA. To elucidate the function of DAZAP1, we studied the expression and subcellular localization of DAZAP1 during spermatogenesis. RNA *in situ* hybridization showed that in adult testes *Dazap1* was expressed most abundantly in early premeiotic cells, from intermediate spermatogonia to preleptotene spermatocytes, and the level of expression decreased dramatically afterward. We generated two anti-DAZAP1 antibodies, one against a recombinant protein containing the C-terminal half of DAZAP1, and the other against an oligopeptide containing the last 19 amino acid residues of DAZAP1. Both antibodies bound to *in vitro* synthesized DAZAP1, and both detected a 46 kD protein in mouse testis extracts. Immunostaining of mouse testicular sections using affinity-purified antibodies showed a delay in the translation of *Dazap1* mRNA. DAZAP1 was first detected in both the cytoplasm and nuclei of mid-pachytene spermatocytes in stage VII tubules. In round spermatids DAZAP1 was detected mainly in nuclei, whereas in elongated spermatids DAZAP1 was present in the cytoplasm. DAZAP1 therefore appears to shuttle between the nucleus and the cytoplasm, and could be involved in RNA transport. In the cytoplasm, DAZAP1 was found not to be associated with polyribosomes.

**Endonuclease-Independent L1 Retrotransposition.** *T.A. Morrish, J.V. Moran.* Human Genetics, University of Michigan, Ann Arbor, MI.

Retrotransposition-competent L1s (RC-L1s) are 6.0 kb and contain a 5' untranslated region (UTR), two open reading frames (ORF1/ORF2), and a 3' UTR that ends in a poly (A) tail. ORF1 encodes an RNA binding protein, while ORF2 encodes a protein with endonuclease (EN) and reverse transcriptase (RT) activities. L1 likely mobilizes by target-site primed reverse transcription (TPRT). During TPRT, L1 EN cleaves the target sequence 5'-TTTT/A-3', liberating a 3' hydroxyl, which serves as a primer for reverse transcription of L1 RNA by the L1 RT. How the resultant cDNA joins to genomic DNA remains unknown. To ask if this process involves DNA repair proteins, L1 retrotransposition was assayed in a Chinese Hamster Ovary (CHO) cell line defective in non-homologous end joining (*xr-1*), and the corresponding wild-type parental cell line (4364a). As expected, RC-L1s readily retrotranspose in 4364a cells, and missense mutations in either the EN or RT domain reduced retrotransposition by 2-3 orders of magnitude. Remarkably, EN-independent (but RT-dependent) retrotransposition occurs in *xr-1* cells near wild-type levels. Comparison of insertion events in *xr-1* cells reveals that RC-L1s and EN-deficient L1s retrotranspose by different mechanisms. Five insertions derived from an RC-L1 have the predicted structure (i.e., they are 5' truncated, end in a poly (A) tail, integrate into a consensus L1 EN cleavage site, and generally are flanked by target site duplications (tsds)). By contrast, eight insertions derived from EN-deficient L1s have unusual structures; six are 3' truncated, none insert into an EN cleavage site, and all lack tsds. Detailed analysis of three EN-deficient integration events provides evidence that L1 can integrate at existing breaks in chromosomal DNA. Interestingly, in one instance 55bp of nucleolin RNA was co-retrotransposed with L1 RNA, suggesting that L1 intermediates may contain at least two mRNAs. In summary, our data suggest that pre-existing nicks in chromosomal DNA can function as primers to initiate cDNA synthesis of L1 RNA in an endonuclease-independent manner. This proposed mechanism curiously is analogous to that of telomerase, and provides an *in vivo* example of RNA mediated DNA repair.

**In Search of L1 Retrotransposition Intermediates.** *D.A. Kulpa, J.N. Athanikar, J.V. Moran.* Human Genetics, University of Michigan, Ann Arbor, MI.

LINES (L1s) are present in 850,000 copies in the human genome, comprising »21% of DNA. The majority of L1s cannot retrotranspose because they are 5' truncated or mutated; however, approximately 60 remain retrotransposition-competent (RC-L1s). RC-L1s are 6kb in length, and contain a 5' untranslated region (UTR), two open reading frames (ORF1 and ORF2), and a 3' UTR with a polyadenylic acid tail. ORF1 encodes an RNA binding protein (ORF1p), while ORF2 encodes a protein with endonuclease (EN) and reverse transcriptase (RT) activities (ORF2p). L1 retrotransposition requires the transcription of L1 RNA, its transport to the cytoplasm, and subsequent translation of its two open reading frames. Recent genetic experiments indicate the L1-encoded proteins preferentially bind to the transcript from which they were translated (i.e., they demonstrate a *cis*-preference) to form ribonucleoprotein (RNP) particles, which are proposed intermediates in the retrotransposition pathway. We currently are exploiting the *cis*-preference mechanism by selectively tagging L1s in an effort to test whether RNPs are indeed retrotransposition intermediates. Here, we demonstrate that L1s containing an epitope tag at the carboxyl terminus of ORF1p remain retrotransposition competent, and that the epitope tagged protein as well as its RNA localizes to cytoplasmic RNP complexes. Missense mutations in ORF1p, which block L1 retrotransposition, also block its ability to localize to RNPs. By contrast, a missense mutation in the RT domain of the ORF2p, which abolishes retrotransposition, does not affect localization of ORF1p. Together, our results demonstrate that ORF1p plays an important role in RNP formation, and lend support to the hypothesis that RNPs are L1 retrotransposition intermediates.

**Deletion of Azoospermia Factor b(AZFb) in infertile men caused by non-homologous recombination between Alu and LINE-1 elements.** *E. MORO<sup>1</sup>, A. FERLIN<sup>1</sup>, A. ROSSI<sup>1</sup>, P. MARIN<sup>1</sup>, B. DALLAPICCOLA<sup>2</sup>, C. FORESTA<sup>1</sup>.* 1) Medical & Surgical Sciences, University of PADOVA, ITALY; 2) Department of Medical Genetics, University of ROME.

Microdeletions of the Yq are the most common mutation observed in infertile males, where they affect one or more azoospermia factors (AZFa, b and c). Understanding of the AZF structure and gene content and mapping of the deletion breakpoints in infertile men are still incomplete. About fifty percent of the Y chromosome consists of repetitive elements, such as Alu, DNA transposons and retroviral sequences so that illegitimate recombination mechanisms have been evoked as possible causes of AZF deletions. Recently, two homologous retroviral sequences of the HERV family have been identified in the AZFa region and it has been suggested that their recombination is causing most of AZFa deletions. AZFb region has been less analyzed due to its complex structure. It has been proposed that RBMY-1 gene family represent the candidate gene, being expressed only in the testis and specifically in germ cells. However, deletions within AZFb that do not remove RBMY-1 have been described and no RBMY-1 point mutation have been identified yet. Patients with AZFb deletion not involving RBMY-1 seem to have indistinguishable proximal and distal breakpoints, suggesting a common responsible mechanism. We have reviewed the AZFb map of BAC clones and shown that it contains different inverted repeats. Using sequence-tagged sites (STS) analysis approach we have identified common breakpoints in four unrelated infertile individuals with deletion within AZFb. By means of electronic analysis we found a block containing an Alu element in the distal breakpoint, and another block containing a cluster of LINE-1 elements in the proximal breakpoint region. These findings sustain an illegitimate recombination between Alu and LINE1 elements as a cause of the AZFb deletion. The four male infertile patients were not deleted for the active copy of RBMY-1 gene family. It can be hypothesized that the deletion may have deregulated RBMY-1 expression or alternatively other genes mapped in the AZFb may have a role in the spermatogenesis.

**SVA elements are novel active human retrotransposons that cause disease.** *E.M. Ostertag, Y. Zhang, H.H. Kazazian, Jr.* Dept. of Genetics, University of Pennsylvania, Philadelphia, PA.

SVA elements were previously described as composite retroposons, consisting of a SINE-R region, a VNTR region, and an Alu region. Our database analysis of SVA elements suggests that they are non-autonomous retrotransposons, which are mobilized by the retrotransposition machinery of the L1 retrotransposon. The following data support our hypothesis: 1) SVA elements end in an AATAAA poly-A signal, followed immediately by an A-rich tail. This structure is similar to the L1 3' end and may be required for the integration process. 2) SVA elements have target site duplications (TSDs) identical to L1 TSDs, suggesting that they are created by the L1 endonuclease. 3) SVA elements are occasionally 5' truncated, a phenomenon common during L1 retrotransposition. In fact, we propose that SINE-R retroposons are simply 5' truncated SVA insertions. 4) SVA elements are able to transduce 3' flanking sequence, an indirect consequence of using the L1 retrotransposition process. 5) SVA elements can 5' invert during the retrotransposition process, another phenomenon common during L1 retrotransposition. The report of an evolutionarily recent insertion of a SVA element into the fukutin gene suggested that SVA elements may be currently active. We have now identified other recent SVA insertions, an insertion into the Btk gene (previously described as a SINE-R insertion), and an SVA-mediated transduction (see #4 above) inserted into the  $\alpha$ -spectrin gene (previously described as a novel SINE insertion). We find many copies of SVA elements with greater than 99% identity to the SVA insertions, supporting recent activity. Additionally, we are able to identify the empty site of one SVA insertion precursor, suggesting that some SVAs are polymorphic in the population and therefore recently active. Lastly, we demonstrate in a cultured cell assay that SVA elements are active non-autonomous retrotransposons and that they are able to retrotranspose using the L1 retrotransposition machinery.

**Novel HERV-K genes (ERV3 and ERV4) were mapped to autoimmune disease loci on chromosome 3. J.**

*Sugimoto<sup>1</sup>, N. Matsuura<sup>2</sup>, T. Oda<sup>1</sup>, Y. Jinno<sup>1</sup>.* 1) Molec Biol, Res Ctr Med Sci, Ryukyu Univ Sch Medicine, Okinawa, Japa; 2) Dept Pediatr, Kitasato University School of Medicine, 1-15-1, Kitasato, Sagamihara 228-8555, Japan.

Human endogenous retroviruses (HERVs) are LTR-containing retroelement, which are widely spread throughout the human genome. The vast majority of HERV sequences are dysfunctional due to the accumulation of multiple nonsense mutations. HERV-K genes, one of the HERV family members, are estimated to reside as about 30 to 50 copies in the haploid human genome. Recently HERV-K18/IDDMK12,22 has been shown to code for a superantigen and to possibly implicate in the pathogenesis of autoimmune diabetes. To explore the pathological role in human disorders, we tried to identify transcriptionally active other members of HERV-K genes. Preceding the isolation, expression status was examined by RT-PCR and sequence using mRNAs from various tissues. In addition to detection of HERV-K18/IDDMK12,22 in peripheral leukocytes, two novel HERV-K genes (ERV4 and ERV5) were detected in placenta, lung, testis, and peripheral leukocytes, then subsequently isolated from a BAC library using oligonucleotide-probes and characterized. Although their expression could not be confirmed in normal tissues tested by northern blot analysis, substantial promoter activity of their 5' LTRs was demonstrated in luciferase assays using teratocarcinoma cell lines. Thus, they seem to have a potential to be actively transcribed. These results indicated that subtle base changes in LTR sequences could be responsible for gene regulation such as tissue specificity of HERV-K expression. To evaluate the involvement in any human diseases, G3 RH panel using markers designed from flanking sequences on BAC clones were performed. ERV4 and ERV5 were mapped to chromosomal regions 3q21-q25.2 and 3cen-q13, respectively. Recent progress of human genome project helped us to know the precise gene location on 327kb (Hs3\_22567) and 898kb (Hs3\_22660) clone contig. In these regions several susceptibility loci for autoimmune diseases (type 1 diabetes, MS, SLE, and RA) were reported by genome-wide linkage studies. ERV4 and ERV5 could play a role in pathogenesis of these diseases.

**The FMR1 Message Facilitates Translation by Internal Ribosome Entry.** *P. Chiang, L. Carpenter, F. Tassone, P.J. Hagerman.* Department of Biological Chemistry, School of Medicine, University of California, Davis, California.

Fragile X syndrome, the leading heritable form of mental impairment, is nearly always caused by large expansions of a CGG trinucleotide repeat element in the promoter region of the FMR1 gene, with consequent absence of FMR1 protein (FMRP). For most individuals with fragile X syndrome, absence of FMRP is due to transcriptional silencing. However, for some individuals, no protein is produced despite continued activity of the FMR1 gene. This observation suggests that translation of the FMR1 message is impaired, presumably due to the expanded CGG element in the 5' untranslated region (UTR) of the FMR1 message, although no causal relationship between the size of the CGG element and efficiency of translation has been established. To examine the properties of the FMR1 5'UTR, nested deletions were generated within a normal FMR1 5'UTR, for both monocistronic and dicistronic (luciferase) reporter constructs. Surprisingly, in transient transfection experiments performed with cell lines of both neural and lymphoid origin, a ~30 nucleotide segment in the 5'UTR was found to promote translation by internal ribosome entry. Additional controls indicate that the enhanced activity of the downstream reporter is not due to readthrough from the upstream cistron, nor is it due to translation of cryptic monocistronic transcripts. The functional significance of this internal ribosome entry site (IRES) is not known at present, although it may act as a target for context-dependent regulation of the translation of FMR1 mRNA.

**Pharmacological Reactivation of the *FMRI* Gene of the Fragile X Syndrome.** *G. Neri*<sup>1</sup>, *M.G. Pomponi*<sup>1</sup>, *R. Pietrobono*<sup>1</sup>, *P. Chiurazzi*<sup>2</sup>. 1) Institute of Medical Genetics, Catholic University, Rome, Italy; 2) Department of Pediatrics, University Hospital, Messina, Italy.

Fragile X syndrome is the leading cause of heritable mental retardation, with a prevalence in the general population of 1:4000 males. Most fragile X patients have an amplified CGG repeat in the promoter of the *FMRI* gene, which becomes abnormally methylated and inactive. We demonstrated that reactivation of the fully mutated gene can be achieved by treating patients' lymphoblasts with the demethylating drug 5-azadeoxycytidine (*Hum Mol Genet* 7: 109-113, 1998) and, although at very low levels, also with the histone deacetylase inhibitors 4-phenylbutyrate or butyrate, that should cause histone hyperacetylation. However, when 4-phenylbutyrate or butyrate were used with 5-azadeoxycytidine, a marked synergistic effect was observed (*Hum Mol Genet* 8:2317-2323, 1999), thus confirming that DNA hypermethylation and histone deacetylation are sequential steps leading to the transcriptional silencing of the fully mutated *FMRI* gene. We now report on the correlation between reactivation of the gene following treatment with 5-azadeoxycytidine and actual demethylation of the promoter. By bisulfite sequencing we determined that the treatment leads to a nearly complete demethylation of the promoter. On the other hand, Southern analysis after digestion of the DNA with methylation sensitive enzymes suggests that demethylation of the CGG sequence is probably more limited. This could explain why in cells with larger CGG expansions the attainable level of reactivation is less than in cells with shorter expansions. We also intend to verify whether treatments with histone deacetylase inhibitors determine a significant level of histone hyperacetylation and/or DNA demethylation of the *FMRI* promoter. Supported by grants from the FRAXA Foundation and from Sigma-Tau.

**Cell type specific effect of CTG expanded repeats on the expression of a reporter gene.** *C. Montanez<sup>1</sup>, B. Cisneros<sup>1</sup>, R. Korneluk<sup>2</sup>, F. Depardon<sup>1</sup>.* 1) Genetics and Molecular Biology Department, Cinvestav, IPN. Av. I.P.N. 2508. C. P. 07360. Mexico, D.F. Mexico; 2) Solange Gauthier Karsh Molecular Genetics Laboratory, Children's Hospital of Eastern Ontario, Ottawa, Ontario K1H 8L1, Canada.

Myotonic dystrophy (DM) results from the expansion of an unstable (CTG)<sub>n</sub> trinucleotide repeat within the 3'-untranslated region (3'-UTR) of the DMPK gene (human chromosome 19q13.3). The mechanism by which the CTG repeat expansion mutation leads to the clinical phenotype of DM is unknown. In order to understand how the CTG expanded repeats located at the 3' untranslated region exerts an effect on gene expression, we analyzed the expression of the reporter gene CAT containing at the 3' untranslated region 0, 5, 45 and 90 CTG repeats in L6 rat myoblasts and SH-SY5Y human neuroblastoma cell lines. For this, RT-PCR, Western blots, in vitro translation and Cat activity determination assays were performed. Our results show that the expression of the CAT reporter gene at the transcription level was similar in all constructs and cell lines analyzed. Most of the CAT mRNAs encoded by all plasmids used were detected in the cytoplasmic fraction. Interestingly, CAT activity and synthesis was dramatically reduced in L6 cells transfected with the CAT vectors carrying 45 and 90 CTG repeats. In opposition to this, the CAT expression was found to be unaltered in SH-SY5Y human neuroblastoma cells. These results show that the CTG expanded repeats inhibitory effect on CAT expression, is cell type dependent.

**Functional studies on the Human 5'-CGG-3'-Binding Protein CGGBP1 (p20).** *F. Naumann, H. Müller-Hartmann, H. Deissler, W. Doerfler.* Institute of Genetics, University of Cologne, Cologne, Germany.

From the nuclei of human HeLa cells, we have isolated a 20 kDa protein which binds specifically to 5'-CGG-3' repeats, either in synthetic oligodeoxyribonucleotides or in the 5'-upstream region of the FMR1 gene on human chromosome Xq27.3. The loss of the FMR1 (fragile X mental retardation) gene function has been implicated in the causation of the fragile X syndrome which is associated with an unstable trinucleotide repeat. The specific binding of CGGBP1 is compromised when the repeat sequence is methylated. The amino acid sequence of three peptides in the CGGBP1 has been determined, and an EST clone with the matching nucleotide sequence has been available. Screening of the protein data bases has not revealed a related sequence. The genomic nucleotide sequence of the gene for the human CGGBP1 has also been determined, and the gene structure has been analysed. The human gene maps to the paracentric region on the short arm of chromosome 3 as shown by FISH. The human CGGBP1 is ubiquitously expressed. It can be alternatively spliced and polyadenylated. The CGGBP1 gene is highly conserved among mammals and birds. Cloning of the murine gene revealed a 98% identity in the amino acid sequence. To investigate the function of the murine CGGBP1 *in vivo*, we have initiated a conditional gene targeting experiment in C57BL/6 mice and have completed appropriate constructs. In cotransfection experiments, the activity of the FMR1 promoter in luciferase constructs is reduced by the overexpression of the CGGBP1. Upon transfection of the CGGBP1 cDNA construct into HeLa cells, transcription of the endogenous FMR1 gene is also decreased. In a quest for additional CGGBP1 targets, we have initiated microarray experiments using RNA from human HeLa cells that had been transfected with a HCMV promoter-CGGBP1 construct or with control constructs. Several differentially expressed candidate genes in cells overexpressing CGGBP1 are currently investigated. How many cellular genes are affected in their transcriptional activity by the presence of the CGGBP1? [This research was supported by the Center for Molecular Medicine Koeln - TV13].

**Alpha1A voltage-dependent calcium channel gene with expanded CAG repeats exerts caspase dependent cytotoxicity in HEK cell lines.** *K. Owada<sup>1</sup>, T. Kubodera<sup>1</sup>, K. Ishikawa<sup>1</sup>, M. Li<sup>1</sup>, T. Tsunemi<sup>1</sup>, S. Toru<sup>1</sup>, T. Tanabe<sup>2</sup>, H. Mizusawa<sup>1</sup>.* 1) Department of Neurology and Neuroscience, Graduate School, Tokyo medical and Dental University, Japan, MD; 2) Pharmacology and Neurobiology, Graduate School, Tokyo medical and Dental University, Japan, MD.

Spinocerebellar ataxia type 6 (SCA6) is caused by small CAG repeat expansion which code polyglutamine in the alpha1A voltage-dependent calcium channel gene (CACNA1A). Although the slowly progressive degeneration and loss of Purkinje cells is the main feature in SCA 6, the mechanisms that CACNA1A with CAG-repeat expansion leads to neurodegeneration have not been clarified. However, a line of evidence suggests that the Purkinje cell neurodegeneration may be associated both with functional alteration of calcium channel and expanded polyglutamine itself that causes microaggregation of mutated protein as seen in other polyglutamine diseases. To clarify the mechanism of cell death in aspect of polyglutamine toxicity, we generated HEK cell lines which stably express human CACNA1A either with normal 13 or expanded 28 CAG-repeats. Although the repeat expansion did not show cell toxicity under normal condition, serum deprivation stress markedly increased TUNEL positive apoptotic cells in the CAG-repeat expanded cell lines. In addition, caspase inhibitor suppressed the cell death induced by serum deprivation. These results suggest that CAG-repeat expansion of CACNA1A exerts caspase depending cytotoxicity in HEK cell lines.

**A comparative study of SCA7 cell models and human brain: recruitment of proteins into inclusions and activation of caspase-3** è. C. Zander<sup>1,5</sup>, J. Takahashi<sup>2</sup>, KH. Hachimi<sup>4</sup>, H. Fujigasaki<sup>1</sup>, C. Duyckaerts<sup>2,4</sup>, A. Brice<sup>1,3</sup>.  
1) INSERM U289; 2) Laboratoire de Neuropathologie Escourolle; 3) Fédération de Neurologie; 4) INSERM U106: Hôpital de la Salpêtrière, 47 boulevard de l'Hôpital, 75651 Paris, Cedex 13, France; 5) Dep. of Molecular Medicine, Karolinska Institute, Stockholm 17176, Sweden.

Spinocerebellar ataxia type 7 (SCA7) is one of the nine known polyglutamine diseases. SCA7 is an autosomal dominant neurodegenerative disorder, characterized by visual loss and cerebellar ataxia. Pathologically, there is a progressive pigmentary macular degeneration and predominant neuronal loss in the cerebellar cortex, brain stem and inferior olivary complex. The molecular pathways leading to selective neuronal death in SCA7 are poorly understood.

We have established a cell culture system based on transiently expressed tagged variants of SCA7 in two human cell lines: HEK293 (embryonic kidney) and SH-SY5Y (neuroblastoma), that mimic several of the major characteristics of SCA7. The cells readily formed fibrillar aggregates with an amyloid-like structure that recruited other proteins. In this study we have characterized these cells and compared the inclusions with those in human SCA7 brain tissue. This will allow comparison with SCA7 mice models and other polyglutamine disorders. There were consistent indirect signs of an ongoing abnormal protein folding, including the recruitment of proteasome subunits and heat shock proteins. Occasionally, there was also sequestration of transcription factors in the brain (CBP and mSin3a) and in a small subset of the aggregates in the SH-SY5Y cells (CBP and p53). A possible role of caspase-3 activation in SCA7 pathogenesis was evoked in our study by its recruitment into the aggregates/inclusions. Finally, on the ultrastructural level there were signs of catabolic dysfunction and nuclear indentations as major cell stress response in the transfected cells.

**Antisense expression at the human *XIST* locus does not prevent localization of the *XIST* RNA.** *J.C. Chow*<sup>1</sup>, *L. Hall*<sup>2</sup>, *J.B. Lawrence*<sup>2</sup>, *C.J. Brown*<sup>1</sup>. 1) Dept Medical Genetics, Univ British Columbia, Vancouver, Canada; 2) Univ Massachusetts Medical Centre, Worcester, MA.

Mammals employ X-inactivation to transcriptionally silence most genes on one of the two X's in females. This process requires *XIST*, an untranslated RNA that is expressed exclusively from the inactive X. The localization of the transcript to the inactive X in interphase nuclei suggests that the RNA may have a structural role. In mouse, an antisense transcript that may regulate *Xist* expression initiates 15 kb downstream of *Xist* and completely overlaps the *Xist* locus. Targeted deletions of the antisense promoter indicate that it is involved in both imprinted and random X-inactivation. We have identified antisense transcription at the human *XIST* locus that also appears to be specific to undifferentiated cell types, being observed in two different embryonal carcinoma lines, N-Tera2D1 and Hs 444, but not in somatic cells. Unlike the murine antisense transcript, the human transcript does not completely overlap the *XIST* gene and is not correlated with destabilisation of the sense transcript. While no expression of the human antisense transcript is seen in somatic cells, transient expression can be induced by demethylation, suggesting that, as with the *XIST* gene, methylation is important in silencing of the locus.

To examine the role of the antisense transcript in the localisation of *XIST* to the X chromosome, we have transfected a PAC containing at least 20 kb flanking the transcriptional start sites of both the sense and antisense transcripts into human somatic cell lines. We have identified a transfectant that expresses both sense and antisense transcripts, and despite substantial antisense expression, RNA-FISH indicates that the sense *XIST* transcript still forms a large signal that localises to surrounding chromosomal material. Therefore, antisense expression does not appear to significantly decrease sense *XIST* levels or preclude localization in somatic cells. Our results favor models of antisense action involving developmental, stage-specific factor binding over models involving antisense RNA destabilisation of the *XIST* RNA.

**The ICF syndrome as a model for studying inactive X silencing: methylation versus acetylation.** *R.S. Hansen<sup>1</sup>, S.M. Gartler<sup>1,2</sup>*. 1) Medicine/Medical Genetics, University of Washington, Seattle, WA; 2) Genetics, University of Washington, Seattle, WA.

