In order to explore the parental age as a possible risk factor for nonsyndromic cleft lip and/or palate (NSCL/P), we analyzed the age of parents in 123 children with NSCL/P (cases) and in 81 unaffected children (controls).

The median age of cases and controls was the same (13.9 vs. 14.1 years). However, we found a significant difference between the mean maternal age of cases and controls (25.8 vs. 26.4;  $P=0.005$ ), as well as between the mean paternal age of cases and controls (28.7 vs. 31.4;  $P=0.000003$ ). Mothers who were 20 years old and younger and also fathers who were 20 years old and younger had the highest risk of having a child affected with NSCL/P. Detailed analysis of epidemiological characteristics was done for subgroups according to cleft diagnosis. A strong relationship was found between the young paternal age and unilateral NSCL/P ( $P=0.006$ ). A similar association was found between the young age of mothers and unilateral NSCL/P ( $P=0.014$ ) and bilateral NSCL/P ( $P=0.022$ ).

The data from two different South American sites in Chile (Antofagasta and Chillan) were then compared. In both samples, one half of the mothers who gave birth to a child with bilateral NSCL/P were 24 years old or younger. Similar studies are currently being conducted in other areas of South America. The results of such studies will help to understand etiology of cleft anomalies in South America and thus enable us to develop preventive measures to decrease the prevalence of these serious congenital anomalies.

The field work for this study was supported by funding from ROTAPLAST International, Inc.

Program Nr: 1211 from the 2001 ASHG Annual Meeting

**Power of Cellular Automata for Identifying Gene-Gene and Gene-Environment Interactions.** *J.H. Moore, L.W. Hahn.* Program in Human Genetics, Vanderbilt University, Nashville, TN.

We have previously developed a cellular automata (CA) approach to identifying gene-gene and gene-environment interactions (Moore and Hahn, in press). Briefly, CA are dynamic systems that consist of arrays of discrete cells. The state of a cell at each time step is determined by the current states of neighboring cells. CA can be used to perform computations by taking advantage of features such as massive parallelism. We have adapted a CA to accept an array of genotypes and/or environmental classes as input and produce an array as output that can be used to classify sibs as affected or unaffected (e.g.  $f(010110|\text{affected}) = 111111$  or  $f(100010|\text{unaffected}) = 000000$ ). CA models are optimized using machine learning and evaluated using 10-fold cross-validation and permutation testing. The goal of this study was to evaluate the power of CA models in the presence of noise. Using four different epistasis models, we simulated discordant sib-pairs with 5% genotyping error, 5% phenocopy, 20% phenocopy, or 50% genetic heterogeneity. We find that the CA approach retains > 95% power in the presence of genotyping error or phenocopies and > 75% power in the presence of genetic heterogeneity. We conclude that the CA approach is robust to common sources of noise and should be added to the repertoire of methods for identifying and characterizing gene-gene and gene-environment interactions.

**Statistical Analysis of Genotypic Association Data with HAPMAXII.** *M.L. Hamshere<sup>1</sup>, P.J. Giles<sup>1</sup>, M. Krawczak<sup>2</sup>, M.J. Owen<sup>1</sup>.* 1) Psychological Medicine, UWCM, Cardiff, UK; 2) Medical Genetics, UWCM, Cardiff, UK.

HAPMAXII is a software package that facilitates the analysis of genotypic association data in population- and family-based samples (<http://psychmed.uwcm.ac.uk/hapmaxii>). HAPMAXII is an extension of the original HAPMAX (Krawczak et al., *Hum Genet* 1988). The software is designed so that both trio and case-control data sets can be included in the same analysis. Markers on autosomal and sex chromosomes, including deleted regions can be incorporated into the analysis. An EM algorithm (Dempster et al., *J. R. Stat. Soc. B* 1977) is employed to obtain maximum likelihood estimates of the haplotype frequencies. A choice of start vectors is available to include the phase-unknown individuals into the analysis. The user can then investigate the sensitivity of the haplotype frequency estimates to the start vector. Likelihood ratio statistics and analytical and empirical significance levels are produced. A range of other statistics can be supplied by HAPMAXII, including the Lewontin's disequilibrium coefficient  $D'$  (Hedrick, *Genet* 1987) and a test for Hardy Weinberg equilibrium in population-based data (Guo and Thompson, *Biometrics* 1992).

**Genetic background cluster analysis : theory and applications.** *B.A. Thiel<sup>1</sup>, S. Kardia<sup>4</sup>, M. Province<sup>5</sup>, D.C. Rao<sup>5</sup>, N.J. Schork<sup>1,2,3</sup>.* 1) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH; 2) Program for Population Genetics and Department of Biostatistics, Harvard University School of Public Health, Boston, MA; 3) The Jackson Laboratory, Bar Harbor, ME; 4) Department of Epidemiology, University of Michigan, Ann Arbor, MI; 5) Division of Biostatistics, Washington University School of Medicine, St. Louis, MO.

Population samples (families, sibpairs, individuals, etc.) ascertained for gene mapping studies are often assumed to be largely independent, representative, and homogenous with respect to the population from which they are drawn. Testing these assumptions can be difficult without any *a priori* knowledge of possible sources of non-independence or genetic background heterogeneity. We describe a suite of strategies for testing the genetic heterogeneity of a sample of individuals. The proposed techniques make use of genotype data collected on sampled individuals at markers distributed throughout the genome. The strategies are flexible and can be used for a variety of purposes including controlling for cryptic stratification in genetic association studies, reconstructing genealogies and genetic relationships, and investigating human molecular diversity. Although we focus on important methodological detail, such as the determination of the number of clusters in a sample and analytic techniques used to determine the clustering (such as factor analysis and other similarity matrix-based cluster methods), we also provide an example of these methods with large genetic epidemiological samples from the NHLBI Family Blood Pressure Program. We also discuss the shortcomings of our strategy as well as areas for further research.

Program Nr: 1214 from the 2001 ASHG Annual Meeting

**Machine Learning Optimization of Neural Network Architecture Improves the Identification of Gene-Gene and Gene-Environment Interactions.** *M.D. Ritchie, J.S. Parker, L.W. Hahn, J.H. Moore.* Program in Human Genetics, Vanderbilt University, Nashville, TN.

Neural networks (NN) have been proposed as a method for detecting and characterizing gene-gene and gene-environment interactions. However, most applications of NN use a fixed set of genetic loci as input and a fixed number of hidden layer nodes and node connections. With these NN, only the weights of the network connections are optimized. This greatly limits the flexibility of the NN that in turn limits the power of the NN to identify functional loci. The goal of this study was to develop a NN approach that uses machine learning for optimizing both the selection of genetic loci as input and the NN architecture in addition to the NN weights. Essentially, this method evolves the structure of the neural network and identifies the functional loci out of a pool of many candidates. The best models identified by the NN are then evaluated using 10-fold cross validation and permutation testing. Using simulated data, we have demonstrated that this approach improves the identification of gene-gene interactions and facilitates interpretation of multilocus results. This study supports the idea that NN will be an important statistical tool for the study of complex multifactorial diseases.

**The power of whole genome association studies that exploit linkage disequilibrium.** *N.J. Schork*<sup>1,2,3</sup>. 1) Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH; 2) Program for Population Genetics and Department of Biostatistics, Harvard University School of Public Health, Boston, MA; 3) The Jackson Laboratory, Bar Harbor, ME.

There is a great deal of controversy surrounding whole genome association studies for mapping disease-predisposing genes. Much of this controversy is rooted in an ignorance about the strength of linkage disequilibrium (LD) between alleles at neighboring polymorphic loci. LD strength can basically be used to gauge the probability that observed marker locus alleles will act a good "surrogates" for unobserved disease relevant alleles. Both theoretical and empirical studies have been pursued to assess LD strength and the results of these studies vary considerably.

We present a method for assessing the power of association studies that uses actual data on LD strength. Our strategy uses novel theoretical constructs to account for uncertainty in LD strength (among other unknown parameters) and can be used to assess population-specific and genome-region specific association studies in addition to whole-genome studies. Our proposed methods are flexible and more compelling than traditional strategies for answering such questions as: "how dense a map of markers is needed for a genome-wide association study" or "what is the likely error rate associated with genetic association studies that exploit LD?" Numerous examples are given that make use of data in the public domain.

**Fifteen years after Chernobyl accident: the analysis of genetic consequences registered in the population of Belarus.** *G.I. Lazjuk<sup>1</sup>, P. Verger<sup>2</sup>, E. Robert<sup>3</sup>, H.G. Ilyina<sup>1</sup>, I.A. Kirillova<sup>1</sup>, Zh.P. Kravchuk<sup>1</sup>, I.V. Novikova<sup>1</sup>, I.V. Naumchik<sup>1</sup>, N.V. Rumyantseva<sup>1</sup>.* 1) Belarus Institute for Hereditary Diseases, Minsk, Belarus; 2) Institute de Protection et de Surete Nucleaire, Paris, France; 3) European Institute of Genomutations, Lyon, France.

Since 1982 Belarus National Registry (BNR) for obligatory registered congenital malformations (ORCM) monitors annually about 90,000 births and over 2000 pathologically examined medical abortuses (MA). The Registry recorded a significant increase of ORCM and embryonic anomalies found in MA, in the population of Belarus (Lazjuk G. et al., 1993, 1995, 1996). The most significant increase was registered in the areas with Cs<sup>137</sup> contamination density over 555kBq/km<sup>2</sup>.

To determine the factors causing this increase, the studies have been started within International Health Effect project, with Belarus Institute for Hereditary Diseases (Minsk, Belarus), Institute de Protection et de Surete Nucleaire (Paris, France), and European Institute of Genomutations (Lyon, France) as participating sides.

The main preliminary conclusions:

1. The data stored at BNR can be used for the analysis of CM dynamics, since the methods of data collection and CM nomenclature suit EUROCAT recommendations, and the figures reflecting the completeness of ORCM in the contaminated areas before and after the accident differ only slightly.

2. In Belarus a number of pregnancies with abnormal embryonic development is being increased.

3. Recently the differences between the rates of increase of ORCM frequencies in the control and contaminated areas were becoming smaller, however, the total ORCM frequency for 13-year period was recorded to be 12% higher in the contaminated areas than in the control ones.

**Meckel syndrome in Northern Ireland - evidence for possible segregation distortion?** *A.C. Magee, N.C. Nevin.*  
Regional Genetics Service, Belfast City Hospital Trust, Belfast, Northern Ireland.

Meckel syndrome (MS) - first described in 1822 - is one of the well-recognised, autosomal recessive, multiple congenital anomaly syndromes. The main diagnostic criteria comprise occipital encephalocele, polydactyly, cystic changes in the kidneys and hepatic fibrosis. The ascertainment and epidemiology of MS in Northern Ireland (NI) suggest the possibility of segregation distortion, which has been described in other Mendelian inherited conditions. From 1977 to 2000, 27 cases of MS (11 male, 13 female, 3 sex not determined) have been retrospectively ascertained in 10 families. The diagnosis was confirmed by post-mortem in at least one case from each family. The incidence of MS in NI is therefore estimated at 1/25,000. All couples, except one of Indian origin, were Northern Irish. In 2 families, the parents were consanguineous, being first cousins. Pedigrees were obtained for all families. It was noticeable that these parents seemed to have a higher than expected recurrence of MS. Pregnancy rate in the families ranged from 3 to 10. The total number of pregnancies was 63, with 12 first trimester miscarriages. There were 24 healthy sibs (9 male, 15 female). Thus, 27 of a total of 51 sibs (53%) had MS. When this is corrected for truncate single ascertainment, by eliminating one case from each sibship, the proportion of affected sibs is 33.3%. This is significantly higher than the 25% expected with autosomal recessive inheritance and suggests segregation in favour of the Meckel allele.

**Methylenetetrahydrofolate Reductase and Congenital Heart Defects: Evidence for Gene - Environment**

**Interaction.** *J.S. Zeiger<sup>1</sup>, J.B. Hetmanski<sup>1</sup>, I. McIntosh<sup>1</sup>, C. Loffredo<sup>2</sup>, T.H. Beaty<sup>1</sup>.* 1) Johns Hopkins Medical Institutions, Baltimore, MD; 2) Georgetown University, Washington, DC.

**Purpose:** Congenital heart defects (CHD) represent a major public health issue; collectively they are the most common birth defect creating a considerable medical, emotional and economic burden. This case-control study tested for the possible involvement of two polymorphisms in the gene encoding for methylenetetrahydrofolate reductase (MTHFR), C677T and A1298C, in the etiology of congenital heart defects.

**Methods:** Four types of heart defects were examined: aortic stenosis (AS, n=33), coarctation of the aorta (CoA, n=56), pulmonic stenosis (PS, n=72), and atrial septal defects (ASD, n=62). Cases and controls (n=308) for this study were drawn from the Baltimore-Washington Infant Study, a population based study conducted between 1981 and 1989 to examine risk factors for CHD. Odds ratios with 95% confidence intervals were calculated to test for associations between genotype and case/control status, and to test for interactions between genotype and environmental factors. Separate analyses were performed for Caucasians and African-Americans due to the differences in their allele frequencies.

**Results:** There were no differences between cases and controls for either of the MTHFR variants. Heavy alcohol use (OR = 6.76, 95% CI = 2.61-17.51) and heavy smoking (OR = 4.70, 95% CI = 1.38-16.04) increased risk for PS among Caucasians. There was some evidence of interaction between smoking and the A1298C genotype among African American PS cases (OR nonsmokers = 0.98, 95% CI = 0.27-3.42; OR smokers = 3.03, 95% CI = 1.09-8.52).

**Conclusions:** Smoking may be a risk factor for congenital heart defects alone and in the presence of the MTHFR A1298C variant.

**Genetic disease in offspring of survivors of childhood and adolescent cancer.** *J.J. Mulvihill<sup>1</sup>, L.C. Strong<sup>2</sup>, L.L. Robison<sup>3</sup> and Investigators of the Childhood Cancer Survivor Study.* 1) Department of Pediatrics, Children's Hospital Oklahoma, Oklahoma City, OK/JNCI; 2) The University of Texas M.D. Anderson Cancer Center, Houston, TX; 3) Department of Pediatrics, University of Minnesota, Minneapolis, MN.

No environmental agent has been proved to cause human germ cell mutation seen as genetic disease in offspring. Cancer survivors often receive intensive chemotherapy and radiotherapy that cause human and experimental somatic mutations and animal germline mutations. To study environmental germline mutagenesis, we used the Childhood Cancer Survivor Study, a retrospective cohort of 14,054 children diagnosed with common cancers before age 21 years and surviving at least 5 years, at 25 US and Canadian institutions (JNCI 2001;93:618). Participants were 54% male, 87% white, and 64% between ages of 20 and 39 years at follow-up; 44% received combination surgery, radiotherapy, and chemotherapy. Genetic disease in patients, families, and offspring were ascertained by self-administered questionnaires; verification by records is underway. Genetic and congenital disease occurred in 158 (3.7%) of 4,214 offspring of survivors, compared with 102 (4.4%) of 2339 offspring of controls; there were no apparent differences in the proportion of offspring with cytogenetic syndromes, single-gene defects, or simple malformations. These preliminary results, if confirmed after verification, provide reassurance that cancer treatment using modern protocols does not carry a large risk for genetic disease in offspring conceived many years after treatment. (NIH grant CA55727).

**MUTATIONAL HOTSPOTS AND HYPERVARIABLE NUCLEOTIDE MOTIFS IN THE NON-CODING HUMAN mtDNA CONTROL REGION.** *B. Malyarchuk, M. Derenko.* Genetics Lab, Biological Probl of the North, Magadan, Russia.

It is not known why the hypervariability of certain mtDNA sites exists. It seems likely that DNA context predisposes to mutation processes, leading to point mutations, deletions and duplications. It is possible that a certain nucleotide motifs are responsible for increased variability of the human mitochondrial genome. To test this hypothesis, we have performed a search for short hypervariable motifs based on analysis of mtDNA control region variation data in human populations. In order to determine hypervariable sites among nucleotide positions in the noncoding region, we have analyzed the frequency of appearance of identical mutations in mtDNA sequences belonging to the different phylogenetic haplogroups of mtDNAs. As a result, 14 nucleotide positions, where mutations appeared independently in 6-11 of 15 mtDNA haplogroups analyzed, were found in the 360 base pair segment of the mtDNA non-coding region. The contextual analysis of the hypervariable positions distribution has allowed to reveal at least three types of nucleotide motifs, which are characterized by increased level of mutagenesis in respect to single-nucleotide substitutions - GTAC (for nps 16093, 16129, 16304, 16311), ACCC (for nps 16172, 16256, 16265, 16291, 16294, 16298, 16390) and CCTC (for nps 16189, 16356, 16362). It was found that these motifs are often associated with direct repeated sequences, including tandem repeats. Moreover, the hypervariable motifs CCTC and ACCC as components of the poly-C tracts are the part of direct repeats, leading both to deletions and tandem duplications in human mtDNA. The data received allow us to conclude that the human mitochondrial genome instability is caused considerably by mutation processes predetermined by DNA context. The similarity of the hotspot point mutations with regard to the position and kinds of mutations in different mtDNA haplogroups and the predominance of the transitional hotspots allow to suggest that these mutations are primarily spontaneous in origin and arise mostly from DNA replication error induced by certain mtDNA nucleotide motifs. This work was supported by grants of RFBR (00-06-80448) and Frontiers in Genetics (99-04-30).

**The Arab Genetic Disease Database: A National Database of Genetic Disorders.** A.S. Teebi<sup>1</sup>, S.A. Teebi<sup>2</sup>, C.J. Porter<sup>2</sup>, A.J. Cuticchia<sup>2</sup>. 1) Division of Clinical and Metabolic Genetics, Department of Pediatrics, Hospital for Sick Children, Toronto, ON, Canada; 2) Department of Bioinformatics, Hospital For Sick Children, Toronto, ON, Canada.

The Arab Genetic Disease Database (AGDDB) is a curated catalogue of genetic disorders found in Arab populations. The Arabs are a highly diverse set characterized by high rates of consanguineous marriages, increased frequencies of autosomal recessive disorders and elevated frequencies of new disorders and variants. Until recently, they have been poorly studied. The textbook *Genetic Disorders among Arab Populations* (Teebi and Farag, 1997, OUP) was the first serious attempt to compile the existing data on the subject, and subsequently generated a large amount of interest and research on disorders of Arab populations. The first release of AGDDB is based on information in that book, which included data from disparate, often unrefereed/indexed sources. The AGDDB data schema is relational, comprised of key data elements and their important attributes. It is centered around the element of the Disorder Report, with elements for Clinical data, Genomic data (including protein), Population data and Reference data also present. Population-specific variants and detailed frequency reporting is included. The Arab Genetic Disease Consortium (30 investigators, 18 countries) is responsible for annotating, editing and reviewing AGDDB data. When the initial indexing of data is finished, AGDDB will contain over 1000 unique disorder entries. Entries are cross-linked with their counterparts in OMIM and GDB, and similar associations to relevant locus-specific and central mutation databases are in the works. The database is queriable by keyword across all its fields, and logical operators are allowed. More focused searches may be performed on disorder, gene name, OMIM number, population and citation. The first release of AGDDB will be freely accessible at <http://www.agddb.org/> in September of 2001. AGDDB is the first population-specific variation and disorder database, and can serve as a robust prototype for the cataloguing of such data in other populations.

**Y-CHROMOSOME POLYMORPHISMS AND THE PEOPLING OF GRAN CANARIA.** *D. Castro-de-Guerra*<sup>1</sup>, *M. Bortolini*<sup>2,3</sup>, *M. Thomas*<sup>2</sup>, *J. Aguilar*<sup>2</sup>, *L. Angel*<sup>1</sup>, *F. Sánchez-García*<sup>4</sup>, *J. Rodríguez-Gallego*<sup>4</sup>, *M. Déniz-Naranjo*<sup>4</sup>, *J. Soria*<sup>5</sup>, *J. Arellano*<sup>6</sup>, *A. Auóon*<sup>7</sup>, *F. Salzano*<sup>3</sup>, *N. Bradman*<sup>2</sup>, *A. Ruiz-Linares*<sup>2</sup>. 1) Laboratorio de Genética Humana, IVIC, Caracas, Caracas, Venezuela; 2) The Galton Laboratory, Department of Biology, University College London, UK; 3) Dep. de Genet., UFRGS; 4) Servicio de Inmunol., Hosp. de Gran Canaria, Gran Canaria; 5) Dep. d Hematol., Hosp. de la Santa Creu i Sant Pau, Spain; 6) Centro de Cien. de la Salud, Trasera Hosp. Insular, Gran Canaria; 7) Inst. de Med. Trop., Spain.

The Canary Islands were initially colonized around 4,000 years ago by people probably originating in North West Africa. In the past few centuries, Europeans and Sub-Saharan Africans have moved into the islands as a consequence of the Spanish colonial expansion. To evaluate the origin of Canarian male lineages and examine the history of admixture of this population we typed four Y-biallelic markers: DYS271, DYS287, M9, 92R7, and six Y-STRs: DYS19, DYS388, DYS390, DYS391, DYS392, DYS393 in 196 samples from Gran Canaria, Spain and Morocco. We observed that the majority (83%) of Canarian Y-chromosomes are of Spanish origin, but an important North African contribution was also detected (17%). Contrasting mtDNA and Y data sets corroborates a history of directional mating involving preferentially Spanish males and native Canarian females. A similar trend has been reported for other areas of the former Spanish Empire although considerable regional variation is likely to exist and is illustrated by comparing our findings in Gran Canaria with those from Antioquia (Colombia).

**Contribution of UCSNP-43 and UCSNP-19 within the Calpain-10 gene to risk of type 2 diabetes stratified by environment.** *J.M. Norris<sup>1</sup>, C.D. Engelman<sup>1</sup>, M.M. Barmada<sup>2</sup>, R.E. Ferrell<sup>2</sup>, L.K. Moss<sup>1</sup>*. 1) Dept. of Preventive Medicine and Biometrics, Univ of Colorado Health Sciences Center, Denver, CO; 2) Dept. of Human Genetics, Univ of Pittsburgh Graduate School of Public Health, Pittsburgh, PA.

Type 2 diabetes may result from an interaction between genetic susceptibility and environment. The single-nucleotide polymorphisms, UCSNP-43 and UCSNP-19, located in the calpain-10 gene on chromosome 2 (calpains are a family of non-lysosomal cysteine proteases) have shown linkage and association with diabetes in an Hispanic-American population. In addition, epidemiological studies have found an association between diabetes risk and both high dietary fat and low physical activity. We used the transmission/disequilibrium test (TDT) and the sib TDT (s-TDT) to look for linkage to type 2 diabetes in 859 Hispanic individuals from families living in the San Luis Valley in Colorado. This analysis performs a TDT when parental data are available, and a s-TDT when they are not, and calculates a combined z-score ( $z'$ ). We also stratified the analyses by dietary fat and physical activity levels of the diabetic proband to examine potential gene-environment interactions. UCSNP-43 and UCSNP-19 were measured in the laboratory of Dr. R.E. Ferrell. Dietary intake over the past year was collected from the diabetic proband using the Block food frequency questionnaire. Lifetime (prior to diabetes diagnosis) occupational and leisure physical activity was collected using the Kriska Physical Activity Questionnaire. Overall, the TDT/s-TDT found no linkage of either UCSNP-43 or UCSNP-19 to type 2 diabetes in these Hispanic-American families ( $z' = 0.629$  and  $1.089$ , respectively). Stratification by dietary fat and physical activity levels resulted in similar non-significant results. In summary, UCSNP-43 and UCSNP-19 are not linked to diabetes in our population, nor does there appear to be a gene-environment interaction between these SNPs and diet or physical activity in the etiology of type 2 diabetes.

**Genotype and phenotype correlations in oligozoospermic and azoospermic men with Y chromosome**

**microdeletions.** *K. Kucheria*<sup>1</sup>, *K. McElreavey*<sup>2</sup>, *R. Dada*<sup>1</sup>. 1) Dept Anatomy, Div Genetics, All India Inst Medical Sci, New Delhi, India; 2) Institut Pasteur, Immunogenetique Humaine, Paris, France.

10-15 % of couples encounter difficulty to procreate. In 40-50% of these cases the male partner has qualitative or quantitative abnormalities of sperm production. Spermatogenic failure is associated with microdeletion of the long arm of the Y chromosome. Three regions AZFa, AZFb and AZFc on long arm of Y chromosome are critical for spermatogenesis. These 3 loci act at different stages of germ cell development and deletion of each results in a characteristic phenotype. Deletion of AZFa, AZFb, AZFc regions results in Sertoli Cell Only syndrome (SCO), maturation arrest and hypospermatogenesis respectively. One hundred and two infertile males with oligozoospermia and azoospermia were analysed for cytogenetic and molecular profile. Cytogenetic and semen analysis was done in each case. Testicular Fine Needle aspiration Cytology was collected whenever possible. In 70 cytogenetically normal cases, microdeletion analysis was done using STS-PCR approach using primers sY84, sY86 (AZFa); sY127, sY134 (AZFb); sY254, sY255 (AZFc). The STS was considered as absent after 3 amplification failures. Eight of the 70 cases had deletion of at least one of the AZF locus. Four cases had AZFc deletions, three cases had AZFa and AZFb deletions and one case showed AZFb deletion alone. Two cases with AZFa+AZFb deletions had SCO syndrome and 1 case of AZFc deletion showed hypospermatogenesis. In the present study the frequency of microdeletion was 9.9 %. This figure is similar to that reported in three different European populations (Italian, French and Danish) suggesting that, the worldwide incidence of Y microdeletions is likely to be similar, if a common clinical criteria and marker set are used. Thus in a significant number of idiopathic cases of male infertility there is an underlying genetic cause. Detection of these microdeletions aids in better management of these infertile couples should they opt for Assisted Reproductive Technology.

**Genetics of male infertility in Iran.** *C. Krausz<sup>1</sup>, L. Quintana-Murci<sup>1</sup>, H. Sayar<sup>2</sup>, K. McElreavey<sup>1</sup>*. 1) Immunogenetique Humaine, Institut Pasteur, Paris, France; 2) Blood Transfusion Service, Tehran, Iran.

An analysis of the Y chromosome was performed on DNA samples from 46 men with idiopathic male infertility (azoospermia and severe oligozoospermia) of Iranian origin. Microdeletions of the Y chromosome were found in 11 % of Iranians. All microdeletions were in the AZFc region. Y chromosome microdeletions were not observed in a control group of more than 500 individuals from this region. These results are consistent with the microdeletion frequencies that we have previously reported in European populations (France, Italy and Denmark), where a common clinical and molecular protocol was followed. In the Iranian population, consanguinity was noted in 26% of all cases, including one case with a Y microdeletion. A family history of infertility was observed in 17% of Iranian cases including one large family with a case of premature ovarian failure. Inter- and intrafamilial variability of the infertile phenotype was observed. The transmission of the phenotype suggests genetic heterogeneity, and is compatible with X-linked, autosomal dominant and autosomal recessive sex-limited modes of inheritance. The data suggest that familial cases of infertility may be more common than previously supposed.

**Identification of genetic risk factors associated with infertility. A Y chromosome haplogroup is associated with reduced sperm counts.** *K. McElreavey<sup>1</sup>, L. Quintana-Murci<sup>1</sup>, E. Rajpert-De Meyts<sup>2</sup>, N. Jørgensen<sup>2</sup>, M. Jobling<sup>3</sup>, Z. Rosser<sup>3</sup>, N. Skakkebaek<sup>2</sup>, C. Krausz<sup>1</sup>.* 1) Immunogenetique Humaine, Inst Pasteur, Paris, France; 2) University Department of Growth and Reproduction, Rigshospitalet, Copenhagen, Denmark; 3) Department of Genetics, University of Leicester, Leicester, U.K.

In man, infertility is associated with microdeletions of specific regions of the long arm of the Y chromosome. This indicates that factors encoded by the Y chromosome are necessary for spermatogenesis. However; the majority of men with either idiopathic azoospermia or oligozoospermia have a grossly intact Y chromosome and the underlying cause of their infertility is unknown. We hypothesised that some of these individuals may carry other rearrangements or sequence variants on the non-recombining region of the Y chromosome that may be associated with reduced spermatogenesis. To test this hypothesis, we typed the Y chromosome in a group of Danish men with known sperm counts and compared the haplotype distribution with that of a group of unselected Danish males. We found that one class of Y chromosome, referred to as haplogroup 26+, was significantly overrepresented (27.9%;  $P < 0.001$ ) in the group of men with either idiopathic oligozoospermia (defined as  $< 20 \times 10^6$  sperm/ml) or azoospermia compared to the control Danish male population (4.6%). This study defines, for the first time, a class of Y chromosome that is at risk for infertility in a European population. This observation suggests that selection may be indeed active on the Y chromosome, at least in the Danish population. We are currently extending this study to include other populations in Germany, Iran, Turkey and India. The relationship between the Y chromosome background and various semen parameters, including high sperm counts, is also being tested in Danish and Finnish populations. This observation suggests that selection may be indeed active on the Y chromosome, at least in the Danish population, raising the possibility that it could alter the pattern of Y chromosome haplotype distribution in the general population.

**Estimation of individual admixture in Trinidad: application to a case-control study of systemic lupus**

**erythematosus(SLE).** *M. Molokhia*<sup>1</sup>, *A.L. Patrick*<sup>2</sup>, *E. Parra*<sup>3</sup>, *J. Ye*<sup>3</sup>, *M.D. Shriver*<sup>3</sup>, *A.J. Silman*<sup>4</sup>, *P.M. McKeigue*<sup>1</sup>. 1) Epidemiology Unit, London School of Hygiene & Tropical Medicine, London,UK; 2) Ministry of Health, Port of Spain, Trinidad & Tobago; 3) Anthropology Department, Penn State University, State College, Pennsylvania, US; 4) ARC Clinical Sciences Unit, University of Manchester, Manchester,UK.

Objective: To distinguish between genetic and environmental explanations for high risk of SLE in west Africans compared with Europeans by studying the relation of risk to individual admixture. Methods: Cases of SLE, together with controls matched for age, sex and neighbourhood, were sampled from northern Trinidad, excluding those with Indian or Chinese names. Individuals were typed with a panel of 30 SNP markers chosen to have large frequency differentials between the three non-Asian parental populations (west African, European, Native American). Individual admixture (proportion of the genome that has ancestry from each parental population) was estimated from the marker genotypes. Results: This analysis was restricted to the 44 cases and 77 controls who reported that they had no Indian or Chinese ancestry and had been genotyped. Mean proportion of African admixture (M) was estimated in a Bayesian analysis using Markov chain simulation as 0.78 in cases, 0.71 in controls ( $p=0.04$ ). In a logistic regression analysis, the risk ratio associated with unit change in M (from 0 to 1) was estimated as 15.8 (95% CI 1.1 - 227). This association was strengthened after adjustment in the analysis for socioeconomic factors and for religious affiliation. Conclusion: Risk of SLE in this admixed population is strongly related to the proportion of west African admixture, consistent with a genetic explanation for the higher risk of SLE in west Africans compared with other ethnic groups. This result provides a basis for designing studies to localize the genes underlying this effect by studying people of mixed descent using a panel of markers across the entire genome.

**Complex segregation analysis of obsessive-compulsive disorder in families with pediatric probands.** *G.L. Hanna<sup>1</sup>, T.E. Fingerlin<sup>2</sup>, J.A. Himle<sup>1</sup>, G.C. Curtis<sup>1</sup>, K.R. Chadha<sup>1</sup>, D.Q. Koram<sup>1</sup>, M. Boehnke<sup>2</sup>.* 1) Dept Psychiatry, Univ Michigan, Ann Arbor, MI; 2) Dept Biostatistics, Univ Michigan, Ann Arbor, MI.

Obsessive-compulsive disorder (OCD) is a psychiatric disorder affecting one percent to three percent of the population. Evidence from twin and family studies supports a genetic etiology for OCD. Three previous segregation analyses have implicated a gene of major effect in OCD. The purpose of this study was to establish a more precise mode of inheritance for OCD in families ascertained through pediatric probands. Complex segregation analyses of 52 families (35 case and 17 control) were performed by using regressive models as programmed in REGTL in the S.A.G.E. package. A total of 654 individuals were used in the analyses. Both definite and subthreshold OCD were considered affected. In analyses without gender effects, the environmental and sporadic models were clearly rejected. The dominant and additive models were also rejected, whereas the general Mendelian (codominant) and recessive models were consistent with the observed data. In analyses with gender effects, the environmental and sporadic models again were strongly rejected, as were the dominant, additive, and recessive models. The general Mendelian (codominant) model remained the most parsimonious explanation for the observed data. The results provide further evidence for a major locus in the etiology of OCD.

**The effect of parental age on the occurrence of Neurofibromatosis 1.** *J. Tzenova*<sup>1</sup>, *H. Joe*<sup>2</sup>, *V.M. Riccardi*<sup>3</sup>, *J.M. Friedman*<sup>1</sup>. 1) Department of Medical Genetics; 2) Department of Statistics, University of British Columbia, Vancouver, BC, Canada; 3) The Neurofibromatosis Institute, La Crescenta, CA.

New mutations account for half of all patients with neurofibromatosis 1 (NF1), and about 80% of new mutations occur in the paternally-inherited allele. The exception is large deletions, which are predominantly maternal in origin. Typical NF1 may also occasionally result from somatic mutations. Previous studies of paternal age among patients with sporadic NF1 have been inconclusive. We postulated that failure to find a paternal age effect in these studies may have resulted from inclusion of patients with large deletions and somatic mutations, for whom no paternal age effect would be expected.

In order to test this possibility, we used data collected from 280 sporadic and 389 familial NF1 patients. We excluded 11 (3.9%) exceptionally mild sporadic cases as possible somatic mosaics and 14 (5.0%) sporadic cases with the large deletion phenotype. We compared paternal age in the remaining 255 sporadic probands to 100 familial probands for whom both the paternal and maternal ages at birth were known. The mean paternal age for the sporadic probands (31.71 years) was significantly greater ( $p = 0.017$ ) than that for familial probands (29.87 years). The results were unaffected by ethnicity or year of ascertainment.

We also studied the effect of maternal age on transmission of the abnormal *NF1* allele. We found no significant difference between the maternal age at birth of 74 proband children of affected mothers and that of 63 proband children of affected fathers. Logistic regression of affection status in 334 children of affected women and 146 children of affected men in 239 families showed no significant relationship with gender of the affected parent, maternal age at birth of the child, paternal age at birth of the child, or birth order. Probands were excluded from this analysis to reduce ascertainment bias. We conclude that there is suggestive evidence for a paternal age effect on the occurrence of sporadic NF1 but that neither maternal nor paternal age at birth affects the occurrence of familial NF1.

**Mutation analysis of the *BRCA1*-interacting genes *ZBRK1* and *BRIP1* among *BRCA1/2*-negative probands from breast/ovarian cancer families.** *J.P. Struewing, J.L. Rutter, M.R. Dávila, A.M. Smith, M.H. Greene, M.A. Tucker.* Div Cancer Epidemiology & Genetics, NCI, NIH, Bethesda, MD.

Two potential breast cancer susceptibility genes, encoding the *BRCA1*-interacting proteins *ZBRK1* and *BRIP1* (originally termed *BACH1*) have recently been identified in yeast two-hybrid screens using *BRCA1* as bait. Previous mutational analysis of *ZBRK1* has not been reported, but analysis of *BRIP1* among 65 early-onset breast cancer cases identified two missense mutations. By aligning the Genbank mRNA records of *ZBRK1*, encoding a zinc finger containing protein and *BRIP1*, encoding a helicase, with genomic fragments, we developed PCR primers to amplify the 4 exons of *ZBRK1* and the 20 exons of *BRIP1* from genomic DNA. We sequenced the resulting PCR amplicons from probands from 22 families with potentially inherited breast/ovarian cancer, all of whom were negative for *BRCA1/2* mutations. Families had at least one case of male breast cancer, two cases of ovarian cancer, or three or more cases of breast and ovarian cancer. A *ZBRK1* missense mutation Gln393His was identified in two subjects, altering a conserved Gln residue in the 7<sup>th</sup> of eight C2H2 zinc finger motifs. It is not yet known whether this alteration segregates with cancer in these families. We also identified three silent *ZBRK1* mutations Asp35Asp, Cys236Cys, and Pro373Pro and a 3'UTR variant 2067C>T in 4 or more subjects each. For *BRIP1*, in addition to the common missense mutation P919S and the silent mutations E879E and Y1137Y previously described, we identified two intron variants in 11 subjects each. We also identified intron variants IVS5-31G>C in two probands, IVS14+26delT and IVS19+82T>A in one proband each, and a Gln540Leu missense mutation in a single proband. Gln540Leu is a non-conservative amino acid change identified in an individual with inflammatory breast cancer but was not identified in her three relatives with breast cancer who were tested for this variant. Based on sequencing of *ZBRK1* and *BRIP1* in 22 *BRCA1/2*-negative probands from inherited breast/ovarian cancer families, it appears unlikely that mutations in these genes account for a large fraction of inherited forms of breast cancer.

**Pancreatitis-associated human cationic trypsinogen gene (PRSS1) mutations as a vehicle for better understanding trypsinogen evolution and physiology.** *J.M. Chen, T. Montier, C. Ferec.* INSERM-EMI 01 15, Etablissement Français du Sang-Bretagne, Université de Bretagne Occidentale, and Centre Hospitalier Universitaire, 46 rue Félix Le Dantec, 29275 Brest, France.

Historically, trypsinogens are one of the most extensively studied models for protein structure and function and for evolution of multigene families. The identification of mutations in the human cationic trypsinogen gene (PRSS1) as a cause of hereditary pancreatitis (HP) has attracted renewed attention to this familiar enzyme. While this finding offers better means for diagnosis, family testing and treatment of the disease, we show how pancreatitis-associated PRSS1 mutations (eg., D22G, K23R, N29I, and R122H) can be used as a vehicle for better understanding trypsinogen evolution and normal physiology.

Based upon a critical evaluation of the current mutational and functional analysis data in the context of a comprehensive amino acid sequence comparison of trypsinogens from various vertebrate species, insights into the molecular evolution of trypsinogens can be seen in three stages. Firstly, activation peptide sequences are subject to strong selection pressure to minimize trypsinogen autoactivation in higher vertebrates. Secondly, the R122 autolysis site, which is supposed to act as a "fail-safe" mechanism against intrapancreatic zymogen activation, has evolved in mammals. Thirdly, evolutionary divergence from T to N at residue 29 provides additional advantage in the human cationic trypsinogen. These observations, when considered in conjunction with the current knowledge of the complicated biogenesis and biochemistry of trypsin(ogen), enabled us to propose that, in the human cationic trypsinogen, the strongly selected activation peptide as the first-line and the R122 autolysis site as the second-line of the built-in defensive mechanisms that the body has evolved against premature digestive enzyme activation within the pancreas, respectively, and the positively selected N29 in PRSS1 as an "amplifier" to the R122 "fail-safe" mechanism. Continued research of the PRSS1 gene in the disease may reveal further fascinating details of trypsinogen evolution and physiology.

**Characterization of b-globin haplotypes among an admixed, population-based cohort of newborns with sickle cell disease.** *D.C. Crawford*<sup>1</sup>, *M. Caggana*<sup>2</sup>, *C. Tempelis*<sup>3</sup>, *K.B. Harris*<sup>2</sup>, *F. Lorey*<sup>3</sup>, *C. Nash*<sup>4</sup>, *K. Pass*<sup>2</sup>, *R. Olney*<sup>1</sup>. 1) National Center on Birth Defects and Developmental Disabilities, Centers for Disease Control and Prevention; 2) Wadsworth Center, New York State Department of Health; 3) Genetic Disease Branch, California Department of Health Services; 4) Division of Health Assessment and Screening, Illinois Department of Public Health.

Sickle cell disease (SCD) is caused by a single mutation in the b-globin gene on chromosome 11. Current evidence based on b-globin haplotypes suggests that the HbS mutation arose only in Africa, more than once. Previous studies suggest that migration and subsequent admixture are responsible for some of the b-globin haplotype diversity sampled in North America. To better characterize this diversity in the United States, we identified 617 newborns in California, New York, and Illinois identified with SCD through newborn screening in 1992-1993. Using stored bloodspots, we genotyped 432 samples for the restriction site polymorphisms (RSPs) *XmnI*, *HindIII*-Gg, *HincII*-yb, *HincII*-d, and *HinfI*. Among African-American (n=744) and Hispanic chromosomes (n=64), 15 and six haplotypes were identified, respectively. All six haplotypes found in the Hispanic population were also found among African-Americans, suggesting that the origin of the HbS mutation found among these Hispanics is of African descent. For both populations, ~89% of chromosomes were represented by the same three haplotypes. Furthermore, the expected haplotype heterozygosity was similar between the two populations. For the African-American population, however, observed haplotype heterozygosity (0.493) was significantly lower than expected ( $p < 0.02$ ). Examination of the individual RSPs revealed that Hispanics had a greater expected heterozygosity at *HindIII*-Gg ( $0.488 \pm 0.06$ ) and *HincII*-d ( $0.417 \pm 0.06$ ) compared with African-Americans ( $0.340 \pm 0.02$  and  $0.279 \pm 0.02$ , respectively). Also, the African-American population had a statistically significant increase in observed heterozygosity at *XmnI* ( $p < 0.01$ ). These results probably reflect the recent, complex migration and admixture experienced by both populations in the United States rather than selective forces related to the HbS mutation.

**Mitochondrial DNA diversity among Altaians.** *M. Derenko*<sup>1</sup>, *T. Grzybowski*<sup>2</sup>, *B. Malyarchuk*<sup>1</sup>, *G. Denisova*<sup>1</sup>, *J. Czarny*<sup>2</sup>, *V. Kakpakov*<sup>3</sup>, *D. Miscicka-Sliwka*<sup>2</sup>, *I. Zakharov*<sup>3</sup>. 1) Genetics Lab, Inst Biological Prob of North, Magadan, Russia; 2) Institute of Forensic Medicine Ludwik Rydygier's University School of Medical Sciences, Bydgoszcz, Poland; 3) Vavilov Institute of General Genetics, Moscow, Russia.

To investigate the origin and evolution of aboriginal populations of Altai and Sayan region we present here mtDNA analysis (HVS-1 and HVS-2 sequencing combined with RFLP) of Altaians (n = 110) and compare them with the populations of North, East, Central Asia and West Eurasia that have historically had a great influence to Altaians. The Altaians studied exhibit the high percentage (48.2%) of haplogroup M (M\*, C, D, E, G, Z) mtDNA lineages. The overall pattern of the frequency distribution of the M mtDNA haplogroups is similar to the other East Asian populations where M haplogroup and its subhaplogroups comprise about 50% of mtDNA lineages. East Asian mtDNA haplogroups B and F were found in Altaians with the frequencies of 3.6% and 8.2%, respectively. Lineages, characteristic to western Eurasian mtDNA haplogroups (H, U, J, T, X, I) were found in Altaians at frequency 32.7%, with the haplogroup U lineages being prevalent (18%) and most substructured (U1, U2e, U3, U4, U5). The remaining 7.3% of Altaian mtDNAs comprise of the haplogroup N\* and N1a. Thus, the Altaians studied exhibited both Asian-specific (65%) and West Eurasian (35%) mtDNAs. Phylogeographic analysis shows that the Asian-specific component of Altaian mtDNA gene pool represented mostly by typically Siberian/Central Asian lineages whereas West Eurasian component has a more complicated structure. A considerable amount of these lineages have West Asian ancestry reflecting the imprints of the early Europeoid migrations along the Steppe Belt. Some of Altaian mtDNAs (from U2e, U4, and X groups) may have autochthonous origin testifying thereby the complexity of population history of Altai region. This work supported by grants from Russian Foundation for Basic Research (99-06-80430) and from the Ludwik Rydygier Medical University in Bydgoszcz (BW 90/01).

**Mitochondrial DNA polymorphism in the populations of Siberia and Central Asia: lineages of East-Eurasian and West-Eurasian origin.** *M.V. Golubenko<sup>1</sup>, T. Kivisild<sup>2</sup>, V.B. Salukov<sup>1</sup>, K.V. Puzyrev<sup>3</sup>, J.O. Soltobaeva<sup>4</sup>, V.N. Tadinova<sup>1</sup>, E.R. Eremina<sup>5</sup>, T.P. Muraviova<sup>1</sup>, V.P. Puzyrev<sup>1</sup>, R. Villems<sup>2</sup>.* 1) Institute of Medical Genetics, Tomsk, Russia; 2) Estonian Biocentre, Tartu, Estonia; 3) Institute of Cardiology, Tomsk, Russia; 4) Kyrghiz Medical Academy, Bishkek, Kyrghizstan; 5) Buriat div. of the Institute of paediatrics and Human Reproduction, Ulan-Ude, Russia.

MtDNA polymorphism has been investigated in 9 aboriginal peoples of Siberia and Central Asia (Tuvinians, Buriats, Northern Altai, Southern Altai, Yakuts, Kyrghis, Uzbeks, Tadjiks), by the screening of the restriction sites which determine the main mtDNA haplogroups (A, B, F, H, U, M: C, D); for the Altai, Uzbeks, Tadjiks, Kyrghiz, HVS-I sequences also have been determined. Total sample size was about 1200 individuals. In all populations the haplogroups of both West-Eurasian and East Eurasian origin are presented, but their frequencies vary broadly. The highest haplogroup diversity is observed in some Central Asian populations (Kirghiz, Uzbeks, Tadjiks). The populations, except Tadjiks, may be divided into two groups. In the populations of Kirghiz, Uzbeks, and Altai, two main branches of mtDNA tree are presented with considerable frequencies: the haplogroups of West-Eurasian origin (H, I, J, T, U, X) and those of East-Eurasian origin (A, B, F, M, N9). Siberian populations possess mainly lineages of Asian origin with prevalence of haplogroup M (70-80%). The frequency of West-Eurasian haplogroup H in Siberia is no more than 5%, as well as the frequency of haplogroup U (up to 8% in some local populations). The populations of Tuvinians, Buriats, Yakuts, Kyrghiz, Tadjiks, and Altai, show the presence of four founding Native American haplogroups (A, B, C, D). In Tadjiks, the total frequency of the lineages of East-Asian origin is about 10%. So the spreading of mtDNA lineages in North-East Eurasia is in accordance with anthropological affinity of the populations and with their territorial locations, with every ethnicity having specific pattern of haplogroups structure and frequencies.

**Y-associated Polymorphism in the Iranian Population.** *H. Najmabadi*<sup>1</sup>, *M.F. Hammer*<sup>2</sup>, *B. Moghimi*<sup>3</sup>, *A.R. Noorian*<sup>3</sup>, *M.R. Keikhaee*<sup>4</sup>, *P. Pasalar*<sup>5</sup>. 1) Dept Molecular Biol, Torrance, CA; 2) Department of Ecology and Evolutionary Biology, University of Arizona, Tucson, AZ; 3) Tehran University of Medical Sciences, School of Medicine, Tehran, Iran; 4) University of Welfare and Rehabilitation, Tehran, Iran; 5) Department of Biochemistry, Tehran University of Medical Sciences, Tehran, Iran.

There is a non-recombining region on the human Y chromosome which can be used to investigate human evolution during the last 200`000 years. This polymorphic region, which is highly conserved, includes the Y Alu insertional Polymorphism or YAP element (DYS 287), the poly (A) tail associated with the YAP element and a tetranucleotide microsatellite (DYS 19). In this study, we have collected DNA samples from seven major ethnic groups in Iranian population and determined its Y-associated polymorphic variation. Having analyzed the genetic diversity data, we can determine different patterns of evolutionary migrations in Iran.

**Y chromosome markers indicate a lack of clustering in the Hindu caste system.** *S.R. Indugula<sup>1</sup>, S. Mastana<sup>2</sup>, B. Su<sup>1</sup>, G. Sun<sup>1</sup>, S.S. Papiha<sup>3</sup>, B.M. Reddy<sup>4</sup>, P. Underhill<sup>5</sup>, R. Chakraborty<sup>6</sup>, L. Jin<sup>6</sup>, R. Deka<sup>1</sup>.* 1) Dept Environmental Hlth, Univ Cincinnati, Cincinnati, OH; 2) Loughborough University, Loughborough, England; 3) University of Newcastle upon Tyne, Newcastle, England; 4) Indian Statistical Institute, Calcutta, India; 5) Stanford University, Stanford, CA; 6) University of Texas Health Science Center, Houston.

The Hindu caste system is amongst the most complex social structures and its origin has been studied from various perspectives. Hierarchical stratification among the castes varies regionally, which is compounded by regional endogamy and linguistic diversity. We have studied 668 males from 16 regional populations from the Indian subcontinent, belonging to various caste groups, at 12 binary polymorphisms on the Y chromosome. Two haplogroups defined by markers M52C and M45A are predominant in all of the studied populations. Other haplotypes are shared across geographical boundaries and hierarchically defined varnas (caste status). A principal component analysis indicates a lack of clustering of individual varnas both within and between regions. Our initial observations are suggestive of past population movements within the subcontinent before the formation of the Hindu caste system together with population migrations from various routes contributing to the current complex population structure.

**Inter- and Intra-Island Genetic Diversity in Adriatic Populations of Croatia: Implications for Studying Complex Diseases in Isolated Populations.** *I. Martinovic Klaric<sup>1</sup>, L. Jin<sup>2</sup>, R. Chakraborty<sup>2</sup>, R. Deka<sup>2</sup>, L. Barac<sup>1</sup>, M. Pericic<sup>1</sup>, N. Smolej Narancic<sup>1</sup>, I. Rudan<sup>3</sup>, B. Janicijevic<sup>1</sup>, P. Rudan<sup>1</sup>.* 1) Institute of Anthropological Research, Zagreb, Croatia; 2) Department of Environmental Health, University of Cincinnati, Cincinnati, OH; 3) University of Zagreb, Zagreb, Croatia.

Anthropological data from the Croatian Adriatic islands ( $n = 66$ ) indicate that the island populations have remained considerably isolated from each other. To examine the effects of such isolation on patterns of gene diversity at microsatellite loci, we have studied the coefficient of gene differentiation ( $G_{st}$ ) between villages within islands as well as between islands using allele frequencies at 9 STR loci (D3S1358, vWA, FGA, THO1, TPOX, CSF1PO, D5S818, D13S317, and D7S820) in 31 villages of 4 islands (Hvar, Krk, Brac, and Korcula). Overall, none of the villages exhibits significant departure from Hardy-Weinberg expectations of genotype frequencies at these loci. Decomposition of heterozygosity ( $H$ ) as well as allele size variance ( $V$ ) indicated significant inter-island gene differentiation ( $G_{st}$  based on  $H = 0.003$ ,  $P < 10^{-4}$ ;  $G_{st}$  based on  $V = 0.004$ ,  $P = 0.007$ ), while the between villages within island component of genetic variation remain non-significant ( $G_{st}(H) = 0.003$ ,  $P = 0.073$ ;  $G_{st}(V) = 0.002$ ,  $P = 0.315$ ). The coefficient of coancestry  $q$  for the sampled unrelated individuals vary from village to village, ranging from 0 to 0.022, with an average of 0.010. Comparison of estimates of inbreeding coefficient ( $F$ ) based on genealogical data from these villages indicates that while  $q$  and  $F$  values are moderately correlated across villages,  $q$  is comparatively smaller (nearly one-half) than  $F$ . In other words, the high mutation rate at these STR loci diluted the effect of small effective size in producing correlation of alleles within individuals. The non-significant  $G_{st}$  between villages within the islands is an advantage for disease-gene association studies using microsatellite loci, since data from several villages within each island may be pooled to enlarge the sample size without introducing population substructure effects on the association results.

**LONG INTERSPERSED ELEMENTS (LINEs) AND THE GENETIC VARIABILITY OF NATIVE**

LINE-1 (L1) elements represent a large family of mammalian retrotransposons. Individuals with specific insertions are related by descent and have a known ancestral state, which is the absence of the insertion. The PCR assay employed is simple and utilizes two PCR reactions for genotyping each LID (LINE Insertion Dimorphism). The first amplification uses both 5' and 3' flanking unique sequence primers for the PCR. The second PCR contains a subfamily-specific primer and a 3' flanking unique sequence primer. In this study, we are characterizing the genetic diversity of polymorphic LINE elements (LIDs 1-6) in different South American Native populations, as well as, in other related human groups. So far, the samples include individuals from South America (Arhauaco, Toba, Guahibo, Karitiana, Suru, Lengua and Ayoreo); North America (Navajos) and Asia (Siberian Eskimo, Tuvinian, and Chinese). The frequency data for the LID1 insertion in these populations ranged from 0.15 for the Navajos to 0.48 for the Ayoreo. The data for LID5 in South American populations showed a high incidence of the occupied allele that varied from 0.7 for the Ayoreo to its complete fixation for the Karitiana. A comparison of the levels of heterozygosity for LID5 shows that it is lower than for LID1, since the presence of the insertion reached very high frequencies for this locus in those groups. So far, these two loci are showing a different pattern, and will be very interesting to see what the entire data is going to tell us about the genetic relationships among Native Americans and Asiatics in the peopling of the Americas scenario.

**Latitudes and the mc1r gene polymorphism among Asian populations.** *K. Nakayama*<sup>1</sup>, *R. Ootsuka*<sup>1</sup>, *A. Soemantri*<sup>2</sup>, *M.N. Isa*<sup>3</sup>, *S. Pookajorn*<sup>4</sup>, *I-H. Pan*<sup>5</sup>, *S. Harihara*<sup>1</sup>, *T. Ishida*<sup>1</sup>. 1) School Sci, Tokyo Univ; 2) School Med, Diponegoro Univ; 3) School Med, Univ.Sains Malaysia; 4) Faculty Arch, Silpakorn Univ; 5) School Med, Natl.Taiwan Univ.

Melanocortin 1 receptor (MC1R) is a key regulator of the mammalian melanogenesis. MC1R is coded by the mc1r gene that is only one identified gene accountable for the gradual human skin pigmentation found in geographically and ethnically different populations. We have studied diversity of the mc1r gene among 1012 individuals from a total of 29 Asian populations. PCR-direct sequencing, -SSCP, and -RFLP have been employed. We considered an African mc1r nucleotide sequence as the wild type. We identified nine nonsynonymous and two synonymous mutations including seven novel ones in this study. We found the absence of nonsynonymous mutations among heavily pigmented New Guinean Highlanders and the Veddas in Sri Lanka. This is consistent with the previous hypothesis that the mc1r gene has been under functional constraint to maintain substantial pigmentation against the high dose of ultra violet (UV) light in the equatorial regions and the mutated MC1R has been eliminated by purifying selection. Several Mongoloid groups living in high latitudes, showed an excess of nonsynonymous mutations. Our neutrality test has failed to detect the evidence of selection, however, this was comparable to the patterns of nonsynonymous mutations in the Europeans who are lightly pigmented. Light pigmentation in the Europeans is presumed as the result of weak UV light intensity that has relaxed the functional constraint against MC1R. We calculated  $q(s)$  of mc1r gene among subjected populations. The value showed a significantly positive correlation with latitudes (Kendall's  $\tau=0.371$ ,  $P<0.005$ ). It is indicated that selective force of UV light intensity, which is correlated with latitudes, generates geographical diversity of the mc1r gene; populations in higher latitude possess larger allelic diversity. These observations support (1) the existence of a universal distribution of the mc1r gene polymorphism and (2) the potentiality of the mc1r gene as a genetic basis for geographic adaptability of human skin pigmentation.

**Estimation of the Time to the Most Recent Common Ancestor by Tree-Partition.** *H. Tang*<sup>1</sup>, *D. Siegmund*<sup>1</sup>, *P. Shen*<sup>2</sup>, *P. Oefner*<sup>2</sup>, *M. Feldman*<sup>3</sup>. 1) Dept of Statistics, Stanford University, Stanford, CA; 2) Stanford Genome Technology Center, Stanford University, Stanford, CA; 3) Dept of Biological Sciences, Stanford University, Stanford, CA.

For a sample of DNA sequences that exhibits variation, a quantity of interest is the time to the most recent common ancestor of the sample, or TMRCA. When the sample is randomly taken from a population, the TMRCA provides information on the age of this population. If the sample consists of sequences sharing some other kind of unique event polymorphism (UEP), such as a disease mutation, the TMRCA represents a lower bound for the age of this mutation. We propose a statistical method of estimating the TMRCA of a sample of DNA sequences whose variation is characterized by single nucleotide polymorphisms (SNPs). Neither the proposed point estimate nor its confidence interval depends on the demographic history of the population, such as population size, growth, or migration pattern. Simulations show that the estimator is approximately unbiased, and that the confidence interval has approximately correct coverage probability in most situations. Performance of this estimator is compared with existing methods based on coalescence under the simplifying demographic assumptions that make the coalescent methods applicable. The new method is applied to SNPs on worldwide samples of human Y chromosome and mitochondrial DNA (mtDNA). The coalescence time for the extant Y chromosome population is estimated as 92,000 years (95% confidence interval: 61,000 to 129,000 years) corresponding time for the mtDNA population is much older at 226,000 years (95% confidence interval: 198,000 to 269,000 years).

**Patterns of genetic diversity at cytokine loci (*IL-13*, *IL-4*) in Andean populations: distinguishing the effects of selection and demographic history.** *E. Tarazona*<sup>1</sup>, *S. Fuselli*<sup>2</sup>, *D. Luiselli*<sup>2</sup>, *D. Pettener*<sup>2</sup>, *S.A. Tishkoff*<sup>1</sup>. 1) Department of Biology, University of Maryland, College Park, MD; 2) Unit of Anthropology. University of Bologna. Italy.

Since the end of the last glacial era, different parasites responsible for infectious diseases have constituted important selective pressures acting on the human genome. Because intra- and extra-cellular parasites activate immune responses of types Th1 and Th2, respectively, the regulatory genes involved in these pathways have been potentially targets of selection during human evolution. We have initiated a project to study genetic variability of cytokines associated with Th1 and Th2 immune responses in different human populations. Our primary aim is to understand how evolutionary forces acting on specific regions of the genome (selection, mutation, recombination) or on the whole genome (demographic history) could have shaped patterns of genetic diversity and linkage disequilibrium (LD). As a first step, we have studied three Peruvian native populations from the Andes, where infections by extra-cellular parasites are highly prevalent. We are examining genetic variation in genes that regulate the Th2 pathway, interleukin-4 (*IL-4*) and interleukin-13 (*IL-13*), and the extent of LD at different distances from these genes. We have tested several hypotheses of different types and levels of selection acting on these genes against a null hypothesis constructed using the patterns of variability of several neutral loci studied in these populations (Y-chromosome, mt-DNA, autosomal microsatellites). The analysis of these markers suggests that these populations of Andean farmers 1) conserve the signature of an ancient population expansion that likely occurred before the peopling of the Andes (20-25 ky ago) and 2) there is no evidence of drastic reductions in population size associated with the history of these populations. Comparison of genetic variability observed at *IL-4* and *IL-13* with these neutral markers allows us to discriminate among the evolutionary forces that have shaped the pattern of LD in this region and to characterize the signature of selection in the human genome. **HUMAN EVOLUTION AND BANTU MIGRATION: An Analysis of Alu insertion polymorphisms. M.C.**

*Terreros<sup>1, 2</sup>, D. Rojas<sup>1</sup>, L. Mateus-Pereira<sup>1, 3</sup>, J. Rodriguez<sup>1, 4</sup>, N. Popovich<sup>1</sup>, L.R. Adrien<sup>1</sup>, L.M. Ruiz<sup>1</sup>, R.J. Herrera<sup>1</sup>.*

1) Dept Biol, Florida Intl Univ, Miami, FL; 2) Comision de Investigaciones Cientificas (CIC), Argentina; 3) Depto genetica, Universidade Federal do Rio Grande do Sul, Porto Alegre, RS, Brazil; 4) Department of Anthropology, University of Santiago de Compostela, Spain.

Alu elements comprise the most numerous family of short interspersed repetitive elements (SINEs) in the human genome. Alu elements are thought to be derived from the signal recognition particle 7SL RNA gene. Most Alu elements are around 300 nucleotides (nt) in length and are present in 500,000 copies per haploid genome. Alu insertion polymorphisms are excellent markers for human evolutionary studies because of their properties including being stable mutation events for which the ancestral state is known to be the absence of the Alu element. In this study, a polymerase chain reaction (PCR) assay was used to examine the frequency of Alu insertions in polymorphic loci. These Alu elements were used to analyze unrelated individuals in different populations outside and inside of the African continent to follow the migration that happened during the period of history known as Bantu expansion. This was one of the largest migrations beginning approximately 1000 BC that continued into the nineteenth century of the Christian era with profound effects on the history of subequatorial Africa. The Bantu spread from Nigeria and Cameroon toward the east and south started during the Iron Age, in Neolithic times (around 1000 B.C). The phylogenetics analysis of these Alu insertion polymorphisms supports the theory that the Bantu migration arose in the Central West Coast of Africa and spread to the west, southwest and southern coast of the African continent.

**Signature of selection at the G6PD locus inferred from patterns of nucleotide variation and linkage**

**disequilibrium in Africans.** *B.C. Verrelli<sup>1</sup>, G. Argyropoulos<sup>2</sup>, G. Destro-Bisol<sup>3</sup>, S.M. Williams<sup>4</sup>, S.A. Tishkoff<sup>1</sup>.* 1) Biology, Univ Maryland, College Park, MD; 2) Pennington Biomed Res Center, Baton Rouge, LSU, LA; 3) Anim/Hum Biol, "La Sapienza", Italy; 4) MeHarry Med College, Nashville, TN.

Mutations within the glucose-6-phosphate dehydrogenase (G6PD) gene that result in reduced enzyme activity affect more than 400 million people and are responsible for a number of haemopathologies. G6PD deficiencies have also been implicated in malarial resistance and more than 130 coding-sequence mutations have been identified. The most common alleles in Africa are B (normal enzyme activity), A (85% activity), and A- (12% activity), which is strongly correlated with malarial endemicity. A recent study utilizing both SNPs within the G6PD gene (Xq28) and microsatellites within close proximity found both strong linkage disequilibrium (LD) and a unique haplotype structure associated with the B/A/A- polymorphism that indicates a recent origin and rapid increase in frequency of the A- allele, likely associated with the spread of malarial infection (Tishkoff et al., *Science*, in press, 2001). Our current study consists of DNA sequence data for 5kb of the G6PD gene from Africans (n=75) and compares it to samples of non-Africans (n=25) and chimpanzees (n=4). Our sample of B, A, and A- alleles reveals several previously uncharacterized SNPs. Although the ancestral B allele dominates in frequency, B haplotypes possess significantly less SNP variation than A/A- haplotypes, suggesting that the A allele was historically greater in frequency and that the B allele has recently increased in populations, possibly due to positive selection. Comparative analysis with the chimpanzee data also shows a pronounced split of the B and A/A- haplotypes into two distinct clades implying balancing selection. The pattern of sequence variation associated with the three common G6PD alleles not only confirms the recent and rapid increase of the A- allele, but also indicates that the A/B polymorphism has had both an ancient and recent evolutionary impact on human populations. Additionally, in an effort to further characterize the signature of selection in the human genome, we investigated LD at various distances from the G6PD gene.

**Y chromosome polymorphisms indicate an ancient migration from the Himalayas to Japan.** *B. Su<sup>1,2</sup>, G.V. Ramana<sup>3</sup>, S.H. Lu<sup>3</sup>, B. Wen<sup>4</sup>, R. Deka<sup>1</sup>, P. Underhill<sup>5</sup>, R. Chakraborty<sup>1</sup>, L. Jin<sup>1,4</sup>.* 1) Dept of Environmental Health, University of Cincinnati, Cincinnati, OH; 2) Laboratory of Comparative Genomics, Kunming Institute of Zoology, Chinese Academy of Sciences, Kunming, China; 3) Human Genetics Center, University of Texas-Houston, Houston, TX; 4) Institute of Genetics, School of Life Sciences, Fudan University and Morgan-Tan International Center for Life Sciences, Shanghai, China; 5) Department of Genetics, Stanford University, Stanford, CA.

The Alu insertion polymorphism on the Y chromosome (YAP+) has a characteristic distribution in worldwide populations, mainly restricted in Africa, Central Asia and East Asia. The ongoing controversy on the origin of YAP+ and its mysterious occurrence in East Asia, i.e. dominant in Tibetan and Japanese populations but basically absent in other East Asian populations call for further studies along this ancient human lineage. Here we report our preliminary result on a systematic screening of YAP+ in more than 2,500 male individuals from 70 world populations. Nine Y chromosome biallelic markers derived from the YAP+ polymorphism and seven Y chromosome micro satellites were typed in 172 YAP+ individuals from Africa (35), South Asia (9), Southeast Asia (12) and East Asia (116). Our results showed that African and Asian YAP+ are distinctive from each other due to a deep genetic divergence. No evidence was found to support the hypothesis of an Asian origin of YAP+. Among the East Asian YAP+, Tibetans are the most diversified population and have the haplotype ancestral to those in Japanese, indicating an ancient migration from the Himalayas to Japan. In addition, a relatively recent migration of YAP+ from Tibet to Yunnan (southwestern China) was also implied by the homogenous YAP+ haplotypes in Yunnan ethnic populations, which was signified by the low microsatellite diversity and an almost fixed unique microsatellite allele at locus DYS392 in Yunnan populations.

**The effects of positive selection on the frequency spectrum of mutations and on patterns of linkage disequilibrium.** *M.F. Przeworski*. Statistics, Oxford Univ, Oxford, England.

Considerable debate has focused on what proportion of changes fixed between species are favorable, as well as what types of substitutions are most likely to have been selected. Answers to these questions will help to understand the genetic basis of adaptation and may also aid in the identification of regions of functional importance. A mode of selection of particular interest is a selective sweep, in which a strongly favored variant arises and quickly increases in frequency until it fixes in the population. Here, I examine coalescent models of a single sweep and of recurrent (but non-overlapping) sweeps. The first model is salient to loci where there is independent evidence of recent selection while the second might be more appropriate for randomly chosen loci. I examine the effects of these types of positive selection on pairwise measures of linkage disequilibrium as well as on estimates of the population recombination rate. I also consider the power of "tests of neutrality" to detect the effects of selective sweeps.

**Sequence Variations of Interleukin-1 receptor antagonist (IL-1Ra) gene in humans and non-human primates.**

Y.Q. Wang<sup>1,2</sup>, J.C. Luo<sup>1</sup>, B. Su<sup>1,3</sup>, C. Machado<sup>4</sup>, J. Bachevalier<sup>4</sup>, J. Reveille<sup>4</sup>, R. Chakraborty<sup>1</sup>, L. Jin<sup>1,5</sup>. 1) Dept. of Environmental Health, University of Cincinnati, Cincinnati, OH; 2) Institute of Genetic Resources, Nanjing Normal University, Nanjing, China; 3) Laboratory of Comparative Genomics, Kunming Institute of Zoology, Chinese Academy of Sciences, Kunming, China; 4) University of Texas Health Science Center, Houston, TX; 5) Institute of Genetics, School of Life Sciences, Fudan University and Morgan-Tan International Center for Life Sciences, Shanghai, China.