The inactive X is silenced by a multiplicity of factors whose interrelationships have yet to be fully worked out. To understand the relative roles of such factors, one approach is to study the inactivation system when it is at least partially destabilized. The rodent-human somatic cell hybrid with a human inactive X is one such model system that has been used to study inactive X silencing for the last 25 years. Destabilization of X inactivation in this system appears to result, at least in part, from an alteration of the XIST RNA sex chromatin body. The ICF immunodeficiency syndrome provides a new cellular model for studying the human inactive X silencing complex. We and others have shown that ICF syndrome can result from mutations in the *DNMT3B* DNA methyltransferase gene. This methyltransferase targets various forms of heterochromatin including the inactive X, and we have shown that all gene-associated CpG islands on the inactive X appear to be hypomethylated. These regions are commonly found to be mildly advanced in their time of replication and retain normal silencing. In cases of markedly advanced replication, however, escape from inactivation is found. Sex chromatin structure, including XIST RNA association, appears normal in these cells. We now report new examples of escape from inactivation in ICF as well as new examples of advanced replication timing for single copy and repeated sequences. In addition, our recent studies of histone acetylation in ICF female cells provide an interesting challenge to the view that methylation in heterochromatic regions brings about deacetylation by attracting deacetylases. We find that even though the CpG islands of the inactive X in ICF female cells are extensively hypomethylated, the histones are hypoacetylated normally at the cytological level. These data also call into question the need for hyperacetylation in the regions of genes that escape inactivation.

**XIST Expression from the Active X: A Hybrid Model System for Studying the Role of XIST independent of Gene Silencing.** *E.S.H. Kwok, K. Harris, C.J. Brown.* Medical Genetics, Univ British Columbia, Vancouver, BC., Canada.

X-inactivation results in the transcriptional silencing of one of the two X chromosomes present in mammalian female cells. XIST expression from the inactive X (Xi), and subsequent coating of the Xi by the XIST RNA, marks the initial major observable characteristic of X-inactivation. The Xi then begins to exhibit features of heterochromatin such as hypermethylation, histone deacetylation, late replication, and the recruitment of core histone variants. Ultimately most X-linked genes on the Xi become silenced, but the exact mechanistic events between XIST expression and the final heterochromatic state of the Xi remain unclear.

To better understand the relationship between XIST, heterochromatin, and silenced gene expression, we have developed a model system to examine which features of heterochromatin can be induced by XIST independent of gene silencing. Rodent/human hybrids containing active human and mouse Xs were demethylated to reactivate XIST/Xist expression. Previous work showed that while human XIST fails to localize to the human X, the mouse Xist localizes normally. In both cases no silencing of X-linked genes was observed. To verify this hybrid cell system as a model for studying the effects of XIST/Xist independent of inactivation, we characterized the methylation and expression status of 8 mouse/human genes and found them to be unchanged. This confirmed the lack of X-linked gene silencing despite the presence of XIST/Xist expression.

The first feature of the Xi we are investigating is the colocalization of the histone variant macroH2A1.2 (mH2A), since the loss of Xist expression has been shown to result in mH2A delocalization. We have made a macroH2A-GFP construct to be expressed in the described model system to study whether XIST expression is sufficient to recruit mH2A to the X chromosome, or if mH2A localization requires the silenced chromatin structure of the Xi. How mH2A and other features act in the presence of XIST but in the absence of a silenced Xi state will help define their roles in X-inactivation.

**DNMT1 is not required for maintenance of *XIST* repression in human cancer cells.** *L.R. Vasques, M. Soukoyan, L.V. Pereira.* Dept. Biologia, Instituto de Biociencias, Universidade de São Paulo, SP, Brazil.

In mammals, dosage compensation of X-linked gene products between XY males and XX females is achieved by transcriptional inactivation of one X chromosome in females. The *XIST/Xist* gene is expressed exclusively from the inactive X ( $X_i$ ), and seems to trigger initiation of X chromosome inactivation (XCI) in cis. Repression of *XIST/Xist* on the active X ( $X_a$ ) chromosome upon differentiation has been associated with methylation of its 5' region. This region is hypermethylated on the  $X_a$ , where *XIST/Xist* gene is repressed, and hypomethylated in the *XIST/Xist* expressing  $X_i$ . To date, four different mammalian DNA (cytosine-5) methyltransferase (MTases) have been identified: Dnmt1, Dnmt2, Dnmt3a and Dnmt3b. Dnmt1 is constitutively expressed, has higher activity in hemi-methylated DNA, and thus has been recognized as a maintenance MTase. The role of Dnmt1 in the process of DNA methylation and XCI has been extensively studied in mice, where Dnmt1 activity has been shown to be causally involved in maintenance of global DNA methylation and particularly in the transcriptional repression of the *Xist* gene.

In humans, disruption of the *DNMT1* gene by homologous recombination in the human carcinoma cell line HCT116 (46, XY) led to a reduction of only 20% of overall DNA methylation. These data indicated that human DNMT1 is involved in DNA methylation differently than its murine counterpart, and prompted us to investigate the role of DNMT1 in the process of maintenance of *XIST* gene repression on the  $X_a$  in that human cell line. We show that methylation of the *XIST* promoter region and *XIST* transcriptional repression is sustained in DNMT1 deficient cells. Treatment of these cells with 5-aza-2-deoxycytidine leads to demethylation of the *XIST* promoter region and *XIST* gene expression. Our results in the human cell line HCT116 indicate that, although methylation is required for maintenance of *XIST* repression in the X chromosome, DNMT1 is not the MTase involved in this process in humans. Moreover, they suggest that the role of that enzyme in human XCI may not be extrapolated from data obtained in mice.

**First do no harm: an ethical counseling dilemma.** *D.L. Thull, S.M. O'Neill.* Cancer Genetics Program, UPCI/Magee Womens Hosp, Pittsburgh, PA.

An almost 17 year old young woman was referred by her PCP for genetic counseling and possible testing for *BRCA1* and *BRCA2*. The proband's maternal history was highly suspicious of the Hereditary Breast-Ovarian Cancer (HBOC) syndrome. Her mother was diagnosed with breast cancer at age 25 and died at age 34. Many maternal relatives were noted to have early onset breast or ovarian cancer. The proband is very concerned about her breast cancer risk, performs frequent self-breast exams and has already had a clinical breast exam, mammography and ultrasound screening. In obtaining the family history, first from the proband's stepmother and then from a maternal aunt, a history of Huntington Disease (HD) was elicited. Three of the proband's maternal uncles are affected with HD as was her maternal grandfather. The proband is somewhat aware of the HD in the family. Her stepmother had known of only one affected uncle and the grandfather. The referral raised the ethical issues of patient autonomy and nonmaleficence with respect to cancer predisposition testing in an adolescent. Furthermore, the presence of HD in the family raised the question of the legal responsibility of the genetic counselor to discuss HD versus the ethical concern regarding the potential to overwhelm and cause excessive mental burden to the young proband.

**Prenatal counseling in Friedreichs ataxia. An unexpected and unwelcome outcome.** *H. Cox, J. Macpherson.*  
Wessex Clinical Genetics Service and Regional Genetics Laboratory, Princess Anne Hospital, Southampton,  
Hampshire, United Kingdom.

Friedreichs ataxia is the most common autosomal recessive hereditary ataxia. Classically, the onset of symptoms occurs before 20 years of age. In 1996 the gene for Friedreichs ataxia was discovered. The majority of affected individuals are homozygous for an unstable expansion of GAA repeats in the first intron of the frataxin gene on chromosome 9 (normal= <20 repeats). The availability of a diagnostic test has led to the recognition of a broader phenotype with a later onset of symptoms. Carrier frequency in the general population is 1/110. The risk to offspring of both affected patients and healthy carriers is therefore low.

A healthy 30 year old woman whose 28 year old sister suffers from Friedreichs ataxia presented to us in the 15th week of her first pregnancy. Her sister's diagnosis was confirmed and she was counseled that the risk to her offspring was low (1/660). She and her partner requested carrier testing for further reassurance. The patient was found to have expansions in both alleles (estimated sizes of 160 and 1200 repeats). Both of her partner's repeat sizes fell within the normal range. Our patient's sister had symptoms from 18 years of age. Diagnosis was at 25 years of age and she remains fully ambulant. Expansion sizes were estimated to be 300 and 1200. Meiotic instability of the smaller expansion would account for the difference in allele sizes and clinical presentation between the 2 sisters. Our patient was shocked by this molecular diagnosis, declined neurological examination and denies any neurological symptoms.

As genetic testing becomes possible for more recessive disorders, many patients request that genetic counseling be backed up by a test. Failure to counsel the consultand regarding her a priori risk of having Friedreichs ataxia resulted in an unexpected predictive test in pregnancy. This report is a timely reminder to genetic counsellors that carrier testing can be fraught with difficulties.

**Treatment of Multiple Sclerosis: Teratogenic Concerns and Other Aspects of Reproductive Counselling.** *A.D. Sadovnick, C. Guimond, E. Dwosh.* Medical Genetics, VHHSC-UBC, Univ British Columbia, Vancouver, B.C., Canada.

Multiple sclerosis (MS) is the most common neurological disorder affecting young adults during the ages when reproduction is a major consideration. Two-thirds of affected individuals are females. Genetic factors are known to influence MS susceptibility and evidence suggests that they also may impact on clinical course. Young couples, one of whom has MS, are increasingly approaching genetic clinics to request information on reproduction.

MS treatments fall into three categories: (1) symptom-specific (e.g. fatigue, bladder incontinence, optic neuritis, ataxia); (2) relapse/exacerbation management and (3) disease modifying (e.g. immunosuppressants believed to reduce the number of clinical relapses/exacerbations and lesions on MRI). Within each category, a variety of therapeutic agents are used singly or in combination. Thus, each individual's clinical course and treatment regime must be reviewed in detail as a critical component of reproductive counselling. This is true for all affected consultands, whether male or female, although some concerns will be specific to females.

The impact of commonly used therapeutic agents will be discussed with respect to fertility, teratogenicity, and breastfeeding. In addition to teratogenic concerns, other topics relevant to reproductive counselling for persons with MS will be outlined. These include (1) Effects of MS on Pregnancy (conception, pregnancy management, delivery, pregnancy outcome); (2) Effects of Pregnancy on MS (short-term and long-term concerns); (3) Contraception; (4) Recurrence Risks and (5) Psychosocial Issues.

**Identification of familial breast cancer risk during prenatal genetic counseling.** *Y. Furman, D. Cutillo, D. Ramsey, A.E. Donnemfeld.* Genzyme Genetics, New York, NY and Philadelphia, PA.

Family history data regarding breast cancer, obtained at the time of prenatal genetic counseling, was tabulated during the months of March through May, 2001. 70 genetic counselors from 13 states obtained detailed family history information during all prenatal counseling sessions. The family history information was uniformly obtained and prepared in accordance with the recommendations for standardized human pedigree nomenclature (*Am J Hum Genet*, 56;745,1995). Information was entered immediately following the counseling session utilizing a lap-top clinical computer system to ensure accurate and complete data collection. During this 3-month interval, 7,551 patients were seen for prenatal genetic counseling. The mean maternal age of patients was 32 years (range 15-48). 791 patients (10.5%) were identified as having a family history of breast cancer. First degree relatives with breast cancer (mothers and sisters) of the expectant couple were identified on 392 occasions (5.2%). There were 233 maternal and 159 paternal first degree relatives identified. Second degree relatives (aunts and grandmothers) of the expectant couple were identified on 321 occasions (4.3%). There were 240 maternal and 81 paternal second degree relatives identified with breast cancer. There were 139 families with 2 affected relatives, 28 families with 3 affected relatives and 4 families with 4 affected relatives. 13 pregnant women and 2 expectant fathers had themselves been diagnosed with breast cancer. There were 7 males with breast cancer identified. The vast majority of patients who gain access to genetic counseling do so in the prenatal setting. Despite the fact that the primary indication for referral of prenatal patients involves a discussion of fetal risk for a genetic disorder, there is also an opportunity (and an obligation) to provide a thorough and comprehensive risk assessment for other genetic disorders identified during the counseling session, including breast cancer. Our experience is that these patients, although commonly anxious about their pregnancies, are receptive to a discussion of breast cancer risk if a significant family history is identified.

**Communication of Cancer Risk with Family Members and Evaluation of Duty to Inform.** *J. Choi<sup>1</sup>, C. Arbayo<sup>1</sup>, S. Sand<sup>1</sup>, P. Mantha<sup>1</sup>, K. Blazer<sup>1</sup>, R. Nedelcu<sup>1</sup>, M. Grant<sup>2</sup>, J. Weitzel<sup>1</sup>, D. MacDonald<sup>1</sup>.* 1) Dept Clinical Cancer Genetics; 2) Dept Nursing Research and Education, City of Hope (COH) Nat'l Medical Ctr, Duarte, CA.

More information is needed about the impact of the genetic cancer risk assessment (GCRA) process on risk perception, communication and healthcare in women concerned about hereditary breast or ovarian cancer. As part of this study, women with a personal or family history of breast or ovarian cancer were mailed follow-up questionnaires post-GCRA. We report here observations on risk communication and perceptions of duty to inform relatives of cancer risk, for the first 100 participants (51 subjects had breast cancer, 6 had ovarian cancer, and 43 were unaffected). Almost all participants discussed cancer risk with appropriate first-degree relatives after counseling. Ninety-two percent discussed risk with sisters. Among the 72% of women who discussed risk with brothers, 13/28 tested positive for a *BRCA* mutation and all informed their brothers regardless of whether the brothers had daughters, demonstrating integration of knowledge about cancer risk in these men's families. Six of the 8 women who discussed risk with more distant relatives had informative genetic testing results, perhaps showing that informative genetic testing motivated discussion with more distant relatives. Encouragingly, 71% reported that post-counseling they were better prepared to discuss risk with relatives because of a better understanding of risk and risk management. The most common barriers to discussing risk were: no contact with relatives (31%), relatives too far away (19%). Ninety-six percent of respondents felt that a duty to inform relatives about cancer risk exists. Interestingly, 18% felt that both they and the healthcare provider bear this responsibility. These preliminary findings suggest that GCRA influences risk communication positively and provide important data regarding beliefs about duty to inform that could help establish standard of care concerning genetic information. This research was supported by funds from the California Breast Cancer Research Program of the University of California, Grant Number 5BP-0051.

**The medical geneticists role in the multidisciplinary breast cancer pre-surgical treatment planning conference.**

*S.R. Young<sup>1</sup>, K.A. Brooks<sup>1</sup>, S. Kaneko<sup>1,2</sup>, W.M. Butler<sup>3</sup>.* 1) Dept OB/GYN, Univ South Carolina, Columbia, SC; 2) Dept OB/GYN, Nagoya City Univ, Japan; 3) Dept Med, Palmetto Health Alliance, Columbia, SC.

Historically, the Breast Cancer Conference has been composed of pathologists, surgeons and oncologists who gathered post-surgery to discuss pathology findings and treatment options. New imaging technologies and better treatment options have allowed the development of Pre-surgical Treatment Planning Conferences. For the last 6 years medical geneticists at our institution have been attending the weekly Conferences. As the important role of genetics in cancer diagnosis, prognosis and treatment became more apparent the geneticists have been called upon more. The cancer geneticists are now vital conference members as demonstrated in the following cases. A 53-year-old woman was presented regarding a planned lumpectomy. Prior to the conference a genetic counselor had telephoned the patient and learned of a paternal history of breast cancer and Ashkenazi Jewish ancestry. At the conference immediate predisposition gene testing was recommended, citing recent studies that favor less conservative surgery in the presence of BRCA1/2 mutations. Testing was positive for a BRCA1 mutation and the patient underwent mastectomy and is considering further prophylactic surgery. A 35-year-old woman with a palpable mass and no family cancer history was presented. Mammography suggested two lesions that appeared to be separated by 2-3 cm. Core biopsies of both lesions showed invasive cancer. Separate primaries could indicate an inherited cancer predisposition and mastectomy would be considered. If the two lesions were actually contiguous, more conservative surgery could be utilized. While additional imaging could address this question, a molecular approach could yield helpful information. A battery of molecular markers could be studied in both core biopsies. Concordance would suggest common origin; whereas, dissimilarity would suggest separate primaries. Tumor conferences at many medical centers have now become presurgical treatment planning conferences. Genetic counselors and medical geneticists can add knowledge and experience to these Conferences and contribute to overall patient care.

**Using Video Conferencing to Extend Genetic Cancer Risk Assessment Expertise to Community-Based Medical Centers.** *S. Sand*<sup>1</sup>, *R. Nedelcu*<sup>1</sup>, *I. Grady*<sup>2</sup>, *J. Congleton*<sup>3</sup>, *K. Blazer*<sup>1</sup>, *J. Choi*<sup>1</sup>, *D. MacDonald*<sup>1</sup>, *J. Weitzel*<sup>1</sup>. 1) Clin Cancer Genetics (CCG), City of Hope (COH) Natl Med Ctr, Duarte, CA; 2) North Valley Breast Clinic (NVBC), Redding, CA; 3) Good Samaritan Regional Medical Center, Phoenix, AZ.

Comprehensive genetic cancer risk assessment (GCRA) services are often limited to academic medical centers in large, urban communities. The COH *Cancer Screening & Prevention Program Network* (CSPPN) provides GCRA and conducts weekly CME-accredited, multi-disciplinary Working Group conferences to review all cases. The NVBC, staffed by a breast surgeon and nursing staff, provides GCRA since the nearest genetic counselor (GC) is 150 miles away. A CSPPN satellite in Phoenix, AZ, staffed by a board certified nurse/GC, provides GCRA with clinical and programmatic support from the CSPPN. **Objective:** To address geographic disparity in access to quality GCRA, we investigated the use of multipoint videoconferencing (VC) as a tool for collaboration between the CSPPN and two distant community medical centers. **Methods:** The COH CCG Technology Transfer Research project, supported by the California Research Program, was established to foster access to comprehensive GCRA in communities lacking such services. We installed VC units in the two community-based centers to provide consultation and case management through the Working Group (including experts in medical & surgical oncology, gastroenterology, clinical genetics, genetic counseling, and clinical research), which provides consensus on pedigree analysis, mutation probability, testing strategies, and medical management advice, with interactive discussion from all participants. **Results:** In the first six months, the NVBC presented 17 cases and the Phoenix satellite presented 13 cases. The VC-mediated collaboration resulted in improvement of pedigree and pathology documentation, recommendations for genetic testing and patient management, and identification of potential candidates for chemoprevention and epidemiology research studies. **Conclusion:** VC is a valuable tool for extending GCRA expertise to community-based medical centers and enhances accrual to cancer prevention studies.

**Independent De Novo 22q11.2 Deletions in Two First Cousins with Velocardiofacial Syndrome.** *S.C. Saitta, S.E. Harris, D.A. Driscoll, B.S. Emanuel, D. McDonald-McGinn, E.H. Zackai.* Div Human Genetics, Childrens Hosp Philadelphia, Philadelphia, PA.

Deletions of chromosome 22q11.2 are found in the vast majority of patients with Velocardiofacial/DiGeorge Syndrome (VCFS/DGS). The deletion is estimated to occur in 1:4000 live births, making it the most frequent human microdeletion syndrome. The overwhelming majority of deletions are de novo, with 10% or less inherited from an affected parent. Parental origin studies have previously proven useful to exclude germline mosaicism in an extended family with 2 affected relatives with a 22q11.2 deletion (Driscoll et al, 1997). Here, a second family of 2 unaffected siblings (brother and sister) who each had a child with VCFS/DGS and 22q11.2 deletion as detected by FISH with probe N25. The size of each deletion was determined using FISH with multiple probes from 22q11.2 and both were found to be 3 Mb, the most commonly seen deletion. FISH was normal in the parents of each affected child. We used 6 highly polymorphic microsatellite repeat markers from within 22q11.2 to determine the parental origin of each cousins deletion. This analysis confirmed that in each case, the deletion occurred in a maternally derived chromosome 22. Thus, these were independent de novo deletion events, and we were able to exclude germline mosaicism as the underlying mechanism for affected cousins in this family. These findings underscore the extremely high frequency with which the 22q11.2 deletion occurs in the general population, and demonstrate the important role that PCR-based parental origin determination can have in determining recurrence risks and counseling such families. Although the risk is no higher than the general population, relatives may consider prenatal testing for the 22q11.2 deletion in future pregnancies.

Program Nr: 1126 from the 2001 ASHG Annual Meeting

**Education about etiology and prevention of cleft lip and palate anomalies for Asians families.** *S. Pai, H. Oh, C. Shidara, T. Mosby, M. Tolarova.* Cleft Prevention Program, School of Dentistry, San Francisco, CA.

Cleft lip and palate anomalies are serious and among most common birth defects affecting 1 in every 550 newborns. The prevalence is even higher among American Indians and Asians.

Our goal was a building of public awareness in the field of orofacial cleft (OFC) anomalies in Asian families.

We developed an educational material on etiology and prevention of OFC for Mandarin, Korean and Japanese speaking families. We took into consideration differences in cultural background of each of these ethnically different populations.

**CULTURE DIFFERENCES.** Even though there are obvious cultural differences between individual Asian populations, several common characteristics exist that need to be taken into consideration. Asian men are more active in social-economic activities and women are more responsible for family's diet and health, children's education, and all sorts of matters regarding family. Women are often blamed and also have guilty feelings, if they have a child with a congenital or acquired defect.

**CONCLUSIONS.** It is extremely important to consider cultural differences, customs and taboos in any educational activities focused on prevention of cleft lip and palate anomalies in Asian families. Usual approach, successfully used in Caucasian families, must be modified in order to respect cultural background. Any issues related to family planning must respect leading men's role in majority of Asians families. When prevention protocol requires changes in the life style and dietary pattern, sensitive approach - respecting often deep cultural roots - has to be taken to deliver the message.

The development of the original pamphlet in English and Spanish was supported by MOD Northern California Chapter Community Service Grant.

**Genetic Counseling for Ultrasound Anomalies: Report of a National Genetic Counseling Program.** *D.M. Cutillo, K. Fordham, D. Ramsey, A.E. Donnenfeld.* Dept Clinical Operations, Genzyme Genetics, Philadelphia, PA.

The national prenatal genetic counseling program in Genzyme Genetics encompasses various regions and includes 55 genetic counselors. Starting in January 2001, an integrated clinical computer system began which documents data on all genetic counseling sessions. From January-May 2001, 15,921 patients were seen for genetic counseling. For the indication of abnormal ultrasound, data on 1255 patients was available. The following complete data was gathered on all 1255 patients: maternal age, ethnic background, exposures, family history, and testing and procedure options offered. 92 different types of ultrasound anomalies were identified. The four most common ultrasound anomalies seen were: choroid plexus cyst (24.5%), echogenic intracardiac focus (10.3%), pyelectasis (6.8%), echogenic bowel (6.7%). As part of our clinical practice guideline on ultrasound anomalies, all patients were counseled regarding the option of prenatal diagnostic procedures appropriate for the gestational age, including CVS, amniocentesis, and detailed fetal anatomic survey (if not previously done). All patients' decisions were documented. For invasive prenatal diagnostic procedures (CVS, Amnio) (23.1%) accepted a procedure, (67.6%) declined a procedure, and (9.3%) were undecided about a procedure at the conclusion of the genetic counseling session. Chromosome abnormalities detected: Choroid plexus cyst (4.3% Trisomy 18), echogenic intracardiac focus (2.3% Trisomy 21, 2.3% 47,XX+mar), pyelectasis (2.3% Trisomy 21), echogenic bowel (11.6% Trisomy 21). In most cases of chromosome abnormalities, additional US anomalies were present, there was one case of isolated choroid plexus cyst associated with Trisomy 18, and one case of isolated pyelectasis with Trisomy 21. The introduction of an integrated national clinical computer system, with the capacity to ensure accurate and reliable data input following the genetic counseling session, enhances our ability to: 1) Document patient decisions following the genetic counseling session, 2) Develop specialized education programs for our genetic counselors, 3) Monitor adherence to our clinical practice guidelines, 4) Collect and report data on large numbers of patients.

**Psychosocial impact of genetic testing for tuberous sclerosis complex (TSC).** *B. Clark-Gay<sup>1</sup>, A.J. Tucker<sup>1</sup>, M.A. Assel<sup>1</sup>, D.A. Johnston<sup>2</sup>, K.-S. Au<sup>1</sup>, H. Northrup<sup>1</sup>.* 1) Department of Pediatrics, The University of Texas Medical School; 2) Department of Biomathematics, M.D. Anderson Cancer Center, Houston, TX.

Tuberous sclerosis complex (TSC) is an autosomal dominant disorder with a prevalence of 1/6700. The clinical manifestations are highly variable among individuals, with seizures and mental retardation often causing significant morbidity. Two TSC genes have been identified: TSC1(9q34) and TSC2(16p13). Approximately 60%-80% of individuals diagnosed with TSC have a detectable mutation. Genetic testing for TSC has recently become available on a clinical basis, yet the psychosocial impact of genetic testing in this population remains unexplored.

The study objectives included developing a genetic counseling protocol for disclosing genetic testing results while assessing the impact of the results. Thirty subjects completed a study questionnaire and SCL-90-R before result disclosure and one month following result disclosure. Forty percent of the individuals were adults affected with TSC, and 60% were unaffected parents receiving a result on their affected child. The top three motivations for genetic testing were (1) to understand the cause of TSC, (2) to help family members, and (3) to obtain information about recurrence risk. Reproductive concerns were not listed as a primary reason for testing; however, the data suggest that reproductive decisions might be impacted by the genetic testing results. Unaffected parents receiving results on their affected child did not exhibit a statistically significant change in psychological symptoms after result disclosure. However, affected individuals reported significantly fewer psychological symptoms after result disclosure. The results were statistically significant for a reduction in symptoms of depression ( $p=0.034$ ), hostility ( $p=0.038$ ), and global severity index ( $p=0.026$ ). Our data suggest that genetic testing for TSC does not cause psychological distress, and genetic testing within a genetic counseling setting may result in a reduction of psychological symptoms in affected individuals. The findings may be helpful to genetics providers and consumers to aid in integrating molecular testing for TSC into clinical practice.