Interleukin-1 (IL-1) is a major mediator of inflammation and exerts pleiotropic effects on immune system. In the process of rheumatism, it is one of the pivotal cytokines in initiating disease. Interleukin-1 receptor antagonist, a natural modulator existing in the body, can bind IL-1 receptor and block its effects. To investigate genetic variations of this modulator in humans and non-human primates, the IL-1Ra was sequenced covering all the six exons of this gene, in 12 humans (*Homo sapiens*), 11 chimpanzees (*Pan troglodytes*), 4 gorillas (*Gorilla gorilla*), 2 orangutans (*Pongo pygmaeus*), 1 siamang (*Hylobates syndactylus*) and 1 rhesus monkey (*Macaca mulatta*). A total of 3,873 bp DNA sequence was obtained including 1925 bp in the exons and 1948 in the non-coding regions. There are 338 variant sites across species including 34 in the exons, 197 in the introns and 107 in the 5'/3' flanking regions. In the exons, two synonymous sites were observed in humans, 1 in chimpanzees and 1 in gorillas. Two amino acid changes exist between human and chimpanzee/gorilla and no non-synonymous changes were detected within species. In the non-coding regions, 18 variable sites exist in humans, 24 in chimpanzees and 5 in gorillas. Neutrality test didn't indicate any deviation from the neutral model.

**mtDNA sequence diversity in Antioquia (Colombia).** *A. Ruiz-Linares*<sup>1,2</sup>, *I. Soto*<sup>2</sup>, *C. Duque*<sup>2</sup>, *J. Ospina*<sup>2,3</sup>, *G. Bedoya*<sup>2</sup>, *L.G. Carvajal-Carmona*<sup>1,2</sup>. 1) The Galton Laboratory, Department of Biology, University College London, UK; 2) Laboratorio de Genetica Molecular, Facultad de Medicina, Universidad de Antioquia, Colombia; 3) Departamento de Psiquiatria, Facultad de Medicina, Universidad de Antioquia, Colombia.

We recently used Y-chromosome and mtDNA markers to assess the ethnic background of the population of Antioquia in North West Colombia. This population has a history of isolation and since its founding in the 16th-17th centuries has expanded over a thousand times (to a current size of about 3-4 million). A Native American ancestry was detected in about 1% of Y-chromosomes and in around 90% of mtDNA lineages indicating that it was mostly native women and immigrant men that founded Antioquia. To assess more fully the female ancestry of this region we sequenced mtDNA hypervariable segment I in 85 individuals with confirmed Antioquian ancestry. Of these, 74 carry variants characteristics of the major founder Amerind lineages: 40 belong to haplogroup A, 28 to haplogroup B, 5 to haplogroup C and 1 to haplogroup D. Among the 11 non-Amerind sequences identified 2 correspond to European lineages while 9 have an African ancestry. Consistent with the high frequency of Native American mtDNA lineages in Antioquia, the mitochondrial diversity in the province is similar to that of Amerind populations and is significantly lower than in most European populations. Antioquian Amerind sequence diversity is consistent with a constant population size ( $Tajima's D = -0.58$   $P > 0.05$ ;  $F_u$  vs  $F_s = -4.66$   $P > 0.05$ ), the distribution of pair-wise sequence mismatches showing two distinct peaks at 0 and 6 mismatches. Most human mtDNA sequence data show evidence of a Pleistocene demographic expansion with the absence of such a signal having been detected in hunter-gatherers and in some Native American populations. The absence of a signal of population expansion in Antioquia and in some Native Americans could relate to the Native population collapse caused by the Spanish colonization. This pattern could also be influenced by the strong drift affecting many Native American populations, particularly in South America.

**The Dopamine Beta-Hydroxylase C-1021T Polymorphism: Evolutionary Origins and Relationship to Plasma DBH Activity in Nonhuman Primates.** *C.P. Zabetian<sup>1,3</sup>, G.M. Anderson<sup>2</sup>, R. Hoppenot<sup>3</sup>, J.R. Kaplan<sup>4</sup>, J.F.*

*Cubells<sup>1,3</sup>*. 1) Dept of Psychiatry, Yale Univ, New Haven, CT; 2) Child Study Ctr, Yale Univ, New Haven, CT; 3) Dept of Psychiatry, VACHS, West Haven, CT; 4) Dept of Pathology, Wake Forest Univ. School of Med., Winston-Salem, NC.

Dopamine beta-hydroxylase catalyzes the conversion of dopamine to norepinephrine. Human plasma DBH enzyme activity levels vary over 100-fold between individuals. We have recently identified a novel, putative functional polymorphism (C-1021T) in the 5' upstream region of the DBH gene that accounts for 35-52% of the total variation in activity in samples from African-American, European-American, and Japanese populations. Individuals homozygous for the minor T allele have very low activity levels. A previous study of nonhuman primates revealed levels of variation in plasma DBH activity comparable to that found in humans. In this study, we examined the evolutionary history and relationship to phenotype of the DBH C-1021T polymorphism in nonhuman primates. We obtained plasma and DNA samples from great apes (*Pan troglodytes*, *Pan paniscus*, *Gorilla gorilla*, *Pongo pygmaeus*), gibbons (*Hylobates* spp.), old world monkeys (*Papio* spp., *Macaca* spp.), and new world monkeys (*Saimiri sciureus*). Preliminary sequencing and genotyping results indicate that the T allele is ancestral, and that the C allele arose at some point between the divergence of orangutans and gorillas from the chimpanzee-human lineage. All chimpanzee (*Pan troglodytes*, *Pan paniscus*) and gorilla samples studied to date are homozygous for the C allele. Collection of additional samples is ongoing to determine if the C-1021T polymorphism exists in hominoid species other than humans, and if so, whether a close association exists between genotype and plasma DBH activity. Supported by: USDVA, NIDA, NARSAD.

**The Acadian USH1C 9-repeat VNTR(t,t) allele arose independently of the 3-repeat VNTR(t,t) allele.** *S. Savas*<sup>1</sup>, *S.S Ng*<sup>1</sup>, *P.L. Deininger*<sup>2</sup>, *M.A. Batzer*<sup>3</sup>, *B.J.B Keats*<sup>1</sup>. 1) Department of Genetics, Louisiana State University Health Sciences Center, New Orleans, LA; 2) Tulane Cancer Center, Department of Environmental Health Sciences, New Orleans, LA; 3) Louisiana State University Biological Computation and Visualization Center, Baton Rouge, LA, USA.

A 45 bp VNTR was identified in intron 5 of the Usher syndrome type IC gene (USH1C). The 9-repeat VNTR allele is in complete linkage disequilibrium with the USH1C mutation in the Acadian population, and is characterized by the presence of two repeat units at the 3' end that contain a T at the eighth nucleotide position rather than a G (VNTR(t,t)). This VNTR does not display meiotic or mitotic instability, and the 9-repeat VNTR(t,t) allele is found solely in Acadian USH1C patients. We analyzed 152 unrelated individuals (32 Acadian, 20 African, 48 European, 52 Asian) with repeat sizes ranging from 2 to 8, and found that one Acadian and three European individuals were heterozygous for a 3-repeat VNTR(t,t) allele. All other alleles in this sample had only one repeat unit at the 3' end with a T (VNTR(t)). Additionally, among the parents of Acadian USH1C patients, we found one who had the 3-repeat VNTR(t,t) allele and the 9-repeat VNTR(t,t), demonstrating that homozygosity for the VNTR(t,t) structure is not sufficient to cause USH1C. In order to gain insight into the origin of the 9-repeat VNTR(t,t) allele, we obtained haplotypes at 11 SNPs in close proximity to the VNTR locus for the chromosomes containing the VNTR(t,t) alleles, and found that the 3-repeat VNTR(t,t) haplotype was quite different from the 9-repeat Acadian VNTR(t,t) haplotype. These results indicate that the 9-repeat VNTR(t,t) allele arose independently of the 3-repeat VNTR(t,t). Moreover, we propose that unequal crossing-over is a likely explanation for the differently sized VNTR(t) alleles as well as the rare 3- and 9-repeat VNTR(t,t) alleles.

**Regression trees to select maximally-linked phenotypes in relative-pair linkage analysis of multivariate traits.**

*C.M.T. Greenwood*<sup>1,2,3</sup>, *M. Lemire*<sup>1</sup>, *K. Morgan*<sup>1,3</sup>. 1) Research Institute of the McGill University Health Centre, and the Montreal Genome Centre, Montreal, Quebec, Canada; 2) Department of Epidemiology and Biostatistics, McGill University; 3) Departments of Human Genetics and Medicine, McGill University.

We have developed a nonparametric relative-pair linkage analysis method appropriate for highly multivariate phenotypic data. This method adaptively finds subsets of phenotypes that demonstrate the strongest evidence for linkage. In each family and for a particular locus, the difference between observed and expected identical-by-descent (IBD) allele sharing is calculated for all pairs of individuals informative for linkage. Then, classification and regression trees are used to develop predictions for these IBD differences using pair-level covariates based on the phenotypes. Hence, we can identify subsets of pairs with high mean levels of allele sharing. Bootstrapping can be used to stabilize cutpoint selection, and cross-validation optimizes the size of the regression tree. The tree predictions are then used to identify successive subsets of pairs among whom the evidence for linkage is measured.

We applied our method to 414 pairs of individuals from 68 multiplex families ascertained for asthma. A regression tree was grown using IBD estimates at a candidate chromosomal region. After cross-validation, the regression tree identified no phenotypic traits that were strongly associated with increased allele sharing. However, to illustrate our algorithm, we chose a tree with 5 terminal nodes. In 132 pairs, who had either low asthma severity scores and low IgE or high atopic indices, a non-parametric linkage score of 3.32 was obtained. The significance of this test for linkage will be evaluated by simulation.

This approach can be used to filter high-dimensional phenotypic data. For example, gene-gene interactions might be identified by including mutation information at known candidate genes among the phenotypic data. However, due to the adaptive nature of the algorithm, results must be interpreted cautiously and validated in independent data.

**Linkage simulation enhances decision making strategies for study of lung cancer (LC) pedigrees.** *M.de Andrade*<sup>1</sup>, *J. Slusser*<sup>1</sup>, *C.I. Amos*<sup>2</sup>, *J. Bailey-Wilson*<sup>3</sup>, *P. Fain*<sup>4</sup>, *M.W. Anderson*<sup>5</sup>, *G. Petersen*<sup>1</sup>. 1) Health Sciences Research, Mayo Clinic, Rochester, MN; 2) Epidemiology, UT M.D. Anderson Cancer Center, Houston, TX; 3) NGHRI, Bethesda, MD; 4) University of Colorado, CO; 5) University of Cincinnati, OH.

As the Genetic Epidemiology of Lung Cancer Consortium identifies high risk LC families, a challenge has been in deciding which families/individuals to study, given high sporadic rate and difficulty of accrual. **Objective:** To assess the value of linkage simulation for data collection as a way to inform data collection and fine mapping of high risk LC pedigrees. **Methods:** One thousand replicates of a 40 member multiplex genotyped LC pedigree were simulated using SLINK and GENEHUNTER, compared to the observed NPL score (1.7) with a 13-allele marker. We evaluated maximum information in the pedigree that could be obtained with fine mapping. **Results:** Bimodal distribution of expected NPL scores were observed with this pedigree structure. Compared to the observed NPL score, the pedigree was found to contain additional power to detect linkage by fine mapping. The inclusion of a newly diagnosed affected LC individual will give sufficient power to detect linkage. **Conclusions:** Linkage simulation of individual pedigrees can enhance decision-making in LC mapping studies. Following genome scanning, simulation studies of the power to detect linkage by fine mapping in specific families may direct data collection strategies.

**Combined Linkage and Association Interval Mapping of Quantitative Trait Loci.** *R. Fan<sup>1</sup>, M. Xiong<sup>2</sup>*. 1) Dept Health Evaluation Sciences, 600 Centerview Drive, Pennsylvania State Univ, Hershey, PA 17033; 2) Human Genetics Center, University of Texas-Houston, P.O. Box 20334, Houston, Texas 77225.

Two methods, linkage analysis and linkage disequilibrium mapping, are usually utilized for mapping quantitative trait loci (QTL). Both linkage analysis and linkage disequilibrium mapping have their advantages and disadvantages. Using only one marker, one may carry out linkage analysis. Using two or more markers, it is possible to flank the QTL by interval mapping. In this report, we propose joint linkage and linkage disequilibrium interval mapping of QTL by considering likelihoods which utilizes flanking marker informations and includes both recombination fractions and linkage disequilibrium coefficients as parameters. We carry out the analysis of model building, parameter estimations and power calculations to show the advantages of the method: (1) both population and family pedigree data can be used simultaneously; (2) population data can provide information for linkage disequilibrium mapping, and family pedigree data can provide information for both linkage analysis and linkage disequilibrium mapping; (3) interval mapping can provide fine mapping for the location of QTL.

**An adaptive test procedure for linkage analysis of quantitative traits.** *E.I. Drigalenko.* Neuropsychiatry & Behavior Sci, Texas Tech Univ Health Sci Ctr, Lubbock, TX.

A method of linkage analysis for a binary trait (a complex disease) is described that is based on sib pairs and takes into account the mode of inheritance of the trait. Under assumptions that the trait is determined by one two-allele locus, Hardy-Weinberg equilibrium, and no allelic association, the likelihood function is derived as a function of variance components. It is shown that the previously proposed affected sib pair tests comprise a family of studentized efficient score statistics. They are based on a hidden parameter, the recessive angle, which describes the mode of inheritance of the trait. Its extreme values give the two commonly used two-allele and mean test statistics. An environmental factor has been taken into account. The empirical distribution function is advocated to evaluate the significance level of the test. The proposed method is distribution-free, the locally most powerful against small values of the genetic variances, based on the distribution function under the null hypothesis, and controls the type I error even if the trait parameters are misspecified.

**The genealogy of Fanconi Anaemia patients homozygotic for the type I and type II Afrikaner mutations. S.**

*Jansen<sup>1</sup>, T. Pearson<sup>1</sup>, NV. Morgan<sup>2</sup>, AJ. Tipping<sup>2</sup>, LP. Kuyt<sup>3</sup>, CG. Mathew<sup>2</sup>.* 1) Dept Human Genetics, Med Fac, Univ Orange Free State, Bloemfontein, 9300, South Africa; 2) Division of Medical and Molecular Genetics, GKT School of Medicine, 8th Floor Guys Tower, Guys Hospital, London Bridge, London SE1 9RT, UK; 3) Department of Human Genetics, Free University of Amsterdam, Van der Boechorststraat 7,1081-BT Amsterdam, The Netherlands.

Fanconi anaemia (FA), a rare autosomal recessive genetic disorder, is known to occur at a higher than normal incidence among the white Afrikaans speaking population of South Africa. The disease is characterised by progressive bone marrow failure, starting predominantly in childhood, various phenotypic abnormalities as well as an increased sensitivity to the clastogenic agents diepoxybutane (DEB) or mytomycin C (MMC), resulting in chromosomal aberrations. Initial genealogical investigations on 12 families affected by FA but with unknown mutational status, identified Guillaume Nel and/or his spouse Jeanne de la Batt as common ancestors. A founder effect, the cause of the high incidence of FA among this population group, was further substantiated by results obtained through complementation studies and mutation screening, showing the predominance of complementation group A and mutation types I, II and III. The existence of three mutation types among the descendants of Guillaume Nel and Jeanne de la Batt raised the possibility of more than one founder pair or family being involved. For this reason an additional genealogical investigation was carried out, limited to seven and six FA parents carrying respectively the Afrikaner types I and II mutations. Apart from GN/JDLB, HDP and wife CD also featured prominently as possible founders for the FANCA Afrikaner type I mutation whereas either PV or MDP are candidate founders of the FANCA Afrikaner type II mutation.

**General Tests for Departures from Hardy-Weinberg Proportions with Pedigree Data.** *D.J. Schaid, S.K. McDonnell, J.M. Cunningham, B.J. Peterson, S.N. Thibodeau.* Mayo Clinic, Rochester, MN.

When performing genome scans for linkage of genetic markers with traits, it is critical to eliminate genotyping errors, which can dramatically reduce the evidence for linkage. In addition to evaluating Mendelian transmission of markers, the quality of markers can be evaluated by testing whether the marker genotype frequencies adhere to Hardy-Weinberg proportions (HWP), because an excess number of homozygotes can indicate undetected alleles. The common tests for HWP require independent subjects, to avoid an inflated rate of false claims. When analyzing pedigree data, the independent founders of the pedigrees can be used, yet they are frequently not available for the study of older-onset disease. Two approaches have been used to circumvent this problem. A common approach is to randomly sample one subject per pedigree. However, this approach is inefficient, and has the potential to miss problem genotypes simply due to the random sampling. A second approach depends on a probability model for the genotypes, and uses residual deviations from the fit of the model to account for correlated data. This approach can be inefficient because it does not directly account for the different types of relationships among pedigree members. We propose new methods to test for departures from HWP with pedigree data that use all study subjects while accounting for dependencies among relatives. The methods are general enough to consider a variety of departures, using different weighting schemes, while reducing the degrees of freedom in order improve power. For example, one weighting scheme is sensitive to departures due to an excessive number of rare homozygotes. In addition to the global tests for departure from HWP, we propose pedigree diagnostic statistics to examine the influence of each pedigree. These diagnostics can be useful to identify problem pedigrees. Our new methods are applied to our ongoing genome-wide linkage study of hereditary prostate cancer to illustrate the benefits of this type of statistical quality control.

**A novel meta-analysis method which corrects for publication bias.** *G.P. Sreekumar<sup>1</sup>, D.V. Zaykin<sup>1</sup>, L.A. Zhivotovsky<sup>2</sup>*. 1) Department of Population Genetics, GlaxoSmithKline Inc., Research Triangle Park, NC; 2) Institute of General Genetics, Russian Academy of Sciences, Moscow, Russia.

Recent interest in the genetics of common complex diseases has resulted in numerous linkage and or association studies. The goal of these studies is to find the disease susceptibility genes, which confers risk for the disease (which may in fact be very small, considering the complexity of these diseases). Common methods combine such information through meta-analytic approaches, for example by evaluating the distribution of sum or a product of p-values (sometimes transformed), often weighted by the size of the studies. The major flaw of this approach is that the probability of a particular study being published is positively correlated with the significance of the obtained result and thus the combined estimate is likely to be largely inflated. Here we provide a method that is robust against the publication bias and that allows a test for the presence of association between genetic polymorphisms and the disease. The method explores the fact that the distribution of significant p-values depends on the presence of the actual effect.

Asthma is one of the common chronic childhood diseases in developed nations. Mapping of susceptibility loci for asthma is hampered by high population frequency, incomplete penetrance, phenocopies and genetic heterogeneity. Although significant progress has been made in the mapping of asthma susceptibility loci in the past several years, even large studies have low power to map genes of modest effect. We applied our meta-analysis technique to several candidate gene studies published in the literature and found that the following candidate genes were found to be significantly associated with asthma. Fc epsilon receptor beta (p-value=1e-05), Interleukin 4 receptor (p-value=0.01), Interleukin 4 (p-value=2e-05), Tumor necrosis factor (p-value=7e-05), and Angiotensin converting enzyme (p-value=0.05).

**Concordances between self-reported disease and laboratory results of family members participating in a genetic family study of diabetic nephropathy. Results from the San Antonio Center of the multi-center FIND. R.**

*Plaetke<sup>1</sup>, N. Arar<sup>1</sup>, C. Garcia<sup>1</sup>, C. Goyes<sup>1</sup>, V. Sartorio<sup>1</sup>, F. Ting<sup>1</sup>, I. Kawalit<sup>1</sup>, R. Duggirala<sup>2</sup>, M. Stern<sup>2</sup>, H. Abboud<sup>1</sup>.* 1) Div Nephrology, Dept Med; 2) Div Epidemiology, Dept Med; Univ Texas Health Sci Ctr, San Antonio, TX.

The Family Investigation of Nephropathy and Diabetes (FIND) searches for diabetic nephropathy (DN) genes. As one of 8 centers, we have enrolled 40 Mexican American families through a proband with end stage renal disease (ESRD) since December 2000. Each family has on average 2.5 members (range:1-9). We received lab results from 100 subjects: 40 probands, 60 relatives (58 siblings; 2 parents). From 13 families, we currently have only probands' lab results.

Of the 40 probands, 19 were females; average age was 56.2 years. Average age of onset for diabetes was 34 years (range:17-55), and 53.3 years for ESRD (range:35-68). On average, probands had 19.7 years diabetes before receiving dialysis. 91.9% had diabetes <sup>3</sup>9 years before needing dialysis.

Relatives were on average 56.3 years old (range:32-87), 72% were females. 34 relatives reported diabetes, 3 reported ESRD. Family members were tested for diabetes (HbA1C) and kidney function (urine albumin/creatinine and protein/creatinine, serum creatinine, BUN). Lab tests showed that 18 of the 34 diabetic relatives had microalbuminuria or proteinuria. 26 relatives reported not having diabetes. 12 had HbA1C<sup>3</sup>6.0 (range: 6-13). 5 had HbA1C<sup>3</sup>7.0 and were classified as diabetics; 2 of them had microalbuminuria or proteinuria. 5 subjects with 6.0£HbA1C<7.0 had microalbuminuria or proteinuria. Among the 14 relatives with HbA1C<6.0, 3 had microalbuminuria or proteinuria.

We will present (1) the goal of our center in the FIND, (2) updated information about the probands and the concordances between self-reports and lab results, and (3) correlate lab results with their currently collected self-reports about their kidney status.

This research has been funded by the NIDDK/NIH (DK57295) and the San Antonio Area Foundation.

Program Nr: 1258 from the 2001 ASHG Annual Meeting

**Liability Groups in Linkage Analysis.** *S.S. Shete, C.I. Amos.* Dept Epidemiology, Univ Texas MD Anderson CA Ctr, Houston, TX.

In this note we present a way of incorporating individual specific liability classes for linkage analysis. In linkage studies, we may have information about different covariates. In this method, one uses the best fitting model obtained by segregation analysis. This model will give parameter estimates such as familial effects, covariate effects, age of onset effects, and susceptibility. Here we show how these estimates can be used to form individual specific liability classes and how one can use standard linkage analysis program LINKAGE to perform such analysis.

**Strategies for SNP Selection for Linkage Disequilibrium Mapping.** *A. Aelony, S. Lewitzky, K. Yu, A. Parker, J. Meyer, R. Martin.* Dept Human Genetics, Millennium Pharmaceuticals Inc, Cambridge, MA.

Recent advances involving the Human Genome Project and associated genomics consortia have populated public databases with an abundance of information on Single Nucleotide Polymorphisms (SNPs) in the form of a dense genome-wide map. Despite this new wealth of SNP information, many questions remain regarding the impact of SNP selection on power to detect linkage disequilibrium (LD) in fine mapping studies. In the analysis of a single SNP, we explore the impact of allele frequency on power. We then proceed to more realistic scenarios where multiple SNPs in a small region are analyzed, to determine how combinations of allele frequencies can be chosen to optimize power. We simulate nuclear family data with population parameters based on values observed in a study of schizophrenia in a Finnish population. For specified disease models, we compare power of single-point TDT-based LD methods among different SNP selection strategies. Results are controlled for multiple testing, taking into account background LD using recently developed Monte Carlo methods.

**Characterization of Marker-Marker Linkage Disequilibrium in a Finnish Founder Population.** *M. Harmon*<sup>1</sup>, *K. Rinard*<sup>1</sup>, *G. Barnes*<sup>1</sup>, *A. Foti*<sup>1</sup>, *C. Reeves*<sup>1</sup>, *G. Chan*<sup>1</sup>, *A. Parker*<sup>1</sup>, *J. Lonquist*<sup>2</sup>, *T. Paunio*<sup>2</sup>, *C. Richard*<sup>4</sup>, *L. Peltonen*<sup>2,3</sup>, *J. Meyer*<sup>1</sup>, *R. Martin*<sup>1</sup>. 1) Human Genetics, Millennium Pharmaceuticals, Cambridge, MA; 2) National Public Health Institute, Helsinki, Finland; 3) Human Genetics, UCLA School of Medicine, Los Angeles, CA; 4) Genetics Institute, Wyeth-Ayerst Research, Cambridge, MA.

As part of a study of schizophrenia in a Finnish population, we are fine mapping a 35cM region containing a possible disease susceptibility locus or loci on chromosome 1q32-42. A total of 216 microsatellite and 50 SNP markers are typed in two independent samples. One sample drawn from the general population of Finland consists of 278 nuclear pedigrees; the second is from an internal isolate in the northeast of Finland and is made up of 168 nuclear pedigrees, 122 of which can be linked into one large pedigree. Average spacing of microsatellites is 150 kb apart, however markers are non-uniformly distributed: 40% are spaced  $\leq 10$  kb apart, 30% between 10 and 100 kb, and another 30% between 100 kb and 1 Mb. We are investigating the extent of linkage disequilibrium (LD) in our experimental data and how it varies over this 35cM region. Several LD coefficients including Lewontin's  $D'$  are calculated from founder haplotypes, estimated from pedigree data using Simwalk, by performing multiple independent runs and pooling estimates. Preliminary results for SNPs looking at 332 chromosomes in 83 pedigrees (with both parents typed) from the general Finnish population sample indicate that LD with  $D'$  of at least 0.6 extends up to 150 kb. As SNPs tend to vary according to mutability and heterozygosity when compared with microsatellites we also compare LD estimates in subintervals containing both marker types to determine whether LD estimates may differ depending upon the type of marker used. Comparisons are also made across samples to look at how historic population bottlenecks may affect levels of LD. Finally, to assess the affect of varying amounts of missing genotype data on haplotype estimates and subsequently the LD coefficients based upon them, we stratified pedigrees according to the number of typed parents and compared the resulting LD measures.

**Genetic associations between pubertal growth and skeletal maturity in healthy boys and girls.** *B. Towne<sup>1</sup>, S.A. Czerwinski<sup>1</sup>, E.W. Demerath<sup>1</sup>, A.F. Roche<sup>1</sup>, J. Blangero<sup>2</sup>, J.S. Parks<sup>3</sup>, M.R. Brown<sup>3</sup>, R.M. Siervogel<sup>1</sup>.* 1) Wright State University School of Medicine, Dayton, OH; 2) Southwest Foundation for Biomedical Research, San Antonio, TX; 3) Emory University School of Medicine, Atlanta, GA.

A number of single gene defects result in disturbances of both skeletal growth and skeletal maturation, but little is known of the nature of shared genetic influences on skeletal growth and maturation during normal childhood development. In this study, we examined the genetic architecture of skeletal growth and maturation during the pubertal growth spurt. Individual growth curves were fitted to serial stature data from 158 boys and 205 girls in 105 families in the Fels Longitudinal Study using the triple logistic method in the program AUXAL (Bock et al., 1994). Each individual's age (AGE) at minimum height velocity (MHV) before puberty, and at peak height velocity (PHV) during puberty, were obtained, along with their height (HT) and growth velocity (GV) at those ages. These 363 boys and girls also had hand-wrist radiographs taken within one year before and after the timing of their MHV and PHV from which skeletal age (SA) assessments were made using the FELS method (Roche et al., 1988). Estimates of SA at MHV and SA at PHV were derived by interpolation. The heritability of each trait was estimated using SOLAR (Almasy and Blangero, 1998); a modified version of SOLAR was used to estimate genetic correlations between SA at MHV, and SA at PHV, and the other traits. The heritabilities were: AGE at MHV = 0.82, HT at MHV = 0.61, GV at MHV = 0.72, SA at MHV = 0.67, AGE at PHV = 0.82, HT at PHV = 0.59, GV at PHV = 0.59, and SA at PHV = 0.56. The genetic correlations were: SA at MHV & AGE at MHV = 0.53, SA at MHV & HT at MHV = 0.53, SA at MHV & GV at MHV = -0.36, SA at PHV & AGE at PHV = 0.36, SA at PHV & HT at PHV = (0), and SA at PHV & GV at PHV = -0.55. Overall, these findings reveal: 1) highly significant heritabilities of different parameters of physical growth in stature, and of skeletal maturity, during puberty; and 2) incomplete (or no) pleiotropic effects of genes on parameters of physical growth in stature and skeletal maturity during puberty. Supported by NIH grants HD12252, HD36342, and MH59490.

**Founder effects and the peopling of the New World.** *S. Bourgeois*<sup>1</sup>, *E. Zietkiewicz*<sup>1</sup>, *V. Yotova*<sup>1</sup>, *R. Michalski*<sup>3</sup>, *A. Ruiz-Linares*<sup>4</sup>, *D. Labuda*<sup>1,2</sup>. 1) Research Center, Hopital Sainte-Justine, and; 2) Pediatrics Department, University of Montreal, Montreal, QC, Canada; 3) Victoria Hospital, Prince Albert, SK, Canada; 4) The Galton Laboratory, University College, London, United Kingdom.

Genetic studies of maternally inherited mitochondrial DNA and paternally inherited Y-chromosome do not provide clear distinction between the three linguistic groups of the American populations believed to represent three independent waves of the New World colonization through Beringia. Here, we present the data on a nuclear, X-linked marker studied in NaDene and Paleoindian populations. *Dys44* haplotypes consist of 35 segregating sites found within 8 kb of the intronic DNA flanking exon 44 of the dystrophin gene on Xp21. Out of the ten major haplotype families identified in a worldwide sample (n=1315) of the X-chromosomes, three are of particular interest. The haplotype families B002 and B005 with the overall worldwide frequencies of 23% and 6.5%, respectively, appear to be virtually absent in the populations from Northern America (NaDene and Ojibwa), as well as from Central (Maya) and Southern America (Karitiana). This finding provides an argument for a single founder effect that includes both Paleoindian and NaDene speakers. On the other hand, the frequency of the haplotype family B004 is dramatically increased in Maya (32%) and even more so in Karitiana (69%) , compared to 3.3% in Ojibwa and 7.5% in NaDene. This suggests local founder effects related to the colonization of Central and Southern America, but not correlated with the major linguistic subdivisions. Additional data that are currently being collected on the *dys44* diversity in American populations will be presented in correlation with the existing evidence of mitochondrial and Y-chromosome diversity. The present evidence points to a single major colonization event and subsequent diversification of the population of the New World. (Supported by CIHR; S.B. has a studentship of HSJ Research Center).

**The HGDP-CEPH genome diversity cell line panel.** *H.M. Cann*<sup>1</sup>, *C. De Toma*<sup>1</sup>, *A. Marcadet-Troton*<sup>1</sup>, *J. Dausset*<sup>1</sup>, *G. Thomas*<sup>1</sup>, *H.T. Greely*<sup>2,3</sup>, *L.L. Cavalli-Sforza*<sup>3</sup>. 1) Foundation Jean Dausset, CEPH, Paris, France; 2) Law School, Stanford University, Stanford, CA; 3) Department of Genetics, Stanford University School Medicine, Stanford, CA.

Human genome diversity studies, involving the typing of various populations with polymorphic markers, provide information concerning their genetic histories and the extent of polymorphism and, relevant for mapping genes for complex traits, about linkage disequilibrium in their respective genomes. The Human Genome Diversity Project (HGDP) and the *Centre d'Etude du Polymorphisme Humain* (CEPH) have undertaken a collaboration to collect and produce lymphoblastoid cell lines (LCLs) from populations throughout the world in order to promote and coordinate genome diversity studies. An initial phase of the collaboration is now completed: 1066, already-existing, mycoplasma-free LCLs from various populations and milligram quantities of corresponding high quality DNAs are banked at CEPH. These LCLs originate, for the most part, from indigenous groups in sub-Saharan and north Africa; west, east, central, north and southeast Asia; New Guinea and Melanesia; Europe and the Americas. In general, some 50 populations are represented.

DNA from these cell lines will be distributed to investigators who are ready to collaborate with HGDP-CEPH by typing DNA from all LCLs with their markers and contribute the typing results to a central database. The DNAs will also be typed with a subset of 400 well-mapped STRs from the Marshfield collection (Dr. J. Weber). Those investigators who undertake resequencing studies of relatively large genome regions need not necessarily sequence DNAs from all the panel populations nor from all LCLs within a population. Cell lines will not be distributed.

Identifying information for each LCL is limited to the sex and population and geographic origin of the sampled individual. Local ID numbers of LCLs received at CEPH have been transformed to different code in order to preserve subject identity. The informed consent practices used for taking the original blood specimens, many obtained 10-20 years ago for production of these cell lines, are being evaluated.

**Survey of Ashkenazi Jewish SNPs in a 471 kb region of chromosome 9q31 as compared to the public SNP database (dbSNP).** *S.P. Gill<sup>1</sup>, M. Leyne<sup>1</sup>, J. Mull<sup>1</sup>, M.P. Cuajungco<sup>1</sup>, C.M. Robbins<sup>2</sup>, I. Makalowska<sup>2</sup>, A. Blumenfeld<sup>3</sup>, M. Brownstein<sup>2</sup>, J.F. Gusella<sup>1</sup>, S.A. Slaugenhaupt<sup>1</sup>.* 1) Harvard Inst Human Genetics, Mass General Hosp, Boston, MA; 2) NIH, Bethesda, MD; 3) Hadassah Univ Hosp, Jerusalem, Israel.

Familial Dysautonomia, (FD) is an autosomal recessive neuropathy with a carrier frequency of 1:30 in Ashkenazi Jews. We recently reported that FD is caused by 2 mutations in the I $\kappa$ B kinase complex-associated protein (*IKBKAP*) gene on chromosome 9q31. The 471 kb candidate region for FD contained 8 genes. Prior to the identification of the FD mutations, we screened the coding sequence of each candidate gene and found several SNPs. Using haplotype analysis, 2 of these SNPs enabled us to reduce the candidate region to a 178 kb interval containing 5 genes. We generated the complete genomic sequence of this region in both affected and control cosmids. Direct comparison of the sequences identified 152 differences including 26 variations in the length of dTn tracts, 1 VNTR, and 125 SNPs. Examination of the SNPs in this region reported in dbSNP reveals very little overlap with our polymorphisms. In the 8 coding regions we identified 22 coding sequence SNPs, while dbSNP reports a total of 17. Interestingly, only two of these SNPs are the same. Evaluation of all SNPs (coding and non-coding) across the 178 kb candidate region again reveals little overlap, with dbSNP reporting 83 SNPs while we have identified 125 in the Ashkenazim. Our coding sequence SNPs were identified by sequencing 4 individuals, and the non-coding SNPs were the result of comparing only 2 individuals. Nonetheless, we identified more SNPs during our screen than are reported in dbSNP, despite the fact that they typically result from comparison of a greater number of sequences. Our results demonstrate that the SNP database is not likely representative of specific ethnic isolates, a point that should be considered by investigators using SNPs for linkage and association studies. Further, we demonstrate that screening a very small number of individuals (2-4) in the study population will likely yield a significant number of SNPs in the gene or region of interest.

**Haplotype analysis of chemokine and chemokine receptor polymorphisms.** *V.J. Clark<sup>1,2</sup>, R.J. Peterson<sup>3</sup>, M. Dean<sup>1</sup>.*  
1) Laboratory of Genomic Diversity, NCI at Frederick, Frederick, MD; 2) InterCollege Graduate Program in Genetics, Pennsylvania State University, University Park, PA; 3) Celadon Laboratories, Inc. 387 Technology Drive, College Park, MD.

Chemokines are small intercellular signaling molecules that recruit immune cells to the site of inflammation and infection. Chemokine and chemokine receptor variants influence susceptibility to HIV-1 infection, progression to AIDS, and the efficiency of the immune system. More recently, these proteins have been implicated in tumorigenesis and metastasis in breast and other cancers. Therefore, studies of variation in these genes, and their cell-surface receptors, may be crucial to understanding how gene function affects the complex process of cancer.

Haplotype analysis of Single Nucleotide Polymorphisms (SNPs) has been increasingly important in the study of complex disease. In this study, we have identified haplotypes of SNPs in chemokine and chemokine receptor gene clusters found on chromosomes 3p21, 4q21 and 17q11-12. Forty SNPs in both coding and non-coding regions of chemokine and chemokine receptor genes were genotyped using the 5 nuclease assay (TaqMan). Haplotype frequencies were determined in European-Americans and African-Americans, as well as in native African and Asian populations using the Expectation-Maximization (EM) algorithm. Analyses of pairwise comparisons of SNP frequencies describe the patterns of linkage disequilibrium over tens and hundreds of kilobases in each gene region. To further describe the haplotype structure, pedigree analyses of 40 multi-generation CEPH families have been performed to determine the haplotype phase of whole chromosomes.

These analyses are an important first step in describing the haplotype structure and the structure of linkage disequilibrium in chemokine and chemokine receptor genes. The nature of the extent haplotype structure of these regions will be determined in a study of a worldwide population panel. As a final step, these haplotypes will be used in association studies of case/control samples for breast cancer (n=200), AIDS-related Kaposi sarcoma (n=508), and AIDS-related lymphoma (n=200).

**HLA POLYMORPHISMS IN PAKISTANI ETHNIC GROUPS.** *A. Mohyuddin, Q. Ayub, S. Khaliq, A. Mansoor, K. Mazhar, S. Rehman, R. Qamar, S.Q. Mehdi.* Biomed & Genet Engg Labs, Dr. A. Q. Khan Research Labs, Islamabad, Pakistan.

HLA population genetic analyses have been carried out in many world populations, but no major studies have been performed on the Pakistani populations. In this study the HLA -A, -B, -C, -DRB and DQB1 loci of seven Pakistani ethnic groups have been analyzed in an attempt to study the genetic diversity of Pakistani populations and to examine the phylogenetic relationship of the different Pakistani races with respect to each other as well as to other world populations. The populations selected for the study include Baloch, Brahui, Parsi and Sindhi from the south and Burusho, Kalash and Pathan from the north of Pakistan. HLA typing was carried out using polymerase chain reaction with sequence specific primers (PCR-SSP). Neighbor joining trees based on allele frequencies were constructed and correspondence analysis was carried out. Diversity was observed in the allele and haplotype distribution between the seven Pakistani ethnic groups. Analyses based on HLA- A, -B, -C, -DRB1 and DQB1 allele frequencies revealed the Kalash and Parsi populations to be distinct from each other and the remaining Pakistani populations. The Baloch and Brahui were closely related to one another. The Sindhi were closer to the Pathan and Burusho populations than to the neighboring Baloch and Brahui populations indicating admixture between the northern and southern populations of Pakistan. Phylogenetic and correspondence analyses comparing the Pakistani populations to various other world populations (HLA- A, -B and -C allele frequency data from the 11th and 12th International Histocompatibility Workshops) showed that the Pakistani ethnic groups, with the exception of the Parsi, lie within the cluster of the European and Asian Indian populations. The Parsi population however shows a striking affinity to the Iraqi Jews. These results help in studying the origins of the various Pakistani populations and provide a background for a variety of applications including tissue typing and HLA and disease association studies in Pakistan.

**Genetic diversity in Mongolians and Japanese: A comparison of Y-chromosome, mitochondrial DNA and X-chromosome variations.** *B. Munkhbat*<sup>1,2</sup>, *K. Tounai*<sup>1</sup>, *T. Katoh*<sup>1</sup>, *T. Ikuta*<sup>1</sup>, *H. Ando*<sup>1</sup>, *A. Yamamoto*<sup>1</sup>, *R. Sato*<sup>1</sup>, *G. Oyungerel*<sup>2</sup>, *G. Tamiya*<sup>1</sup>, *N. Munkhtuvshin*<sup>2</sup>, *K. Tokunaga*<sup>3</sup>, *H. Inoko*<sup>1</sup>. 1) Dept. of Molecular Life Science, Tokai University School of Medicine, Isehara, Kanagawa, Japan; 2) National Institute of Health, Mongolian Medical University, Ulaanbaatar, Mongolia; 3) Dept. of Human Genetics, Graduate School of International Health, The University of Tokyo, Tokyo, Japan.

The assessments of genetic diversity in human populations have long been studied by mitochondrial DNA, Y-chromosomal, and various types of autosomal polymorphism. Among various genetic markers used, highly mutable markers such as microsatellites (short tandem repeats, STR) are most suitable for examining recent events and the relationships among closely related populations. Their characteristics such as genome-wide distribution, high degree of polymorphism, ease of the typing by automated multiplex PCR, have resulted in a relatively wide use of microsatellite markers during last decade. The development of highly polymorphic microsatellite markers on the non-recombining region of the human Y-chromosome would allow determining the best haplotypic resolution and therefore would make it the most powerful tool to study genetic diversity in human populations. Therefore, we have attempted to identify novel microsatellite markers on human Y-chromosome. Eighteen novel, Y-specific, and polymorphic microsatellite markers (5 tri-, 10 tetra-, and 3 pentanucleotide) were developed from the comprehensive human sequence data that are accumulating in publicly available databases and applied for population study. Here, we will present the analysis of within- and between-population genetic diversity in 4 Mongolian and Japanese populations using 18 newly identified and 15 known Y-specific markers in comparison with Caucasians and other human populations. Furthermore, the results obtained from the variations in Y-chromosome loci will be compared with the variations in mitochondrial DNA and X-chromosome.

**A Study of the Greek Ancestry of Northern Pakistani Ethnic Groups using 115 Microsatellite Markers. A.**

*Mansoor<sup>1</sup>, Q. Ayub<sup>1</sup>, R. Qamar<sup>1</sup>, K. Mazhar<sup>1</sup>, S. Khaliq<sup>1</sup>, S. Siddiqi<sup>1</sup>, S. Rahman<sup>1</sup>, M. Papaioannou<sup>2</sup>, S.Q. Mehdi<sup>1</sup>.* 1) Biomedical and Genetic Engineering Division, Dr. A. Q. Khan Research Laboratories, Islamabad, Pakistan; 2) Unit of Prenatal Diagnosis, Center for Thalassemia, Laiko General Hospital, Athens, Greece.

Pakistan lies in a region that has witnessed multiple invasions and migrations over the centuries and is therefore composed of diverse ethnic groups. Three northern Pakistani populations, the Pathans, the Burusho and the Kalash claim descent from Greek soldiers who were left in this region after Alexander's invasion of the Indian sub-continent in 327-323 B.C. The Burusho reside in Hunza and Nagar Valleys, which are located in the Karakorum mountains and speak the language isolate Burushaski. The Pathan tribes inhabit the North West Frontier Province of Pakistan and parts of neighboring Afghanistan and speak Pushto, an Indo-European language. The Kalash have been isolated for centuries in the Hindu Kush mountain ranges of northern Pakistan and speak Kalasha, which is also an Indo-European language. To investigate the genetic relationship between extant Greek population and the three Pakistani ethnic groups, forty unrelated samples from each population were analyzed using 115 autosomal microsatellite markers. Tri (17) and tetranucleotide (98) were typed by multiplex PCR and analyzed on ABI 377 sequencer using Genescan software (2.1). VisTA and DISPAN programmes were used for principal component analysis and for calculating the genetic distances between these populations. The heterozygosity values for all loci varied between 0.71 (Kalash) to 0.74 (Greeks). The Kalash population was the least heterozygous and had the lowest number of unique alleles. The principal component analysis of allele frequency data grouped the Pathans and the Burushos with the Greeks. A phylogenetic tree generated using DAS values also separated the Kalash from the other three populations with the bootstrap value of 100% from 10,000 replications. The clustering of the Burusho and Pathans with the Greeks suggests that the gene flow has occurred between these populations.

**Dynamics of microsatellite genetic diversity in the Indian Subcontinent.** *S.S. Mastana*<sup>1</sup>, *G. Sun*<sup>2</sup>, *S.S. Papiha*<sup>3</sup>, *R. Deka*<sup>2</sup>. 1) Dept Human Sci, Human Gen Lab, Loughborough Univ, Loughborough, England; 2) Department of Environmental Health, University of Cincinnati, Cincinnati, OH 45267. USA; 3) Department of Human Genetics, University of Newcastle on Tyne. England.

We have analyzed genetic variation at 13 STR loci (CODIS core loci) in a sample of 16 ethnically and geographically diverse endogamous caste and tribal populations of the Indian subcontinent. A wide spectrum of allelic distribution at different loci was visible in different geographical and ethnic populations. Overall populations within geographical regions showed greater degree of similarity. Statistically significant differences were observed in a large number of inter-population comparisons. FGA locus was the most polymorphic in a majority of populations with 17 observed alleles. Other highly polymorphic loci in Indian subcontinent include D21S11(15 alleles) and D8S1179(10 alleles). FGA locus had the highest average heterozygosity (86%) and the lowest was observed for TPOX (69%). Average heterozygosity for all loci was 0.79. Coefficient of genetic diversity showed a narrow range for different loci (0.007 to 0.026) with an average of 1.4%, which indicates that these populations are at an early stage of micro-differentiation. Phylogenetic trees and principal component analysis computed from microsatellite allele frequencies provide support for socio-cultural and geographical assignment of these populations. Comparisons are in progress with other genetic markers including mtDNA and Y-chromosome. We also computed forensic and paternity statistics. Lowest match probability and highest exclusion probability was observed for the FGA locus. Combined match probability was low ( $1$  in  $8.99 \times 10^{12}$  to  $2.9 \times 10^{13}$ ), and combined exclusion probability was  $> 99.999\%$ . There was no evidence of association of alleles between loci studied, so these loci seem to comprise a suitable group of markers for population genetic purposes and for paternity and forensic testing. This study was supported by NIH grant GM45861, NIJ grant 98-LB-VX-002 and funds from Loughborough University.

**A nuclear marker for the southern route out of Africa.** A.D. Lovell<sup>1</sup>, E. Zietkiewicz<sup>1</sup>, V. Yotova<sup>1</sup>, M. Batzer<sup>3</sup>, D. Labuda<sup>1, 2</sup>. 1) Research Center, Sainte Justine Hospital, and; 2) Pediatrics Dept, U of Montreal, Montreal, QC, Canada; 3) LSU, Baton Rouge, LA, USA.

The out of Africa scenario proposes two major routes of modern human dispersal from Africa. The northern route, through the Levant into Eurasia, is supported by fossil remains and genetic data; an earlier, southern route, through the horn of Africa and along the southern Asian coast to South East Asia, awaits experimental documentation. We present here a nuclear marker that provides support for the southern route out of Africa. The *dys44* haplotype consists of 35 segregating sites within an 8kb segment flanking exon 44 of the dystrophin gene on Xp21. *Dys44* haplotypes were analyzed in a sample of 1315 chromosomes from all over the world. The haplotype family B002 is found at high frequencies in Sub-Saharan Africa (26%), East Asia (30%) and Oceania (49%), and at very low levels in Europe (4%) and the Americas (1%). Comparing populations from the putative southern and northern migrations statistically supports ( $p < 0.001$ ) the observation that B002 follows the southern route. Four alleles of a T-repeat, occurring within the *dys44* segment, are associated with B002 haplotypes in Africa, while only one of these alleles is found outside Africa, suggesting that B002 did not originate in Asia. Furthermore, the frequency of an *Alu* insertion, within the dystrophin intron 44, increases dramatically from Africa (9%) to Melanesia (60%); this pattern is consistent with a lack of substantial back-flow of genes from Asia to Africa. Our findings suggest that B002 distribution provides a genetic record of the hypothesized southern route out of Africa. To add resolution and further test B002 as a marker, samples from Eastern Africa and Southern Asia need to be analyzed. (*Supported by Canadian Institutes of Health Research*).

**Variation in PPARb is associated with lower fasting glucose and insulin levels in Hispanic and Non-Hispanic white individuals.** *S.P. Moffett<sup>1</sup>, M. Barmada<sup>1</sup>, E. Feingold<sup>1</sup>, C.M. Damcott<sup>1</sup>, B. Guner<sup>1</sup>, J.A. Marshall<sup>2</sup>, R.H. Hamman<sup>2</sup>, J.M. Norris<sup>2</sup>, R.E. Ferrell<sup>1</sup>.* 1) Human Genetics, University of Pittsburgh, Pittsburgh, PA; 2) University of Colorado, School of Medicine, Denver, CO.

The peroxisome proliferator activated receptors (PPARs), members of the nuclear receptor subfamily, influence the expression of genes involved in pathways such as fatty acid metabolism, glucose transport and energy regulation. Insulin can activate the PPARs by phosphorylating the protein. PPARb is one of the three PPAR isoforms and is expressed at moderate levels in most tissues, although high levels are found in the large intestine. We screened the coding sequence of the PPARb gene for common polymorphisms to determine if genetic variation in the gene is associated with glucose or insulin levels. A silent C to T substitution was found in exon 6 at nucleotide 72054 (Genbank accession # AL022721) using SSCP and sequencing for mutation detection. This variant, PPARb6, alters an Nde I restriction site which was used to genotype the polymorphism in a group of Hispanic (H) and Non-Hispanic (NH) white individuals enrolled in the San Luis Valley Diabetes Study (n=764). Allele frequencies in the two ethnic groups were similar ( $q=0.137$  in H and  $q=0.127$  in NH). Analysis of variance showed associations between the less common allele of PPARb6 and lower fasting glucose ( $p=0.013$ ), fasting insulin ( $p=0.034$ ) and HOMA IR ( $p=0.013$ ), a derived measure of insulin resistance. Regression models including PPARb6, sex and skin reflectance as a measure of ethnicity were then tested. PPARb6 and skin reflectance were found to be significant predictors of variation in  $\ln(\text{fasting insulin})$  ( $p=0.001$ ) and  $\ln(\text{HOMA IR})$  ( $p=0.0003$ ) while PPARb6, skin reflectance and sex were all significant predictors of  $\ln(\text{fasting glucose})$  ( $p<0.0001$ ). These results suggest a role for PPARb in glucose regulation and insulin metabolism independent of sex and ethnicity in this population.

**Genomic approaches to DNA identification of kidnapped children: Progress of the Argentina project.** *K.N.*

*Owens<sup>1</sup>, M-C. King<sup>1, 2</sup>.* 1) Department of Genomic Sciences, University of Washington, Seattle, WA; 2) Department of Medicine, University of Washington, Seattle, WA.

During the Argentine military dictatorship of 1975-1983 at least 250 young children were taken from their biological families. Ongoing efforts by the Abuelas de Plaza de Mayo to identify these missing children, now young adults, have integrated DNA evidence. The challenge is matching rediscovered children with their respective biological families using incomplete information. We have found mtDNA sequences to be particularly useful. Any mitochondrial relative will match a missing child, a particular advantage given that both parents are deceased in the majority of these families. For each case, we sequenced 675 bp at the mtDNA origin of replication and maintain a database of mtDNA sequences of surviving relatives, discovered children of unknown identity, and population controls. Diversity of sequences in this population is high; 81% of families have mtDNA sequences unique in the Argentine database. Unique sequences reflect the occurrence of rare variants on ancestral haplotypes. The average difference between sequences from unrelated persons in the database is 11.2 nucleotides. If the mtDNA sequences of a rediscovered child match a surviving family, we genotype multiple nuclear loci to test the hypothesis of relationship. It is useful to evaluate allele-sharing at multiple loci of all available relatives with an undisputed sibling of the disappeared child. This proportion of shared alleles is compared to the proportion shared by the child of unknown identity with the same relatives. This approach provides an alternative to methods that depend on population-specific allele frequencies.

**Global variation in the IL-10 C-592A and eotaxin C-1382A AIDS-resistance SNPs.** *J.J. Martinson, P. Aldred.*  
Institute of Genetics, University of Nottingham, Nottingham UK.

Many host loci are known to affect the rate of progression to AIDS following infection with HIV-1. In the early stage of infection, HIV-1 targets macrophages: the cytokine IL-10 inhibits macrophage development, reducing the available population of target cells for HIV, but a C/A SNP in the IL-10 promoter affects rates of HIV infection and AIDS progression. The A form of the SNP increases these, probably by down-regulating IL-10 and thereby enhancing macrophage proliferation. The chemokine eotaxin is one of the normal ligands for CCR3, a chemokine with a minor role in HIV infection. A C/A SNP in the eotaxin promoter nevertheless affects the rate of HIV infection, but not of AIDS progression in individuals who do become infected. The A allele is protective, but the mode of action whereby eotaxin achieves this is presently not known. We have determined the global distribution of these two SNPs using a large sample of DNAs typed previously for SNPs in CCR5. Each of these SNPs is polymorphic in all populations studied, although the allele frequencies vary greatly. For the IL-10 accelerator A allele, the highest frequency of 65% was seen in southern Chinese. Other Asian populations showed this allele at frequencies between 15% and 40%. In Caucasian populations, the A allele frequency varied from 12-25%, whereas in African populations this allele was slightly more common (30-35%). For eotaxin, Caucasian populations generally showed a slightly higher frequency of the protective A allele (15-40%) than Asians (5-20%) or Africans (2-7%). African populations had both low levels of the eotaxin resistance allele and high levels of the IL-10 susceptibility allele, which may partly explain the rapid spread of AIDS in sub-Saharan Africa. Data from these two loci alone show that there is a great deal of variation between populations in the levels of innate resistance and susceptibility to HIV infection and AIDS progression. As more loci are found to affect these processes, inter-population differences in disease resistance will become ever more important in the prediction of viral transmission rates and in the development of AIDS vaccines.

**Patrilinear origins of Pakistani ethnic groups.** *R. Qamar*<sup>1,2</sup>, *Q. Ayub*<sup>1,2</sup>, *A. Mohyuddin*<sup>1,2</sup>, *K. Mazhar*<sup>1</sup>, *A. Mansoor*<sup>1</sup>, *S. Khaliq*<sup>1</sup>, *T. Zerjal*<sup>2</sup>, *C. Tyler-Smith*<sup>2</sup>, *S.Q. Mehdi*<sup>1</sup>. 1) Biomedical and Genetic Engineering Division, Dr. A. Q. Khan Research Laboratories, Islamabad, Pakistan; 2) Department of Biochemistry, University of Oxford, Oxford, UK.

Pakistan lies on the postulated route followed by anatomically modern *H. sapiens* out of Africa. Besides being the cradle of the Indus Valley Civilization this region of Asia has been influenced by various human migrations and invasions over the millennia. The origins of present day Pakistani populations was investigated by typing 16 biallelic unique event polymorphisms, and 21 multiallelic, short-tandem-repeat (STR) loci, including six previously unreported STRs, mapping on the non-recombining portion of the human Y chromosome. More than 800 individuals representing 15 Pakistani ethnic groups were analyzed. The northern Pakistani ethnic groups included in this study were the Balti, Burusho, Hazara, Kalash, Kashmiri, Meos, Pathans and Rajputs. The southern groups included the Baloch, Brahui, Makrani Baloch, Makrani Negroid, Mohannas, Parsi and Sindhis. The combination of the biallelic markers identified 11 stable Y chromosomal lineages, referred to as haplogroups, in the Pakistani population. Notable differences were observed in the Hazara and Mohanna ethnic groups. The former claim to be descendants of Genghis Khan and this fact is substantiated by analysis of their haplogroup 10 Y chromosomes, which is found at high frequencies in populations from Central Asia, China and Mongolia. The Mohannas are reputed to be the indigenous populations of Sindh in southwestern Pakistan. Their Y chromosomal lineages are significantly different from the other Indo-European speaking ethnic groups residing in Pakistan, including their neighboring Sindhi populations. The language isolate group of Burushos and the Dravidian speaking Brahuīs were not much different from their geographic neighbors within Pakistan. Based upon the principal component analysis of haplogroup frequencies the Pakistani ethnic groups were closely related to each other and the Europeans. Most Pakistani populations had the M20 A to G transition. This polymorphism has not been found at a significant frequency elsewhere in the world.

**The relationship of Apolipoprotein E and ACE to coronary heart disease among Southwest Hispanics, African Americans and Caucasians.** *D.P. Rojas<sup>1</sup>, L.H. Mateus Pereira<sup>1, 2</sup>, I. Fernandez<sup>1</sup>, M.C. Terreros<sup>1, 4</sup>, A. Socorro<sup>1</sup>, R.J. Herrera<sup>1</sup>, F. Huffman<sup>3</sup>.* 1) Biological Sciences, Florida International University, Miami, FL; 2) Depto. Genetica, Universidade Federal do Rio Grande do Sul, Porto Alegre, RS, Brazil; 3) Department of Dietetics and Nutrition, Florida International University, USA; 4) Comision de Investigaciones Cientificas (CONICET), Argentina.

Coronary heart disease (CHD), a leading cause of mortality and morbidity in industrialized countries is a multifactorial disease caused by the interaction of polymorphic inheritance and environmental factors. An understanding of the genetic make up that predisposes and contributes to development of risk factors for CHD is critical to understand the pathogenesis of this disease. The objective of this study is to determine the relationship of the ACE (angiotensin converting enzyme) Alu element insertion polymorphism and Apo E polymorphism (E2, E3, and E4 variants) as factors that contribute to the development of CHD. The human DNA samples used in this work are from three different ethnic backgrounds Hispanic, African American of non-Hispanic origin, and White of non-Hispanic origin with equal number of men and women at each group. There is no previously reported information on young diverse populations (college students) that focuses on ACE and Apo E polymorphisms. The DNA was extracted from serum using a Quiagen mini kit. The Alu insertion polymorphism used in this study was ascertained by PCR-based method using gene counting to obtain the insertion and lack of insertion frequencies. For the Apo E gene we are using a RFLP method described elsewhere (REF). The results of this study may help to identify the factors involved in CHD among young sub-population groups of different ethnicities. Thus it can provide greater insight into the potential utility of admixed populations for the mapping of complex traits.

**Diversity of paternal lineages in populations of Siberia and Central Asia.** *V.A. Stepanov<sup>1</sup>, V.P. Puzyrev<sup>1</sup>, V.N. Kharkov<sup>1</sup>, S. Roots<sup>2</sup>, M.G. Spiridonova<sup>1</sup>, Z.O. Soltobaeva<sup>3</sup>, R. Villem<sup>2</sup>.* 1) Lab Evolutionary Genetics, Inst Medical Genetics, Tomsk, Russia; 2) Estonian Biocentre, Tartu, Estonia; 3) Kirghiz Medical Academy, Bishkek, Kirghizia.

Y-chromosome variation was analyzed in a sample of 600 individuals from nine indigenous populations of Siberia (Tuva, Buriat, Northern and Southern Altai, Evenk, Yakut) and Central Asia (Kirghiz, Uzbek, Tajik). Paternal lineages was constructed using 11 biallelic and 7 microsatellite loci. Distribution of 10 biallelic haplogroups (HGs) forming the parsimonious genealogical tree displays distinct ethno-geographic differences. Most frequent haplogroups in the total sample were HG3 (26.4%) and HG16 (23.2%). HG16 encompassed 35-90% of Y chromosomes in Yakuts, Buriats and Evenks, whereas HG3 reached the highest frequency in Altai and Kirghiz populations. Principal component analysis of biallelic data shows that populations of Central Asia and Altay-Sayan region clearly separated from the Eastern Siberians because of high frequency of HG16 in the latter. Using the molecular variance of microsatellite loci within the biallelic HGs we estimate the time to the most recent common ancestor for several frequent HGs. According our data, the coalescent age of HG3 which is widely distributed in Europe and Northern Asia is around 13200 YBP. The STR diversity associated with HG12 provided age estimate of about 6250 YPB, and the age of HG16 which is derivate of HG12 was estimated as about 4250 YPB. Our findings suggest that the Y-chromosome variation correlates with antropological characteristics of the populations and their spatial localization rather than their linguistic affiliation.

**East European gene geography of 3'ApoB VNTR polymorphism.** *D.A. Verbenko<sup>1</sup>, O.P. Balanovsky<sup>1</sup>, E.V. Balanovskaya<sup>2</sup>, E.K. Khusnutdinova<sup>3</sup>, S.A. Limborska<sup>1</sup>.* 1) Human Genetics Department, Institute of Molecular Genetics of Russian Academy of Sciences, Moscow, Russian Federation; 2) Research Centre for Medical Genetics of Russian Academy of Medical Sciences, Moscow, Russian Federation; 3) Institute of Biochemistry and Genetics (Ufa Scientific Centre) of Russian Academy of Sciences, Ufa, Russian Federation.

Apolipoprotein B gene VNTR (variable number of tandem repeats) polymorphism is commonly used to distinguish individuals in forensic science. Moreover, ApoB minisatellite diversity combined with other ApoB gene polymorphisms is one of the major parts in atherosclerosis association studies. Last time papers shown the great possibilities of use the minisatellite in microevolutionary processes research. In spite on worldwide study of 3'ApoB distribution East European populations are not generally presented yet. Our data are based on healthy individuals polymorphisms from East Slav (Russians, Byelorussians, Ukrainians), Volgo-Uralic (Bashkirs, Komis, Chuvashes, Tatars, Udmurts, Mordvinians, Mari), Adhyg and Kalmyk populations.

The principal components of variability were extracted from all 3'ApoB VNTR allele frequencies to reveal integrative diversity. The complex estimate of the prediction probability of all points of the real was taken into account in order to construct principal component variability maps properly. A set of geographic variability maps was constructed on the base of principal component digital matrixs for all map points.

The map of first principal component of variability reflect homogenous plateau encompassed with two variability gradients. The plateau is situated on Russian Plain - which is the place of East Slavs living. One of the gradients spread from Kalmykia through Karpaty Mountains to Baltic Sea. Another gradient has its maximum in Ural Mountains. Both gradients have common minimum in Kalmykia. The minimum position may be explained with Oriental lineage of Kalmyks. One can see that ApoB geographic distribution in East Europeans reflects ethnic and geographis borders of the region.

**Single nucleotide polymorphisms in 539 human genes.** *J.A. Schneider, T. Acharya, R. Jiang, G.F. Vovis, J.C. Stephens.* Population Genomics, Genaissance Pharmaceuticals, New Haven, CT.

We discovered 6,808 SNPs in approximately 1.4 Mb of genomic DNA from 539 human genes. DNA sequencing was performed on one chimpanzee and 82 unrelated individuals including African-Americans, Asians, European-Americans and Hispanic Latinos. The data were collected from specific gene regions including exons, exon-intron boundaries, untranslated regions and 5' and 3' flanking regions. Characterization of these SNPs revealed information about mutational, selective and demographic processes that have influenced patterns of human genetic diversity. We found that ~40% of our SNPs were mutations of either base in a CpG dinucleotide, consistent with the fact that CpG dinucleotides are prone to methylation. While numerous SNPs were population-specific, approximately 20% were observed in all four ethnic groups. For some SNPs, we found that the rare human allele matched the corresponding chimpanzee nucleotide, contrary to the expectation that the common human allele should be ancestral. Recurrent mutation or recent selection could explain this observation. The distribution of polymorphisms within these genes may indicate a historical population expansion, since 481 out of 539 genes had a negative Tajima's D value. Together, these results suggest that human genetic diversity is the result of a complex interplay of evolutionary forces.

**HUMAN X-CHROMOSOMAL LINEAGES IN EUROPE REVEAL MIDDLE EASTERN AND ASIATIC**

**CONTACTS.** *F.X. Xiao*<sup>1</sup>, *E. Zietkiewicz*<sup>1</sup>, *V. Yotova*<sup>1</sup>, *J.P. Moisan*<sup>3</sup>, *I. Arrieta*<sup>4</sup>, *D. Labuda*<sup>1, 2</sup>. 1) Research Center, Hospital Sainte-Justine, and; 2) Pediatrics Dept, U of Montreal, Montreal, QC, Canada; 3) CHRU, Nantes, France; 4) UPV, Bilbao, Spain.

European genetic data using classical genetic markers and DNA polymorphisms revealed an east-west frequency gradient often interpreted as evidence for the migration of Neolithic farmers spreading agriculture from the Middle East. However, it is not clear how to discern the genetic record tracing routes of the first peopling of Europe during the Upper Paleolithic or of other, later movements. We have analyzed nuclear haplotypes composed of 35 polymorphic sites in an 8 kb intronic DNA flanking exon 44 of the human dystrophin gene on Xp21 in a worldwide sample of chromosomes. Out of ten haplotype families identified, three are restricted to Africa and seven are shared by populations from all the continents. Within Eurasia, haplotype B001 is found at similar, high frequencies in Europe, the Middle East and Asia, while haplotype B003 is mainly concentrated in Europe and the Middle East. Haplotype B002 decreases in frequency from the Middle East to Europe, while haplotypes B005, B006 and B008 show the opposite tendency. On the other hand, we also observe frequency gradients from Asia to Europe: decreasing in the case of haplotypes B002 and B005, and increasing in the case of B003. The distribution of B006, a strong marker of Northern populations, appears relatively even from Europe to Central Asia. These patterns give a signal of the gene flow being as strong between the Middle East and Europe as between Central Asia and Europe. (*Supported by CIHR; F.X.X. has a fellowship of HSJ Research Center*).

**Yq microdeletion screening in 120 Iranian infertile men.** A. Hatami<sup>1</sup>, M.A. Sadighi Gilani<sup>2</sup>, L. Abbasi Moheb<sup>1</sup>, P. Afsharian<sup>3</sup>, S. Molla Mohammadi<sup>2</sup>, M.K. Javan<sup>1</sup>, H. Pak<sup>2</sup>, H. Najmabadi<sup>1</sup>. 1) Genetics Research Center, University of Social Welfare and Rehabilitation Sciences, Tehran, Iran; 2) Andrology department, Rooyan institute, Tehran, Iran; 3) Department of Clinical and Experimental Genetics, Rooyan Institute.

Infertility affects 10-15% of couples seeking to have children. Male factor is the leading cause in about 50% of cases. Recent studies have established the concept of a genetic basis for male infertility. Although macroscopic deletions are uncommon in infertile men (0.5%), the existence of microdeletions in AZF(Yq 11.22-23) has been reported in 3-20% of idiopathic oligo/azoospermic men. DAZ and RBM are two multicopy gene families which are expressed only in testes and have an important role in spermatogenesis. They are located at AZFc and AZFb (interval 6 of Yq) respectively. Microdeletions in these regions cause severe oligozoospermia or azoospermia. In IRAN, there has been no comprehensive study on microdeletion screening of infertile men. In this study 23 STS were selected to screen for Yq microdeletions. One hundred and twenty azoospermic and oligozoospermic individuals were selected. Cytogenetic, hormonal and other causes of infertility have been ruled out in these men. Our results indicate 8 out of 120 individuals with Yq microdeletions (6.6%).

**Sample size calculations for association studies of gene-gene interaction.** *W.J. Gauderman.* Dept Preventive Medicine, Univ Southern California, Los Angeles, CA.