**Genetic Counseling for Primary Care Providers: Use of Standardized Patient as a Model for Education in**

**Genetics.** *G. Adamo*<sup>1</sup>, *R.E. Hawkins*<sup>1</sup>, *C.J. Macri*<sup>2</sup>. 1) NCA Medical Simulation Center, Uniformed Services University, Bethesda, MD; 2) Department of Obstetrics and Gynecology, Uniformed Services University, Bethesda, MD 20814.

Advances in the Human Genome Project have accelerated the need for education in medical genetics for all healthcare providers. Experts in the field have recognized that the majority of patient evaluation and care in genetics in the future will be offered by primary care providers. Because the basic education of these healthcare providers may not have included the many new advances in medical genetics, our project addresses the educational needs of this population. We have created a library of standardized patient cases which portray patients with breast, colon and ovarian cancer, polycystic kidney disease, hemochromatosis, cystic fibrosis, and sickle cell anemia among others. The cases offer opportunities for providers to practice and demonstrate their skills in a safe, educational environment. These encounters are used to improve and assess their skills, knowledge and attitudes about medical genetics. For example, in a routine clinic visit the provider is challenged to elicit patient concerns, family history, a three generation pedigree, and the specific history of sickle cell anemia in family members. The National Capital Area Medical Simulation Center was established by the Uniformed Services University in 2000 to enhance the educational process of medical and nursing students, residents and practicing professionals. This state of the art simulation center features a 12-exam room clinical skills laboratory and a computer laboratory area that are used for teaching and assessment activities. The computer laboratory allows web based searches of pertinent medical and genetic information to be used by primary care providers interacting with standardized patients. The providers are instructed to use the web based material and searches, in order to gather information necessary to address specific patient needs. Standardized patients offer a unique opportunity to provide intensive educational experiences for primary care providers in complex multi-disciplinary fields such as medical genetics.

**Parental evaluation of the experience of being informed that a child has a cleft lip and/or palate.** *A.L. Byrnes, M.L. Marazita, N.W. Berk, M.E. Cooper.* University of Pittsburgh, Pittsburgh, PA.

To assess parental satisfaction, differences between parental experiences and preferences with respect to cleft lip and/or palate informing interviews were investigated. A within group comparison of a sample of parents of children with orofacial clefts ascertained from a multidisciplinary craniofacial center was conducted. The Health Professional-Parent Communication Questionnaire (Strauss et al., 1995) was used to obtain information about informing interview experiences and preferences with respect to eleven dimensions of health professional behavior. Descriptive statistics, Wilcoxon matched-pairs signed-ranks analyses, and chi-square analyses were performed. Results revealed that the majority of parents were informed of a child's cleft lip and/or palate at the time of birth (87%) by a physician (87%). These findings were consistent with those reported by Strauss et al. (1995). Parents in this sample wanted informing health professionals to be in greater control of the informing conversation ( $p=0.0033$ ), to show more caring ( $p<0.0001$ ) and confidence ( $p<0.0001$ ), to show more of their own feelings ( $p=0.0140$ ), to give parents more of an opportunity to talk ( $p<0.0001$ ) and show feelings ( $p<0.0001$ ), to make a greater effort to comfort parents ( $p<0.0001$ ), to provide more information ( $p<0.0001$ ), to initiate more of a discussion about the relationship between clefts and mental retardation/learning disabilities ( $p<0.0001$ ), and to provide more referrals to other parents ( $p=0.0353$ ). With the exception of health professionals showing their own feelings, Strauss et al. (1995) also found significant differences between parental experiences and preferences for these dimensions. A positive association between the degree to which parents reported knowing the health professionals at the time of the informing interview, and their satisfaction was identified for ten of the eleven dimensions of health professional behavior ( $0.0001 \leq p \leq 0.0247$ ). Strauss et al. (1995) also found significant associations between knowledge of health professional and six of these behavior dimensions.

**Genetic counseling in hereditary breast/ovarian cancer families in Israel: retention of genetic information and psychosocial impact.** *M. Frydman<sup>1</sup>, M. DiCastro<sup>1,2</sup>, I. Friedman<sup>2</sup>, B. Goldman<sup>1</sup>, E. Friedman<sup>2</sup>.* 1) Genetics Inst, Haim Sheba Medical Ctr, Tel Hashomer, Israel; 2) Oncogenetics Unit, Sheba Medical Center, Tel-Hashomer, Israel.

Genetic counseling for individuals at high risk for developing breast and ovarian cancer (oncogenetic counseling) involves consultees education as the genetic basis of inheritance in cancer, evaluation of cancer risk, psychological evaluation, and genetic testing for germline mutations in BRCA1/BRCA2 genes. In mutation carriers, cancer risk can be objectively verified and even semiquantified, whereas mutation non-carriers may actually be recategorized as "average cancer risk". The long-term psychosocial impact of oncogenetic counseling on consultees and the retention of oncogenetic information are uncertain. We retrospectively interviewed 155 women who underwent oncogenetic counseling in a single medical center in Israel in 1996 and 1998, 29 BRCA1/BRCA2 mutation carriers and 126 non-carriers. A validated questionnaire that evaluated self-reported distress and anxiety symptoms before and after counseling, as well as the retention of relevant genetic information (e.g., individual and offspring cancer risk, early detection schemes) one and three years after the initial consultation was filled by study participants. Overall, oncogenetic counseling had a minimal effect on anxiety related symptoms. Mutation carriers report of anxiety-associated symptoms such as sleeplessness, "bad mood", more frequently than non-carriers following oncogenetic counseling. As expected, 61.8% of carriers and only 30% of non-carriers accurately remembered the genetic risk and preventive and early detection schemes. We conclude that no overt adverse psychosocial effects can be attributed to oncogenetic counseling, and that there is an ongoing need to emphasize oncogenetic information to high-risk individuals.

**Epidemiological impact of genetic counselling and predictive testing for myotonic dystrophy.** *J. Mathieu, C. Tremblay, C. Prevost.* Dept Neurology, Complexe Hosp de la Sagamie, Chicoutimi, PQ., Quebec, Canada.

The prevalence of myotonic dystrophy type 1 (DM) is very high in the Saguenay-Lac-Saint-Jean (SLSJ) region, a geographically isolated region in the northeastern part of the province of Quebec (Canada). In SLSJ, a program of genetic counselling for DM patients and their families was introduced in 1981 and a program of predictive testing is offered to the population since 1988. In order to determine the effect of genetic counselling and predictive testing on the prevalence of the DM phenotypes, we compared the demographic characteristics and the phenotypes of the DM patients over the last 15-year interval (1985-2000). During this period, the median age of the DM patients increased from 34.5 years to 44.0 years ( $p < 0.00001$ ). The median age of the congenital, childhood and classic DM patients increased respectively from 9 to 24 years ( $p < 0.001$ ), 24 to 33 years ( $p = 0.01$ ) and 35 to 44 years ( $p < 0.001$ ). In this time interval, the proportion of patients with a congenital or a childhood phenotype remained stable but the proportion of patients with a classic phenotype decreased from 75% to 61% and, the proportion of patients with a mild phenotype increased from 6% to 20% ( $p < 0.001$ ). In the last 5 years, among the 63 newly diagnosed patients, 43% had a mild DM phenotype detected only by DNA analysis. The reasons for the significant ageing of the DM population in SLSJ region are complex and include a low natality rate throughout the Quebec population, a reduction in births at risk due to genetic counselling and an increase in the number of mildly affected patients often recognized at an older age only by predictive testing. The shift in the distribution of the DM phenotypes toward mildly affected individuals is expected to accelerate in the future.

**Patient Confidentiality vs. Duty to Warn At-Risk Relatives: The Experiences of Genetics Counselors. R.B.**

*Nation*<sup>1</sup>, *E. Jeungst*<sup>2</sup>, *G.L. Wiesner*<sup>1</sup>, *N.H. Robin*<sup>1</sup>. 1) Genetics; 2) Bioethics, Case Western Reserve Univ, Cleveland, OH.

When a patient refuses to inform relatives of their risk for genetic disease, a genetic counselor (GC) is faced with conflicting ethical obligations. On one hand, there is the obligation to respect and protect their patient's right to privacy. On the other hand, there is the obligation to prevent harm and promote the welfare of family members. This suggests a responsibility to warn at-risk relatives, even without the patient's consent. Unfortunately, there is little to guide the GC when faced with this situation. There is no legal standard, and the guidelines of various societies leave considerable room for subjective interpretation. Furthermore, there is little literature on our clinical experience with this, as most studies have been based on theoretical situations. Interestingly, most have found that GCs were less likely than medical geneticists to overrule patient confidentiality. To examine the actual clinical impact of this issue, we surveyed ~1,300 National Society of Genetic Counselor (NSGC) members to examine their experience with this conflict. GCs were invited to answer a survey that was posted on the Internet or available at the 19th NSGC Conference. The survey addressed GCs' experience with patients' refusal to share genetic information with at-risk relatives, and the factors that lead to their decision whether to warn or not. 119/259 (46%) respondents had a patient refuse to notify an at-risk relative. Only 24 (9%) reported seriously considering warning without consent, and only 1 did. This case had special circumstances, as the at-risk relative was also a patient of the GC. Three factors consistently made the GC less likely to warn: patient's potential emotional reaction, relative and patient's emotional relationship, and the chance that the relative was aware of the disease by another means. These results suggest that in clinical experience this conflict is usually resolved by respecting patient autonomy. While several factors may have contributed to this, emotional factors were the most critical in deciding not to warn. Respondents also indicated they viewed notifying relatives without consent outside the GCs role and responsibility.

**Counseling concerns with cystic fibrosis mutation analysis.** *G.A. Jervis<sup>1</sup>, R. Montenegro<sup>2</sup>, B.G. Kousseff<sup>1</sup>*. 1) Regional Genetics Program, Univ South Florida, Tampa, FL; 2) Bayfront Maternal Fetal Medicine St. Petersburg, FL.

Cystic fibrosis (MIM#219700) is an autosomal recessive disease caused by mutations in the cystic fibrosis conductance regulator gene (CFTR) located on chromosome 7q31. Manifestations of the disease include pancreatic insufficiency, meconium ileus, chronic bronchopulmonary infections and elevated sweat chloride concentrations. To date, over 900 CFTR mutations have been identified. We present an African American family referred during their third pregnancy because they have two sons with a clinical diagnosis of cystic fibrosis. The oldest son (MC) had meconium ileus and surgery for duodenal atresia. He uses a gastric tube and is on enzyme therapy. The younger son (JC) is asymptomatic but allegedly had a positive sweat test. Parents are healthy and have no family history of cystic fibrosis. Molecular studies performed at Genzyme Genetics laboratory revealed: Father- DF508/(-); Mother- DF508/D1270N; MC- DF508/DF508; JC- DF508/D1270N; Amniocytes- DF508/D1270N. Thus, the mother, JC and fetus have the same genotype. The pregnancy resulted in a healthy male with a normal sweat test. If the offspring had all three mutations, then the maternal mutations would have been in cis. There are reports that double mutant CFTR alleles are more common than expected (Human Molecular Genetics, 1995,4:1169). The three DF508/D1270N individuals are most likely compound heterozygotes. The phenotype of DF508/D1270N has been reported with normal pulmonary and pancreatic function (World J Urol, 1193:11,82), which explains the asymptomatic state of these individuals. However, there are reports that males with DF508/D1270N have congenital bilateral absence of vas deferens (CBAVD). So, the two sons with DF508/D1270N genotype will be evaluated for CBAVD and counseled accordingly. This family illustrates the complexity of genotype-phenotype correlations in cystic fibrosis and demonstrates that certain combinations of CFTR mutations can result in asymptomatic phenotype but may have consequences for fertility.

**Risk Reduction Behavior in Individuals and Families at High Risk for Breast/Ovarian Cancer Syndrome: The UCSF Cancer Risk Program Experience 1996-2000.** *J.L. McLennan, E.B Crawford, A.E. Toland, J.L. Ziegler, D. Tripathy, L.J. Esserman.* Cancer Risk Program, UCSF Comprehensive Cancer Center, San Francisco, CA.

**Introduction.** The Cancer Risk Program at UCSF provides genetic counseling and testing for individuals at high risk of developing breast/ovarian cancer syndrome within the framework of a prospective study aimed at reducing their cancer risk. Since its inception in 1996, 1038 potential clients have contacted the Program of whom 463 agreed to genetic counseling. We offered genetic testing for BRCA1 and BRCA2 mutations to counseled individuals whose risk of being a carrier exceeded 10%; (BRCAPRO software). **Method.** In a cross-sectional design, we analyzed the outcomes after counseling and testing 170 individuals who enrolled in the Program between 10/96 and 12/00. Group I tested positive (n=80) for a deleterious mutation in BRCA1 or BRCA2. Group II (n=90) was tested and found NOT to have known deleterious mutation in either BRCA1 or BRCA2 (Ashkenazi founder analysis, n = 47, full sequence analysis, n= 43). No true negatives and no subjects with variants or polymorphisms were included in either group. **Results.** In an interim outcomes analysis (n= 70), both groups reported high level adherence (>95%) to recommended screening guidelines for both breast and ovarian cancer. Over 80% reported positive lifestyle changes (improved diet, more exercise, and less stressful cancer worries). 47% of Group I chose prophylactic contralateral or bilateral mastectomy and the majority (95%) were later satisfied with the decision. 72% of Group I chose prophylactic ovarian surgery [BRCA1 91% v BRCA2 72%] and after careful histopathology review, two mutation carriers had Stage I cancer in their ovaries. 95% of both groups shared information about genetic test results with other family members, but only half of families with a mutation carrier proband have opted for further genetic testing. **Conclusion.** Genetic counseling and testing in our experience is associated with positive risk reduction behavior in the majority. Probands should be encouraged to inform other relatives at risk to amplify the cancer prevention effect of genetic testing in families.

**Evidence that Depression-Screening is Useful in Prenatal Genetic Counseling.** *M. Jurek<sup>1</sup>, J. Edwards<sup>1</sup>, C. Lovell<sup>1</sup>, C. Singletary<sup>1</sup>, V. Vincent<sup>1</sup>, C.M. Wolpert<sup>2</sup>.* 1) Genetic Counseling Program, University of South Carolina, S.C. 29203; 2) Duke University Medical Center Durham, N.C. 27710.

Depression commonly occurs in women during pregnancy. If left untreated, depressive symptoms have been associated with an increased risk for preeclampsia, low birth weight, and post-partum depression. Surprisingly, in the United States there are no formal depression-screening programs targeted towards prenatal patients. Genetic counselors are uniquely poised to offer depression screening given that the typical prenatal genetic counseling session includes psychosocial assessment. The objective of this study is to examine whether genetic counselors recognized symptoms of depression in the prenatal advanced maternal age population. We hypothesized that a standardized depression-screening questionnaire would be most effective in identifying depression in this patient population. Prenatal patients were asked to complete a standardized depression inventory, the Beck Depression Inventory (BDI-II) in the waiting room prior to their prenatal genetic counseling session. A board-certified, prenatal genetic counselor that was blinded to the results of the BDI-II completed a psychosocial assessment for depression after the session. A supervising genetic counselor scored the patient's BDI-II and compared the two methods for concordance. Women identified as depressed were informed of their results and referred to their health care provider by the supervising genetic counselor. Of the thirty-five patients who volunteered for the study, 10 (28.57%) screened positive for depression on the BDI-II. Only three of these 10 patients were identified by their prenatal genetic counselor as having symptoms of depression, representing a 30 % concordance in between the BDI-II score and the genetic counseling assessment. This pilot data suggests that a significant percentage of depressive symptomatology in AMA prenatal patients may not be apparent to the genetic counselor using routine methods. Incorporating a formal depression-screening tool such as the BDI-II may be useful in a prenatal setting.

**Assessment of the Effectiveness of Genetic Counselling by Telephone Compared to a Clinic Visit.** *K.K. Sangha<sup>1</sup>, A. Dircks<sup>2</sup>, S. Langlois<sup>2</sup>*. 1) Dept. of Medical Genetics, University of Alberta Hospital, Edmonton, Alberta, Canada; 2) Dept. of Medical Genetics, University of British Columbia, Vancouver, British Columbia, Canada.

Maternal serum screening, also known as triple screen, is used during pregnancy to assess the risk of carrying a fetus with specific chromosome abnormalities or an open neural tube defect. A blood test administered between 15 and 20 weeks of pregnancy measures the levels of three proteins in the maternal serum to calculate the risk to the fetus of having trisomy 18, trisomy 21, or open spina bifida. All pregnant women in British Columbia (BC), Canada are eligible to have maternal serum screening and the test is optional. All women who screen positive (approximately 8% of all women tested) are eligible for genetic counselling and are offered amniocentesis. The purpose of this study is to determine what differences (if any) exist in patients understanding and/or anxiety when genetic counselling for a positive triple screen result is conducted in person versus over the telephone. Currently, all genetic counselling sessions for positive triple screen result are conducted in person in the Provincial Medical Genetics Programme at BC Children's and Women's Health Centre in Vancouver. In this study each patient who agreed to participate was given the choice to have her genetic counselling session in person or over the telephone. Through the use of a brief written post-counselling questionnaire, each patient was assessed for her understanding of the information presented in the session, and her anxiety regarding her risk. In this small pilot study, there were no statistically significant differences detected in patients' understanding or anxiety when genetic counselling for a positive triple screen for Down syndrome was conducted by telephone versus in person.

**The Impact of DNA Analysis on Genetic Counselling for 276 Retinoblastoma (RB) Families.** *J. Sutherland*<sup>1,2,4</sup>, *J. Anderson*<sup>2</sup>, *S. Richter*<sup>2</sup>, *B. Gallie*<sup>1,2,3,4</sup>. 1) The Retinoblastoma Program, Ophthalmology, Hospital for Sick Children; 2) Solutions by Sequence, Inc; 3) Ontario Cancer Institute/Princess Margaret Hospital, University Health Network; 4) University of Toronto, all in Toronto, Ontario; Canada.

Clinical care and genetic counselling for RB families is enhanced by knowledge of the precise mutation in the proband. Without DNA analysis, counselling consists of presenting several scenarios, each dependant on when the predisposing RB1 mutation occurred. Statistics were generated from a FileMaker Pro database used by *Solutions*. Mutations were identified and reported for 276 probands (specificity >85%). Within our own institution, counselling was provided for 182 probands' families. Mutation detection was particularly useful in counselling parents of isolated cases of unilaterally affected children by discriminating somatic, non-germline RB from heritable disease. After two RB1 mutations identified in tumor but not in blood, 89%(86/97) probands then counselled to have reduced tumor risk for the other eye and for other lifetime cancers. Despite the lack of family history, 11%(11/97) of unilateral probands had germline mutations. Counselling and screening then proceeded as for bilateral families. Of 125 non-familial, bilaterally affected probands, 96%(69/72) of tested parents were normal, suggesting *de novo* mutations. Probands' sibs are tested for the mutation because of the possibility of germline mosaicism in the parent. Statistics predict 50% of offspring of adult, bilateral survivors are predisposed to RB tumors. DNA analysis identified the children at risk for tumor development. The children who are not, could safely opt out of examinations under anesthetic and clinical examinations could be reduced or eliminated. Thus for 91% of families, DNA analysis reduced relatives' risk to 1 in 20,000, sparing sibs and cousins from invasive clinical screening under anesthetic. In conclusion, the ability to alleviate uncertainty in counselling strongly supports DNA testing for RB. DNA analysis identifies which scenario to address and personalizes risks for relatives allowing greater decision-making power for the families.

**Clinical interpretation and recommendations for patients with a variant of uncertain significance in BRCA1 or BRCA2: a survey of genetic counseling practice.** *N.M. Petrucelli<sup>1</sup>, N. Lazebnik<sup>1</sup>, K.M. Huelsman<sup>2</sup>*. 1) Department of Medical Genetics, Henry Ford Hospital, Detroit, MI; 2) Division of Human Genetics, Children's Hospital Medical Center, Cincinnati, OH.

**Purpose:** To document current practices in breast cancer genetic counseling and to identify areas of variability in practice for patients with a variant of uncertain significance (VUS) in the BRCA1 or BRCA2 gene. **Methods:** Three hundred and seventeen active members of the National Society of Genetic Counselors (NSGC) were sent an invitation via electronic mail to participate in an online questionnaire. The online questionnaire consisted of 22 questions divided into 3 sections: clinical experience with VUS, clinical meaning of VUS, and risk perceptions and clinical recommendations for given clinical situations involving a VUS. Some open-ended questions were provided to allow respondents greater flexibility in their answers and the opportunity to give qualitative comments. **Results:** Of the total 295 members meeting eligibility criteria, 57 (19.3%) responded. During the pre-test counseling session for a BRCA risk assessment patient, the vast majority of counselors (80.7%) mention VUS as a possible test result. However, only 49.1% report having given such a result to their patients. Furthermore, only 63.2% (36) felt as though their patients understood the meaning of a VUS test result. When asked to conclude the implication of a VUS and make medical management recommendations, the responses were varied. Nevertheless, a good proportion of counselors expressed the importance of testing other family members to help clarify the probands risk and aid in medical management issues. **Conclusion:** While the recent recommendations by the American College of Medical Genetics suggest standards for the interpretation of sequence variations, they do not provide guidelines for making clinical recommendations based on these variations. The results of this study reveal significant diversity in the personal interpretation of a VUS test result, ultimately leading to various clinical recommendations. This suggests a need for clinical management standards as well.

**Pretest Counselling Post Testing: Experiences of Providing Genetic Counselling Services to Participants in a Population Based Study of the Prevalence and Penetrance of BRCA1 and BRCA2 Mutations in Ovarian Cancer.**

*S. Randall*<sup>1</sup>, *L. Bradley*<sup>1</sup>, *S. Narod*<sup>2</sup>, *K.J. Murphy*<sup>1</sup>, *B. Rosen*<sup>1</sup>. 1) Familial Ovarian Cancer Clinic, Princess Margaret Hosp., Toronto, ON, Canada; 2) University of Toronto Dept. of Public Health Sciences, Toronto, ON, Canada.

Genetic counselling for hereditary breast and ovarian cancer has typically involved in-depth pretest counselling sessions for those individuals eligible to have genetic testing for mutations in the BRCA1 and BRCA2 genes. It is only following such thorough counselling where issues such as insurability, employability, and psychological impact are discussed, that a blood sample for genetic testing can be drawn. Once genetic testing results are available, the patient returns to the clinic for another visit to discuss the full implications of the results with respect to their clinical management.

Here we describe the experience and results of offering genetic counselling to a series of women with ovarian cancer that provided blood samples for genetic testing for mutations in the BRCA1 and BRCA2 genes. These women were offered genetic testing as part of a research protocol to determine the prevalence and penetrance of germline BRCA1 and BRCA2 mutations in women with ovarian cancer.<sup>1</sup> Genetic counselling services were provided only to those women electing to receive their test results.

Of the 1024 eligible women that were diagnosed with epithelial ovarian tumors in Ontario between January 1995 through December 1996, 649 (63%) agreed to provide blood samples. To date, 124 (19%) of these women have accepted a referral for genetic counselling in order to receive their test results, 58 of whom were seen in our center. We evaluate here the effectiveness of this form of genetic counselling in comparison to more traditional methods. We also evaluate the uptake of genetic testing for hereditary breast and ovarian cancer as compared to that found in the routine cancer genetics clinic.

1. Risch et al 2001. *AJHG* 68:700-710.

**Participant satisfaction with genetic counseling/testing and psychosocial adjustment at a university-based family cancer registry.** *J.L. Seldon, L.C. Kwan, J.E. Bower, P.A. Ganz.* Jonsson Comp Cancer Ctr, Univ California, Los Angeles, Los Angeles, CA.

In 1998, the UCLA Familial Cancer Registry and Genetic Evaluation Program was established to identify individuals and families at increased risk for familial cancer. One Registry objective is to serve as a resource of subjects whose informed consent participation may contribute to genetic, behavioral, and other hypothesis driven research protocols. All Registry participants are asked to contribute biological specimens such as blood/tissue and complete the following baseline and annual follow-up data: demographics, hazardous work exposures, psychological measures, quality of life, diet, physical activity, tobacco/alcohol use, medical history, cancer screening, other health practices, and detailed pedigree. A second objective is to provide genetic counseling/testing to individuals at high risk for cancer predisposition mutations. Psychosocial and genetic knowledge data are collected prior to genetic counseling, at time of blood collection, and at 1, 6, and 12 months post-testing. Satisfaction with genetic counseling/testing is collected 1 month post-testing. Overall, Registry participants (n=169) did not show elevated levels of psychological distress. Scores on standardized measures of depressive symptomatology, anxiety, and quality of life all fell well within normal limits. Level of distress about genetic counseling and testing (n=47) was also low overall. However, we did see an increase in test-related distress among individuals who tested positive; distress levels increased at 1 month post-testing, and continued to rise at 6 months in this group. In contrast, test-related distress decreased among individuals who tested negative. The increase in test-related distress was followed by an increase in depression scores among participants testing positive, suggesting that issues related to cancer risk may have had a broader impact on mood as participants contemplated post-testing decisions such as prophylactic surgery and chemoprevention. Regardless of test results, the participants were highly satisfied with the genetic counseling/testing experience.

**Levels of genetics knowledge and distress: A comparison of cancer survivors and unaffected women in a BRCA1/2 testing program.** *K.A. Schneider, A.B. Chittenden, L.M. DiGianni, A.F. Patenaude, R. Gelman, J.E. Garber.* Dana Farber Cancer Inst, Boston, MA.