In the study of complex diseases, it is important to test hypotheses related to gene-gene (GxG) interaction. The success of such studies depends critically on obtaining adequate sample sizes. In this paper, we describe a method for computing sample size requirements for studies of GxG interaction. We focus on three case-control study designs, including the matched case-control, case-sibling, and case-parent designs. All three types of studies can be analyzed using conditional logistic regression, which is used as a unifying theme in the development of sample size calculation methods. Comparisons of sample size requirements for detecting GxG interaction indicate that the case-parent design typically requires half the number of matched sets compared to the other two designs. As an example, we describe a study of two common recessive genes for which 270 matched case-control pairs would be required to detect a GxG interaction of moderate magnitude with 80% power. By comparison, the same study would require 319 case-sibling pairs, but only 146 case-parent triads. A software program that computes sample size for studies of GxG, and for studies of gene-environment (GxE) interaction, is freely available and may be downloaded from the website <http://hydra.usc.edu/gxe>.

**Identifying tuberculosis disease resistance genes using Quantitative Phenotype Analysis.** A.A. Awomoyi<sup>1</sup>, A. Marchant<sup>2</sup>, G. Sirugo<sup>3</sup>, K. McAdam<sup>3</sup>, S.A. Tishkoff<sup>1</sup>, J. Blackwell<sup>4</sup>, M. Newport<sup>4</sup>. 1) Department of Biology, University of Maryland College Park, MD.20742; 2) Institute of Molecular Medicine, Oxford UK; 3) Medical Research Council Labs, Fajara The Gambia; 4) Cambridge Institute for Medical Research Cambridge UK.

Tuberculosis (TB) is a complex trait in which host genetics, environmental factors and the pathogen play a role in development of the disease phenotype, making it difficult to identify specific genes involved. Gene mapping may be simplified by regarding the disease phenotype as a constellation of underlying quantitative traits which can be studied independently. Macrophage activation, a crucial stage in initial host defense against intracellular pathogens, is a complex process which involves several genes: defects of macrophage activation may result in increased susceptibility to TB. We used in vitro cytokine responses to lipopolysaccharide (LPS), and lipoarabinomannan (LAM), in healthy blood donors as phenotypic markers of macrophage activation in conjunction with candidate gene association studies to answer two questions relating to genetic regulation of macrophage activation in TB: do macrophage candidate genes regulate microbial induced responses and do macrophage candidate genes influence susceptibility to TB? TNF, IL-1 and IL-10 responses showed considerable heterogeneity in this population. Polymorphisms in macrophage candidate genes were analysed in relation to this phenotypic variation. These included new polymorphisms detected within the promoter of the IFNGR1 gene that occur within or close to functional elements. The TNFA -863, LTA NcoI, IL-1RN and NRAMP1 (INT4) alleles were shown to influence macrophage cytokine levels significantly. A case control association study conducted in parallel identified association between the following alleles and TB: TNFA -308, TNFA -238, IL1B, IFNGR1, IL9, NRAMP1 (INT4) and NRAMP1 CA repeat. These results indicate that analysis of quantitative traits underlying a complex disease trait may be a useful tool in mapping candidate genes in infectious diseases such as TB.

**Association between the apolipoprotein E polymorphism and the severity of coronary artery disease in the NHLBI-sponsored Women's Ischemia Syndrome Evaluation (WISE) Study.** *Q. Chen*<sup>1</sup>, *S.E. Reise*<sup>2</sup>, *D. Pauly*<sup>3</sup>, *B. Sharaf*<sup>4</sup>, *D. McNamara*<sup>2</sup>, *R. Holubkov*<sup>5</sup>, *C.N. Bairey Merz*<sup>6</sup>, *M.I. Kamboh*<sup>1</sup>. 1) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA; 2) Department of Medicine, University of Pittsburgh, Pittsburgh, PA; 3) Department of Medicine, University of Florida, Gainesville, FL; 4) Department of Medicine, Rhode Island Hospital, Providence, RI; 5) Department of Epidemiology, University of Pittsburgh, Pittsburgh, PA; 6) Department of Medicine, Cedars-Sinai Research Institute, Pittsburgh, PA.

Genetic variation in the apolipoprotein E (APOE) gene is a significant determinant of variation in plasma cholesterol levels and it also affects the risk of coronary artery disease (CAD). In this study, we examined the association of the APOE polymorphism with coronary stenosis in 575 white women from the NHLBI-sponsored Women's Ischemia Syndrome Evaluation (WISE) study, a multicentered study designed to address issues related to ischemic heart disease diagnosis and pathophysiology in women. Subjects were classified as having normal (<20% stenosis, n=224), mild/minimal disease (20 to 49% stenosis, n=148) and significant disease (<sup>≥</sup>50% stenosis, n=203). Logistic regression was used to compute adjusted odds ratios (ORs) and 95% confidence intervals (CI). The frequency of the *APOE*\*4 carriers (E2/E4, E3/E4, E4/E4) was significantly higher in the diseased group (<sup>≥</sup>20% stenosis) compared to the normal group (<20% stenosis) with an OR of 2.04 (95% CI: 1.29-3.23; p=0.0023). Similarly, the stratification of the data based upon the number of diseased vessels (none, single, double and triple) showed that the frequency of *APOE*\*4 carriers was significantly higher in the triple diseased vessel group than the combined group of none, single and double diseased vessels (OR=4.36, 95% CI=2.09-9.10; p<0.0001). These data support the hypothesis that the *APOE*\*4 allele is a risk factor not only for the presence of CAD, but also for the angiographic severity of the disease in white women.

**Interaction between the Hepatic Lipase 514(C/T) Polymorphism and Dietary Fat Intake Modulates HDL-C Levels and HDL Subfractions: The Framingham Heart Study.** *L.A. Cupples<sup>1</sup>, K. Tucker<sup>2</sup>, D. Corella<sup>2</sup>, S. Demissie<sup>3</sup>, P. Couture<sup>2</sup>, E.S. Tai<sup>2</sup>, P.W.F. Wilson<sup>4</sup>, E.J. Schaefer<sup>2</sup>, J.M. Ordovas<sup>2</sup>.* 1) Dept Epid/Biostatistics, Boston Univ Sch Public Health, Boston, MA; 2) Lipid Metabolism Laboratory, Jean Mayer-USDA Human Nutrition Research Center on Aging, Tufts University, Boston, MA; 3) Data Coordinating Center, Boston Univ Sch Public Health, Boston, MA; 4) Boston Univ School of Medicine, Boston, MA.

Hepatic lipase (HL) is a key determinant of HDL metabolism that catalyses the hydrolysis of triglycerides and phospholipids in lipoproteins. Four polymorphisms in complete linkage disequilibrium have been identified in the region upstream of the transcription initiation site of the HL gene (LIPC), defining what is known as the -514T allele. The -514TT genotype is associated with decreased HL activity and increased HDL-C levels. However, the effect is variable among populations, suggesting gene-environment interactions. We have examined interaction effects between the 514(C/T) LIPC polymorphism, dietary fat and HDL-related measures in a sample of 1314 males and 1353 females participating in a large prospective study: The Framingham Offspring study. Our data shows that carriers of the TT genotype and consuming 15% dietary fat have HDL-C concentrations 10 mg/dL higher than TT carriers consuming 35% of energy as fat. Conversely, carriers of the CC genotype consuming a low fat diet have lower HDL-C levels (-8 mg/dl) as compared with those consuming a high fat diet. A similar interaction was observed for large HDL (HDL2) levels, whereas the opposite effect was seen for small HDL (HDL3) levels. Our data, in this large, population-based cohort, demonstrate a significant interaction between the 514(C/T) LIPC polymorphism and dietary fat that modulates HDL-C levels and HDL subclasses in this population. Therefore, the LIPC locus is a significant determinant of the marked individual variability in plasma HDL-cholesterol responses to fat intake. Specifically, TT subjects have an impaired adaptation to higher fat diets that could result in higher cardiovascular risk.

**Genome-wide scan for loci affecting normal adult height in the Framingham Study.** *N. Mukhopadhyay<sup>1</sup>, D.N. Finegold<sup>1</sup>, M. Larson<sup>2</sup>, L.A. Cupples<sup>3</sup>, R.H. Myers<sup>4</sup>, R. Ferrell<sup>1</sup>, D.E. Weeks<sup>1</sup>.* 1) Dept Human Genetics, Univ Pittsburgh/Sch Pub Health, Pittsburgh, PA; 2) Framingham Heart Study, Framingham, MA; 3) Boston University/ School of Public Health, Boston, MA; 4) Boston University/ School of Medicine, Boston, MA.

Height is an ideal example of a polygenic quantitative trait shared by all humans. Previous linkage analysis studies have focused on growth-related factors and individuals with abnormally short stature. Since findings from plants and animals suggest that often a large proportion of the variance for a polygenic trait is controlled by a small number of genes with significant effects, we analyzed data from 1,720 individuals from 333 families from the Framingham Heart Study in order to map loci influencing normal adult height. These individuals are from two cohorts, the first ascertained in 1948 via a random sample of households in Framingham, MA, and the second Offspring cohort in 1971. Individuals in the original cohort have undergone biennial examinations since inception of the study, while individuals in the Offspring cohort have been examined usually every 4 years. The first height measurement for individuals between the ages 20-55 years were analyzed using variance component linkage analysis on extended pedigree structures and extended Haseman-Elston linkage analysis on the component nuclear families with sex and cohort as covariates. Marker data were generated by the Marshfield Mammalian Genotyping Service for 401 markers on chromosomes 1-22, 24 markers on X, and 2 markers in the pseudo-autosomal region of the X chromosome. Nine chromosomes with 11 peaks with  $-\log P$ -values greater than 2.0 were detected. Three chromosomes demonstrated peaks with  $-\log P$ -value greater than 3.0. None of the regions with significant  $-\log P$ -values corresponded to the location of known genes in the neuro-endocrine growth hormone axis. We are currently evaluating (in silico) the regions under these peaks for candidate genes contributing to final adult height. D.N. Finegold and D.E. Weeks contributed equally to this work. The data are from the National Heart, Lung and Blood Institute's Framingham Heart Study at Boston University.

**Testing the association of quantitative traits and haplotypes considering treatment effects.** *Z. Meng<sup>1,2</sup>, D.V. Zaykin<sup>1</sup>, M.G. Ehm<sup>1</sup>, B.S. Weir<sup>2</sup>*. 1) Population Genetics, GlaxoSmithKline Inc, Res Triang Prk, NC; 2) Bioinformatics Research Center, Department of Statistics, North Carolina State University, Raleigh, NC.

To study how genes are related to efficacy and safety of a medicine, pharmaceutical companies are genotyping multiple markers in candidate genes in samples collected in clinical trials. Challenges for analysis include lack of validated statistical genetic methods, multiple correlated genetic markers, ethnic diversity, and low sample sizes. The development of methods of analysis that take into account the nature of genetic data including allelic, genotypic, and haplotype effects in addition to ethnic diversity are critical to extracting maximum information. We propose a model relating a single marker to a quantitative trait by separating the allelic additive and dominance effects, and have extended the results to haplotypes. We also consider the effects of treatments and their interactions with markers on the quantitative trait.

We illustrate the performance of our method on simulated and real data. We compare our model to an analysis of variance approach based on marker genotypic classes. We illustrate the power of utilizing multiple markers with a haplotype approach versus single markers.

**Determination of genotypic marker information to optimally evaluate the role of candidate genes.** *A.S. Jannot<sup>1,2</sup>, M. Reese<sup>2</sup>, C. Krähenbühl<sup>2</sup>, B. Cutayar<sup>2</sup>, F. Clerget-Darpoux<sup>1</sup>.* 1) Unité 535, INSERM, Le Kremlin-Bicêtre, France; 2) ValiGen, La Défense, France.

In multifactorial diseases a strategy is to focus on candidate genes to evaluate their effect on the disease, in other terms to model the correlation between genotypes and phenotypes. The MASC (Marker-Association-Segregation-Chi 2) method (Clerget-Darpoux et al, 1988) was designed for such modeling. Because of the high number of markers (usually SNPs) available on each candidate gene, one has to deal with a very high number of possible genotypes. One problem then is to decide which categories of genotypic markers to use for efficient modeling. The aim of this study is to find the minimum number of genotypic categories offering the best discrimination between groups of genotypes that have a similar distribution of their phenotypes.

We compare the power of several discrimination methods based on the analysis of variance, considering different strategies, i.e. studying the genotypes of each SNPs separately or as the whole set of SNPs. We perform our study - using 6 SNPs in the *CETP* (cholesterol acetyl transferase) gene - with different underlying genetic models involving one or two loci in a quantitative trait assuming different types of interaction between the loci.

We show that, under interaction models with a low marginal effect of each SNP, the methods, which study the effect of each SNP separately, do not offer a good discrimination of the genotypes. In such cases, the use of the complete set of SNPs may be much better in detecting the right categories for the discrimination of the genotypes.

In most current studies, the first step to reduce the number of SNPs is to apply ANOVA on each SNP separately. We show that by doing so, some genetic effects in complex disease may not be detected and that some candidate genes may be wrongly discarded in this early step.

**Association of 5' untranslated region deletion/insertion polymorphism in the ATP-binding cassette transporter A1 (ABCA1) gene with plasma lipid levels in Asian populations.** *J.H.H. Tan<sup>1</sup>, C.K. Heng<sup>1</sup>, H.Y. Yang<sup>2</sup>, Y.S. Tan<sup>3</sup>, M.C. Tong<sup>3</sup>, P.S. Low<sup>1</sup>, N. Saha<sup>1</sup>.* 1) Department of Pediatrics, National University of Singapore; 2) Department of Biochemistry, National University of Singapore; 3) National Heart Center, Singapore.

The ATP-binding cassette transporter A1 (ABCA1) plays a key role in cholesterol and phospholipid efflux. Mutations in the gene are related with depressed high density lipoprotein-cholesterol (HDL-C) levels and increased incidence of coronary artery disease (CAD) among Tangier disease patients. In the general population, polymorphisms in the gene may also contribute to subtle variations in lipids/lipoproteins. We study a previously observed 1 nucleotide deletion/insertion (2G, 3G alleles respectively) polymorphism in the 3 main ethnic groups of the Singapore male population. It occurs in the 5' untranslated region of exon 2. In the presence of the 3G allele, a *Bst*I restriction site is created. 3G allele frequencies between healthy and CAD groups in each race were similar (healthy: Chinese=0.16, n=247; Malays=0.19, n=176; Indians=0.27, n=231; vs CAD: Chinese=0.16, n=515; Malays=0.20, n=113; Indians=0.27, n=160). Within each of the 3 healthy cohorts, we tested for effect of the polymorphism on lipid profiles. Among Malays, individuals with 3G3G genotype had lower apolipoprotein A1 level ( $p=0.046$ ). Indians with the 3G3G genotype showed higher total cholesterol (TC) ( $p=0.014$ ) and low density lipoprotein-cholesterol (LDL-C) ( $p=0.025$ ); they also tended to have lower HDL-C levels ( $p=0.067$ ). In this population study, we demonstrate that less favorable lipid/lipoprotein profiles in healthy male individuals are associated with certain 2G/3G genotypes and its effect is ethnicity-dependent.

**Introduction of the multivariate Dale model in genetic association studies.** *K. Van Steen<sup>1</sup>, N. Tahri<sup>2,3</sup>, G.*

*Molenberghs<sup>1</sup>.* 1) Center for Statistics, Limburgs Universitair Centrum, Diepenbeek, Belgium; 2) INSERM U.525, C.H.U. Pitié Salpêtrière, Paris, France; 3) Genset SA, Genomics Research Center, RN7 site snecma, Evry, France.

Large-scale case-control association studies based on a dense map of markers have received increasing attention in recent years. A possible explanation for this growth is their potential use in identifying genomic regions of disease predisposing mutations. It is well known that most regions of relevance to a disease may have several base positions within them that when mutated either directly contribute to disease susceptibility or have some related physiopathological effects.

Until now, one of the most common methods to study the combined effects of several markers at different positions is logistic regression. For this approach we observe that if genotypic marker information is incorporated in a classical logistic model at the covariate level, due to the potential linkage disequilibrium between the markers, we have to face the problem of multicollinearity (Neter et al., 1996). Hence, sensitive statistical methods are needed in the identification of multiple susceptibility genes associated to complex diseases.

Here we introduce the multivariate Dale model (Molenberghs and Lesaffre, 1994), which is sometimes referred to as the multivariate (global) odds ratio model, into the world of statistical genetics. Not only is this model more intuitive, the use of a multivariate model also enables the investigation of existing correlations between markers. Interpretations remain straightforward and similar to those drawn in a classical logistic modeling framework. Benefits and drawbacks of the multivariate Dale model are pointed out. While applying the model to real-life case-control samples genotyped on SNPs within candidate regions and candidate genes, we discuss the results under different classical genetic model assumptions.

**COMT haplotype relative risk for substance dependence in four populations.** *K. Xu<sup>1</sup>, W. Mangal<sup>1</sup>, S. Nagarajan<sup>1</sup>, E. Ferro<sup>1</sup>, X.H. Liu<sup>2</sup>, D. Goldman<sup>1</sup>.* 1) Laboratory of Neurogenetics, National Institute on Alcoholism, Rockville, MD. 20852; 2) Department of Psychiatry, West China University of Medical Science, Sichuan 610041, PR China.

Evidence for a dopaminergic mechanism of reward is found in animal models of substance dependence and in the human [Volkow et al, 1996]. Dopamine also appears critical in prefrontal executive cognition crucial in impulse control. Catechol-O-methyltransferase (COMT) metabolizes released dopamine, as well as other catecholamine neurotransmitters. A common polymorphism, Val158Met, exerts a four-fold effect on enzyme activity and the higher activity Val158 allele which may be associated with lower brain dopamine levels- was associated to poorer prefrontal cognitive executive function in various datasets [Egan et al, 2001, Lipsky et al]. Previously the Val158 allele was also linked to drug abuse [Vandenberg et al, 1997], a result confirmed in a Haplotype Relative Risk study of heroin addicts but not in a subsequent case-control study of such patients. We attempted to replicate the association to substance dependence in large, relatively well-defined Finnish, Southwest Indian, Plain Indian, and Chinese populations, and using genomic control loci to test for stratification, and a multiple locus COMT haplotype consisting of 287G>A, 372C>T, 1243A>G, and 1883G>C, in addition to Val158Met [1947A>G]. 5-exonuclease assays were developed for the five SNPs and 2500 individuals were genotyped. The linkage phenotype was heroin dependence in the Chinese and alcoholism in the other populations. Haplotypes and linkage disequilibrium were compared across populations, revealing population-specific haplotypes and LD relationships. In particular, there was a large reduction of haplotype diversity in the Plains Indians, and multiple haplotype backgrounds were seen for Val158 and Met158 in the other populations. For the Chinese population case/control comparison [N= 450 vs N=304], there was no evidence for association of COMT Val158Met or individual COMT loci to heroin dependence, nor was population stratification detectable using genomic control loci.

**ASSOCIATION OF SPECIFIC IL4 RECEPTOR SNPs WITH TYPE I DIABETES IN FILIPINOS.** *T.L.*

*Bugawan<sup>1</sup>, M. Alejandrino<sup>2</sup>, D.B. Mirel<sup>1</sup>, A. Panelo<sup>3</sup>, C.M. Solfelix<sup>3</sup>, P. Pozzilli<sup>4</sup>, R. Buzzetti<sup>5</sup>, R.L. Reynolds<sup>1</sup>, A.M. Valdes<sup>1</sup>, H.A. Erlich<sup>1,2</sup>.* 1) Roche Molecular Systems, Alameda, CA; 2) CHORI, Oakland, CA, USA; 3) Inst. of Studies on Diabetes, Manila, Philippines; 4) Libera Universita Campus Biomedico, Rome; 5) La Sapienza, University of Rome.

Over 50% of the genetic predisposition to type 1 diabetes (T1D), a multifactorial autoimmune disorder, has been attributed to the HLA region. Within the HLA region, multiple loci, such as HLA-DRB1, -DQA1, -DQB1, and to a lesser extent, -DPB1 and -A contribute to the genetic risk. Among Filipinos, HLA class II and class I genes also play a critical role in susceptibility to T1D. These patients have been previously characterized for C-peptide levels and for autoantibodies to islet cell autoantigens. We have examined the role of SNPs within a panel of candidate genes, consisting primarily of cytokine and cytokine receptor genes in the Filipino population. Here we report the association of the IL4-R gene with T1D among Filipinos. Eight SNPs (I50V, N142N, E375A, L389L, C406R, S478P, Q551R, and S761P) within the IL4-R locus were examined by comparing the genotype frequencies between patients and controls. In general, homozygotes for the majority allele at these SNPs showed an increased frequency among patients and heterozygotes showed a decreased frequency. For example, the L389L IL4-R SNP (G to T base change)  $p=0.004$ , the frequency of genotype GG is 88% in patients vs. 67% in controls, while the frequencies of genotype GT and TT are 11% vs. 31% and 1% vs. 2%. Moreover, at I50V we found that Ile carriers were 4.16 more likely to be GAD+ than the Valine homozygous ( $p>0.01$ ). The analysis of linkage disequilibrium (LD) patterns revealed that four of these SNPs (E375A, L389L, C406R, S478P) showed very strong LD, revealing two major allelic lineages. An inferred haplotype (complex allele) consisting of primarily of minority SNPs at these sites appeared to confer protection (OR=0.4,  $P=0.01$ ). The minority allele at some IL-4R SNPs have been associated with asthma and atopic allergy, a Th2-mediated disease. We propose that the minority allele at IL4-R may predispose to a Th2-like response and to confer some protection from T1D.

**Application of Haplotype-based Methods to Case-only Studies of Gene-by-Environment Interaction. M.D.**

*Fallin<sup>1</sup>, W.L. Kao<sup>1</sup>, Y. Yao<sup>1</sup>, N.J. Schork<sup>2</sup>.* 1) Dept of Epidemiology, Johns Hopkins University Bloomberg School of Public Health, Baltimore, MD; 2) Dept of Epidemiology and Biostatistics, Case Western Reserve University School of Medicine, Cleveland, OH.

Recently, several investigators have proposed using case-only studies to investigate multiplicative gene-by-environment (GxE) interactions using single-locus genotypes. When an assumption of independence between the genetic and environmental factors of interest in the control population is met, this approach can have greater efficiency than a case-control design. We propose a case-only method for assessment of GxE interaction using multi-locus haplotypes. Haplotype-based methods for disease-gene identification have considerable advantage over single-genotype tests due to their ability to identify unique chromosomal segments that harbor disease variants. In light of the high genomic frequency of single nucleotide polymorphisms (SNPs) and the increasing ease of SNP identification and genotyping, we recently developed a SNP-based haplotype frequency testing approach for unrelated case-control data (Fallin et al 2001). We now propose the extension of this method to case-only tests for GxE interaction. Our method estimates haplotype frequencies from multiple SNP genotypes using the E-M algorithm and tests for heterogeneity of haplotype frequencies between cases exposed to the environmental factor and cases not exposed to the environmental factor using a likelihood ratio test. Furthermore, given the likelihood of sparse data when considering observed haplotypes, a random permutation approach to the assessment of empirical p values is employed. The type 1 error as a function of violations from GxE independence among the control population as well as the power of this method under several models of interaction, haplotype or exposure frequencies, and main effect sizes are calculated through Monte Carlo simulations. We show the use of SNP-based estimated haplotypes increases the power of case-only GxE tests in situations where the functional SNP is not typed or where several disease-associated mutations or haplotypes exist.

**Association of TNFA and TNFB polymorphisms with response to oxidative stress in coal miners.** *A.E. Jedlicka<sup>1</sup>, R. Nadif<sup>2</sup>, M. Mintz<sup>1</sup>, J-P. Bertrand<sup>3</sup>, F. Kauffmann<sup>4</sup>, S. Kleeberger<sup>1</sup>.* 1) Dept Environmental Health, Johns Hopkins Univ, Baltimore, MD; 2) INSERM U420, Vandoeuvre, France; 3) Service Medical HBL, Freyming-Merlebach, France; 4) INSERM U472, Villejuif, France.

Genetic factors that modify the response to oxidative stress are largely unknown. The influence of TNFA and TNFB polymorphisms on blood antioxidant enzyme activities was studied in miners exposed to two environmental oxidative stresses: coal mine dusts and smoking. In a longitudinal study, 231 coal miners from the Lorraine Bassin were genotyped for polymorphisms in TNFA (-308 position) and TNFB (first intron). Blood antioxidant enzymes [Cu<sup>++</sup>/Zn<sup>++</sup> SOD, glutathione peroxidase (GSH-Px) and catalase], total antioxidant, and selenium concentrations were measured. Cumulative and current smoking and occupational exposure were recorded. Chest X-rays were scored according to International Labor Office (ILO) classification of pneumoconiosis radiographs. Results indicate GSH-Px activity was decreased in miners heterozygous (1/2) or homozygous (2/2) for the TNFA mutant allele (41.6 v 37.1 U/g hemoglobin (Hb), p=0.03). The greatest difference was in miners with high current exposure (40.6 v 34.0 U/g Hb, p=0.01). In miners with cumulative dust exposure  $\leq 68$  mg/m<sup>3</sup>.y, no difference in GSH-Px activity was found between miners of any TNFA genotype. GSH-Px activity was decreased in miners with genotype 1/2 or 2/2 and cumulative dust exposure >68 mg/m<sup>3</sup>.y [gene-environment (GxE) interaction p=0.05]. No interaction was found with smoking. For TNFB, catalase activity was lower in miners homozygous for the mutant allele (p=0.02). The TNFB polymorphism, smoking and ILO profusion grade were significantly and independently related to catalase activity. GxE interaction (TNFB \* smoking) was observed with the strongest difference in ex-smokers (p=0.01). Interaction with ILO grade was observed; the strongest difference was in miners with ILO 1/1 or more (p=0.07). The conclusion did not change after simultaneously considering smoking and ILO grade. Results show the influence of TNFA and TNFB polymorphisms on the response to biologically measured oxidative stress and interactions with environmental oxidants.

**Comparison of Single-Point and Selected Haplotype-Based Association Statistics for Case-Control Data. S.**

*Lewitzky<sup>1</sup>, R. Martin<sup>1</sup>, K. Rinard<sup>1</sup>, A. Aelony<sup>1</sup>, A. Parker<sup>1</sup>, K. Yu<sup>1</sup>, G. Abecasis<sup>2</sup>, J. Meyer<sup>1</sup>.* 1) Human Genetics, Millennium Pharmaceuticals Inc., Cambridge, MA; 2) University of Oxford, Oxford, United Kingdom.

With the growing availability of information on SNPs throughout the genome, SNPs will undoubtedly play an increasingly important role in case-control association studies. However, many questions remain regarding the optimal choice of analytic methods. Single-point association statistics are relatively easy to compute and interpret, but, unless the functional variant itself is analyzed, they may be less powerful than methods that test for preserved founder haplotypes. However, haplotype-based methods raise numerous questions including how to account for unphaseable and ungenotyped markers, and how to choose appropriate haplotype lengths for analysis.

Using simulated SNP haplotype data for case-control samples, we compare single-point and selected haplotype-based association statistics under a variety of models of disease haplotype preservation and background linkage disequilibrium, assuming patterns of missing genotype data as observed in our actual association studies. We assume no population stratification. For single-point analysis we employ Fisher's Exact Test for a 2x2 contingency table. For haplotype-based analysis, we employ a recently developed EM-based software package (see abstract by Abecasis et al.) to estimate haplotype frequency distributions among cases and among controls. Using these distributions we calculate several haplotype association statistics, and empirically estimate their null distributions by repeatedly sampling case and control haplotypes, with replacement, from a merged haplotype frequency distribution. Some of these statistics are based on differences between case and control haplotype frequency distributions; others are based on within-group haplotypic similarity; still others are based on contrasting within-group similarity to between-group similarity. We compare these statistics for power, false-positive rate, and localizability.

**Association study of the tryptophan hydroxylase gene and bipolar affective disorder in Taiwan.** *H.S. Sun<sup>1</sup>, C.Y. Wu<sup>1</sup>, CathyS.J. Fann<sup>3</sup>, T.M. Chen<sup>1</sup>, T.J. Lai<sup>2</sup>.* 1) Institute of Molecular Medicine, National Cheng Kung University Medical College, Tainan, Taiwan; 2) Department of Psychiatry, Chung Shan Medical and Dental College Hospital, Taichung, Taiwan; 3) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan.

Bipolar affective disorder (BPD), also known as manic-depressive illness, is a chronic, severe mood disorder characterized by adult onset and episodes of mania and depression. Little is known about the underlying causes of this common and severe illness which has estimated a lifetime prevalence of 0.5% to 1% in various populations. Although the family, twin and adoption studies strongly suggested genetic factors in etiology, searching for predisposing genes by linkage analyses have been fraught with difficulty. Current studies using the candidate gene approach have suggested that serotonergic neurotransmission and metabolism were associated with several psychiatric and behavioral traits including BPD, depression, suicidality, alcoholism, and mental control. Tryptophan hydroxylase (TPH) is the rate-limited enzyme in the biosynthesis of the neurotransmitter serotonin and has been studied extensively for the involvement in the etiology of psychiatric and suicidal behaviors. The objective of this study is to investigate association of the TPH gene and the BPD in Taiwan by candidate gene approach. The allele frequencies of TPH intron 7 polymorphism in 183 unrelated Taiwanese are 0.52 and 0.48 for the "A" and the "C" allele, respectively. A significant association of the TPH polymorphism to Taiwanese bipolar patients was obtained ( $P = 0.03$ ). Furthermore, a marginal association of CC genotype comparing to the AC + AA genotypes with BPD was also obtained ( $P = 0.05$ ). TPH polymorphism was associated with BPD in French. The present study confirms this association in Taiwanese thus suggesting a functional variant(s) in or close to the TPH gene may predispose individuals to bipolar disorder.

**An association of the G Protein Beta 3 Subunit C825T polymorphism and systolic blood pressure in the Old-Order Amish using a regression of offspring on one parent (ROOP) method.** *G.J. Papanicolaou<sup>1</sup>, W. Siffert<sup>2</sup>, P. Platte<sup>3</sup>, A.J. Stunkard<sup>4</sup>, C. Francomano<sup>5</sup>, A.F. Wilson<sup>1</sup>.* 1) Genometrics Section, NIH/NHGRI/IDRB, Baltimore, MD; 2) Dept. Pharmacology, Univ. Hospital Essen, Germany; 3) Cntr. Psychobiol. and Psychosomatic Res., Univ. Trier, Germany; 4) Dept. Psychiatry, Univ. PA, Phil., PA; 5) NIA, NIH, Baltimore, MD.

A number of independent studies have reported an association between the G-protein beta 3 subunit (GNB3) 825T allelic variant and hypertension. As part of an ongoing study of obesity in the Old-Order Amish, the 825T variant was determined in seven families of 157 individuals. Phenotypes measured included height, weight, body mass index (BMI), systolic and diastolic blood pressures, and physical activity. Standard statistical methods were initially used to investigate allelic and genotypic associations between this G-protein variant and quantitative measures of systolic and diastolic blood pressures and BMI. A variation on a new regression-based method (ROMP) of testing for an association between a quantitative trait and a SNP was used to determine if the 825T variant had an effect on obesity-related traits. ROMP is an extension of quantitative genetic theory, and is based on the traditional linear regression of offspring on mid-parent value and on the inclusion of a candidate locus effect as a covariate of the regression. A variation of this method, based on the regression of offspring on one parent (ROOP) was used to estimate the heritability of the traits, test whether the heritability of the trait was greater than zero, test for an association between the SNP and the trait, and estimate the heritability attributable to the SNP. Of the traits considered, the 825T variant had the largest effect on systolic blood pressure. The heritability of systolic blood pressure in this sample was greater than zero ( $p=0.0235$ ) and estimated to be 0.38. The heritability attributed to the 825T variant ( $p=0.053$ ) was estimated to be about 0.04. This suggests that in this sample of the Old-Order Amish the 825T allele was responsible for about 10% of the additive genetic portion of the phenotypic variation in systolic blood pressure.

**A case-control study of selected candidate genes in the Hispanic population of San Luis Valley, Colorado.** *E.J. Parra<sup>1</sup>, C. Bonilla<sup>1</sup>, C.L. Pfaff<sup>1</sup>, S. Dios<sup>1</sup>, A.V. Buchanan<sup>1</sup>, K.M. Weiss<sup>1</sup>, R.E. Ferrell<sup>2</sup>, J.A. Marshall<sup>3</sup>, R.F. Hamman<sup>3</sup>, M.D. Shriver<sup>1</sup>.* 1) Dept Anthropology, Penn State Univ, University Park, PA; 2) Dept Human Genetics, Univ. Pittsburgh, Pittsburgh, PA; 3) Dept of Preventive Medicine and Biometrics, School of Medicine, Denver, CO.

We have carried out a case-control study in a sample of diabetics and controls from the Hispanic population of San Luis Valley, Colorado. We have studied several polymorphisms within five candidate genes previously reported to be associated with type 2 diabetes or related phenotypes in other Hispanic populations (CAPN10, GNB3, PPARG, SUR1 and KCNJ11). Additionally, we have genotyped 14 ancestry informative markers to determine the Native American and European contribution in the sample and to test for the presence of population structure, which could potentially cause false positive results. The Native American genetic contribution in the total sample was estimated to be 37.8%, and the European contribution 62.2%. No significant difference in Native American genetic contribution was observed between the diabetic and control group (38.7% and 36.7%, respectively), and no evidence of the presence of population structure was detected. We have not observed any evidence of association of type 2 diabetes and the CAPN10 gene, which has been recently reported to be the putative diabetes susceptibility gene located in the NIDDM1 region on chromosome 2. No evidence of association was observed for GNB3 and PPARG. Finally, several polymorphisms in the SUR1 and KCNJ11 genes, which code for the two subunits of the beta-cell ATP-sensitive potassium channel and are closely linked on chromosome 11, showed suggestive evidence of association with type-2 diabetes ( $0.01 < p < 0.05$ ). However, further analysis of the data indicates that these polymorphisms are unlikely to have a major effect on the susceptibility to diabetes. This research has been supported in part by grants from NIH/NIDDK (DK53958) and NIH/NHGRI (HG02154) to M.D.S.

**Quantitative Similarity-Based Association Tests Using Population Samples.** *H. Zhao, S. Zhang.* Epidemiology & Public Health, Yale Univ Sch Medicine, New Haven, CT.

Although genetic association studies using unrelated individuals may be subject to bias caused by population stratification, alternative methods that are robust to population stratification such as family-based association designs may be less powerful. Furthermore, it is often more feasible and less expensive to collect unrelated individuals. Recently, several statistical methods have been proposed for case-control association test in a structured population that may be robust to population stratification. In this presentation, we propose a quantitative similarity-based association test (QSAT) to identify association between a candidate marker and a quantitative trait of interest using unrelated individuals. For the QSAT, we first determine whether two individuals are from the same subpopulation or from different subpopulations using genotype data at a set of independent markers. We then perform an association test between the candidate marker and the quantitative trait by incorporating such information. Simulation results based on either coalescent models or empirical population genetics data show that the QSAT has correct type-I error rate in the presence of population stratification, and the power of the QSAT is higher than that using family-based association designs.

Program Nr: 1299 from the 2001 ASHG Annual Meeting

**Correlated Time-dependent Model.** *Q. Yue, G. Bonney.* National Human Genome Center, Howard University, Washington, DC.

It is quite common in genetic analysis to use family based data. The family based data is often correlated by subgroups such as families. Within each subgroup the members may share a common risk probability for some diseases. On the other hand, most diseases are also time dependent. Therefore it is worthwhile to consider a model to deal with correlated and time dependent data in the genetic analysis for family diseases.

In our paper, we try to give and implement such a model to study the genetic basis for type 2 diabetes. The model, which we called Shared Lifetime Risk of failure Model, is based on two distributions: survival distribution and risk distribution. This model is going to be implemented in our software G.E.M.S.

**Development of High-Throughput Genotyping Assays and Their Application to the Study of Tuberculosis**

**Susceptibility.** *A.H.Y. Poon*<sup>1</sup>, *A. Jiménez-Corona*<sup>2</sup>, *M. Palacios-Martínez*<sup>2</sup>, *J. Sifuentes-Osornio*<sup>3</sup>, *A. Ponce-de-León*<sup>3</sup>, *M. Bobadilla*<sup>3</sup>, *M. Kato*<sup>3</sup>, *P.M. Small*<sup>4</sup>, *M.L. García García*<sup>2</sup>, *E. Schurr*<sup>1</sup>. 1) Centre for the Study of Host Resistance, McGill University, Montreal, Quebec, Canada; 2) Instituto Nacional de Salud Pública, Cuernavaca, Mexico; 3) Instituto Nacional de Ciencias Médicas y de Nutrición "Salvador Zubirán", Mexico City, Mexico; 4) Medicine, Stanford University, Stanford, CA, USA.

Tuberculosis, caused by *Mycobacterium tuberculosis*, remains one of the most important infectious diseases worldwide. Tuberculosis has a strong host genetics component and it is widely accepted that tuberculosis susceptibility is a polygenic trait. Hence, we have developed Taqman assays for a number of anti-mycobacterial immune response genes. While Taqman assays are useful for high throughput genotyping of single nucleotide polymorphisms (SNP), the proportion of randomly selected SNPs that can be successfully adapted to Taqman assays is not known. We selected 38 SNPs in 21 immune response genes, encoding cytokines, cytokine receptors and signal transduction molecules. Following a standardized protocol and using a test panel of 80 unrelated individuals Taqman assays were developed, evaluated for their robustness and 25/38 (66%) were shown to produce reliable SNP genotypes. The developed assays are presently being used in a population-based case control study of tuberculosis risk in the Orizaba Health Region located in the state of Vera Cruz in south-eastern Mexico. The incidence of tuberculosis in this area is 42.6/100,000. We have enrolled 216 tuberculosis cases, 212 household controls and 216 neighbourhood controls matched for sex, age and ethnicity. *M. tuberculosis* cultures have been established from all enrolled cases. All tested candidate alleles were found to be in Hardy-Weinberg equilibrium among the three groups. Preliminary tests failed to detect significant associations between the known tuberculosis susceptibility genes NRAMP1, IL12RB1, IL1A and IL1B with the disease phenotype. This finding suggests the presence of population specific susceptibility factors that will be investigated in further detail.

**Involvement of vitamin D receptor and HLA loci in host susceptibility to tuberculosis in the Ache of Paraguay.**

*A.K. Wilbur, J.R. Feurstein, A.M. Hurtado, A.C. Stone.* Dept Anthropology, Univ New Mexico, Albuquerque, NM.

A number of studies show that host genetics play a significant role in determining susceptibility and resistance to tuberculosis. Research in various areas of the world has shown that multiple loci are usually involved, and that these loci differ by population. Native American populations experience some of the highest rates of tuberculosis in the world, and our work is the first to focus on an indigenous South American group, the Ache of Paraguay. In this project we use molecular biological techniques to examine the potential relationship between tuberculosis susceptibility and the human leukocyte antigen (HLA) and vitamin D receptor (VDR) loci, which have been implicated in tuberculosis susceptibility in other non-Native American populations. Two-hundred eighty-two Ache have thus far been tested for tuberculosis using PCR of IS6110, and of 56 percent of these are positive. These preliminary results correlate highly with PPD skin tests and indicate that Ache suffer high prevalence of tuberculosis. Preliminary HLA tests at the DQB1 locus on 14 individuals show that the most prevalent allele is 0302,0307, with 6 of those tested carrying least one copy of the allele. One individual also carries allele 0615, and two others have 0402. Six remaining individuals appear to have new alleles not detected by the kits we are currently using. These early data show that Ache are a highly endogamous population, and as such, provide a unique opportunity to examine the effects of genetic differences among related individuals on susceptibility/resistance to tuberculosis.

**Genetic transmission of tuberculosis-related traits.** *C.M. Stein<sup>1</sup>, R. Mugerwa<sup>3</sup>, P. Peters<sup>2,3</sup>, J. Elner<sup>2</sup>, R.C. Elston<sup>1</sup>, H.K. Tiwari<sup>1</sup>, C.C. Whalen<sup>1,2</sup>.* 1) Epidemiology & Biostatistics, Case Western Reserve Univ, Cleveland, OH; 2) Tuberculosis Research Unit, Case Western Reserve University, Cleveland, OH; 3) Makerere University School of Medicine, Kampala, Uganda.

Though the underlying cause of tuberculosis (TB) is bacterial, susceptibility to TB may be influenced by genetic factors. To investigate possible intermediate phenotypes for TB, we analyzed a set of cytokine profiles, which were chosen based on the current biologic model for TB. These traits included antigen-stimulated whole blood assays for interferon-g (IFN), tumor necrosis factor-a (TNF), transforming growth factor-b (TGF), and the ratio of IFN to TNF. We analyzed these data in 285 pedigrees from a community in Uganda with a high prevalence of TB. These intermediate phenotypes were adjusted for previous BCG vaccination, tuberculin skin test reactivity, sex, HIV status, body mass index, and age, to reduce confounding from environmental factors. Estimates for heritability of these traits were greater than 14%, and TNF in particular had an estimated heritability of 68%. Analyses adjusting for tuberculin skin test reactivity and disease status yielded similar results. Because of the high heritability of TNF, we conducted a segregation analysis of this trait, which suggested a major gene effect on TB. A principal components analysis of IFN, TNF, and TGF reflected the immunologic model of TB. In this analysis, the first component explained more than 38% of the variation in the data. Our analysis illustrates the value of such intermediate phenotypes in mapping susceptibility loci for TB.

**Epigenetic heterogeneity at imprinted loci in normal populations.** *T. Sakatani*<sup>1,2</sup>, *M. Wei*<sup>3</sup>, *M. Katoh*<sup>1</sup>, *C. Okita*<sup>1</sup>, *D. Wada*<sup>1</sup>, *K. Mitsuya*<sup>1</sup>, *M. Meguro*<sup>1</sup>, *M. Ikeguchi*<sup>4</sup>, *H. Ito*<sup>2</sup>, *B. Tycko*<sup>3</sup>, *M. Oshimura*<sup>1</sup>. 1) Department of Molecular Cell & Genetics, School of Life Science, Faculty of Medicine, Tottori University, Yonago, Tottori, Japan; 2) First Department of Pathology, Faculty of Medicine, Tottori University, Yonago, Tottori, Japan; 3) Department of Pathology and Institute of Cancer Genetics, Columbia University College of Physicians and Surgeons, New York, USA; 4) Department of Surgery I, Faculty of Medicine, Tottori University, Yonago, Tottori, Japan.

Genomic imprinting is the phenomenon by which the two alleles of certain genes are differentially expressed according to their parental origin. Since relaxation or loss of monoallelic expression of these genes is found in many human hereditary disorders and in tumors, imprinted genes are thought to influence normal embryonic growth, development and behavior. However, despite suggestive evidence, it has not been clarified if the allelic expression patterns of imprinted genes varies within the normal population. In the present study, to establish a standard for allelic expression status of imprinted genes in a general population, we collected peripheral blood leukocyte samples from 262 Japanese normal individuals in 68 families and analyzed for the expression status of *IGF2*, *SNRPN* and *IMPT1* (*TSSC5/ORCTL2/BWR1A/ITM*) genes. By RFLP analysis, the parental origin of alleles was determined for 38 cases for *IGF2*, 36 cases for *SNRPN* and 34 cases for *IMPT1*. In all cases, *SNRPN* was expressed exclusively from the paternal allele, but paternal allele-specific expression of *IGF2* was relaxed in some cases. In all informative cases, maternal allele-specific expression of *IMPT1* was relaxed, and each individual exhibited a distinct quantitative allelic bias. In additional nine cases, the allelic expression bias of *IMPT1* remained constant when re-examined after six months. Our findings add to the accumulating evidence for variable allelic expression at multiple loci in a normal human population. This epigenetic heterogeneity can be a stable trait, and it is possible that it will influence individual phenotypes. This work was supported by CREST of Japan Science and Technology Corporation (JST).

**Complex segregation analysis of ventilatory threshold measured before and after a 20-week endurance exercise training program: the HERITAGE Family Study.** *M.F. Feitosa<sup>1</sup>, T. Rice<sup>1</sup>, T. Rankinen<sup>2</sup>, A.S. Leon<sup>3</sup>, J.S. Skinner<sup>4</sup>, J.H. Wilmore<sup>5</sup>, C. Bouchard<sup>2</sup>, D.C. Rao<sup>1</sup>, S.E. Gaskill<sup>6</sup>.* 1) Division of Biostatistics, Washington University School of Medicine, St Louis, MO; 2) Pennington Biomedical Research Center, Louisiana State University, Baton Rouge, LA; 3) School of Kinesiology and Leisure Studies, University of Minnesota, Minneapolis, MN; 4) Department of Kinesiology, Indiana University, Bloomington, IN; 5) Department of Health and Kinesiology, Texas A & M University, College Station, TX; 6) Department of Health and Human Performance, Human Performance Laboratory, University of Montana, MT.

Familial aggregation has been demonstrated for maximal oxygen uptake ( $VO_{2max}$ ), both in the sedentary state and in response to exercise training. This study investigates the presence of a major gene for  $VO_2$  at the ventilatory threshold ( $VO_{2vt}$ ) and the proportion of  $VO_{2vt}$  to  $VO_{2max}$  ( $VT\%VO_{2max}$ ), at baseline and in response to 20-weeks of exercise training using data from 336 White subjects (100 pedigrees) and 169 Black subjects (111 pedigrees), from the HERITAGE Family Study. Effects of age, weight, fat mass and fat free mass have been removed separately in each of eight sex by generation by race groups, using stepwise regression procedures. Segregation analysis was performed using PAP, including investigations of genotype-specific effects of covariates. There is strong evidence of a major gene, with frequencies of 0.175 and 0.141 in the upper distribution that account for 52% and 43% of the variance in baseline  $VO_{2vt}$  and  $VT\%VO_{2max}$ , respectively, in White families. Genotype-specific-covariate effects were not significant. However, the segregation results were inconclusive for the responses to training in White subjects, as well as for baseline and training response in Black subjects, probably due to insufficient power because of reduced sample sizes. The consistent genetic signals for  $VO_{2vt}$  and  $VT\%VO_{2max}$  suggest that these should be investigated in further genetic analysis using linkage and association studies.

**Evidence for inherited susceptibility to common colorectal cancer.** *G.P. Crockford<sup>1</sup>, J.H. Barrett<sup>1</sup>, F.T. McDermott<sup>2</sup>, E.A. Debney<sup>2</sup>, E.S. Hughes<sup>2</sup>, D.J.S. St John<sup>2</sup>, D.T. Bishop<sup>2</sup>.* 1) Genetic Epidemiology Division, Imperial Cancer Research Fund, Leeds, W. Yorks, England; 2) Dept of Gastroenterology, The Royal Melbourne Hospital, Melbourne, Australia.

We investigate the evidence for an inherited susceptibility to colorectal cancer (CRC) taking account of families with Mismatch Repair (MMR) mutations in a series of 525 probands and their first and second degree relatives. Four families were known to have MMR germline mutations, 21 had an extended family history of CRC, suggestive of Hereditary Non-Polyposis Colorectal Cancer (HNPCC); 5 fulfilled the Amsterdam II criteria for HNPCC. Segregation analysis under a liability model was performed using PAP (Hasstedt 1994) to fit single gene, polygene and mixed models. Analyses were performed on (i) all 525 pedigrees, (ii) the 521 without known MMR mutations and (iii) data sets with random removal of families based on their probability of having MMR. Results on the 521 families are broadly representative of all analyses. Single major gene models found evidence for a rare, dominantly inherited predisposition to CRC, allele frequency of 0.023 and lifetime risk of 19% (to age 80 years) in gene carriers and 2% to non-carriers. Under the mixed model a common dominant gene, allele frequency 0.33, 33% heritability and lifetime risk of 5% to gene carriers and zero to non-carriers, was the preferred model. The rare dominant model was rejected ( $p < 0.001$ ). Goodness of fit tests obtained by simulation found that the mixed model best approximates the total number of affected relatives while the rare dominant model better predicts the number of families with more than 2 affected relatives. The mixed dominant and the rare dominant models provide good estimates of risk of disease to relatives, with the rare dominant model best able to distinguish differences in risk by age of proband. We conclude that having taken account of MMR genes in this data set there is still evidence for an inherited susceptibility to CRC which is best modelled by a common dominantly inherited gene and polygenic variance. **A putative codominant gene and smoking account for cancer susceptibility in families of pancreatic cancer**

**patients.** *J.F. Korczak<sup>1</sup>, J.S. Barnholtz-Sloan<sup>1</sup>, M. Schenk<sup>1</sup>, S.H. Bunner<sup>1</sup>, M. Kinnard<sup>2</sup>, A.G. Schwartz<sup>1</sup>, D.H. Garabrant<sup>3</sup>.* 1) Karmanos Cancer Inst and Wayne State Univ, Detroit, MI; 2) Case Western Reserve Univ, Cleveland, OH; 3) Univ of Michigan, Ann Arbor, MI.

Pancreatic cancer (PC) is the fourth leading cause of cancer-related mortality in the USA (ACS, 2001). We recently reported familial aggregation of PC in first-degree relatives of 247 newly diagnosed PC patients ascertained through hospitals, physicians, and tumor registries in southeastern Michigan. The relatives' smoking history was also found to be a significant risk factor (Schenk et al., 2001). Additional preliminary analysis suggested an excess of lymphoma (L) and ovarian cancer (OC) in the relatives.

To determine whether transmission of a putative disease gene could account for the observed familial aggregation, we considered anyone with PC, L, or OC as affected and performed segregation analysis using Class A logistic regressive Models 1 (variable age of onset) and 2 (variable susceptibility), implemented in the computer program S.A.G.E. REGTL. For each model, hypotheses of genetic, environmental, or no transmission were tested against a general model with arbitrary transmission probabilities. Analyses were performed either with or without smoking (ever/never) as a covariate, assuming Hardy-Weinberg proportions.

According to the Akaike Information Criterion (AIC), Model 1 fit the data as well as or better than Model 2 for all transmission hypotheses, regardless of whether smoking was included. However, without smoking, all Model 1 transmission hypotheses were rejected, compared to the general model. Inclusion of smoking in Model 1 led to the rejection of all hypotheses except that of codominant inheritance, which provided the most parsimonious fit to the data according to AIC. For this model, the frequency of the disease allele, A, was 0.136, the mean ages of onset were 27.8, 66.1, and 85.2 years for genotypes AA, AB, and BB, respectively, and the cumulative incidence of PC, L, or OC to 80 years of age was 3.6%

These findings may provide a foundation for gene mapping studies in familial pancreatic cancer.

**B-CLL: Familial aggregation and anticipation.** *S.S. Strom, Y. Gu, M. Selvan, F. Chan, M.J. Keating.* The University of Texas M.D. Anderson Cancer Center, Houston, TX.

The etiology of CLL is mainly unknown although studies suggest that both environmental and genetic factors exist. To analyze familial aggregation we conducted a family study of 577 consecutive B-CLL patients registered at M. D. Anderson between 1990 and 1999. Detailed history of all cancers was obtained for 3800 first degree relatives (FDR). A random sample of 25% hematological cancers was verified by medical records. The observed number of cancers in the FDR was compared to the expected number in the general population using Connecticut Cancer Registry age-, sex- and calendar years-specific incidence rates. A small increase in overall cancer was found. The standardized incidence ratio for all invasive cancers among FDR was 1.1 [observed (O)/expected (E)=538/487, 95% confidence interval (CI)= 1.10-1.20]. There were 102 hematological cancers reported: 39 CLL, 11 HD, 23 NHL, 7 multiple myeloma and 22 leukemias. A significant excess was found for CLL among 1380 siblings (O/E= 12/0.98=12.28, CI=6.34-21.46), 572 fathers (O/E=17/1.6=10.59, CI=6.16-16.95) and 573 mothers (O/E= 10/1.18=8.44, CI=4.04-15.53). We identified 21 sib-sib pairs. The risk of developing CLL in FDR was 2.4 times higher among relatives of patients diagnosed before age 55. We analyzed anticipation (decreased age of onset from one generation to the next) in the 26 pedigrees with cases of CLL in two generations. The mean age of diagnosis in the older generation was 64 (SD=12.8 ) years and 50 (SD=6.4) in the younger one. Using the Kaplan-Meier method, the age difference between the survivor functions was highly significant (log-rank test: p, 0.0001).

In summary, familial aggregation, young age of onset, and anticipation in parent-offspring pairs might contribute further insight into the role that genetics plays in the etiology of CLL. Molecular characterization of predisposing genes will be necessary to understand the role of anticipation in CLL. Supported by the Wolf Creek program.

**b-cell dysfunction is heritable in Latino families of probands with gestational diabetes.** *R.M. Watanabe<sup>1</sup>, C.D. Langefeld<sup>2</sup>, A.H. Xiang<sup>1</sup>, E. Trigo<sup>1</sup>, S. Hernandez<sup>1</sup>, F. Berrios<sup>1</sup>, T.A. Buchanan<sup>1</sup>.* 1) USC Keck School of Medicine, Los Angeles, CA; 2) Wake Forest University School of Medicine, Winston-Salem, NC.

We have shown that Hispanic women who develop gestational diabetes (GDM) during pregnancy have a specific b-cell phenotype characterized by a propensity to fail in the presence of chronic insulin resistance and is predictive of type 2 diabetes. We are recruiting and phenotyping Latino families consisting of a GDM proband and her non-diabetic siblings. Phenotyping includes oral (OGTT) and tolbutamide-modified intravenous (IVGTT) glucose tolerance tests, and body composition by DEXA. IVGTT data are analyzed using Bergman's Minimal Model to derive insulin sensitivity ( $S_I$ ). b-cell function is assessed as incremental 30-minute insulin during the OGTT (30'dINS) and incremental area under the insulin curve during the first 10 minutes of the IVGTT (acute insulin response, AIR). We also compute the disposition index (DI), a measure of the ability of the b-cell to compensate for insulin resistance, as the product of AIR and  $S_I$ . Heritability ( $h^2$ ) was estimated using the variance components approach adjusting for age, gender, and BMI. To date, our sample consists of 40 males and 91 females in 31 nuclear families with an average sibship size of 4.2 (range 2-10). All individuals were non-pregnant and had fasting plasma glucose <126 mg/dl at time of testing. Mean ( $\pm$ SD) age was  $35\pm 9$  yrs and BMI was  $29\pm 6$  kg/m<sup>2</sup>. We observed strong  $h^2$  for AIR ( $72\%\pm 23$ ;  $p<0.0001$ ) and DI ( $56\%\pm 25$ ;  $p=0.005$ ) and significant  $h^2$  for 30'dINS ( $40\%\pm 20$ ;  $p=0.021$ ).  $h^2$  for insulin resistance as measured by  $S_I$  ( $33\%\pm 24$ ;  $p=0.09$ ) or homeostasis modeling (HOMA;  $8.7\%\pm 15$ ;  $p=0.52$ ) was not significant. Both BMI ( $78\%\pm 24$ ;  $p<0.00001$ ) and total body fat ( $48\%\pm 16$ ;  $p=0.0002$ ) exhibited strong heritability. Removing BMI as a covariate in the analyses of insulin sensitivity and secretion did not alter the results. The significant  $h^2$  for two independent measures of insulin secretion and a measure of b-cell compensation for insulin resistance suggest there are genetic determinants of the b-cell defect that predicts diabetes in our patients. Our findings support a genetic approach to identification of the fundamental cause(s) of this defect.

**Complex segregation analysis of obsessive-compulsive disorder in Mexican pedigrees.** *K.A. Weissbecker<sup>1</sup>, M.I. Green-Leibovitz<sup>1</sup>, B. Camarena<sup>2</sup>, G. Rinetti<sup>2</sup>, J. Ezzell<sup>1</sup>, D.K. Winstead<sup>1</sup>, H. Nicolini<sup>2</sup>.* 1) Dept. of Psychiatry and Neurology and Hayward Genetics Program, Tulane Med Ctr, New Orleans, LA; 2) Instituto Mexicano de Psiquiatría, Mexico City, Mexico.

Obsessive-Compulsive Disorder (OCD) is characterized by obsessions (intrusive and persistent ideas or thoughts) and compulsions (senseless, repetitive purposeful behaviors) which interfere with normal functioning. We explored the mode of inheritance of OCD and the effect different definitions of the affected phenotype had on the outcome of the analyses. Seventy-seven OCD patients were ascertained at the Instituto Mexicano de Psiquiatría, in Mexico. Psychiatric diagnoses were obtained from 523 relatives either by direct interview or the family history method. We performed a segregation analyses under class A logistic regressive models using the REGTL computer program (S.A.G.E.). Model 1 of REGTL, which presumes genotype (or "type") influences the age of onset of the disease state was implemented. Relatives of the probands were classified as affected by two phenotypic definitions and separate analyses were run. Under the narrow definition, only relatives with definite OCD were classified as affected (N= 34). The broader definition also classified relatives with "sub-clinical" OCD as affected (N=59). Individuals with sub-clinical OCD have excessive obsessions and/or compulsions, but there is little interference with normal functioning. Using the narrowly defined affected phenotype, the sporadic, all environmental and all Mendelian models were rejected when compared the unrestricted models which estimated transmission probabilities. Under the broad phenotype, the sporadic and environmental models were rejected, but not the Mendelian models. The codominant or arbitrary models, which allow for three age of onset distributions, did not significantly improve the likelihood of the data. The most parsimonious model was autosomal dominant with a very low disease allele frequency and a mean age of onset of 15.42 for the AA and AB genotypes with 57% penetrance. These analyses confirm the presence of a major gene in the etiology of OCD when sub-clinical OCD is included in the disease phenotype.

**Familial clustering of nephropathy in hereditary amyloidosis TTR Val30Met.** *J. Sequeiros<sup>1</sup>, L. Lobato<sup>1, 2, 3</sup>, I. Beirao<sup>2, 3</sup>, M. Silva<sup>2</sup>, P. Costa<sup>3</sup>, S. Guimaraes<sup>2</sup>, A. Sousa<sup>4</sup>.* 1) UnIGENe - IBMC, Univ Porto, Porto, Portugal; 2) Dept Nephrology, Hosp Santo Antonio, Porto, Portugal; 3) CE Paramiloidose, INSA; 4) Dept Pop Studies, ICBAS, UP.

Familial amyloid polyneuropathy type I, FAP, is due to a point mutation in the transthyretin gene (TTR Val30Met) and is inherited as an autosomal dominant. It manifests mainly as a peripheral neuropathy; renal disease can be present. We now studied the frequency and familial predisposition to kidney disease in FAP. A prospective survey in the 3 main regions of FAP in Portugal was conducted in 1990-2000. In the same period, FAP patients from other areas who developed end-stage renal disease (ESRD) and their affected relatives, were also followed. Proteinuria  $>0.3\text{g/l}$  or renal insufficiency (creatinine  $>1.2\text{mg/dl}$  or serum urea  $>50\text{mg/dl}$ ) were criteria for nephropathy, and proband the first ESRD patient in the family; 496 patients (247M/249F), 165 families, were evaluated. Nephropathy was present in 194 patients (87M, 107F), 39% FAP subjects studied, involving 86 kindreds. ESRD was found in 33 families, 47 (15M, 32F), 9.4% of all FAP patients and 24.2% of nephropatic. Outside the main areas we registered 27 kindreds with 34 ESRD patients. We ascertained 60 probands, and 276 patients in their families; 81 of the 158 patients with overt nephropathy had ESRD. In any area, there was a higher frequency of clinical nephropathy in families of probands, than in those without patients progressing to ESRD (46% vs 28%,  $p<0.01$ ); 32 probands had sibs on the study. In sibships of probands, 78% had renal features, half with ESRD. Among first-degree relatives, 56.4% presented renal features. Sibs had a higher proportion of ESRD ( $p<0.002$ ) compared to other 1st-degree relatives, a OR 5.3 (CI 95%: 1.716). In conclusion, (1) nephropathy was present in 1/3 patients from classical areas of FAP; (2) affected relatives, and particularly sibs, of ESRD patients were more prone to develop nephropathy. This familial aggregation of renal disease in FAP suggests the influence of additional genetic factors.

**Linkage disequilibrium maps of human chromosomes.** *A. Collins, N. Maniatis.* Human Genetics, Univ Southampton, Southampton, England.

Positional cloning of disease genes depends on linkage and allelic association (also called linkage disequilibrium or LD). Neither the linkage nor LD map is proportional to the sequence-based map. To the degree that LD reflects recombination it can extend the low resolution of the linkage map (a region with extensive LD might coincide with a recombination cold spot). We need an LD map to facilitate positional cloning, extend the resolution of the linkage map, compare populations and detect selective sweeps and other events of evolutionary interest. A key property of a chromosome map, whether physical or genetic, is that its distances are additive and we require a standard LD map to which population specific maps are roughly proportional with deviations that mirror the effects of gene frequency, selection, mutation, time and drift. The Malecot prediction of association ( $r$ ) is  $(1-L)Me^{-ed}+L$ , where  $L$  is the bias at large distance,  $M$  reflects mono or polyphyletic origin and  $e$  is the exponential decline of  $r$  with distance  $d$ . A natural measure for the length of the  $i^{\text{th}}$  map interval is  $e_i d_i$  where  $e_i$  estimates the Malecot parameter when the two markers that flank the interval are paired with all other markers and  $d_i$  is the length of the interval on the physical map in Kb. The minimal error variance from the regression of  $e_i d_i$  on the sex-averaged linkage map determines the optimal estimator of  $e_i$ . We consider here a number of ways to establish additivity of LD distances. Given an optimal LD map at higher resolution than the linkage map the LD information may be integrated within adjacent reference markers. Alternative approaches to establishing an LD map can be evaluated by comparing fit to the Malecot model. The optimal LD map, however obtained, should fit better than either the linkage map and, particularly, the physical map. Sequence-based maps that integrate sex-specific linkage maps have been created for human chromosomes 21 and 22. For LD mapping we used version 9 of the CEPH database. The marker spacing is near the limit for LD mapping but, for certain chromosome regions, is very useful for evaluation of alternative approaches. We present here our findings for these chromosomes.

**A simple genotype-quantitative phenotype relationship in humans: a case study of T cell receptor Vbeta6.7.** *K.R. Ahmadi<sup>1,2</sup>, M. Hall<sup>2</sup>, P.J Norman<sup>3</sup>, R. Vaughan<sup>3</sup>, T.D Spector<sup>1</sup>, J.S Lanchbury<sup>2</sup>*. 1) Twin Research & Genetic Epidemiology Unit, St.Thomas' Hospital, UK; 2) Molecular Immunogenetics Unit, Department of Rheumatology, GKT School of Medicine, King's College London; 3) South Thames Tissue Typing, Guy's Hospital, London, UK.

The success achieved in mapping monogenic disease genes has failed to carry over to diseases with complex etiology. Although sparse data exist, most of our knowledge concerning the relationship between an underlying genotype and its dependent quantitative phenotype has either come from model animal systems (bristle counts in *Drosophila*) or over-simplified population simulation studies.

The monoclonal antibody OT145, recognises an allotypic variant of the T cell antigen receptor beta chain variable region called VB6.7. Discounting factors such as experimental error and random noise, quantitative variation in the OT145-recognised epitope should be largely genetically determined. A 15-allele short tandem repeat (STR) marker is located in the first intron of the TCRVB6.7 gene. We measured VB6.7 as a quantitative trait and typed the VB6.7-associated STR in a sample of 45 identical and 73 non-identical female Caucasoid twin pairs.

The heritability of VB6.7 level was 86%. Linkage of the STR to VB6.7 wasn't detected, but the omnibus test of association was highly significant ( $p=1 \times 10^{-9}$ ). However, the association parameter only accounted for 24% of the total variance in VB6.7, leaving 62% of the variance unaccounted for. Through simulations, we show that the QTL heritability can only be fully represented by a marker that is in perfect linkage disequilibrium (LD) with the QTL, a measure which is independent of sample size. These results show that even for homogenous traits with high heritability and theoretically perfect genotype-phenotype correlation, association mapping of quantitative traits can be problematic. For the attributable effect to be quantified accurately with small sample sizes, sufficient LD must exist between marker and QTL alleles which must be in phase and comparable in frequency.

**Molecular analysis of haplotype diversity associated with haemoglobin E in Vietnam.** *R.K Basran, J.B Clegg, A.J Boyce, R.M Harding.* Institute of Molecular Medicine, University of Oxford, Oxford, England.

Haemoglobin E (b26 glu—>lys) is one of the most common haemoglobin variants in Southeast Asia. Its high frequency is probably due to the protection it confers against malaria. The frequency of Hb E in the S'Tieng, an ethnic minority group located in southern Vietnam with origins in Thailand, is 45%. The main aim of this study is to investigate the role of recombination and gene conversion in generating haplotype diversity associated with Hb E. The absence of Hb E in Africa and the Mediterranean where malaria is endemic suggests that the contribution to haplotype diversity of independent recurrent Hb E mutations is minimal.

Seven RFLPs distributed within 63 Kb of the b-globin gene cluster on chromosome 11 have been typed to determine the haplotypes of 210 Hb E chromosomes, all from individuals homozygous for Hb E. We have also inferred 62 haplotypes from normal chromosomes in individuals heterozygous for Hb E. Between five RFLPs (the 5' sub-haplotype) and two RFLPs flanking the b-globin gene (the 3' sub-haplotype) is a well characterized hotspot for recombination. We see different distributions of haplotypes associated with the normal and Hb E chromosomes. 67 % of the Hb E chromosomes are associated with the +/- 3' sub-haplotype, which only comprise 10% of the normal chromosomes. Hb E on the +/- 3' sub-haplotype associates with five different 5' sub-haplotypes, reflecting recombination at the hotspot. Of these, three haplotypes are common among Hb E chromosomes, but only one is common among normal chromosomes. Hb E is also found in association with the other three possible 3' sub-haplotypes (-/+, -/-, +/+) probably through gene conversion. We are also investigating the extent to which linkage extends from the hotspot (both 5' and 3') by typing SNPs up to 5 Mb away in individuals who have homozygous Hb E haplotypes. A panel of SNPs from the SNP Consortium database have been tested in the S'Tieng and only 37% of the characterized SNPs were found to be polymorphic in this population. Preliminary results indicate that linkage extends up to 1 Mb away from the mutation.

**Homozygosity of the prion Met129Val polymorphism increases risk of developing clinical early-onset but not late-onset Alzheimer's disease.** *B. Dermaut<sup>1</sup>, E. Croes<sup>2</sup>, M. Cruts<sup>1</sup>, M. Van den Broeck<sup>1</sup>, C.M. van Duijn<sup>1,2</sup>, C. Van Broeckhoven<sup>1</sup>.* 1) Department of Molecular Genetics, Flanders Interuniversity Institute for Biotechnology (VIB), University of Antwerp, Antwerpen, Belgium; 2) Department of Epidemiology and Biostatistics, Erasmus Medical Center, Rotterdam, The Netherlands.

The clinical distinction between familial early onset Alzheimer's disease (AD) and familial Creutzfeldt-Jakob disease (CJD) is sometimes difficult. In some cases, histopathological hallmarks of both disorders are observed simultaneously. Moreover, familial aggregation of CJD with dementia due to other causes than CJD has been reported repeatedly. These observations suggest that common pathogenic factors may underly both CJD and other types of dementia, including AD. As homozygosity of the Met129Val polymorphism in the prion protein gene (PRNP) is a well established genetic risk modulator of all types of human prion diseases, we investigated the role of this locus on the risk for developing AD. In two Dutch population based series of early (n=122) and late-onset AD (n=245), genotype frequencies of the PRNP Met129Val polymorphism were compared to an age matched control group (n=287 and n=244 respectively). Results were corrected for age and gender using logistic regression. Genotype frequencies were in Hardy-Weinberg equilibrium in both control groups ( $p > 0.2$ ). While we found no effect of the Met129Val polymorphism on the risk of late-onset AD, we observed a statistical significant influence of Met129Val in the group with early-onset AD. Using the Met/Val genotype as a reference, homozygosity resulted in a 1.81 times increased risk (95% CI 1.10-2.98;  $p = 0.02$ ). In Val homozygotes the risk of developing early-onset AD was 2.43 times increased (95% CI 1.15-5.11;  $p = 0.02$ ). These results suggest that PRNP Met129Val is genetically associated with clinically diagnosed early but not late-onset AD.

**Gene-environment interactions and linkage disequilibrium in familial analysis of complex diseases.** *V. Chaudru, M. Rosenberg, F. Demenais.* INSERM EMI 00-06, Evry, France.

Investigating gene-environment (GxE) interactions in chronic diseases is of interest once a disease gene has been mapped to a region where there is linkage disequilibrium (LD). Our goal was to assess by simulations : 1) how LD can influence the power to detect GxE, 2) how ignoring GxE can affect detection of LD.

Affection status, environmental factor and marker data were simulated in 165 nuclear families of varying size. The liability to the disease was generated under a model including a disease gene interacting with an environmental factor, a polygenic component and random environment. The proportion of total variance due to each component was : 15% for the gene, 15% or 25% for GxE component, 30% or 35% for the polygenic component, the remaining being due to random environment. The disease prevalence was 10%. Four models were considered for the disease gene : 2 dominant models with allele frequency ( $q$ ) equal to 0.1 or 0.3 and displacement between homozygous means,  $t$ , of 1 or 0.78 and 2 recessive models with  $q$  being 0.3 or 0.5 and  $t$  equal to 1.35 or 0.99. We generated a tightly linked SNP with allele frequencies equal to the disease gene frequencies and varying LD with that gene : no LD ( $D/D_{max}=0$ , where  $D$  is the measure of LD), CLD ( $D/D_{max}=1$ ), ILD ( $D/D_{max}=0.5$ ). One hundred replicates of family samples were generated for each set of parameters. Segregation-linkage analyses of the simulated data were conducted using the regressive threshold model.

When there is CLD, power to detect GxE is greater than 90%. When there is ILD, the power to detect GxE is only reduced to 90% when  $q < 0.3$  and  $t > 1$ . However, this power is decreased to 60% when  $q = 0.5$  with weak GxE and drops to 40-50% when  $t < 1$ . When there is no LD, the power decreases to 50%-75% for  $q < 0.3$  and  $t > 1$  and to 20-35% when  $q = 0.5$  or  $t < 1$ . Alternatively, ignoring an existing GxE in the analysis may affect the detection of the true LD model : CLD is correctly detected in  $> 70\%$  of replicates while ILD is supported in 40-60% of cases. Taking into account both GxE and LD appears of importance in analysis of complex diseases.

**The 4002AtoG polymorphism of the CFTR gene can interfere with the detection of the common 1282X and 3905insT mutations that occur within exon 20: Implications for carrier screening.** *Y.K. Goldberg<sup>1</sup>, S. Brown<sup>2</sup>, S. Nakagawa<sup>1</sup>, L.H. Kellner<sup>1</sup>, S.J. Gross<sup>1</sup>, H.M. Nitowsky<sup>1</sup>.* 1) Dept Ob-Gyn; Montefiore Medical Ctr, Bx, NY; 2) Dept Ob-Gyn; Columbia University NYC, NY.

Population screening for carriers of cystic fibrosis mutations (CFM) is becoming increasingly common, and a variety of molecular strategies for the detection of CFM in the CFTR gene have been developed. A multiplex PCR/oligonucleotide ligation assay (Applied Biosystems(ABI)), allows for the simultaneous detection of 31 common CFM. In the course of screening approx. 3600 persons, we have noted that in 0.3% the amplicon containing exon 20 fails to amplify. Individuals in whom exon 20 failed to amplify were shown to be homozygous for the previously described 4002AtoG polymorphism that occurs within exon 20. Although the polymorphism is silent and presumably neutral, its presence evidently interferes with PCR amplification within the context of the ABI CFM assay. Failure to amplify is easily detected in homozygous (PCR products are absent) but presumably remains undetected in heterozygotes. Therefore, CFM occurring in cis with the polymorphism will not be detected using this assay. Hardy-Weinberg equilibrium predicts that about 10% of all persons in our population are carriers of the 4002AtoG polymorphism. This is significant since the 1282X CFM, which is present in about 1/40 (2.5%) of Ashkenazi Jewish (A.J.) individuals, occurs within exon 20. The extent to which carriers of the 1282X CFM are misdiagnosed as normal with the ABI assay depends on the degree to which there is linkage-disequilibrium (LD) between 1282X and 4002AtoG. We studied the frequency of the 4002AtoG polymorphism in our A.J. population. In a series of 137 persons, we found that 10 are heterozygous for the 4002AtoG polymorphism as determined by PCR amplification followed by restriction digestion. This indicates that our prediction of heterozygote freq. for the 4002AtoG polymorphism (based on the number of persons failing to amplify exon 20 with the ABI assay) appears to be correct and needs further investigation. We are now determining the degree to which there is LD between 1282X and 4002AtoG.

Program Nr: 1317 from the 2001 ASHG Annual Meeting

**Linkage disequilibrium in human populations and the design and interpretation of association studies.** *D.B. Goldstein, M. Weale, C. Capelli, J. Wilson.* Biol/Galton Lab/Wolfson House, Univ Col London, London, England.

The appropriate design and interpretation of association studies requires detailed information about the patterns of linkage disequilibrium (LD) in human populations. Here we use published and unpublished data to assess the distribution of LD as a function of genetic distance between sites in multiple genomic regions in multiple Eurasian populations, focusing attention on the implications for study design and interpretation. We also describe a quantitative framework for assessing the expected power of association studies based on the observed distributions of LD.

**Fine-mapping strategies using sequential optimal parameter selection.** *R.B. Martin, K. Yu, S. Lewitzky, A. Parker, J. Meyer.* Human Genetics, Millennium Pharmaceuticals Inc, Cambridge, MA.

For complex disorders, linkage genome scans typically are able to localize a disease susceptibility locus to within a region of around 20-30cM. Once such a region has been identified, fine-mapping often proceeds using linkage disequilibrium (LD) analysis applied on a series of increasingly dense marker maps. However, it remains unclear for general situations how marker location, allele frequency, and number of markers can be chosen to optimize this fine-mapping process.

We propose a fine-mapping strategy that can be used in conjunction with single-point LD methods by describing marker choice as a sequential optimal parameter selection problem. Using linkage information as a prior to guide marker location, an initial set of markers is selected and analyzed, and significance levels are corrected for multiple testing taking into account observed gametic disequilibrium. The algorithm terminates if either a stopping criterion involving significance is met or if the number of iterations becomes too large, else it repeats with an expanded set of markers. Marker selection may be controlled both by linkage disequilibrium estimates calculated during the process and by initial linkage data.

The aim is to maximize the probability of stopping within a small region surrounding the disease susceptibility locus, in which maximal LD exists due to the presence of untrimmed ancestral haplotypes descended from a common founder. By optimizing marker selection and employing a sequential testing strategy, we hope to minimize the number of markers used and thus avoid multiple testing problems that could make it difficult or impossible to detect the disease susceptibility locus. The method is benchmarked using simulated data based upon a study of schizophrenia in a Finnish population.

**Association analysis: within-sibship sampling variation and solutions.** *C. Li, M. Boehnke.* Dept Biostatistics, Univ Michigan, Ann Arbor, MI.

In classical case-control studies, we sample independent affected and unaffected individuals and tally their alleles (or haplotypes) into a  $2 \times k$  table, where  $k$  is the number of alleles. We then test for independence between the alleles and affection status, or equivalently, for equal distribution of alleles in the affected and unaffected groups.

Often we sample affected siblings and other relatives of the affected individuals to do linkage analysis for the disease of interest. The affected relatives' information is not used in case-control studies, resulting in inefficient use of data.

We propose two methods to use efficiently genotype data of affected sibships. One is to count all alleles of an affected sibship, but down-weight the sibship so that its total allele contribution is 2. The relative efficiency of this method vs. the standard one is 1.3 for sib pairs and 1.5 for sib trios. The Pearson's chi-squared test can be performed as usual. We also introduce a likelihood ratio statistic and a permutation test.

Another method is to down-weight an affected sibship of size  $k$  so that its total contribution is  $4k/(k+1)$  (Broman 2001 *Genet Epidemiol* 20:307-315). Under no linkage and no association, the resulting allele frequency estimates have the smallest variance among all weighted averages of individual sibship allele frequencies. It is slightly more efficient than the first method if we have sibships of variable sizes. However, given tight linkage, this method may over count alleles for larger sibships and inflate the type I error rate.

Analytical and simulation results show that these methods are more powerful than using just case-control data under a variety of sibship sizes and disease models. Further, when we have data of affected siblings, selection of one affected individuals per sibship in the standard method is quite arbitrary and introduces variability. For example, for an allele of frequency 0.05, it is not unusual to have frequency estimates varying from 0.039 to 0.061 for 200 sib pairs.

**Association analysis by data mining tools.** *P.A. Onkamo*<sup>1</sup>, *P. Sevon*<sup>1,2</sup>, *V.V. Ollikainen*<sup>1</sup>, *H.T.T. Toivonen*<sup>3</sup>, *H. Mannila*<sup>3</sup>, *J. Kere*<sup>1</sup>. 1) Finnish Genome Center, University of Helsinki, Finland; 2) Department of Computer Science, University of Helsinki, Finland; 3) Nokia Research Center, Helsinki.

We have previously developed a data-mining based method, Haplotype Pattern Mining (HPM), to find trait- or disease-associated patterns in densely mapped family or case-control data (AJHG 67: 133-145, 2000). Here, we demonstrate the practical utility of this approach for fast and easy evaluation of association in gene mapping studies. Also, we present a refined method for assessing the ancestral haplotypes and their contribution to the overall association, the TreeDT. The HPM algorithm finds trait-associated haplotype patterns, possibly containing gaps. All patterns found are ordered by their strength of association to the phenotype, and the patterns exceeding a given threshold level are used for prediction of gene location. The list of associated patterns can be used to deduce the number, lengths, and relevance of the ancestral haplotypes to the trait association. The significance of markerwise association scores can be evaluated by a permutation procedure implemented in the program. The method is scalable to any kind of markers, including SNPs. It can be used for populations with different kinds of histories, given that the marker map is dense enough to have marker-marker linkage disequilibrium. The traits may be either binary (categorical) or quantitative. The algorithm is very fast, so, for example, scanning a data of 80 microsatellite markers and 450 chromosomes takes approximately one minute on a Sun Ultra 10 workstation. This also enables high numbers of iterations to be done on permutation tests. The TreeDT is based on discovering and assessing tree-like patterns in genetic marker data similar to the input for HPM. By the TreeDT approach, the historical recombinations, i.e., the coalescent history of a chromosomal area is estimated. The resulting trees are evaluated with a specific tree disequilibrium test. Compared to HPM, TreeDT gives a more detailed picture of the association of specific haplotypes. We have found it to be more powerful than HPM in certain situations, particularly if several founder mutations are present in the data (Sevon et al., in press).

**The use of linkage disequilibrium measures for discriminating between two subpopulations of the North-Netherlands.** *I.M. Nolte, G.J. te Meerman.* Medical Genetics, University of Groningen, Groningen, Netherlands.

Some years ago, Van der Meulen and te Meerman (1997) developed a multi-locus method for measuring linkage disequilibrium between markers. It is based on excess haplotype sharing over the linkage equilibrium expectation. Haplotype sharing was defined as the number of markers that two haplotypes share going from a locus both in telomeric and in centromeric direction. The mean sharing of all pairs of haplotypes is compared with the mean haplotype sharing under linkage equilibrium (LE). The LE expectation is simulated by randomizing the observed alleles over the haplotypes independent of other loci. We tested this linkage disequilibrium measure on both simulated and empirical data. Firstly, haplotypes were simulated according to a Markov chain with a variety of different inter-marker correlations in order to test the validity and the sensitivity of this measure. Secondly, haplotypes were obtained from several projects for which we collected DNA of trios. These trios had to come from the three provinces Friesland, Groningen and Drente in the North-Netherlands. From linguistic studies, it appeared that there are differences between the two subpopulations of Friesland and Groningen. We therefore selected unrelated Friesians and Groningers on the basis of postal codes of their grandparents. This yielded so far 92 Groninger and 763 Friesian haplotypes. LD was determined in the Groninger haplotypes and in 100 subsets of 92 randomly selected Friesian ones. P-values for the tests whether there is more LD in the Friesians were determined by use of randomization statistics. It appeared that indeed the Friesians form a more homogeneous population, as LD in the Friesian haplotypes is significantly stronger than in Groninger haplotypes. In the near future, we hope to compare these results with LD in the Hutterites in order to get an idea of the strength of LD in these two populations. Van der Meulen, M.A. and te Meerman, G.J. 1997. Association and haplotype sharing due to Identity by Descent, with an application to genetic mapping. In Genetic mapping of disease genes (eds. Pawlowitzki, I-H., Edwards, J.H. and Thompson, E.), p 115-135. Academic Press, London.

**SNP analysis of the human chromosome 22 using APEX arrays.** A. Metspalu<sup>1</sup>, J. Zernant<sup>2</sup>, E. Lõhmussaar<sup>1,2</sup>, R. Mägi<sup>2</sup>, K. Kepp<sup>1</sup>, T. Puurand<sup>2</sup>, N. Tõnisson<sup>2</sup>, I. Valvas<sup>2</sup>, H. Pavel<sup>2</sup>, G. Slavin<sup>2</sup>, R. Andreson<sup>1,2</sup>, A. Kurg<sup>1</sup>, M. Remm<sup>1,2</sup>.  
1) Dept Biotechnology, Univ Tartu\Estonian Biocentre, Tartu, Estonia; 2) Asper Ltd. Tartu, Estonia.

Sequence variants in the human genome are responsible for the genetic component of disease, individuality and drug response. In order to find associations between SNPs and phenotype, large sample sets need to be genotyped with high-density markers. Large-scale, population-based case-control studies have been limited because neither SNP maps nor genotyping technology have been adequate to fulfill these needs yet. With chromosome 22 fully sequenced and an SNP map constructed, we have performed genotyping on Estonian samples and CEPH families with 1279 SNP markers. An array with 5200 oligonucleotides was spotted to genotype each SNP twice from both DNA strands simultaneously using APEX technology. Allele frequencies, Hardy-Weinberg equilibrium and heterozygosities were calculated for each typed marker. Software was developed to calculate  $D'$  for the whole 33Mb of ch22 and GOLD (*Graphical overview linkage disequilibrium*) plots were constructed. Preliminary results demonstrate that LD is not continuous, and there are islands with high LD separated by low LD spots. Also, the APEX genotyping technology itself was tested by generating over 270 000 genotypes. It appears that SNPs from TSC will need additional testing to find out useful SNPs in respect of the technology and genetics.

**The USH1C gene in Acadians contains at least three rare variants.** *B.J. Keats<sup>1</sup>, S. Savas<sup>1</sup>, B. Frischhertz<sup>2</sup>, M.Z. Pelias<sup>1</sup>, M.A. Batzer<sup>3</sup>, P.L. Deininger<sup>2</sup>.* 1) Department of Genetics, Louisiana State University Health Sciences Center, New Orleans, LA; 2) Tulane Cancer Center, Department of Environmental Health Sciences, New Orleans, LA; 3) Louisiana State University Biological Computation and Visualization Center, Baton Rouge, LA, USA.

Mutations in the USH1C gene, which encodes harmonin, are associated with Usher syndrome type IC (USH1C). In Acadian patients, a mutation (216G>A) was identified in exon 3 and a 45 base pair variable number of tandem repeat (VNTR) polymorphism was found in intron 5 of the USH1C gene. The Acadian patients were found to be homozygous for the 9-repeat allele of this VNTR, which had an unusual structure. PCR-amplification of the VNTR region and restriction enzyme analysis of exon 3 showed that this 9-repeat VNTR is in complete linkage disequilibrium with the 216G>A mutation in exon 3 in the Acadian population. Of 58 unaffected and unrelated Acadians, one was heterozygous for the 9-repeat VNTR allele and the 216G>A mutation, indicating that the disease frequency may be as high as 1 in 14,000 in this population. Analysis of 340 random samples from five ethnic groups (African, African-American, Asian, European, Hispanic) showed the presence of a 9-repeat VNTR in only one Hispanic sample. Thus, the 9-repeat VNTR allele is rare in populations around the world. The Hispanic individual did not have either the 216G>A mutation or the Acadian VNTR structure, suggesting that the 216G>A mutation and the associated 9-repeat Acadian VNTR are restricted to the Acadian population. Additionally, analysis of haplotype data for surrounding markers shows significant linkage disequilibrium over more than six centimorgans, supporting a fairly recent origin of both the 216G>A mutation and the 9-repeat Acadian VNTR in the Acadian population.

**Incorporating parental phenotypes into the quantitative TDT.** *B.S. Maher, M.M. Vanyukov, R.E. Ferrell, M.L. Marazita.* University of Pittsburgh, Pittsburgh, PA.

The transmission disequilibrium test for quantitative traits (QTDT) is a powerful method for analyzing association between genetic markers and quantitative traits. An advantage of the QTDT is that it avoids spurious association due to population stratification. A major disadvantage of QTDT is the need to collect parental genotypes, or sibs to reconstruct parental genotypes. This problem is magnified in several situations (e.g., late age-of-onset). To address these difficulties, several methods have been proposed to eliminate the need for parental genotypes in the family based framework. The focus here is the situation in which parents are readily available and can be easily and inexpensively phenotyped. One potential advantage of collecting parents is the incorporation of parental phenotypes into the QTDT. We explored the power gain from using parental phenotypes as covariates in the QTDT. Specifically, we included parental phenotypes using two approaches. In the first approach, we incorporated both parents phenotypes as covariates in the QTDT as proposed by Rabinowitz (*Hum Hered* 1997; 47: 342-350). In the second, we treated each parental transmission separately while using a trait value equal to the residual of the regression of the offspring phenotype on the opposite (non-transmitting) parent's phenotype. Additionally, we applied the method to parent-child trios collected as part of our ongoing research into the liability to Attention Deficit Hyperactivity Disorder.

**When is the bias caused by population stratification negligible?** *R. Jiang, J. Dong.* Dept Mathematical Sci, Michigan Technological Univ, Houghton, MI.

Population stratification is always a concern in association analysis. It is well documented that case-control samples from non-homogeneous populations could cause bias in association measures. There are three possible remedies. The first one is to match cases and controls. It is difficult to know how much matching between cases and controls is enough. The second is to use family based methods, like the transmission/disequilibrium test. For late onset diseases, collecting family data is difficult. The third is to test the existence of population stratification by using unlinked markers. Since population stratification does not always cause significant bias, we believe that it is better to estimate the bias itself than to test the existence of population stratification. Our goal is to provide a formula for practitioners to estimate the bias caused by population stratification in individual situations. They can decide whether the bias is negligible, and whether further remedies need to be taken. Our method is to consider a homogeneous and a non-homogeneous populations with the same allele frequencies, penetrances, and prevalences. The non-homogeneous population consists of  $k$  subpopulations with different allele frequencies etc. We then find a formula for the ratio of an association measure  $p(\text{excess})$  in homogeneous and non-homogeneous populations. Our conclusions are: The farther the marker locus is from the disease locus, the larger the bias will be. The older the disease mutation is, the larger the bias will be. Thus, the smaller the linkage disequilibrium is, the larger the bias will be. For the purpose of fine mapping, population stratification is not a serious problem if the disease is not too old (less than 400 generations old) and the maximum genetic distance between the marker and disease loci is less than one cM. There is also no need to take population stratification into account if the genetic distance is less than two cM and the disease mutation is less than 200 generations old. In case-control studies, in order to avoid false positives caused by population stratification, it is enough to stratify the sample according to large ethnic groups. It is unnecessary to further stratify Caucasians according to their ethnicity.

**The Use of the Disposition Model For Genetic Analysis. II. Regression of Genetic Markers on Disease Status in Case-Control and Sib-Pair Studies.** *J. Kwagyan, V. Apprey, G.E. Bonney and Statistical Genetics and Bioinformatics Unit. Natl Human Genome Ctr, Howard Univ, Washington, DC.*

Sib-pair analysis is a tool widely used for the genetic determination of complex diseases. Affected sib-pairs should share alleles IBD more often than expected under random Mendelian segregation. In practice, the situation is more complicated because one cannot unambiguously determine the number of alleles shared IBD at every position along the genome. Methods for sib-pair analysis are primarily based on studying individual genetic markers one at a time. When data on controls are available, it is usual to use them only for association studies and to ignore them in linkage analysis. Conversely, in regression analysis to determine the association of markers with a given disease, the dependence among sib-pairs is ignored or a member of one affected pair is chosen. Association and linkage may be mixed in a way difficult to distinguish in practice. Here, we study an application of the disposition model of Bonney 1998, which allows for within-individual and between-sib dependence in the regression analysis of genetic markers on disease status in case-control and sib-pair studies, separately or simultaneously. Within-person dependence measures departures from Hardy-Weinberg equilibrium; between-sibs dependence modeled in terms of IBD measures departures from no linkage; while the regression of the logit of the population allele frequency on disease status and other covariates permits the assessment of marker disease association. A structured model fitting process is introduced allowing these effects to be assessed in turn. The calculations are implemented in the computer package, G.E.Ms.

**Logistic Regression analysis for case/control genetic association studies: combining genetics and epidemiology. F.**

*Macciardi*<sup>1</sup>, *A. Morabito*<sup>3</sup>, *E. Mundo*<sup>1</sup>, *B. Lerer*<sup>2</sup>. 1) Neurogenetics Section, CAMH, Clarke Division, Dept. of Psychiatry, University of Toronto, Toronto, ON, Canada; 2) Biological Psychiatry Laboratory, Hadassah Medical Organization, Hebrew University, Jerusalem, Israel; 3) Dip di Medicina, Chirurgia ed Odontoiatria, Universita' di Milano, Milano, Italy.

The ultimate goal of genetic association studies is to identify gene(s) responsible for a given disease. To detect a genetic association the easiest design is the case-control approach, which usually applies a chi-square analysis to look at the significance of an association. The design is simple and does not depend on any population genetic theory or model, other than the one that the strength of an association between genes increases when physical and genetic distances between them decrease. The major problem with the case-control design is the identification of an appropriate control sample to avoid spurious associations due to potential confounding factors related to population admixture or stratification. To deal with these issues, various methods have been proposed, such as the use of unrelated polymorphisms together with the candidate marker(s) to evaluate the extent of "random" association (Devlin & Roeder, 1999). We propose an alternative approach to detect genetic association with a case-control design, based on the application of a logistic regression (LR) model. The LR model allows for the simultaneous consideration of risk and/or qualitative and quantitative confounding factors. The LR outcome is equivalent to the Mantel-Haenszel test (MH) for multiple contingency tables or to other procedures, like the Cornfield test. Moreover, the LR approach has the advantage that allows for multiple confounding factors, which may or may not show a combined or complex interaction effect on the outcome measure. A working example of the LR approach is provided and compared with the simpler M-H and Cornfield statistics, showing that the major advantage of LR concerns the estimate of the Odds Ratios.

**Linkage Disequilibrium in the Mixe Amerindians and Han Chinese across three large genomic regions.** *K.A. Mather, G. Thomson.* Integrative Biology Department, The University of California, Berkeley, CA.

Analysis of a northern European population reveals regions of several cM with a high density of markers in linkage disequilibrium (LD). In ten regions of the genome, this clustered LD is greater than that found in the HLA (Human Leukocyte Antigen) region (Huttley et al., *Genetics* 152:1711-22). The high LD regions identified are likely to be experiencing selection in the Caucasian population, making them good candidates in a search for regions experiencing selection in other populations. However, if selection pressures vary among populations evolving in different environments, patterns of LD may not be consistent between populations. It is therefore of interest to determine if the high LD regions identified in Caucasians also exhibit high LD in other populations with different demographic histories.

We analyzed LD in two non-Caucasian populations (Mixe Amerindians from the Oaxaca valley in Mexico and Han Chinese) for regions on chromosomes 6 (the HLA region), 20 (a control region that did not show high LD in the Caucasian population), and 22 (a region of high LD in the Caucasian population). The Mixe population is small and isolated. In contrast, the Han population has historically been larger, less isolated, and have experienced more population growth. These populations have been separated for relatively long amounts of time, so it is likely that each population has been subject to distinct selective pressures. We examined eleven (CA)<sub>n</sub> microsatellite markers spaced about 0.5 Mb apart in each region for forty individuals from each population. We measured the amount of LD in each region relative to the HLA region. We found that LD patterns are (a) heterogeneous among regions on chromosomes 6, 20 and 22 and (b) different among Caucasian, Han and Mixe populations for a given region. These results show that LD patterns are both population specific and species wide.

**Family-based tests of gene-gene and gene-environment interaction for general nuclear family configurations.** *S.L. Lake, N.M. Laird.* Biostatistics, Harvard School of Public Health, Boston, MA.

While assuming that disease susceptibility is principally due to one genetic locus has been used with much success in mapping studies, this assumption may not suffice when exploring the role candidate genes play with other genes and/or exogenous factors in modifying disease risk. In these cases, tests that detect gene-gene and gene-environment interactions are required.

We present a simple test statistic that can be used to study genetic interaction. It is applicable to any type of nuclear family configuration (eg missing parental information and/or multiple (un)affecteds), while still retaining the robust properties of family-based association tests. The method is sensitive to interactions on the multiplicative scale. Statistical inference is provided through a permutation algorithm that produces valid p-values while avoiding tenuous asymptotic assumptions.

The method is illustrated and compared to other approaches via simulation and by application to the family data of the Childhood Asthma Management Program (CAMP). Of interest in the CAMP study is the identification of genes and environmental exposures that may act synergistically in the development of childhood asthma.

**Association analysis of angiotension I-converting enzyme (ACE)-gene polymorphisms with blood pressure. X.**

*Zhu<sup>1</sup>, D. Yan<sup>2</sup>, A. Luke<sup>1</sup>, A. Weder<sup>3</sup>, A. Chakravarti<sup>2</sup>, R.S. Cooper<sup>1</sup>.* 1) Preventive Med & Epidemiology, Loyola Univ Medical Ctr, Maywood, IL; 2) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 3) Division of Hypertension, University of Michigan, Ann Arbor, MI.

The angiotension I-converting enzyme (ACE) gene polymorphisms have been studied intensely in cardiovascular disease (CVD), although the genes contribution to CVD is still being defined. In this study, we sampled 611 and 640 individuals from 188 African-American and 155 White families, respectively. We genotyped 6 polymorphisms within the ACE gene. Single polymorphism association analysis showed marginal association between diastolic blood pressure and one of the polymorphisms in White population ( $p=0.04$ ). Haplotypes were then resolved using the program SIMWALK2 in two populations separately. The cladistic analysis between ACE activity and haplotypes defined two clades which had a significantly differently effect on ACE activity in both populations. Using the two clades, we performed association analysis with BP again. Significant evidence of association to DBP was found for white sample ( $p=0.02$ ), and marginal evidence of association to DBP was found among African Americans ( $p=0.05$ ). This finding of an association between the ACE gene and DBP is consistent with our recent finding in a Nigerian sample. In conclusion, we found that the ACE gene variants associated with ACE activity also affect blood pressure.

**Distribution of Crohn's disease susceptibility haplotypes in European families.** *H. Zouali<sup>1</sup>, S. Lesage<sup>1</sup>, M. Chamaillard<sup>1</sup>, JP. Czarnd<sup>2</sup>, J. Belaiche<sup>3</sup>, S. Almer<sup>4</sup>, C. Tysk<sup>5</sup>, C. O'Morain<sup>6</sup>, M. Gassul<sup>9</sup>, R. Modigliani<sup>7</sup>, JF. Colombel<sup>8</sup>, M. Sahbatou<sup>1</sup>, G. Thomas<sup>1</sup>, JP. Hugot<sup>1</sup>.* 1) Fondation Jean Dausset, Paris, France; 2) Paris, France; 3) Liege, Belgium; 4) Linkping, Sweden; 5) Rebro, Sweden; 6) Dublin, Ireland; 7) Paris, France; 8) Lille, France; 9) Barcelona, Spain.

**Background** : IBD are complex genetic disorders of unknown aetiology. The NOD2 gene was recently identified as a susceptibility gene for Crohns disease. Three NOD2 gene mutations were identified on the same common background.

**Aim** : To estimate the distribution of the 3 CD susceptibility haplotypes in Europe. **Patients and Methods** : A total of 232 CD families recruited through a large European consortium were genotyped for 8 intragenic SNPs located within the NOD2 gene. Haplotypes were build using the GeneHunter package. The 4 haplotypes defined by the same common background were considered. Three of them carrying each of the 3 mutations R675W, G881R or 980fs981X and one haplotype without any of these variants were analysed using one CD patient per family. Haplotypes were classified in 5 groups according to either the geographical origin of the patient ancestors or the recruitment country: France (n=117), Belgium (n=20), Scandinavia (Sweden and Denmark, n=7), SEC (South European Countries including Italy, Spain, Portugal and North of Africa, n=20), and Mixed (patients with ancestors originating from France and an other country, n=16). The frequencies of the 4 haplotypes within the groups were compared by a Chi square test. **Results** : A significant difference was observed in the haplotype distribution ( $\chi^2=21,6$ , ddl=12,  $p<0,05$ ). The haplotype carrying the 980fs981X mutation was more frequent in France and Belgium when compared to the other groups and was not found in Scandinavia. **Conclusion**: The results do not argue for a single founder effect in Europe. Genotyping strategies of the NOD2 gene for genetic diagnosis must be adjusted according to the country of origin.

**Classifying Disease Chromosomes Arising From Multiple Founders.** *K. Yu<sup>1</sup>, R. Martin<sup>1</sup>, J. Meyer<sup>1</sup>, A. Whittmore<sup>2</sup>.*  
1) Human Genetics, Millennium Pharmaceuticals, Cambridge, MA; 2) Health Research and Policy, School of Medicine, Stanford University, Stanford, CA.

With the increasing availability of high-density marker data, various fine-scale mapping methods have been proposed for using haplotype information to locate disease susceptibility loci. In the setting of the case-control study, samples of case and control haplotypes are collected, and the locus (or loci) for the disease mutation is estimated by comparing haplotype structure among cases to that among controls. One practical difficulty arising in such haplotype mapping is founder heterogeneity; that is, not all case chromosomes inherit a disease-causing mutation from the same ancestral chromosome. One approach to dealing with founder heterogeneity is to separate case haplotypes according to their mutational origins before doing genetic mapping. We propose a non-parametric clustering method to accomplish this goal. The method finds one cluster at a time, with the cluster consisting of case haplotypes that are most likely to share a common founder.

The clustering algorithm has three steps. First, a top-down peeling procedure is used to find a sequence of subsets that are candidates for a cluster. Then, a random permutation procedure is used to find an 'optimal' subset from those candidates. Finally, a bottom-up pasting procedure is used to expand the optimal subset by adding back haplotypes that were mistakenly removed during early stages of the peeling process until a stopping rule is met. Once a cluster has been found, the same procedure can be applied to the remaining set of haplotypes to find other possible clusters. Simulation analyses suggest that in situations with moderately strong ancestral effects (i.e., more than half of the case haplotypes from the same founder), the method can accurately identify the largest group of haplotypes that are descendants from a common founder. Further simulations are being conducted under genetic models more appropriate for complex disorders, based on a study of schizophrenia in a Finnish population.

**Using estimates of individual admixture to study the genetics of phenotypic traits: skin pigmentation in African Americans.** *C.L. Pfaff<sup>1</sup>, E.J. Parra<sup>1</sup>, J. Ye<sup>1</sup>, A. Massac<sup>2</sup>, R.A. Kittles<sup>2</sup>, M.D. Shriver<sup>1</sup>*. 1) Department of Anthropology, Pennsylvania State University; 2) National Human Genomes Center at Howard University.

The availability of molecular panels has been important in the practical application of most genetic mapping methods. Here we report on a panel of ancestry-informative markers (AIMs) that demonstrate high allele frequency differences between Africans and Europeans. These AIMs can be used to estimate the European and African proportional ancestry at the population sample level, subgroup level (e.g. cases and controls for a dichotomous phenotype), and individual level. Estimates at both the subgroup and individual level can be very instructive regarding the genetics of the phenotypes of interest and provide the foundation for mapping the genes underlying these traits (Admixture Mapping). Using skin pigmentation as a model phenotype, we demonstrate how such studies could proceed. We typed 21 AIMs, of which 4 were candidate genes for skin pigmentation differences between Africans and Europeans, in a sample of African American individuals from Washington, DC. The allele frequency difference between Africans and Europeans ranged from 36% to 99.7%. We observed a strong correlation between estimates of individual admixture and skin pigmentation (measured by the melanin index). When analyzed individually, 9 of the AIMs, including 2 candidate genes, showed significant association with skin pigmentation. The high rate of association between AIMs and an ancestry-dependent phenotype, in this case skin pigmentation, indicates that the trait is genetic, and that there is a significant degree of population structure in the sample. In order to correct for this structure, we used the estimate of individual admixture as a covariate. After making the correction, only one candidate gene, oculocutaneous albinism type 2 (OCA2), remained significant, and none of the other AIMs showed association. These results indicate that OCA2 is one of the genes contributing to the differences in pigmentation levels between African and European populations.

**Generating haplotype data with pre-specified pair-wise LD and allele frequencies.** *A. Wille*<sup>1, 2</sup>, *T.F. Wienker*<sup>1</sup>. 1) IMBIE, Bonn University, Bonn; 2) Laboratory of Statistical Genetics, Rockefeller University, New York.

Linkage disequilibrium (LD) mapping using SNPs has proven to be a valuable tool for fine-mapping of disease genes. However, the variation of LD in intensity and range makes it impossible to describe dense sets of SNP markers sufficiently without taking simultaneously into account information on pairwise LD of all marker pairs. Due to its dependencies on marker distance, cross-over interference and grossly reduced informativity of bi-allelic markers, LD between adjacent markers does not determine LD among all marker pairs, although markers are arranged in a linear order on the chromosome.

Correlation among markers influences the performance of fine-mapping methods and simulation studies evaluating this performance should model LD among sets of markers realistically. Here, we explore an approach based on the EM algorithm to generate haplotype data with pre-specified pairwise LD among all markers and pre-specified allele frequencies.

For haplotypes comprising  $k$  bi-allelic loci, the restriction imposed on the data ( $k$  values for allele frequencies and  $k(k-1)/2$  values for the pairwise LD) can be viewed as incomplete data specification that corresponds to multiple complete data specifications of haplotype frequencies. Thus, the EM algorithm provides a mean to determine the maximum likelihood estimate of haplotype frequencies conditional on LD and allele frequency realizations.

The maximum likelihood estimates can then be used directly, or as parameters in an underlying Dirichlet distribution, to generate haplotype data with the pre-specified values of pairwise LD and allele frequencies.

**Strategies for Genome-wide Association Studies: Optimization of Study Designs by Stepwise Focusing Method.** A. Saito, N. Kamatani. Division of Statistical Genetics, Institute of Rheumatology, Tokyo Women's Medical University, Tokyo, Japan.

**Purpose:** Recently, genome-wide association or linkage disequilibrium (LD) studies have attracted much attention because of the introduction of high-throughput genotyping systems. However, the limitations of such studies are often the total cost for the genotyping or the sample size. Therefore, it is important to estimate the optimal conditions for the study given the limited number of individuals or the limited amount of the cost for the genotyping. In the present study, we have developed "stepwise focusing method" a new approach for such studies and estimated the conditions that give the maximum statistical power.

**Materials and Methods:** Stepwise focusing method consists of two (or more) steps. In the first focusing step, the samples from both case and control groups are genotyped at a certain number of SNP markers (for example 50,000), and the markers that showed significant inter-group differences by the chi-square test using 2x2 allele number table at a relatively high p-value (for example 0.1) are selected. It means that most of the selected markers in the first step are likely to be the false-positive markers. In the second step, the markers selected in the first step are tested using the samples obtained from a different set of case-control samples. In the second step, a larger number of subjects and a lower p-value are used for the selection of the markers. We performed an extensive simulation studies to estimate both the type I error rate and the power of the test using various parameters such as genotype relative risk, disease allele frequency, sample size, and so on.

**Results and Conclusions:** When there are limitations in such conditions as sample size and total number of genotypings, the stepwise focusing method turned out to give the optimal conditions and be more powerful than the conventional methods.

**Estimation of small map distances using chromosome data from an isolated population.** *N.H. Chapman<sup>1</sup>, J. Crumley<sup>3</sup>, T.M. Fujiwara<sup>2,3</sup>, K. Morgan<sup>2,3</sup>, E.A. Thompson<sup>1</sup>.* 1) University of Washington, Seattle, WA; 2) McGill University, Montreal, QC; 3) Research Institute of the McGill University Health Centre, Montreal QC.

Modern sex-averaged genetic maps are based on 8 of the CEPH families, in which 184 meioses are scored. Maps are therefore of limited precision, and the order of some markers cannot be resolved. Misspecification of the marker map leads to bias in multipoint linkage analysis, and accurate fine-scale maps are desirable for linkage disequilibrium mapping. We present a novel approach to the estimation of small map distances, using the pedigree of a large isolated population (North American Hutterites), and simulated genetic data on chromosomes sampled from that population.

A *junction* is a point on a chromosome where DNA from two distinct ancestors meets. Junctions are formed when a crossover event occurs in a region where the two parental chromosomes are not identical by descent relative to the founder population. Therefore the number of junctions accumulated in an interval contains information about the genetic length of the interval. We sample individuals from the population, and count the number of junctions in the interval of interest on each of their chromosomes. Using the pedigree for these individuals, we calculate the expected value, variance and covariance of the number of junctions existing in that interval on each chromosome. These moments depend only on the genetic length  $d$  of the interval. We use a quasi-likelihood approach to model data consisting of junction counts in the interval whose length we wish to estimate, on  $2n$  chromosomes from  $n$  individuals of the population.

Our approach results in unbiased estimates of  $d$ , and good estimates of the variance of the estimate. The standard deviation of the estimate based on a dataset of 200 chromosomes from 100 randomly selected Hutterites is approximately half that for the traditional estimate based on 184 meioses in the CEPH pedigrees. We also describe some of the challenges involved in extending this approach to more realistic data.

**Markov chain Monte Carlo methods for the calculation of likelihoods in genetic linkage studies.** *A.W. George<sup>1</sup>, M. Bogdan<sup>1</sup>, E.M. Wijsman<sup>2</sup>, E.A. Thompson<sup>1</sup>.* 1) Statistics, University of Washington, Seattle, WA; 2) Division of Medical Genetics, University of Washington, Seattle, WA.

Mapping disease genes via linkage analyses requires the calculation of likelihoods on pedigrees which often contain missing marker phenotypes, inbreeding loops and highly polymorphic regions of linked markers. For such data the space of underlying inheritance patterns, upon which exact and sampling based calculations are based, is huge and tightly constrained by observed marker phenotypes. Consequently, exact likelihood computations are intractable and sampling based methods suffer irreducibility and convergence problems. Presented is a sampling based method for the estimation of likelihoods in general pedigrees. This estimation process is less susceptible to mixing problems due to the inclusion of a number of recent advances in Markov chain Monte Carlo methods, namely joint updates of the patterns of inheritance across loci and meioses, integrated proposals, Metropolis-Hastings restarts via sequential imputation and Rao-Blackwellization estimators. The methodology is assessed through its application to three sets of real data originating from a genetic study into Early-Onset Alzheimers disease. Two of the data sets consist of three linked markers inviting comparison with exact results. The third data set demonstrates the true potential of the methodology where a gene is mapped relative to 11 tightly linked markers. Work supported by NIH grant GM-46255.

Program Nr: 1338 from the 2001 ASHG Annual Meeting

**Optimal Study Designs for Detecting and Replicating Susceptibility Loci using Affected Sib-Pair Linkage Analysis.** *M.E. Smolkin, L.W. Hahn, J.L. Haines, J.H. Moore.* Program in Human Genetics, Vanderbilt University, Nashville, TN.

Minimizing type I errors (i.e. false-positive results) is of primary interest in the linkage analysis of complex multifactorial diseases. Cross-validation (CV) is an approach to minimizing type I errors that has been applied to a variety of linkage studies, most commonly by distributing families into a group used to detect susceptibility loci and an independent group used to verify or replicate the linkage findings. For a single major locus, equal sample sizes provide the most power. However, the percentage of families in each group that is required to maximize power for detecting multiple loci is not currently known. To investigate this question, we simulated a 10cM map in 1200 affected sib pairs. We simulated 100 datasets for each of four different two-locus models (dominant by dominant, dominant by recessive, recessive by recessive, and additive) using previously published disease allele frequencies and penetrance functions (Goldin and Weeks, *AJHG* 53:908-915, 1993). Each functional locus was located on a different chromosome and tightly linked to one marker. Additional complex models are under study. We randomly divided each dataset into a detection group and a replication group ranging in sample size from 100 to 1100 and 1100 to 100, respectively. For each division of the data we assessed the power of affected sib-pair linkage analysis to detect and to replicate each functional locus using an MLOD of 1.0 as the criterion for statistical significance. For the models studied, we found that detection and replication datasets of equal size provided the maximum power to both detect and replicate the susceptibility loci. These results validate that the common approach of using equally sized datasets may in fact be the optimal approach.

**Comparison of age at diagnosis, histologic subtype, and site of tumor in patients with familial vs. sporadic non-Hodgkin lymphoma.** *C.M. Vachon, T.M. Habermann, J.R. Cerhan.* Mayo Clinic, Rochester, MN.

A family history of hematolymphoproliferative malignancies has been associated with an increased risk of non-Hodgkin lymphoma (NHL). However, there are few data on the characteristics of familial versus sporadic NHL. Using the NHL registry at the Mayo Clinic, we conducted a study to compare clinical characteristics (age at diagnosis, histologic subtype, and primary site of NHL) between patients with sporadic and familial NHL. In 2001, we identified all new cases of adult NHL diagnosed between 1986 and 2000 at the Mayo Clinic and mailed out a family history questionnaire to those not known to be deceased. The questionnaire solicited extensive family history information on lymphoma and leukemia in all first-degree ( $1^{\circ}$ ) relatives. Each NHL patient was classified into one of four family history (FH) categories based on their self-report of leukemia or lymphoma in  $1^{\circ}$  relatives: no FH, FH of lymphoma, FH of leukemia, FH of both lymphoma and leukemia. We identified 2038 living cases of NHL diagnosed between 1986 and 2000 for the mail-out questionnaire; of these, we had a current address on 1790. We received complete FH information on 1241 patients (69%). Age at diagnosis of NHL ranged from 17-89 years (mean=65 yrs.) and 54% of our cases were male. First-degree FH of lymphoma was reported by 72 patients (6%),  $1^{\circ}$  FH of leukemia by 50 patients (4%) and  $1^{\circ}$  FH of both in 12 (1%), comprising 167  $1^{\circ}$  relatives with leukemia or lymphoma. FH was most often reported in a brother (35% of time for lymphoma, 39% for leukemia and 50% for both). There was no association between histologic subtype (diffuse, follicular, small lymphocytic, high-grade or peripheral T-cell) or site of NHL (nodal versus extranodal) and  $1^{\circ}$  FH. However, there was an association between age at diagnosis and  $1^{\circ}$  FH (p-value=0.04); patients with no FH had an earlier age at diagnosis than patients with a FH (mean=62.9 for no FH vs. 66.2, 68.3, 64.5 for FH of lymphoma, leukemia and both, respectively). This association has also been seen in a population-based case-control study of NHL and is contrary to evidence from other cancer sites that illustrate earlier ages at onset for genetic forms of cancer.

**Sibling risk ratios and correlations of social and cognitive traits in autistic sib pairs.** *R.M. Cantor-Chiu<sup>1</sup>, M. Alarcon<sup>2</sup>, D. Geschwind<sup>2</sup> and AGRE Consortium.* 1) Human Genetics; 2) Neurology, UCLA, Los Angeles, CA.

Autism is genetically complex with an early childhood onset and a sibling relative risk estimated between 45 and 150. The disorder is characterized by repetitive-restricted behaviors and deficits in language and social skills. Results of genome scans of the autism diagnosis have been inconsistent. Sub-phenotypes of autism displaying a significant sibling risk ratio (srr) or correlation (sc) within autism affected sib-pairs, are good candidates for linkage analysis and can be useful for stratification of families in efforts to reduce heterogeneity. We estimated the srr of categorical items and sc of quantitative items of the Autism Diagnostic Interview (ADI) in 152 affected sibling pairs from The Autism Genetic Resource Exchange (AGRE; Geschwind et al., 2001). The fraction of positive responses to an item (p1) was estimated in the first-born autistic sibs (fbs). P2 is the fraction of positive responses in the second born autistic sibs (sbs) of only positive fbs.  $Srr = p2/p1$ . Items specifically addressing obsessive and compulsive manifestations were tested. While .19 of fbs resisted trivial changes in their environment, .53 of their sbs showed similar resistance ( $srr = 2.76, p = .00001$ ). .50 of fbs and .66 of sbs exhibited a repetitive use of objects ( $srr = 1.33, p = .01$ ). Srr estimates for 1) problems with changes in routine, 2) presence of compulsions and rituals, and 3) unusual preoccupations, were not increased. Special musical talent was seen in .18 of fbs and .33 of their sbs ( $srr = 1.8, p = .04$ ). Quantitative ADI items assessing cognitive development and exhibiting significant sibling correlations were: age at first word ( $r = .32, p = .0006$ ), age at first phrase ( $r = .26, p = .02$ ) and their difference ( $r = .23, p = .05$ ). While these srr estimates are lower than those for the autism diagnosis, fewer genes may contribute to these more specific phenotypes and individual genes may have higher srrs. As with all genetically complex disorders, the effects of common sibling environment, which can be estimated from the study of autistic twins, may be responsible for these significant risk estimates and correlations.

**Attention-Deficit/Hyperactivity Disorder (ADHD): Power simulations to detect linkage in extended pedigrees in the Paisa community of Colombia.** *M. Arcos-Burgos*<sup>1,2</sup>, *F.X. Castellanos*<sup>3</sup>, *F. Lopera*<sup>2</sup>, *D. Pineda*<sup>2</sup>, *L.G. Palacio*<sup>2</sup>, *K. Berg*<sup>1</sup>, *J. Bailey-Wilson*<sup>1</sup>, *M. Muenke*<sup>1</sup>. 1) NHGRI, NIH, Bethesda, MD; 2) University of Antioquia, Medellin, Colombia; 3) NIMH, NIH, Bethesda, MD.

Twin, adoption, family and association studies have shown that genetic factors contribute to the etiology of Attention-Deficit/Hyperactivity Disorder (ADHD). Several of these studies converge in explaining the predisposition to ADHD as the consequence of a Mendelian major gene. Additionally, purely environmental or cultural causes have been excluded. We have collected pedigree data on ADHD from multigenerational families with the goal of genetically mapping a putative gene predisposing to ADHD. All ADHD phenotypes were based on DSM-III and DSM-IV criteria. Here, we present the results of a power simulation using SIMLINK to detect linkage of ADHD to simulated marker loci in these families. ADHD was assumed as a dichotomous trait with incomplete penetrance and a phenocopy rate of 3% in males and 0.2% in females. We simulated cosegregation of the trait and a marker locus in our pedigrees with a set of recombination fractions. The ADHD trait was assumed to be genetically heterogeneous between pedigrees and different proportions of families linked to the same loci (alpha) were assumed. As shown in Table 1, in 27 of the most informative families, a LOD of 27.41 ( $\alpha=100$ ,  $\theta = 0.0$ ) was estimated. Even with an  $\alpha$  value of 25% at a  $\theta$  value of 0.05 enough power to detect linkage is observed for these pedigrees. These data demonstrate the relative benefits of using extended and multigenerational families for genetic mapping studies in ADHD as opposed to using nuclear or sporadic cases. Table 1.

Theta	eLOD 25%	eLOD 50%	eLOD 75%	eLOD 100%
0	2.40	7.45	16.00	27.41
0.05	2.15	5.87	12.08	19.56

**A comprehensive analysis of ch.6p21-22 region in multiple sclerosis (MS).** *L.F. Barcellos<sup>1</sup>, J.L. Haines<sup>2</sup>, J.B. Rimmler<sup>3</sup>, S. Caillier<sup>1</sup>, R.R. Lincoln<sup>1</sup>, M.A. Pericak-Vance<sup>3</sup>, S.L. Hauser<sup>1</sup>, J.R. Oksenberg<sup>1</sup>.* 1) University of California, San Francisco, CA; 2) Vanderbilt University Medical Center, Nashville, TN; 3) Duke University Medical Center, Durham, NC.

An underlying and complex genetic susceptibility plays a clear role in multiple sclerosis (MS) etiology. The HLA-DR2 haplotype (DRB1\*1501 DQB1\*0602) within the major histocompatibility complex (MHC) on chromosome 6p21 has consistently demonstrated both linkage and association with MS in family and case-control studies. Several recent reports of MS and other HLA-associated autoimmune diseases including type 1 insulin dependent diabetes (IDDM) and inflammatory bowel disease (IBD) suggest the presence of a second susceptibility locus telomeric to HLA-DR near microsatellite marker D6S461. In this study, 404 rigorously ascertained MS families were examined (total genotyped individuals=1864) comprised of 98 multiplex (total affecteds=271, ASPs=172) and 306 simplex families. An initial screen of 6p21-22 was performed in multiplex families using 24 markers spanning approx. 20 Mb. Linkage and association (using pedigree disequilibrium test or PDT) to HLA-DR (MLS=3.9, q=0.15; p=0.01 respectively) and nearby markers G51152 and TNFB (MLS=2.9, q=0.20 and 2.5, q=0.20; p=0.02 and 0.01, respectively) was observed. Modest evidence for linkage to D6S461 (MLS=2.4, q=0.20), located 10 Mb telomeric to HLA-DR, was also present. HLA-DR, D6S461 and 3 flanking markers (D6S1691, D6S1050 and D6S1029) were also examined in simplex families. Although a strong DR association was detected ( $p < 10^{-7}$ ), significant results for other markers were not observed in simplex or combined family datasets. The combined dataset was also stratified based on DR2 status in affected members to identify potential interaction effects within the 6p21-22 region; none were detected. Though modest linkage to D6S461 was found in multiplex families, it was restricted to DR2 positive families only, and can be attributed to the close proximity of this marker to DR. Although an additional gene (s) within the MHC may modulate clinical expression in a subset of patients, our findings do not support the presence of a second MS susceptibility locus near D6S461.

**Candidate gene validation and disease gene identification in a population from Northern Sweden.** *M. Holmberg, J. Jonasson, K. Lejon.* UmanGenomics, Umea, Sweden.

The molecular tools required to dissect complex disease are becoming available. Discovery genetics, expression analyses and animal models now generate large numbers of candidate genes that may predispose to or cause complex disease. The next critical step is to associate variations in the candidate genes with the appropriate disease phenotype. The essential factors in association studies of complex disease is the population structure, the number of well defined cases available for analysis, and last but not least the quality of the controls. The powerful approach of using unrelated cases and controls is limited by the ability to find adequately matched controls. The optimal controls can be identified in a prospective population-based cohort where there is no bias in the selection of cases and controls. UmanGenomics has access to a 15 years old prospective population-based Biobank, collected from the relatively homogenous population of Vasterbotten in Northern Sweden. The Biobank contains DNA and Plasma samples and biochemical and life style data from >66.000 individuals. The Biobank is integrated with high quality disease registers, and today a substantial number of well characterized cases of common diseases like diabetes, myocardial infarction, stroke and prostate cancer are available. Cases can be matched with controls collected under identical conditions with identical biochemical and environmental information available, which ensure that optimal controls are selected - a prerequisite for success in association studies of complex disease. Furthermore, a number of subphenotypes of disease including glucose tolerance, blood lipid levels, blood pressure etc. has already been determined for all 66.000 individuals and other biochemical markers can be analysed in the plasma fraction. This allows for the association of less genetically complex phenotypes to genetic variation. UmanGenomics resources are ideally suited for association studies of complex disease. We will in detail describe the advantage of our Biobank for candidate gene validation and present our program for disease gene identification.

**Testing for population subdivision in four large case-control cohorts.** *K.L. Lunetta<sup>1</sup>, R.S. Wells<sup>1</sup>, M. Seielstad<sup>2</sup>, K. Ardlie<sup>1</sup>*. 1) Genomics Collaborative, Inc, Cambridge, MA; 2) Harvard School of Public Health.

Population subdivision is often implicated as a cause of the high number of false-positive disease-marker associations reported in the literature, but to date few if any carefully matched case - population control samples have been rigorously examined to determine if detectable population subdivision is present. Here, we investigate population subdivision in four large case-control samples. A total of 3486 individuals were genotyped for 9 unlinked microsatellite markers chosen to have maximal allele frequency differences among populations. 40 additional random unlinked SNPs are currently also being genotyped. The patient samples consist of 1) 500 US Caucasians with hypertension 2) 500 US Caucasians NIDDM patients 3) 500 Polish NIDDM patients, and 4) 243 US African Americans with hypertension. For all samples, controls were matched 1:1 to individual cases on age, sex, self-reported ethnicity, and, in the US samples, geographic region in which they reside. In the African American sample, we required both parents and all four grandparents of cases and controls to be self-reported African American. In each sample, we tested for substructure using the sum of the individual Pearson  $\chi^2$  statistics comparing case and control allele frequencies for the nine microsatellite markers. We found no evidence for stratification in any of the samples: p-values for the four samples were .63, .34, .48, and .97, respectively. While these markers should have reasonable power to detect relatively obvious substructure, they are unlikely to detect more subtle stratification. The additional 40 SNPs typed for the same individuals will improve our power to detect lower levels of stratification, and will provide a comparison with the microsatellite results.

Our results suggest that carefully matched case-population control samples similar to our US Caucasian, African American, and Polish samples are unlikely to contain gross levels of substructure that would result in large numbers of false positive associations.

**A comparison of cost-effectiveness between microsatellite and single nucleotide polymorphism markers in genomewide linkage disequilibrium testing.** *J. Ohashi, K. Tokunaga.* Dept Human Gen, Grad Sch Med, Univ Tokyo, Tokyo, Japan.

Microsatellite (MS) markers are expected to be more powerful for linkage disequilibrium (LD) testing, compared to single nucleotide polymorphism (SNP) markers. However, more SNPs can be analyzed at the same cost because of the low-cost genotyping. Although the efficiency in LD testing has been compared between MS and SNP markers, the efficiency should be determined by a cost-effectiveness, or resources of money in the study. In order to address this problem, a simple deterministic model is used for the calculation of LD between marker and disease alleles. Here, mutation at the marker locus and recombination between the marker and disease loci are assumed in the model. For the comparison of MS and SNP markers, a statistical power with a proper significance level of  $\alpha$ , corrected by the number of testing, is calculated based on chi-square statistic. The obtained power is largely dependent on the initial situation (e.g., allele frequencies of the disease and marker loci). Also, the power is influenced by the number of testing when the Bonferroni correction is applied. As the number of markers is increased, the genetic distance between the disease and the marker loci is decreased. Although LD between them becomes strong with decreasing the genetic distance, the power is not always increased due to the Bonferroni correction. The present model will provide a guideline for selecting a suitable genetic marker in genomewide LD testing when the resources of money are limited.

**Genomic Control Methods to Adjust for Population Stratification for Candidate-Gene Association Studies.** *S.L. Slager, D.J. Schaid.* Mayo Clinic, Rochester, MN.

Large-scale case-control studies will be required to find genes of modest effect. However, since unrelated controls may be used, these studies may be affected by population stratification and therefore be subject to an increased false positive rate. To correct for the effect of population stratification, some adjustment to the candidate-gene test statistic ( $T$ ) is necessary. Assuming the candidate gene has two alleles, Devlin and Roeder (*Biometrics* 55:997, 1999) proposed a simple adjustment,  $T/l$ , which asymptotically follows a  $\chi^2$  distribution with 1 df. The quantity  $l$  is estimated from a distribution of  $m$  independent statistics,  $Y_i$ , for  $i=1, \dots, m$ , where  $Y_i$  is generated by testing the association between the trait and the  $i$ th diallelic "null" marker. These  $m$  null markers are assumed to be independent of the disease of interest and of each other. If there is no population stratification effect, the expected value of  $l$  is 1; otherwise it is greater than 1. Devlin and Roeder's proposed method and the method proposed by Reich and Goldstein (*Genet Epi* 20:4, 2001) estimate  $l$  using only the first moment of the marker distribution, but an improved correction can be obtained by using both the first and second moments. A precise correction is important because it can affect the false positive rate or power of the candidate-gene test statistic (for example, a correction that is too large results in a candidate-gene test that is too conservative). We present new methods to estimate  $l$ , as well as new methods to better approximate the distribution of  $T/l$ . The power and the type I error rate of each adjusted candidate-gene test — using the proposed methods — are computed from simulated data and compared with those that were previously proposed by Devlin and Roeder (1999) and Reich and Goldstein (2001).

**A comparison of the power of the variance components method and revised Haseman-Elston method in the presence and absence of non-random ascertainment.** *Y. Yao*<sup>1</sup>, *A. Sorant*<sup>2</sup>, *A. Wilson*<sup>2</sup>. 1) Epidemiology Department, Bloomberg School of Public Health, Johns Hopkins University, Baltimore, MD; 2) NIH/NHGRI, Baltimore MD.

Although the variance components (VC) method has been suggested as one of the more powerful methods to detect linkage when pedigrees are randomly selected, the power is likely to be reduced when the assumption of a multivariate normal distribution of the underlying trait locus is violated, as under non-random ascertainment. The revised Haseman-Elston (RHE) method, which regresses the cross product of the siblings mean-corrected phenotypes on the proportion of alleles shared IBD, is reported to provide greater power than the traditional H-E method without inflating type I error rate. In this study, the statistical properties of both methods were evaluated, and the power to detect linkage and the type I error rate of the VC and RHE methods were compared under random and non-random ascertainment. In addition to random sampling, we selected families with three ascertainment methods: selecting families with at least one offspring with phenotype exceeding a given threshold (H1); at least two offspring whose phenotypes exceed the threshold (H2); and extremely discordant offspring, one whose phenotype exceeds a high threshold and one whose phenotype is below a low threshold (ED). Results show that the VC and RHE methods have similar power to detect linkage under random ascertainment. For the models considered, the power of the VC method was often increased under ascertainment method H1, but consistently reduced under methods H2 and ED. The power of the RHE method was consistently increased under H1 and ED, but slightly reduced under H2. This comparison can potentially serve as a guideline for choosing statistical approaches in mapping quantitative traits.

**Little Evidence for Bias Due to Population Stratification in a Population-Based Study of Non-Hispanic Blacks and Whites.** *J.S. Pankow<sup>1</sup>, M.A. Province<sup>2</sup>, S.C. Hunt<sup>3</sup>, D.K. Arnett<sup>1</sup>*. 1) Division of Epidemiology, University of Minnesota, Minneapolis, MN; 2) Division of Biostatistics, Washington University School of Medicine, St. Louis, MO; 3) Cardiovascular Genetics, University of Utah, Salt Lake City, UT.

Undetected population stratification may increase the probability of finding spurious associations in genetic studies of unrelated individuals, but the magnitude and relative importance of this bias is unclear. We conducted association tests for 6 common phenotypes (obesity, hypercholesterolemia, hypertension, diabetes, renal dysfunction, and cardiovascular disease (coronary heart disease or stroke)) using 368 highly polymorphic markers typed for a genome-wide scan. The study population included 444 unrelated subjects (231 non-Hispanic blacks, 213 non-Hispanic whites) randomly selected from 5 U.S. communities as part of the Hypertension Genetic Epidemiology Network (HyperGEN) of the NHLBI Family Blood Pressure Program. Phenotype prevalences ranged from 9% for renal dysfunction to 50% for hypertension, while prevalence ratios comparing blacks versus whites ranged from 2.4 for renal dysfunction to 0.7 for hypercholesterolemia. In crude analyses pooling both ethnic groups, the percentage of markers statistically significantly associated with diabetes (8.4%), hypertension (7.9%), and renal dysfunction (7.6%) was somewhat higher than that expected under the null hypothesis (5.0%). However, the percentage of associated markers did not exceed 6% for any of the phenotypes after controlling for self-reported ethnicity. Summary tests for population stratification (Pritchard and Rosenberg, 1999) incorporating all 368 markers were statistically significant for diabetes, hypertension, and renal dysfunction in crude analyses, but not after adjustment for ethnicity. These data provide little or no evidence that undetected stratification within self-reported ethnic groups led to an increased probability of finding spurious associations in our study population. Other factors such as gene-environment interactions, linkage disequilibrium, and chance may be more likely explanations for inconsistencies between genetic association studies.

**Comparison of the distributions of FMR1 alleles in a normal population and in a population with cognitive disorders.** *A.H. Alegria, L. Rengifo, H. Serrano, D. Gaviria, E. Aguilar.* Basic Sci, Fac Med, Univ Tecnologica de Pereira, Pereria, Risara, Pereira, Colombia.

The Fragile-X syndrome is one of the most frequent causes of mental retardation in humans and is associated with a fragile chromosomal site at Xq27.3. This fragility is due to the expansion of a repetition 5-(CGG)  $n-3$  that occurs naturally in the 5 UTR region of FMR1 gene. The distribution of this repeat is between 6 and 60 for normal individuals, between 60 and 200 for premutated alleles and more that 200 for affected individuals. A number between 41 and 60 is considered intermediate. We studied the distribution of normal, intermediate and premutated alleles for patients with cognitive and behavior disorders, and for healthy individuals in Risaralda Colombia SA, using PCR and Southern blot techniques. The population with behavior disorders corresponds to cases of autism, autistic behavior, mental retardation excluding Fragile X, learning disorders and attention disorders. We compared the results in the two populations, using statistical analysis. For the normal population, 1171 alleles corresponding to 364 women and 443 men were considered, and for the population with behavior disorders the sample contained 284 alleles of 80 women and 124 men. The proportions of normal, intermediate and premutated individuals in the sample of the normal population were 97.8%, 1.9% and 0.3% respectively. In the population with behavior disorders, the percentages of normal, intermediate and premutated alleles were 97.5%, 1.4% and 0.35% respectively. The most frequent case was 30 repetitions in both groups, with 79.6% of the cases in the normal population, and with 72.44% of the cases in the population with behavior disorders. A test of difference of variances was made, and it was found that the difference is not statistically significant. Given equal variances, the means were compared and it was determined again that there was no significant difference. Finally the proportions of normal, intermediate and premutated individuals were compared in both populations and it was found that they are statistically equal.

**Associations between putative risk factors and Alzheimers disease according to gene polymorphisms using a large case control study.** *Z. Yamagata<sup>1</sup>, S. Tang<sup>1</sup>, Y. Shindo<sup>1</sup>, Y. Takeda<sup>1</sup>, T. Mizutani<sup>1</sup>, T. Asada<sup>2</sup>.* 1) Department of Health Sciences, Yamanashi Medical University, Yamanashi, Japan; 2) Department of Psychiatry, Tsukuba University, Japan.

We evaluated the association between putative risk factors and Alzheimers disease (AD) according to gene polymorphisms. The subjects were 407 patients (168 men and 239 women: age at onset  $69\pm 10$ ) with a diagnosis of probable AD based on the NINCDS-ADRDA criteria and 398 spouses (162 men and 236 women: age  $69\pm 9$ ) of the subjects served as a control. The risk factor interview was developed specifically for this study to assess 17 putative risk factors. APOE gene polymorphisms were determined by the polymerase chain reaction restriction fragment length polymorphism (PCR-RFLP) method. The triplet (CGG) repeat polymorphisms of very low-density lipoprotein receptor genes (VLDLr) were genotyped by the PCR fragment analysis software of Long Read Tower<sup>TM</sup> sequencer. The estimating odds ratio and the multiple logistic analysis were performed by SAS statistic analysis package to evaluate the association. This study was conducted after obtaining written informed consent from the subjects or their guardians. The genetic analysis revealed that the AD was associated with VLDLr as well as APOE: the odds ratio was 2.98 for the e4 allele. The frequency of the 5-repeat allele of VLDLr was significantly higher in AD than in the control ( $p < 0.04$ ). The odds ratio for 5-repeat allele was 1.56 (95% CI=1.32-1.78). Some of the putative risk factors including aging, family history of AD, education years, napping and the death of a partner were confirmed as risk factors for AD. Though most of these risk factors were not interactive with gene polymorphisms, onset age was associated with APOE but not VLDLr. In addition, limited habitual napping for up to 60 min had a protective effect against the development of AD especially for carriers of the APOE e4 (OR=0.49, 95% CI=0.33-0.73).

**A Comparison of Two Methods for Detecting Interactions Among Genetic Polymorphisms in Matched Case-Control Studies.** *C.S. Coffey<sup>1</sup>, P.R. Hebert<sup>2</sup>, J.H. Moore<sup>3</sup>, M.D. Ritchie<sup>3</sup>, H.M. Krumholz<sup>2</sup>, T.M. Morgan<sup>2</sup>, J.M. Gaziano<sup>4</sup>, P.M. Ridker<sup>4</sup>.* 1) UAB School of Public Health, Birmingham, AL; 2) Yale Univ School of Medicine, New Haven, CT; 3) Vanderbilt Univ School of Medicine, Nashville, TN; 4) Brigham and Women's Hospital, Harvard Medical School, Boston, MA.