The BRCA1/2 testing experience might be different for cancer survivors compared to women who have never had cancer. We compared genetics knowledge and depression and anxiety scores for 86 breast or ovarian cancer survivors and 72 unaffected women in a BRCA1/2 testing program. Demographics were similar for both groups including education and income levels. All participants had at least a 10% chance of having BRCA1/2 mutations. Positive results were reported to 38 women (19 cancer survivors, 19 unaffecteds) and negative results were reported to 104 women (55 cancer survivors, 49 unaffecteds). Variant results were excluded. Participants completed a 20-item knowledge questionnaire at baseline and 2 weeks post-results. Depression and anxiety subscales of the Brief Symptom Inventory (BSI) were completed at baseline and 4 months post-results. **RESULTS:** Knowledge scores were higher among unaffected women than cancer survivors both at baseline (66.52 vs 57.24,  $p=.02$ ) and post-results disclosure (72.05 vs 63.76,  $p=.005$ ). Knowledge scores rose for both groups from baseline to post-results. Overall depression and anxiety scores for cancer survivors and unaffected women were not different at either measurement, but cancer survivors showed improved scores from baseline to 4 months post-results [anxiety mean score: 48.7 to 45.6, depression mean score: 50.1 to 47.7]. Sorting the groups by test results, we found that cancer survivors with negative results had improved anxiety and depression scores and cancer survivors with positive results had improved anxiety scores. Unaffected women had unchanged depression and anxiety levels regardless of result. **SUMMARY:** Cancer survivors were less knowledgeable than unaffected women about testing both at baseline and 2 weeks after results disclosure, although knowledge scores improved for both groups. Cancer survivors distress scores decreased with results whereas test results did not alter scores in unaffected women.

**Genetic Screening Pocket Facts Card: An educational tool for primary care practitioners.** *S.S. Brooks, J.D. Krogh, N.J. Zellers, E. Nikezic-Ardolic.* Human Genetics, New York State Inst Basic Res, Staten Island, NY.

For many medical disciplines pocket cards are available containing critical information practitioners can review while providing patient care. Based on this model we developed a *Genetic Screening Pocket Fact Card* containing practical genetic information for clinicians. Topics covered included conditions in the eastern Jewish population, fragile X mental retardation syndrome, hemoglobinopathies and cystic fibrosis. The cards measured 7 by 14 inches when open and 3.5 x 7 inches when folded. They were laminated for durability. In addition to the card, a patient information sheet was developed with information about genes, recessive inheritance, screening, prenatal testing, carrier frequencies and additional information sources. These tools were distributed to 6500 primary care physicians in New York City. The physicians were asked to return a 6 question survey. Besides indicating their type of practice, they assessed on a scale of 1-5 (least-most) how frequently genetics was discussed with their patients; whether the information presented was clear; whether the pocket guide would be useful to them; how much they would be willing to pay for additional copies; and whether the patient information was useful for their practice. Preliminary results of the survey show that internists are least likely, pediatricians and family practitioners somewhat likely and obstetricians most likely to discuss genetics with their patients. All groups felt that the information presented was clear. Obstetricians indicated that they would use the guide most often, followed by family practitioners, pediatricians, and internists. Most groups found the patient information sheets useful as well. Despite the positive response to the information 36% of those surveyed would not be willing to pay for additional copies. Those willing to pay would spend \$1. However, we did receive several requests for multiple additional copies. Overall, there was a very positive response from clinicians for this novel genetic educational tool. *This project was funded by a community service grant from the Greater N.Y. March of Dimes.*

**Genetics education in New England family practice residencies.** *W.G. Feero<sup>1</sup>, P. Haddow<sup>2</sup>, D.K. Olson<sup>1</sup>.* 1) Maine-Dartmouth Family Practice Residency Program, Augusta, ME; 2) Foundation for Blood Research, Scarborough, ME.

Family practice physicians are likely to play a major role in delivery of genetic health care to rural and underserved communities in the United States. In 1999 the American Academy of Family Practice(AAFP) established training guidelines for genetics in family practice residencies. One year after the establishment of these guidelines we surveyed the program directors of 17 New England family practice residencies to determine the extent to which genetics is a part of resident training. Furthermore, we sought to determine factors that might affect the presence of genetics training in the curricula. 13/17 of programs responded, three reported having a formal curriculum in genetics. Those with a formal curriculum reported 5-10 hours(1/3) and >10 hours(2/3) of genetics training during the three years of residency training. Those without formal curricula all estimated less than 10 hours of genetics training. Within the limitations of the survey size, there was no correlation between the size of the program, accessibility of medical geneticists to the program, priority ascribed to genetics in training by program directors, or the level of health care provided at the primary teaching hospital and the presence of a formal curriculum. Most commonly, genetics training was reported to occur in the context of pediatric rotations. 10/13 programs reported using a genetics screening questionnaire for new obstetric patients, 1/13 programs reported using a genetics screening questionnaire for new adult patients. Three conclusions may be drawn from this survey. First, based on this sample, a minority of family practice programs have formally integrated genetics into residency training. Second, the presence of genetics resources does not influence the presence of a genetics curriculum, suggesting that other factors (competing training priorities, for example) may determine the presence of a curriculum. Finally, these results suggest family medicine training emphasizes pediatric and obstetrical aspects of genetics, and may not be preparing residents to deal with adult-onset genetic disorders.

**Incorporating Cultural Assessment Approach to Regimens Employed in Conducting Genetic Family Studies.**

*N.H. Arar, R. Plaetke, H. Abboud.* Dept Medicine, Div Nephrology, Univ Texas Health Sci Ctr, San Antonio, TX.

Current approaches in conducting genetic family studies (GFS) focus on the biological aspects of genetic diseases, while the sociocultural dimensions are given secondary importance. Understanding the sociocultural aspects of the enrollment process provides important insight into how subjects interpret and value their participation in GFS. We have developed and applied a new instrument using cultural assessment approach (CAA) to our recruitment procedures in the Family Investigation of Nephropathy and Diabetes (FIND) study at UTHSCSA. The CAA was developed based on data collected during semi-structured interviews with 32 subjects. 20 diabetic nephropathy (DN) probands with a family history of diabetes and 12 relatives. Subjects mean age was 53 years. 44% were males and 56% were females. 64% were Mexican-Americans, and 52% had a high school education. Applying the CAA takes about 30 minutes. The instrument is composed of 33 closed-ended questions regarding subjects' (1) ethnomedical beliefs about the genetic nature of DN (2) attitudes towards participation in the FIND study and (3) awareness of ethical issues and risks related to participation. CAA allows building rapport between recruiters and subjects, identifying subjects' attitudes towards participation and exploring sociocultural factors and ethical issues related to participation. Integrating the CAA to our recruitment procedures in FIND has increased our efficiency by targeting efforts towards the willing subjects while addressing the concerns of the undecided. We administered the CAA to 50 DN probands to evaluate their attitudes towards participating and inviting their relatives to the FIND study. 29 probands were willing, 6 were undecided and 15 were unwilling. We contacted 35 probands and enrolled 31 families in the FIND study (Family enrollment rate is 88.5%). By identifying and excluding the unwilling subjects, CAA has saved at least 30% of the recruiters' efforts. We will discuss the theoretical paradigm behind the CAA and present some cases to illustrate how the CAA enhances (1) awareness of genetic diseases and (2) enrollment in GFS yet meet participants needs. This work was funded by NIDDK.

**Increasing physicians' knowledge of hereditary hemochromatosis using a novel web-based delivery method.** *C.I.*

*Barash*<sup>1</sup>, *M.R.G. Taylor*<sup>2</sup>, *C. Pacifici*<sup>3</sup>. 1) Genetics, Ethics & Policy, Boston, MA; 2) University of Colorado Health Sciences Center, Denver, CO; 3) Northwest Media Inc.

**Background:** Genetics knowledge is advancing rapidly, but integration of this information into clinical medical practice has not increased at the same pace. Sizeable resources have been committed to educating primary care providers about the growing relevance of genetics to clinical medicine, yet few if any training programs have demonstrated significant improvements in knowledge and understanding. **Methods:** We constructed and evaluated a prototype Web site designed to promote diagnostic acumen by increasing physicians' knowledge about Hereditary Hemochromatosis (HH), <http://hh.northwestmedia.com>. The training used a self-paced multimedia approach to present state-of-the-art knowledge on HH. The approach was suitable for training practitioners with various knowledge bases, skill levels, and learning styles. We will demonstrate the site and present results from our evaluation of the approach. **Results:** Fifty-seven physicians completed a 43-item knowledge questionnaire administered on the site, pre- and post-intervention. The sample included training physicians in internal medicine and family practice; 38% of the sample was female, and 17% were from non-White ethnic groups. The majority of participants reported that they had not spent any time learning about the "new genetics." Roughly one-third reported managing an HH patient previously. Using a 2-tailed paired difference t-test, results indicated that subjects made highly significant improvements in knowledge from pre- (Mean= 73.8%, SD=6.82) to post-intervention (Mean=80%, SD=5.05),  $t(56)=6.59$ ,  $p=.001$ . Subjects had the most difficulty with items in two specific areas: the genetics of HH, particularly genotype/phenotype associations, and treatment/management. Users reported a broad range of preferred learning styles. Overall satisfaction with the site was excellent. **Conclusions:** Medical institutions in the U.S. and abroad struggle with similar cost and time constraints to achieve efficient and effective medical education. This study documents the efficacy of an innovative tool in the field of medical learning practices.

Program Nr: 1147 from the 2001 ASHG Annual Meeting

**Generation of Case Studies for the Teaching of Medical Genetics.** *K.A. Fleiszar, R.C. Martin, P. Johnson.* Biol, Col Sci & Mathematics, Kennesaw State Univ, Kennesaw, GA.

From 1983 until 1993 over 500 genetic consultations were completed and recorded by KAF. These consultations provided an excellent source of case studies for the teaching of medical genetics. With support from KSU's Student Assistants in Learning and Teaching (SALT) program, two students (RCM and PJ) were hired to transfer this information into a database using the software program *Progeny 2000*. Prior to beginning the data entry, issues of confidentiality were addressed. Selected cases were then entered into pedigree form using this program. Once entered, student case studies were generated by modification of these original pedigrees. Thirty of these case studies were used spring 2001 in the upper level Medical Genetics course (Biology 3327). The student was required to obtain information concerning his/her assigned case study from the instructor. Students submitted a paper addressing the recommendations to be made to the consultand of this family relative to the specific RFR (reason for referral). At a minimum, these recommendations included appropriate pre- and postnatal diagnostic tests, explanations of those tests and their risks, risk assessment for family members immediately impacted by the RFR and explanations of the expected prognosis for the disorder involved. In addition to the summary paper, one other disorder manifested in the family was chosen for a detailed poster presentation. At the end of the semester, use of these case studies was assessed. Were they an effective way of teaching about heritable and non-heritable birth defects? What difficulties were encountered by the students in interpreting family information? What problems were encountered in conveying information about risks and recommendations? Results of this assessment are reported. Additional cases are being recorded and will be used for Medical Genetics as well as General Genetics (Biology 3300), Biology of Cancer (Biology 4630) and Chromosome Preparation and Analysis (Biology 4427). Biology 3327 and 4427 are required courses for the baccalaureate program in Cytogenetic Technology at KSU.

Program Nr: 1148 from the 2001 ASHG Annual Meeting

**Design and Outcomes of an Intensive Course in Cancer Risk Assessment.** *K.R. Blazer, D.J. MacDonald, J. Choi, R.A. Nedelcu, S. Sand, J.N. Weitzel.* Dept of Clinical Cancer Genetics, City of Hope Comprehensive Cancer Center, Duarte, CA.

Cancer risk assessment (CRA) is a new discipline that requires knowledge of both oncology and genetics. There is a growing need for clinicians cross-trained in these specialties. The City of Hope (COH) *Center for Cancer Genetics Technology Transfer Research* designed and conducted an intensive two-week cancer genetics training course for masters-educated genetic counselors and advanced practice nurses, funded by the California DHS Cancer Research Program. A central goal was to increase access to competent CRA services in outlying California communities, while expanding the sphere of COH *Cancer Screening & Prevention Program* research. Twelve participants (one-half from each discipline) were competitively selected on the basis of academic merit, demonstrated need in their community and institutional support. The CME/CEU-accredited course (70 hours) provided didactic and case-based learning modules, workshops, surrogate patient counseling and wetlab sessions in a format designed to enhance interdisciplinary interactions. Students completing the course have access to the program's interdisciplinary staff and other clinicians through the *Cancer Genetics Link* web-board, a novel internet discussion board for continued practice-based learning. Questionnaires were administered prior to and immediately after the course, and again six months after course completion. Knowledge of clinical cancer genetics increased by 34 percent at the immediate post-course timepoint. Additional impact measures included assessment of effectiveness of teaching methods, participant satisfaction and impact of knowledge gain on practice patterns through the six-month post-course timepoint. Overall, the course was well received and resulted in additional clinicians with screening-level competence in cancer risk counseling, practicing in areas with defined need for cancer risk assessment services.

**Multidisciplinary Genetic and Prenatal Diagnosis Education Via Internet in a Rural State.** *S. Barringer<sup>1</sup>, K. Icke<sup>1</sup>, B. Butler<sup>1</sup>, T. DuBose<sup>1</sup>, B. Karczeski<sup>2</sup>.* 1) University of Arkansas for Medical Sciences, Departments of Ob/Gyn and Radiology, Little Rock, AR; 2) Johns Hopkins University, DNA Diagnostic Laboratory, Baltimore, MD.

Facing a shortage of sonographers in our state, especially high-risk obstetrics and prenatal sonographers, the genetic counselors and radiology instructors at UAMS developed a 2 credit, internet based course entitled Advanced Obstetric Sonography, Genetics, and Pathology. Designed for senior Diagnostic Medical Sonography (DMS) students at UAMS, the course included 16 Web-based lectures, weekly bulletin board class discussions, reading assignments, problem-based case questions, and 2 examinations. Rural obstetric and genetic patients in states such as Arkansas do not always receive the highest quality ultrasounds during their pregnancies, due to the limited educational background of some ultrasonographers/physicians. This course was piloted in our DMS program as a means of reaching and improving rural healthcare education. Additionally, this program enabled many students completing off-site clinical practicums to remain at those sites while still taking courses. We also wanted to examine the feasibility of using this method of education to enable health-care providers obtain continuing education credits. Lectures were posted using WebCT software. Topics included basic genetics, diagnosis of fetal ultrasound anomalies, embryology of these birth defects, teratogen risks, role of the sonographer on the obstetrical care team, and psychosocial counseling in cases of fetal abnormalities. Various relevant links were included in these lectures for further reading. The "bulletin board" allowed for open discussion on these topics. After their final examination, students were asked to evaluate several components of the course. The overall content/method of the course was rated a 4.2 out of 5 on the Likert scale. Several important benefits and limitations regarding this method of teaching were noted. In the future, we hope to develop more distance genetic education courses for the underserved Great Plains region, as well as offer continuing education via distance education methods.

Program Nr: 1150 from the 2001 ASHG Annual Meeting

**Evaluating a Multimedia Program 'Medical Genetix'.** *S.A. Metcalfe*. Education Unit, MCRI, and Dept Paediatrics, The University of Melbourne, Royal Children's Hospital, Parkville, Australia.

An interactive multimedia program, Medical Genetix, has been developed, which features 7 more common single-gene and chromosomal disorders that often form the clinical framework for understanding genetic principles within medical and allied health courses. After evaluation during developmental stages, the program has been further evaluated as a self-directed learning resource (SDL) and for use within computer-based practical classes. Overall, feedback has been extremely favourable with many positive comments about the usefulness and interactive aspects of the program. At the University of Melbourne, students undertaking a Graduate Diploma of Genetic Counselling have used sections of the program as an SDL tool. The mean score for 'helpfulness in assisting learning' was 8.7 out of 9, with 5 conditions studied by the current cohort. Students especially liked the self-testing questions and the clinical relevance, whilst their knowledge improved post-use when tested. All medical students (undergraduate) used parts of the program in 1st and 2nd year within timetabled prac classes. In one prac, students gave a mean rating of 7.7 out of 9 for its usefulness in helping their understanding of karyotyping and molecular pathogenesis of chromosomal conditions. Interestingly, only about 28% of medical students had used the program earlier as an SDL resource, others often citing lack of time as their reason. With a different cohort, when the student guide to the problem-of-the-week (muscular dystrophy) stated that the program contained material assessable in exams, use of the program increased to about 60%. Of these students, 73% gave the program a rating of between 7-9 out of 9 as a helpful source of information, compared with 62% who gave textbooks the same rating. In general, at the University of Melbourne, medical students may not often use multimedia programs unless they are timetabled and/or compulsory, a trend seen not only for Medical Genetix. Nevertheless, students who did use Medical Genetix have found it very useful as a learning resource and it seems to be particularly helpful for graduate students, such as those studying genetic counselling.

**Theory and Practice in Teaching Human Genetics to Undergraduate, Non-Science Majors.** A.M. Hott<sup>1</sup>, C.A. Huether<sup>1</sup>, J. McInerney<sup>2</sup>, H. Bender<sup>3</sup>, C. Christianson<sup>1</sup>, J. Jenkins<sup>4</sup>, A. Wysocki<sup>5</sup>, G. Markle<sup>1</sup>, R. Karp<sup>1</sup>, R. Fowler<sup>6</sup>. 1) University of Cincinnati, Cincinnati, OH; 2) Natl. Col. for Health Prof. Ed. in Gen., Baltimore, MD; 3) University of Notre Dame, Notre Dame, IN; 4) Swarthmore College, Swarthmore, PA; 5) Natl. Inst. of Nursing Res., Bethesda, MD; 6) San José State University, San José, CA.

Based upon a Human Genetics Education (HGE) workshop at the 1999 Am. Soc. of Human Genetics (ASHG) meeting, the I & E committee appointed an *ad hoc* committee to review HGE at the undergraduate collegiate level. Specifically, the charge was to produce a series of recommendations about content and pedagogy for undergraduate courses that should include significant content in human genetics. The committee's initial focus has been on Introductory Biology courses for Non-science majors. The committee developed a list of 6 main concepts and 43 sub-concepts it felt should be taught in such courses. An Internet survey instrument was then designed for course instructors to determine the degree to which these concepts and sub-concepts were being taught. The total hours spent on each concept were determined, as were the relative importance and emphasis an instructor attached to each sub-concept (1-5 scale with 5 highest). A total of 357 responses from both 2-year and 4-year institutions were obtained. An average of 15.6% (14.4 hrs) of the time spent in all introductory, non-science major biology courses studied is devoted to the area of genetics/human genetics. Of the six main concepts, the highest average time spent was on Transmission of the Genetic Material (3.0 hrs), with 1.8 hours committed to Genetics and Society (fifth lowest). In all sub-concepts except one, a statistically significant higher *importance* was reported compared to the *emphasis* individuals were able to give that sub-concept in the course. This disparity between importance (3.9) and emphasis (3.4) represents a significant challenge for improving HGE in non-science major biology courses, since one of the logical causes for this difference is time. Instructors recognize the importance of genetics as a major component of biology education but are unable to give the emphasis it demands.

**Expanding the multi-disciplinary team in South Africa - Advanced Genetic Nurse.** *E. Pietersen<sup>1</sup>, C. Cupido<sup>1</sup>, D. Kibel<sup>2</sup>, R.S. Ramesar<sup>1</sup>.* 1) Human Genetics, University of Cape Town, Cape Town, Western Cape, South Africa; 2) Psychiatry, University of Cape Town, Cape Town, Western Cape, South Africa.

The clinical implication of information emerging from the Human Genome Project has compelled nurses to review, as well as expand, their scope of practice. Nursing staff involved in genetic research programmes have the advantage of "hands on" experience with the discipline of genetics. These nurses end up developing expertise on an ad hoc basis and are obliged to become leaders in the practice of genetic nursing. The task of the genetic nurse is going to become more complex with forays into the genetics of complex inherited disorders. Since 1997 the Department of Human Genetics at the University of Cape Town has been involved in research related to bipolar affective disorder. To date we have recruited 810 individuals from 139 families. This recruitment prefaced an intensive molecular investigation into the biological basis of bipolar disorder. Involvement in this psychiatric genetic research programme highlighted (a) the need for nurses to interrogate the family history of psychiatric subjects / patients from a genetic perspective (over and above the known clinical psychiatric perspective) (b) the fact that relatives of individuals with psychiatric disorders, in this particular study bipolar disorder, are at higher risk for other psychiatric disorders (ie. major depressive disorder, alcohol abuse, schizophrenia) and (c) the fact that bipolar disorder exists very likely as part of a spectrum of disorders which may reflect common biological pathways. Within the scope of practice of psychiatric nursing, the need for an emergence of professional psychiatric nurses with an understanding of clinical and genetic heterogeneity, molecular genetics, and inheritance of complex disorders, cannot be ignored. This background will create a new niche for an advanced psychiatric genetic professional nurse who will be able to be a patient advocate with regard to issues around genetic counselling, pharmacogenetics, as well as medical ethical issues pertaining to, for example genetic services (predictive testing in particular) and research.

**A Statewide Project To Educate and Raise Awareness About "The New Genetics": The CGEP Project in Vermont.** *R.R. Wallace-Brodeur<sup>1</sup>, E. Mahoney<sup>2</sup>, K. Richardson-Nassif<sup>1</sup>, L. Burke<sup>1</sup>, D. Yandell<sup>1</sup>.* 1) University of Vermont, Burlington, VT; 2) Saint Michael's College, Colchester, VT.

A major hope for the Human Genome Project is that it will provide important new insights into the role of inheritance in human health, behavior and disease. This knowledge will lead to opportunities for improved disease management, prevention and public health genetics, but will also create the need for rapid and effective public and professional education related to new genetic technologies. The Community Genetics and Ethics Project (CGEP) is an NHGRI-ELSI funded educational project designed to educate and raise awareness about 'the new genetics' across Vermont. The statewide project has partnered with community organizations and existing state networks to facilitate access to the broadest possible audience including professional, lay, and special-interest groups. CGEP is organized in a "concentric circles" model, with initial contact occurring in intensive 2 to 3 day retreats. Retreat participants are then called upon to facilitate interaction with broader audiences via local, community-based discussion groups and public "town meeting" style forums.

To date, CGEP has coordinated 12 multi-day retreats for diverse professional groups, 25 book discussion groups, and town meeting style evening forums around the state. All events target the specific audience using a mixture of lecture, panel, and small group discussion formats. A survey instrument is used to assess the project's impact and significant changes in knowledge and attitude questions have been seen. Target audiences have a high level of interest but varying levels of concern related to ELSI issues, and misconceptions are abundant in the rural population we serve. Access and "mode of entry" into specific subgroups are a major challenge, but our experience suggests that targeting preexisting well-organized networks or community organizations will be most successful. Barriers to raising awareness and educating the general population about ELSI issues and the "new genetics" can be overcome by sustained and carefully coordinated educational interventions.

**Evaluating Men's Interest in Interactive Technology Use to Facilitate Prostate Cancer Education and Risk Counseling.** *D. Watkins Bruner, A. Parlanti, S. Raysor, S. Mazzone, T. Sargent.* Population Science, Fox Chase Cancer Center, Philadelphia, PA.

Men at increased risk for prostate cancer, as defined by family history and race, have unique information needs regarding prostate cancer risk factors and screening. Participants attending the Prostate Cancer Risk Assessment Program (PRAP) at Fox Chase Cancer Center currently receive a standardized educational process with a health educator to help them achieve an understanding of their prostate cancer risk and to prepare them for health care decisions related to that risk. While this information is critical for making informed decisions at the time of screening, the format is often inconvenient for participants, labor intensive for staff, and does not suit all learning styles. Purpose: To conduct a pilot study to determine if men in a prostate cancer risk assessment program would be interested in using technology to receive educational information about prostate cancer risk and screening. Method: Participants in the PRAP were asked to complete a survey about their current access to and use of certain technology including personal computers. They were also asked about their preferences in modalities for receiving information about health, prostate cancer risk and prostate cancer screening. Results: Of the 21 respondents, the mean age was 50 with 47.6% Caucasian, 47.6% African American and 4.8% other. 85.7% reported a family history of prostate cancer. 81% reported owning or having access to a personal computer with 66.7% using the personal computer one or more hours per week. 71.4% indicated an interest in receiving prostate cancer information using an interactive computer program and 76.2% responded that they would feel comfortable answering questions about their personal risk for prostate cancer using various forms of technology. Conclusion: Men at increased risk for prostate cancer that are seeking prostate cancer screening express an interest in interactive media and technology to learn about prostate cancer risk and screening. This provides incentive to develop and implement an interactive multimedia program to aid men in understanding their risk for prostate cancer.

**Unintended messages: The ethics of teaching genetic “dilemmas”.** *H.C. Gooding<sup>1</sup>, B. Wilfond<sup>1</sup>, K. Boehm<sup>2</sup>, B.B. Biesecker<sup>1</sup>*. 1) Medical Genetics Branch, NHGRI, Bethesda, MD; 2) Office of Communication and Education, NIDCR, Bethesda, MD.

The teaching of bioethics often uses challenging cases. However, these cases may cause harmful messages to be received by certain communities. One such example is the "Case of Dwarfism," presented shortly after the discovery of the common mutation for achondroplasia in 1994 and subsequently disseminated in bioethics and educational materials. This case describes a couple, both affected with achondroplasia and expecting a child, who plan to terminate the pregnancy if prenatal diagnosis reveals the fetus is of average stature. It is often employed as a teaching case for health professionals, designed to stimulate debate over their role as the gatekeepers of access to genetic testing. It is more broadly applied to compel audiences to examine their views on reproductive freedoms and the limits of parental autonomy. While this case may challenge stereotypes about the appropriate uses of prenatal diagnosis, it potentially fosters a more subtle stereotype about the community it intends to serve. It presents people with achondroplasia as motivated to make reproductive decisions only by their perceptions of their physical features. However, a recent study of people affected with achondroplasia revealed that the majority considered knowing the prenatal genetic diagnosis of average stature unimportant and that only 2% would consider termination based on this finding. Using this case to challenge the view of what makes for a "healthy baby" may actually deny that those with achondroplasia simply share the common parental desire for healthy children of any stature. Furthermore, it may cause health care professionals to make assumptions about the desires of clients that would inhibit open discussion about the individual needs of people considering genetic testing. While such cases remain important teaching tools in genetics, we should be aware of our own inadvertent messages and their potential for creating discriminatory attitudes.