A matched case-control study is often used to investigate associations between genetic polymorphisms and risk of disease. Traditionally, when many polymorphisms are of simultaneous interest, conditional logistic regression models have been used to examine interactions and estimate appropriate relative risks. However, it becomes difficult to fit a model and examine interactions if the number of polymorphisms of interest becomes moderately large. The Multifactor Dimensionality Reduction Method (Ritchie et al. *AJHG* 69, 2001) eliminates this high dimensionality problem, allowing simultaneous examination of a large number of genetic polymorphisms. However, it is not possible to estimate relative risks using this method if more than two groups are required to adequately summarize the data.

Researchers must weigh the strengths and weaknesses of the two approaches when choosing an analysis plan for a particular study. In this presentation, we illustrate how the two methods may be combined to give a clearer overall picture than that obtained using either method alone. We illustrate the use of the two methods with an analysis from the Physicians Health Study. The study was conducted to examine possible interactions among the angiotensin converting enzyme (ACE) insertion/deletion, plasminogen activator inhibitor-1 (PAI-1) 4G/5G, and tissue plasminogen activator (tPA) insertion/deletion gene polymorphisms on risk of myocardial infarction. The overall results for the two methods were consistent, with both methods suggesting an interaction between the ACE I/D and PAI-1 4G/5G polymorphisms on the risk of MI.

**Non-Parametric Alternatives For Mapping Quantitative Trait Loci Using Genome-Wide Scan Data: Statistical Comparisons and an Application to Slow Beta EEG Waves.** *S. Ghosh*<sup>1</sup>, *B. Porjesz*<sup>2</sup>, *H. Begleiter*<sup>2</sup>, *T. Reich*<sup>1</sup>. 1) Dept Psychiatry, Washington Univ Sch Medicine, St Louis, MO; 2) Dept Psychiatry, State Univ New York Health Science Center, Brooklyn, New York.

Non-parametric linkage analysis is more robust than parametric analysis because of its insensitivity of trait distributional assumptions. We have explored two non-parametric methods, one based on ranks (Randles and Wolfe 1979), and the other based on kernel smoothing [KS] (Silverman 1986) for mapping quantitative trait loci using genome-wide scan data on sib-pairs. Our statistical procedure exploits the empirical relationship between the squared difference in sib-pair trait values and the estimated multipoint identity-by-descent scores at different points on the genome. We have developed suitable test statistics for linkage corresponding to the two methods. We have compared these methods with the linear regression [LR] method of Elston et al. (2000) using Monte-Carlo simulations and have shown that our methods are more robust with respect to assumptions underlying trait genotype-specific expectations, variances and epistasis. When there are deviations from the assumptions, the KS method outperforms the LR method. However, as expected, when the assumptions are satisfied, the LR method is more powerful, but only marginally, in detecting linkage than the KS method. Although the rank-based method does not yield high power, it is more powerful than the LR method when there are deviations from distributional assumptions. We have used the KS method to analyze data on Slow Beta EEG waves collected by the Collaborative Study on the Genetics of Alcoholism project. We have obtained statistically significant signals of linkage (evaluated using bootstrap) on Chromosomes 1, 4, 5 and 15. Although many of the linkage peaks are also obtained by the linear regression strategy, the p-values corresponding to the peaks are lower for the KS method, indicating a greater sensitivity of the KS method. We have also investigated the presence of epistatic interactions between regions exhibiting significant linkage. Evidence of epistasis was found between regions on Chromosomes 1 and 4 with those on Chromosome 15.

**A simulation-based method for applying standard statistical tests to extended pedigree data.** *N.J. Camp*<sup>1,2</sup>, *J.M. Farnham*<sup>2</sup>. 1) Genetic Research, IHC, UT; 2) Genetic Epidemiology, University of Utah, UT.

Standard statistical tests such as contingency table analysis, Armitage's trend test, McNemar's test (TDT), regression analysis (quantitative TDT) and survival analysis are valid only when individuals used in the analyses are independent. If biologically related individuals are used, the variance estimates for these statistics are biased and can lead to an increase in type I error. Large extended pedigree resources, ascertained primarily for prior linkage analysis, contain affected individuals with high likelihood of being genetic in nature. Unfortunately, their relatedness invalidates tests such as those mentioned above. Validity can be regained by randomly sampling a single case from each pedigree, but this leads to severe loss of informativeness and power. Extensions to some of the methods listed above, usually for specific pedigree types, have been proposed (Abecasis et al, 2000, George et al, 2000, Martin et al, 2000, Slager and Schaid, 2001). Here we propose a simulation-based approach which is general for both resource structure (mixtures of singletons to large extended pedigrees can be used) and statistical test. The initial step is to select the cases and controls to be used in the chosen test. This can range from a few from each pedigree to all possible. The statistic of interest is then computed for the observed (real) data, for example, a chi-squared statistic for a case-control or TDT, or a t-statistic for a coefficient in a regression. To assess the significance of this observed statistic, an empirical null is simulated. Estimates for allele frequencies (genotype frequencies) are calculated from the total resource, and these values are used to perform a gene-drop through the pedigrees. The resulting genotypes constitute a null genotypic configuration and these are used to calculate a null statistic. Repeating this several hundred times, an empirical null distribution is created and the significance of the observed statistic can be evaluated.

Our method is intuitively simple to understand, flexible in the types of tests to which it can be applied and allows for maximal use of the information in an extended pedigree resource.

**Estimation and Comparison of Ordered Allele Frequencies from Case-Control and Sib-Pair Data.** *G.E. Bonney, V. Apprey, J. Kwagyan.* National Human Genome Ctr, Howard Univ, Washington, DC.

We present results from a systematic study of the estimation of genetic marker allele frequencies when the samples are non-random as in case-control and sib-pair studies, and when the alleles may be ordered by their sizes. Association studies, non-parametric linkage analysis and recent molecular techniques allowing for the measurement of a large number of alleles at each marker locus have created a need to examine the estimation of gene frequencies from such non-random samples. An implication of Hardy-Weinberg equilibrium, commonly assumed in classical and recent approaches, is the random association of alleles in the gene pool during the formation of genotypes. Case-control, sib-pair and other non-randomly selected samples of individuals are not generally representative of the gene pool. In our work, we start with a theoretical definition of population allele frequency that is actually implicit in classical formulations. The definition immediately points to the natural, unbiased and efficient estimator and its standard error, both with explicit formulas. Samples of individuals or well-characterized family units such as sib-pairs may be used. An assumption of Hardy-Weinberg equilibrium is not required. The dependence within such units is automatically taken into account. Another problem created by modern molecular analysis is the large number of alleles ordered by size measured at each locus, which generates very sparse data. We use our formulas to create charts from the empirical distribution function. The chart shows which alleles ordered by size that may be effectively combined. This way of combining alleles is less ad hoc than existing methods. The calculations have been programmed in G.E.MS. Some data on chromosome 20 markers and type 2 diabetes are used as illustration.

**Lack of evidence for familial aggregation of breast and prostate cancer in the Minnesota Breast Cancer Family Study using a correlated frailty model approach.** *D.M. Grabrick, T.M. Therneau, J.R. Cerhan, C.A. Janney, R.A. Vierkant, T.A. Sellers.* Health Sci Research, Mayo Clinic, Rochester, MN.

Evidence for familial clustering of breast and prostate cancer is mixed. We conducted a multisample cohort study of prostate cancer within an existing study of 426 multigenerational families ascertained through female probands diagnosed with breast cancer between 1944 and 1952. Three groups of males were sampled: 804 blood relatives and 536 marry-ins from families with four or more breast or ovarian cancers in the female blood relatives (high risk families), and 484 blood relatives in families where only the proband was affected with breast cancer (low risk). A total of 118 prostate cancers were reported.

To make the most use of the detailed three-generation pedigree data, a Cox model with random effects (frailty) was fit, using the kinship matrix as the correlation structure of the per-subject random effects. This approach fully accounts for the effects of differential follow-up time and age of onset, while accounting for pedigree structure. As expected, fits to only the female/breast or male/prostate data showed a significant genetic component for the risk of incident disease. However, they were not related. The relative risk of prostate cancer associated with the frailty term (which estimates a man's level of genetic risk that is manifest as increased risk of breast cancer in his female relatives) was 1.1 (95% C.I.: 0.8-1.3) with the inclusion of parity in the breast cancer model. Therefore, we did not see any evidence for an association between breast and prostate cancer using this model.

Using ordinary Cox regression, the rate of prostate cancer among blood relatives in high risk families was significantly lower than among marry-ins (RR=0.6, 95% C.I.: 0.4-0.9). The rate of prostate cancer among blood relatives in low risk families was not significantly different from the rate among marry-ins (RR=0.8, 95% C.I.: 0.5-1.2). The fact that a more careful approach did not validate the simple group comparison emphasizes the importance of the methodological approach to studying familial aggregation.

**The influence of zygosity and chorion type on fat distribution in young adult twins — Consequences for genetic twin methodology.** *R.J.F. Loos<sup>1,2</sup>, G. Beunen<sup>2</sup>, R. Fagard<sup>3</sup>, C. Derom<sup>1</sup>, R. Vlietinck<sup>1</sup>*. 1) Centre for Human Genetics; 2) Department of Sport and Movement Sciences; 3) Hypertension and Cardiovascular Rehabilitation Unit, Katholieke Universiteit Leuven, Leuven, Belgium.

The twin design is frequently applied to estimate the relative contribution of genes and environment to a variety of traits, including body composition. An adverse intra-uterine environment has been associated with abdominal fat distribution. Twins often have a low birth weight and a short gestation. Therefore, they may have an increased risk to develop abdominal obesity. Furthermore, monozygotic monochorionic twins (MZMC) have a larger intra-pair birth weight difference compared to monozygotic dichorionic twins (MZDC). If adult anthropometry is programmed in utero, this may affect the intra-pair correlations in adulthood and, consequently, also the results from the classic twin method to estimate genetic and environmental influences. In the present study, we compared the absolute values, the intra-pair differences, and the intra-pair correlations of body mass, height, BMI, and abdominal fat distribution of 424 MZMC, MZDC and dizygotic (DZ) twin pairs (aged 18—34 yrs). DZ, MZDC and MZMC twins did not differ for most anthropometric characteristics. Only MZ women tended ( $p=0.03$ ) to accumulate more abdominal fat compared to DZ twins. Overall, the contribution of zygosity and chorion type to adult anthropometry was rather low (1.7%). Although the intra-pair birth weight difference of MZMC pairs (10.5% in men, 12.3% in women) was significantly larger compared to that of MZDC (6.9% and 9.2% resp.) pairs, the intra-pair differences in adult anthropometry were similar for both MZ twin types. Also the intra-pair correlations of MZMC and MZDC pairs were strikingly alike, suggesting no significant influence of the prenatal environment on adult concordance. In conclusion, the substantial difference in the prenatal environment of MZMC and MZDC twins did not result in a difference in intra-pair concordance of adult anthropometry and fat distribution. Therefore, we suggest that the chorion type of MZ twins does not bias the twin design and the estimation of the genetic contribution to adult anthropometry.

**Relationship inference from trios of individuals in the presence of typing error.** *S. Sieberts*<sup>1</sup>, *E.M. Wijsman*<sup>2</sup>, *E.A. Thompson*<sup>1,2</sup>. 1) Dept Statistics, Univ Washington, Seattle, WA; 2) Dept Biostatistics, Univ Washington, Seattle, WA.

Errors in genetic data consist of two different types: relationship misspecification and genotyping error. Both of these error types can seriously affect the inference drawn from linkage studies. Typical methods for resolving these errors consider pairs of individuals. When possible, considering a third related individual can increase the power to detect both types of error. We have developed a program, using a hidden Markov model, to compute likelihoods, given genotypes at multiple linked loci for trios of individuals, in the presence of genotyping error. This program, ECLIPSE, is available for download from <http://www.stat.washington.edu/thompson/Genepi/Eclipse.shtml>. Here we apply the method to marker data of the well-analyzed COGA study, and to an uncleaned dataset (LPPG). For the COGA data, we find that inferring relationships among trios of individuals requires fewer markers than inferring pairwise relationships. In one example, a pair of reported full sibs has a LOD (base 10) of 0.745 using all 285 markers. When we include another reported full sib in our analysis, the LOD is 14.88. In sibships where the inferred pairwise relationships are incompatible, examining individuals in trios can clarify relationships. In previously uncleaned datasets, allowing for typing error is essential when comparing trios of individuals since a true relationship of full sibs may be excluded by the reported data. In analyses of the LPPG data, we find that allowing for genotyping error can distinguish between full sibs with Mendelian error and more distant relationships. Analysis of trios has the advantage that, even in the absence of parental data, typing errors that cause Mendelian incompatibilities are detected. In one example, we discover a mother-daughter sample switch by including the mother's two siblings. An analysis of the reported sibs indicates 42 Mendelian incompatibilities and a LOD of -29.2, assuming a 2% genotyping error rate. An analysis of the two sibs with the putative daughter result in a LOD of 56.0 in favor of a full sib trio relationship, assuming a 2% error rate. In this inferred sib trio, typing error results in one Mendelian incompatibility.

**Latent class models for identifying patterns of DNA methylation.** *K.D. Siegmund.* Dept Preventive Medicine, Univ Southern California, Los Angeles, CA.

DNA methylation is being measured at 10 candidate genes on a population-based sample of 300 subjects with colorectal adenomas. Investigators propose to identify a subset of patients with aberrant DNA methylation and characterize these subjects with respect to risk factors for adenomas.

In a simulation study, we compare four methods for clustering subjects into groups, based on their pattern of DNA methylation: 1. a methylation index, 2. agglomerative hierarchical cluster analysis (using Manhattan distance and group average linkage), 3. latent class mixture model and 4. latent class classification model. We model dichotomous measures of DNA methylation, as a function of covariates, using the logistic link. For approaches 1 and 2, we cluster both the raw observations and the residuals from a logistic regression analysis. For approaches 3 and 4, we model the covariate effects in the latent class analysis. In the latter two approaches, parameter estimates are obtained using the EM algorithm (mixture model) or CEM algorithm (classification model). We compare misclassification rates and parameter estimates for two unobserved classes, with either no measured covariate effects, locus-specific covariate effects, or subject-specific covariate effects (e.g. age). Overall, we observe the lowest misclassification rate for the latent class mixture model. In a model with age effects, clustering the residuals decreased the misclassification rate for the methylation index for clusters of equal size, but not for clusters of unequal size. In general, clustering residuals increased the misclassification rate for the hierarchical cluster analysis. Parameter estimates for the mixture model appeared unbiased. The classification model appeared to overestimate the difference between group means.

In summary, a latent class analysis is a flexible approach to cluster analysis that permits the incorporation of measured covariates. It can yield lower misclassification rates than alternate approaches, at the cost of more computing time. Currently we are extending the latent class model for measures that are a mixture of discrete and continuous values.

**GenLib: A web-site for power computations for linkage analysis.** *A.A. Todorov<sup>1</sup>, B.J. Keats<sup>2</sup>, A.C. Heath<sup>1</sup>*. 1) Dept Psychiatry, Washington Univ Sch Medicine, St Louis, MO; 2) Dept Biometry & Genetics, Louisiana State University Med Ctr, New Orleans, LA.

**Description:** GenLib is a web-accessible software library with a user-friendly interface to perform power computations for twin, linkage and association studies. The aim of the project is to permit power computations under realistic conditions while minimizing the burden to the user. Users can perform power computations under one- and two-locus genetic models, while varying sampling and/or experimental scheme. Specific programs include: searches for efficient sampling schemes for linkage analysis, basic design of experiments in pharmacogenetics, power computations for multipoint linkage analysis with reduced marker polymorphism with user-provided genetic maps and allelic frequencies. The web-site also permits power computations for key ancillary analyses, e.g., latent class/latent trait methods for phenotype definition.

**Output:** Analyses run on our network of Alpha and Sun computers. Output for short analyses is received immediately on screen. For longer analyses, users are directed by e-mail to an URL containing the results of the analyses. Typically, output consists of a short paragraph describing the statistical methods with references, accompanied by summary tables and graphs. All elements, including tables and graphs, can be directly copied into a word-processing program (e.g., Ms-Word or WordPerfect).

**Illustrations:** In the present, we will provide two illustrations of power computations performed using this software: (i) a joint linkage analysis of a dichotomous phenotype and a correlated continuous trait under selective sampling with additional twin data, and (ii) linkage analysis for a multivariate dichotomous phenotypes under non-normal assumptions.

Supported in part by grants AA-12232 and AA-07728.

**Genetic Susceptibility/Resistance to Dental Fluorosis Among Different Mouse Strains.** *E.T. Everett<sup>1</sup>, M. McHenry<sup>1</sup>, N. Reynolds<sup>1</sup>, H. Eggertsson<sup>2</sup>, J. Sullivan<sup>2</sup>, C. Kantmann<sup>2</sup>, A. Martinez-Mier<sup>2</sup>, G.K. Stookey<sup>2</sup>.* 1) Oral Facial Development, Indiana Univ Sch Dentistry, Indianapolis, IN; 2) Oral Health Research Institute, Indiana Univ Sch Dentistry, Indianapolis, IN.

Fluoridation of community water supplies for the prevention of dental caries remains one of the top ten public health interventions of the last century. The safety and efficacy of fluoride use has been well demonstrated. Concurrent with the decline in dental caries has been an increase in the prevalence of dental fluorosis (DF). Between 7.7% to 80.9% of the population in communities with fluoridated water and 2.9% and 42% of the population in communities with nonfluoridated water develop DF. While the increase in DF primarily involves very mild and moderate forms, an increase in the number moderate and severe DF occurs as well. Greater than optimal fluoride exposure comes from a variety of sources: toothpastes and mouth rinses containing fluoride, dietary fluoride supplements, self-applied fluoride gels, and professionally applied products. We hypothesize that DF represents a complex condition caused by both environmental and genetic factors. We have chosen to test this hypothesis using genetically separate inbred strains of mice and because mice continually erupt their incisors (active amelogenesis). Twelve strains of mice (129P3/J, A/J, BALB/cJ, C3H/HeJ, C57BL/6J, C57BL/10J, CBA/J, DBA1/J, DBA/2J, FVB/NJ, SJL/J, and SWR/J) were treated with varying concentrations (0, 25, and 50ppm) of fluoride in their drinking water for 60 days. Utilizing clinical criteria and quantitative light fluorescence (QLF) assessment of lower incisors, mice clustered into three phenotypic groups: resistant strains (129P3/J, FVB/NJ, CBA/J, and DBA/1J); intermediate (SWR/J, BALB/cJ, C57BL/10J, and DBA/2J); and sensitive (A/J, SJL/J/ C3H/HeJ, and C57BL/6J). The A/J strain was found to be most susceptible to develop rapid and severe DF, whereas the 129P3/J strain was the most resistant, showing little to no effects. These data support that genetics (host factors) do play a role in DF resistance and susceptibility and allow us initiate QTL mapping to identify specific genes contributing to DF resistance and susceptibility.

**Common founder mutations among Hispanic Patients with ataxia-telangiectasia (A-T).** *M. Mitui<sup>1</sup>, S. Castellvi-Bel<sup>1</sup>, G. Coutinho<sup>1,2</sup>, Y. Huo<sup>1</sup>, X. Sun<sup>1</sup>, R.A. Gatti<sup>1</sup>.* 1) Pathology, UCLA School of Medicine, Los Angeles, CA 90095-1732; 2) Instituto de Biofisica Carlos Chagas Filho, UFRJ, Brazil.

We have genotyped A-T families from Hispanic countries to determine the contribution of different ethnic groups to the present-day Hispanic population affected by A-T. We have studied a total of 66 new patients (22 Spanish, 21 Brazilians, 22 Hispanic-Americans, and 1 Chilean). Genomic DNA was isolated from whole blood and genotyped with four microsatellite markers within and flanking the ATM gene, an interval spanning ~1.4 cM. Alleles for each marker were standardized to sample CEPH 1347-02. We identified 31 haplotypes in Spain (4 recurring), 25 in Brazil (4 recurring), and 35 in Hispanic-Americans (3 recurring). Mutation screening was performed by PTT, SSCP, and dHPLC; this has allowed the identification of 70% of the alleles to date. A total of 55 different mutations were detected, the majority were truncations or splicing defects. Only two missense mutations were identified, both of them located within the kinase domain, affecting highly conserved amino acids. In most cases, shared mutations were carried on shared haplotypes, indicating common founder mutations. However, two Spanish mutations were observed on more than one haplotype: IVS21+1G>A on haplotypes [H] and [J], and 8977C>T on haplotypes [B] and [N]. These data might represent recurrent mutational events in the ATM gene. In Brazil, four haplotypes accounted for 48% (10 of 21) of the patients. Recurring haplotypes were observed in 59% of the of the Spanish A-T patients, 62% of the Brazilians, and 41% of the Hispanic-Americans. These data indicate that preliminary haplotyping greatly simplifies mutation identification in populations with recurring haplotypes.

**The frequency and molecular genetics of CF in Belarus.** *G.L. Tsukerman*<sup>1,2</sup>, *N.I. Mosse*<sup>2</sup>, *K.A. Mosse*<sup>2</sup>. 1) Reproductive Genetics Institute, Chicago, IL; 2) Institute for Hereditary Diseases, Minsk, Belarus.

A few years ago the frequency of delta-F508 mutation was studied in 2, 598 newborns alleles. The frequency of delta-F508 mutation heterozygote carriers in Belarus newborns population was revealed 0.014 or 1:72. As this mutation accounted for 63% of CF alleles in our patients, so CF incidence was to be 1:8108. Then a pilot whole population neonatal screening for CF was started. A successful two-tier screening strategy for CF using an initial estimation of IRT at cut-off 70 ng/ml followed by direct CF gene analysis was conducted. Sweat test was done in all the cases where IRT value was above of the cut-off. Totally 146 701 newborns were screened and 18 (eighteen) cases of CF were diagnosed. This means that the incidence of CF in newborns population of Belarus is 1:8150. The expected and observed incidence of CF in Belarus revealed absolutely the same numbers, which are far from 1:2500. 232 CF alleles were examined in Belarus patients. The samples were screened for the presence of the following mutations that were originally identified in European population: delta F-508, R334W, R347P, G542X, S549N, R553X, W1282X, N1303K. Analysis has shown that delta F-508 mutation covered 63% of CF chromosomes, R334W 0.4%, R347P 0.4%, G542X 1.3%, S549N 0.4%, R553X 0.4%, W1282X 0.9%, N1303K 2.5%. Recently, a large genomic deletion of CFTR gene that is frequently observed in Central and Eastern Europe was identified. The mutation, termed CFTRdel2, 3(21kb), deletes 21,080 bp spanning introns 1-3 of CFTR gene (T. Dork et. al., 2000) Our data show that the mutation is particularly common in Belarus - 4.3% of all CF chromosomes.

**Determination and Analysis of >30,000 SNP Allele Frequencies in Three Defined Populations and CEPH Pedigrees from SNPs Identified by The SNP Consortium.** *M.S. Phillips, V.M. Ankeney, D.W. Morris, J.F. Studebaker, M.A. Donaldson, J.A. Lathrop, F.-S. Kuo, A.V. Alfisi, G.A. Gelfand, M.G. Pohl, M.T. Boyce-Jancino.* Orchid BioSciences, Inc., Princeton, NJ.

In collaboration with The SNP Consortium (TSC), Orchid BioSciences has determined the allelic frequencies for more than 30,000 SNPs obtained from the TSC database. The SNP allelic frequencies are being determined on samples derived from three different defined populations and selected CEPH pedigrees. The three different populations consist of approximately 40 individuals from each of the Caucasian, African American and Asian (composed of 75% Japanese and 25% Chinese) populations. The ultimate goal of the project is to have information and functional assays for the development of useful SNP panels for at least 60,000 TSC SNPs screened against all 3 populations. Selection of the SNPs is genome wide with a slight emphasis on genes involved with drug metabolism and those, which are potential targets for drug development. Using Orchids proprietary high throughput single-base primer extension technology, SNP-IT™, individual genotypes have been determined for each of the samples in the respective populations. This equates to well over 7.2 million genotypes to be completed by the end of the project. Orchid is performing the SNP-IT™ genotyping on multiple ultra-high throughput platforms. One platform is Orchids completely automated SNPstream 25K system, which uses 384 well plates with a colorimetric readout. The other platform being utilized is Orchids SNPcode, which uses Affymetrix GenFlex™ chips coupled with multiplex PCR and primer extension to perform the analysis of 1000 SNPs at a time on a single sample. A selection of the 60,000 TSC SNPs is also being analyzed on 10 CEPH pedigrees (80 individuals) for the determination of SNP linkage and haplotypes within families. Analysis of the SNPs on the CEPH pedigrees will provide the initial components for a linkage disequilibrium (LD) map of the genome. The results of these studies will form the basis for the first defined human SNP map and generate the resources necessary to conduct genome-wide association studies.

**The effect of sequencing errors on the frequency spectrum of segregating mutations.** *J.D. Wall.* Dept Organismic & Evol Biol, Harvard Univ, Cambridge, MA.

The distribution of frequencies of single nucleotide polymorphisms (called the "frequency spectrum") has often been used to make inferences about human demographic history. For example, an excess of rare polymorphisms is commonly interpreted as evidence for a recent increase in the human population size. However, confounding factors, such as natural selection, ascertainment bias or experimental error, can make it difficult to interpret the observed patterns of polymorphism. Here we present some simple models of sequencing error, and explore through simulations what effect they have on the expected frequency spectrum. We find that ignoring the effects of sequencing errors when they actually exist can lead to erroneous inferences regarding human demographic history. If genotyping preascertained polymorphisms has a significantly lower error rate than sequencing, it may be more informative to first ascertain polymorphisms in a sample of size 2 or 3, then determine the frequencies from a much larger sample.

**Frequency of CYP3A and MDR-1 polymorphisms in Healthy Volunteers and Commercial Ethnicity Panel.** S.A. Henry<sup>1</sup>, E.A. Foot<sup>2</sup>, G.P. Sreekumar<sup>1</sup>, V.D. Schmith<sup>2</sup>, S.A. Asquith<sup>1</sup>, T. Saunders<sup>1</sup>, D. Dow<sup>1</sup>, R. Hussein<sup>1</sup>, B. Bahari<sup>1</sup>, Z. Xue<sup>1</sup>, D.S. Montgomery<sup>1</sup>, M. Dickins<sup>3</sup>, I.J. Purvis<sup>1</sup>, M.J. Stubbins<sup>1</sup>, A.J. Yeo<sup>1</sup>. 1) Genetics Research, GlaxoSmithKline, RTP, NC; 2) Clinical Pharmacology & Experimental Medicine, GlaxoSmithKline, Brentford, Middlesex, TW8 (ET, UK and RTP, NC 27709 US; 3) DMPK, GlaxoSmithKline, Brentford, Middlesex, TW8 9ET, UK and RTP, NC 27709 US.

Understanding the presence and frequency of genetic variation in the enzymes and transporters involved in the absorption, distribution, metabolism and excretion of drugs is of critical importance in interpreting variability in drug response. Knowing the frequency of these variants in healthy volunteers and ethnic groups will allow extrapolation of data obtained from a predominantly Caucasian population in Phase I studies to other populations. CYP3A4/5 and MDR1 are of particular interest due to their roles in metabolizing/transporting the majority marketed drugs. In this study, following appropriate informed consent, DNA samples were collected from 129 healthy Caucasian subjects in phase I clinical trials. A panel of taqman assays for 5 variants in CP3A4,3A5 and MDR1 were developed. These assays were used to genotype the clinical trial samples and to determine allele frequencies in 3 ethnic populations using 50 commercially available DNA samples from each of Caucasian(CC),African-American(AA)and Hispanic (H)populations.All markers genotyped were in Hardy-Weinberg equilibrium. Frequencies for the minor alleles in CYP3A4 A816G and CYP3A5 T-369G were significantly lower in CC(1% and 6%)compared to AA(71% and 60%)and H(11% and 24 %).The frequency of the T allele in MDR1 C3435T was significantly lower in AA (17%)compared to CC(51%)and H(40%),while the frequency of the G allele in MDR1 T2793G was significantly higher in AA(94%)compared to C(55%)and H(63%). This data needs to be considered when conducting studies in different parts of the world. The allele and genotype frequencies in the CC clinical trial subjects were not significantly different from the CC from the ethnicity panel indicating that these healthy subjects are representative of the general population.

**Pharmacogenomics study of glucocorticoid sensitive and resistant asthma predicts glucocorticoid responsiveness with high accuracy.** *H. Hakonarson<sup>1</sup>, U.S. Bjornsdottir<sup>2</sup>, E. Halapi<sup>1</sup>, F. Zink<sup>1</sup>, H. Helgadóttir<sup>1</sup>, I. Bjarkarson<sup>1</sup>, T. Arnason<sup>1</sup>, F. Thorarinsson<sup>1</sup>, A.S. Gudmundsdóttir<sup>1</sup>, S. Ingvarsson<sup>1</sup>, L. Amundadóttir<sup>1</sup>, M. Andresdóttir<sup>1</sup>, E.A. Adalsteinsdóttir<sup>1</sup>, D. Gislason<sup>2</sup>, T. Gislason<sup>2</sup>, M. Gurney<sup>1</sup>, J. Gulcher<sup>1</sup>, K. Stefansson<sup>1</sup>.* 1) deCode Genetics, Inc, Reykjavik, Iceland; 2) Department of Pulmonary Medicine, National University Hospital, Reykjavik, Iceland.

For most drugs, the genetic variations that determine clinical drug response remain to be uncovered. We compared gene expression profiles in freshly isolated peripheral blood mononuclear (PBM) cells from glucocorticoid (GC)-sensitive (S) and GC-resistant (R) asthmatics using gene array technology. We searched for genes with sufficient power to predict GC-S (responders) and GC-R (non-responders) asthmatics with high accuracy, using a naive Bayesian classifier. Total RNA was extracted from unstimulated PBM cells and from cells treated with IL-1b/TNF $\alpha$  in the absence and presence of GC treatment. Expression of multiple genes was examined using gene array technology in 60 asthmatic patients and 15 control subjects. Collectively, 2.4 million datapoints were analysed. The classifier was trained on a cohort of 14 GC-R and 14 GC-S patients. Fifty genes were selected by the classifier that predicted the correct GC-response phenotype with over 80 % accuracy ( $p < 0.05$ ). When the algorithm was applied to a second cohort of 30 asthmatics, the predictive accuracy of the classifier to predict GC-R asthma was 86%. The expression profile in control subjects was similar to that of GC-S patients. Preliminary results in 24 asthmatics indicate similar predictive accuracy in terms of leukotriene antagonist response. We conclude that this study is the first to characterize gene expression profiles in freshly isolated PBM cells that differ in GC-R and GC-S asthmatics and provided sufficient power to predict clinical response to GC with high accuracy. The genes identified are currently being searched for SNPs. This type of pharmacogenomics platform may lead to the development of novel therapeutic strategies and diagnostic tests.

**TWO NEW RECURSIVE LIKELIHOOD CALCULATION METHODS FOR GENETIC ANALYSIS.** *A. Yuan, G.E. Bonney.* National Human Genome Center, Howard University, Washington , DC.

Recursive likelihood calculations for genetic analysis of pedigree data employ variations of the Elston-Stewart (ES) and the Lander-Green (LG) algorithms. With the ES algorithm, the number of loci may be limited but not the pedigree size. With the LG algorithm, the reverse is the case, i.e., the pedigree size may be limited but not so much the number of loci. We introduce two new algorithms for likelihood models over pedigree. In one algorithm, the likelihood function is factored into a product of all father-mother-offspring-trios. This allows for great gains in computational speed. In the second algorithm, the likelihood function is, in effect, approximated by a product over all persons in the pedigree, with each factor having only one summation over unobserved genotypes. This is faster than the former method, and yields very good results if the effects of the underlying loci are not large. The methods are implemented in G.E.M.S., and studies in univariate trait are presented.

**Group sequential methods in genotype-disease association studies that are unlikely to reject the null hypothesis.**

*R. Aplenc*<sup>1,2</sup>, *H. Zhao*<sup>2</sup>, *T. Rebbeck*<sup>1</sup>, *K. Probert*<sup>1</sup>. 1) CCEB, Univ Pennsylvania, Philadelphia, PA; 2) Children's Hospital of Philadelphia, Philadelphia, PA.

**Introduction:** Molecular epidemiological association studies use valuable biosamples and incur material and labor costs. Statistical methods for early genotyping termination of studies that cannot reject the null hypothesis may conserve biosamples and costs. Group sequential methods (GSM) allow clinical trials to be terminated early for significant differences between treatments. We hypothesized that a group sequential boundary (GSB), that compares a test statistic to values for acceptance and rejection of the null hypothesis, allows early genotyping termination if the null hypothesis were true. **Methods:** We simulated the GSB in a case-control study of GST m and q genotypes and prostate cancer (CEBP, 8:283-7, 1999). This study reported a positive association of GST q null (OR= 1.61, p=0.0068, N=720) and a negative association of GST m null (OR=.998, p=0.991, N=630). Acceptance and rejection boundaries were defined using EAST™ software with an overall  $\alpha$  and  $\beta$  of 0.05 and 0.80. These boundaries were used in a simulation of 1000 repetitions of case/control genotyping. Cases and controls were randomly sampled without replacement, in proportion to their relative frequencies, and in groups of 90 to simulate genotype acquisition from PCR analysis. A  $\chi^2$  test statistics was calculated for each group of 90 samples (a "look") and compared to predefined boundaries for study termination. **Results:** On average, GST m genotyping terminated at 3.8 looks. GST m genotyping was not stopped at looks 1 and 2, but was terminated in 354 simulations at look 3, in 476 simulations at look 4, in 152 simulations at look 5, and 17 simulations at look 6. The GSB decreased the average number of genotyped biosamples to 426, or 67.7% of the total sample. GST q genotyping was stopped in 12.2% of simulations. **Conclusion:** The GSB allows early termination of genotyping when the null hypothesis is true. Early termination of GST m genotyping saves an average 32.2% of biosamples from unnecessary genotyping. The GSB has an acceptable frequency of inappropriate termination. Funded by the Doris Duke Foundation.

**Association of Candidate Polymorphisms with Diabetic Retinopathy.** *J.P. Burke<sup>1</sup>, V.S. Pankratz<sup>1</sup>, D.J. O'Kane<sup>2</sup>, P.J. Dyck<sup>3</sup>*. 1) Health Sciences Research, Mayo Clinic, Rochester, MN; 2) Laboratory Medicine and Pathology; 3) Neurology.

The incidence of diabetes is increasing rapidly in the United States. Individuals with type 1 (dm1) or type 2 (dm2) diabetes are at a substantially increased risk of developing complications such as neuropathy, nephropathy and retinopathy. Although blood glucose is a major risk factor for diabetes complications, it fails to explain a majority of the severity of complications. A number of potential etiological pathways have been identified for the development of diabetic complications. These include the renin-angiotensin system, vascular homeostasis, advanced glycation end products, and the polyol pathway. Our initial goal is to examine the association of 7 candidate polymorphisms identified within these pathways with the development and severity of diabetic complications in the Rochester Diabetic Neuropathy Study (RDNS), a population based prospective study of approximately 400 individuals with diabetes living in Rochester, MN on January 1, 1986. Our long-term goal is to construct improved models to predict those at increased risk of developing diabetic complications. Preliminary analyses, including 96 dm1 and 162 dm2, have been conducted. Standardized criteria were used to define dm1, dm2, neuropathy, nephropathy and retinopathy. The frequency of neuropathy, nephropathy and retinopathy were 58.3%, 22.1% and 83.0% in dm1 individuals, respectively, and 48.2%, 44.4% and 65.6% in dm2 individuals, respectively. A significant association was found between apoE4 T3937C SNP and the presence of retinopathy in individuals with dm1 (T/T: 70.2% vs. 41.7%,  $P=0.047$ ). In addition, a significant association was found between aldose reductase C106T SNP and the presence of retinopathy in individuals with dm2 (C/C: 30.4% vs. 55.6%,  $p=0.018$ ). Lastly, a borderline association was found between aldose reductase C106T SNP and the presence of nephropathy in individuals with dm1 (T/T: 22.2% vs. 5.0%,  $p=0.080$ ). We conclude that there were significant associations between polymorphisms in the apoE4 and aldose reductase genes and presence of diabetic complications, particularly retinopathy. These associations may lead to improved prediction models of diabetic complications.

**Genetic variation in apolipoprotein D affects the risk of Alzheimer's disease in African Americans.** *P.P. Desai<sup>1</sup>, H.C. Hendrie<sup>2</sup>, R.M. Evans<sup>3</sup>, J.R. Murrell<sup>4</sup>, S.T. DeKosky<sup>1,5</sup>, M.I. Kamboh<sup>1,5</sup>*. 1) Human Genetics, Univ of Pittsburgh, Pittsburgh, PA; 2) Psychiatry, Indiana Univ, Indianapolis, IN; 3) Neurology, Indiana Univ, Indianapolis, IN; 4) Pathology & Laboratory Medicine, Indiana Univ, Indianapolis, IN; 5) Psychiatry, Univ of Pittsburgh, Pittsburgh, PA.

Several genetic and environmental factors have been implicated in the onset and pathology of Alzheimer's disease (AD). Among genetic factors, apolipoprotein E (APOE) alters susceptibility to AD. Although African Americans appear to have a higher prevalence of AD than Whites, a weaker association has been seen between *APOE\*4* and AD among African Americans. These observations suggest that additional unidentified genetic and environmental factors may explain the increased risk of AD among African Americans. Recently, the product of a new candidate gene, apolipoprotein D (APOD), has been shown to be involved in the processes of neuroregeneration and neurodegeneration. We have identified several polymorphisms in the APOD gene, which are unique to populations of African ancestry. In the present study we examined the role of four APOD genetic variants (Intron 1, codons 36, 108, 158) in modifying the risk of AD in 70 African Americans with AD (mean age 81.43±0.81) and 163 nondemented subjects (mean age 77.78±0.55) from a population-based cohort in Indianapolis. Although the *APOE\*4* allele frequency was higher in cases than controls (0.293 vs. 0.199; p=0.035), the age and sex adjusted odds ratio (OR) was not significant (OR=1.52; 95%CI: 0.84-2.74; p=0.17). Two of the APOD polymorphisms (Intron 1 and codon 36) showed an association with AD. The *Intron 1\*2* allele was associated with a higher AD risk with an age, sex and APOE adjusted OR of 2.29 (95%CI: 1.19-4.43; p=0.013). The frequency of codon 36/GT genotype was higher in AD cases than controls (4.3% vs. 1.2%), with an adjusted OR of 4.24 (95%CI: 0.66-27.14; p=0.13). Our data suggest that the risk of AD among African Americans is modified by genetic variation in APOD. Larger population-based or case-control studies, together with functional studies may help to elucidate the structure-function relationship of APOD genetic variants in the etiology of AD.

**Lack of association between thermolabil variant C677T in MTHFR gene and neural tube defects in the State of Yucatan, Mexico.** *L.J. Gonzalez-Herrera<sup>1</sup>, M.G. Garcia-Escalante<sup>1</sup>, I. Castillo-Zapata<sup>1</sup>, J. Canto-Herrera<sup>1</sup>, J.M. Ceballos-Quintal<sup>1</sup>, D. Pinto-Escalante<sup>1</sup>, A. Gonzalez-Del Angel<sup>2</sup>.* 1) Laboratorio de Genetica. CIR, Universidad Autonoma de Yucatan, Merida, Yucatan, Mexico; 2) Departamento de Investigacion en Genetica Humana. Instituto Nacional de Pediatria. Mexico,D.F.

Neural tube defects (NTD) are the most prevalent isolated congenital malformations (6.6 in 1000) in the State of Yucatan, Mexico. The thermolabil variant C677T in MTHFR gene leads to altered homocysteine metabolism and it is considered an associated risk factor for NTD. However, the association has been controversial and it seems to be dependent of the C677T variant frequency, which is heterogeneous among populations. So, The objective of this work was to determine the association of thermolabil variant C677T in MTHFR gene with NTD in the State of Yucatan, Mexico, where NTD are highly prevalent and with Mayan native background. A case-control study was performed with 60 newborn subjects affected with NTD (52 spina bifida, 3 anencephaly and 5 encephaloce) and 100 control healthy volunteers from yucatecan general population as well as 54 mothers of NTD children and 56 control mothers who had healthy offspring. The C677T variant in MTHFR gene was identified by PCR technique and restriction with HinF I enzyme. Among NTD subjects, odds ratios for the variant C677T homozygosity and heterozygosity were 1.35 (0.48-3.8) and 1.45 (0.56-3.82) respectively, relative to wild type homozygotes and 1.13 (0.70-1.83) for C677T allele relative to wild type allele, whereas for mothers, odds ratios were 1.21 (0.35-4.15), 2.01 (0.67-6.11) and 1.4 (0.59-1.84), respectively. Genotype frequencies among control groups were according to Hardy-Weinberg expectations ( $p > 0.33$ ). No statistically significant associations were observed for any genotype or allelic condition ( $p > 0.05$ ), suggesting that the thermolabil C677T variant is not an associated risk factor for having NTD neither to have affected offspring in the yucatecan population. Gene-gene or gene-environment interactions should be evaluated since they might increase the risk for NTD in the studied population.

**SNP genotyping on genome wide amplified DOP-PCR template.** *S.F.A. Grant, R. Tolle.* Genetic Epidemiology, LION Bioscience, Heidelberg, Germany.

DOP-PCR (degenerate oligonucleotide primed polymerase chain reaction), employs a degenerate primer (5'-CCGACTCGAGNNNNNNATGTGG-3') to produce unspecific uniform amplification of DNA. This approach has been successfully applied to microsatellite genotyping<sup>1</sup>

With the increasing demand for higher throughput single nucleotide polymorphism (SNP) genotyping, the quantity of genomic DNA often falls short of the number of assays required. We investigated the use of DOP-PCR to generate template for our SNP genotyping methodology of template-directed dye-terminator incorporation assay with fluorescence polarization (FP-TDI) detection. We compared the original cycling protocol<sup>1</sup> with the methodology outlined by Roche in their 'DOP PCR Master' kit for in situ hybridization and comparative genome hybridization (CGH). Results were analysed with respect to feasibility, allele loss, genotyping accuracy and storage conditions.

The original cycling procedure gave an error rate of approximately 4%: 96°C 8min initial denaturation, 8 cycles of 93°C 1min, 30°C 1min, and 72°C 3min, and then 28 cycles of 93°C 1min, 60°C 1min, and 72°C 3min. In comparison the Roche cycling protocol, which prolongs extension times, yielded an error rate lower than 1%: 95°C 5min initial denaturation, 5 cycles of 94°C 1min, 30°C 1.30min, ramping to 72°C over 3min (3.5°C/15s) and 72°C 3min and then 35 cycles of 94°C 1min, 62°C 1min and 72°C 2min (and increasing by 14s each subsequent cycle) and a final extension step of 72°C 7min.

Degradation of the DOP-PCR stored at -70°C has been observed. By adding vector DNA in excess (100ng to a 10ul PCR product) to act as a template for residual nuclease activity, degradation is minimised.

In conclusion, we have successfully used DOP-PCR to amplify our genomic DNA collection for subsequent SNP genotyping. The cycling protocol proposed by Roche produced fewer typing errors than the original methodology.

**Identification of three novel polymorphisms in the MJD1 gene and their frequency study in a Portuguese population.** *M.C. Costa<sup>1</sup>, C. Santos<sup>1</sup>, A. Ferro<sup>1</sup>, M. Santos<sup>1</sup>, J. Sequeiros<sup>1,2</sup>, P. Maciel<sup>1,3</sup>.* 1) UnIGENE, IBMC, Univ. Porto, Portugal; 2) Depto. de Estudos das Populações, ICBAS, Univ. Porto; Portugal; 3) Inst. Sup. Ciências da Saúde-Norte, Portugal.

Machado-Joseph disease (MJD) is an autosomal dominant neurodegenerative disorder of late onset, caused by an expansion of a (CAG)<sub>n</sub> tract in the MJD1 gene. We made a multiple alignment sequence (BLAST 2 sequences) between known cDNA variants transcribed by the MJD1 gene and a BAC clone of human genomic DNA from chromosome 14, BAC R-529H20. This comparison suggested the possible existence of six unknown single nucleotide intragenic polymorphisms (SNPs) at variable positions in the MJD1 gene. In order to confirm this, we have studied 76 individuals from a Portuguese control population, using PCR amplification and SSCP analysis for each potential SNP. For four of the possible polymorphisms we had no variants in the population studied, but we have confirmed the existence of three novel polymorphisms:  $\text{GTT}^{527}/\text{GTC}^{527}$ ,  $\text{C}^{1178}/\text{A}^{1178}$  and  $\text{A}^{1294}/\text{G}^{1294}$ . The polymorphism  $\text{GTT}^{527}/\text{GTC}^{527}$  (Val/ Val) is located in the coding region, and the others  $\text{C}^{1178}/\text{A}^{1178}$  and  $\text{A}^{1294}/\text{G}^{1294}$  are located in the 3'non-coding region of cDNA variants of MJD1 gene, MJD2-1 and MJD1-1, respectively. The frequencies on the population studied for genotypes for  $\text{GTT}^{527}/\text{GTC}^{527}$  were: T/T- 0,18, C/C- 0,42, and T/C- 0,40; for  $\text{C}^{1178}/\text{A}^{1178}$  were: C/C- 0,04, A/A- 0,71 and C/A- 0,25; and for  $\text{A}^{1294}/\text{G}^{1294}$  were: A/A- 0,03, G/G- 0,71 and A/G- 0,26. All these novel SNPs are in Hardy-Weinberg equilibrium. These intragenic polymorphisms can be useful (1) for the study of the origin of the MJD mutation(s); (2) for the study of recombination events (proposed by several authors to be involved in the instability of trinucleotide repeats); (3) for distinction of chromosomes with alleles of identical size in genetic tests (homoallelism); (4) and for the study of genetic modifiers of the in the region flanking the MJD1 gene.

**Genetics studies in isolated Amerindian community: Warao in the Orinoco delta.** A. Arends, M. Chacin T., M. Bravo Urquiola, M. Alvarez, T. Arends de O., A. Ciarello, A. Cardenas. Hematology, Hosp Universitario de Caracas, Caracas, Venezuela.

The Waraos are an Amerindian tribe of 20,000 subjects, who live in the Orinoco River Delta, in the northeastern part of Venezuela, very close to the Atlantic Ocean. They are dedicated to fishing and swamp scavenging and show very strong cultural differences with the surrounding Amerindian groups. Two hundred individuals belonging to two small Warao communities: Cangrejito and Winiquina were studied to determine if there had been any admixture with other populations. Hemoglobin analysis were carried out by HPLC and electrophoresis, Hb A2 was measured by cation exchange column and Hb F by alkali denaturation. Hematological parameters were determined by automatic cell counter (Coulter).  $\beta$  thalassemia mutations were determined by ARMS-PCR and  $\beta$  globin gene haplotypes frequency by PCR-RFLP of 5 polymorphic sites in 170 chromosomes. We found a higher degree of anemia in children, and most of them with nutritional deficit, 2 carriers of gen  $\beta^s$ , 4 with high levels of Hb A2 (3.5-5%), two of them carried the CD39 mutation. HPFH, found 25 years ago, was present in 7 members of a large kindred, with 2-8% of Hb F. Haplotype 2 was the most frequent (26%), followed by haplotype 6 (22%), and the non-reported to our knowledge, atypical Warao haplotype in a frequency of 13%, 2 individuals were homozygous for this haplotype. The finding of 8 alleles with haplotype 3 in apparently non-related individuals and the presence of two alleles with the CD39  $\beta$  thalassemia mutation are clear evidence of recent admixture. In earlier studies, 30 years ago, of some genetic markers in this Amerindian tribe, there had not been any indication of admixture with caucasoid and african subjects. The Warao occasionally venture out of the delta to trade overseas with Trinidad and Tobago, and upstream towards more populated and mixed Venezuelan villages. We postulate that the high frequency of the Warao haplotype in this isolated community is possible due to genetic drift, because of the high degree of endogamy among these small communities. Financial Support: CONICIT S1-95000696, CDCH-UC.

**Human progesterone receptor gene polymorphisms and endometrial cancer risk.** *G.M. Boezen<sup>2</sup>, S.E. Hankinson<sup>1,3</sup>, P.J. Lescault<sup>1</sup>, G.A. Colditz<sup>1,3</sup>, D.J. Hunter<sup>1,3</sup>, I. De Vivo<sup>1,3</sup>.* 1) Dept Medicine, Channing Lab, Harvard Medical Sch, Boston, MA; 2) Dept of Epidemiology, Univ of Groningen, The Netherlands; 3) Dept of Epidemiology, Harvard Sch of Public Health, Boston, MA.

The progesterone receptor gene is a member of the steroid receptor super-family of transcription factors. The gene is mainly expressed in the female genital tract, the breast and the brain. Endometrial cancer is a model system in which to study PR variants, given that the role of progesterone is to act primarily as an antagonist to estrogen-mediated cell proliferation. Therefore, variants within the PR receptor may be of particular importance in the endometrium. Blood was collected in 1989 from participants of the Nurses' Health Study cohort. Using the human genome working draft sequence (GI:8570374), we screened the 8 exons, splice sites and promoter region. All 187 documented cases of invasive endometrial cancer through 1996, and 561 matched controls, were genotyped using various methods. We inferred haplotypes based on wild type (WT) vs. variant (V) (het&homozygotes) combinations of the observed polymorphisms, and in addition by using the EM-algorithm. Logistic regression was performed, for all inferred haplotypes separately, controlling for potential confounders. We found a total of 6 variable sites. Novel variants were found in the promoter region (+44C/T, +332G/A), and in the coding region S344T, G393G, V660L, H770H. We also confirmed the Alu306 polymorphism. S344T, V660L, H770H and Alu306 were in complete linkage disequilibrium ('framework', FrW). Prevalence of variant carriers was (cases vs. controls) 12% vs. 14% for +44C/T; 15% vs. 15% for +332G/A, 61% vs. 56% for G393G, and 27% vs. 30% for FrW. Subjects with V332G/A / WTFrW (OR=1.66; 95%CI=0.94-2.92) or V332G/A / VFrW (1.24; 0.38-4.00) were somewhat more likely to be cases compared to WT332G/A / WTFrW; those with VG393G / WTFrW (1.21; 0.78-1.88) or VG393G / VFrW (1.03; 0.53-2.01) were slightly more likely to be cases compared to WTG393G / WTFrW. Polymorphisms S344T, V660L, H770H and Alu306 are in complete linkage disequilibrium, thus constructing a haplotype-framework. This framework is not associated with endometrial cancer risk.

**The 165/166delGG@insC mutation in the paracellin-1 gene is a common polymorphism.** D.E.C. Cole<sup>1,2</sup>, Z. Liu<sup>2</sup>, B.Y.L. Wong<sup>2</sup>, C. Wei<sup>2</sup>. 1) Dept of Laboratory Medicine & Pathobiology, University of Toronto, Toronto ON, Canada; 2) TGH Genetic Repository, University Health Network, Toronto ON, Canada.

Paracellin-1 (PCLN1), a member of the claudin tight junction protein family, has been identified as a crucial component mediating paracellular divalent cation conductance in the thick ascending limb of the loop of Henle. *PCLN1* mutations have been identified in patients with the recently delineated hypomagnesemia-hypercalciuria syndrome. In a search for variants of the *PCLN1* gene, we sequenced all 5 exons using published intronic primers. In 16 young healthy Caucasian adults, no variation was detected in exons 2 to 5. In exon 1, we found a 165/166delGG@insC mutation in 7 of 16 samples (6 heterozygotes; 1 homozygote). For all 8 variant alleles, there was an associated IVS1+10T@C SNP. To determine allele frequencies in different ethnic groups, we genotyped leukocyte DNA from 70 Caucasians, 50 Afro-Americans, and 45 Asians using PCR and *Bsa*JI digestion. There was no evidence of Hardy-Weinberg disequilibrium. The variant allele frequencies in Caucasian (0.23), Afro-American (0.10), and Asian (0.01) groups were significantly ( $p < 0.01$ ) different from one another. Given the published start site, this polymorphism would induce a frameshift at codon 55 (Arg55fs) and a stop codon at amino acid position 71, resulting in an aberrant protein product truncated just prior to the first transmembrane domain. Although the 165/166delGG@insC mutation has been suggested to be pathogenic, the high frequency of this allele in three ethnic groups and the existence of homozygotes in the general population make it unlikely that it is deleterious. We speculate that the second in-frame methionine codon (position 71) with a suitable Kozak consensus sequence is the preferred start codon *in vivo*. This position is homologous to the start site of rat, mouse, and bovine paracellins, and other claudins. Further study is required to determine the nature of the transcripts and the functional translation start site(s) *in vivo*.

**Polymorphisms of the fibrinogen gene : their association with cord blood fibrinogen levels and family history of coronary artery disease in Singapore neonates.** *S.C. Quek, C.K. Heng, S. Hong, P.S. Low, N. Saha.* Dept Pediatrics, National Univ Singapore, Singapore.

**Introduction:** Elevated plasma fibrinogen is known to be a risk factor of coronary artery disease (CAD) in adults. We report the results of cord fibrinogen studies in term infants of the 3 races (Chinese, Malays, Asian Indians) in multiracial Singapore. **Patients and Methods:** Cord fibrinogen levels of healthy term newborns of the 3 races were assayed by the Clauss's method. Subjects with a family history (FH) of CAD in 1 or more first/second degree relative(s) were categorized FH+. The association of FH, 5 polymorphisms of the fibrinogen gene (-148C/T, +1689T/G, *BclII*, *TaqI*, T312A) with fibrinogen levels of the 3 ethnic groups was examined. **Results:** Cord fibrinogen levels (mg/dl) were significantly lower in the Indians ( $117\pm 60$ ) compared to the Chinese ( $128\pm 54$ ) and Malays ( $128\pm 63$ ) at  $p=0.006$  after adjusting for the confounding effect of birth weight and gestational period. There were also significant differences in cord fibrinogen levels with respect to FH of CAD in Chinese and Malay babies, but not in Indians. The mean cord fibrinogen levels in those with negative and positive FH were 134.40/113.12 ( $p<0.0005$ ) and 134.97/115.36 ( $p=0.007$ ) in Chinese and Malays respectively. Given that fibrinogen is a risk factor for CAD, the unexpectedly higher levels in the FH- neonates and the high-risk Asian Indians was contradictory to findings in adults and puzzling. All polymorphisms studied were not significantly associated with fibrinogen levels. However, the rare allele frequencies (FH- vs FH+) for the +1689T/G (0.12 vs 0.31) and T312A (0.33 vs 0.24) sites were significantly higher for the Indians ( $p<0.0001$ ) and lower for the Malays ( $p<0.05$ ) in the FH+ group, respectively. **Conclusions:** Significantly lower cord fibrinogen levels were found in Chinese and Malay babies with a FH of CAD compared to the Indians. Although the fibrinogen gene polymorphisms were not significantly associated with fibrinogen levels, their allelic frequencies of the +1689T/G and T312A sites were significantly different between FH+ and FH- neonates in the Indian and Malay babies, respectively.

**Testing of the origin of the bS gene in a non-negroid venezuelan population.** *L. Pineda*<sup>1</sup>, *H. Chirino*<sup>2</sup>, *L. Borjas*<sup>1</sup>, *W. Delgado*<sup>1</sup>. 1) Molecular Genetic Laboratory, Medical Genetic Unit, University Zulia, Zulia, Venezuela; 2) Medicine Faculty, Francisco of Miranda University, Falcon, Venezuela.

The studies carried out on the distribution of the bS gene in the world has qualified as african negroid marker. In Venezuela, the presence of bS gene has been correlated with an important contribution of african people to the genetic composition of those populations, however, at the northwest of the country there is a non negroid population named Toas Island, where 1 of 8 people is carried of the bS gene. Since this gene is related in disequilibrium of linkage with 5 haplotypes of the b-globin cluster, 4 of them, have been predominantly found in african continent, the aim of this research was to clarify about the origin of the bS gene in the Toas Island using these haplotypes. Five polymorphic restriction sites of the b-globin cluster were characterized by PCR: HincII-5'e, HindIII-Gg, HindIII-Ag, HincII-fb and HincII-3'fb in 87 members (parents and offspring) of 22 families that were segregating the bS gene (AAxAA: 17 and AAxAS:5). Segregation analysis permitted to identify the bS and bA chromosomes. The 61.36%(54/88)of the haplotypes were atypical and, only 6.8% were african haplotypes:(Benin:3, Senegal:2 and Bantu:1). The atypical haplotype ---+- was found linked to the bS gene in the 51.86% and like to african haplotypes (22.2%)was not present in bA chromosomes. This results and the historic documentation about this population are not in concordance with the findings in others regions of the american continent in relation to the african origin of the bS gene, on the contrary, they support the autochthonous origin of the bS mutation in Toas Island.

**Novel O6-methylguanine-DNA methyltransferase single nucleotide polymorphisms (SNPs) detected among healthy individuals from the Swedish normal population.** *A. Platz, S. Ma, K. Smoczynski, J. Hansson, U. Ringborg, S. Egyhazi.* Department of Oncology and Pathology, Cancer Centre Karolinska, Karolinska Hospital Stockholm, Sweden.

The DNA repair protein O6-methylguanine-DNA methyltransferase (MGMT) is involved in the cellular defense against alkylating agents. Genetic alterations in the MGMT gene may impair the cellular capacity to remove alkyl groups from the O6-position of guanine, raising mutation rates and as a consequence increase the risk of cancer, whereas genetic alterations leading to increased MGMT activity may contribute to intrinsic resistance to alkylating drugs. We assessed genetic variation in the 5'-noncoding region and the 5 exons of the MGMT gene among 76 healthy volunteers from the Swedish population with the aid of single strand conformation polymorphism (SSCP) combined with nucleotide sequence analysis. In total eleven SNPs were detected, 5 in the 5'-noncoding region, one in exon 1, two in exon 3 and three in exon 5. Six of these SNPs are novel, five were located in the 5'-noncoding region and one in exon 5. The registered SNP frequencies ranged from 0.7 to 36%. Not much is known on the functional significance of MGMT SNPs. Comparative studies on MGMT variant frequencies among patient populations and in vitro studies of the cloned variants are in progress in order to clarify the clinical impact of the recognized genetic variability.

**Single-Nucleotide Polymorphisms at Several Cancer Susceptibility Genes Do Not Conform to the Infinite Site model of Mutation.** *A. Renwick<sup>1</sup>, P. Bonnen<sup>2</sup>, D. Triikka<sup>2</sup>, D. Nelson<sup>2</sup>, R. Chakraborty<sup>3</sup>, M. Kimmel<sup>1</sup>.* 1) Dept Statistics, Rice Univ, Houston, TX; 2) Dept Human Molec Genetics, Baylor Coll Med, Houston, TX; 3) Human Genetics Ctr., Univ Texas at Houston, Houston, TX.

The Infinite Site Model (ISM) is generally employed to explain the observed diversity at the human Single-Nucleotide Polymorphism (SNP) sites. However, it was also observed that there exists a considerable variability of diversity along the human genomic sequence. In addition, the SNP sites are discovered using procedures, which tend to leave out the less frequent variants, leading to a possible ascertainment bias in site-specific estimates of diversity. We examine the discovery process, assuming a model, which includes the ISM as a special case. We assume that full sequencing of a genome region is carried out in a limited discovery sample of chromosome. Once this is done, the primers developed are used to type a larger sample of chromosomes. By fitting our model, not only we can estimate the extent of ascertainment bias, but also conclude, which version of the model fits the data best. Application of this theory to SNP polymorphisms at over 50 sites encompassing five cancer-susceptibility genes (ATM, BLM, BRCA1, RECQL and WRN) suggests that: (i) SNP data within each of these genomic regions are best approximated by a model different from the ISM and (ii) the observed variability among different regions is unlikely to be due to differences in discovery procedures. We provide adjusted estimates of genetic diversity at SNP sites. The absence of fit to the ISM within specific genomic regions indicates possible influence of one or more factors, such as reverse or recurrent mutation, selection and recombination. (Research supported by NIH grants GM 58545 and CA75432).

**Four polymorphisms in the angiotensinogen gene and risk of hypertension and cardiovascular disease. The Copenhagen City Heart Study.** A.A. Sethi<sup>1, 2</sup>, B.G. Nordestgaard<sup>1, 2</sup>, H. Sillesen<sup>2</sup>, R. Steffensen<sup>2</sup>, G. Jensen<sup>2</sup>, A. Tybjaerg-Hansen<sup>1,2</sup>. 1) Department of Clinical Biochemistry; 2) University of Copenhagen, Denmark.

The angiotensinogen gene has been associated with hypertension, ischemic heart disease (IHD) and ischemic cerebrovascular disease (ICVD). We investigated the hypothesis that 2 promoter polymorphisms (A(-20)C and G(-6)A) along with 2 previously described polymorphisms (T174M and M235T) in the angiotensinogen gene, alone, combined, or as haplotypes, were associated with hypertension, IHD, or ICVD. In three case-control studies, 4950 individuals with hypertension were compared with 4234 individuals from the general population without hypertension, and 1805 patients with IHD and 920 patients with ICVD were compared with 7965 controls from the general population. Relative allele frequencies of -20C and -6A in the general population were 0.15 and 0.40. When combining the four polymorphisms, we identified 8 different haplotypes in 9191 individuals from the general population. The following results are based on the 6 most frequently observed haplotypes, and the ten most frequent genotype combinations (<sup>31</sup>). Systolic and diastolic blood pressure along with pulse pressure did not change as a function of either promoter polymorphism or the ten genotype combinations of all four polymorphisms in women and men. On multifactorial logistic regression analyses, women homozygous for the (-6)A mutation versus non-carriers had an odds ratio for hypertension of 1.26(95% confidence interval, 1.03-1.55), which increased to 1.52(1.11-2.07) if they in addition were homozygous for 235Thr, and to 1.72(1.02-2.90) if they also were heterozygous for (-20)C. No significant association was found between genotype and hypertension in men, nor between haplotypes and hypertension in either gender. On multifactorial logistic regression analyses, neither promoter polymorphism, alone, in combination with T174M and M235T, or as haplotypes predicted IHD or ICVD. In this study, double homozygosity for (-6)A and 235Thr along with heterozygosity for (-20)C is a risk factor for hypertension in women but not in men. The angiotensinogen gene mutations do not predict IHD or ICVD.

**Frequency of C677T MTHFR Mutation in the Yucatecan and Mayan native populations.** *G.M.G. Garcia-Escalante<sup>1</sup>, L.J. Gonzalez-Herrera<sup>1</sup>, J.M. Ceballos-Quintal<sup>1</sup>, I. Castillo-Zapata<sup>1</sup>, D. Pinto-Escalante<sup>1</sup>, A. Gonzalez-Del Angel<sup>2</sup>.* 1) Laboratorio de Genetica, UADY Merida, Yucatan, Mexico; 2) Departamento de Investigacion en Genetica Humana. INP, Mexico D.F.

The homozygosity for the MTHFR 677T mutation has been considered an associated risk factor for altered folate metabolism and transport diseases like cardiovascular, cerebrovascular, venous thrombosis, longevity, neural tube defects, pregnancy/eclampsia, diabetes, cancer and psychiatry. The T allele is distributed widely among populations showing a high heterogeneity in the prevalence. The frequency is high among Europeans 44% whereas it is within the range from 0 to 94% among Africans. In some Mexican native populations, the T allele frequency is: Tarahumaras 36%, Huicholes 56%, Purpechas 57%, and mestizos 44%. For Yucatecan and Mayan native populations, this information is unknown. It is relevant to know how the C677T allele is distributed in these populations, which have high prevalence of newborn with neural tube defects and cardiovascular diseases. The purpose of this study was to investigate the frequency of the C677T MTHFR mutation between the Yucatecan and Mayan native populations. The C677T mutation was analysed by PCR and the amplified fragments of 198 bp were digested with HinfI restriction enzyme from ADN of Yucatecan healthy volunteers (n=76) and healthy Mayan natives (n=73). Results show that the genotypic frequencies in the Yucatecan population were 29% (22/76) of homozygotes TT, 50% (38/76) of heterozygotes CT and 21% (16/76) of homozygotes CC. For Mayan native population, genotypic frequencies were 41% (30/73) (TT), 45% (33/73) (CT) and 14% (10/73) (CC). These frequencies were in accordance to Hardy-Weinberg expectations in both populations ( $p > 0.33$ ). The allelic frequency was 54% for Yucatecans and 64% for Mayans. Significant differences were not found among both groups ( $p = 0.23$ ). The obtained C677T allele frequencies in the studied populations are high compared with other non-Mexican-populations ( $p < 0.01$ ). The high allelic frequency in these populations might be considered in order to determine risks for having associated diseases with folate metabolism.

**Sequence variation and linkage disequilibrium in the human genome.** *L.M. Frisse<sup>1</sup>, A. Bartoszewicz<sup>1</sup>, J.D. Wall<sup>2</sup>, R.R. Hudson<sup>2</sup>, A. Di Rienzo<sup>1</sup>*. 1) Human Genetics, University of Chicago, Chicago, IL; 2) Ecology & Evolution, University of Chicago, Chicago, IL.

The rate at which linkage disequilibrium (LD) decays with physical distance in human populations has been the subject of considerable debate. Computer simulations and empirical studies have resulted in estimates of LD that extend only a few kilobases from a common SNP, while other studies have documented LD over stretches greater than 100 kb. In order to characterize the effects of population history on LD, we have analyzed ten independent 10 kb non-coding regions in three populations, Italian (European), Hausa, (African), and Chinese (Asian). For each region, a 1-2 kb segment at each end was amplified and sequenced resulting in a set of "locus pairs". By sequencing only the ends of each region, we were able to sample a larger number of independent genomic regions. While re-sequencing every individual in the sample may reduce the number of individuals we are able to examine, it eliminates ascertainment bias from the sample. In addition, it allows the comparison of polymorphism levels, frequency spectrum and LD levels for the same genomic regions and population samples. The results of this survey show that LD decays at different rates in different ethnic groups. In the African sample, the rate of decay of LD with distance is consistent with a simple equilibrium neutral model with effective population size of approximately 10,000 and average recombination rate. However, the decay of LD is much slower in both non-African samples. This observation may be due to the different demographic history of these groups. We also investigate the role of gene conversion to LD decay. We show that the observed pattern of LD is consistent with substantial levels of gene conversion. This leads to the expectation that LD decay over short distances is more rapid than previously thought based on models that included only cross-over.

**Genetic diversity and population structure of two historically related Latin-American populations.** *L.G. Carvajal-Carmona*<sup>1,2</sup>, *R. Ophoff*<sup>3</sup>, *S. Service*<sup>3</sup>, *I. Soto*<sup>2</sup>, *J. Hartiala*<sup>3</sup>, *G. Bedoya*<sup>2</sup>, *J. Ospina*<sup>4</sup>, *V. Reus*<sup>5</sup>, *N.B. Freimer*<sup>3</sup>, *A. Ruiz-Linares*<sup>1,2</sup>. 1) Galton Laboratory, Dept of Biology, University College London, London, England; 2) Laboratorio de Genetica Molecular, Facultad de Medicina, Universidad de Antioquia, Colombia; 3) Center for Neurobehavioral Genetics, School of Medicine, UCLA, USA; 4) Departamento de Psiquiatria, Facultad de Medicina, Universidad de Antioquia, Colombia; 5) Department of Psychiatry, School of Medicine, UCSF, USA.

We are conducting genetic mapping studies in the populations of the Central Valley of Costa Rica (CVCR) and of Antioquia (Colombia). These two populations were established in the 16-17th centuries mostly by the admixture of a small number of Spanish and Native Americans founders. Since their establishment these two populations have remained relatively isolated and have expanded over a thousand times (to a current size of about 3-4 million). Most of the Spanish founders of both areas originated in Southern Spain while the majority of the female founders were from Amerind populations most likely of the Chibchan-Paezan linguistic family (common in lower Central America and North-West South America). To examine the genetic relatedness of the populations currently living in the CVCR and in Antioquia we compared data for 4 mtDNA RFLPs, 10 Y-chromosome polymorphisms and 11 autosomal microsatellites. Both populations exhibited similar levels of genetic diversity with no significant genetic differentiation between them at any of the markers tested. The frequency of Native American haplotypes was similar both for the Y chromosome (CVCR: 5%, Antioquia: 1%) and for mtDNA (CVCR: 83%, Antioquia: 90%), with the mtDNA haplotype distribution being not significantly different from Chibchan-Paezan populations. The similar demographic history and genetic makeup of CVCR and Antioquia should facilitate comparative disease gene mapping in samples from these populations, particularly through the use of LD approaches.

**Assessment of Stratification in Linkage and Association Samples.** *N.C. Martin, S.J. Broxholme, L.R. Cardon.* Bioinformatics, Wellcome Trust Centre for Human Genetics, Oxford, England, United Kingdom.

Population stratification is often cited as a primary contributor of inflated false positive rates in genetic association studies. As a result, a number of robust family-based association strategies have been devised. These methods can protect against inflated Type I error due to sample mixing, but are also very inefficient in their usage of genotype data. An alternative to this strategy has been developed in the form of genomic control (J.K. Pritchard and N.A. Rosenberg, 1999, *Am.J.Hum.Genet.* **65**, 220-228; S.A. Bacanu, B. Devlin, and K. Roeder, 2000, *Am.J.Hum.Genet.* **66**, 1933-1944) in which anonymous genetic markers are used to assess the background degree of stratification and control for it when it is present.

Here we apply the method of Pritchard and Rosenberg to publicly available genome-screen data sets to evaluate the level of stratification in existing samples. The CEPH collection provides an illustrative example for these analyses, comprising more than 30 families that have been genotyped on up to 9,000 genetic markers. Random selection of a set of 40 unlinked markers was conducted 5000 times to evaluate the test statistic distribution. The results indicate a high level of homogeneity in the Utah samples, but increasing heterogeneity in the total sample on addition of the French, Amish and Venezuelan collections. These outcomes show promising sensitivity in the stratification test as a global indicator of sample heterogeneity.

**Eastern African origin of the human maternal lineage cluster, ancestral to people outside of Africa.** *T. Kivisild<sup>1</sup>, M. Reidla<sup>1</sup>, E. Metspalu<sup>1</sup>, J. Parik<sup>1</sup>, T. Geberhiwot<sup>2</sup>, E. Usanga<sup>3</sup>, A. Chaventre<sup>4</sup>*. 1) Estonian Biocentre, Tartu University, Tartu, Estonia; 2) Karolinska University, Stockholm, Sweden; 3) Kuwait University, Kuwait; 4) University Bordeaux 2, France.

More than 95% of non-Africans share a common African maternal ancestor in mtDNA haplogroup L3 via its two sub-clusters M and N. Other sub-clusters of haplogroup L3 are specific to different regions inside Africa. To cast further light on the regional diversification of the African mtDNA pool, in particular to the origin and the spread of haplogroup L3, we have analyzed control and coding region variation in >550 samples from Ethiopia, Egypt and Morocco against the data available for southern and western Africans. Based on complete mtDNA sequences we constructed and rooted the phylogenetic tree relating unambiguously all major African lineage clusters. We also identified a new eastern African mtDNA clade, branching between the roots of haplogroups L2 and L3. This evidence together with a high sequence variation in other sub-clusters of L3 suggests an eastern African origin of haplogroup L3. Phylogeographic founder analysis and coalescent calculations allude to a breakdown of the regional isolation in Africa from the start of the Holocene period.

**DNA polymorphisms of 127 genes on chromosome 21 in Chinese populations.** *W. Huang<sup>1,2</sup>, J.X. Shi<sup>1</sup>, H.F. Xi<sup>3</sup>, Z.W. Jiang<sup>1,3</sup>, K.X. Zhang<sup>1,2</sup>, Y. Wang<sup>1</sup>, L. Jin<sup>1,3</sup>, Z. Chen<sup>1,2</sup>.* 1) Chinese National Human Genome Center at Shanghai, Shanghai, China; 2) Rui Jin Hospital, Shanghai Second Medical University, Shanghai, China; 3) The Institute of Genetics, Fudan University, Shanghai, China.

Single-nucleotide polymorphisms (SNPs) are the most abundant form of genetic variations and have a great potential for mapping genes underlying complex genetic traits. The ultimate value of SNPs for linkage and association mapping depends in part on the allele frequencies of the markers and inter-marker linkage disequilibrium across populations. Although a great deal of effort has been invested in the identification of SNPs, limited information is available of the SNPs including their distribution and allele frequencies on the worldwide populations. As an initial step toward construction of an SNP database of the Chinese populations, we studied the SNPs in 127 genes with known function on chromosome 21 in 30 Chinese individuals derived from different populations along with European and African samples as references. Three chimpanzee samples were also included in this study. Among 60 genes (spanning 318,000 bp) that have been fully analyzed, we identified 549 SNPs. Transition occurred 2.7 times more frequently than transversion. There are 136 SNPs in coding regions, among which, 76 SNPs (55.9%) are non-synonymous. Three genes (AIRE, SOD1 and PRKCBP2) showed deviation from the expectation of neutrality. For 10-20% of the SNPs, their allele frequencies vary substantially among different Chinese ethnic groups and more so with the world populations. 8.9% of the SNPs are specific to Chinese populations and 17.9% can not be found in one of the two reference populations (European and African), suggesting the fallacy of relying SNP discovery on 'model' ethnic groups. For inter-species comparison, we identified 790 nucleotide differences between Human and Chimpanzee over a total of 75,249 bp from 20 genes (1.05 %) and some are shared between species. These data provided interesting first glimpse into the pattern of variation across the genomes among different populations, which suggest that the differences between populations should be considered in the selection of SNPs for the study of complex diseases.

**The Heritability of Early Onset Male Pattern Baldness.** *D.R. Nyholt<sup>1</sup>, N.A. Gillespie<sup>1</sup>, A.C. Heath<sup>2</sup>, N.G. Martin<sup>1</sup>.* 1) Genetic Epidemiology Lab, QIMR, Brisbane, Australia; 2) Department of Psychiatry, Washington University School of Medicine, St Louis, Missouri, USA.

Common baldness (androgenetic alopecia, AGA) is the most common form of hair loss in humans. In Caucasians, normal male hair loss, commonly known as "male pattern baldness" (MPB), is noticeable in about 20% of men aged 20, and continues to steadily increase with age, so that a male in his 90's has a 90% chance of having some degree of MPB.

In addition to being among the most common natural conditions that make men self-conscious, recent studies indicate associations of MPB with benign prostatic hyperplasia (BPH), coronary heart disease, hyperinsulinaemia and insulin-resistance-associated disorders such as obesity, hypertension and dislipidaemia, and that MBP is a risk factor for clinical prostate cancer (CaP). Measures of hair loss were obtained in the course of an interview study of a community-based sample of Australian twin individuals. Ratings, in terms of a global description of hair loss using the Hamilton-Norwood scale (a standard classification scheme which has been shown to have good test-retest reliability), were obtained for a total of 476 MZ and 408 DZ male pairs plus 143 MZ and 154 DZ male individuals aged between 25 and 36 years. Homogeneity test results indicated all stages of hair loss represent the same process (dimension). Subsequently, univariate genetic analysis assumed a single liability dimension (SLD) threshold model. Genetic analysis of the raw categorical data scores using Mx revealed that an additive genetic and non-shared environmental (AE) model best explained individual differences in MPB and that 81% of the total variance could be attributed to additive genetic effects (i.e., a heritability of 81%). Our current sample includes 81 DZ pairs concordant for hair loss, and 132 DZ pairs discordant for hair loss and is an excellent sample in which to pursue quantitative trait locus (QTL) linkage analysis for major genes influencing MPB.

**Breast-feeding and the risk of breast cancer in BRCA1 and BRCA2 mutation carriers.** *H. Jernstrom*<sup>1, 2</sup>, *H.T. Lynch*<sup>3</sup>, *P. Ghadirian*<sup>4</sup>, *B. Weber*<sup>5</sup>, *S.A. Narod*<sup>2</sup>. 1) Department of Oncology, The Jubileum Institute, Lund, Sweden; 2) Centre for Research in Women's Health, SWCHSC, Toronto, ON, Canada; 3) Dept. of Preventive Medicine and Public Health, Crighton University School of Medicine, Omaha NE; 4) Epidemiology Research Unit, Centre Hospitalier de l'Univ. Montreal, PQ, Canada; 5) Depts. of Medicine and Genetics and Abramson Family Cancer Research Inst., Univ. of Pennsylvania, Philadelphia, PA.

Several studies have reported that the risk of breast cancer (BC) decreases with increasing duration of breast-feeding. For most studies, the protective effect is greater for premenopausal than for postmenopausal women. An early age at first full-term pregnancy and increasing parity are associated with reduced risk of BC in the general population. However, among BRCA1 and BRCA2 carriers, pregnancy is associated with an increased risk of early-onset BC. The potential for breast-feeding to reduce the risk of BC in BRCA1 and BRCA2 mutation carriers is currently unknown. To evaluate the influence of breast-feeding on the risk of hereditary BC, we conducted a matched case-control study in women who carry deleterious BRCA1 or BRCA2 mutations. Cases were 411 mutation carriers who been diagnosed with BC, and controls were 411 mutation carriers without a history of BC. Cases and controls were matched for age and parity. Information about pregnancies and breast-feeding practices was derived from a questionnaire administered to the women during the course of genetic counseling. Among BRCA1 mutation carriers, the total duration of breast-feeding was sign. shorter for BC cases than for unaffected controls (6.8 vs 9.2 months;  $P = .002$ ). BRCA1 carriers who had breast-fed for more than one year were 40 % less likely to have BC than those who breast-fed for a shorter period OR 0.59 (95 % CI 0.40-0.87;  $P = .009$ ). A protective trend with total duration of breast-feeding was present ( $P = .02$ ). Among BRCA2 mutation carriers, no protective effect was observed from breast-feeding of any duration. BRCA1 carriers who breast-feed for more than one year have a sign. reduction in their risk of BC. Breast-feeding does not appear to confer protection against BC in BRCA2 mutation carriers.

**SNPSTRs: Inferring human evolutionary history from tightly-linked autosomal polymorphisms.** *M.J. Jobin<sup>1</sup>, P. Underhill<sup>2</sup>, A. Lin<sup>2</sup>, A. Knight<sup>1</sup>, L.L. Cavalli-Sforza<sup>2</sup>, J.L. Mountain<sup>1,2</sup>.* 1) Department of Anthropological Sciences, Stanford University, Stanford, CA; 2) Department of Genetics, Stanford University, Stanford, CA.

The mitochondrial genome and the non-recombining portion of the Y chromosome have provided a great deal of information regarding human history in part because there is no recombination within these segments. To extract additional information encoded within the autosomal regions of the nuclear genome, we have developed an approach to the assessment of histories of short autosomal DNA segments. Each such segment includes one short tandem repeat (STR) locus and at least one single nucleotide polymorphism (SNP). We call the combination of an SNP and STR a SNPSTR, and have developed a method for empirically determining phase for double (or multiple) heterozygotes. The SNPs and STR are chosen to be within a degree of proximity that allows recombination to be set to zero, so that the system may be assumed to have a single history. Because the STR and SNPs have dramatically different mutation rates, they provide information of very different resolution. Here we introduce the data derived from the SNPSTR systems we have developed thus far, including the global distribution of the haplotypes of SNPSTR systems on chromosomes 22 and 9. While even a single system sheds light on human evolutionary history, the power of the approach lies in combining the results from multiple SNPSTR systems.

**Genetic contribution to waist circumference, hip circumference and waist-to-hip ratio in a lean population: the Korean Cardiovascular Genome Study.** *S.H. Jee<sup>1,2</sup>, H.Y. Park<sup>1</sup>, J.H. Kwon<sup>1</sup>, E.K. Im<sup>1</sup>, E.Y. Cho<sup>1</sup>, J.H. Lee<sup>1</sup>, Y.S. Jang<sup>1</sup>.* 1) Cardiovascular Genome Center, seoul, south Korea; 2) Graduate School of Health Science and Management.

A major gene for abdominal visceral fat area was found in several studies conducted in Western population. Some studies, however, have found after controlling for total fat mass that this major genetic effect was not as strong. To address this issue, we investigated environmental, familial, and genetic influences on waist circumference (WC), hip circumference (HC) and waist-to-hip ratio (WHR) before and after controlling for total fat mass, in 640 members of 78 families who had participated in Korean Cardiovascular Genome Study. Maximum likelihood methods were used to fit several genetic and nongenetic models of inheritance to these data to determine whether an unobserved Mendelian major gene could explain the familial distribution of WC, HC and WHR. Adjustments for age, age<sup>2</sup>, body mass index, smoking, alcohol consumption, and exercise were carried out separately for males and females by multiple regression procedures for WC, HC and WHR phenotypes prior to segregation analysis. WHR was normal distributed and ranged from 0.67 to 1.36, with a mean of 0.84 (male, 0.82 and females, 0.87). WC ranged from 55.5 to 122.8 cm in the entire sample. Correlations between WHR and WC decreased slightly after adjustment for covariates, but remained highly significant. Regression models were used to test genetic and non-genetic models in these 78 families. Segregation analysis did not provide statistical evidence of a major gene controlling either HC or WHR. Mendelian single-locus models with two underlying genotypic distributions were best supported by these data on WC, even after controlling for total fat mass, and this putative major gene explained the 25.8% of variance in adjusted WC. Future linkage studies may be worthwhile to further clarify the mechanisms controlling WC.

**Association between polymorphisms in TNF alfa and beta loci and 9 STR's within HLA region and R/S to Visceral Leishmaniosis in a Colombian population.** *N. Mesa*<sup>1</sup>, *P. Granda*<sup>1</sup>, *AV. Valencia*<sup>1</sup>, *ID. Velez*<sup>3</sup>, *S. Agudelo*<sup>3</sup>, *G. Bedoya*<sup>1,2</sup>, *A. Ruiz-Linares*<sup>1,4</sup>. 1) Molecular Genetics Group, University of Antioquia, Medellin, Antioquia, Colombia; 2) Departamento de Biología, Facultad de Ciencias Exactas y Naturales; 3) Programa para el estudio y control de enfermedades tropicales (PECET). University of Antioquia; 4) Galton Laboratory, University College London.

Leishmaniosis is a parasitic disease produced by hemoflagelated parasite, of which two clinical forms are recognized: the visceral Leishmaniosis (LV) caused by species of the complex *L. donovani* and the cutaneous Leishmaniosis (LC) caused by different species of *Leishmania*. LV is characterized by recurrent chronic fever, esplenomegalie, pancitopenic, weight loss and a high mortality. Segregation analysis has indicated that some genetic determinant could exist with a bigger effect in the susceptibility to the Leishmaniosis and its clinical progression. We evaluated by means of a study of cases and controls, the association grade between resistance/susceptibility (R/S) to the LV and genetics markers (STR's) in HLA region and well as polymorphism in TNF alfa and beta loci. For which, the individual cases were selected with infection antecedents, located in a LV focus from the Caribbean Colombian Coast. The control group with positive Montenegro test, but with out LV an antecedent was paired to the cases by sex, age and exposition risk. Genotipification was done by PCR-RFLP's for loci TNF alfa and beta and 9 STR's in HLA clusters genes (chromosome 6) were resolved using ABI 310 Genetic Analysis. Neither allelic nor genotypic frequencies exhibited significant differences when comparing TNF alfa and beta loci in controls and cases ( $P= 0.5$ ). In spite of the two groups did not show significant genetic structuration, ( $F_{st} = -0.0029$ ), significant differences with respect to linkage disequilibrium for some loci pairs appeared when comparing cases and control groups. We expect to continue evaluating other genomic regions that could be involved in R/S to LV and to elucidate the role of ethnic component in genetic etiology for this disease hence this population have an Amerindian filiation. Grant 9809 University of Antioquia.

**Effects of Population Substructure on the Homozygosity Test of Neutrality under the Stepwise Mutation Model.**

*H. Xu*<sup>1</sup>, *A. Renwick*<sup>2</sup>, *M. Kimmel*<sup>2</sup>, *R. Chakraborty*<sup>1</sup>. 1) Human Genetics Ctr, Univ Texas Houston, Houston, TX; 2) Dept Statistics, Rice Univ, Houston, TX.

The composite parameter,  $q = 4Nm$ , where  $N$  is the effective population size and  $m$  is the mutation rate, is an important parameter explaining the statistical properties of genetic variation. Thus, the differences of estimates of  $q$  based on alternative summary measures of variation have been used to develop test statistics to detect natural selection, presence of population substructure, and signatures of past demographic history of populations. In this investigation we show that these test procedures cannot be uncritically used to analyze data on microsatellite loci. Based on analytical as well as simulation studies of coalescent theory, we show that for microsatellite loci evolving via a stepwise mutation model, the number of segregating allele ( $k$ ) is not a sufficient statistic for  $q$ . Consequently, the relationship of expected homozygosity ( $F$ ) and number of segregation alleles ( $k$ ) is different as  $q$  changes. Furthermore, presence of population substructure differentially impacts the relationship of  $F$  and  $k$ . For small  $q$  (say,  $q < 1.0$ ), substructuring generates an excess of  $F$  for a given  $k$ , while the relationship is reversed (i.e., deficiency of  $F$ ) when  $q$  becomes large, particularly when  $k$  is large. As a consequence, the assertion that population substructure mimics the effect of overdominant selection appears to be true only for microsatellite loci with comparatively higher mutation rates and/or in populations of large effective size. (Research supported by NIH grants GM 41399 and GM 58545).

**Different maternal contribution to genetic structures of ethnic populations from Xinjiang Province in China.** *Y-G. Yao, Y-P. Zhang.* Lab. Cellular & Molec. Evol., Kunming Inst. Zool., CAS, Kunming, Yunnan, People's Republic of China.

Previous studies have shown that there were extensive genetic admixture in the Silk Road region. In the present study, we analyzed mtDNA data of 218 individuals from 5 ethnic populations from Xinjiang Province, China, which has been the via route of the Silk Road. In a simple way, we just classified the haplotypes identified into different haplogroups that have been described elsewhere and computed their relative frequencies, to show whether there are any differences in the genetic structure of these populations that performed various cultures. A decreasing frequency of the European-specific haplogroup was observed in these populations, with the highest value present in Uygur (42.6%), followed by Kazak (33.3%), Mongolian (20.4%), and Hui (6.7%), while no European types was found in Han population. Even in the frequencies of the Asian haplogroups, a clear difference was observed among these populations. Combined with the historical records and culture of these populations, recent migration, exogamous, and different extent of cultural isolation might be possible explanations for the observed various maternal contributions to the genetic structure in these ethnic populations.

**Genetic risk factors for cardiovascular disease and hypertension in high-altitude and low-altitude Native American populations.** *J.L. Rupert<sup>1</sup>, K. Kidd<sup>2</sup>, L.E. Norman<sup>3</sup>, M.V. Monsalve<sup>1</sup>, P.W. Hochachka<sup>4</sup>, D.V. Devine<sup>1</sup>.* 1) Pathology and Laboratory Med., Univ British Columbia, Vancouver, BC, Canada; 2) Department of Genetics, Yale University, CT; 3) Stanley Humphries Secondary School, Castlegar, BC, Canada; 4) Department of Zoology, Univ British Columbia, Vancouver, BC, Canada.

There is evidence suggesting that cardiovascular disease (CVD) and hypertension (HT) are less common in high-altitude populations than in those living at sea level. This may reflect increased cardiovascular efficiency associated with adaptive responses to prolonged hypoxia exposure. There are numerous genes with alleles that have been associated with increased risk for CVD and HT. We hypothesised that, over the hundreds of generations that humans have lived in the Andes, selection favouring adaptive cardiovascular fitness may have acted to eliminate these alleles from the gene-pool. To test this hypothesis, we determined allele frequencies for four polymorphisms in the renin-angiotensin system and three polymorphisms in the coagulation cascade in Quechua, an indigenous Andean population, and two lowland populations: Mayans from the Campeche State of the Yucatan and Caucasians of Western European descent. The polymorphisms examined were the insertion/deletion polymorphism in intron 16 of the angiotensin converting enzyme gene (ACE I/D), the C/A1166 mutation in the untranslated 3' region of the angiotensin 2 receptor (type 1) gene, an intronic substitution in the renin gene (G/AI9-83) and the Met235Thr polymorphism in angiotensinogen (AGT); as well as the Arg353Gln polymorphism in Factor VII, the Val34Leu polymorphism in factor XIII and the 5' A/G transition at base -854 in the b-fibrinogen gene. In all cases, allele frequencies were in Hardy-Weinberg equilibrium and, although allele frequencies in the Amerindians differed from those in the Caucasians at several loci (ACE, AGT and b-fibrinogen -854), there were no significant differences in frequency between the two Native American populations. These data suggest that selection has not favoured transmission of alleles at these loci in the Quechua, a high-altitude native population.

**Application of log-linear model of inference on disease susceptibility gene effects under independence of genotype and age.** *N. Tanaka<sup>1</sup>, T. Kinoshita<sup>2</sup>, T. Asada<sup>3</sup>, Y. Ohashi<sup>1</sup>*. 1) Dept Biostatistics, Univ Tokyo, Tokyo, Japan; 2) Dept psychiatry, National center of neurology and psychiatry, Tokyo, Japan; 3) Dept Psychiatry, Inst Clinical Medicine, Univ Tsukuba, Ibaraki, Japan.

Case-control studies provide a powerful approach for detecting disease susceptibility genes or markers that are in linkage disequilibrium with such loci. We focus particularly on situations wherein the genes of interest play roles in several diseases, and allele frequency among disease-free subjects consequently decrease with age. One approach frequently used for analyzing case-control data is logistic model, however, it cannot accommodate the dependence of genotype and age. Using log-linear-models we propose a hierarchical procedure providing a valid method for assessing the interaction in such situation. To assess the bias due to occurrence of other diseases, a theoretical calculation is presented. Then a proposed procedure is applied to simulated data and the observed data of Alzheimer disease and ApoE. By using our procedure, an appropriate inference on genetic effects can be derived whether the interaction is a gene-age interaction or merely a bias which due to occurrence of other diseases.

**Score statistics for linkage based on preferential transmission: when are they valid tests of association? J.**

Wicks<sup>1,2</sup>. 1) Inst. for Molecular Bioscience, Univ Queensland, St Lucia, Australia; 2) Department of Mathematics, Univ of Queensland, St Lucia, Australia.

Tests for linkage based on the preferential transmission of a particular marker allele to affected children can have considerably more power to detect linkage for complex diseases than traditional sib-pair or LOD-score methods. If such tests are also valid tests of association, then they have the additional property that positive results are suggestive of tight linkage between the disease gene and the marker, and can therefore be useful in localising disease genes.

Score statistics based on preferential transmission for a bi-allelic marker have the general form

$$(N_1 - N_2)^2 / \text{var}(N_1 - N_2) \quad (1)$$

where  $N_i$  is a function of the data counts corresponding to preferential transmission of marker allele  $A_i$ , and  $\text{var}(N_1 - N_2)$  is the variance, or an estimate thereof. The first statistic of this kind to be devised was the TDT. Various statistics of the form of (1) have since been devised for different types of nuclear families, and recently, for general pedigrees also (Martin et al, 2000).

In deriving a statistic of the form (1) to test for linkage, there are often a number of alternatives for  $\text{Var}(N_1 - N_2)$  which may be used. What we show is that this choice is the deciding feature in determining whether or not statistics of this form are valid tests of association as well as linkage. The TDT is a valid test of association as well as linkage for nuclear families with one affected child only. However, our results show that if the variance used in the TDT is replaced by a different variance estimate, then the resulting statistic is a valid test of *both* linkage *and* association when used with nuclear families with any number of affected children and with affected members of larger pedigrees also.

**Regional microsatellite variation in Finland.** *E.T. Salmela*<sup>1,2</sup>, *P. Lahermo*<sup>1</sup>, *M-L. Savontaus*<sup>3</sup>, *P. Sistonen*<sup>4</sup>, *J. Kere*<sup>1</sup>.  
1) Finnish Genome Center, University of Helsinki; 2) Department of Genetics, University of Turku; 3) Department of Medical Genetics, University of Turku; 4) Finnish Red Cross Blood Transfusion Center.

Even though the relationships between the Finns and other European populations have been subject to study and numerous disease gene studies have been successfully conducted among the Finns, the population structure of Finland has received little attention. We measured variation in the allele frequencies of 31 microsatellite markers from 15 different chromosomes among the Finnish population. The selection of the markers was based on the occurrence of rare alleles in the Finnish population observed during the routine genome wide scans performed at the Finnish Genome Center. Blood samples of 465 males were collected from different parts of Finland and grouped into nine subpopulations based on the birthplaces of their grandparents. The purpose of the study was to measure the quality and quantity of genetic variation within and between different regions of Finland. The earlier observations based on blood group markers have suggested substantial differences in the allele frequencies of individual markers on the community level but more subtle ones on the county level, and they were supported in this analysis. The total amount of variation was not conspicuously different between the regions of late and early settlement, although differences in the amount of variation between the individual counties within these two groups could be seen. No clear East-West cline was observable in the initial analysis. North Carelians in the east and Swedish-speaking Ostrobothnians in the west had the largest amount of deviations from the average allele frequencies of the Finns. These observed trends are expectable with regard to the Finnish population history.

**The origins of the Negroid Makrani population from Pakistan: maternal and paternal perspectives.** *L. Quintana-Murci<sup>1</sup>, R. Qamar<sup>2</sup>, S.Q. Mehdi<sup>2</sup>, Q. Ayub<sup>2</sup>, A. Mohyuddin<sup>2</sup>, T. Zerjal<sup>4</sup>, H.J. Bandelt<sup>3</sup>, K. McElreavey<sup>1</sup>, C. Tyler-Smith<sup>4</sup>.*  
1) Dept Human Immunogenetics, Pasteur Inst, Paris, France; 2) Biomedical & Genetic Engineering Division, Islamabad, Pakistan; 3) University of Hamburg, Germany; 4) Department of Biochemistry, University of Oxford, UK.

The Negroid Makrani population live near the Makran Coastal range in south-western Pakistan and are considered to have strong African roots based on anthropological and cultural evidence. The origins and affinities of this population have been investigated through a detailed genealogical study of mitochondrial DNA (mtDNA) and Y chromosome variation. RFLP and control region (CR) sequence analysis revealed that more than 40% of the Makrani mtDNA lineages belong to sub-Saharan African lineages, including L1a, L2, L3b and L3d. These lineages were not observed in more than 300 individuals belonging to other Pakistani ethnic groups, including Hazara, Hunza, Brahui, Parsi, Pathans, Balouchi, Sindhi and Kalash Kafirs. The Eurasian haplogroup U is the second most represented lineage (25%) in this population, the most dominant subcluster being the ancient U2 lineage. Haplogroup M, which has been proposed to trace an ancient migratory coastal pathway from East-Africa to India, was found at only 6% in the Negroid Makrani, but at more than 30% in the other coastal populations. The proportion of typical western-Eurasian lineages (H, I, J, T, X) in this population is notably lower than in the other Pakistani groups. In sharp contrast, the Y chromosome haplogroup distribution in the Negroid Makrani population is similar to the other Pakistani populations and distinct from African populations. The most represented lineages are haplogroups 3 (30%), 9 (18%) and 1 (18%). In conclusion, the study of the maternal and paternal gene pool of the present-day Negroid Makrani reflects that the sub-Saharan African contribution is mainly of matrilineal origin and that the African male-mediated gene flow has been very limited. Together, these results are consistent with significant directional mating between local males and females related to Bantu-speaking populations from sub-Saharan Africa.

**Genetical diversity of two isolated African-Brazilian populations.** *K.A. Sandes<sup>1</sup>, W.A. Silva Jr<sup>2,3</sup>, S.M.B. Sousa<sup>1,4</sup>, A.A.L. Barbosa<sup>1</sup>, P.L. Santos<sup>1</sup>, M.O.Q. Santos<sup>1</sup>, P.R.V. Bastos<sup>1</sup>, E.S. Souza<sup>1</sup>, M.A. Zago<sup>2,4</sup>.* 1) Universidade Estadual do Sudoeste da Bahia-Jequie-UESB; 2) Centro de Terapia Celular - Hemocentro de Ribeirao Preto; 3) Universidade Federal do Para - Nucleo Santarem; 4) Faculdade de Medicina de Ribeirao Preto - Universidade de Sao Paulo, Brazil.

Barra and Sao Goncalo are two communities located in Bahia, a State in the northeast region of Brazil. Both of them are constituted by black individuals who are descendent of ancient slaves brought from Africa. These communities are considered isolated in reproductive and cultural aspects, since they show high levels of endogamy and low migration levels. With the purpose of studying the genetical diversity of these isolated communities, we have analyzed the mitochondrial DNA hypervariable segment (HVS I) and have compared the sequences with the reported data from Caucasian, African and Amerindian populations. This segment from 220 individuals was amplified by PCR and sequenced in an ABI377™ automated sequencer. Thus far, 127 sequences have been analyzed and 56 different haplotypes have been identified. On the basis of the "Cambridge reference sequence" (Andrews et al., 1999), 93 variable sites were observed, 67 (72%) of them being polymorphic. The 16,223 (C®T) polymorphic site was the most frequent both in Barra and in Sao Goncalo (96%), a polymorphism reported to be found in 91% of typical African lineages. In average, 7% of the studied lineages were classified as being Amerindian. The FST values show that only 13.25% of the total genetic variation are attributed to differentiation between the two communities, which means that 86.75% correspond to the variability within each population. Although the two communities have similar origins and history, they do not share any common sequence.

**Founder effect in North-Eastern Quebec and the extent of the genetic signature associated with the myotonic dystrophy mutation.** V. Yotova<sup>1</sup>, E. Zietkiewicz<sup>1</sup>, E. Lemieux-Blanchard<sup>1</sup>, M. Labuda<sup>1</sup>, S. Bourgeois<sup>1</sup>, D. Labuda<sup>1</sup>, J. Fortin<sup>2</sup>, P. Lepage<sup>2</sup>, T.J. Hudson<sup>2</sup>, A. Lescault<sup>3</sup>, C. Laberge<sup>3</sup>. 1) Research Center, Hopital Sainte-Justine, Montreal, Quebec, Canada; 2) MGH Research Center, McGill University, Montreal Genome Center, Montreal, Quebec, Canada; 3) Centre hospitalier, Universit Laval, Ste-Foy, Quebec, Canada.

Myotonic dystrophy is frequent in French-Canadian population of North-Eastern Quebec (1:650). This dominant disorder is due to a CTG-triplet expansion in the DMPK gene on chromosome 19q13 (OMIM160900). Rather than directly analyzing the expansion, we wanted to define a unique haplotype composed of single-nucleotide polymorphisms, a SNP signature, eventually amenable to automatic screening. By the same token, we investigated the extent of the ancestral carrier-haplotype conservation in a young population issued from a founder effect and addressed the hypothesis of a single introduction of the DM-mutation in North-Eastern Quebec. SNPs were found *in silico* as well as experimentally in a population panel by DHPLC and subsequent sequencing. Twenty of these SNPs were typed in 51 DM-families by allele-specific oligonucleotide hybridization. The resulting haplotype extends over 2.3 Mb according to the recent UCSC map. There are two groups of DM haplotypes. The first, presumably young, is represented by a haplotype seen in 34 copies and a minor recombinant (2 copies). The second is represented by four variants (5, 5, 3 and 2 copies) that can be mutually related through single recombinations. These two groups could therefore represent two separate entries of the DM-chromosomes. On the other hand, they share a shorter core haplotype, suggesting a relatively recent common origin for both groups; genealogical data will help to trace it back in time. In conclusion, the DM-mutation appears to be associated with a limited number of unique SNP-signatures that are not shared with non-affected chromosomes; shorter segments of these haplotypes are relatively common in the population; our data demonstrate an important increase in the extent of linkage disequilibrium that can be related to the young age of the population of Quebec. (Supported by RMGA FRSQ).

**Effect of the Her2 V655I polymorphism on breast cancer risk in BRCA1/2 mutation positive and negative families.** *J.L. Rutter, N. Chatterjee, S. Wacholder, J. Struewing.* Division of Cancer Epidemiology and Genetics, National Cancer Institute, Bethesda, MD.

Overexpression of the Her2 proto-oncogene has been implicated in carcinogenesis of breast cancer, and is associated with poor prognosis. A polymorphism at codon 655 results in a valine to isoleucine change, and the valine allele has been associated with an elevated risk of breast cancer. We asked whether this Her2 V655I polymorphism could be an important susceptibility biomarker for breast cancer risk in women with and without BRCA1/2 mutations. We have a community-based collection of DNA samples and personal and family cancer history data on 5,318 Ashkenazim volunteers from the Washington, DC area. We extended the kin-cohort method to estimate age-specific breast cancer penetrance by Her2 variant status and also by the joint status of Her2 and BRCA1/2 mutations. Kin-cohort analysis uses the disease history of the relatives of the genotyped volunteers to estimate risk, and the volunteer's genotype information to infer a probabilistic distribution of the possible genotypes among the individual relatives. A subset of 769 subjects was identified that maximizes the information content with the fewest number of assays: 116 were BRCA1/2 mutation carriers, 454 were breast or ovarian cancer survivors or had two first degree relatives with breast cancer or a single relative with breast cancer before the age of 50, and 199 subjects were randomly selected. Her2 genotype frequencies for these 769 volunteers were 74% I/I, 23% I/V, and 2% V/V. Cumulative risks of breast cancer up to age 50, 60, and 70 were calculated. Breast cancer risk was significantly elevated for the BRCA negative/Her2 valine positive subjects, with relative risks (RRs) of 1.71, (95% CI 1.21, 5.76), RR = 1.40 (CI = 1.15, 4.19), and RR = 1.40 (CI = 1.18, 3.32) in the three age groups, respectively. Age-specific relative risks were similar among BRCA1/2 positive subjects, although these did not reach statistical significance due to low numbers. These results suggest that the risk of breast cancer is increased in carriers of the Her2 valine allele, and that the risk may be greater in younger women.

**The coalescence times of human genes and the divergence times of human populations.** *N.A. Rosenberg, M.W. Feldman.* Department of Biological Sciences, Stanford University, Stanford, CA.

The *divergence time* of two populations is the length of time that has elapsed since the populations arose from an ancestral group, while the *coalescence time* of a set of copies of a gene is the length of time since the most recent common ancestor of the gene copies was alive. If no migration has occurred between two descendant populations, the coalescence time of a given locus for a sample taken from the two populations must predate the divergence time of the populations. If migration has occurred, however, the coalescence time may be more recent than the divergence time. Using analytical results and simulations, we describe the relationship between coalescence times and divergence times in population genetic models with and without migration. Two main parameters impact this relationship: the ratio of the divergence time in generations to the size of each population ( $TD/N$ ) and the total number of migrants entering each population during each generation ( $Nm$ ). For small values of  $TD/N$ , the coalescence time exceeds the divergence time by a proportionately large amount. For large values of  $TD/N$  and small values of  $Nm$ , this excess is fairly small. If both  $TD/N$  and  $Nm$  are large, the probability that coalescence is more recent than divergence approaches 1. A bimodal distribution of coalescence times across loci is a signature of an intermediate amount of migration between descendant populations.

Selecting reasonable values for  $TD/N$  and  $Nm$ , the ancient coalescence times of certain human genes are seen to lie well within the predicted distribution of coalescence times under a recent origin of modern humans from an African founder population. These coalescence times are also consistent with a more ancient origin followed by migration among descendant populations. Additionally, the relatively ancient coalescences of Native American lineages need not contradict a relatively recent entry of humans into the New World. Genome-wide distributions of coalescence times from different subsets of the global population should soon become useful for testing hypotheses about the divergence times of human populations.

**ELAC2(HPC2) variation does not contribute to elevated prostate cancer risk in the Afro-Caribbean population of Tobago.** *P.R. Shea<sup>1</sup>, R.E. Ferrell<sup>1</sup>, A.L. Patrick<sup>2,3</sup>, L.H. Kuller<sup>2</sup>, C.H. Bunker<sup>2</sup>.* 1) Departments of Human Genetics and; 2) Epidemiology, University of Pittsburgh, Pittsburgh, PA; 3) Tobago Regional Health Authority, Trinidad and Tobago.

Recently, ELAC2 was identified as a positional candidate gene for prostate cancer (PCa) susceptibility. Two common missense variants, Ser217Leu and Ala541Thr, were found to be associated with familial and sporadic PCa, particularly among cases diagnosed prior to age 60. Previous studies have included a limited number of individuals of African ancestry. Afro-Caribbean males from Tobago have an elevated screening-detected prevalence of PCa (135/1000 in men over 50 years of age). As part of a systematic attempt to identify genes that influence the risk of PCa in the Tobago population, we screened 93 cases and 196 controls for the ELAC2 217L and 541T alleles reported to increase risk of PCa. The Tobago population was found to be homozygous for the common A541 (low-risk) allele in all cases and controls. The frequency of the 541T allele in African Americans was previously reported to be 0.8% compared to 3.2% in Caucasians. The proportion of the 541T allele in African Americans suggests that it is a Caucasian allele present in African Americans due to admixture. This is consistent with historical data suggesting that there is little non-African admixture in the Tobago Afro-Caribbean population. The frequency of the "high-risk" 217L allele in the Tobago cases was 0.21 compared to 0.23 in controls. In order to eliminate the possibility of African-specific alleles in ELAC2, we sequenced the entire coding region of ELAC2 in 24 Tobago prostate cancer patients and did not observe any additional variation. These data suggest that the PCa susceptibility gene, ELAC2, identified in Caucasians does not contribute to the elevated risk of PCa in the Tobago population.

**Fecundity is a familial trait in the Old Order Amish.** *T.I. Pollin<sup>1</sup>, R. Agarwala<sup>2</sup>, A.A. Schäffer<sup>2</sup>, A.L. Lodge<sup>1</sup>, T.M. King<sup>3</sup>, A.R. Shuldiner<sup>1</sup>, B.D. Mitchell<sup>1</sup>.* 1) University of Maryland, Baltimore, MD; 2) National Center for Biotechnology Information, NIH, Bethesda, MD; 3) University of Texas, Houston, TX.

Few studies have examined the genetic influences on fecundity in human populations. The Old Order Amish may be useful for this purpose because their religious beliefs strongly encourage large families and prohibit the use of contraception, and they are a closed founder population with well-documented genealogies dating back to the 18th century. From a large Amish genealogical database, we selected for analysis of fecundity the 2246 members who (1) were descendants of one or both of the genealogy's founders, (2) had survived to at least age 60 by the time the genealogy was compiled (1988), (3) had married only once and (4) were married to an individual meeting the first three criteria. These individuals (comprising 1123 couples) had an average of  $7.1 \pm 3.5$  (mean  $\pm$  SD) children, with a range from 0 to 18. Mean number of children did not change over time (maternal birth cohort years 1787-1927; Pearson correlation coefficient = -0.03,  $p = 0.40$ ).

Using quantitative genetic methods, we estimated the heritability of fecundity, considered as a quantitative trait, to be significantly greater than 0 ( $h^2 = 0.15 \pm 0.02$ ;  $p = 3.7 \times 10^{-24}$ ). Seventy-four individuals (37 couples) had no children, indicating a frequency of complete infertility of 3.3%. However, the ratio of the sibling recurrence risk of this trait to the overall risk did not differ appreciably from 1 [ $I_s = 0.74$ ; 95% CI: (0.30, 1.80)].

We conclude that there is significant evidence for familial aggregation of fecundity in this population, although we were unable to detect a significant genetic influence on gross infertility. The observed familial nature of fecundity may result from either familial clustering of behavioral characteristics or alternatively from genetic influences on reproductive biology.

To be presented by J. Sequeiros instead of A. Sousa.

Program Nr: 1406

**Familial amyloid neuropathy (FAP Met30) in Portugal: a combined use of family studies and a 60 years' register in the assessment of anticipation of age-at-onset and of the evolutionary dynamics of the gene.** A. Sousa<sup>1,2,3</sup>, A.M. Silva<sup>2,4</sup>, M. Marta<sup>2,4</sup>, J. Sequeiros<sup>1,3</sup>, T. Coelho<sup>2,5</sup>. 1) Dept Population Studies, ICBAS, Porto, Portugal; 2) Unidade Clinica Paramiloidose, HGSA, Porto, Portugal; 3) UNIGENE, IBMC, Univ. Porto, Portugal; 4) Dept Neurology, HGSA, Porto, Portugal; 5) Dept Neurophysiology, HGSA, Porto, Portugal.

Familial amyloid neuropathy, an AD disease due to a point mutation in chr18q11.2-q12.1, was first described in Portugal by Andrade (1952). Portugal represents the largest focus of the most frequent mutation worldwide (Val30Met). Between 1939 and December 1999, 1599 patients (from 478 independent kindreds) were diagnosed at HGSA/CEP in Porto (Portugal), 925 of which since molecular diagnosis became available (in 1985). Proband's who report absence of disease in either parent have increased. This does not represent de novo mutations but incomplete penetrance in previous generations, as often proven by molecular diagnosis. Mean age-at-onset was significantly higher in patients with no affected parent (45.3 yrs., SD 12.6) than in patients with one affected parent (31.6 yrs, SD 7.1). We studied 428 parent-offspring pairs, where both were affected and observed at the Center in the past 60 years: mean anticipation was 7.1 yr. (SD 10.4), being 9.5 yrs. when the disease was maternally inherited and 4.4 yrs when the transmitter was the father. After excluding pairs involving a proband, mean anticipation was still 6.4 yrs. In order to correct for a cohort effect (excess of offspring with early onset), we also excluded pairs where offspring were born before 1950: mean anticipation was still 6.6 yrs. A random sample of pairs yielded a similar result. These methods of correction for ascertainment point out to a true biological phenomenon. On the other hand, among 221 families diagnosed since 1985, 112 probands (mean age-at-onset: 33.8 yrs) had one affected parent while for the other 109 (mean 48.4) FAP was unknown in previous generations. These two apparent antithetical features (anticipation running in families and probands of new families having later onset) need further investigation in order to understand the evolutionary dynamics of this mutation.

**Postgenome Strategies for Mapping Disease Susceptibility Loci.** *B. Rannala, J.P. Reeve.* Department of Medical Genetics, University of Alberta, Edmonton, AB, Canada.

The imminent availability of a complete annotated human genome sequence (AHGS) necessitates the development of new methods for disease gene mapping. Existing methods assume that no information is available about the position of a disease mutation prior to a marker-based study of affected individuals. However, the distribution of genes across the genome modifies the probabilities that particular regions harbor disease mutations. If combined with an extensive database of single nucleotide polymorphisms (SNPs) or other markers, an AHGS can also influence the choice of genetic markers; different strategies are possible such as choosing markers uniformly over a region, preferentially choosing markers within exons, etc. Information from databases that catalogue the positions of mutations in known disease genes can also be used as a guide in marker choice. New multipoint statistical methods are presented for mapping disease susceptibility mutations using either linkage analysis, or linkage disequilibrium analysis, and taking full account of information from a human mutation database and an AHGS. Monte Carlo computer simulations are used to study the statistical accuracy and power of these methods. The accuracy and power of several strategies for choosing SNPs or other markers, in the context of an AHGS, for use in mapping studies of either simple, or complex, genetic disorders are also examined by computer simulation.

**Geographic latitude and frequency of the G protein b3 subunit (GNb3) C825T variant are strongly associated with blood pressure in a worldwide ecological analysis.** *J.H. Young, W.H.L. Kao, A. Chakravarti, M.A. Levine, M.J. Klag.* Departments of Medicine, Epidemiology and Genetics, Johns Hopkins, Baltimore, MD.

Climatologic factors that vary by latitude influence blood pressure (BP) and may have driven evolution of genes involved in BP regulation. To test this hypothesis, we determined the extent to which latitude and the hypertension candidate variant C825T of GNb3 contribute to inter-population variation in BP. Phenotype data were obtained from the Intersalt Study, a worldwide epidemiologic study of BP in 52 populations. Standardized protocols were used to measure systolic blood pressure (SBP), 24-h-sodium excretion (24-h-Na), body-mass index (BMI), and alcohol intake; population averages of each variable were used for these analyses. Estimates of the GNb3 825T frequency were obtained from previously published studies of this allele in populations that were ethnically similar and geographically approximate to Intersalt populations. Regression analyses were performed using 35 of 52 Intersalt sites with available genotype data. Mean SBP (mmHg) ranged from 96.0 to 127.0 (mean = 117.5). Absolute latitudes ranged from 0.18 to 61.6 degrees and 825T frequencies ranged from 0.21 to 0.85. In univariate analyses, latitudes were associated with mean SBP while 825T frequencies were not ( $P < .001$  and  $P = 0.9$ , respectively). However, after adjusting for latitude, 825T frequencies were strongly and positively associated with mean SBP ( $P < .001$ ). In univariate analysis, latitude explained only 28% of the variation in mean SBP; however, when 825T frequencies were added to the model, these two variables accounted for 65% of the inter-population variation in mean SBP. Adjustment for mean 24-h-Na, BMI or alcohol intake did not change these results significantly. The ecological nature of this analysis limits causal conclusions; 825T frequency may represent other latitude-correlated gene variants that influence BP or a non-genetic aspect of ethnicity related to BP. This study shows that latitude and GNb3 C825T are strong predictors of inter-population variation in SBP. These results suggest that ecological studies may be effective tools for the identification of genes involved in BP regulation.

**Parallels and contrasts in female and male human evolutionary history.** *P. Shen<sup>1</sup>, H. Tang<sup>2</sup>, P. Passarino<sup>5</sup>, B. Do<sup>1</sup>, R. Sung<sup>1</sup>, K. Davis<sup>1</sup>, C. Sharfe<sup>1</sup>, L.L. Cavalli-Sforza<sup>3</sup>, M.W. Feldman<sup>4</sup>, P.J. Oefner<sup>1</sup>.* 1) Genome Technology Ctr; 2) Departments of Statistics; 3) Departments of Genetics; 4) Departments of Biological Science, Stanford Univ., Palo Alto, CA; 5) Department of Cell Biology, University of Calabria, Rende, Italy.

Binary polymorphisms associated with the non-recombining region of the human Y-chromosome (NRY) and mitochondrial DNA preserve the paternal, respectively maternal genetic legacy of our species that has persisted to the present, permitting inference of human evolution, population affinity and demographic history. Using both denaturing high-performance liquid chromatography and dye-terminator sequencing, we screened 108 males from the five continents on 70 kb of NRY sequence, including the genes DFFRY, DBY, UTY1, TB4Y and EIF1AY, and 400 representatives of >50 ethnic groups on 15.6 kb of non D-loop mtDNA sequence. A total of 127 NRY and 1,709 mtDNA variable sequence sites were found, respectively. Based on genetic distance and mismatch distribution analysis a minority of East Africans, Sans and Pygmies represent the descendants of the most ancestral patrilineages of anatomically modern humans and their effective population size appears to have remained constant. Mismatch analysis shows that all other mtDNA and NRY lineages split from this ancestral group ~130,000 and ~72,000 years ago, respectively. There is strong evidence for a major expansion having occurred in mtDNA and NRY effective population size about 50,000 and 33,000 years ago. Mitochondrial DNA data suggest a second population expansion ~12,000 years ago in Europe at about the time of the Neolithic migration into Europe. A tree-partition method that does not depend on the demographic history of the population was used to estimate the time to the most recent common ancestor (TMRCA). The estimated TMRCA for NRY was ~92,000 years, while that for mtDNA was ~230,000 years. The discrepancy between NRY and mtDNA age estimates is the result of a significant reduction in variability on the NRY caused by selection, or demographic differences between males and females that led to the replacement of a substantial portion of the indigenous male pool in Africa.

**Reconstructing the prehistory of Ugandan populations.** *D. Barkhan*<sup>1</sup>, *T. Jenkins*<sup>1</sup>, *W. Byarugaba*<sup>2</sup>, *H. Soodyall*<sup>1</sup>. 1) MRC/Wits/SAIMR Human Genetic Diversity and Disease Research Unit, Dept. of Human Genetics, SAIMR/University of the Witwatersrand, Johannesburg, South Africa; 2) Department of Pathology, Makerere University, Uganda.

We have used mitochondrial DNA (mtDNA) and Y chromosome DNA to examine the gene pool of present day Ugandan populations. Our sample from Western Uganda represents four Bantu-speaking ethnic groups.

*mtDNA studies:* We screened for the presence of the mtDNA 9bp deletion in 259 unrelated individuals and sequenced ~800bp of the mtDNA control region in 89 individuals. The 9bp deletion was found in 18/259 individuals (6.9%). Control region sequencing revealed that 8/11 (72.7%) individuals with the deletion had sequence profiles representing the common form of the deletion in Africa. We derived 72 unique mtDNA types defined by 111 polymorphic sites from pairwise comparisons of sequences. MtDNA types associated with the 9bp deletion clustered in a separate branch in the NJ-tree. The tree could not resolve mtDNA types found in individuals from the different ethnic groups. Using the established mtDNA haplogroup nomenclature, we estimated that 40% of mtDNA types found in Ugandans belong to haplogroup L1, 16% to haplogroup L2 and 44% to haplogroup L3.

*Y chromosome studies:* We used the Y *Alu* insertion polymorphism (YAP) and four short tandem repeats (DYS393, DYS19, DYS390, DYS391) to derive Y chromosome haplotypes in 120 males. We derived 29 unique haplotypes. Three YAP+ haplotypes (YAP+-15-17-21-10, YAP+-14-17-21-10 and YAP+-13-15-21-10) together represented 48% of Ugandan Y chromosomes. We used networks to examine the distribution of Y chromosome haplotypes among the different ethnic groups, and to examine the evolutionary relationships of haplotypes found in Ugandans and neighbouring populations.

We discuss the genetic affinities of Ugandan populations with other sub-Saharan African populations, and evaluate relative female and male contributions to the gene pool of present day Ugandans.

## **Y-CHROMOSOME BIALLELIC POLYMORPHISMS AND NATIVE AMERICAN POPULATION**

**STRUCTURE.** *M. Bortolini*<sup>1,2</sup>, *F. Salzano*<sup>2</sup>, *C. Bau*<sup>2</sup>, *Z. Layrisse*<sup>3</sup>, *M. Petzl-Erler*<sup>4</sup>, *L. Tsuneto*<sup>4</sup>, *K. Hill*<sup>5</sup>, *A. Hurtado*<sup>5</sup>, *D. Castro-de-Guerra*<sup>3</sup>, *G. Bedoya*<sup>6</sup>, *A. Ruiz-Linares*<sup>1,6</sup>. 1) Department of Biology, University College London, London, UK; 2) Departamento de Genetica, Universidade Federal do Rio Grande do Sul, Porto Alegre, Brasil; 3) Departamento de Genetica, UFP, Curitiba, Brazil; 4) IVIC, Caracas, Venezuela; 5) Department of Anthropology, UNM, Albuquerque, USA; 6) Laboratorio de Genetica Molecular, Departamento de Fisiologia y Bioquimica, Facultad de Medicina, Universidad de Antioquia, Medellin, Colombia.

We recently evaluated South Amerind population structure using data from mtDNA RFLPs and Y-chromosome STR and failed to detect a significant difference in migration rates between males and females (Mesa et al., 2001:AJHG; 67: 1277-1288). However, the high mutation rate of STR might affect estimates of genetic structure for the Y-chromosome. To assess the dependence of our conclusions on the type of Y-chromosome marker analyzed we examined 7 Y-biallelic markers in 356 individuals from 17 Native South American populations. Data for most of these markers are also available for a number of native populations from Central and North America. Within and between population diversity was also assessed for these regions using available mtDNA RFLPs data. For both Y-chromosome and mtDNA markers we observe increasing levels of population structure from North to South America with Central America showing intermediate values. This trend is more pronounced for Y-chromosome than for mtDNA, resulting in an inversion of the relative male/female migration rate between North and South America (from about 3/1 to 1/2). These new analyses are consistent with our previous findings and emphasize the importance of genetic drift in the evolution of Native American populations.

**DNA Pooling, Genome Control and Association Studies.** *L. Hill, A. Jawaid, P. Sham, R. Plomin.* SGDP Research Centre, Institute of Psychiatry, King's College London, London, UK.

In case-control studies, ethnic stratification can lead to spurious associations between loci and phenotype. If population samples are well matched, then allele frequencies will tend to be similar between cases and controls for unlinked markers, and will only show significant allele frequency differences when the marker is near susceptibility loci. If stratification is present, however, then more widespread allele frequency differences should be detected. Most association studies to date have only examined candidate regions, containing small numbers of markers. Ethnic stratification cannot be eliminated in these instances, unless additional unlinked markers are genotyped. Pritchard and Rosenberg (*Am J Hum Genet*, 65:220-228, 1999) suggest that, for microsatellites, genotyping an additional 15 - 20 unlinked loci are sufficient to test for stratification.

As part of a genome wide association scan for cognitive ability, we have examined 1847 SSR markers at approximately 2 cM intervals throughout the genome using DNA pooling as a screening tool. Prior to including all 1847 markers, we studied 60 markers on chromosome 1 as a paradigm study, to ascertain that our case-control samples are not subject to stratification. We extended genomic control to DNA pooling using estimated allele frequencies to calculate a Chi squared statistic for each marker, which were then summed to generate the stratification statistic. The genomic control results based on DNA pooling indicated that no stratification was present ( $p = 0.986$ ). To our knowledge, this is the first genome wide association scan to assess stratification using the genome control method with DNA pooling.

**Analysis of population structure of Japanese population using genotype data of genome wide hundreds of SNPs.**

*R. Yamada*<sup>1</sup>, *H. Kawakami*<sup>2</sup>, *M. Yamaguchi*<sup>3</sup>, *E. Tatsu*<sup>1</sup>, *A. Sekine*<sup>4</sup>, *K. Yamamoto*<sup>1</sup>, *Y. Nakamura*<sup>4</sup>, *T. Tsunoda*<sup>3</sup>. 1) Laboratory for Rheumatic Diseases, SNP Research Center, RIKEN, Tokyo, JAPAN; 2) Laboratory of Molecular Medicine, Human Genome Center, Institute of Medical Science, University of Tokyo, Tokyo, JAPAN; 3) Laboratory for Medical Informatics, SNP Research Center, RIKEN, Tokyo, JAPAN; 4) Laboratory for Genotyping, SNP Research Center, RIKEN, Tokyo, JAPAN.

Linkage disequilibrium mapping is used to locate disease susceptibility loci. This technique, using a dense map of single nucleotide polymorphisms (SNPs), has been advocated as the method of choice for complex genetic diseases. A serious problem with linkage disequilibrium mapping has been suggested that population structure could lead to many spurious associations between genetic markers and a disease phenotype, especially for studies using samples from ethnically heterogeneous region. Japanese population has been considered to be less heterogeneous, and, therefore, more appropriate for linkage disequilibrium mapping than many other populations in the world, because of its ethnic isolation both historically and geographically, although no analysis based on genotype data has been reported. In order to obtain evidence of homogeneity of Japanese population, we investigated population structure of Japanese population with genotype data of hundreds of individuals and of hundreds of unlinked SNPs distributed throughout the genome. We adopted two analytical methods. One method is to assess existence of difference in population structure between two sample groups from geographically different sampling locations in Japan, by analyzing chi square statistics computed for multiple contingency tables constructed for an association test between allele frequency of each SNP and sub-populations. The other is to infer population structure by model-based clustering method using Markov chain Monte Carlo algorithm incorporating genotype data of multiple SNPs. We found that no significant population structure existed between two sample groups, each of which represented one of the two largest Japanese metropolises, Tokyo and Osaka.

**Inbreeding in Eastern Antioquia (Oriente), Colombia.** *I. Soto-Calderon<sup>1</sup>, P. Montoya<sup>1</sup>, J. Ospina<sup>1</sup>, G. Bedoya<sup>1</sup>, A. Ruiz-Linares<sup>1,2</sup>.* 1) Laboratorio de Genetica Molecular, Departamento de Fisiologia y Bioquimica, Facultad de Medicina, Universidad de Antioquia, Medellin, Colombia; 2) The Galton Laboratory, Department of Biology, University College London.

The population of the province of Antioquia in North-West Colombia was established in the 16th-17th century through the admixture of a small number of immigrants (mostly Spanish) and Native Americans. Historical records indicate that the demographic growth of this region occurred in relative isolation and several founder effects for Mendelian disorders have been documented in the province. Some of the oldest Antioquian settlements were established to the East of the province (Oriente region) where a concentration of cases for Mendelian (albinism, cystic fibrosis) and complex (bipolar) disorders has been noted. We surveyed surname frequencies in Antioquian municipalities and found that the Oriente region differed significantly from other areas. The inbreeding coefficient estimated from isonymy in three Oriente municipalities ranged between 0.01 and 0.02 with 7 surnames accounting for about 50% of those present in this area. To examine the temporal trend in inbreeding, information from census records for the years 1667, 1786, 1813, 1843 and 1851 and from marriage and baptismal Church records between 1720 and 1836 was examined for one of the oldest Oriente municipalities (Marinilla). The inbreeding coefficients estimated from surname frequencies varied between 0.006 and 0.008 with a trend towards an increase throughout the 19th century. For the period between 1800-1813 information on consanguineous marriage dispensations resulted in an inbreeding coefficient of 0.002. The level of inbreeding in Oriente as assessed by these two methods is similar to that seen in other human population isolates and indicates favorable conditions for genetic mapping studies in Antioquia.

**GAA triplet-repeat variation at the Friedreich ataxia locus in Nahuatl Indians of Mexico.** *R.M. Clark<sup>1</sup>, S. Bhatti<sup>1</sup>, E. Alonso<sup>2</sup>, P. Yescas<sup>2</sup>, A. Rasmussen<sup>2</sup>, S.I. Bidichandani<sup>1</sup>.* 1) Biochemistry & Molecular Biology, University of Oklahoma Health Sciences Center, Oklahoma City, OK; 2) Neurogenetics, Instituto Nacional de Neurologia y Neurocirugia Manuel Velasco Suarez, Mexico City, Mexico.

Friedreich ataxia (FRDA) is caused by abnormal expansions of a polymorphic GAA triplet-repeat sequence in the first intron of the frataxin gene. Normal and mutant chromosomes have 6-60 and 100-1700 triplet repeats, respectively. Population studies have shown that the people of Europe, North Africa, Middle East and India have the same distribution of GAA triplet-repeat alleles; 85% alleles contain 6-12 triplets (short normal, "SN"), 10-15% contain 13-60 triplets (long normal, "LN"), and approximately 1% of the chromosomes have pathologic expansions with >100 triplets. Haplotype analyses indicate that expanded alleles arise from a sub-population of LN alleles (those with at least 34 uninterrupted GAA triplets). In fact, people from East Asia (Japan, China, and South East Asia) have a significantly lower frequency of LN alleles (<1%), and consequently have a very low incidence of FRDA. A study of 66 chromosomes from Algonquin speaking Amerindians (Quebec and Ontario) showed a complete lack of LN alleles, apparently supporting an ancestral link with the populations of East Asia. We have conducted a study of a large cohort of another North American Indian population, the Nahuatl Indians of Mexico. Contrary to the data from Algonquins, we identified 7 LN alleles among the 344 Nahuatl chromosomes analyzed (2%). Analysis of 166 non-FRDA chromosomes from an otherwise unselected cohort of Mexican individuals revealed 10 LN alleles (6%), i.e., the Nahuatl population has a significantly lower prevalence of LN alleles ( $P = 0.0014$ ). These data have important public health implications for the incidence of FRDA among the native Indian populations of North America, in addition to the anthropological implications regarding their ancestral origin(s).

**Androgen receptor gene CAG and GGN polymorphic repeats and obesity in older adults.** *D.R. Gustafson, B.M. Koppnati.* Dept Nutrition & Food Sciences, Utah State Univ, Logan, UT.

The genetic basis for obesity and body fat distribution in humans is unclear. The X-linked androgen receptor gene (AR) has two polymorphic trinucleotide repeats in exon 1 related to transcriptional activity of the androgen receptor. Since differences in sex hormone metabolism relate to obesity patterns in men and women, AR variants may relate to obesity. We investigated the association between indices of obesity and AR (CAG)<sub>n</sub> and (GGN)<sub>n</sub> polymorphisms in a cross-sectional study of 103 men (51-93 years) and 117 women (51-92 years). AR (CAG)<sub>n</sub> and (GGN)<sub>n</sub> were quantified using Perkin Elmer Applied Biosystems GeneScan analysis software. Body weight, height, and waist and hip circumferences were measured. Waist was measured at the umbilicus (wstumb), iliac crest (wstili), and mid-way between the iliac crest and lowest rib (wstwst). Waist-to-hip ratios (WHRUMB, WHRILI, and WHRWST) were also calculated. Women who were both homozygous for (CAG)<sub>n</sub> ≥ 25 and homozygous for the two most common (GGN)<sub>n</sub> (=17 or =18) had higher wstumb (93.43±14.86 vs 85.02±10.19, p=0.003), wstili (97.02±10.83 vs 91.61±10.36, p=0.014), wstwst (88.20±11.68 vs 80.33±8.64, p=0.000), WHRUMB (0.908±0.081 vs 0.869±0.060, p=0.012), WHRWST (0.859±0.071 vs 0.821±0.052, p=0.005), and hip (102.61±10.36 vs 97.77±7.93, p=0.014) compared to women without this allele combination. The odds ratio (OR) related to the upper 25% of women with this allele combination was significant for wstumb (OR=5.29, 95% CI 1.48-18.92), wstwst (OR=3.62, 95% CI 1.15-11.39), WHRUMB (OR=5.61, 95% CI 1.57-20.02), and WHRWST (OR=5.29, 95% CI 1.48-18.92). Men who had both (CAG)<sub>n</sub> ≥ 23 and rare (GGN)<sub>n</sub> (≠ 17), had a higher mean WHRUMB (0.990±0.042 vs 0.971±0.049, p=0.043) and WHRILI (0.991±0.052 vs 0.967±0.047, p=0.017) compared to men without this allele combination. The OR related to the upper 25% of men with this allele combination was significant for WHRILI (OR=6.05, 95% CI 1.19-30.82) and WHRWST (OR=6.05, 95% CI 1.19-30.82). AR (CAG)<sub>n</sub> and (GGN)<sub>n</sub> allele combinations are strongly associated with obesity indices in older adults. Sponsored by NRICGP/USDA Award No. 97-35-207-4619 and Utah Agricultural Experiment Station.

**A duplication at the D10S526 microsatellite locus generates a bimodal distribution of allele sizes.** *P. Bender*<sup>1</sup>, *W. Beggs*<sup>1</sup>, *L. Toji*<sup>1</sup>, *J. Beck*<sup>1</sup>, *D. Long*<sup>2</sup>, *F. de Waal*<sup>2</sup>, *R. Johnson*<sup>1</sup>. 1) Coriell Institute, Camden, NJ; 2) Living Links Center, Yerkes Regional Primate Research Center, Emory University, Atlanta, GA.

The Coriell Institute uses the D10S526 microsatellite tetra-nucleotide repeat in the routine genotyping of its cell lines for DNA identification because of its high heterozygosity. Initial genotyping of 200 alleles indicated a heterozygosity of .84 and a PIC value of .83. Now that thousands of alleles have been genotyped, it is obvious that there is a bimodal distribution of allele sizes. Alleles are either 190 to 218 bp (short) or 226 to 258 bp (long). No alleles have been observed at 222 bp. Individuals occur who are homozygous either for the long and short alleles or are heterozygous, with long and short alleles. The molecular basis for this bimodal distribution could be explained by an ancient duplication of a short allele, generating the longer alleles with two polymorphic repeat regions separated by a short non-repetitive sequence. To investigate this possibility, short and long alleles were isolated from polyacrylamide gels and sequenced. The sequence results demonstrate that whereas the short alleles have a single polymorphic tetra-nucleotide repeat, long alleles have two polymorphic repeat regions separated by an invariant dinucleotide. This finding complicates the interpretation of allele scoring and increases the number of long alleles. Two long alleles of the same size may, therefore, not be identical. For example, a 20 repeat allele could result from the presence of an 11 repeat in the first region followed by a 9 repeat in the second region, or a 9 repeat in the first region followed by an 11 repeat in the second region. Such homonym alleles have been identified by sequence analysis. The origin of this duplication was investigated by genotyping non-human primates. Twenty-four chimpanzees (*Pan troglodytes*) and one bonobo (*Pan paniscus*) were genotyped for the D10S526 microsatellite. None of the 50 alleles analyzed were long. Thus, either the long allele is not present in primates or occurs at a low frequency. These results indicate that the duplication may be a late event in human evolution and that the long alleles are specific to the *Homo sapiens* lineage.

**Evolution of Microsatellite Loci and Past Demography of Modern Humans.** *M. Kimmel*<sup>1</sup>, *A. Renwick*<sup>1</sup>, *R. Deka*<sup>2</sup>, *R. Chakraborty*<sup>3</sup>. 1) Dept Statistics, Rice Univ, Houston, TX; 2) Dept Environmental Health, Univ of Cincinnati, Cincinnati, OH; 3) Human Genetics Ctr, Univ Texas at Houston, Houston, TX.