**Knowledge of genetic discrimination in healthcare practitioners in a large metropolitan area.** *R. Nedelcu<sup>1</sup>, P. Mantha<sup>1</sup>, J. Yu<sup>1</sup>, S. Sand<sup>1</sup>, J. Choi<sup>1</sup>, B. Schwerin<sup>2</sup>, K. Blazer<sup>1</sup>, S. McCaffrey<sup>1</sup>, D. McDonald<sup>1</sup>, J. Weitzel<sup>1</sup>.* 1) Clinical Cancer Genetics, City of Hope Cancer Ctr, Duarte, CA; 2) Cancer Legal Resource Center, Western Law Center for Disability Rights and Loyola Law School, Los Angeles, CA.

While a great deal of discussion has taken place in the medical community regarding genetic discrimination, little effort has been made to formally assess the knowledge and beliefs of those who influence access to genetic counseling and genetic testing, such as primary care physicians and nurses. A 35 item questionnaire on cancer risk knowledge and attitudes was administered to 134 participants at an all-day symposium on cancer risk, screening and prevention. To address knowledge of state and federal laws and beliefs about genetic discrimination and the extent of their effect on referral practices, we included a 10-item survey, with clinical vignettes which was completed by 129 participants. Most of the respondents were physicians (34%), nurses (37%) and genetic counselors (14%). Overall, 51% believed carriers of a genetic mutation have difficulty obtaining insurance, and 24% would not encourage genetic testing despite the presence of a family history of cancer. An interesting finding was that 56% were concerned about genetic discrimination in a woman with breast cancer at 32, but 66% would not be concerned about this issue for the woman's unaffected sister. This is an important observation, since if the woman with cancer experiences discrimination, it is more likely due to her diagnosis, while the greatest potential for insurance discrimination may be among unaffected carriers of cancer-predisposing mutations. Almost 90% of respondents believed the potential for genetic discrimination exists regardless of protective state or federal legislation. Additionally, 25% believed documented cases of genetic discrimination of unaffected carriers existed despite a lack of published cases. We conclude that a great deal of misinformation exists regarding insurance discrimination based on genetic testing for cancer predisposition, and an educational effort directed at healthcare professionals is imperative to address this.

Program Nr: 1157 from the 2001 ASHG Annual Meeting

**The reproductive behaviour in families with Fabry disease after genetic counselling. A 20 year follow-up.** S.A. Sorensen, L. Hasholt, K. Rosenberg. Dept. of Medical Genetics, University of Copenhagen, Copenhagen N, Copenhagen, Denmark.

In Denmark six families are known with Fabry disease. These families were traced and examined in the 1970's. All families were given genetic counselling and were informed about the possibility of prenatal investigation.

In the 20 year period after the genetic counselling 34 pregnancies occurred in heterozygotes. Prenatal investigation was done in 21 cases which revealed ten male fetuses with a Fabry mutation. In all but three of these cases the pregnancy was terminated. In the remaining cases five were male fetuses with a normal alpha-gal A gene, and six were female fetuses which all were born.

Among the children born of heterozygotes who did not have a prenatal investigation three boys were born with a Fabry mutation and in further three boys the gene status is currently unknown.

Our results show that genetic counselling and prenatal investigation in families screened for Fabry disease has a considerable effect on the prevention of new cases, but still not all cases are prevented.

**Genetic counseling for BRCA testing: Considerations for young female clients.** *A.A. Parlanti, A. Naumer, E. Ross, M.B. Daly.* Population Science, Fox Chase Cancer Center, Philadelphia, PA.

The potential risks and benefits of BRCA counseling and genetic testing can vary among client populations. As a result genetic counselors must adapt the content of sessions to benefit the client. Young women, 30 years and younger, are one example of a small but distinct population of clients. Currently there are limited reports regarding the lifestyle, screening behaviors, cancer risk perceptions, and anxiety levels for this group of women. The present study aims to determine the number of female participants ages 30 and younger in Fox Chase Cancer Center's Family Risk Assessment Program and to identify similarities and differences compared to older participants. Of the 1712 individuals who have participated from 1991-2001, 262 (15.3%) were women ages 30 or younger at the time of their initial phone call (average of 26.3yr). All completed an initial phone survey and health history questionnaire and participated in individual risk counseling sessions. 82.6% had a familial or hereditary pattern of breast or ovarian cancer in their maternal family and 29.5% in their paternal family. Compared to the women older than age 30, there were significant differences in level of education, marital status, religion, employment status and income level. As expected, older women reported significantly higher rates of mammography and breast biopsy, although rates of BSE were similar. While both groups thought their risk of getting breast or ovarian cancer exceeded that of other women their age; the younger women rated their risk significantly higher than the older women. However the younger women had significantly less frequent thoughts about developing breast cancer and those thoughts had less effect on their mood and daily activities. Additional information, including genetic knowledge, lifestyle, and future preventative planning was also analyzed. In general, we propose that this group of women differ physically, emotionally and socially from older women seeking genetic counseling for BRCA and that by understanding these differences genetic counselors can modify counseling by addressing the unique needs of these young women.

**Genetic & Psychological Implications for Adolescent Females at Risk for Familial Breast Cancer.** *M. Cappelli*<sup>1,3</sup>, *Y. Korneluk*<sup>3</sup>, *S. Verma*<sup>4</sup>, *A. Hunter*<sup>2</sup>, *E. Tomiak*<sup>4</sup>, *J. Allanson*<sup>2</sup>, *C. DeGrasse*<sup>5</sup>, *L. Corsini*<sup>5</sup>, *L. Humphreys*<sup>3</sup>. 1) Psychology, Children's Hospital of Eastern Ontario, Ottawa, ON; 2) Genetics, Children's Hospital of Eastern Ontario, Ottawa, ON; 3) Psychology, University of Ottawa, Ottawa, ON; 4) Ottawa Regional Cancer Centre, Ottawa, ON; 5) Ottawa Women's Breast Health Centre, Ottawa, ON.

Adolescent daughters at risk for familial breast cancer represent a group at increased risk for emotional problems. To date, however, this population has been understudied and this study included the largest sample group of adolescent daughters of breast cancer patients to date. We compared 62 mother-daughter pairs in which the mother had been treated for breast cancer (BC group) to 51 families from the general population (GP). (Mean age of women=45 years, and mean age of daughters=15 years; averaged 3 years post-treatment for Stage I or II BC). Participants completed an assessment battery of standardized and validated measures to assess psychological functioning, breast cancer, and genetic issues. Results indicated that adolescent daughters of breast cancer patients had higher levels of knowledge about breast cancer risks ( $p<.05$ ). Whereas 28% of adolescents in the BC group were more likely to have heard about breast cancer gene testing, only 11% of GP adolescents group had heard of it ( $p<.05$ ). BC group adolescents perceived the treatments for breast cancer as less effective and significantly more debilitating than girls in the general population ( $p<.05$ ). They also reported higher levels of concern about breast cancer than did adolescent girls in the general population ( $p<.05$ ). Overall, the BC group did not differ from the GP group on measures of psychological adjustment and family functioning. Additional analyses of the sub-group of breast cancer patients and their daughters indicated that maternal HQL and family functioning were important predictors of adolescent reports of their psychological adjustment. These results suggest that positive family functioning can help to buffer the negative effects maternal illness on adolescent social functioning. Genetic attitudes were independent of how well mothers and daughters coped.

**Sequencing the human genome: An assessment of media coverage and public reactions.** *B.A. Bernhardt, E. Tambor, N.A. Holtzman, G. Geller.* Genetics/Public Policy Studies, Johns Hopkins Medical Inst, Baltimore, MD.

Media coverage of the June 2000 announcement of the sequencing of the human genome was enormous. Not much is known, however, about public reactions to the sequencing. Because the mass media is a primary source of health information for most people, we analyzed the content of media reports of the genome sequencing. We also assessed public awareness of and reactions to the announcement. Within two weeks of the announcement, we conducted a random digit dialing phone survey of Maryland residents. Responses to open-ended questions were coded for qualitative and quantitative analysis. 58% of the 407 survey respondents had heard about the announcement, nearly all through the media, with television cited as the major information source. Caucasians, men, respondents over 40 and those with some college education were more likely to have heard. The majority reported a positive initial reaction, with expectations for improved treatment or prevention of disease. Most thought such advances would occur within the next ten years. 61% of respondents mentioned at least one negative outcome of genome sequencing, most commonly privacy/discrimination, and 14% thought that sequencing might lead to human cloning. African Americans were more likely than Caucasians to report a negative reaction ( $p < .001$ ), primarily related to religious concerns and mistrust of scientists. We also conducted a content analysis of 49 media reports cited by survey respondents as their source of information about the genome sequencing. Among the reports analyzed, newspaper/wire reports focused primarily on what had been done and who was involved while television reports focused more on medical and ethical implications. Ethical concerns most frequently covered included discrimination, gene patenting and "designer babies". These findings confirm that much of the public is aware of genetic advances and hold mixed reactions to them, with optimism about future medical benefits tempered by concern about possible risks and abuses. There is a need for continued public discourse, including through the media, to address concerns and clarify misperceptions regarding the Human Genome Project.

**Providing information at the point of care: Educational diagnostic reports from a genetic testing service**

**provider.** *L.M. Goos<sup>1</sup>, I. Silverman<sup>1</sup>, L. Steele<sup>2</sup>, T.L. Stockley<sup>2</sup>, P.N. Ray<sup>2</sup>.* 1) Dept. of Psychology, York University, Toronto, Ontario, Canada; 2) Paediatric Lab Medicine, Hospital for Sick Children, Toronto, Ontario, Canada.

Genetic test requisition by non-geneticists is on the rise, and is expected to increase as the availability and public awareness of genetic testing grows. The need for physician education in genetics has been identified in numerous studies, and practice-based educational initiatives have generally been found to be most effective. The Molecular Genetics Laboratory at the Hospital for Sick Children has developed a program to provide physician-directed information at the point of care. Physicians requesting molecular testing receive the Diagnostic Report as well as an Information Sheet describing the requested test. Semi-structured telephone interviews were conducted to gather information about the clarity of the Diagnostic Report and Information Sheets, the utility of the Information Sheets in physicians' practice, and the use of the report during consultations with patients. Fifty-five interviews were conducted, representing 45% of physicians contacted during the study period. Those interviewed had between 6 and 43 years in practice, and ordered less than 1 test per month to more than 40. 45% of the interviewees were pediatricians or pediatric specialists; 29% were genetic specialists. The remaining 26% were specialists in other areas or were general or family practitioners. 43% of those interviewed were unfamiliar with some of the information on the Information Sheet. The test methodology and sensitivity were most often identified as novel information. 52% of pediatricians or pediatric specialists were unfamiliar with some aspect of the Information Sheet, despite being the highest consumers of testing services in this sample. Pediatricians also rated the Information Sheet highest in terms of its usefulness in their practice, followed by genetic specialists and other physician categories. Overall, physicians confirmed the utility of the Information Sheet as an educational tool in practice, and in other non-patient educational activities in which they are involved.

**Possessive versus non-possessive eponyms: What is the current status?** *B.N. Chodirker, A.E. Chudley.* Departments of Pediatrics and Child Health & Biochemistry and Medical Genetics, University of Manitoba, Winnipeg, MB.Canada.

For years, geneticists have advocated against the use of the possessive form of an eponym as the author neither had nor owned the disorder (Lancet. 1975 1;1(7905):513). Therefore, Down syndrome is preferred to Down's syndrome. Although OMIM uses the non-possessive form exclusively, Dr. McKusick considered the use of the possessive form optional for some disorders such as Huntington disease due to the long usage of the possessive form or the difficulty in pronouncing some non-possessive eponyms. The purpose of this study was to determine the relative frequency of the possessive versus non-possessive forms of eponyms. Medline searches were conducted for articles published in English in the years 1996-2000 inclusive. Article titles were searched for the following: "Down syndrome"(DS), "Turner syndrome"(TS), "Marfan syndrome"(MS), "Huntington Disease"(HD), "Parkinson Disease" (PD) and "Alzheimer Disease" (AD) as representative examples of syndromes and diseases with eponyms. Searches were also done for the possessive form of these eponyms. The percent usage of the non-possessive form was as follows: DS = 58%, TS = 60%, MS = 67%, AD = 15%, PD = 4%, HD = 17%. The use of the non-possessive form was more common with syndromes: 60% vs. 12% ( $p < 0.001$ ). The pattern of use depended on the country of publication. For example, articles published in the United States were more likely to use the non-possessive form than articles published in England i.e. 74% vs. 42% ( $p < 0.001$ ) for syndromes and 18% vs. 3% for diseases ( $p < 0.001$ ). Genetics journals i.e. journals with "Genet" in their title, were more likely than non-genetics journals to use the non-possessive form i.e. 93% vs. 56% ( $p < 0.001$ ) for syndromes and 37% vs. 11% for diseases ( $p < 0.001$ ). These data show that the use of the non-possessive form of the eponym is not yet widely accepted and is not yet universally used by geneticists. We believe that the continued use of both systems creates confusion. We would recommend that journal editors adopt a uniform system for the use of eponyms. Geneticists should be advocating for the use of the non-possessive form of eponyms.

**Knowledge about hereditary breast cancer among early-onset breast cancer survivors.** *S. Miesfeldt*<sup>1</sup>, *W.F. Cohn*<sup>2</sup>, *M.E. Ropka*<sup>2</sup>, *S.M. Jones*<sup>3</sup>. 1) Dept Internal Medicine; 2) Dept Health Evaluation Sciences; 3) Cancer Center; Univ Virginia, Charlottesville, VA.

Little is known about hereditary breast cancer (HBC) knowledge among women with breast cancer (BC). This study assessed if women with early-onset BC (<50 years): 1) have the necessary HBC knowledge to address the need for genetic counseling; and 2) show differences in knowledge based on HBC risk. Participants responded to two mailed questionnaires. The Knowledge, Attitudes and Beliefs Questionnaire (KABQ) evaluated understanding of BC risk factors and HBC knowledge. The Family History Questionnaire (FHQ) assessed whether participants had personal or family histories that met HBC risk criteria. Women diagnosed < age 50 years during 1994-97 were recruited from 34 Virginia hospitals. Based on FHQ responses, women were categorized as having suspected HBC vs. presumed sporadic breast cancer (SBC). Of 314 respondents, 273 (87%) returned both questionnaires. Average age of respondents was 47.5 years. 91% were Caucasian, 7% African-American and 2% Asian-American. 138 met HBC risk criteria; 135 were presumed to have SBC. Most knew common BC risk factors, including family history of BC. 31% recognized family history of non-breast cancers as a BC risk factor. 62% knew that prophylactic mastectomy does not completely eliminate BC risk. Most recognized that not all women carrying a BC mutation will develop BC (72%) and that men can develop BC (96%). In contrast, the majority selected "I don't know" for several items concerning characteristics of HBC, including: potential risk transmission through a father (58%); risk of early-onset BC among mutation carriers (55%); increased risk of male BC in mutation carriers (71%); increased risk for other types of cancers (61%); and bilateral BC (62%). Knowledge regarding HBC did not vary between women at risk for HBC and those with presumed SBC. These data show limitations in HBC knowledge among early-onset BC survivors, and highlight the need for educational materials regarding HBC for these women.

**GeneTests and GeneClinics: genetic testing information for a growing audience.** *R.A. Pagon<sup>1,2</sup>, P. Tarczy-Hornoch<sup>1</sup>, M.L. Covington<sup>2</sup>, P.K. Baskin<sup>1</sup>, J.E. Edwards<sup>1</sup>, M. Espeseth<sup>1</sup>, C. Beahler<sup>1</sup>, T.D. Bird<sup>1</sup>, B. Popovich<sup>3</sup>, C. Nesbitt<sup>1</sup>, C. Dolan<sup>1</sup>, K. Marymee<sup>1</sup>, N.B. Hanson<sup>1</sup>, W. Neufeld-Kaiser<sup>2</sup>, G. McCullough Grohs<sup>2</sup>, T. Kicklighter<sup>1</sup>, C. Abair<sup>1</sup>, A. Malmin<sup>1</sup>, M. Barclay<sup>1</sup>, R.D. Palepu<sup>1</sup>.* 1) University of Washington, Seattle, WA; 2) Children's Hospital and Regional Medical Center, Seattle, WA; 3) Xenon Genetics, Vancouver BC.

Over the last decade, genetic testing has moved steadily out of research venues and into medical practice. The audience for genetic testing information has become international and expansive, and includes healthcare providers, patients, educators, policy makers and media. This presentation describes the growth and usage of two companion NIH- and HRSA-funded genetic testing information resources, GeneTests ([www.genetests.org](http://www.genetests.org)) and GeneClinics ([www.geneclinics.org](http://www.geneclinics.org)), which reflect this trend. Since 1993, GeneTests (né Helix) has grown from a national genetic testing laboratory directory of ~110 listings to an international directory of clinical and research labs (~500 labs, ~800 diseases), a US clinic directory (~950 clinics), an educational/teaching resource, and a source of summary data reflecting trends in genetic testing of increasing interest to educators, policy makers and the media. GeneClinics, founded in 1997 as an expert-authored, peer-reviewed, disease-specific information resource relating genetic testing to patient care, now contains more than 110 full text entries. The combined resources are accessed ~1,000,000 times/year by a diverse audience, of which about 20% is non-US and about 35% is the public. For non-geneticist healthcare providers, diverse search strategies help identify testing available in their specialties, and a hierarchical display of search results aids in differential diagnosis.

**State of clinical genetics and genetics education in academic internal medicine departments.** *M.R.G. Taylor.*  
University of Colorado Health Sciences Center, Denver, CO.

The genetics revolution has led to the recognition that many adult-onset disorders have a genetic basis. Clinical genetics, historically a pediatric-based discipline, has growing importance in the medical care of adult patients. The present number of board certified (BC) geneticists with training in adult medicine is insufficient to meet the growing needs of this population. Accordingly, internal medicine-trained physicians (internists), who deliver much of the medical care to adult patients, may be called upon to evaluate and treat patients with genetic illnesses. Previous authors have shown that internists know and understand less about genetic principles and conditions than their peers (e.g. pediatricians, obstetricians, family practitioners). Academic internal medicine departments (AIMDs) train the bulk of practicing internists in the U.S. The responses of AIMDs to the challenges raised by advances in adult clinical genetics have not been well characterized. A survey tool, querying chairpersons of AIMDs about their responses to advances in genetics, was sent to 155 AIMD chairpersons. 58% (90/155) were returned with usable data. Only 18% (16/90 responses) of the AIMDs had faculty members who were BC geneticists; 11% (11/90) had only one BC geneticist; 24% (21/87) employed genetic counselors. 72% (64/89) offered formal didactic teaching about specific genetic conditions for training internists. Of this group, 44% (28/64) included instruction taught by BC geneticists. Thus, only 31% (28/89) of AIMDs surveyed offer formal didactic genetics programs taught by BC geneticists. 93% (82/88) of chairpersons agreed that the majority of genetic diagnoses in adult patients are made by internists who are not well trained in genetics. 77% (68/88) agreed that all AIMDs should include faculty that have formal training in clinical genetics and 36% (31/87) indicated that they were trying to hire a BC geneticist in the next two years. **These data highlight that BC geneticists appear to have a limited role currently in AIMDs in terms of providing clinical service and educational expertise. There is interest in increasing the involvement of BC geneticists in AIMDs..**

**Knowledge and attitudes of Israeli Arab adolescents regarding consanguineous marriages - implications for educational programs.** *T. Shohat, O. Romano-Zelekha, L. Jaber, M.S Green.* Israel Center for Disease Control, Ministry of Health, Tel Hashomer, Israel.

Consanguineous marriages are very common in the Israeli-Arab population. It was shown that the prevalence of cousin-cousin matings is as high as 40%. As a result, the main cause of infant mortality in this population is congenital malformations. Several educational programs were established in attempt to reduce this phenomena. In a national survey of 2933 Arab schoolchildren age 16-17 (comprising 20% of all Arab children at this age group) we evaluated the knowledge and attitudes regarding consanguineous marriages. 45.8% of the study participants scored less than 60 on the knowledge questionnaire. Male sex, lower parental education, and being engaged at the time of the study were independently significantly associated with poor knowledge. Although 80% knew that consanguineous marriages could affect the health of the offspring, only 50% understood what congenital malformations were. 73.8% of the study participants expressed attitudes against consanguineous marriages. Male sex, lower parental education, having a relative with congenital malformation, being engaged at the time of the study, and poor knowledge of the possible consequences of consanguineous marriages were significantly associated with attitudes supporting such marriages. 30% of those engaged at the time of the study were engaged to first cousins. 50% of those who thought that getting married to a relative was an important custom that should be followed, reported that they would have done so even knowing the increased risk for health problems to their offspring. The results of this study demonstrate the need to increase the level of knowledge of adolescents regarding consanguineous marriages. However, since consanguineous marriages have deep roots in the Arab population, efforts must be greatly directed to educate individuals of the possibilities of preconception and prenatal testing for various diseases.

**Effective International Collaboration in Rare Disease Research.** *P.F. Terry<sup>1</sup>, S.F. Terry<sup>1, 8</sup>, A.S. Marais<sup>2</sup>, I. Pasquali-Ronchetti<sup>3</sup>, C. Boyd<sup>4</sup>, E. Johnson<sup>5</sup>, T. Le Roux<sup>6</sup>, L. Bercovitch<sup>7</sup>.* 1) PXE International, Inc, Sharon, MA; 2) University of Cape Town, South Africa; 3) University of Modena, Italy; 4) University of Hawaii, Honolulu, HI; 5) Barrow Neurologic Institute, Phoenix, AZ; 6) Lasalle College, Newton, MA; 7) Brown University, Providence, RI; 8) Genetic Alliance, Washington, DC.

Lay advocacy groups accelerate and focus research on a rare disorder. Lack of data about its manifestations, natural history and epidemiology limits research on a disorder. Often the limited number of individuals with the disorder limits the funding possibilities and makes the acquisition of patient samples and data difficult. Further, the agenda of researchers and participants can diverge in ways that ultimately delay progress toward a treatment and cure. Pseudoxanthoma elasticum (PXE) is a rare genetic disorder. PXE International, a lay advocacy organization founded in 1995, initiates, supports and funds research. Also providing support for affected members and their families, it has focused and accelerated research. Establishment of various offices and programs in 21 countries throughout the world has been critical to providing genetic services and supporting research. Empowering the individuals in various countries and cultures requires an investment of resources in the laboratories of these communities. The PXE International Blood and Tissue Bank has branches in Italy and South Africa. The results of efforts made by PXE International are a 15 laboratory consortium, a multidisciplinary approach forging collaborations amongst many specialists, a focused agenda which accelerates research in the service of the interests of the patient population, and increased congressional awareness for real outcomes of medical research funding. The organization is also uniquely able to safeguard confidentiality by acting as a 'firewall' between researchers and participants. Genetic lay advocacy using this model can greatly benefit both research and patient populations, furthering both the common and divergent goals of each.

**Clinical and Genetics Difficulties in Huntingtons disease Reduced Penetrance Alleles.** *A. Sanchez<sup>1</sup>, C. Badenas<sup>1</sup>, T. Marcos<sup>2</sup>, E. Muñoz<sup>3</sup>, D. Jimenez<sup>1</sup>, M. Mila<sup>1</sup>.* 1) Genetica, Hosp Clinic, Barcelona, Catalonia, Spain; 2) Psicologia, Hosp Clinic, Barcelona, Catalonia, Spain; 3) Neurologia, Hosp Clinic, Barcelona, Catalonia, Spain.

Huntingtons disease (HD) is a progressive neurodegenerative disorder characterized by involuntary movements, cognitive disturbances and emotional problems and inherited as an autosomal dominant trait with an average age of onset within the fourth decade of life. It was generally accepted that the disease was 100% penetrant, but nowadays it is not so clear. The molecular defect consists in a CAG repeat expansion in the IT15 gene. In normal chromosomes the CAG repeats range from 9 to 29 whereas they are expanded beyond 41 repeats in HD chromosomes. The range between 36-41 CAGs is considered of reduced penetrance and the risk of developing the disease is uncertain. We have detected 80 patients with alleles of reduced penetrance in the screening of 250 HD Spanish families: 68 of them (32%) are clinically affected and 12 were studied in presymptomatic testing. The mean age of onset in the reduced penetrance group was 52.5, which is higher than the age of onset in our HD population (43.3). We will like to point out that 22% of patients with alleles in this range were considered apparently sporadic. These results indicate the difficulty in the clinical diagnosis of HD when a reduced penetrance allele is present, due to its atypical clinical manifestations, specially in HD patients with late onset and in sporadic cases. We will like to highlight the difficulty of genetic counseling in this range.

**Complex Segregation Analysis of Exercise Heart Rate and Blood Pressure at Baseline and in Response to 20 Weeks of Endurance Training: The HERITAGE Family Study.** *P. An<sup>1</sup>, I.B. Borecki<sup>1</sup>, T. Rankinen<sup>2</sup>, L. Perusse<sup>3</sup>, A.S. Leon<sup>4</sup>, J.S. Skinner<sup>5</sup>, J.H. Wilmore<sup>6</sup>, C. Bouchard<sup>2</sup>, D.C. Rao<sup>1</sup>.* 1) Washington University School of Medicine, St. Louis, MO; 2) Pennington Biomedical Research Center, Baton Rouge, LA; 3) Laval University, Quebec, Canada; 4) University of Minnesota, Minneapolis, MN; 5) Indiana University, Bloomington, IN; 6) Texas A&M University, College Station, TX.