The group involving these authors, previously analyzed several large data sets involving di-, tri- and tetranucleotide repeat loci throughout the human genome. We also developed new statistical tools to analyze these data. In the present communication, we carry out a comparative analysis of these data sets, in the context of the molecular evolution of short repeat-DNA and past demography of populations harboring these loci. The tools we use involve decomposition of genetic diversity, coalescent simulations under variable rate and pattern of mutation (e.g. admixture of large-step mutational changes, constraints etc.), as well as analysis of ascertainment bias of human versus primate microsatellites. The conclusions can be summarized as follows: (i) Di- and tetranucleotide loci fit the stepwise mutation models with mutation rate varying from locus to locus and large allele-size changes occurring in about one-tenth of mutants. (ii) Trinucleotide loci are better fitted by models involving constraints on the number of repeats. (iii) Mutation rates differ among these three types of loci. In anonymous or non-gene associated loci, the highest mutation rate occurs in dinucleotides, the lowest in tetranucleotides. However, in disease-related trinucleotides, even in normal subjects, the mutation rate seems to be highest than in anonymous loci. (iv) The data seem to be consistent with the hour-glass scenario of demographic expansion of modern humans. (v) The extent of difference observed between diversities of homologous human and primate microsatellite loci cannot be explained by ascertainment bias alone. It suggests a higher mutation rate of human, as compared to primate, microsatellites. The results are discussed in view of other findings concerning evolution of human and non-human microsatellites. (Research supported by NIH grants GM 41399, GM 45816 and GM 58545).

**Multiple haplotypes in DM2 indicate multiple founder mutations.** *C.L. Liquori<sup>1</sup>, K. Ricker<sup>2</sup>, J.F. Jacobsen<sup>1</sup>, L.J. Rasmussen<sup>1</sup>, K.A. Dick<sup>1</sup>, J.C. Dalton<sup>1</sup>, J.W. Day<sup>1</sup>, L.P.W. Ranum<sup>1</sup>.* 1) Institute of Human Genetics, University of Minnesota, Minneapolis, MN; 2) Department of Neurology, University of Würzburg, Germany.

Myotonic dystrophy (DM) is the most common form of muscular dystrophy in adults. The existence of more than one genetic type was recognized after genetic testing became available for myotonic dystrophy type 1 (DM1). DM1 is caused by a CTG expansion within the 3' UTR of the *myotonia dystrophica-protein kinase* gene. The mechanism by which this untranslated expansion causes DM remains unclear. To better define DM pathogenesis, we have studied a second genetic form of DM, myotonic dystrophy type 2 (DM2). We previously mapped the DM2 locus to chromosome 3q21 and refined the region to 2cM with 10 recombinant chromosomes. Linkage disequilibrium analysis in parent-offspring trios from 64 DM1-negative families narrowed the region to ~320 Kb with several markers in linkage disequilibrium (*CL3N58* ( $p < 0.000001$ ), *CL3N59* ( $p = 0.0001$ ), *CL3N84* ( $p = 0.0001$ ), and *CL3N99* ( $p = 0.0075$ )). We discovered that DM2 is caused by a CCTG expansion in intron 1 of the *zinc finger protein 9* gene (see Ranum, *et al.*). We determined haplotypes for 74 families with genetically-confirmed DM2 using 18 new STR markers in the DM2 region. All of the families are Caucasian with the majority of German descent. We found two distinct haplotypes. 60 families share haplotype A, which spans ~425 Kb. Of those families, a subset show an ancestral recombination event, reducing the size of the shared chromosomal region to ~320 Kb. 14 families share haplotype B, which spans ~800 Kb. Families with either haplotype have consistent clinical features and the CCTG expansion. Fine mapping with additional markers will be done to determine if the A and B haplotypes converge close to the mutation. We have also identified 23 families that lack both the DM1 and DM2 expansions, indicating the existence of at least one additional DM gene (DM3).

**Expression and population studies of the TATA-box binding protein polyglutamine region at normal and expanded lengths.** *S.J. Reid<sup>1</sup>, M.I. Rees<sup>1</sup>, W.M.C. van Roon-Mom<sup>2</sup>, A.L. Jones<sup>3</sup>, M.E. McDonald<sup>4</sup>, G.T. Sutherland<sup>1</sup>, M.J. Owen<sup>3</sup>, M. Dragunow<sup>5</sup>, R.G. Snell<sup>1</sup>.* 1) Department of Molecular Medicine, University of Auckland Medical School, Auckland, New Zealand; 2) Department of Anatomy and Radiology, University of Auckland Medical School, Auckland, New Zealand; 3) Department of Psychological Medicine and Medical Genetics, University of Wales College of Medicine, Cardiff, UK; 4) Molecular Neurogenetics Unit, Massachusetts General Hospital, Charlestown, USA; 5) Department of Pharmacology, University of Auckland Medical School, Auckland, New Zealand.

Several inherited, late onset, neurodegenerative diseases are associated with expansion of CAG repeats within coding regions, resulting in pathogenic glutamine tracts in the respective proteins. TATA-box binding protein (TBP) contains a polymorphic polyglutamine (polyQ) coding repeat ranging in size from 25-42, clearly extending into the pathogenic (>37) threshold repeat length observed in polyQ disorders. Indeed, a de-novo polyQ expanded TBP allele was recently reported in a patient with a sporadic, early-onset neurodegenerative disorder, showing that a disease phenotype is associated with TBP polyQ expansions. To assess the population distribution of TBP alleles, we carried out a large population study of the TBP polyQ repeat coding sequence, which did not reveal expansions larger than 41, suggesting a biological selection against further expansion, or that the expansion has reached a stable equilibrium. However, allele frequency studies of different human populations indicate that the repeat is at least ancestrally unstable. To identify the critical repeat length in TBP that may result in a disease with long term population effects, a cellular model of protein misfolding was used, expressing full length TBP carrying polyQ expansions. We found that insoluble intracellular inclusions are formed in a repeat length dependant manner, with a threshold level of inclusion formation. These results show that expansions within TBP produce a protein with altered structural properties in a manner reminiscent of other polyQ human diseases.

**Association of the Apolipoprotein E (APOE) Gene with Age-Related Macular Degeneration (AMD): A pooled case-control study.** *S.A. Schmidt<sup>1</sup>, M.B. Gorin<sup>2</sup>, C.C.W. Klaver<sup>3</sup>, K.W. Small<sup>4</sup>, J.L. Haines<sup>5</sup>, E.A. Postel<sup>1</sup>, A.M. Saunders<sup>1</sup>, C.M. van Duijn<sup>3</sup>, D.E. Weeks<sup>2</sup>, R. Ferrell<sup>2</sup>, A. Agarwal<sup>5</sup>, M.A. Pericak-Vance<sup>1</sup> for the APOE-AMD Consortium.* 1) Ctr Human Genetics, Duke Univ Medical Ctr, Durham, NC; 2) Univ of Pittsburgh Graduate School of Public Health/School of Medicine, Pittsburgh, PA; 3) Erasmus Univ Medical School, Rotterdam, The Netherlands; 4) The Jules Stein Eye Institute, Univ of California, Los Angeles, CA; 5) Vanderbilt Univ Medical Ctr, Nashville, TN.

AMD is a complex genetic disorder affecting older adults. The APOE4 allele has been reported to have a protective effect on AMD risk, while the APOE2 allele may increase disease risk. We have combined three independent data sets of Caucasian patients and controls (two US and one European) to study the role of APOE in AMD and to examine whether familial vs. sporadic cases of AMD represent different disease etiologies based on APOE-associated risks. Analysis of an additional US AMD data set is ongoing in order to strengthen and refine our results. Based on the currently available data comparing n=524 AMD cases and n=1187 controls with respect to APOE genotypes, we were able to confirm the protective effect of the APOE4 allele (age- and sex-adjusted odds ratio (OR) 0.54, 95% confidence interval (CI) 0.41-0.72, p=0.0001). The effect of APOE4 did not differ significantly between males and females and was consistent across all age groups. This overall effect was primarily due to cases (n=342) with a familial etiology (OR 0.43, 95% CI 0.30-0.60, p=0.0001). When only sporadic cases (n=182) were examined, the APOE4 effect was no longer statistically significant (OR 0.81, 95% CI 0.53-1.23, p=0.32). Evidence for an increased risk conferred by the APOE2 allele was found only for sporadic male patients (OR for male patients 2.72, 95% CI 1.38-5.35, p(interaction)=0.02 from logistic regression). In conclusion, these data strongly confirm that the APOE4 allele reduces the risk of AMD, particularly for patients with a positive family history of the disease. For male patients without a family history, the APOE2 allele appears to increase the disease risk, whereas this effect is absent in females.

**Utility of Hereditary Hemochromatosis (HH) Mutation Detection Tests in patients and relatives from a region with low prevalence of disease causing mutations.** *F.F. Fay<sup>1</sup>, M. Campodonico<sup>1</sup>, J. Daruich<sup>2</sup>, H. Tanno<sup>3</sup>, J. Rey<sup>2</sup>, J. Sorda<sup>2</sup>, O. Fay<sup>1</sup>, J. Findor<sup>2</sup>.* 1) Dept Molecular Biol, CIBIC, Rosario, Argentina; 2) Hospital de Clinicas San Martin - Buenos Aires; 3) Hospital del Centenario - Rosario.

**Introduction:** HFE gene mutation detection is used in populations from Northern-European origin as a confirmatory test for HH, and in the pre-symptomatic diagnosis of their first-degree relatives. Its utility has not been established in settings with lower prevalences of disease causing mutations.

**Aims:** To determine the presence of HFE gene mutations (C282Y and H63D) in patients with HH and their relatives, and to establish the clinical utility of this test in our region.

**Material and Methods:** C282Y and H63D mutations were investigated in 35 HH patients. From 15 patients (index cases) 30 first degree relatives were also studied (26 sons from 12 patients and 4 brothers from the other three). Mutation detection was performed using a multiplex PCR.

**Results:** From the 35 studied patients, 12 (34%) were C282Y homozygous, 7 (29%) were H63D heterozygous, 1 (3%) was double-heterozygote, 4 were C282Y heterozygous, 3 H63D heterozygous and 8 were wild type. Regarding the studied relatives, there were 8 with HH related mutations; 2 Hom282, 2 Hom63, and 4 Double-Het. The remaining 22 relatives had no disease causing genotypes.

**Discussion:** In HH patients the sum of Hom C282Y, Hom H63D and Double-Heterozygotes accounts for the 57% of the cases, which could justify the use of this tool as a diagnostic complement. The greater benefit is seen in the screening of relatives from those patients with one of the disease causing genotypes, since in 60% (6/11) of the latter there were relatives with genetic predisposition. On the other hand, in 38% (8/21) of the studied relatives we found disease causing mutations. These persons are being evaluated periodically to detect any increase in iron deposits, so preventive measures could be taken in advance.

Program Nr: 1423

**Informed choice and prenatal screening: comparison of same day vs return visit testing.** *T.M. Marteau, E.R. Dormandy, S. Michie.* Psychology & Genetics Res Grp, King's College London, London, England.

*Objective:* To test the hypothesis that rates of informed choice are higher when testing requires a return visit than when conducted as part of a routine antenatal appointment.

*Design:* Prospective, descriptive study.

*Setting:* Two hospitals in England.

*Participants:* 1500 women offered serum screening for Down syndrome.

*Outcome measures:* Informed choice, derived from measures of **knowledge** about the screening test, **attitudes** towards undergoing the test, and test **uptake**.

*Results:* Rates of informed choice were higher for same day than for return visit testing (64% vs 44%, CI<sub>95</sub> of difference 16, 26%). Regardless of levels of knowledge, same day testing did not result in more women with negative attitudes having the test than did return visit testing (9% vs 8%). However, return visit testing resulted in more women with a positive attitude towards testing **not** having the test than did same day testing (21% vs 7%, CI<sub>95</sub> of difference 9, 16%).

*Conclusion:* Screening offered as part of a routine visit appears to facilitate informed choice amongst those with positive attitudes towards screening without impairing informed choice amongst those with negative attitudes.

**Carrier screening for four common diseases in the South African Ashkenazi Jewish population.** *R. Kerr, C. Graf, F. Essop, B. Dangerfield, A. Krause.* Department of Human Genetics, School of Pathology, South African Institute for Medical Research and the University of the Witwatersrand, Johannesburg, South Africa.

Several inherited diseases have been recognized as occurring more commonly in the Ashkenazi Jewish population, including Tay-Sachs disease (TSD), cystic fibrosis (CF), Fanconi anaemia group C (FA-C) and Canavan disease (CD). Population carrier frequencies for the four diseases have been determined in other countries. Worldwide data reflect the following carrier frequencies: CF (1/24), TSD (1/27), CD (1/58) and FA-C (1/66). Ashkenazi Jews in South Africa may have some genetic differences from other Ashkenazi groups - e.g. Bloom syndrome, which has a carrier frequency of 1/80 in USA Ashkenazi Jews, has never been reported in South Africa. In order to offer carrier screening and accurate risk calculations for these conditions as part of our routine diagnostic service, it is essential that we generate carrier frequencies specific to the population we serve. Approximately 250 Ashkenazi Jewish South African individuals are being screened for the population-specific mutations which have been identified for each disease. Two CF mutations (DF508 and W1282X), two TSD mutations (intron 12 G→C splice mutation and exon 11 4bp insertion mutation), two CD mutations (C693A and A854C) and one FA-C mutation (IVS4+4A→T) will be tested for. Screening for Canavan disease in the South African Ashkenazi Jewish population reveals a carrier frequency of 1/93, which is approximately 2 times lower than frequencies reported elsewhere. TSD carrier frequencies for the South African Ashkenazi Jewish population have been determined using the enzyme assay (1/26). This rate will be refined using molecular techniques.

**Iranian Human Mutation Gene Bank.** *M.K. Javan, M. Neishabouri, A. Hajibeigi, K. Kahrizi, Y. Shafaghati, F. Pourfarzad, N. Nikzad, H. Najmabadi.* Genetics, Univ. of welfare and Rehabilit, Tehran, Tehran, Iran.

For over a decade prevention of the common genetic disorders was a national programme in Iran. The result of our ten years study on carrier identification and prenatal diagnosis of genetic diseases, has revealed the existence of a wide spectrum of mutations for certain diseases in this country. This is a reflection of Iran's long history of foreign invasion, immigration, cultural exchange and also the high prevalence of interfamilial marriages, creating a multiethnic society with the highly heterogeneous gene pool. During the last four years investigation we have established a DNA bank of all genetic disease with Mendelian mode of inheritance studied in Iran. Some of the samples are assigned to common or novel mutations and some others belong to patients with clinical profiles associated with a particular genetic disease but unidentified mutation. This bank stores patient and his/her first degree relatives DNA together with a comprehensive pedigree and clinical profile for each sample. To improve our diagnostics, we found it essential to establish a link between our findings and the other research projects elsewhere in the world by presenting our experimental projects and this DNA bank on line. Our web site as well as providing opportunities for us to collaborate with outside, offers a free of charge valuable sample resource to all the researchers in the world, who are working on various aspect on genetic disorders from prenatal diagnosis to gene structure and function. This article introduces the structure and the content of this DNA bank.

**An effective pooling strategy for feasible newborn screening of *GBJ-2* gene mutations.** *M. Caggana*<sup>1</sup>, *S. Duva*<sup>1</sup>, *H. Ostrer*<sup>2</sup>, *C. Oddoux*<sup>2</sup>, *R. Ruben*<sup>3</sup>, *K. Pass*<sup>1</sup>. 1) Wadsworth Ctr, NYSDOH, Albany, NY; 2) New York University School of Medicine, NY, NY; 3) Albert Einstein College of Medicine, Bronx, NY.

Congenital deafness affects approximately 1 per 1,000 newborns in the US. The causes of non-syndromic deafness are heterogeneous, with genetic factors accounting for 50-75%. In the absence of screening, the average age at diagnosis is 14 months, thus by waiting for a conventional diagnosis, an important window of opportunity for early intervention is missed. Approximately one-half of autosomal recessive congenital deafness is caused by mutations in the *GBJ-2* gene, which codes for the gap junction protein, Connexin-26. Mandatory hearing screening has been implemented recently in several states including New York. We undertook a pilot project to assess the feasibility of screening all newborns for two *GBJ-2* mutations (35delG, a pan-ethnic mutation and 167delT, a mutation more frequently found in individuals of Ashkenazi Jewish descent). A consecutive series of anonymous newborn dried blood specimens were tested (N=2,071) for both mutations by allele-specific oligonucleotide hybridization in single wells. This sample is representative of a 2-day workload for the NYS newborn screening program. Once the positive samples were identified, they were blinded and pooled by a factor of 8 thereby reducing the number of amplification procedures in 96-well plates from 22 to 3. All positive samples in the individual experiment were correctly identified in the pooled experiment, suggesting that it is plausible to sufficiently automate and manage this workload. The carrier frequencies of 35delG for Whites (n=1,111), Blacks (n=401), and "others" (n=107) were 2.16%, 0.25%, and 1.87% respectively. One homozygote for 35delG was identified. The overall allele frequency for del35G in this screening sample is 0.7%. For 167delT, the carrier frequencies were 0.36% in Whites, 0.28% in Hispanics, and 0.93% in "others". No homozygotes for 167delT were identified. The overall allele frequency for 167delT in this screening sample was 0.14%. Use of DNA analysis with audiometry will serve to "rule-in" the diagnosis of deafness permitting parents to pro-actively enroll their infants in intervention programs.

**Perilymphatic fistulae associated with *DFNBI*-related hearing loss.** C. Oddoux<sup>1</sup>, R.J. Ruben<sup>2</sup>, H. Ostrer<sup>1</sup>. 1) Division of Human Genetics, New York University School of Medicine, New York, NY; 2) Department of Otolaryngology, Montefiore Medical Center and Albert Einstein College of Medicine, Bronx, NY.

Mutations in the *DFNBI* gene produce prelingual hearing loss that is always sensorineural and is typically moderate to severe. Vestibular function is unaffected and no other phenotypic abnormalities have previously been observed. Little is known about the course of the hearing loss as most of the published studies have focused on children or adults evaluated well after the onset of deafness and these patients were not followed prospectively. Four children carrying two mutant alleles (combinations of 30delG and/or 167delT) were detected by *DFNBI*-mutation analysis of 26 children with sensorineural hearing loss who were followed prospectively by a single otolaryngologist. Retrospective review of their records revealed a common anatomic defect in the footplate of the oval window of five middle ears—a perilymphatic fistula. This defect was associated with progressive hearing loss in three of the four children. The fourth child had a particularly severe course of otitis media which could have accelerated progression of hearing loss. In some cases closure of the leak was associated with an increase in speech discrimination.

These observations suggest that individuals carrying two mutant *DFNBI* alleles may not be identified by newborn screening programs that use auditory brain stem responses to test for hearing loss. As a result, children with *DFNBI*-related deafness might be missed during the first year or two of life because the assumption may be made that their hearing is normal. This in turn would have a negative impact on the child's language acquisition. Early identification may require a direct genetic test for *DFNBI* mutations in the newborn period. The favorable responses of patients to the surgical interventions presented here, suggests that this issue merits further study to determine whether early intervention can delay the onset of hearing loss possibly to postlingual period which would have a major impact on language acquisition.

**Pendrin gene mutation analysis for children with sensorineural hearing loss.** *V. Lip<sup>1</sup>, N. Lindeman<sup>1</sup>, M.A. Kenna<sup>2</sup>, B-L. Wu<sup>1</sup>.* 1) Department of Laboratory Medicine & Pathology, Children's Hospital, Boston, MA; 2) Department of Otolaryngology, Children's Hospital, Boston, MA.

**BACKGROUND:** Pendred syndrome (PDS) is an autosomal recessive disorder characterized by congenital sensorineural hearing loss, cochlear malformation, and thyroid goiter, and is due to mutation of the Pendrin gene at 7q31. Currently, diagnosis is predicated upon clinical and radiological findings. Because the thyroid disease does not develop until late childhood/early adulthood and can progress to cancer, early molecular diagnosis may lead to aggressive thyroid monitoring and preventive therapy. Molecular diagnosis is facilitated by the clustering of most (~60%) significant mutations (L236P, K369E, A372V, E384G, T416P, 2111insGCTGG, T721M, and H723R) within exons 6, 9, 10, and 19. **METHODS:** We developed a two-step assay for Pendrin mutations, using PCR with primers flanking/overlapping the "hot spot" exons 6, 9, 10, and 19, followed by automated sequence analysis. Blood samples from 63 patients with hearing loss were tested. **RESULTS:** Pendrin exons 6, 9, 10, and 19 were successfully amplified from all 63 samples. Mutations were detected in 5 samples. These included a known mutation (T416P), a silent mutation (L729L), an intronic mutation, and a novel mutation (F335L), found in two unrelated patients. **CONCLUSION:** Molecular diagnosis of Pendred syndrome by PCR-sequencing is feasible and diagnostically useful. In addition to detecting patients with known mutations, we have identified a novel mutation (F335L) in two unrelated deaf children. Longer clinical follow-up will be needed to determine if this mutation is associated with Pendred syndrome.

Program Nr: 1429 from the 2001 ASHG Annual Meeting

**The European Directory of DNA Laboratories (EDDNAL).** *C.S. Albott, L. Van Maldergem.* Centre de Gntique Humaine, Institut de Pathologie et Gntique, Loverval, BELGIUM.

A rapid increase in the number of genetic diseases open to a DNA based diagnostic test has given rise to the need for a comprehensive directory of European laboratories and a listing of the services they can offer. In 1995, the European Directory of DNA Laboratories (EDDNAL) was established to meet this need. Our work investigates the diversity among European diagnostic centers and the way in which the EDDNAL web-site ([www.eddnal.com](http://www.eddnal.com)) is able to provide information on diagnostic services provided in the different EU member states. We performed a review of the literature to ascertain the differences among European diagnostic laboratories of Europe as well as the problems specific to these countries. We describe how the EDDNAL registry provides information on the Access, Availability and Quality Ascertainment throughout the European community. In addition, we present schemes for circumventing the previously ascertained problems. The on-line directory is designed to promote information exchange between European centres and to improve awareness of the availability of services for rare genetic conditions. The development of the EDDNAL database and web-site should result in an overall decrease in the total cost of DNA diagnoses of rare genetic disorders due to a European concerted approach based on the prevalence of such disorders.

**A web-based expert system for gene mutation nomenclature.** *J. Li, W. Kimberling and Center for the Study and Treatment of Usher Syndrome.* Dept. of Genetics, Boystown National Research Hospital, Omaha, NE.

Unequivocal gene mutation nomenclature is essential for reporting and testing sequence changes (mutations and polymorphisms) efficiently and accurately. It is also critical for creating and maintaining integrated locus-specific mutation databases. A nomenclature system has been recommended and currently largely accepted to describe sequence changes at DNA, RNA and protein levels. It has stimulated the consistent and explicit description of sequence changes. However, reports with not quite precise nomenclature of sequence changes can still be found partially due to authors failing to abide by the nomenclature rules strictly. Thus therefore retards the development of integrated mutation databases. To assist scientists to follow the rules of nomenclature stringently and easily, we are developing a web-based expert system for gene mutation nomenclature. Through an interactive question and answer process, one can easily, accurately, and consistently obtain the proper names of sequence variations. The expert system is currently being evaluated as a method of providing consistent nomenclature for creating and maintaining Usher syndrome mutation databases, but would be applicable to all genetic disorders. The system is programmed with Active Server Pages (a web programming language) interacting with both the locus information database and the oligo primer database for Usher syndrome that developed in Microsoft SQL server. It is currently accessible on the Boys Town National Research Hospital intranet and will be accessible on the World Wide Web in the future. In addition, the issues about the numbering of nucleotides and how to develop a consistent numbering system of nucleotides among different reference sequences in a long term will be also discussed.

**The COPPER plate system: Effective use of DHPLC for clinical application.** *H. Yoshihashi, T. Suzuki, K. Kosaki.*  
Dept of Pediatrics, Keio Univ Sch Med, Tokyo, Japan.

The more the molecular geneticists unravel the genetic basis of inherited diseases, the more the practicing clinical geneticist get frustrated because they are confronted with a situation in which molecular diagnostic tests cannot be offered to the patients simply because of the cost and labor associated with such testing. A cost-effective and automated strategy needs to be implemented. Denaturing high-performance liquid chromatography (DHPLC), the new technology, based on temperature-modulated liquid chromatography and a high-resolution matrix was implemented in a way suitable for clinical application. Primers were designed so that all of the primers would have the same annealing temperature. In this way, all the exons can be amplified simultaneously in a single PCR machine. Primer pairs were aliquoted on a 96-well format PCR plate referred to as COPPER plate (Condition-Oriented-PCR primer-Embedded-Reactor). The COPPER plate was accompanied with a corresponding computer programs optimized for DHPLC analysis of the particular PCR product. COPPER plates and accompanying computer programs were developed for analysis of the NEMO gene (incontinentia pigmenti), the JAGGED1 gene (Alagille syndrome), and the P63 gene. All the exons could be analyzed sequentially by the optimized method and all the operation were completely automatic once the operator sets the plate and starts the "gene-specific" analysis program. The P63, NEMO, and JAGGED1 package consists of 8, 9, and 30 primer pairs. Using the COPPER plate, we have identified several mutations: C835T (R279C) mutation in P63, C550T (R184C) mutation in JAGGED1, and C184T (R62X), 1116delT, and 1161-1167insC mutations in NEMO. COPPER plates for the DHPLC technology, when complemented with the COPPER plate system, offers an ideal tool for mutation analysis in clinical applications. The key aspects to setting the operating parameters will be discussed.

**Use of conformation sensitive gel electrophoresis (CSGE) for mutation analysis of complex connective tissue**

**genes: COL1A1, COL1A2, COL2A1, COL11A1 and FBN1.** *J. Korkko<sup>1</sup>, I. Kaitila<sup>2</sup>, D. Prockop<sup>1</sup>, L. Ala-Kokko<sup>1</sup>.* 1) Ctr Gene Therapy, Tulane Univ Health Sci Ctr, New Orleans, LA; 2) Dept Clin Genet, Helsinki Univ Hosp, Finland.

Fibrillar collagens provide structural support for connective tissues. Collagen I is a major protein of skin, tendon and bone and collagen II is the main component of cartilage and the vitreous of the eye. Collagen XI found in same tissues as collagen II, but it is a minor component. The genes coding for these proteins are complex in that they consist of over 50 exons and have a highly repetitive structure. Therefore, it has been difficult to establish a practical and reliable method for mutation detection in these genes. During the last few years we have adapted the procedure of conformation sensitive gel electrophoresis (CSGE) for these genes and analyzed patients with different osteochondrodysplasias for mutations. The mutation detection rates are the following: COL1A1/COL1A2 analysis in patients with osteogenesis imperfecta (OI): OI type I 88%, OI type II 83%, OI type III 83%, OI type IV 73% and OI vs abuse 4%. Conclusion: The vast majority of the OI is caused by collagen I gene defects. In OI vs child abuse only 2 of 52 patients had COL1A1/COL1A2 defect. COL2A1 mutations were found in 95% of the patients with hypo- and achondrogenesis II, in 64% of the patients with spondyloepiphyseal dysplasia and in 75% of patients with Kniest dysplasia. Conclusion: Achondrogenesis II/hypochondrogenesis is virtually always caused by COL2A1 mutations. Collagen II defects are common, but not the only cause of SED/SEMD. 74% of the patients with Stickler or Marshall syndromes have mutations in either the COL2A1 or COL11A1 gene. In general Stickler syndrome seems to be more commonly associated with the COL2A1 gene, and Marshall syndrome with the COL11A1 gene. We have initiated testing of CSGE to detect mutations in the FBN1 gene in patients that meet the revised diagnostic criteria for Marfan syndrome (DePaepe et al., Am J Med Genet, 1996). Preliminary results indicate that CSGE is highly sensitive (about 90%) and specific in detection of mutations in the FBN1 gene.

**The use of unequal expression as a rapid diagnostic tool for neurofibromatosis 2.** *H.-O. Nguyen, B. Heinrich, M. MacCollin.* Department of Neurology, Massachusetts General Hospital, Charlestown, MA.

Neurofibromatosis 2 (NF2) is an autosomal dominant disorder characterized by the development of multiple nervous system tumors. Although pre-symptomatic diagnosis of NF2 patients affords better final outcomes, current molecular diagnosis methods based on exon scanning are costly, time-consuming and frequently fail to detect underlying mutations. We have previously shown that 83% of known mutations are underexpressed in messenger RNA from patients with NF2. We thus explored the use of altered expression of disease bearing alleles as a rapid and simple molecular test for NF2. Three assays in the untranslated region (UTR) of the *NF2* gene were developed utilizing polymorphisms which create or destroy restriction enzyme recognition sites. Heterozygosity in genomic DNA amongst a cohort of 31 unrelated individuals ranged from 10 to 25%, with 14 individuals polymorphic at least in one assay. Total cellular RNA from peripheral blood leukocytes was reverse transcribed using oligo-dT primers and amplification of alleles in mRNA was compared to that in genomic DNA. Qualitative analysis on ethidium bromide stained gels was frequently adequate to detect unequal expression in heterozygous NF2 patient samples compared to unaffected controls. Quantitative levels of expression were determined using FAM label of a single primer. Differences in expression levels were evaluated by an automatic sequencer using area-under-curve values associated with each allele. Although unequal expression was apparent in heterozygous NF2 patient samples, mixing experiments using known homozygous samples revealed that this method consistently underestimated the over represented allele. Delay in extraction of RNA from whole blood samples augmented unequal expression by decreasing the amount of the under represented allele. Unequal expression of disease bearing alleles can be easily assayed in peripheral blood specimens, and may be a powerful method of rapid and inexpensive molecular diagnosis in this and other autosomal dominant disorders.

**SMA carrier detection using TaqMan technology : Implications for genetic counseling.** *E. Vial, P. Burllet, L. Viollet, A. Munnich, S. Lefebvre.* INSERM U393, Hopital Necker Enfants Malades, Paris, France.

Spinal muscular atrophy (SMA) is an inherited neuromuscular disease characterized by specific degeneration of the anterior horn cells of the spinal cord leading to muscle atrophy. It is the second most common fatal autosomal recessive disorder, with a carrier frequency of 1/40. In most cases (>95%), SMA is caused by the homozygous loss of the telomeric survival motor neuron gene (SMN1) located within a duplicated element in a highly unstable region of chromosome 5q13. All patients and 95% of control individuals carry the copy gene, SMN2. We report a single step duplex real-time quantitative PCR with the Taqman technology for the detection of SMN1 heterozygous status. SMN1 gene dosage is based on a single base pair difference between SMN1 and SMN2 exon 7. This Taqman method relies on the comparison of the amount of the very specific PCR product generated from the SMN1 exon 7 with the amount of product generated from the albumin (ALB) disomic reference gene at exponential phase. A theoretical single cycle difference between these two amounts shows an heterozygous deletion of SMN1 exon 7. Studying a series of 108 parents (obligate carriers) we found that 5,5% (6/108) of them had two SMN1 genes, indicating either a cis duplication, a neomutation (de novo deletion) or a germinal mosaicism. This rapid test is currently used in our laboratory for genetic counseling in SMA families and for SMN1 gene dosage in SMA patients prior to mutation screening. The test has already been offered to 20 couples. One of the non-related individuals with a theoretical risk of 1/40 was found to carry an heterozygous deletion of SMN1 exon 7. Her husband ( the SMA relative) had two SMN1 copies with a starting theoretical risk of 1/2. The probability for this couple to give birth to an affected child raises from 1/320 to 1/80. The implications of these data for genetic counseling is that one must take into consideration both parents in the evaluation of the risk and in the decision to propose prenatal diagnosis.

**Contacting Huntington carriers and non-carriers for research purposes after pre-symptomatic testing.** C.C. Verschuuren<sup>1</sup>, E.H. Sikkens<sup>1</sup>, J.C.H. Oostrom<sup>2</sup>, K.L. Leenders<sup>2</sup>, A.J. vanEssen<sup>1</sup>. 1) Clinical Genetics department, University Hospital Groningen, the Netherlands; 2) Neurology department, University Hospital Groningen, The Netherlands.

*Introduction:* Pre-symptomatic testing for Huntington disease is done in our hospital at the department of Clinical Genetics according to the international protocol. After the testing procedure is completed there is usually no further contact with the tested persons. For a research project at the Neurology department and P.E.T.Center pre-symptomatic Huntington carriers and controls were needed. This confronted us with an ethical dilemma because an unannounced contact can give emotional distress for a carrier and a non-carrier. To legitimize the contacting of this group for research purposes we scored their reactions to this unannounced request for participation to a neuro-imaging investigation.

*Methods:* After approval of the ethical commission 70 persons (31 carriers, 39 non-carriers) counseled between 1994 and 2000 were contacted by mail. This mailing contained an introduction letter of the clinical geneticist, an information leaflet about the research project and a questionnaire. In this questionnaire the reaction to our unannounced mailing could be scored from very disturbing to no problem on a scale from 1 to 5. One follow-up call was made 3 weeks later to the carriers that had not responded. *Results:* The response rate was 75%(23/31) in carriers and 60%(23/39) in non-carriers. Telephone contacting of the carriers that had not-responded showed that 10%(3/31) were lost to follow up and 10%(3/31) had not responded because they had symptoms, which was an exclusion criterion for this study. 39%(9/23) of the responding carriers and 9%(2/23) of the responding non-carriers refused participation in the research project. In the questionnaire only 6.5% (3/46) of the responders scored (very) disturbing (score 1 or 2). All of these were carriers. *Conclusion:* Unannounced research request was fairly well accepted by (pre-symptomatic) carriers and non-carriers of Huntington disease with whom contact was closed because their counseling procedure at our department of clinical genetics was finished.

Program Nr: 1436 from the 2001 ASHG Annual Meeting

**Molecular testing for late onset neurodegenerative disorders: a health care professionals' perspective.** *RSR. Paiva, I. Lopes-Cendes.* Department of Medical Genetics, University of Campinas, Campinas, SP, BRAZIL.

**Objective:** To evaluate and compared opinions of five health professional groups about molecular testing for Huntington disease and spinocerebellar ataxias.

**Methods:** A structured questioner was sent to 530 health professionals, divided into 5 groups: 80 clinical geneticists, 100 neurologists, 100 psychiatrists, 150 psychologists and 100 nurses. All 530 professionals were practicing in clinics and/or hospitals in Sao Paulo State, Brazil.

**Results:** A total of 125 questionnaires (23.5%) were returned, varying from 30% of clinical geneticists to 18% of neurologists. Sixty-two % of the neurologists interviewed were currently following patients with one of these disorders; as opposed only 29% of geneticists and 16% of psychiatrists ( $p < 0.01$ ). Most geneticist and neurologist were aware that molecular tests are available for these disorders (96% and 84%, respectively). However, only 42% of the geneticists and 6% of the neurologists would feel comfortable dealing with issues related to molecular testing in their practice. Instead, the majority of professionals interviewed would refer their patients and family members to a specialized clinic for testing and counseling.

**Conclusion:** Although issues related to molecular testing for Huntington disease and spinocerebellar ataxia have been extensively discussed and recommendations have been issued by many medical societies, most health care professionals in Brazil, including clinical geneticists, do not feel comfortable dealing with testing and counseling issues in their practices.

**Clinical characteristics of individuals with germline mutations in *BRCA1* and *BRCA2*: Analysis of 10,000 individuals.** A.M. Deffenbaugh<sup>1</sup>, J.E. Reid<sup>2</sup>, M. Hulick<sup>1</sup>, B.E. Ward<sup>1</sup>, B. Lingenfelter<sup>1</sup>, K.L. Gumper<sup>1</sup>, T. Scholl<sup>1</sup>, S.V. Tavtigian<sup>2</sup>, D.R. Pruss<sup>2</sup>, G.C. Critchfield<sup>1</sup>, T.S. Frank<sup>1</sup>. 1) Myriad Genetic Laboratories, Salt Lake City, UT; 2) Myriad Genetics, Salt Lake City, UT.

In order to assess the characteristics of individuals in whom mutations in *BRCA1* and *BRCA2* were diagnosed in a clinical setting, we analyzed the results of 10,000 consecutive gene sequence analyses for mutations anywhere in the *BRCA1* and *BRCA2* genes (7491 analyses), or for three specific Ashkenazi Jewish founder mutations (2539 analyses), through information provided via a test requisition form. The presence and prevalence of mutations were correlated with personal and family history of cancer, ancestry, gender and invasive vs. noninvasive breast neoplasia. Mutations were identified in 1720 (17.2%) of the 10,000 individuals tested, including 968/4843 (20%) women with breast cancer and 281/824 (34%) with ovarian cancer. Mutations were as prevalent in high-risk women of African (25/133, 19%) and other ancestries as those of European ancestry (712/4379, 16%). *BRCA1* and *BRCA2* mutations were significantly less prevalent in women diagnosed with ductal carcinoma-in-situ ("DCIS") before age 50 than in women with invasive breast cancer diagnosed at a comparable age and with a comparable family history (13% vs. 24%,  $p = 0.0007$ ). Of the 74 mutations identified in individuals of Ashkenazi ancestry through full sequence analysis of both *BRCA1* and *BRCA2*, 16 (21.6%) were non-founder mutations including 7 in *BRCA1* and 9 in *BRCA2*. 21 of 76 (28%) men with breast cancer carried mutations of which more than one third occurred in *BRCA1*. We conclude that specific features of an individual's personal and family history can be used in a clinical setting to identify those most likely to carry mutations in *BRCA1* and *BRCA2*.

**The Carrier Clinic - a new model for oncological practice?** *A.T. ARDERN-JONES<sup>1</sup>, G. MITCHELL<sup>2</sup>, R.A. EELES<sup>1,2</sup>.*  
1) THE ROYAL MARSDEN NHS TRUST, LONDON, UK; 2) THE INSTITUTE OF CANCER RESEARCH  
SUTTON AND LONDON UK.

Patients with germ line mutations in cancer predisposition genes are at markedly increased risk of developing cancer. Furthermore, having developed cancer once does not preclude the development of further primaries. The early symptoms of cancer may be subtle or masquerade as benign disease. It is essential for nurses caring for families with gene mutations to have an understanding of cancer and its presentation in addition to the psychological support that is needed to realise the significance of symptoms that may seem non-threatening to the patient. This paper describes two clinical cases of BRCA gene carriers and one of a teenager whose mother is a carrier of the deleterious TP53 mutation where urgent referral was expedited following incidental reported symptoms by the patient during a follow up call from the clinical nurse specialist. Currently with the ever increasing information that pertains to gene carriers and their risks of developing other cancers it is essential that carriers have contact with a suitably informed person. At the Royal Marsden Hospital in London UK an annual follow up gene carrier clinic has been set up and this clinic acts as a gate keeping clinic for such families. This is staffed by a multidisciplinary team and both the nursing and medical staff have in-depth oncological as well as genetic training. Patients are kept in touch on a regular follow up basis by the nurse specialist and may contact the department at any time for any worries or concerns. The clinic team liaises closely with other practice specialists tailoring these contacts to the patients needs. We propose that families that have been found to carry cancer-predisposition genes are followed up in Carrier Clinics to provide up to date information and recommendations for management of these high-risk individuals.

**Clinical Genetic Testing for Mutations in the RB1 Gene using Direct Sequencing and Denaturing High Performance Liquid Chromatography.** *T. Ganguly<sup>1</sup>, C. George<sup>1</sup>, T. Dunbar<sup>1</sup>, L. Godmilow<sup>1</sup>, A. Ganguly<sup>1</sup>, K.*

*Nichols<sup>2</sup>.* 1) Department of Genetics, University of Pennsylvania, School of Medicine, Philadelphia, PA; 2) Children's Hospital of Philadelphia Pediatric Oncology, Philadelphia, PA.

Bilateral retinoblastoma, an embryonic retinal neoplasm presenting during early childhood, is associated with germline mutations in the RB1 tumor suppressor gene. Unilateral retinoblastoma, however, is due to somatic alterations, with only 10% of children harboring germline RB1 gene defects. To facilitate genetics counseling, we developed a highly specific and sensitive protocol for RB1 gene testing using DNA-based sequence analysis. In our assay, the RB1 coding sequences consisting of 27 exons, and all exon intron boundaries, are PCR amplified and sequenced directly. Using a set of 10 normal control DNA samples, we identified polymorphisms in introns 1, 3 and 17, the most commonly identified variants present in the RB1 Mutation database. Validation for mutation detection was performed using DNA derived from 20 retinoblastoma specimens for which underlying RB1 mutations had previously been identified. Following blinded analysis, we detected all mutations using direct sequence analysis. Next we performed a pilot study evaluating retinoblastoma patients with bilateral (n=5) or unilateral (n=5) disease. In 4 out of 5 (80%) patients with bilateral retinoblastoma, we identified germline RB1 mutations. For the unilateral cases, we identified 3 (60%) RB1 mutations, one of which was germline. These results are consistent with prior efforts reporting a 50-75% mutation detection rate for bilateral retinoblastoma patients. To improve the sensitivity and speed of mutation detection, and to reduce costs, we are currently evaluating the DHPLC system (Transgenomics) which is based on heteroduplex analysis of DNA fragments. Although analysis by DHPLC has been sensitive for most of the exons tested, the sensitivity is influenced by various parameters including DNA sequence, melting profile, run temperature and PCR reagents. Optimization of RB1 gene testing will facilitate genetics counseling and future management of retinoblastoma patients.

**DHPLC versus gel based SSCP/Heteroduplex: a comparative analysis for high throughput screening of HNPCC genes.** *J.F. Harvey<sup>1</sup>, C. Curtis<sup>1</sup>, P. Duncan<sup>1</sup>, D. Bunyan<sup>1</sup>, D. Eccles<sup>2</sup>.* 1) Wessex Reg Genetics Lab, Salisbury District Hosp, Salisbury Wiltsh, England; 2) Wessex Clinical Genetics Service, Princess Anne Hospital Southampton England.

We have previously described a rapid highly sensitive screen of 2 of the 6 mismatch repair genes mutated in HNPCC, hMLH1 and hMSH2. We transferred the 96 well microtitre plate format originally designed for high throughput gel based SSCP/heteroduplex analysis, to the dHPLC WAVE platform and detected all 24 unique mutations/polymorphisms previously found by gel based SSCP/heteroduplex analysis. We now describe a retrospective dHPLC study of 23 HNPCC families previously screened negative by SSCP/heteroduplex analysis. Mutations were detected in 7 unrelated patients (30 percent) including 3 stop and 4 splice site mutations. On re-running these mutated fragments by gel based SSCP/heteroduplex analysis we found 3 of the 5 mutations could now be detected, but only by using a range of gel conditions. Two mutations found in 4 unrelated patients remained undetected. Using a range of gel parameters is impractical and expensive for high throughput applications and highlights the variable sensitivity of gel based SSCP/heteroduplex analysis, questioning the continued use of SSCP/heteroduplex analysis in diagnostics for large scale mutation analysis.

**Results of a Stool BAT-26 Assay in People With HNPCC.** *S.J. Laken<sup>1</sup>, H.T. Lynch<sup>2</sup>, J.C. Urbanowski<sup>1</sup>, C. Deters<sup>2</sup>, A.P. Shuber<sup>1</sup>, P. Watson<sup>2</sup>.* 1) Exact Sciences, Maynard, MA; 2) Creighton University, Department of Preventive Medicine and Public Health, Omaha, NE.

People with Hereditary Non-Polyposis Colorectal Cancer (HNPCC) have an 80% lifetime risk of developing colorectal cancer (CRC). As these cancers may show accelerated carcinogenesis with early onset, patients are advised to begin colonoscopy screening beginning at the age of 20 to 25 and repeated every one to two years for the rest of their lives. Despite the fact that colonoscopy has shown the ability to reduce the mortality and incidence of CRC in this group, as many as 30% of HNPCC gene carriers do not follow these recommendations. In addition, patients who are compliant with these screening recommendations may still develop interval CRC. A stool based CRC screening test was developed which may have clinical value in the noncompliant patient or between colonoscopy screening years. This test is designed to detect mutations in BAT-26, a marker for microsatellite instability, a common feature in HNPCC colorectal cancers and adenomas.

A total of 47 patients were recruited to participate in this study. Three patients were excluded because they were determined to be mutation negative after their colonoscopy (all three had normal colonoscopies and negative stool tests). Of the remaining 44 patients, three were found to have CRC at colonoscopy (2 Dukes A and 1 Dukes C) and one patient had advanced adenomas as determined by size (a 2-3 cm tubular and a 1 cm hyperplastic). The stool test was positive in one of the patients with CRC (Dukes A) and in the one patient with polyps. The two cancers from patients that were negative by the stool assay were tested for microsatellite instability, and mutations in BAT-26 were present in only one. All 40 patients with negative colonoscopies were negative by the stool assay. This stool assay has shown the ability to detect early stage disease with 100% positive predictive value, and may have use as an adjunct to colonoscopy screening in people with HNPCC.

**Risk-based referral to a clinical cancer genetics program: a study paralleling the real world of non-research covered service.** *S.M. O'Neill<sup>1,2</sup>, V.G. Vogel<sup>1</sup>, E. Feingold<sup>2</sup>, R.E. Ferrell<sup>2</sup>, J.A. Peters<sup>3</sup>, W.S. Rubinstein<sup>4</sup>.* 1) Comprehensive Breast Program and Cancer Genetics Program, UPCI/Magee Womens Hospital, Pittsburgh, PA; 2) Dept. of Human Genetics, University of Pittsburgh, PA; 3) Clinical Genetics Branch, NCI, Rockville, MD; 4) Evanston Northwestern Healthcare, Northwestern University Medical School, Chicago, IL.

Genetic counseling and testing for BRCA mutations is a prototype for other common adult-onset disorders. We assessed uptake of a cancer genetics program (CGP) referral not covered by research funds in 211 subjects given a computerized breast cancer risk assessment (BRA) in the biopsy and treatment clinics of an urban women's hospital. Subjects completed questionnaires assessing psychological status and knowledge and attitudes about breast cancer (BC), cancer risk counseling, and genetic testing. Of 120 women with no previous history of BC undergoing breast biopsy, 63 (53%) were referred to the CGP on the basis of a Gail or Claus model risk <sup>3</sup>twice the population risk. Of 91 BC patients, 43 (47%) were offered referrals for a mutation risk <sup>3</sup>10% based on the Couch, Shattuck-Eidens, Frank, or BRCAPRO statistical models. At 6-18 months post-referral, only 1/63 unaffected, but a greater proportion (13/43; 30%) of affected, women made CGP appointments, and 10 had testing. Of the decliners, 74 were re-interviewed to elicit reasons for lack of follow-up. Main reasons cited by unaffected women included perceived low risk after benign biopsy results, lack of family history, and satisfaction with the BRA. Affected women cited a dissimilar spectrum of reasons: lack of time, sufficient risk information from their physicians and the BRA, and fear of insurance discrimination. High income was the greatest predictor of uptake ( $p = 0.006$ ). "Not wanting anymore tests" was a significant barrier ( $p = 0.03$ ). Most women (81%) said genetic risk assessment should be routine, suggesting annual mammography or OB/GYN visits as the most effective setting. Studies to date have focused on uptake of genetic testing offered to women as part of cost-free research studies. Uptake of referral may be less in the clinical arena and may depend on timing or setting of the referral.

**Application of the Bethesda and Amsterdam Criteria and the Incidence of Identifiable Genetic Hallmarks of HNPCC.** *S.K. Palmer, T.J. Monroe, M.A. Luchtefeld, J. Miller.* Molecular Biology, Spectrum Health, Grand Rapids, MI.

Purpose: Colorectal cancer (CRC) occurring in young patients and those with a strong family history, increases the suspicion of hereditary nonpolyposis colorectal cancer (HNPCC). It is possible patients may not fit established predisposition criteria and still be diagnosed with HNPCC. The priority of this study was to establish a genetic testing program for families in the state of Michigan who are likely to have or who are at increased risk of developing HNPCC. Individuals were enrolled in the study based on accepted Bethesda/Amsterdam criteria and consented to genetic analysis to evaluate current diagnostic testing regimes. Methods: CRC patients less than 40 years of age and/or those with a documented strong family history of CRC and other cancer were initially screened for Microsatellite Instability (MSI) using the 5 recommended Bethesda Consensus loci. DNA extracted from paraffin embedded or fresh frozen tumor was amplified by PCR using fluorescent labeled primers and electrophoresed on an ABI 377 instrument. MSI identified at 2 or more of the 5 loci was recorded as a positive result. MSI+ patients were further characterized by immunohistochemical (IHC) staining. Sequence analysis of hMLH1 and hMSH2 was additionally performed on selected patients meeting Amsterdam, Amsterdam Modified, or Amsterdam Minus Criteria. DNA was extracted from peripheral blood and the complete coding regions of both genes were amplified by PCR. PCR products were sequenced and aligned with those previously published. Results: Tumor analysis was initially attempted from 89 samples of CRC patients age 40 or less. Results were obtained for 86 samples: 17 pts were found to be MSI+. 11 of these were shown to lack expression of MLH1 or MSH2 as shown by Immunohistochemical staining. Sequence analysis of those patients meeting Amsterdam Criteria is in progress. Conclusion: In the less than 40 year old patients with CRC, MSI+ tumors were present in 19.8%. 64.7% of the MSI+ patients were found to have protein abnormalities in hMLH1 or hMSH2 genes. Sequence analysis of hMLH1 and hMSH2 genes will allow further evaluation of our selection criteria and screening methodologies.

**Development of a Pediatric Cardiovascular Genetics Clinic.** *S.D. Fernbach<sup>2</sup>, J.A. Towbin<sup>1</sup>, W.J. Craigen<sup>2</sup>, J.W. Belmont<sup>2</sup>.* 1) Pediatric Cardiology, Texas Children's Hospital, Houston, TX; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

The Cardiovascular Genetics Clinic at Texas Children's Hospital was formed five years ago to provide diagnostic consultation, genetic counseling and clinical care for patients and their families with congenital cardiovascular disorders. Many children with chronic, complex disorders are seen in multiple subspecialty clinics and it was felt that a multidisciplinary approach would be well received by families. The team consists of a pediatric cardiologist, two geneticists and a genetic nurse. Children are referred for evaluation of Marfan syndrome (n=65), Muscular Dystrophy (n=46), Mitochondrial Myopathy (n=18), Williams (n=13), Noonan (n=12), Turner (n=13), and VCFS/DiGeorge (n=5) syndromes, other Chromosome Abnormalities (n=6), Mucopolysaccharidoses (n=5), Friedreich's Ataxia (n=1), disorders of cardiac muscle, cardiac conduction as well as other conditions (n=32).

Pedigrees are obtained in a telephone interview prior to the clinic visit. An echocardiogram, ECG, and chest x-ray may be ordered on the day of the clinic visit. The family history and results of the tests are discussed, a physical examination is performed and recommendations for additional testing are reviewed. For newly diagnosed children, description of the condition, treatment plans, the genetic etiology, inheritance and recurrence are discussed. When appropriate, print materials about the genetic condition, informative websites and support group information are given. Initially, families are seen frequently to determine the effectiveness of treatment, assess their understanding of the child's disorder, their coping skills and to review the genetic information. Two hundred and sixteen patients were seen in the year 2000 with referrals from cardiologists, geneticists, neurologists, ophthalmologists, pediatricians as well as self referrals.

**Is MTHFR C677T polymorphism a risk factor in Branch retinal vein occlusion (BRVO)?**. *D. Napper<sup>1</sup>, K. Yanamandra<sup>1</sup>, T.F. Thurmon<sup>1</sup>, J.A. Bocchini Jr<sup>1</sup>, R. Dhanireddy<sup>1</sup>, L.M. Kooragayala<sup>2</sup>*. 1) Dept Pediatrics, Louisiana State Univ Med Ctr, Shreveport, LA; 2) Dept Ophthalmology, Louisiana State University Med Ctr, Shreveport, LA.

Methylenetetrahydrofolate reductase (MTHFR), a rate limiting enzyme in the folate metabolism, converts methylenetetrahydrofolate to methyltetrahydrofolate in the remethylation pathway of homocysteine to methionine. A common polymorphism C677T in the MTHFR gene reduces MTHFR enzyme activity causing hyperhomocysteinemia and hypomethylation of DNA, leading to cardiovascular and cerebrovascular diseases in addition to its involvement in the birth defects such as neural tube defects (NTD), Down syndrome, and orofacial clefts, etc. MTHFR C677T, Factor V Leiden G1691A (FVL) and Prothrombin G20210A (PTII) are known to be risk factors in hereditary thrombophilia. Retinal vascular occlusion (RVaO) including both arterial (RAO) and veinal occlusions (RVO), is the most common retinal vascular disorder after diabetic retinopathy. Although MTHFR C677T was reported to be a risk factor in various abnormalities as mentioned earlier, its role in retinal vascular abnormalities was not well studied. Our laboratory has been studying MTHFR C677T, FVL, and PTII polymorphisms in the newborn and pregnant population from Northwest Louisiana for the past several years. Presently we are studying the role of MTHFR C677T polymorphism in the RVaO patients from Northwest Louisiana attending our LSU medical school Retina Clinic. We have studied so far 62 patients with RVaO comprising of 65% African-Americans (AA), 30% Caucasians, and 5% others. There were 48 RVO patients and 14 RAO. Among the RVO, 35 were AA and 10 were Caucasians. Eighteen AA had BRVO and 17 AA had CRVO. Nine Caucasians had BRVO and 1 had CRVO. Two Asians had BRVO and one Hispanic had CRVO. The remaining patients had RAO. Our data revealed that African-American patients with BRVO carry statistically significant two-fold higher C677T heterozygosity compared to the control AA population (Relative Risk 2.42). Further larger studies are needed to confirm these results. Data and statistics from various RVaO patients and from various ethnic groups will be presented.

Program Nr: 1446

**Screening of Factor V Leiden (G1691A), Prothrombin G20210A and Protein C Gene Mutations in Thrombosis Patients.** *T.A. Ulutin, J. Altinisik, H.O. Ates, M. Cengiz, N. Sayhan.* Biomedical Sciences Division, Istanbul University, Istanbul, Turkey.

Thrombotic disease is one of the leading causes of morbidity and mortality in the world. As the development of thrombosis is multifactorial, it is known that numbers of hereditary and acquired factors are involved in this process with different mechanisms. It is also known that impairment of the natural inhibitor mechanism which regulates coagulation system mostly plays an important role in hereditary venous thrombosis. The presence of FV Leiden, Prothrombin G20210A and Protein C mutations were examined in thrombosis patients. FV Leiden (G1691A) and Prothrombin G20210A mutations were screened by using PCR and restriction enzyme digestion methods. Out of 50 thrombosis patients 2 were found to be heterozygous and 1 homozygous for FV Leiden mutations (6%) and two heterozygous for Prothrombin G20210A mutations (4%). Out of 25 healthy subjects, one had Prothrombin G20210A mutation (4%), while none of them had FV Leiden mutations (0%). There wasn't any significant difference between patient and control groups (FV Leiden  $p=0.29$ , Prothrombin G20210A  $p=0.74$ ). When exons (2,3,4,5,6,7,8,9) of the Protein C gene were amplified by polymerase chain reaction (PCR) and analysed by single strand conformational polymorphism (SSCP); one exon 2, four exon 3, one exon 4/5, two exon 7, three exon 8, two exon 9-3', two exon 9-5', a total of nine patients were found to have probable mutations while no sample from the control group had any mutations.

**Development of a high-throughput test for the ACE insertion / deletion polymorphism using primer extension and MALDI-TOF mass spectrometry.** *T. Stewart, M. Zetlmeisl, L. Leppin, C. Rodi, M.J. McGinniss.* Molecular Biology, Sequenom, Inc, San Diego, CA.

The insertion / deletion polymorphism in intron 16 of the angiotensin-converting enzyme (ACE) gene at 17q23 may play a role in cardiovascular disease. The insertion allele contains an alu repeat of 288 bp that results in allelic imbalance in heterozygous samples during PCR amplification using standard forward and reverse primers. We used matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF) and primer extension to assess mass differences in insertion (I) and deletion (D) alleles using a homogenous Mass EXTEND™(hME) assay. Due to allelic imbalance during PCR, the peak height of the I allele in heterozygous samples was approximately 30% of the D allele. Our assay was redesigned using a third insertion-specific PCR primer that in addition to the normal two PCR primers ensures nearly equal amplification of both the deletion and insertion alleles. Amplicon lengths of three sizes were generated (two for the insertion allele and one for the deletion allele). Sequenom's patented MassARRAY™ technology was then used for genotyping 91 normal control DNA samples with resulting genotype frequencies of 23% II, 31% DD, and 46% ID. We also genotyped ten interlaboratory DNA proficiency samples and the results from this study were 100% concordant. Direct measurement of primer extension products with mass spectrometry is highly accurate, cost-effective, efficient and eliminates the need for retyping that may be required to avoid mistyping of ID to DD when using conventional electrophoretic methods.

**Genomic Medicine In Developing Countries: Research, Clinical And Ethical Implications For Hereditary Colorectal Cancer In South Africa.** *R.S. Ramesar<sup>1,2</sup>, U. Algar<sup>2,3</sup>, R. Felix<sup>1,2</sup>, J.A. Gilfillan<sup>1,2</sup>, P.A. Goldberg<sup>2,3</sup>.* 1) Department of Human Genetics; 2) Colorectal Cancer Research Consortium; 3) Surgical Gastroenterology Unit, Grootte Schuur Hospital and University of Cape Town, South Africa.

A strong research programme has been established in South Africa with the aim of identifying the genetic defects underlying familial as well as some sporadic forms of colorectal cancer. The identification of at least 12 new disease-causing mutations in the primary candidate genes, hMLH1 and hMSH2, has led to the implementation of a predictive testing protocol to supplement the clinical management of subjects and family members at risk. The search for additional mutations is being speeded up by new technologies. In a single family/clan which is widely dispersed along the West Coast of South Africa, 203 of 529 individuals are involved in the investigation and management protocol. The identification of a novel mutation in exon 13 of the hMLH1 gene has led to genetic test results being made available to over 100 individuals. This specific change has been detected in at least 11 other apparently sporadic individuals, who were screened because they were under the age of 45 years and had right sided tumors. The finding of a common haplotype around the hMLH1 mutation, confirms a strong founder effect for the disorder along the West Coast of SA. Further genealogical and molecular investigations in just 4 of the 11 'sporadic' subjects has revealed each as being the 'tips of HNPCC icebergs'. The important issues have to do with: 1) when is it most appropriate to embark on the use of genetic testing, 2) the ethical implications of having genetic information but not the means/resources for imparting this information to a widely dispersed at-risk population, 3) whose responsibility is it to recruit subjects for testing on a wide scale, and 4) how best to develop capacity. There are large areas of South Africa which remain underserved for health care, with genetics facilities limited to only a few academic centres. At-risk populations may be recognisable but are widely dispersed. This paper highlights the practical issues around Genomic medicine, and its power for complementing conventional medical practice.

**Mutation screening by DHPLC: the learning curve.** *E.A. Lobos, R.D. Todd.* Dept Psychiatry, Washington Univ Sch Medicine, St Louis, MO.

Denaturing high performance liquid chromatography detects sequence variants via differential elution from a heated column by an acetonitrile gradient of mismatched DNA heteroduplexes formed by PCR amplification of heterozygous DNA. It has been advocated as a highly sensitive, specific and inexpensive method to screen for mutations, but researchers can find it problematic to implement as a new technology in the lab. We have recently applied a strategy using DHPLC mutation/variant detection, in a sample of individuals with attention deficit/hyperactivity disorder (ADHD), for exons 2-8 of the dopamine D2 receptor gene. We used limited sequencing to determine the variant nucleotides causing the different characteristic elution patterns. Primers were designed for robust product formation rather than for minimal variation in melting temperature across the length of the amplicon (as is recommended). Nonetheless, variants were detected for 6 of 7 amplicons, with heterozygous patterns for 3 of them exceeding 40% in the sample. However, a second primer was used to facilitate genotyping for a larger sample that reduced the length and homogenized the melting temperature of the fragment with 3 variant sites. Genotypes of homozygous individuals of unknown type were confirmed by addition of aliquots of PCRs of known alternate homozygotes to the samples, then denaturing, reannealing, and analyzing by DHPLC. A 10 microliter PCR volume was usually adequate for the entire analysis of the sample. During this test case, we have learned some basic tactics for economical and effective use of DHPLC, including robust and consistent PCR product yield, testing of the amplicon for suitability for pooling, manipulating the gradient to minimize elution time and reagent use, quick testing and recognition of optimal oven temperatures for heteroduplex detection, and warning signs of potential problems with amplicons. Applying these basic techniques allows us to effectively use DHPLC for additional studies while continuing efforts to reduce cost and hands-on time required to generate and interpret results.

**CFTR Mutation Screening In Hypertrypsinaemic Newborn In Italy.** *R. Padoan<sup>1</sup>, M. Giunta<sup>2</sup>, A. Bassotti<sup>2</sup>, C. Corbetta<sup>3</sup>, A. Ambrosini<sup>3</sup>, D.A. Coviello<sup>3</sup>, M. Seia<sup>3</sup>.* 1) Pediatrics Dept., Ist.Clinici di Perfezionamento, Milano, MI, ITALY; 2) Pediatrics Dpt., University of Milan, Milano, MI, ITALY; 3) Laboratory Dept., Ist.Clinici di Perfezionamento, Milano, MI, ITALY.

In the last seven years the Guthrie card screening program, performed on 169.000 newborns of Lombardia region population, identified 39 affected neonates and 25 hypertrypsinaemic infants presenting borderline sweat test (chloride value between 30 and 60mmol/L). Neonatal hypertrypsinaemia has been recently associated to the presence of increased frequency of CFTR mutations and IVS8-5T polymorphism. The aim of our study was to assess the incidence of rare CFTR mutations or polymorphisms in infants with neonatal hypertrypsinaemia and with a "borderline" sweat test in the first months of life. An extended analysis of CFTR gene was performed on the 25 hypertrypsinaemic infants, using DGGE technique on 11 out 27 exons, sequencing analysis of splice site polymorphism in intron 8 (TG)mTn and sequencing analysis of DNAs that showed an abnormal DGGE electrophoretic pattern. The results identified a total of 17 different CFTR alleles: eight DF508, four R117H, two G542X, two N1303K, two D1152H, R347P, 2183AA->G, 621+1G->A, 2789+5G->A, R553X, R347H, R117L, V1153E, Y1032C, 711+3G->A. In addition we identified a novel mutation D110N . Furthermore IVS8-(TG)mTn polymorphisms were tested, and the haplotype TG12T5 was identified in seven infants. In total we identified 14 compound heterozygotes (seven with two CFTR mutations, seven with one mutation/TG12T5), 10 subjects with only one mutation identified, whereas in only one patient no gene alterations were found. In conclusion we suggest that a high frequency of CFTR gene mutations is present among hypertrypsinaemic neonates presenting a "borderline" sweat test in the first months of life. Moreover we suggests that some immunoreactive trypsin positive neonates are actually affected by a very mild form of CF, an extended genetic analysis is recommended and furthermore clinical follow up in specialised Centres is needed to diagnose mild or atypical forms of CF.

**Standardization of PCR amplification for fragile X trinucleotide repeat measurements.** *J.P. Jakupciak, C.D. O'Connell, D.A. Atha, K.L. Richie.* Biotechnology, NIST, Gaithersburg, MD.

To provide the clinical diagnostics community with accurate protocols and measurements for the detection of genetic disorders, we have established a quantitative measurement program for trinucleotide repeats associated with human disease. In this study, we have focused on the triplet repeat associated with fragile X syndrome. Five cell lines obtained from the Coriell Cell Repository were analyzed after PCR amplification and size separation. These cell lines were reported to contain CGG repeat elements ranging from 29 to 110 repeats. Our initial measurements focused on measurement variability; a) between slab gel and capillary separation systems, b) inter-lane variability (slab gel), c) inter-gel variability, and d) variability associated with amplification. Samples were run in triplicate for all measurements, and the analysis performed using GeneScan analysis software. The repeat sizes were verified by DNA sequence analyses. The standard deviations for inter-lane measurements in slab-gels ranged from 0.05 to 0.35. There was also little variation in size measurements performed on different gels and among PCR amplifications. The CGG repeat measurements performed by capillary electrophoresis were more precise, with standard deviations ranging from 0.02 to 0.29. The slab gel and CE size measurements were in agreement except for the premutation alleles, which yielded significantly smaller sizes by CE.

**Detecting mosaic FMR-1 (fragile X) mutations: Southern blotting versus monoclonal antibody analysis.** *E.C. Jenkins<sup>1</sup>, S.-Y. Li<sup>1</sup>, X.-L. Yao<sup>1</sup>, S. Lanter<sup>1</sup>, V. Sudhalter<sup>2</sup>, R. Belser<sup>2</sup>, X.-H. Ding<sup>3</sup>, G.E. Houck, Jr<sup>3</sup>, A. Glicksman<sup>3</sup>, C.S. Dobkin<sup>3</sup>, S.L. Nolin<sup>3</sup>, W.T. Brown<sup>3</sup>.* 1) Department of Cytogenetics, New York State Institute for Basic Research in Developmental Disabilities (IBR), Staten Island, NY; 2) Department of Psychology, IBR; 3) Department of Human Genetics, IBR.

It has been hypothesized that mosaic fragile X individuals have a better prognosis. To determine the most reliable method for detecting mosaicism, we compared Southern blotting with probe StB12.3 to monoclonal antibody (mAb) FMR-1 protein (FMRP) detection with 1A1 (Chemicon 2160). Among 48 males who exhibited either full or mosaic FMR-1 mutations following PCR and Southern analyses, the percentages of negatively stained or FMRP-negative small lymphocytes ranged from 66-100. Two hundred cells were analyzed per whole blood specimen. However, there was incomplete concordance between the numbers/percentages of cells that were negatively stained with mAb, and Southern analyses relative to detection of mosaicism. For 23 full mutation specimens, the percentages of negatively stained cells ranged from 98.5-100 (14 specimens were 100% negative). In addition, six full mutations had 97-97.5% negatively stained cells. Among 14 mosaics identified with Southern analysis, the percentages of cells that did not stain with mAb 1A1 ranged from 73-98. Of these 14 specimens, 13 correlated well with 1A1 mAb-negative staining that ranged from 73-94%. However, another five specimens that exhibited 66-94% mAb-negative cells, were found to be full mutations on Southern analysis. It is concluded that Southern blotting may be generally more reliable, but mAb detection may be more sensitive in the detection of mosaicism. This work was supported in part by a grant to Dr. Sudhalter from the March of Dimes Birth Defects Foundation 12-FY980227, and in part by the New York State Office of Mental Retardation and Developmental Disabilities.

**MTHFR C677T polymorphism in pregnancies with Chromosomal Defects.** *K. Yanamandra<sup>1</sup>, I. Gadi<sup>2</sup>, D. Napper<sup>1</sup>, H. Chen<sup>1</sup>, J.A. Bocchini Jr<sup>1</sup>, T.F. Thurmon<sup>1</sup>, R. Dhanireddy<sup>1</sup>.* 1) Dept Pediatrics, LSU Medical Ctr, Shreveport, LA; 2) LabCorp. Research Triangle Park, NC.