Major gene effects for HR and BP at 50 W and 80% of VO<sub>2</sub>max at baseline and their chronic changes in response to 20 weeks of endurance training were assessed in 99 White families in the HERITAGE Family Study. Exercise HR and BP at baseline were adjusted for the effects of age and BMI within fathers, mothers, sons, and daughters, respectively. The training responses were adjusted for the effects of age, BMI, and their respective baseline values. We found baseline HR at 50 W was influenced by a major recessive gene effect and a multifactorial effect, which accounted for 30% and 27% of the variance, respectively. Its training response was found to be influenced by a major dominant gene effect, which accounted for 27% of the variance. These major gene effects were independent of the effects of smoking, VO<sub>2</sub>max, and the resting HR levels. No significant genotype specific interaction effects with age, sex, and BMI were found. No major gene effects were detected for exercise BP. Instead, we found baseline BP at 50 W and 80% VO<sub>2</sub>max, and the training responses at 50 W were solely influenced by multifactorial effects, which accounted for about 50%, 40%, and 20% of the variance, respectively. No familiarity was found for training responses in HR and BP at 80% VO<sub>2</sub>max. In addition, the major gene effects for exercise HR were assessed in a pooled data with a small sample of Black participants in HERITAGE. Similar major effects were found, but the transmission from parents to offspring became ambiguous, which would suggest sample heterogeneity. In conclusion, submaximal exercise HR levels at baseline and in response to endurance training were influenced by putative major loci with no genotype specific covariate effects, in contrast to multifactorial components for exercise BP.

**Degree of common genetic determination of peak bone mineral density at the hip and spine in women.** *D.L. Koller, M.J. Econs, S.L. Hui, M. Peacock, C.C. Johnston, Jr., T. Foroud.* Indiana Univ Sch Medicine, Indianapolis, IN.

Fractures of the femoral neck and the lumbar spine account for a substantial portion of the \$13 billion per year spent in the U.S. toward treating the consequences of osteoporosis. Studies of twin and family data have established the heritability of peak bone mineral density (BMD), a strong predictor of fracture risk, at both the femoral neck and lumbar spine; however, it is unknown to what degree common genetic factors affect BMD at these two sites. We have addressed this question in independent sibling pairs from our collection of 351 sets of Caucasian sisters. BMD was measured using DEXA (Lunar DPXL) at the lumbar (L2-L4) spine and femoral neck for each subject. Regression model-fitting was used to adjust the observed BMD values for age and body weight. Genetic model-fitting was performed with the Mx software package (Neale et al, 1994). Univariate models included a genetic component and an environmental component. The bivariate model included common genetic and environmental components acting on both traits, and also unique genetic and environmental components for each trait. Heritability in this sample, computed using the univariate models in Mx, was 83.4% for lumbar spine and 66.8% for femoral neck. These are in strong agreement with values reported previously by our group and others. The standard Pearson correlation between these two BMD measures, which ignores the family relationship of the subjects, was 56.5% for this data set, also in agreement with previously reported values. The bivariate models as fitted with Mx showed that a common set of genetic factors explained 36.7% of the variability of lumbar spine BMD and 34.0% of the variability in femoral neck BMD. Thus, these common factors contribute nearly equal portions of the total variability of each measure; however, common genetic factors contribute a greater portion of the genetic variability of femoral neck BMD ( $34.0\%/66.8\%=50.9\%$ ) as compared with lumbar spine BMD ( $36.7\%/83.4\%=44.0\%$ ). These results strongly support the hypothesis that common genetic factors influence BMD at multiple skeletal sites, but that there are also important unique genetic factors acting at each site.

**SR-B1 variants associated with HDL cholesterol levels in three populations.** *J.J. McCarthy<sup>1</sup>, S. Lewitzky<sup>1</sup>, A. Permutt<sup>2</sup>, B. Glaser<sup>3</sup>, L.C. Groop<sup>4</sup>, J. Meyer<sup>1</sup>.* 1) Millennium Pharmaceuticals, Inc., Cambridge, MA, USA; 2) Division of Metabolism, Endocrinology and Diabetes, Washington University Medical School, St. Louis, MO, USA; 3) Department of Endocrinology and Metabolism, Hebrew University, Hadassah Medical Center, Jerusalem, Israel; 4) Department of Endocrinology, Wallenberg Laboratory, Malmo University Hospital, University of Lund, Malmo, Sweden.

The scavenger receptor class B type 1 (SR-B1) is involved in the selective transport of lipids from HDL cholesterol. We examined polymorphisms in the SR-B1 gene to determine their association with plasma HDL-C levels. Nested sex-specific case-control studies were designed from families originally ascertained for Type 2 diabetes from Finland, Sweden and Israel. Cases (n=558) and controls (n=379) were chosen based on having HDL-C levels below (cases) and above (controls) the sex-specific median for the combined populations. Genotypes for a silent variant in exon 8 (alleles EX8C and EX8T) and an intron 5 variant (alleles IVS5C and IVS5T) were evaluated. All three populations produced similar results. Carriers of EX8C who lacked the IVS5T allele had increased odds of low HDL-C (odds ratio for combined populations of 2.44,  $p < .0001$  and 1.95,  $p < .01$  for women and men, respectively). In women, a second pattern marked by the presence of both EX8C and IVS5T produced  $>4.7$ -fold increased odds of low HDL-C ( $p < .00001$ ) but no association was found in men. These patterns may represent two distinct haplotypes where the underlying variant on the second haplotype acts in a sex-specific manner. These results demonstrate strong, highly significant and reproducible associations with genetic variants in SR-B1 and HDL-C levels.

Program Nr: 1172 from the 2001 ASHG Annual Meeting

**The Use of the Disposition Model For Genetic Analysis. I. Association, Segregation and Linkage Studies. V.**  
*Apprey, J. Kwagyan, G.E. Bonney.* National Human Genome Ctr, Howard Univ, Washington, DC.

The disposition model of Bonney (1998) for binary phenotypes merges the likelihood models of Elston and Stewart (1971) and Morton and Maclean (1974). Unlike the earlier regressive models, the disposition model does not assume that sibs are arranged according to their birth order, and so they are interchangeable. In this presentation, fuller parametrization are described for both segregation and linkage analyses. The regression parametrization includes gene by environment interactions on the logistic as well as the Weibull curves. The inclusion of ascertainment corrections is discussed and the easy implementation in the computer package G.E.Ms noted.

**Haplotype frequency estimation error analysis via the application of bootstrap methods.** *E.D. Kelly<sup>1</sup>, F. Sievers<sup>1</sup>, O.R. McManus<sup>2</sup>*. 1) Hitachi Dublin Laboratory, Hitachi Europe Limited, Dublin 2, Ireland; 2) Dept. of Clinical Medicine, Trinity College Dublin Centre at St. James's Hospital, Dublin 8, Ireland.

Increasingly researchers are turning to the use of haplotype analysis as a tool in population studies, the investigation of linkage disequilibrium, and candidate gene analysis. When the phase of the data is unknown, computational methods, in particular those employing the Expectation-Maximisation (EM) algorithm, are frequently used for estimating the phase and frequency of the underlying haplotypes. Despite its widespread use, there has been little investigation of the degree of error involved in haplotype frequency estimation (HFE) employing the EM process. We have developed an EM-based program for the estimation of haplotype form and frequency from phase-unknown data which incorporates non-parametric bootstrapping for the calculation of accurate error bars. To illustrate its efficacy we present the results when HFE is carried out on data derived from a population of cystic fibrosis patients. Alleles from seven biallelic loci are used. Initially the phase of the data is known and the frequencies of the observed haplotypes are calculated by a simple gene counting method. The phase is then randomised and the haplotype frequencies are recalculated using an EM-based algorithm. The technique of bootstrapping is then applied to generate error bars. The accuracy of the EM method and the sensitivity of the bootstrap procedure to data sizes are assessed via a comparison between the results for the phase-known and the phase-unknown data. It was found that for large data sets the estimation process reproduced the original haplotypes and their frequencies from the randomised data with a high degree of accuracy. As expected, the accuracy of the estimation falls off significantly as less individuals are included in the analysis.

Program Nr: 1174 from the 2001 ASHG Annual Meeting

**Power of Multifactor Dimensionality Reduction (MDR) for Identifying Gene-Gene and Gene-Environment Interactions.** *L.W. Hahn, M.D. Ritchie, J.H. Moore.* Program in Human Genetics, Vanderbilt University, Nashville, TN.

We have previously developed the multifactor dimensionality reduction (MDR) method to identify gene-gene and gene-environment interactions (Ritchie et al. *AJHG* 69, 2001). In brief, MDR is a method that reduces the dimensionality of multilocus information to identify polymorphisms associated with an increased risk of disease. This approach takes multilocus genotypes and develops a model for defining disease risk by pooling high-risk genotype combinations into one group and low-risk combinations into another group. Ten-fold cross validation and permutation testing are used to identify optimal models. The goal of this study was to evaluate the power of MDR for identifying gene-gene and gene-environment interactions in the presence of common sources of noise. Using four different epistasis models, we simulated discordant sib-pairs with 5% genotyping error, 5% phenocopy, 20% phenocopy, or 50% genetic heterogeneity. MDR was able to identify the functional loci with 81-99% power in the presence of genotyping error or phenocopy, and 47-81% power in the presence of genetic heterogeneity. These results demonstrate that MDR is a powerful method for identifying and characterizing gene-gene and gene-environment interactions, even in the presence of some common sources of noise.

**Identifying extreme regions of linkage disequilibrium with dense maps.** *R. Mott, G.R. Abecasis, L.R. Cardon.*  
Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom.

Large compilations of single nucleotide polymorphisms (SNPs) are now available, and significant advances are underway in genotyping throughput, accuracy, and cost. Together, progress in these areas offers great promise for studies of allelic association on a genomic scale. Despite these advancements, it is generally impossible to systematically evaluate long-range haplotype patterns in large datasets of pair-wise linkage disequilibrium (LD). One of the key issues to resolve is the identification and characterisation of regions with generally excessive or low LD. The statistical theory of extreme-scoring segments, originally developed for sequence alignment problems, provides a natural framework for LD assessment. We show that this approach can be used to identify salient topological features in LD matrices. Moreover, significance tests based on the Gumbel extreme value distribution can be used to critically evaluate extreme patterns of LD. Using these methods, we identified excessively long stretches of high and low disequilibrium in the evaluate extreme patterns of LD. Using these methods, we identified excessively long stretches of high and low disequilibrium in the chromosome 22 disequilibrium map, which includes over 1 million pair-wise LD coefficients for 1500 markers. These regions may be the signature of selection intensity or reflect functionally important features in DNA.

**Dynamic Models for Mapping Quantitative Trait with Time-Dependent Genetic Effect.** *M. Xiong, J. Zhao, L. Jin, E. Boerwinkle.* Human Gen Ctr/Houston HSC, Univ Texas, Houston, TX.

Many quantitative traits of interests in genetic studies of complex diseases such as hypertension, obesity and diabetes are known to change with age. The genetic effects of these traits are, in general, time dependent. The appropriate models for time-dependent genetic effects are very useful for mapping quantitative trait loci (QTL) and genetic epidemiology study of complex traits. However, very few statistical models for time-dependent genetic effects have been developed. In this report, a linear and nonlinear dynamic system is proposed to model the time-dependent genetic additive and dominance effects. A quantitative trait is modeled as a functional-coefficient regression in which the genetic effects are treated as fixed functions and environments are treated as random functions. The random functions are modeled as realization of Gaussian processes. The functions are represented by support vector machine. The Kalman filter is used to fit the functional models. The proposed dynamic models have been applied to the genetic studies of hypertension using longitudinal data collected from a population.

**Application of Symbolic Discriminant Analysis to Identifying Multivariate Gene Expression Profiles that Define Autoimmune Diseases.** *J.S. Parker, T. Aune, S. Chan, A. Martin, A. Antar, K. Maas, N. Olsen, J.H. Moore.* Program in Human Genetics, Vanderbilt Univ, Nashville, TN.

It is increasingly clear that our ability to simultaneously measure the expression levels of thousands of genes will revolutionize our understanding of the initiation, progression, and severity of human disease. However, progress in this area is dependent on the development and implementation of analytical methods that are able to identify gene expression patterns that are associated with a particular biological or clinical endpoint. We have previously developed a symbolic discriminant analysis (SDA) approach to identifying biologically or clinically relevant gene expression variables (Moore et al. *Lecture Notes in Artificial Intelligence*, in press). Briefly, SDA is a statistical and computational methodology for finding mathematical expressions, in symbolic form, that can take values of gene expression variables and produce biological or clinical endpoint predictions. SDA models are optimized using parallel genetic programming and are evaluated for their ability to classify and predict observations using 10-fold cross-validation. Permutation testing is used to evaluate statistical significance. The goal of this study was to determine whether SDA is capable of identifying subsets of gene expression variables that define two autoimmune diseases, rheumatoid arthritis (RA) and systemic lupus erythematosus (SLE). We measured the relative expression levels of approximately 4000 genes in a sample of seven RA subjects, nine SLE subjects, and 12 control subjects. The SDA approach identified a subset of four statistically significant genes that were capable of correctly classifying all RA and control subjects and a subset of five statistically significant genes that were capable of correctly classifying all SLE and control subjects. These results demonstrate that SDA is able to automatically identify subsets of autoimmune disease genes and their associated discriminant functions.

**Correlation of Gene Expression Levels with Clinical Covariates in Microarray Experiments.** *W.D. Shannon<sup>1</sup>, M. Watson<sup>2</sup>, A. Perry<sup>2</sup>, K. Rich<sup>3</sup>.* 1) Dept. of Medicine; 2) Dept. of Pathology and Immunology; 3) Dept. of Neurosurgery, Washington Univ School of Medicine, St Louis, MO.

Analyzing microarray data generally starts with a clustering algorithm (e.g., hierarchical cluster analysis, self-organizing maps) to separate genes into subgroups with similar expressions, and then compares the clinical measure of interest across the identified clusters. If the clinical measure, such as tumor grade, is disproportionately present across one or a few clusters, the genes within those clusters may be functionally related to the measure. This "two-stage" analysis is likely to be sub-optimal since the analysis of the gene expressions and clinical measures (i.e., covariates) are performed sequentially. Ideally, a statistician would prefer a single analysis (e.g., correlation or regression) using gene expression and covariate data simultaneously. The Mantel correlation statistic, and its extension to the partial correlation and regression frameworks, allows the simultaneous analysis of expression data and covariates in microarray studies. In this paper, we describe this family of statistics and apply them to a previously published study of seven human oligodendrogliomas (brain tumors) where the expression levels of 1,013 genes and five covariates were analyzed using the "two-stage" approach described above. In the previous analysis, qualitative relationships were found between gene expressions and two of the clinical covariates. In this analysis, the Mantel statistics quantify these relationships, and using permutation tests, provide P values of statistical significance. We also show how the Mantel statistics can be used to rank subsets of genes that are sufficient for tumor grade determination. We propose the use of the Mantel statistics as a valuable contribution to the future of microarray study data analysis.

**Genetic heterogeneity comprising both X-linked and autosomal dominant forms of inheritance in families with familial idiopathic scoliosis.** *C.M. Justice<sup>1</sup>, N.H. Miller<sup>2</sup>, B. Marosy<sup>2</sup>, J. Zhang<sup>3</sup>, E.W. Pugh<sup>4</sup>, A.F. Wilson<sup>1</sup>.* 1) Genometrics Section, NHGRI/NIH, Baltimore, MD; 2) Dept. of Orthopaedic Surgery, Johns Hopkins University, Baltimore, MD; 3) Dept. of Genetics, Johns Hopkins School of Medicine, Baltimore, MD; 4) CIDR, Johns Hopkins University, Baltimore, MD.

Idiopathic scoliosis (IS) is a structural lateral curvature of the spine present in the late juvenile or adolescent period in otherwise normal individuals. It affects 2-3% of the pediatric population, of which 0.2-0.5% require active treatment. Previous studies have suggested autosomal dominant, X-linked and/or multifactorial modes of inheritance. In a large ongoing study of familial scoliosis, 204 families with at least two affected individuals were ascertained and clinically characterized. Phenotypes include degree of lateral curvature, curve type, age of onset and sex. A genome-wide screen for 1200 individuals was performed at the Center for Inherited Disease Research. Since the sample may include both X-linked and autosomal dominant forms of the disorder, the families were stratified on the ratio of the likelihood of each family given an X-linked model relative to that of an autosomal model. The mode of inheritance for families in the upper tail of the distribution was assumed to be X-linked, while families in the lower tail were assumed to be autosomal dominant. Model-dependent and model independent linkage analysis was performed on subsets based on the ranked distribution from both tails of the distribution. Two-point linkage analysis of the top 25% of families in the upper tail of the distribution resulted in positive lod scores for 5 of 8 adjacent markers at a recombination fraction of 0.3. The highest lod score was 1.12 ( $\theta=0.3$ ) for marker CXS1725. Analysis of the top 15% of families resulted in 6 out of 8 adjacent markers positive at a recombination fraction of 0.3. A lod score of 1.85 was obtained for marker CXS1725 ( $\theta=0.2$ ). Genotyping of three additional flanking markers in this area also resulted in positive lod scores. These results support a hypothesis of genetic heterogeneity with a proportion of families having X-linked inheritance.

**Association Between Insulin-Like Growth Factor I (IGF-I) Gene Promoter Polymorphisms and Bone Mineral Density in Elderly Women and Men: The Rotterdam Study.** *F. Rivadeneira<sup>1</sup>, J.J. Houwing-Duistermaat<sup>1</sup>, N. Vaessen<sup>1,2</sup>, A. Hofman<sup>1</sup>, H.A. Pols<sup>1,2</sup>, C.M. van Duijn<sup>1</sup>, A.G. Uitterlinden<sup>1,2</sup>.* 1) Dept. of Epidemiology and Biostatistics, Erasmus University Rotterdam, The Netherlands; 2) Dept. of Internal Medicine, Erasmus University Rotterdam, The Netherlands.

Bone mineral density (BMD), a major determinant of the risk of osteoporosis in later life, is a complex trait influenced by many genes. Conflicting results have been reported, regarding the relation of a dinucleotide-repeat polymorphism in the promoter region of the insulin-like-growth-factor-I (IGF-I) gene to osteoporosis and BMD. In the present study we examined the role of this polymorphism in relation to BMD measurements, using a cross-sectional and follow-up design within the Rotterdam study, a population-based cohort study of determinants of chronic disabling diseases in the elderly. We found the polymorphism to predict the yearly rate of bone loss in 1570 individuals, and not the cross-sectional evaluation of BMD in 2161 individuals. The mean follow-up time between the two BMD measurements used to estimate the yearly rate of BMD change was 23.8 (SD 7.0) months. In women (n=838), the presence of the *192-bp* allele was associated (p for trend = 0.0005) with a lower yearly rate of bone loss (an absolute reduction of 8.8 and 13.2 mg/cm<sup>2</sup> and a relative reduction of 1.5 and 0.5%; for hetero and homozygotes for the *192-bp* allele, respectively). In men (n=732), the genotype effect was only evident (p for trend = 0.05) when taking into account effect modification of age (p=0.06). These findings showed that in elderly Caucasian populations the relationship between this IGF-1 gene promoter polymorphism and rate of BMD loss is different among genders. This is also, the first attempt to evaluate the effect of this polymorphism on BMD with a follow-up approach, permitting to partition the effect of bone mass acquisition during life from the subsequent rate of bone loss, and hence, increasing power. Further evaluation of sequence variation at this locus is needed to determine if the observed effect is a direct consequence of IGF-I mRNA expression or if it is the result of linkage disequilibria with other polymorphisms.

**Cognitive function in neurofibromatosis type 1.** *S. Costabel, A. Iester, M. Bonelli, S. Massa, D. Sambarino, C. Bellini, E. Bonioli.* Pediatrics Department, University, Genova, Italy.

Neurofibromatosis 1 is associated with a broad range of nonspecific cognitive impairment, including low IQ, learning disabilities and behavioral difficulties. Early reports gave marked overestimates of the incidence of mental retardation. Recently many authors have suggested that the frequency of mental retardation (defined as full-scale IQ more than 2 SD below the mean) due to NF1 alone is only slightly higher than in the general population (3%). On the other hand, specific learning disabilities are the most common neurological complication of NF1 in childhood with a frequency of 30-60% of the NF1 patients. In the past many studies have suggested a distinct profile of learning disabilities in children with NF1, with a predominance of visuo-perceptual problems and discrepancy between Verbal and Performance IQ. However, more recent studies have demonstrated that language based learning problems are as common as non-verbal learning deficits. We have evaluated 15 subjects aged 2 to 19 years. All subjects had NF1 according to NIH-criteria. The global IQ was estimated with different and age-related tests: the Brunet-Lezine scale for children below the age of 2 years; the Stanford-Binet Scale for children aged 2 to 10 years; the Weschler Intelligence Scale for Children-Revised (WISC-R) for children aged 10 to 14 years; the Weschler Adult Intelligence Scale (WAIS) in the older patients. Motor abilities were assessed in two areas: visual-motor function using the Raven's Progressive Matrices and perceptual-motor function using the Bender-Gestalt test, which is suitable in the children above 4 years. We have observed a normal full-scale IQ in our patients, with a mild lowering especially in the young ones. We have also observed abnormal results in Bender- Gestalt test, with a greater than 2 years discrepancy between chronological and test-estimated age. On behavioral and neuropsychological assessments we have observed the presence of attentional and organisational deficits; speech problems were observed especially in the younger patients, in whom we have also observed expressive language disorders.

**DIFFERENT ETIOLOGY IN FAMILIAL LOW-GRADE GLIOMA AND HIGH-GRADE GLIOMA ?** *B.S. Malmer, R. Henriksson, H. Gronberg.* Dep of Radiation Sciences, Onc, UME University Hospital, UME, SwedenÅÅ.

**BACKGROUND:** Familial glioma occurs in about 5% of all glioma patients. Only in a few cases cancer-prone syndromes as the Li-Fraumeni syndrome are known in these families. To assess the mode of inheritance and the risk for low-grade and high-grade glioma respectively, we conducted a segregation analyses and a nation-wide cohort study. **METHODS:** We Constructed two cohorts. Firstly, one of first-degree relatives (FDR) to glioma patients diagnosed 1985-1993 in Northern Sweden. A segregation analyses was performed of the 2141 FDR. A second cohort was then constructed from the Swedish Family-data base with all FDR born 1932 -1997 to patients with low-grade glioma (N=15 321 FDR) and high-grade glioma (N =26 635 FDR) diagnosed 1958 to 1997 in all of Sweden. The risk for all FDR and the risk for siblings were calculated using the program PYRS, calculating person-years 1958-1997. The expected rates of low-grade glioma and high-grade glioma were calculated from the population respectively. **RESULTS:** Segregation analyses: The segregation analyses rejected the sporadic model and an autosomal recessive gene provided the best fit. Family cohort study: A increased risk was shown among FDR of low-grade glioma patients (SIR 3.65, 95% C.I 2.31-5.47), and the risk was higher among FDR to probands younger than 40 years (SIR 4.75 95% C.I 2.86-7.42). However, the risk was even higher in the cohort of siblings (SIR 7.00 95% C.I 3.35-12.87). ( Skall du inte skriva ngot om HGG families, Br du inte ocks skriva ngot om risken fr HGG hos LGG probander fr att belgga din hypotes?) In the low-grade glioma families with siblings, there were no other types of cancers within the family. In the high-grade glioma sibling families, there were other types of cancer among the parents to the siblings indicating an aetiology of multifactorial origin or of other cancer-prone syndromes, as the Li-Fraumeni syndrome. **CONCLUSIONS:** This is the first cohort analysis calculating risk for low-grade and high-grade glioma separately. We have identified a new type of familial glioma where an autosomal recessive gene could be involved, especially for siblings in low-grade glioma.

**Familial epilepsy: clinical and epidemiological features in 10 Cuban families.** *C. Llanusa Ruiz*<sup>1</sup>, *R. Garcia*<sup>2</sup>, *L. Paz*<sup>3</sup>.  
1) Genetics Department, Ramon Gonzalez Coro Hospital, Havana City, Cuba; 2) Juan Manuel Marquez Hospital; 3) Facultad Finlay-Albarran.

Epilepsy is considered a complex disease. Genetic and environmental are known to contribute to the etiology of this disorder. Our group is studying familial epilepsy in Cuba, with the goal of delineating its clinical and epidemiological characteristics and eventually identify susceptibility genes. Here we present preliminary data on ten Cuban families with three or more affected individuals with cryptogenic or idiopathic epilepsy and age at onset less than 25 years old, ascertained through index cases from several hospitals and medical centers in Havana City, Cuba. All the affected individuals and close relatives were interviewed. Family history information about relatives status was obtained with two interview methods. Neurological evaluation was performed on every affected family member and the clinical history was reviewed. The most frequent type of epilepsy found was partial, and in some families there were individuals with partial and generalized epilepsy. Empiric recurrence risks were assessed in each family.

**Screening of the HOXA1 and HOXB1 genes in a group of autism subjects.** *Z. Talebizadeh<sup>1</sup>, D.C. Bittel<sup>1</sup>, J.H. Miles<sup>2</sup>, M.G. Butler<sup>1</sup>.* 1) Children's Mercy Hospital and University of Missouri-Kansas City School of Medicine, Kansas City, MO; 2) University of Missouri School of Medicine, Columbia, MO.

HOX genes are neurodevelopmental genes involved in early brain formation. Allelic variations have been reported in the human HOXA1 (at 7p) and HOXB1 (at 17q) genes including a single base substitution (A218G) in a series of histidine repeats and a 9-base insertion after base 88, respectively. Recent evidence from a study of 57 autistic probands (Ingram et al., 2000) suggested a role for the HOX genes in the susceptibility to autism. To further investigate whether allelic variations of the HOXA1 and HOXB1 genes are over represented in autistic subjects, we studied 40 autistic probands using automated direct DNA sequencing. Both allelic variants of each gene were observed among the studied population. The frequency of the different alleles in these two HOX genes were compared between our autism population and those subjects reported previously by Ingram et al. (2000). Confidence intervals were used to determine if a difference between the two proportions existed. For the HOXA1 gene, our autism population had 26% A/G genotype frequency and Ingram et al. found 38% A/G among their autistic probands. This difference was not statistically significant (95% CI: -30% to 8%). In addition, no significant difference was observed between the A/G genotype frequency in our autism population compared with the controls (22%) reported by Ingram et al. (95% CI: -11% to 20%). For the HOXB1 gene, a statistically lower rate of the insertion genotype (+/Ins) was seen in our autism population (25%) compared to the autistic probands (47%) reported by Ingram et al. (95% CI: -42% to -2%). Comparison of the frequency of this genotype in our autistic probands (25%) with their control population (37%) did not indicate any significant difference (95% CI: -29% to 6%). In addition, we found no evidence of an interaction between the HOXA1 and HOXB1 genes. The results of the current study do not support an association between these HOX genes and autism. Therefore, additional studies with autistic subjects should be performed to clarify whether there is any association between the HOX genes and autism.

**MECP2 mutation type, affected domain, X-inactivation and phenotypic outcome in Rett syndrome. L.S.**

*Raffaele*<sup>1,2</sup>, *S.L. Williamson*<sup>1</sup>, *B. Bennetts*<sup>1,2</sup>, *M. Davis*<sup>3</sup>, *C.J. Ellaway*<sup>1,2</sup>, *H. Leonard*<sup>4</sup>, *M-K. Thong*<sup>5</sup>, *M. Delatycki*<sup>5</sup>, *E.M. Thompson*<sup>6</sup>, *N. Laing*<sup>3</sup>, *J. Christodoulou*<sup>1,2</sup>. 1) Metabolic Research, Level 3, Clinical Sciences, The Children's Hospital at Westmead, Westmead, Australia; 2) Dept of Paediatrics & Child Health, University of Sydney, Australia; 3) Centre for Neuromuscular and Neurological Disorders, University of Western Australia, Perth, Australia; 4) TVW Telethon Institute for Child Health Research and Centre for Child Health Research, University of Western Australia, West Perth, Australia; 5) Victorian Clinical Genetics Service, Royal Children's Hospital, Melbourne, Australia; 6) South Australian Clinical Genetics Service, Women's and Children's Hospital, North Adelaide, Australia.

Rett Syndrome (RTT) is a severe neurodevelopmental disorder primarily affecting females and exhibiting marked clinical variability. It is caused by mutations in the dominant X-linked MECP2 (Methyl-CpG-binding protein 2) gene. We have analysed the clinical variability in RTT by correlating the type of MECP2 mutation present, domain affected and degree of skewing of X-inactivation with the phenotype. The coding region of MECP2 was completely sequenced in 81 patients, 67% of whom had mutations. The other patients may have mutations within the 5' or 3' UTRs or other controlling elements, or may represent phenocopies. Symptoms were assigned severity scores that could be tallied to give an overall phenotypic picture. Truncation mutations were associated with more severe phenotypes, as were mutations affecting the methyl-binding domain (MBD). X-inactivation was examined by a methylation assay of the androgen receptor microsatellite. Skewed X-inactivation (>75% expression of a single allele) was found in 43% of 72 patients, which is higher than that seen in a normal population (16.4%, Busque et al 1996). However, there was no relationship between skewed X-inactivation and any of the phenotypic variables, probably because it may be either protective or detrimental. Nevertheless, it is probable that the variant phenotypes seen in RTT are the result of complex interactions between mutation type, domain affected and X-inactivation.

**Type 2 diabetes, APOE gene and the risk for dementia and dementia related pathologies. The Honolulu-Asia Aging Study.** *R. Peila<sup>1</sup>, B.L. Rodriguez<sup>2</sup>, L.J. Launer<sup>1</sup>*. 1) Laboratory of Epidemiology, Demography and Biometry, NIA, NIH, Bethesda, MD, USA; 2) University of Hawaii at Manoa, Honolulu, HI, USA.

Background: Type 2 diabetes has been implicated as a risk factor for dementia but its interaction with genetic risk factors and the associated pathological mechanisms remains unclear. Objective: To determine the association of diabetes alone or in combination with the APOE gene to incident dementia and to examine the combined effect of APOE genotype and diabetes to neuropathological outcomes in the brain. Methods: Data were collected prospectively from a population-based cohort of 2574 Japanese-American men enrolled in the Honolulu-Asia Aging Study (HAAS). Diabetes was ascertained by interview and direct glucose testing (fasting and 2hr) and APOE genotype was characterized. Dementia was assessed in 1991 and in 1994 by clinical examination, MRI and diagnosis according to international guidelines. Complete autopsy information was available on a representative sample of 216 men. Results: After 2.9 years of follow-up, 135 dementia cases were diagnosed; 51 with Alzheimer's disease (AD) without cerebrovascular disease, 25 with AD and cerebrovascular disease, 33 with vascular dementia (VsD) and 28 with other types of dementia. Diabetes was associated with dementia (relative risk [RR], 1.5 [95% CI 1.01-2.2] for total dementia, 1.7 [CI 1.1-2.9] for AD, and 2.4 [CI 1.1-5.3] for VsD). Individuals with both diabetes and e4 allele had a RR of 5.4 (CI 2.1-13.4) for AD compared to those without AD and the e4 allele. In the autopsy sub-group, diabetes was associated with brain infarcts equal or greater than 1 cm and neuritic plaques (NP) (incidence rate ratio [IRR], 1.8 [CI 1.2-2.6]) and IRR, 1.5 [CI 1.1-2.1]). The group with diabetes and the e4 allele had a higher number of NP and neurofibrillary tangles in the hippocampus (IRR, 4.0 [CI 2.2-5.2] and IRR, 2.8 [CI 2.5-3.2]) and higher risk of cerebral amyloid angiopathy (RR 6.5 [CI 1.4-29.6]). Conclusions: Type 2 diabetes is a risk factor for VsD and AD. The association between diabetes and Alzheimer is particularly strong among carriers of the APOE e4 allele. The results on clinical outcome are supported by the pathological data.

**A Genetic Hypothesis for Chiari Type 1 Malformation with or without Syringomyelia.** *M.C. Speer<sup>1</sup>, D.S. Enterline<sup>2</sup>, T.M. George<sup>3</sup>, A. Frankin<sup>1</sup>, L. Mehlretter<sup>1</sup>, C.M. Wolpert<sup>1</sup>, T.H. Milhorat<sup>4</sup>.* 1) Medicine, Duke Univ Medical Ctr, Durham, NC; 2) Radiology, Duke Univ Medical Ctr, Durham, NC; 3) Surgery, Duke Univ Medical Ctr, Durham, NC; 4) Neurosurgery, State University of NY, New York.

The Chiari 1 malformation (CM1) is defined as herniation of the cerebellar tonsils through the foramen magnum and has a prevalence of approximately 1/5000. CM1 is the leading cause of syringomyelia (S). Recently, we and others have proposed a volumetrically "too small" posterior fossa as causative. We propose a genetic hypothesis to at least a subset of CM1/S cases based on familial clustering in a rare disease, co-segregation with known genetic syndromes, and concordance in like-sex twins. We have identified 67 multiplex pedigrees. Some families demonstrate patterns consistent with male-to-male transmission and transmission across more than two generations. Additional support for a genetic hypothesis for CM1/S comes from co-segregation of CM1 with known genetic syndromes including, among others, achondroplasia, Klippel Feil sequence, Hadju-Cheney syndrome, Albright hereditary osteodystrophy (pseudohypoparathyroidism) and hypophosphatemic rickets, most of which involve an abnormality in bone development. Lastly, we identified 8 sets of like-sex twins in our family ascertainment efforts in CM1/S (7 female; 1 male); 7 of 8 are concordant for CM1 (one female twin pair is discordant for CM1). 3 are concordant for associated syringomyelia. Determinations of the range of  $I_s$  are at least 10 across a broad range of prevalence estimates and recurrence risk to siblings. These data are consistent with a genetic hypothesis in at least subset of CM1/S. We hypothesize that the underlying gene or genes for CM1/S will have pleiotropic effects influencing the extent of tonsillar herniation, posterior fossa volume, and/or other variables such as bony abnormalities in the base of the skull and/or syringomyelia.

**Distribution of the GAA repeat of frataxin gene among the Japanese ataxia patients.** *M. Watanabe, X. Zhaoh, S. Nissato, S. Shoji.* Neurology/Inst Clinical Sci, Tsukuba Univ, Tsukuba, Ibaraki, Japan.

To estimate the relative frequency of Friedreich ataxia in Japanese population, we analyzed the GAA repeat of the frataxin gene among the Japanese ataxia patients. Twentyseven familial ataxia patients and seven sporadic ataxia patients were analyzed. No expanded allele was detected. All patients were either homozygous or heterozygous for normal alleles. The smallest allele was 2 repeats and the largest was 7 repeats. All alleles detected were within short normal allele (SN) range that was reported to be up to 10 repeats. In normal European populations, the GAA repeats of the frataxin gene were reported to show a bimodal distribution that was composed of short normal allele (SN) with 5 to 10 GAA triplets and long normal allele (LN) with 12 to 60 triplets. Frequencies of alleles were compared between reported European population and our samples by Yates corrected  $\chi^2$  test of homogeneity. There was a significant difference between these samples ( $\chi^2$  value was 9.27).

**Canadian Collaborative Study of twins with multiple sclerosis.** *C.J. Willer<sup>1</sup>, R. Holmes<sup>2</sup>, I. Yee<sup>2</sup>, N. Risch<sup>3</sup>, A.D. Sadovnick<sup>2</sup>, G.C. Ebers<sup>4</sup> and Canadian Collaborative Study Group.* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, UK; 2) Department of Medical Genetics, University of British Columbia, Vancouver, Canada; 3) Department of Genetics, Stanford University, Palo Alto, CA; 4) Department of Clinical Neurology, University of Oxford, Oxford, UK.

The Canadian Collaborative Study on the Genetic Susceptibility to Multiple Sclerosis (CCPGSMS) is a multi-centre study involving 18 MS clinics across Canada and has ascertained over 18,000 individuals with multiple sclerosis (MS). Every individual identified was asked if they had a twin or triplet. 380 Canadian twin probands and 6 Canadian triplet probands were ascertained in this manner, comprising a total of 368 twin pairs and 6 triplet sets.

Twin pairs lost to follow-up (N=15) and pairs in which the co-twin died at birth (N=30) or before the age of 20 (N=1) were excluded from analyses, such that concordance and zygosity data were available for 322 pairs and 334 probands. There were 125 monozygotic (MZ) and 197 dizygotic (DZ) twin pairs identified. At least one twin had been diagnosed with multiple sclerosis using the standard criteria. The unaffected co-twin was examined whenever possible by a neurologist specializing in MS. Based upon the known twinning rate, the population of Canada and the prevalence of multiple sclerosis, it was estimated that between 350 and 450 twin pairs and 4-7 triplet sets with multiple sclerosis would be identified.

The pairwise concordance rate in MZ pairs was  $20.0 \pm 3.6\%$  (25/125), which was significantly higher than the observed concordance rate in DZ pairs of  $5.6 \pm 1.6\%$  (11/197,  $z = 3.77$ ,  $p < 10^{-3}$ ). Probandwise concordance rates were  $25.9 \pm 3.8$  for MZ twins and  $6.5 \pm 1.8$  for DZ twins ( $z = 4.7$ ,  $p < 10^{-5}$ ). The DZ concordance rate was not significantly different than the observed recurrence risk in siblings of the same probands (18/603,  $z = 1.56$ ,  $p > 0.10$ ). This twin series is currently being examined for differences in early life events and for concordance of clinical phenotype. The implications of this study on models of genetic inheritance of multiple sclerosis are discussed.

**The rate of multiple sclerosis (MS) in relatives of MS patients in the province of Sassari, Sardinia.** *M. Pugliatti<sup>1</sup>, A. Sotgiu<sup>1</sup>, S. Sotgiu<sup>1</sup>, A. Sanna<sup>1</sup>, I.M.L. Yee<sup>2</sup>, G. Rosati<sup>1</sup>, A.D. Sadovnick<sup>2</sup>*. 1) Inst. of Clinical Neurology, University of Sassari, Sassari, Italy; 2) Dept. of Medical Genetics, University of British Columbia, Vancouver, Canada.

Recent epidemiological data show that Sardinians are at very high risk for MS. Geographic isolation and consistent inbreeding rates over time in this population lead to the hypothesis of a relatively greater role for genetic susceptibility in MS compared with other populations. The aim of this study is to quantify the rate of MS in relatives of patients living in the province of Sassari.

Preliminary data are presented on 174 unrelated individuals ("index cases") who were (i) independently ascertained, (ii) of clear Sardinian ancestry based on 4 grandparents, and (iii) fulfilling the Poser et al. Committee diagnostic criteria for definite MS. The gender ratio in the study group was 2.5.

The average age (SD) of the index cases was  $36.0 \pm 9.4$  years. Clinical information was obtained for a total of 6,105 biological relatives of the index cases (1,074 first-, 2,051 second- and 2,980 third-degree relatives). In 25/174 (14.4%) families, at least one person other than the index case had MS. Of these, 6 families (24%) had 2 additionally affected family members and 2 families (8%) had at least 3 additionally affected individuals.

Thirty-five out of 6,105 (0.57%) relatives had been diagnosed as having MS. Among first-degree relatives, 3/326 parents, 14/584 siblings, 1/164 children had MS. Among second-degree relatives, 1/679 nephews and nieces, 2/661 paternal, 1/711 maternal uncles/aunts were affected. Among third-degree relatives, 5/1,473 paternal and 8/1,507 maternal first cousins had MS. These numbers represent crude rates but age-adjusted rates will also be presented.

These findings represent preliminary data of a longitudinal study aimed to give a better comprehension of the role of genetic factors in MS susceptibility among Sardinians living in different provinces.

*Supported by ISS, Rome, FISM, Genoa, grant n. 97/R/69, MURST, Rome and Regione Autonoma della Sardegna..*

**Associations between gene polymorphisms and Alzheimers disease using a large case control study.** *S. Tang<sup>1</sup>, Z. Yamagata<sup>1</sup>, Y. Shindo<sup>1</sup>, Y. Takeda<sup>1</sup>, T. Mizutani<sup>1</sup>, T. Asada<sup>2</sup>.* 1) Health Sciences, Yamanashi Medical University, Japan; 2) Department of Psychiatry, Tsukuba University, Japan.

The subjects were 805 Japanese including 407 patients (168 men and 239 women) with a diagnosis of probable AD based on the NINCDS-ADRDA criteria and 398 spouses (162 men and 236 women) of the subjects served as a control. We analyzed 4 kinds of gene polymorphisms: Apolipoprotein E gene (APOE: e2, e3, e4), Very Low Density Lipoprotein gene (VLDL-R: CGG repeat of exon 3), Interleukin 1 alpha gene (IL1A: a C to T transition in the 5-flanking regulatory region at 889 of the gene) and alpha 1 antichymotrypsin gene (AACT: a microsatellite region consisting of a variable number of dinucleotide repeats, (CT)<sub>n</sub>(AT)<sub>n</sub>). APOE and IL1A gene polymorphisms were determined by the polymerase chain reaction restriction fragment length polymorphism (PCR-RFLP) method. The triplet repeat polymorphisms of VLDL-R and AACT were genotyped by the PCR fragment analysis software of the Long Read TowerV sequencer. The estimating odds ratios (OR) and the multiple logistic regression analysis were performed by SAS statistic analysis package to evaluate the association. APOE: The OR was 2.98 (95% CI=2.51-3.40) for the e4 allele. VLDL-R: The OR for the 5-repeat allele was 1.56 (95% CI 1.32-1.78). IL1A: There was no association between the IL1A (-889) polymorphism and AD. AACT: The frequency of the A10 allele was higher in the AD than in the control but this was not significant. The frequency of the A10 allele significantly increased in the AD patients who did not have APOE e4. The multiple logistic regression analysis indicated that APOE and VLDL-R were significant risks for the development of AD.

**Familial aggregation of second cancers in a childhood sarcoma cohort.** *S. Hwang*<sup>1</sup>, *G. Lozano*<sup>1</sup>, *C. Amos*<sup>2</sup>, *L.C. Strong*<sup>1</sup>. 1) Dept Molecular Genetics, Univ TX MD Anderson Cancer Ctr, Houston, TX; 2) Dept Epidemiology, Univ TX MD Anderson Cancer Center, Houston, TX.

In a childhood cancer cohort designed to characterize familial cancer aggregation, we have observed excess cancer risk in the extended families (kindreds). Increase risk for all types of cancer was characterized by female gender, carrying germline p53 mutation, and younger birth cohort. Excess second and multiple cancers was observed in the cancer-prone families. Here we applied generalized linear models to characterize the second cancer risk aim to better illustrate the cancer phenotype for kindreds with or without germline p53 mutation. We estimated the extent of familial aggregation for second cancer in the cohort under the assumption of linear relationship of cancer risk among the family members. Results of the generalized linear model incorporated generalized estimation equation to adjust for correlation among family members showed a log odds of 0.8 (95% confidence interval: 0.2, 1.4,  $p < 0.01$ ) increase in second cancer risk associated with other family member's second cancer incidence. Germline p53 mutation carriers though had shorter time period between the first and the second cancer diagnoses, the difference was not statistically significant. There was no gender difference in second or multiple cancer risk while birth cohort plays a significant role in individual's risk of multiple cancers.

**Cancer Incidence in BRCA1 Mutation Carriers.** *D.J. Thompson, D.F. Easton and Breast Cancer Linkage Consortium.* CRC Genetic Epidemiology Unit, University of Cambridge, UK.

A number of reports have suggested that the role of BRCA1 in cancer susceptibility is not restricted to the increases in breast and ovarian cancer risk with which it is most commonly associated.

To evaluate the risks of other cancers in BRCA1 mutations carriers we conducted a cohort study of 8121 individuals from 699 families segregating a BRCA1 mutation, ascertained in 30 centres across Europe and North America. Over a quarter of the individuals were known to carry a BRCA1 mutation, and untested family members were weighted according to their estimated probability of being a mutation carrier. Cancer incidence in members of families segregating BRCA1 mutations was compared with expected incidence based on population cancer rates.

BRCA1 carriers were at significantly increased risk of pancreatic cancer (RR = 2.3, 95% CI = 1.3 - 4.1) and of cancer of the uterus (RR = 2.7, 95% CI = 1.7 - 4.2). The uterine cancer excess is not related to tamoxifen use, as it did not decrease when women who could have been prescribed the drug in response to a previous breast cancer were excluded. There was some evidence of an elevated risk of prostate cancer in mutation carriers below 65 years of age (RR = 1.8, 95% CI = 1.0 - 3.3). Seven cases of cancer of the fallopian tube were observed (RR = 49.9, 95% CI = 22.5 - 110.9), and one case of retinoblastoma. Overall, the increased risk of cancer at all sites other than the breast or ovary was small (RR = 1.2, 95% CI = 1.1 - 1.4). These results contrast with those for BRCA2 mutations, which are associated with a larger increased risk of cancers of other types.

**Multiple primary malignancies: A predictor for hereditary cancer syndromes.** *F. Wiklund, H. Grönberg.*

Department of oncology, Umeå, Sweden.

**BACKGROUND:** Early onset and occurrence of multiple primary malignancies are two common characteristics of hereditary cancer.

**AIMS:** To identify patterns of different tumors which might be of interest to identify new hereditary cancer syndromes.

**METHODS:** Between 1.1.1958 and 31.12.2000 a total of 58747 women in the northern part of Sweden were reported to the regional cancer registry. Among these women 689 (1.2%) had a minimum of two malignancies, of which the first cancer was diagnosed before 50 years of age, and 185 (0.3%) women had at least two breast cancers of which the first breast cancer was diagnosed before 50 years of age. These women were followed from date of the second cancer until death or 31.12.2000.

**RESULTS:** Among women with at least two cancers 73 (10.6%) developed a third cancer. The standardized incidence ratio (SIR) of occurrence of a third cancer was 2.3 (95% CI = 1.8-2.9), with a cumulative probability of third cancer occurrence of 40% (95% CI = 28-49%) at 22 years after diagnosis of a second cancer. Among the 185 women with early onset bilateral breast cancer patients 15 subsequent cancers were observed among 13 women. Significantly elevated SIRs was observed for colorectal cancer (SIR = 5.2, 95% CI = 1.7-25.5) and ovarian cancer (SIR = 7.8, 95% CI = 2.1-19.9). An indication of a higher risk for gastric cancer was also observed (SIR = 7.6, 95% CI = (0.9-27.3)).

**CONCLUSIONS:** Cohorts of early onset multiple primary cancer cases has proved to be useful for analysis of new hereditary cancer syndromes. Among women with a minimum of two early onset cancers a cumulative probability of third cancer of 40% was observed. In this pilot study significantly increased risks for colorectal and ovarian cancer was observed among early onset bilateral breast cancer patients. The increased risk for ovarian cancer is well known but the combination of bilateral breast cancer and colorectal cancer is novel. Results from an extended nationwide study, including over 80000 patients with multiple malignancies, will be presented.

**THE OHIO AMISH POPULATION STUDY: PHASE I.** *S.G. Roth, C. Baldia, K. Archer, A. Bowman, S. Call, R. Rau, I. Comeras, J.A. Westman.* The Ohio State University, Comprehensive Cancer Center, Columbus, OH.

The aim of this study is to identify the occurrence and trends of cancers within the Ohio Amish community, a unique founder population in central and northeastern Ohio. Ohio has the largest Amish population of any state and the largest contiguous settlement of Amish in the world, located mostly in Holmes and surrounding counties. The total Amish population eligible for this study was approximately 24,400 living individuals. The *1996 Ohio Amish Directory*, a listing of 4512 Amish households, was used to select 130 Amish households in Holmes, Wayne, Tuscarawas, and Coshocton counties for contact. Households were selected using a simple randomized sampling protocol. To achieve a 10% precision level, 86 households were required to participate in the study. Each selected household was visited by a research assistant from June to December, 2000 and asked to participate through providing a family medical history of the husband and wife's birth families. There were 92 households accrued (71% accrual rate). Four-generation family health histories were obtained including information regarding cancer diagnoses. The average number of individuals, living and deceased, included in each household's history was 284 (total 26,128). Significant overlap of individuals occurs among household histories due to interrelatedness. A relational database is used for in-depth analysis. Confirmation of reported cancer diagnoses is done through medical records and death certificates. No histories represent known hereditary cancer susceptibility syndromes. However, there is an increased incidence of hematological malignancies in at least two extended families. The 1996 data from the Ohio Cancer Incidence Surveillance System is now available for comparison to the data collected through the randomized study. Here, we present a preliminary analysis of cancer occurrence in the Ohio Amish community.

**APOLIPOPROTEIN E POLYMORPHISM IN ANGIOGRAPHICALLY VERIFIED PATIENTS FROM THE ARGENTINIAN POPULATION.** *V.V.G. Bañares<sup>1,2</sup>, G. Peterson<sup>1</sup>, M. , Espeche<sup>1</sup>, G. Barach<sup>1</sup>, R. Gulayin<sup>3</sup>, E. Sisu<sup>3</sup>, M.E. , Ruiz<sup>4</sup>, E. Bravis Lopez<sup>4</sup>, O.H. Pivetta<sup>2</sup>, M.J. Tavella<sup>1,5</sup>.* 1) Programa de Prevencion del Infarto en la Argentina, Universidad Nacional de La Plata,; 2) Centro Nacional de Genética Médica, ANLIS Carlos Malbrán; 3) Servicio de Hemodinamia,; 4) Instituto de Investigaciones Bioquímicas de La Plata, Argentina. Laboratorio Central, Instituto del Torax, La Plata, en la Argentina, Universidad Nacional de La Plata,; 5) Instituto de Investigaciones Bioquímicas de La Plata, Argentina.

Several studies have indicated an association between the e4 allele of the apolipoprotein E and coronary heart disease in some populations. We determined the apo E genotype as described Hixson y col. in 185 samples, 123 belonging to patients with atherosclerotic injury (L) and 62 without atherosclerotic injury (NL) both facts verified by angiography and under-61-year-old. The chi<sup>2</sup> test showed no significant differences when we compared the apo E e4 allele distribution between L vs. NL. Since the n of our control group was considerably small, we compared the allele distribution between our general population (previously reported) and the L group. The chi<sup>2</sup> test shown significant differences (p=0.015). We conclude that these data suggest that the e4 allele could be one factor contributing to increase the susceptibility to coronary heart disease in our population.

**Association between genetic variation of the dopamine D1 receptor gene and essential hypertension in the Korean population.** *J. Be<sup>1</sup>, K.-T. Kim<sup>1</sup>, B.-Y. Kang<sup>1</sup>, C.-C. Lee<sup>2</sup>*. 1) Seoul Bioscience Institute, Seoul, Gangdong-Gu, Korea; 2) Seoul National University.

Essential hypertension is a multifactorial disease, and has been shown to be associated with dopamine D1 receptor (DRD1) gene. The dopamine D1 receptor (DRD1) known to increase sodium excretion by inhibiting Na-H exchanger and Na,K-ATPase activity. The relationship between the genetic variation of the DRD1 gene and essential hypertension in Korean population was investigated by the DdeI restriction fragment length polymorphism (RFLP) pattern of this gene. There were no significant differences between normotensives and essential hypertensives in allele and genotype frequencies. However, the genotype of DRD1 gene was significantly associated with conventional cardiovascular risk factor such as plasma total cholesterol and LDL-cholesterol levels in normotensives ( $P < 0.05$ ). Therefore, our result suggests that Dde I RFLP of DRD1 gene may be useful as genetic marker in the pathogenesis of cardiovascular disease in Korean population.

**Association of the *Taq1* cholesteryl ester transfer protein (CETP) gene polymorphism with high-density lipoprotein cholesterol and coronary artery disease (CAD) in Asian populations.** C.K. Heng<sup>1</sup>, H.Z. Li<sup>2</sup>, H.Y. Yang<sup>2</sup>, Y.S. Tan<sup>3</sup>, M.C. Tong<sup>3</sup>, N. Saha<sup>1</sup>, P.S. Low<sup>1</sup>. 1) Dept Pediatrics, National Univ Singapore, Singapore; 2) Dept Biochemistry, National Univ Singapore, Singapore; 3) National Heart Centre, Singapore.

We genotyped the CETP *Taq1* polymorphism in the Chinese, Malays and Asian Indians in Singapore and determined its impact on plasma lipid profiles and CAD. Angiographically confirmed CAD patients ( $n=623$ ) who were admitted consecutively for by-pass graft were included as cases. The healthy control subjects ( $n=929$ ) were selected from those attending routine medical examinations. They were free of heart ailments, diabetes, hypertension and stroke.

In the healthy populations, the *B1* allele frequency was highest in the Malays (0.59), intermediate in the Chinese (0.53), and lowest in the Indians (0.51). The Malay *B1* frequency was significantly higher than Indians and the Chinese ( $P < 0.05$ ). The genotype distributions were all consistent with Hardy Weinberg expectations.

A significantly lower *B2* allele frequency was observed in the Chinese CAD patients ( $P < 0.01$ ) compared to the healthy controls. The odds ratio for CAD associated with the absence of *B2* was 3.45 (95% CI 1.69 to 7.39) after adjustment for the confounding effect of cigarette smoking and BMI by logistic regression. The association of the genotypes with high density lipoprotein cholesterol (HDL) levels was significant for male Chinese ( $P = 0.007$ ) and female Indians (0.039) in the order  $B1B1 < B1B2 < B2B2$  and could explain about 5% of the total variation in HDL levels in these two ethnic groups. All analyses were carried out with adjustment for the confounding effects of age, BMI and smoking status. The effect of the *Taq1* polymorphism on apolipoprotein A-1 (apoA1) was similar to HDL, with the *B2* allele associated with elevated apoA1 levels in the Chinese males ( $P=0.001$ ) but weakly in the Indian females ( $P=0.07$ ). We did not find any effect of gene-environmental interaction between CETP genotypes and smoking on plasma lipid levels.

**A Multigenic Model of Hypertension.** *S.O. Henderson<sup>1</sup>, P. Bretsky, MS<sup>2</sup>, B.E. Henderson, MD<sup>2</sup>, D. Stram, PhD<sup>2</sup>.* 1) Emergency Medicine, Keck School of Medicine, USC, Los Angeles, CA; 2) Preventive Medicine, Keck School of Medicine, USC, Los Angeles, CA.

Hypertension (HTN) is a major predisposing condition to mortality from stroke, myocardial infarction and renal failure. African-Americans (AA) have excess HTN when compared to other U.S. populations, an excess particularly significant in younger individuals. Latinos, who share many sociocultural characteristics with AA, have a much reduced risk of HTN, and we have previously suggested that genetic, as well as environmental factors, must be important in the predisposition of the AA population to HTN. The Renin-Angiotensin-Aldosterone system is critical to the maintenance of blood pressure. Variants in the Angiotensin-Converting-Enzyme (ACE) and Aldosterone Synthase (CYP11B2) genes have been associated with the risk of HTN. We genotyped AA and Latino members of a large multiethnic cohort (MEC) to determine the frequency of the ACE D/I variant, and the C344T variant in the CYP11B2 gene, and their association with HTN / anti-HTN therapy. **METHODS:** This was an analysis of the frequency of the ACE D/I and CYP11B2 344 C/T polymorphisms in a subset of a MEC. The genotypes of subjects <65 years of age in the cohort were compared to their HTN status. **RESULTS:** A small increase in risk of HTN is seen for subjects with ACE DD in both AA (R.R.=1.46) and Latinos (R.R.=1.23). The D allele is more frequent in AA (58% vs. 48%). There is an increased risk of HTN for CYP11B2 TT in AA (R.R.=1.63), but not for Latinos (R.R.=0.92). In a simple additive model, there is an increasing risk of HTN in AA, with an increasing frequency of the "at risk" ACE D and CYP11B2 T alleles, such that those with two high-risk alleles have a R.R. of 1.57 (95% CI: 0.79, 3.12), with three alleles have a R.R. of 1.74 (95% CI: 0.89, 3.40), and those with four high risk alleles have a R.R. of 2.07 (95% CI: 0.98, 4.39) (p for trend=0.07). No such pattern was observed in Latinos. **CONCLUSION:** The ACE D and CYP11B2 344T alleles appear to make a modest, and additive contribution to the risk of HTN in AA, but not in Latinos. We are continuing to increase the size of the population under study, as well as the number of candidate gene variants.

**High resolution haplotype analysis of the ACE region in essential hypertension.** *J. Nakura<sup>1</sup>, H. Yamagata<sup>1,2</sup>, A. Morishima<sup>1</sup>, K. Uemura<sup>1</sup>, K. Kohara<sup>1</sup>, T. Miki<sup>1</sup>.* 1) Dept Geriatric Medicine, Ehime Univ Sch Medicine, Ehime, Japan; 2) Dept Hygiene, Ehime Univ Sch Medicine, Ehime, Japan.

The D variant in angiotensin-I converting enzyme (ACE) gene is associated with high ACE levels and may be related to increased risk of cardiovascular disease. However, such findings have not been consistent among studies, suggesting that associations between genotypes and diseases may be influenced by additional genetic or non-genetic factors. We previously reported that the ACE polymorphism was associated with cardiovascular disease (*Hum Genet* 107:239,2000) and systolic blood pressure after hospitalization was significantly higher in normotensive male subjects who possessed the D allele (*Hypertens Res* 23:201,2000). To further investigate the influence of the ACE gene region, we genotyped 10 SNPs spanning 26 kb of the ACE gene by ASO method in 100 Japanese hypertensive patients and 100 healthy controls and constructed haplotypes using the computer program HAPLO (*Journal of Heredity* 86:409,995). The haplotype frequency was compared with the data in Caucasian British families. As expected, strong linkage disequilibrium was observed among the SNPs. A total of 38 different haplotypes were observed and two of them accounted for 70%. There was no statistically significant difference in haplotype frequency distributions between cases and controls. However, we found a different frequency distribution pattern of the 9 haplotypes in the Japanese population compared with the distribution pattern previously reported for British families. Moreover, clade C ( recombinant of clade A and B ) did not exist in Japan. These findings may lead to the new consideration of global genetic drift.

**The hepatic lipase gene promoter polymorphism (*LIPC*-480 C>T) is associated with coronary artery calcification in Type 1 Diabetes.** *J.E. Hokanson<sup>1</sup>, S. Cheng<sup>2</sup>, J.K. Snell-Bergeon<sup>1</sup>, M.A. Grow<sup>2</sup>, C. Hung<sup>2</sup>, H.A. Erlich<sup>2</sup>, J. Ehrlich<sup>3</sup>, R.H. Eckel<sup>4</sup>, M. Rewers<sup>1</sup> and CACTI (Coronary Artery Calcification in Type 1 Diabetes).* 1) Preventive Med & Biometrics, Univ Colorado Health Sci Ctr, Denver, CO; 2) Roche Molecular Systems Inc, Alameda, CA; 3) Colorado Heart Imaging, Denver, CO; 4) Dept. of Medicine, Univ Colorado Health Sci Ctr, Denver, CO.

Subjects with Type 1 Diabetes are at increased risk of coronary heart disease (CHD). Coronary artery calcification (CAC) is a measure of subclinical CHD. Hepatic lipase is a rate limiting enzyme in lipid metabolism. We investigated the role of the hepatic lipase gene promoter polymorphism (*LIPC*-480 C>T) and CAC in 91 Caucasian subjects with Type 1 Diabetes.

Among the 48 men and 43 women, the *LIPC*-480 C>T allele frequency was 0.24 and genotypes were in Hardy-Weinberg equilibrium. The *LIPC*-480 T allele was statistically significantly more common in subjects with CAC (see table).

CAC (Au)	n =	<i>LIPC</i> -480 T frequency
0	40	0.14
0.1 - 10	31	0.31
10.1 - 100	22	0.27
> 100	18	0.39

In logistic regression, *LIPC*-480 genotype remained significantly related to CAC, independent of age, sex, duration of diabetes, lipids, and blood pressure.

Thus the hepatic lipase gene promoter polymorphism is associated with the presence of coronary artery calcification in Type 1 Diabetes. If confirmed, the hepatic lipase gene may be an important susceptibility gene for subclinical CHD in Type 1 Diabetes.

**Familial aggregation of cardiovascular disease risk factors in type 2 diabetic families.** *L.A. Lange, L.E. Wagenknecht, C.D. Langefeld, B.I. Freedman, W.A. Riley, S.S. Rich, D.W. Bowden.* Wake Forest University, Winston-Salem, NC.

Atherosclerotic cardiovascular disease (CVD) is a complex disease process with multiple genetic loci likely contributing small individual effects. Targeting a population enriched for type 2 diabetes (T2DM), which is characterized by accelerated CVD, may allow us to detect these effects. An established surrogate measure for CVD is common carotid artery intima-media thickness (CCA-IMT) measured by high resolution B-mode ultrasonography. Other quantitative risk factors for CVD include body mass index (BMI) and lipid measures (HDL, LDL, triglycerides). We hypothesize that these measured CVD risk factors will exhibit a higher degree of heritability in families enriched for T2DM. This sample consisted of 124 individuals (109 diabetics; 109 Caucasians/15 African Americans) from 54 families participating in the Diabetes Heart Study (DHS), a study designed to search for genetic factors contributing to CVD in families enriched for T2DM. The mean ( $\pm$  std) for age was  $60.2 \pm 11.3$  yrs, IMT  $0.65 \pm 0.11$  mm, BMI  $33.2 \pm 8.2$ , HDL  $42.6 \pm 13.9$ , LDL  $116.5 \pm 31.3$  and triglycerides  $192.4 \pm 97$ . Data were analyzed in order to obtain heritability estimates ( $h^2$ ) adjusted for age, gender and ethnicity using the SOLAR software package. BMI and triglycerides were transformed to approximate distributional assumptions. The adjusted  $h^2 \pm$  SE and p-value for IMT ( $0.49 \pm 0.20$ ,  $p < 0.005$ ), square root of BMI ( $0.56 \pm 0.23$ ,  $p < 0.006$ ), HDL ( $0.36 \pm 0.24$ ,  $p < 0.07$ ), LDL ( $0.35 \pm 0.21$ ,  $p < 0.05$ ), and log-triglycerides ( $0.78 \pm 0.21$ ,  $p < 0.0005$ ) all met or were near statistical significance. Since BMI is known to be associated with IMT, we also obtained  $h^2$  for IMT ( $0.52 \pm 0.21$ ,  $p < 0.004$ ) after making an additional adjustment for BMI. Our results support familial aggregation for these CVD risk factors, with IMT, BMI and triglycerides showing the largest heritabilities. These results, taken together with the previous significant  $h^2$  of coronary artery calcium in the DHS population ( $0.50 \pm 0.22$ ,  $p < 0.009$ ; Wagenknecht et al., *Diabetes*, 50:861-866, 2001), suggest that multiple traits are heritable in the DHS sample and that these traits may be important in efforts to map genes contributing to atherosclerotic CVD.

**Genetic basis of variation in carotid artery plaque: The San Antonio Family Heart Study (SAFHS).** *K.J. Hunt<sup>1</sup>, R. Duggirala<sup>1</sup>, H.H.H. Göring<sup>2</sup>, J.T. Williams<sup>2</sup>, L. Almasy<sup>2</sup>, B.D. Mitchell<sup>3</sup>, J. Blangero<sup>2</sup>, D.H. O'Leary<sup>4</sup>, M.P. Stern<sup>1</sup>.* 1) University of Texas Health Science Center, San Antonio, TX; 2) Southwest Foundation for Biomedical Research, San Antonio, TX; 3) University of Maryland School of Medicine, Baltimore, MD; 4) New England Medical Center, Boston, MA.

While many researchers have investigated the genetic basis of carotid artery intima-media thickness, a quantitative marker of sub-clinical atherosclerosis, few studies have focused on the genetic basis of carotid artery plaque (CAP), a discrete marker of sub-clinical atherosclerosis. We investigated the extent to which the presence or absence of CAP was under genetic control in the SAFHS. The study population consisted of 750 individuals distributed across 29 randomly ascertained extended Mexican American pedigrees who participated in the second exam of the SAFHS. Extracranial focal CAP was identified by B-mode ultrasound in the internal and common carotid arteries or the carotid bulb on the right and left side. 51 of 461 women, and 57 of 289 men (aged 18 to 89 years) had evidence of a plaque either in the right and/or left carotid artery. The mean age of participants with and without CAP was 59.2 and 39.3 years, respectively. Using a variance decomposition approach implemented in SOLAR, we performed genetic analysis on the discrete trait CAP (i.e., liability to disease), using a threshold model. Covariates considered in the initial analysis included age, sex, diabetes, current smoking status, and lipid levels, as well as markers of hypertension and obesity. Adjusting for significant age and sex effects only, the heritability ( $h^2 \pm SE$ ) for CAP was significant [ $h^2 = 0.28 \pm 0.15$ , ( $P = 0.01$ )]. Further, after adjusting for additional covariates that contributed significantly to the model ( $P < 0.05$ ; diabetes, systolic and diastolic blood pressure, body mass index, waist circumference, and smoking status) the heritability remained significant [ $h^2 = 0.27 \pm 0.16$ , ( $P = 0.03$ )]. Our results suggest that in the Mexican American population the variation of the discrete trait CAP is under appreciable additive genetic influences after controlling for established cardiovascular risk factors. This work was supported in part by NHLBI grant P01 HL45522.

**Family resemblance for Fat Mass and Fat Free Mass: the Korean Cardiovascular Genome Study.** *Y.S. Jang, E.K. Im, J.H. Kwon, E.Y. Cho, H.Y. Park, S.H. Jee, J.H. Lee.* Dept Cardiology, Yonsei Yonsei Cardiovascular Research institute, Seoul, South Korea.

Obesity is well-known risk factor for cardiovascular disease. The body composition, especially fat mass, is determined by complex phenotype for which multiple genetic and nongenetic factors are involved. Here we applied the regressive model to family data fat mass (FM) and fat free mass (FFM) to investigate the major gene hypothesis in Korean population. The sample consisted of 456 members of 78 families from Korean Cardiovascular Genome Study. Proband was diagnosed hypertension or coronary artery disease. FM and FFM were assessed by bioelectrical impedance (TBF 105, Japan). The data were adjusted for age, age<sup>2</sup>, height, BMI, gender, drinking, exercise, and menopause status prior to analysis. Adjusted factor FM, FFM showed strong familial aggregation with an estimated sibling correlation of 0.27, 0.40 and a smaller parents offspring correlation of 0.13, 0.11 respectively. For FM, the most parsimonious model was a codominant model, and the putative major gene explained the 35.7 % of variance in adjusted FM. The estimated heritability of the FM is 30.4 % by the method of Rice (1997). For FFM, the segregation analysis did not provide statistical evidence of major gene. The differences is partially expressed FFM is more affected by many of environmental factor, kidney function than FM. Our results showed the major gene effect determining the FM in Korean population, and linkage analyses using the genetic markers should be followed for identification of candidate genes.

**The Sca I RFLP of atrial natriuretic peptide gene in Korean essential hypertensives.** *K. Kim<sup>1</sup>, B.-Y. Kang<sup>1</sup>, J.-H. Shin<sup>2</sup>, C.-C. Lee<sup>2</sup>*. 1) Seoulin Bioscience Institute, Seoule, Gangdong-Gu, Korea; 2) Seoul National University.

Essential hypertension is considered to be caused by a complicated combination of genetic and environmental factors. Atrial natriuretic peptide (ANP) has been to suppress renin activity and inhibit the synthesis and release of aldosterone. Therefore, Abnormalities of this peptide caused by genetic variation may be influence the blood pressure. The aim of present study was to examine the relationship between essential hypertension and Sca I RFLP of ANP gene in Korean population. The genotype distribution of this RFLP was significantly different between normotensives and essential hypertensives ( $P < 0.05$ ). However, this genetic marker was not significantly associated with any anthropometric parameters or plasma lipid concentrations in our study group . Therefore, our result suggest that Sca I RFLP of ANP gene may be useful as genetic marker in the ethiology of essential hypertension in Korean population, independent of any cardiovascular risk factors studied.

**Effects of Gene Polymorphisms and Lifestyle Factors on Blood Pressure in a longitudinal study.** *Y. Takeda, Y. Zhang, T. Mizutani, S. Tang, Z. Yamagata.* Health Sciences, Yamanashi Medical University, Tamaho, Yamanashi, Japan.

The purpose of this project was to clarify the relationships among hypertension-related gene polymorphisms, blood pressure and lifestyle factors, as well as their effects on blood pressure changes in a follow-up study of a large Japanese population from 1994 to 1998. The study subjects were healthy unrelated Japanese male employees of a company, aged from 30 to 61 years (mean=42±8.5). Five hundred and thirty subjects were selected at random from among the 1,154 persons. The lifestyles of these 530 subjects were investigated by questionnaire in 1994. A polymerase chain reaction (PCR) analysis was used to detect three hypertension-related gene polymorphisms. The data were analyzed in ANOVA and multiple regression analysis. The mean systolic BP and diastolic BP values were significantly higher in the subjects with the TT genotype of AGT M235T gene polymorphism compared to other genotypes ( $P<0.001$ ). The mean diastolic BP was higher in the subjects carrying the D allele of ACE I/D gene polymorphism, but this difference was not significant. No significant association was observed between AAD gene polymorphism and mean BP. The multiple regression analysis revealed significant correlations of a consistent magnitude between systolic BP and each of the following variables: AGT, family history of hypertension, age, body mass index (BMI) and alcohol consumption ( $P<0.0001$ ). In addition, a significant association between diastolic BP and the ACE gene with adjusted related factors was shown. Smoking was not found to be associated with hypertension in this study population. Our findings suggest that there is an association between AGT gene polymorphism and BP. ACE gene polymorphism had a weak relation to blood pressure. We found no association between AAD gene polymorphism and BP in this Japanese population. The subjects age, BMI, positive family history and alcohol consumption were shown to have strong associations with BP. The results of this study support those of previous epidemiological investigations, except for the absence of a relationship between smoking and BP in this study.

**A Report of Recessive Inheritance in 14 cases with COCKAYNE SYNDROME in 3 families from an Endemic Mexican State, where Genetic Factors (CONSANGUINITY) contribute for the development of the disease. M.B.**

*Gutierrez<sup>1</sup>, J.M.R. Aparicio<sup>1</sup>, M.P. Barrientos<sup>1</sup>, J.L. Penaloza y Senties<sup>1</sup>, C.F. Salinas<sup>2</sup>.* 1) Genetic Epidemiology, Medical Genetics, Endocrinology and Direccion of the Hospital Para el Nino Poblano, Puebla, MEXICO; 2) Craniofacial Genetics, Medical University of South Carolina, USA.

**INTRODUCTION.** 14 cases of cockayne syndrome (CS) from three different families with first and second degrees of consanguinity living in two small towns in a mexican state of Oaxaca were studied. **CASES REPORT.** The clinical manifestation of CS were analized at the Pediatrical Hospital Para el Nio Poblano (HNP) by the multidisciplinary medical staff. The main clinical manifestations were dermatological alterations as photosensitivity to sunligh and predisposition to skin cancer "xeroderma pigmentosum" (XP); endocrinologic alterations as dwarfism and senil appearance; opthalmological findings from cataracts to pigmentary retinal degeneration; neurological alterations as mental retardation and sensorial hearing loss; and upper limbs, lower limbs and vertebral column degeneration was also found. **CONCLUSIONS.** 14 cases with Cockayne Syndrome were diagnosed in three Mexican families from two different Mexican towns where consanguinity rate is high. By taking in cosideration the 140 cases already reported, we might considere to have the 10% of the general population with Cockayne syndrome, in this state. These results confirmed that consanguinity is, as reported, the etiological factor for this genetical disease. **KEYWORDS:** Cockayne Syndrome; xeroderma pigmentosum; autosomal recessive inheritance.

**Familial Aggregation of Hyperemesis Gravidarum.** *M. Schoenberg-Fejzo*<sup>1</sup>, *L. Anderson*<sup>1</sup>, *R. Schoenberg-Paik*<sup>2</sup>. 1) Department of Medicine, UCLA, Los Angeles, CA; 2) Department of Statistics, UCLA Los Angeles, CA.

Nausea and vomiting in pregnancy, or "morning sickness," occurs in 50-90% of all pregnant women. When the symptoms are so severe that individuals require hospitalization and/or therapeutic intervention, women are diagnosed with hyperemesis gravidarum (HG). HG occurs in approximately 0.3-2.0% of pregnant women, and is characterized by severe nausea and vomiting in early pregnancy that leads to at least a 5% weight loss. Symptoms of HG can include ketonemia, ketonuria, dehydration, electrolyte imbalance, ptyalism, gestational hyperthyroidism, and hepatic and renal damage. Little is known about the etiology of HG, which may be an abnormal toxic response to normal hormone levels during pregnancy, or conversely, may be a normal toxic response to abnormal hormone levels or abnormal metabolites during pregnancy. Approximately 70% of patients are prescribed antiemetic drugs of unknown safety and efficacy to treat the symptoms of HG. In an attempt to learn more about HG, we collected surveys from over 226 affected individuals. Our study shows that the 3 most commonly prescribed antiemetics are more strongly correlated with second trimester fetal demise than with having any positive therapeutic effect, suggesting a better understanding of the disease and new treatments is critical. To determine whether HG is amenable to genetic studies, we included questions about family history. All patients were diagnosed by a medical professional to have hyperemesis gravidarum. Of the 226 respondents, 74 reported having at least one sister with a pregnancy history. Of the 74 sister pairs, 21 reported a sister with HG. In addition, 24 affected individuals reported having an affected mother, and 27 reported having an affected secondary relative. We have also recruited 13 families with 3 or more affected individuals. This is the first evidence that there may be a genetic component to the severe form of morning sickness, hyperemesis gravidarum, which may make it amenable to genetic studies of complex disease. We hope that this will lead to a new field of study to identify the genetic basis for hyperemesis gravidarum and lead to development of targeted therapy.

**Twin zygosity and concordance for the autism phenotype.** *A.C. Thomas, K. Osann, C. Modahl, T. Laulhere, M. Smith, J. Escamilla, V. Nguyen, P. Flodman, M.A. Spence.* Human Genetics, Univeristy of California-Irvine, CA.

Autism has been previously demonstrated to have a high heritability. However, no conclusive evidence has been provided regarding phenotypic variation. In this study, ten sets of twins and one set of triplets in which at least one member was diagnosed with Autistic Disorder (AD) were ascertained. Zygosity of the same-sex multiples were determined with greater than 99% accuracy using microsatellite analysis. Subjects were assessed for AD using the Autism Diagnostic Interview (ADI) and the Autism Diagnostic Observation Scale (ADOS). Concordance rates for AD were significantly different between monozygotic (MZ) and dizygotic (DZ) pairs, 100% and 29%, respectively ( $p = .02$ ), indicating a strong genetic component in the development of AD.

Manifestations of autistic behaviors as measured by the ADI and ADOS were compared within concordant MZ pairs ( $n=6$ ), concordant multiples ( $n=8$ , includes both MZ and DZ pairs), and unrelated pairs concordant for AD ( $n=19$ ). Phenotypic variation within the autistic triad was not significantly different for MZ and DZ pairs. Unrelated individuals with AD exhibited greater variation (not statistically significant).

IQ was assessed using the Stanford-Binet Intelligence Scales or the Mullen Scales of Early Learning. MZ pairs concordant for AD were significantly correlated for overall IQ and nonverbal IQ ( $r = 0.94$ ,  $p = 0.003$  and  $r = 0.97$ ,  $p = 0.001$ , respectively). The within-pair correlation coefficient for verbal IQ was moderately high ( $r = 0.70$ ,  $p = 0.094$ ), though not significant. No correlation for IQ was found within DZ pairs and unrelated pairs concordant for AD.

The stronger correlation for IQ observed in MZ twins vs. DZ twins confirms the importance of genetic factors in determining IQ. The weaker correlation between zygosity and autistic behaviors, reveals that epigenetic factors may play a role in determining these parameters. Alternatively, the ADI and ADOS may not be adequate quantitative test measures.

**Age of parents and the risk of cleft lip and palate.** *T. Ellerhorst, C. Owens, H. Oh, J. Mir, T. Mosby, M. Tolarova.*  
Dpt of Orthodontics, UOP School of Dentistry, San Francisco, CA.

Several epidemiological studies have suggested that the age of parents at the time of child's birth may play an important role in the etiology of congenital anomalies. Recent studies have associated a high parental age with sporadic retinoblastoma, prostate cancer, breast cancer, Down syndrome, and Alzheimer disease.