The pioneering work of professor Smithells and his colleagues in 1960s and 70s on the periconceptional multivitamin and folic acid supplementation study to prevent Neural tube defects (NTD) have paved the way for the plethora of reports on the association of Hyperhomocysteinemia, folate and its metabolizing enzyme gene polymorphisms such as methylenetetrahydrofolate reductase (MTHFR), Methionine synthase (MS), Methionine synthase reductase (MTRR), and other enzymes, with birth defects such as NTD. Although not confirmed there may be association of MTHFR C677T polymorphism with Orofacial birth defects. Our laboratory has been working on the role of MTHFR C677T in the pregnant and newborn population from Northwest Louisiana for several years. We have for the first time reported a two-fold higher MTHFR 677TT homozygosity in the pregnant women at risk for chromosomal defects identified through our triple screening program and a very high homozygosity in Louisiana Hispanic pregnant women and newborn infants. MTHFR, a rate limiting enzyme in the folic acid metabolism, converts methylenetetrahydrofolate to methyltetrahydrofolate in the remethylation pathway of homocysteine to methionine. A common polymorphism C677T in the MTHFR gene reduces MTHFR enzyme activity causing hyperhomocysteinemia and hypomethylation of DNA, leading to various abnormalities. In the present study, we have collected 52 amniotic fluid specimens with abnormal karyotypes, studied the MTHFR C677T polymorphism, and compared them with matched controls. After data culling, we found a statistically significant 1.5 fold increase in 677TT homozygosity in chromosomally abnormal specimens of Caucasians (relative risk 1.9). Among those with non-Down syndrome abnormalities, there was a significant 1.7 fold increase (relative risk 4.0). Specimens with non-Down syndrome abnormalities were also significantly associated with 677TT more often than those with Down syndrome (relative risk 2.1). Data, statistics and composition of abnormal karyotypes will be presented.

**Rare and New Beta Thalassemia Mutations in Iran.** *K. Kahrizi<sup>1</sup>, A.A Poorfathollah<sup>3</sup>, N. Amirzadeh<sup>1</sup>, T. Jogathaei<sup>1</sup>, M. Neishabury<sup>1</sup>, A. Hatamy<sup>1</sup>, K. Javan<sup>1</sup>, N. Amirzadeh<sup>1</sup>, C. Oberkanins<sup>4</sup>, W. Krugluger<sup>5</sup>, H. Najmabadi<sup>1,2</sup>.* 1) Genetics, Welfare and Rehabilitation Uni, Tehran, Tehran, Iran; 2) Karimi-nejad Pathology and Genetics Center Tehran, Iran; 3) Iran Blood Transfusion Services Tehran, Iran; 4) Vienna Lab, Labrodiagnostika GmbH Vienna, Austria; 5) Institute of Clinical Chemistry, Rudolfstiftung Hospital Vienna, Austria.

Beta-thalassemia is the most common hereditary disease of Iran, with a broad spectrum of mutations and so far only around of 20 mutations being tested. In order to reduce the birth of affected individuals we need to improve our technical ability in terms of mutation detection. This panel only detect about 70% of our population mutation. About 3 years ago we decided to investigate other mutations in our population in order to ease and speed up prenatal diagnosis. Total of 230 DNA samples from un-identified Beta- Thal cases representing different geographical areas and ethnical group were collected. DNA were tested for new mutation which have been previously reported from other neighboring country by new version of Reverse hybridization (Vienna Lab). One hundred of the remaining samples which they were negative for mutation by reverse hybridization were subjected to sequence analysis, 10 known mutations(-88 C-A, -87 C-G,-28 C-A, 5'UTR+22 G-A, cd 24/25 -GGT, cd 25/26 +T, cd 42/43 +T, cd82/83 -G, IVSI-128 T-G, IVSI-130 G-C)were identified, which can be added to this list of the rare B-thalassemia mutations in Iran. These results further characterize the heterogenous spectrum of b-thalassemia mutations in Iran and will improve the abilities in prenatal diagnosis and carrier detection for b-thalassemia in order to prevent this prevalent disease in this country.

**Hereditary haemochromatosis: pilot study of case-finding approach to early diagnosis in primary care.** *J. Emery<sup>1</sup>, P. Rose<sup>2</sup>, J. Harcourt<sup>2</sup>, K. Robson<sup>3</sup>*. 1) General Practice Research Unit, Institute Public Health, Cambridge UK; 2) ICRF General Practice Research Group, University of Oxford; 3) Institute of Molecular Medicine, University of Oxford.

**Introduction:** Hereditary haemochromatosis (HHC) is a disorder of excessive iron absorption associated with a range of diseases and non-specific symptoms. 1 in 250 people of Northern European origin are homozygous for the commonest mutation (C282Y) that causes HHC. If therapeutic phlebotomy is instigated before the onset of cirrhosis or diabetes, a normal life expectancy is achievable. While doubts remain about the cost-effectiveness of population screening, a case-finding approach to early diagnosis has been proposed. **Aims:** To pilot a case-finding approach to early diagnosis of HHC in primary care. **Methods:** During a 4 week period 14 general practitioners in Oxfordshire completed consultation proformas recording the presence of any symptoms or diagnoses associated with HHC. Patients aged 25-70 with at least one of these symptoms were invited to return for a consultation with a research nurse and be tested for HHC. Patients were tested for the two common genetic mutations (C282Y and H63D) associated with HHC and iron studies were conducted on any C282Y homozygotes or compound heterozygotes (C282Y/H63D). **Results:** 4022 consultations occurred in which 169 patients (4.2%; 95% CI 3.6-4.8) were recorded with a symptom or diagnosis associated with HHC. Of these 88 patients (2.2% 95% CI 1.7-2.6) were aged 25-70 of whom 61 agreed to be tested. The commonest symptoms for which testing was offered were arthralgia (33 patients), diabetes (22) and fatigue (16). No C282Y homozygotes or compound heterozygotes were identified. 3 C282Y heterozygotes, 14 H63D heterozygotes and 2 H63D homozygotes (not associated with iron overload) were identified. **Conclusions:** This pilot study suggests that a case-finding approach is unlikely to be a cost-effective method of identifying patients with HHC. We must await the results of epidemiological studies into the proportion of homozygotes and compound heterozygotes that develop significant disease before making decisions about general population screening for HHC.

**New Jersey Fetal Abnormalities Registry (NJFAR): Recruitment of cases with structural fetal abnormalities.** *K. DePrince, A.J. Fisher, D.L. Day-Salvatore, J.C. Smulian.* New Jersey Fetal Abnormalities Registry, UMDNJ-Robert Wood Johnson Medical School/Saint Peter's University Hospital, New Brunswick, NJ.

NJFAR collects information on pregnancies after 14 6/7 weeks gestation in which a fetal structural anomaly has been identified. Cases are submitted anonymously to NJFAR by selected Maternal-Fetal Medicine practices. When verbal permission by the subject is given, she is contacted by NJFAR personnel via telephone or in person to explain the purpose and procedures of the registry. Written informed consent is obtained if the subject agrees to participate in an extensive interview and allow the release of medical records. We report the experience with recruiting subjects to NJFAR at the largest participating practice (UMDNJ-RWJ Medical School/St. Peter's University Hospital) over the first nine months of operation. All potentially eligible cases with fetal structural abnormalities were identified from September 2000 - May 2001. This list was compared to the list of cases actually reported to NJFAR. Cases were reviewed to determine the proportion of subjects offered participation in NJFAR and what happened when offered. There were 92 subjects eligible to participate of whom 42 (46%) were offered participation. Of these, 39 (93%) agreed to be contacted by NJFAR personnel. Of the 32 subjects actually contacted, 25 (78%) gave verbal consent to participate and 17 (53%) have provided informed consent to date. These data show that the majority (78%) of women who are contacted about participation agree to participate in the in the project. However, the largest obstacles to ascertainment and recruitment were under-reporting of eligible cases to NJFAR and subjects not being asked if they would be willing to be contacted for further information on participation. We speculate that the possible explanations for our findings might include: clinical time constraints for practitioners, staff changes, general reluctance to approach patients about a research study at the time of initial diagnosis, disrupted emotional state of a patient, language barriers, and not incorporating the recruitment protocol into routine practice. (Supported by the CDC and NJ Dept. of Health & Senior Services).

**Birth defects in Brazil: an emerging public health issue.** *D.D.G. Horovitz, M.G. Monteiro, J.C. Llerena Jr., R.A. Mattos.* Inst de Medicina Social, Univ Estado do Rio de Janeiro, Rio de Janeiro RJ, Brazil.

The burden of congenital anomalies in infant mortality and in hospital admissions has long been recognized in developed countries. Their impact in developing countries, such as Brazil, is more difficult to precise, due to infant mortality being mostly related to perinatal causes and infections. The main purpose of this research was to review through the Brazilian Ministry of Health's databases (<http://www.datasus.gov.br>), trends regarding infant mortality from 1980 to 1997, as well as hospital-based mortality related to birth defects (BD). BD were the fourth cause of infant mortality in 1980/81 (6%), rising to 12% and to the second cause of death in 1996/97. Perinatal causes placed first throughout the period; however, a decrease in absolute numbers of deaths related to all mortality causes was observed, except for BD, which continued as a steady plateau. Among state financed hospital admissions in year 2000, 4% of hospital deaths in all pediatric patients were directly related to a BD. This data is certainly an underestimate of the high morbidity of BD, for often only the immediate cause of death is registered in death certificates. However, it reinforces the magnitude of BD in Brazil, comprising a growing proportion of infant deaths as other major mortality causes are controlled. This emerging public health issue points to the need of future health policy strategies, in a country where health is a Constitutional right to be provided by the government to all citizens. We present possible solutions for integrating the fragmented available genetic services, mostly university-based and concentrated in large urban areas, to the recently established public health system (SUS, Sistema Unico de Saude) as a functional network. Also, working to implement a newly introduced BD field in the birth certificate may help to establish a national BD registry. Further public health actions contemplate introducing clinical genetics as a medical specialty in the SUS, creating continuous medical education programs and, most important, increasing public awareness towards the importance and preventive measures regarding BD.

**Financial support: FAPERJ.**

**Influence of genetic factors on infant mortality in Israel.** *J. Zlotogora, A. Leventhal, Y. Amitai.* Public Health Services, Ministry of Health, Israel.

The largest groups of Israeli citizens are Jews (81%), Muslim Arabs (15%), Christian Arabs (2%) and Druze (2%). While in the Jewish population consanguinity rates are low, in the non-Jewish population, particular among Muslim Arabs and Druze consanguineous marriages are frequent (25-45%).

Since the creation of the State of Israel in 1948, there has been a very impressive reduction in infant mortality both among Jews and non-Jews, however, an almost two fold difference is consistent during the years. Indeed, between 1996-1999, the infant mortality rate was twice higher among non-Jews than among Jews (9 and 4.4 per 1,000 live births respectively). Analysis of the factors leading to infant mortality during these years demonstrated that for each etiological category such as prematurity, prerinatal causes or infections, the mortality was higher for non-Jews. However, the most significant differences were found in the rate of congenital malformations and or Mendelian diseases which were responsible for almost 60% of the difference between the two populations. During the 4 years of the study the rate of children with malformations was 3.1 time higher among non-Jews than among Jews (3.94 and 1.25 per 1,000 live birth respectively). A Mendelian disease was diagnosed 8.3 times more frequently among the dead non-Jewish infants than among the dead Jewish infants (1.33 and 0.16 per 1,000 live births respectively).

The differences in the infant mortality rates reflect the higher incidence of congenital malformations and genetic disorders in the Arab population and the lower utilization of the possibility to abort an affected fetus by the Muslim Arabs and the Druze. In order to reduce the impact of genetic factors on the mortality and morbidity, a program for primary prevention and genetic counselling in the community has been initiated.

**Public health strategies to reduce birth defects in Malaysia** . *M. Thong*. Dept of Pediatrics, University of Malaya Med Ctr, Kuala Lumpur, Malaysia .

A major birth defect is defined as an abnormality of prenatal origin that if uncorrected or uncorrectable, significantly impairs normal physical or social function or reduce normal life expectancy. The incidence of major birth defects ascertained from a hospital-based registry at the University of Malaya Medical Centre is 1.8% amongst all births above 24 weeks of gestation. Nearly 30% of these babies died soon after birth despite being managed in a tertiary setting. Only 9.7% had a post-mortem. The 3 commonest birth defects were chromosomal disorders, malformations of the central nervous system and cardiovascular system. No significant differences were found with regards to maternal age, social class, consanguinity, maternal fever/infection, gender or racial groups. Risk factors identified for major birth defects were family history of birth defects, adverse past obstetric events, absence of intake of folate prior conception to first trimester of pregnancy, gestational diabetes or insulin dependent diabetes mellitus and poly or oligohydramnios. Logistic regression analysis identified adverse past obstetric history, absence of intake of folate prior conception to first trimester of pregnancy and the presence of poly or oligohydramnios as independent risk factors for birth defects in Malaysian newborns. Presence of hydramnios is a useful marker for birth defects and an indication for the selective use of limited detailed ultrasonography in pregnancy. Our study showed that relatively simple population-based public health strategies such as periconceptional folate supplementation, appropriate genetic counselling, family studies and screening may reduce birth defects in a developing country such as Malaysia.

**Sickle Cell Screening among Pediatric Latino Immigrants.** *P.J. Gergen<sup>1</sup>, S. Murillo<sup>2</sup>, C.J. Macri<sup>3</sup>*. 1) Center for Primary Care, AHRQ, Rockville, MD; 2) Dept of Pediatrics, Howard University, Washington DC; 3) Dept of OB/GYN, Uniformed Services University of the Health Sciences, Bethesda, MD.

Neonatal sickle cell screening is mandated in approximately 42 of the 50 U.S. states. During the last 20 years immigration has increased the percent of Latinos in the U.S. population. There are no generally accepted guidelines for sickle cell screening among immigrants. As most of the patients with sickle cell disease in the U.S. are African American, it is unlikely that the average clinician considers sickle cell screening to be a priority among their non-U.S. born Latino patients. Therefore we reviewed the medical charts of all non-U.S. born Latino children/adolescents seen at an inner city clinic serving a primarily immigrant Latino population. Approximately 50% of the patients came from El Salvador, 13% from Mexico, 13% from Dominican Republic, and the rest were from the remaining Central/South American countries. The patients ranged in age from 1 month to 23 years at the time of screening. Of the 187 charts screened, 4 or 2.1% were positive for sickle cell trait. All positives received appropriate counseling. Three of the positives were from El Salvador and 1 was from Bolivia. Hemoglobin and MCV values were similar between the sickle cell trait positive and negative groups. U.S. neonatal screening data report a prevalence of sickle cell trait of 0.5% among U.S. born Latinos, 7.1% among African Americans, and 0.2% among whites. Clinicians should include sickle cell screening as part of their initial health evaluation of all their non-U.S. born Latino patients.

**Mammography has poor sensitivity in women below 40 years with family history positive breast cancer.** *M.E. Emanuelsson, F. Wiklund, S. Carlson, H. Gronberg.* Dept. of Radiation Sciences, Umea University, Umea, Sweden.

Background; Inherited factors are common in the ethiology of breast cancer in women below age 40. Currently surveillance with breast exam and mammography is recommended to women with a positive family history (FH) of breast cancer. However, the sensitivity of mammography among these women has not been validated in large studies.

Aim; In a population based study of women below age 40 with breast cancer evaluate the sensitivity of mammography with respect to FH.

Patients and methods; All 173 women with breast cancer before age 40 diagnosed between 1980-1990 in northern Sweden were included. Data on family history, stage, grade, mammography result and treatment were prospectively collected. In 136 women information on both FH and mammography result were available. Multiple logistic regressions were used to evaluate which factors that influence the sensitivity of mammography among these women.

Results; In 51 % of these women the breast tumours were not detected on the clinical mammography done before surgery. The mammography negative cases were even more common among FH positive cancers ( 63%). Mammography negative tumours were also smaller (52% vs. 38%, pT < 20 mm) and node-negative (69% vs. 54%, N0). In the multivariate analysis a positive family history (OR=2,46; 1,00-5,93) and tumour size (< 20 mm) were the only 2 factors that independently influenced the detection rate of breast cancer.

Conclusions; In young women with breast cancer (< 40 years) mammography only detected half of the cancers and the detection rate was even significantly less in women with a positive family history. These results clearly indicate that additional screening techniques has to be evaluated particularly in women with positive FH of breast cancer.

**The combined psychoanalyst-geneticist consultation : a 10 year experience.** *C. BRUN, S. Lyonnet, A. Munnich.*  
Genetics, Necker Hospital, Paris, France.

The time when an information is delivered by the geneticist to the patient is crucial and pathetic. Indeed, the highly efficient diagnostic tools of the geneticist are usually regarded as almost magic by the patient, especially because of their speed and efficiency in supplying conclusive diagnoses and verdicts. Since 1991 psychoanalysts attend the genetic consultations at the Department of Genetics, Necker Hospital, Paris. Attending the consultation and observing the situation, we have noted that despite long and most pedagogical explanations, those informations fall on deaf ears as the patient is scared, staggered by recent traumatic events or informations and he understands very little of the expert's explanations. Because he attends the genetic consultation, the psychoanalyst can play a major role at this point. Sitting beside the geneticist who "reads in the future", the psychoanalyst can speak about what is written. This novel form of cooperation is particularly interesting as i) the psychoanalyst is requested by the geneticist at the time and place of the consultation, ii) the geneticist, facing the patients and the family's drama of transmission, is supposed to deliver a major information which not only refers to formal genetics but also to the personal history of the subject. The psychoanalyst attending this long consultation listens to the patient's story, gives meaning to the process and therefore allows time to start again. Because of the traumatic nature of diagnosis, time is often short-circuited, a feature which prevents the investigation from proceeding further. During the genetic consultation, a recognition and reparation process is initiated. Because the present must become livable, reporting his experience and what he has endured helps the patient or the parents facing their future. The psychoanalyst often meets the patient again during further consultations, alone or with the geneticist and long after the diagnosis has been delivered. These combined consultations provide a time and a space for cross talks between the patient, the geneticist, and the family constellation (including grand parents and sibs) and help facing the problem of the disease, of aging, death and of the succession of generations.

**The changing face of a melting pot America; new challenges in genetic screening.** *J.D. Greenberg, S.W. Morton, M. Jamehdor, J. Siegel-Bartelt.* Kaiser Permanente, Los Angeles, CA.

Recommendations for carrier screening for autosomal recessive diseases are largely based on population risks associated with ethnic background. For the first time, the recent year 2000 US census allowed individuals to state multiple ethnic backgrounds. Nationally, only 2.4% of residents reported 2 or more races; however 4.7% of Californians and 21.4% of Hawaiians reported 2 or more races ([www.census.gov](http://www.census.gov)). This census data is limited in that it reflects the ethnic background of individuals of all ages, rather than reproductive couples. To investigate this issue, we retrospectively surveyed the self reported racial heritage in pregnant women (and their partners) attending for positive expanded AFP screening to a single clinic in urban Los Angeles for 1991/92 and 1999/2000.

The incidence of 2 or more races was 70/473 couples(14.8%), and was stable; 32/197(16.2%)in 1991/92 and 38/276(14.8%)in 1999/2000. In 45/473(9.5%) couples, the patient and her spouse had single, but different racial backgrounds. In 18/473(3.8%)of couples, 3 of the 4 fetal grandparents were from the same racial group. 6/473(1.3%)of couples reported complex ethnic background with 3 or more racial groups. One patient reported that she and her spouse had the same dual racial heritage.

Our results indicate that for this diverse urban population, current recommendations for screening based on ethnic background can continue to be utilized in most couples (~85%). The 14.8% of couples stating racial diversity was about 3 times higher than persons (4.9%)reporting 2 or more races in LA county in the 2000 census. Almost all of these couples had a lowered risk for having a child with cystic fibrosis compared to the overall US population risk (except in european/Ashkenazi couples). This data is likely regional. Geneticists concerned with public health planning should consider local population characteristics when planning screening programs, especially given the significantly greater number of couples with racial diversity than suggested by the US census data.

**Nine-year experience of a National Thalassemia Registry and its role in the control of thalassemia major in Singapore.** *I.S. Ng<sup>1</sup>, G.P. Tan<sup>2</sup>, H.Y. Law<sup>1</sup>.* 1) Div Genetics, KK Women's & Children's Hosp, Singapore, Singapore; 2) National Thalassaemia Registry, Singapore.

Thalassemia is the most common genetic disease in Singapore, with an estimated incidence of ~ 3%. Population screening for thalassemia has been advocated since 1988. In 1992, the National Thalassemia Registry was established to register all newly-diagnosed patients with the thalassemia gene and to invite all first-degree relatives and spouses for counseling and subsidised screening. Notification of cases come from all the hospitals, primary and secondary healthcare facilities and hematological laboratories. Patients are informed of the notification and are then contacted to provide pedigree information. Their relatives and spouses are invited to attend a counseling session in the Registry. Couples identified prospectively to be at-risk for a child with thalassemia major are then offered the option of prenatal diagnosis.

The data from the Registry from 1992-2000 shows that this strategy of extended pedigree tracing and screening with the availability of prenatal diagnosis has been effective in significantly decreasing the incidence of thalassemia major in Singapore. On direct invitation, only 1.4% refused counseling and after the counseling session, only 0.1% refused screening. All the couples identified to be at-risk, opted for prenatal diagnosis by chorionic villus sampling. The number of new patients with thalassemia major has decreased from about 10-15 per year to none in the years 1997 and 2000 and only 1 each in 1998 and 1999. The lifetime healthcare costs for each patient with thalassemia major in Singapore has been estimated to be ~\$500,000. The government expenditure to set up the Registry was \$100,000 and the recurrent yearly expenditure for manpower, running costs and subsidies for screening is \$300,000. This expenditure is more than compensated by the healthcare savings from the dramatic control of the disease in Singapore. These savings can also be diverted to optimising the care of the existing patients with thalassemia major.

**The "Pandora" Box of population-based genetic carrier screening.** *K.E. Ormond<sup>1</sup>, C. McMahon<sup>1</sup>, K. DeMarco<sup>1</sup>, M. Fiddler<sup>2</sup>, E. Pergament<sup>1</sup>.* 1) Northwestern University Medical School, Chicago, IL; 2) DePaul University, Chicago, IL.

**Purpose:** Current population-based genetic carrier screening offers a paradigm of simultaneously testing for multiple genetic disorders unrestricted by geography, race and family history, a likely consequence of the Human Genome Project and the increasing sophistication of recombinant DNA technologies. Our center reports on a three-year experience testing 1,000 individuals for Ashkenazi Jewish genetic disorders (AJGD) and 498 individuals for cystic fibrosis (CF). **Method:** A DNA panel of 5 genetic disorders (Tay Sachs, CF, Canavan, Gaucher, Fanconi Anemia) offered to Ashkenazi couples in late 1997 was expanded to 7 (Bloom and Niemann Pick) in April 2000. CF carrier screening was routinely offered to all couples considering prenatal diagnosis. **Results:** Overall, 182 carriers were identified (1 in 9); 7 couples were at reproductive risk (1 in 100); and, 4 individuals were actually homozygous for gene mutations (Gaucher [2]; CF [2]). **Conclusions:** Based on our experience, it is imperative that programs offering carrier screening must consider the process of informed consent, the impact of screening on the individual, family and society, and the logistical issues related to testing, including the sensitivity of testing based on mutations analyzed and patient background. We propose models that should be proactively developed to address: 1) who decides what conditions are included in carrier screening; 2) what factors determine these decisions; 3) facilitation of autonomous patient decision-making; 4) disclosure to third parties; and, 5) development of educational resources for the general public and health care providers.

**Psychosocial impact of predictive testing for myotonic dystrophy.** *C. Prevost<sup>1</sup>, J. Villeneuve<sup>1</sup>, M. Tremblay<sup>2</sup>, S. Veillette<sup>3</sup>, M. Perron<sup>3</sup>, J. Mathieu<sup>1</sup>.* 1) Complexe Hosp de la Sagamie, Chicoutimi, Qc, Canada; 2) Quebec University at Chicoutimi, Chicoutimi, Qc, Canada; 3) Cegep of Jonquiere, Qc, Canada.

In the Saguenay-Lac-Saint-Jean region (Quebec, Canada), a predictive DNA-testing program for myotonic dystrophy type 1 (DM) has been available as a clinical service since 1988. From 1 to 12 years (median, 5 years) after receiving predictive testing, a total of 308 participants (44 carriers and 264 non carriers) answered a questionnaire to determine reasons for testing and recall of test result, to assess their perception of the psychosocial impact of predictive testing and to measure their actual general well-being, self-esteem and psychological distress. The reasons for wanting to be tested were to learn if children are at risk for DM or for reproductive decision making (75%) and to relieve the uncertainty for themselves (17%). The majority of participants (96.1%) remembered correctly their test result. Among carriers, 19% consider themselves in a worse psychological state, 49% are more worried about their future health, 25% feel less satisfaction about life, 25% present a lower self-esteem and 53% are more concerned about their childrens risk. Among non carriers, 36% find themselves in a better psychological situation, 49% are less worried about their future health, 48% feel more satisfaction about life, 20% present a better self-esteem and 85% are reassured about their childrens risk. The actual general well-being, the self-esteem (Rosenberg Self-Esteem Scale) and the psychological status (Psychiatric Symptom Index) are similar in carriers, in non carriers and in the reference (Quebec) population; these results are not influenced by the number of years elapsed since predictive testing was done. All respondents believe that predictive testing should be available for the at-risk population and the vast majority of carrier (95%) and of noncarriers (93%) would recommend the use of predictive testing to their family members.

**Application of genetically based individual approach in help decision making system.** *H.V. Baranova<sup>1, 2</sup>, E. Albuisson<sup>1</sup>, L. Chapy<sup>2</sup>*. 1) Medical Faculty, Univ d' Auvergne, Clermont-Ferrand, France; 2) IPPM - Interactive Predictive Preventive Medicine Society, Luxemburg.

We present highly personalised internet available help decision making system - Expert System (ES) for interpretation of different laboratory test results (cardiovascular risk, fatty acids spectrum, immune analyses, nutrition) and specially predictive genetic testing. Bioinformatic platform of ES makes possible to perform combined precise analysis and prognosis for each individual according to his peculiarities: lifestyle factors, clinical and genetic data.

Genetic part of ES currently includes 56 main metabolic and predisposition genes and HLA typing. Major goal of ES genetic program is education and presentation of genetically based individual approach in modern medicine. Special attention is paid to environment-gene interactions and pharmacogenetics. Result interpretation and explanations are written in flexible and interactive manner. Three versions: short, normal and long, also as the references are available, according to user request. Other advantages of ES are: 1) informatic model, which allows regular product renewal according to recent achievements; 2) ES with it data bank is a helpful tool in applied research for epidemiological studies.

In conclusion, ES provides a user with highly personalised interactive clinicobiological result interpretation, including last validated information, what is in special interest for physicians. ES data bank exploitation can be also useful in applied research.

**Essential genetics education for non-genetics health professionals (E.C. Project GenEd).** *R. Harris<sup>1</sup>, H.J. Harris<sup>2</sup>, K. Challen<sup>1</sup>, L. Ten Kate<sup>3</sup>, J. Schmidtke<sup>4</sup>, I. Nippert<sup>5</sup>, C. Julian Reynier<sup>6</sup>, U. Kristoffersson<sup>7</sup>.* 1) Dept Medicine, Royal Infirmary, Manchester, England; 2) Brooklands Beacon Medical Practice, Manchester, England; 3) Dept Human Genetics, Free University, Amsterdam, Netherlands; 4) Institut fr Humangenetik Medizinische Hochschule, Hannover, Germany; 5) Institut fr Humangenetik, Mnster, Germany; 6) Institut Centre Regional de lutte contre le cancer Paoli-Calmettes, Marseille, France; 7) Dept Clinical Genetics, University Hospital, Lund, Sweden.

We have evaluated the provision of genetic services in 31 European countries and carried out a series of Confidential Enquiries in UK into counselling by non-geneticists. Urgent recommendations included the need to promote genetics education for non-geneticist health care professionals as the welfare of clients and families are threatened by deficiencies in genetic attitudes, skills and knowledge amongst non-geneticists health professionals (including primary care). Our new study of 1879 referrals has identified the main primary care providers who use genetic centres and confirmed that perceived or real risk of hereditary cancer is the harbinger of the rapidly escalating challenge. The European Commission has therefore funded our GenEd study which assesses genetic attitudes, skills and knowledge, collates current policies and practices for educating non-genetics health professionals and identifies deficiencies. The results of the study will provide an empirical base for new educational programs whose aims are to increase understanding of genetic testing amongst non-genetics health professionals and to raise their awareness of consumer issues in the provision of genetic tests.

**Multidisciplinary community hospital based genetic risk assessment program: a model.** *R.R. Lebel<sup>1,2</sup>, D. Sweet<sup>2</sup>, S. Haibeck<sup>2</sup>, M. Maney<sup>2</sup>.* 1) Genetics Services, Glen Ellyn, IL; 2) Hinsdale Hospital, Hinsdale, IL.

Availability of expert genetics consultation has not typically been found outside of university centers, which are often inconveniently located for suburban and rural consultands. To provide such services in a community hospital, we conceived a clinical program housed in a comprehensive oncology department in a large community hospital known for innovative services. The staff includes a clinical geneticist, an oncologist, and oncology specialist nurses trained in obtaining thorough family and health histories. The hospital foundation supplements funding needs which are beyond the income generated by billing for services. During the first year, the focus was on breast cancer genetics. During that time, we also had consultations for other cancers (uterus, colon, pancreas, etc.), as well as other genetic risk factors (hemochromatosis, osteogenesis imperfecta, cystic fibrosis, etc.) We review the clinical experience of the program, its concept and function, with emphasis on interactions with the general medical staff and hospital administration, and other practical aspects of opening and successfully maintaining such a program.

**Primary care physicians' ethical views.** *J.C. Fletcher<sup>1</sup>, D.C. Wertz<sup>2</sup>*. 1) Keswick, VA; 2) Univ. Mass Med. Schl., Shriver Div., Waltham. MA.

We surveyed 900 US primary care physicians (board-certified in obstetrics, pediatrics, or family practice), randomly selected from the AMA Physician Masterfile. 499 returned anonymous questionnaires on ethics. 75% had referred patients to genetic specialists in the past year. We compared responses with those of 529 US doctoral-level geneticists and 555 MS genetic counselors. More primary care physicians than doctoral-level geneticists or counselors would counsel directly after PND for all 21 fetal conditions listed ( $p < .05$ ). For 13 conditions more primary care physicians would urge carrying to term or provide optimistically slanted information. Fewer primary care physicians than genetics professionals would themselves have abortions for 19 conditions. Fewer physicians (63%) than geneticists (84%) or counselors (87%) said women should have unqualified rights to abortion. Fewer (39% v 54% and 66%) would support the decision of a woman with uncontrolled PKU to carry to term, or support a CF carrier couple who want to take their chances (63% v 79% and 96%). More (45% v 25% and 10%) would suggest sterilization to a blind woman on welfare with genetically transmissible blindness. More (55% v 38% and 16%) said it was socially irresponsible to have children with serious disabilities in an era of PND. More (61% v 50% and 57%) would maintain confidentiality of a patient with HD who will not tell relatives at risk. More would test children for predisposition to Alzheimer (58% v 34% and 15%), alcoholism (76% v 52% and 41%), or HD (66% v 37% and 16%). Fewer (28% v 77% and 79%) thought a 16 yr old should be able to refuse tests. More (53% v 33% and 26%) would tell a school a diagnosis of XYY. Fewer (38% v 62% and 65%) would maintain confidentiality of a bus driver with FH at risk of heart attack on the job. Fewer (52% v 75% and 81%) thought workplace screening should be voluntary.. Results suggest wide divergences between primary care physicians and genetic professionals, with the former more directive and less-autonomy oriented, and a need to establish consistency across professions.

**Appropriate compensation for access to individuals' DNA.** *J.C. Bear.* Memorial University, St John's, NF, Canada.

Access to individuals' DNA is now commonly sought by commercial interests intent on using genomic information to develop new drugs for common conditions. The profitability of such products makes it inappropriate to expect individuals to allow DNA access voluntarily and for free, as is usual now. To establish appropriate compensation, it is necessary to estimate the value of information in individuals' DNA. A common scenario illustrates this procedure. In using affected sib pairs to find a locus at which allelic variation has a significant effect on, for example, obesity, in the order of 1000 individuals' DNA may be assessed to obtain the genomic information from which a targeted molecule can be developed. Approximately 10% of targeted molecules become pharmaceutical products. A new drug for the management of obesity would be expected to generate profits in the order of \$1 billion. Thus, on plausible assumptions, profit of \$100,000 relates to the information in the DNA of each individual studied. Because US pharmaceutical firms' returns to investors approach twice those usual for US corporations, and because initiating drug development from genomic data should increase efficiency, a 50/50 division of profit is reasonable between commercial interests utilizing individuals' DNA information and individuals allowing DNA access. Therefore, in this example, a fee of \$50,000 is appropriate for access to an individual's DNA. In addition, because profits may exceed the initial estimate of \$1 billion, a royalty regime is required to distribute an appropriate portion of any additional profit to individuals providing DNA access. Property rights to tissue may be lost once it is removed from the body. Therefore compensation should be contractually secured before DNA access is granted. The approach outlined here for individuals can be adopted by governments (such as Iceland's) or interest groups representing populations of particular genetic interest, to establish total compensation for their collectivities. If multiple disease susceptibilities are to be assessed, a higher DNA access fee should be established. Because access to their citizens or members could be arranged relatively easily, an efficiency premium could appropriately be required.

**Genes in families: attitudes toward testing and treatment options.** *M.E. Coors.* Healthcare Ethics/Human MedGen, Univ Colorado Health Sci Ctr, Denver, CO.

Educational understanding about medical genetics and the risks and benefits involved are a necessary component of informed consent prior to genetic testing. A pilot study conducted at a schizophrenia research center measured baseline knowledge of genetics and the impact that additional education had on attitudes toward testing and treatment. Parents of children diagnosed or at risk for schizophrenia and controls responded to an in-office survey concerning testing for multifactorial genetic disorders and treatment options. Survey results indicated a satisfactory level of general knowledge about genetics for all participants. Subjects and controls indicated a strong preference in favor of genetic testing for adults. Scores also supported genetic testing for at risk children, even in the absence of treatment options. In contrast, subjects and controls were skeptical about pre-emptive treatment following a positive test for disease genes. Both groups preferred postponing treatment until symptoms appear. There were no statistically significant differences between subjects and controls for any of the categories surveyed.

Subjects and controls then viewed an educational power point tool presenting the science and emphasizing the risks involved with genetic testing. Risks included possible insurance or employment discrimination, stigmatization, breach of privacy, and family conflict. Following the educational session, all participants answered the same survey a second time. Second round scores were not significantly different from first round scores. The results of this pilot study reveal that educational information about the risks and benefits involved had almost no impact on attitudes toward genetic testing and treatment. Results indicate that patients and controls want therapeutic benefit and improved pharmaceuticals to result from genetic testing and are less concerned about the possible risks.

**The "Genetic Family"?: The impact and implications of the "Genetic Revolution" on the definition of family.**

*T.A. Caulfield*<sup>1</sup>, *B.M Knoppers*<sup>2</sup>. 1) Health Law Inst, Univ Alberta, Edmonton, AB., Canada; 2) CRDP, University of Montreal, Canada.

In the past few years, there have been a variety of policy statements calling for more oversight of gene tests for a disease predisposition. There has, however, been little formal commentary on paternity testing. Documents such as the Joint Statement of the ASHG and the ACMG on Genetic Testing in Adoption focus on the right of adopting parents to request and access genetic testing data but not on the impact of the current "genetic revolution" on reemphasising the role of biology in the definition of family. Over the past half century, modern family law has emphasized a more inclusive and flexible notion of family. A number of commentators have suggested that the emerging emphasis on genetic relatedness has the potential to narrow the conception of family to those with whom we share a molecular heritage. Given the complex and mutable nature of family relations, a reliance on simplistic notions of biology can hardly be considered a constructive trend. Factors that may be contributing to this trend include the aggressive marketing strategies used by the paternity testing industry, the judiciary's lack of understanding of the role of genetics in human disease, and a growing belief in the "right" to know one's genetic heritage (e.g., Article 7 of the Convention on the Rights of the Child). This paper will: 1) critique the concerns associated with the impact of genetics on family law; 2) overview the evidence to support the concerns (e.g., a recent survey of Canadian paternity testing case law (Caulfield, 2001)); 3) consider the possible negative implications of an over emphasis on genetics in this context (e.g., possible erosion of the significance of the legal principle of the "best interest of the child"); and 4) provide a number of recommendations for consideration.

**Ten years struggle for prenatal diagnosis (ethical social and technical aspect) in Iran.** *T. Khatibi*<sup>1,2</sup>, *R. Karimi-nejad*<sup>3</sup>, *M.H. Karimi-nejad*<sup>3</sup>, *H. Najmabadi*<sup>2,3</sup>. 1) University of Welfare and Rehabilitation Tehran, Iran; 2) UCLA LA,CA; 3) Karimi-nejad Pathology and Genetics Center.

As we have entered the new millennium, Iran is suffering from more than 25,000 affected Beta Thalassemia major, with the variable carrier frequency in different region of the country in some area as high as 1 in every 4 individuals. The Beta-thal preventions started 10 years ago as self motivated and regulated social need in the form of pre-natal diagnosis. Even though Iran is a religious country and therapeutic abortion was totally unacceptable, but according to the need of society the question was raised: how can we prevent un-treatable hereditary disease without sacrificing religious and cultural traditions. Iranian geneticists decided to hold meeting with religious officials to discuss the role of prenatal diagnosis, particularly for B-thal. Finally few years ago religious leader accepted the fact and issued permission to perform therapeutic abortion up to 16 weeks of gestation for B-thal. Simultaneously, the government began to involve and set up systematic approach for control and prevention of the disease. We have also developed a coverage system that insurance companies will cover this kind of medical expenses, have speed up the prevention program. Two national reference laboratories have been approved by government to help prenatal diagnostic program by providing training, problem solving, quality control and quality assurance for themselves and referral laboratories. Fortunately now we have a system which is compatible with our social beliefs. Majority of expenses paid by insurance companies and approved by international agencies like WHO. The effort of the past few years was showing minimal effect on the society; however, as we enter the long phase we should compare Iran's prevention program with those with the other countries such as Cyprus, Greece and etc. We are expecting this year only 2000 prenatal diagnosis will be done. Our system is very efficient and compatible for the region and can be applied as a functional adaptive system for the other Islamic Countries.

**Experiences of serving on a Research Ethics Committee (REC) in the UK: impact of the 'new genetics'.** A.S. Rigby<sup>1,2</sup>, C.J. Taylor<sup>1,2</sup>, K. Khoaz<sup>2</sup>. 1) Sheffield Children's Hosp, Univ Sheffield, Sheffield, England; 2) Sheffield Teaching Hospitals NHS Trust, Sheffield, England.

Members of RECs in the UK have the responsibility of ensuring that medical research is conducted in an ethical manner. To fulfil this role, RECs must engage in reasonable discussion of the ethical issues in each protocol that they review. The completion of the Human Genome Project brings added ethical complexities. Issues such as consent to participate, confidentiality and gene patenting are more frequently seen on the agenda. We carried out a review of the work of our REC to see what issues were prevalent and to see whether the 'new genetics' would impact on our future workload. Between 1997-99 South Sheffield REC registered 1070 protocols. Both hospital (n=566) and university research (n=343) predominated with a smaller number from general practice (n=25). Most protocols were either 'approved with amendments' or 'ratified' by the committee. Only a small number were rejected. Typical diseases brought to the RECs attention included cystic fibrosis, the rheumatic diseases and various types of cancer. The ethical considerations of the committee were diverse. Many of our discussions centred on the collection and storage of DNA, particularly where other family members were involved, and where study sponsors wished to develop a DNA bank for future and often unrelated use. Long term storage of DNA was also an issue. Some multinational companies were keen to develop gene patents and the patients understanding of these issues was neglected by the researchers. Patient information sheets often treated DNA collection from either blood or tissue as an incidental part of the protocol and made little effort to explain the concepts of genetic risk or commercial gains from DNA analysis. The 'new genetics' is likely to have an impact on the future work of RECs. Ethics committee members must have continual training while researchers must learn to address real ethical concerns; both parties must learn to work together. If they are not able to do so, the completion of the Human Genome Project will be like climbing Mount Everest: a great achievement in itself, but of little value to others.

**Attitude toward ethical issues in severe congenital anomaly: a survey among medical personnel in Taiwan. C.**

*Shiue<sup>1</sup>, C. Chao<sup>2</sup>, W. Tsai<sup>3</sup>, S. Lin<sup>4</sup>.* 1) Dept Pediatrics, Buddhist Dalin Tzu Chi GenHosp, Chia Yi, Taiwan; 2) Nursing School, Chen Kung University; 3) Pediatrics, Chi Mei Hospital; 4) Chen Kung University Hospital, Tainan, Taiwan.

To investigate the ethical issues encountered in caring of children with severe congenital anomalies and attitude of medical staffs in end-of-life decision making, we conducted a survey among pediatricians and pediatric nurses from different hospitals in Taiwan. Questionnaire consisted of 57 questions and four case scenarios was used to score the attitude which were either pro-life or quality of life oriented. Our results were based on a total of 382 respondents. The results showed that (1) Withdrawing and withholding life support in these children was considered as the most difficult ethical dilemma by pediatric nurses. (2) Parents' wish was considered as the most important factor in the decision of to treat or not. (3) Staffs who believed in Buddhism and Daoism took attitudes that were more pro-life oriented (31.20+7.36 vs 29.05+4.56;  $P < 0.05$ ). (4) Nurses in ICU tended to take more quality of life attitude than nurses in general wards. We concluded that understanding the psychosocial factors involved in medical decisions for these patients would help in counseling and clinical practice. And a critical self-analysis of medical personnel's behaviors would lead to a decision making process grounded on a more sound ethical basis.

Program Nr: 1477 from the 2001 ASHG Annual Meeting

**Catalyst for Advancing Research: Collaborations among Industry, Academia and Consumer Organizations.** *S.F. Terry<sup>1, 3</sup>, J. Cody<sup>2</sup>, J. Lewis<sup>3</sup>, P.F. Terry<sup>1</sup>, L.M. Nelson<sup>4</sup>, M.E. Davidson<sup>3</sup>*. 1) PXE International, Inc, Sharon, MA; 2) University of Texas Health Science Center, San Antonio, TX; 3) Genetic Alliance, Washington, DC; 4) National Institute of Child Health and Human Development, Bethesda, MD.

As the field of genetics matures, a number of important changes are taking place. The early stages of genetics research involved the development of technology to sequence the human genome. As proteomics takes center stage, research will require collaborations in well-developed networks of researchers, participants and their respective organizations. These partnerships will be both the catalyst and fuel for acceleration of research that is essential to advancing new understandings. In the past academia and industry have often worked on parallel tracks, apart from the lay advocacy and public sectors. However, there are increasing numbers of research collaborations giving rise to effective and efficient interactive models that can sustain the essential resources for genetics research. Borrowing lessons learned from the semiconductor field, and other successful collaborations throughout the research community, the speakers will describe successful model projects and the key elements which guaranteed the partnerships success.

**Community Genetics Carrier Screening for Multiple Disorders.** A. Proos<sup>1,2,4</sup>, H. Aizenberg<sup>2</sup>, K. Barlow-Stewart<sup>2,3</sup>, L. Burnett<sup>1,2,4</sup>, V. Howell<sup>1,4</sup>, E. Raik<sup>4</sup>. 1) Lab and Community Genetics, Kolling Institute, St Leonards, Australia; 2) Institute of Community Genetics, Wolper Jewish Hospital, Trelawney St, Woolahra, Australia; 3) NSW Geneticsw Education Program, Royal North Shore Hospital, St Leonards, Australia; 4) Pacific Laboratory Medicine Services (PaLMS), Royal North Shore Hospital, St Leonards, Australia.

Australia is a highly multi-cultural country, with its current population derived from more than 200 different national and ethnic groups. We have conducted an eight year study to assess the relative effectiveness of different strategies for introducing community genetics screening programs for asymptomatic genetics carrier detection. Here we report the successful extension of these programs to include three simultaneous genetic disorders: Tay-Sachs disease (TSD), cystic fibrosis (CF), and Thalassaemia (Thal). Methods Subjects consisted of senior high school students, 16 years plus. A genetics education session was organised at school in group-delivery mode, describing principles of genetics inheritance, and clinical significance of the three different genetic disorders. Subjects were provided with brief written material and were encouraged to discuss this material with their family and peers. One week later, confidential access to free laboratory testing (HEXA enzyme activity, CFTR mutation detection, automated Red Cell indices/Blood Film examination) for the disorders was offered to students at school. Informed consent was obtained and individual counselling was available. Results. 67% of subjects elected to proceed onto testing. 50 % of subjects elected to have testing for all three disorders even though 18% of these were low risk for TSD + CF. 4.7 % of subjects tested required genetics counselling when their test results revealed that they were an asymptomatic mutation carrier. 0.8 % of subjects required medical consultation when their haematology test results revealed abnormalities. Conclusion. Test selection although based on ancestry and risk was also influenced by availability. Laboratory protocols for community genetics screening for multiple disorders are feasible.

**The Alfred & Baker Gene Bank - A Cardiovascular Genetic Research Investment.** *C. Williams<sup>1</sup>, A. Dart<sup>1</sup>, C. Reid<sup>2</sup>, G. Jennings<sup>1</sup>.* 1) Cardiology Department, Alfred & Baker Medical Unit, Melbourne, Australia; 2) ANBP II, Alfred & Baker Medical Unit, Melbourne, Australia.

**Background:** Genetic mutations have been proposed to be the underlying cause of hypertension, hyperlipidaemia and coronary heart disease in addition to determining individual responses to drug therapy. Establishing a mechanism through which populations, diseased and healthy, can be readily genotyped however, raises logistic and ethical challenges. Our aim was to establish a cardiovascular (CVD) gene bank for healthy volunteers and individuals with cardiovascular disorders to enable the study of the genetic determinants of CVD.

**Methods:** Individuals with CVD attending the cardiology and cardiac surgery departments of The Alfred are routinely approached to provide a blood sample. Healthy volunteers attending risk evaluation services are similarly approached. Subjects are asked to consent for their sample to be available for genetic analysis. The Alfred Research & Ethics Unit was approached to approve a process whereby consent for genotyping of samples rests with the Ethics Committee rather than having to gain consent from each volunteer for every proposed research project.

**Results:** Following external review from the Victorian Council of Bio-ethics, The Alfred Research & Ethics Committee agreed: a) the gene bank could collect samples for genetic analysis in cardiovascular and clinical research projects; b) samples could be stored indefinitely; c) future analysis of samples would be subject to further ethics applications related to the specific genetic study. Subject involvement has been exceptional and few have expressed reservations about contributing. Less than one in 100 participants approached have declined joining the gene bank. Those who refused did so due to concerns relating to privacy laws. In the first 12 months 700 patients have consented to participate.

**Conclusions:** The Alfred & Baker Gene Bank has been established to provide a resource for ongoing research into the genetic determinants of CVD. Authority for the ongoing use of the samples in future is vested in The Alfred Hospital Research & Ethics Committee.

**Evidence for involvement of the *HFE* S65C Variant in Hereditary Hemochromatosis: Implications for Diagnostic Testing.** *I.M. Buysse*<sup>1,2</sup>, *A. Bartlett*<sup>1,2</sup>, *D.W. Stockton*<sup>1</sup>, *B.B. Roa*<sup>1,2</sup>. 1) Baylor DNA Diagnostic Laboratory; 2) Department of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX.

Hereditary hemochromatosis (HH) is an autosomal recessive disorder characterized by increased iron absorption and iron storage leading to organ damage. Clinical consequences can be prevented by early diagnosis and treatment by phlebotomy. HH in the Caucasian population is associated with two major mutations in the *HFE* gene which are assayed in most diagnostic laboratories. Homozygosity for the severe C282Y mutation accounts for >80% of cases, while compound heterozygosity for H63D and C282Y is associated with HH at a reduced penetrance. A third variant, S65C, was also reported to contribute to HH. We describe one patient with a positive family history and a clinical diagnosis of mild HH, who presented with a transferrin saturation level of 39%, a ferritin level of 512, and elevated iron stores on liver biopsy. This patient was initially tested for H63D and C282Y using ASO hybridization, and found to be heterozygous for C282Y. Further sequence analysis identified him to be compound heterozygous for S65C/C282Y. These alleles appear to be in trans, since a first degree relative was reported as S65C/-. We extended the S65C analysis to a cohort of patients who were previously referred for HH testing. An automated primer extension-based assay, Pyrosequencing, was used in our initial survey for S65C which identified 11 positives out of 181 HH patients (~3% of chromosomes). This group included 7 S65C/C282Y compound heterozygotes out of 81 patients previously tested to be C282Y/-; 2 H63D/S65C compound heterozygotes out of 70 who had tested H63D/-; and 2 S65C heterozygotes out of 30 who had tested negative for H63D and C282Y. Analysis of 90 control individuals identified 1 heterozygote and 1 homozygote for S65C (~1.7% of control chromosomes). Our results are consistent with previous reports that suggest S65C allele enrichment in HH patients, and an apparent risk conferred by the S65C/C282Y compound heterozygous *HFE* genotype. These collective findings raise the possibility of including S65C together with C282Y and H63D in a molecular diagnostic panel for hereditary hemochromatosis.

**Molecular analysis of Duchenne and Becker muscular dystrophy patients in Saudi Arabia.** *R. Majumdar<sup>1</sup>, M. Al Jumah<sup>2</sup>, S. Al Rajeh<sup>3</sup>, E. Chaves-Carballo<sup>4</sup>, M.M. Salih<sup>5</sup>, A. Awada<sup>2</sup>, S. Shahwan<sup>6</sup>, S. Al Uthaim<sup>1</sup>.* 1) Neurogenetics Laboratory, Department of Medicine, King Fahad Natl Guard Hosp, Riyadh, Saudi Arabia; 2) Division of Neurology, Department of of Medicine, King Fahad Natl Guard Hosp, Riyadh, Saudi Arabia; 3) Division of Neurology, King Saud University, Riyadh, Saudi Arabia; 4) Department of Neurosciences, King Faisal Specialist Hospital & Research Center, Riyadh, Saudi Arabia; 5) Department of Pediatrics, King Saud University, Riyadh, Saudi Arabia; 6) Department of Pediatrics, Military Hospital, Riyadh, Saudi Arabia.

**Objective:** The deletion in the dystrophin gene has been reported for many ethnic groups, but until now the mutations in this gene have not been thoroughly investigated in Saudi Duchenne and Becker muscular dystrophy (DMD/BMD) patients. **Methods:** We examined the deletion pattern in the dystrophin gene of the Saudi patients applying multiplex-polymerase chain reaction (PCR). Genomic DNA was isolated from twenty two patients with DMD/BMD confirmed by dystrophin staining on muscle biopsy, eleven patients with clinical suspicion of DMD without muscle biopsy, three patients with limb girdle muscular dystrophy, twelve relatives of the patients, and five healthy Saudi volunteers. Specific exons around the deletion prone regions (hot spots) of the dystrophin gene were amplified. **Results:** The deletion of one or more exons was found in sixteen of twenty two DMD/BMD patients. The deletion in the gene was detected in seven of eleven patients with suspected DMD diagnosis, but not confirmed by dystrophin staining of muscle biopsy. No deletion in the dystrophin gene was detected in control Saudi volunteers, the limb girdle dystrophy patients, and the relatives of patients, as expected. **Conclusion:** The present study suggests that intragenic dystrophin gene deletions (70%) occur with the same frequency in Saudi patients compared with other ethnic groups.

(This study was supported by King Fahad National Guard Hospital and a grant from King Abdulaziz City for Science and Technology, Project AT-18-03).

**An unusual pedigree illustrating the dilemmas posed by screening for the cystic fibrosis mutation R117H.** *J.P. Warner<sup>1</sup>, A.J. Gilfillan<sup>1</sup>, D.J. Porteous<sup>2</sup>, D.R. Fitzpatrick<sup>1</sup>, M.E. Porteous<sup>1</sup>*. 1) Clinical Genetics Service, Molecular Medicine Centre, Western General Hosp, Edinburgh, Scotland; 2) Medical Genetics Section, University of Edinburgh, Molecular Medicine Centre, Western General Hosp, Edinburgh, Scotland.

Antenatal screening for cystic fibrosis (CF) mutations has been available in Edinburgh as a first trimester test since 1990. To date a total of 44000 couples have been tested. In parallel with the screening programme the regional DNA laboratory has been testing proven and suspected CF families and also CBAVD men from infertility clinics. Of 119 R117H carriers identified by the antenatal screening programme 393 were shown to be in cis with the 7T intron 8 variant (R117H 7T). All cystic fibrosis patients tested by the DNA lab over the same period (n=10) with the R117H/DF508 genotype have been shown to have the R117H mutation in cis with the 5T variant (R117H 5T). Of 38 men with CBAVD referred by the regional infertility clinic 3 have the R117H 7T/DF508 genotype which is lower than might be expected. Over the past seven years our interpretation of the R117H 7T/DF508 genotype has changed and we show how the advice given to three couples from a single extended family has changed over time. Given the counselling difficulty associated with predicting a phenotype for R117H 7T/DF508 and the 4 fold excess of R117H 7T over R117H 5T in our population the decision was made in Nov 2000 to remove this mutation from the CF antenatal screening set. On the basis of the handling of this and other families we disagree with the recommendation of the American College of Medical Genetics in their guidelines for population based CF carrier screening (1) that R117H be included in a CF screening mutation set. We believe R117H is not appropriate as a screening mutation and that obtaining fully informed consent for testing is impossible during pregnancy for this mutation. (1) Grody et. al. (2001) Genetics in Medicine vol 3 No.2 pp 149-154.

**Real-time quantitative PCR analysis for alpha-thalassemia-1 of Southeast Asian type deletion in Taiwan.** *D.C. Chu<sup>1</sup>, C.H. Lee<sup>2</sup>, S.W. Cheng<sup>2</sup>, M.H. Lin<sup>1</sup>, D.T. Chiu<sup>1</sup>, T.L. Wu<sup>2</sup>, K.C. Tsao<sup>2</sup>, C.F. Sun<sup>2</sup>, J.D. Liu<sup>3</sup>.* 1) School of Medical Technology, Chang Gung University, Tao Yuan, Taiwan; 2) Department of Clinical Pathology, Chang Gung Medical Center, Lin-Kou, Taiwan; 3) Department of OB/GYN, Chang Gung Memorial hospital, Taipei, Taiwan.

Since homozygosity of the alpha-thalassemia-1 of Southeast Asian (SEA) type deletion results in hydrops fetalis, a novel protocol based on the fluorescent probe involved real-time quantitative polymerase chain reaction (PCR) technique to quantify the relative ratio of intact and aberrant alpha-globin genes in cases with reduced mean corpuscular volume (MCV) has been developed to rapidly screen SEA type deletion in Taiwan. A single TaqMan probe was designed to hybridize both the PCR products of normal alpha-globin gene alleles and the alleles with SEA deletion to ensure identical probe binding efficiency. The ratio of the normal alpha-globin genes to genes bearing the SEA deletion present in each subject was thus determined and expressed in cycle threshold (CT) values. Theoretically, a relative ratio of one to one (normal alpha-globin gene allele / SEA deletion bearing allele) was anticipated in individuals carrying the SEA deletion. Forty-five samples (25 heterozygotes for the SEA deletion and 20 with normal alpha-globin gene alleles) were retrieved from the DNA Study Sample Bank and analyzed retrospectively with this protocol. Data showed that the CT values for the intact alpha-globin gene allele and the allele bearing the SEA deletion in heterozygous individuals were determined to be  $28.74 \pm 1.49$ , and  $26.46 \pm 2.05$ , respectively. Therefore, the ratio of normal alpha-globin gene allele to SEA deletion bearing allele in the carriers was  $1.09 \pm 0.043$ . The CT values for intact alpha-globin gene alleles in normal subjects were determined to be  $28.28 \pm 2.11$ . No ambiguous results were observed from other common aberrant genotypes associated with alpha-thalassemia such as the Philippine type deletion. Based on the results, we concluded that this protocol could provide a rapid approach to mass screen carriers with alpha-thalassemia-1 of SEA type deletion effectively.

**Gastroschisis pregnancies from Northwest Louisiana.** *T.F. Thurmon, K. Yanamandra, D. Napper, R. Dhanireddy, J.A. Bocchini Jr.* Dept Pediatrics-Genetics, Louisiana State Univ, Shreveport, LA.

The Biochemical Genetics laboratory in the department of Pediatrics at LSU medical school, Shreveport, Louisiana, has been screening pregnant women for NTD and Down syndrome defects since 1995 using triple analyte screening. Maternal serum screening results of elevated AFP were confirmed by testing for AFP in the amniotic fluids and by amniotic fluid acetylcholinesterase (ACHE) gel assay in the detection of NTD, Gastroschisis, omphalocele, etc. When we analyzed our elevated Amniotic fluid AFPs and positive ACHE results we found a large proportion of Gastroschisis in the single disorder entities. We found 17 pregnancies with Gastroschisis from the amniotic fluids that were referred to our laboratory for AFP testing. On ethnic stratification we found three African-American patients out of 785 referrals (0.38%), and fourteen Caucasian patients out of 1243 referrals (1.13%). When we checked the characteristics of Gastroschisis pregnancies we found that majority of them were young mothers (over 50% were below 20 years of age at LMP, relative risk of 3.3). No Gastroschisis was detected in the maternal age over 35 years (AMA cases). The season of conception made a difference. The majority of Gastroschisis cases were from the spring conceptions (Jan through April) comprising 60% of the defects when compared to the 33% of normal pregnancies (relative risk of 1.7). Although the cause of Gastroschisis formation is not known it is believed to be due to a vascular disturbance in the omphalomesenteric artery. Gastroschisis being a multifactorial disease, many reports explored environmental status of the pregnancies such as smoking, use of illicit drugs, poor nutrition, teenage pregnancy etc, however, no consensus was reached. Young age and concentration of LMPs in one season in our data are puzzling. Data and statistics will be presented.

**Down Syndrome Screening in *In Vitro* Fertilization Pregnancies: Is there a need for a Human Chorionic Gonadotropin adjustment factor?** L. Rouse<sup>1,3</sup>, T. Marini<sup>1</sup>, D. Grow<sup>2</sup>, P. Pekow<sup>3</sup>, P. Nasca<sup>3</sup>, R. Naeem<sup>1</sup>. 1)

Department of Pathology, Baystate Medical Center, Springfield, MA; 2) Department of OB/GYN, Baystate Medical Center, Springfield, MA; 3) University of Massachusetts School of Public Health and Health Sciences, Amherst, MA.

**Background** Methods for screening Down syndrome during pregnancy involve the measurement of maternal serum (MS) alpha-fetoprotein, MS unconjugated estriol, and MS human chorionic gonadotropin (hCG). Previous studies have suggested that due to increased hCG levels in *in vitro* fertilization (IVF) pregnancies an adjustment factor might be needed. We present the largest series to date studying the levels of hCG during IVF pregnancies and its relationship with the screening outcome using naturally conceived pregnancies as a comparison group. **Methods** The study population consisted of pregnant women with singleton pregnancies during the 5-year study period at Baystate Medical Center with a maternal serum screen (MSS) performed at 15-22.9 weeks of pregnancy. The IVF(exposed) group consisted of all positive singleton pregnancies recorded during the first ultrasound at 5 to 7 weeks after IVF (n=72). The comparison (unexposed) group was selected among naturally conceived pregnancies and matched to the study group at a rate of 3:1 within 2 years of maternal age, and date of MSS (n=216). **Results** Bivariate analyses indicated that the exposed and the unexposed were equally to have statistically similar hCG levels at the time of MSS. An odds ratio of 1.02 with 95% confidence intervals of 0.56-1.85 was calculated for increased hCG levels with a cut-point of 1.22 MoM (Multiples of the Median)(66th percentile) at the time of MSS. The specificity of MSS in the IVF pregnancies equaled 87.5%, and the false-positive level was 12.5%. The specificity of maternal serum screening in the naturally conceived pregnancies was 80.1% and the false-positive level was 19.9%. **Conclusion** Study results indicated that IVF status does not influence the likelihood to have increased levels of hCG when compared with naturally conceived pregnancies at time of MSS, therefore an adjustment factor for hCG levels in the Down's syndrome algorithm may be unnecessary.

**Validity of the analysis of FMRP expression in blood smears as a screening method for the fragile X syndrome in Indian population.** *Z.M. Patel, S.R. Menon, A.K. D'souza, R.A. Adhia, D.A. Sanghavi, H.M. Gawde.* Inst Res Reprod/Genetic Res Ct, Indian Council Medical Res, Mumbai, india.

The fragile X syndrome (FXS) is the leading cause of inherited mental retardation, affecting 1:4000 males in the general population. Characteristic phenotype findings include long face, large ears, macro-orchidism & connective tissue anomalies. Its diagnosis is currently based on the presence of an abnormal cgg repeat expansion at the first exon of the FXS gene (FMR1) which causes the shut down of transcription and subsequent absence of the FXS protein (FMRP). Currently detection of patients and carriers is routinely done by DNA analysis of the cgg repeat. In 1995 an FMRP antibody test was developed to detect the presence of FMRP in lymphocytes from blood smears. Subsequently a pilot study in Netherland proved that amongst males FMRP test was a useful screening method for the FXS. We have tested the validity of the FMRP test to screen males for FXS in India. We studied 90 males with mental retardation of unknown etiology, and 10 normal (males & females). All patients were clinically evaluated and tested for FMR1 mutation (southern blot & PCR). The FMRP test detected 3 patients with full mutation. Males with FXS had an average FMRP expression of 11% (0-21%). Whereas normal males and females had FMRP expression around 86% (64-100%). These results support that the analysis of FMRP expression in blood smears is a valid and simple method to screen males with mental retardation of unknown etiology.

**Rett syndrome in the Israeli population.** *R. Shomrat<sup>1</sup>, T. Naiman<sup>1</sup>, H. Wolf<sup>1</sup>, Y. Yaron<sup>1,2</sup>, A. Orr-Urtreger<sup>1,2</sup>.* 1) Genetic institute, Tel- Aviv Sourasky medical center , Tel Aviv, Israel; 2) Sakler school of medicine, Tel Aviv University, Tel Aviv, Israel.

Rett syndrome (RTT) is a neurodevelopmental disorder which almost exclusively affects females and is characterized by cognitive deterioration with autistic features, loss of acquired skills, stereotypic hand movements, ataxia and epilepsy. Milder variants have also been reported. It is an X-linked dominant disorder that affects 1 in 10 000 to 15 000 females. In most classical cases, mutations have been detected in the MECP2 gene located on Xq28. Most cases are sporadic with de novo mutations. Although presumed to be lethal in males, a few rare cases of males with MECP2 mutations have been described.

Our laboratory provides a genetic molecular diagnostic service for RTT patients and families in Israel. We have, so far tested 26 families using direct sequencing of the entire coding region of the MECP2 gene. The patients were from various Jewish ethnic groups and from Arabic origin.

Of the 26 patients evaluated, only 12 had classical manifestations of RTT, the other 14 patients lacked the full classical RTT diagnostic criteria. Mutation analysis revealed mutations in 11 of the 12 classical cases (91%). No mutation was detected in the other non classical cases. Of the 11 patients with mutations in the MECP2 gene 8 different mutations were found, including 2 insertion mutations that have not been previously described; 2 mutations were located in the methyl CpG binding domain (MBD) and 3 in the repression domain (TRD). 6 mutations were nonsense mutations and 2 were missense. No significant difference of mutation type was noted in the different ethnic groups. Of the 11 cases with mutations 10 were de novo. The familial case consisted of a girl and her brother with severe encephalopathy shared the same 754insC mutation while their mother had no mutation in her peripheral blood leukocyte. This case demonstrates gonadal mosaicism.

**Distribution of normal, intermediate and premutation-size of the FMR1 alleles in a normal population at Risaralda Colombia, SA.** *L. Rengifo, A. Alegria, D. Gaviria, E. Aguilar, J. Rodriguez and Centro de Biología Molecular y Biotecnología de la Universidad Tecnológica de Pereira.* Basic Sci, Fac Med, Univ Tecnológica de Pereira, Pereira, Colombia.

The Fragile-X syndrome constitutes one of the most prevalent hereditary entities causing mental retardation and other behaviour disorders. It is characterized on the molecular level by the expansion of the 5-(CGG)<sub>n</sub>-3 repeat in the untranslated 5' region of the gene FMR1 mapped in the Xq27.3 sensitive folate site. Individuals affected present a characteristic phenotype and cognitive disorders. In order to find the distribution of normal, intermediate and premutation-size FMR1 alleles, a molecular characterization of the FRAXA site was made on 1171 alleles corresponding to 728 X chromosomes of 364 women and 443 men X chromosomes, all normal individuals from 11 towns in Risaralda, Colombia SA. The methods used were PCR and Southern blot techniques. The size of the most frequent allele was 30 repeats of the triplet CGG, in 932 cases (79.6%), followed by the alleles with 20 repeats with 60 cases (5.12%) and by the alleles with 28 repeats with 39 cases (3.33%). The frequency of the normal alleles, between 10 and 40 CGG repeats, was 98% of all individuals (98.2% for men and 97.7% for women). The premutation state appeared in three individuals of the general population (three women), corresponding to 0.37%. For the department of Risaralda, a prevalence of 1/270 was observed. Taking into account that the racial and ethnic composition of this department is typical for the country, these results could be extended to other parts of Colombia.

**Scanning of the whole HFE coding region in HC probands with an incomplete HFE genotype by use of Denaturing High Performance Liquid Chromatography (DHPLC):**. *G. Le Gac*<sup>1,3</sup>, *C. Mura*<sup>2,3</sup>, *C. Ferec*<sup>1,3</sup>. 1) Genetics, Etablissement Francais du Sang-Bretagne; 2) Universite de Bretagne Occidentale; 3) INSERM (EMI 01-15), Brest, France.

Background: Genetic testing for the two common HFE gene mutations, C282Y and H63D, plays an important role both in the diagnosis of the hereditary haemochromatosis (HC) and in the detection of patients at risk of iron overload. However, depending on the population studied, between 4 and 35% of HC probands have an incomplete HFE genotype (they are C282Y or H63D heterozygotes or non-carrier of C282Y or H63D). Based on the recent description of sixteen new mutations within the HFE gene, one may consider of particular interest to scan the whole HFE coding region in this group of HC probands to define if they carry uncommon HFE mutations. The aim of our study was to evaluate the Denaturing High Performance Liquid Chromatography (DHPLC) to set up a rapid and economical screening assay of the complete HFE coding region. Methods: The analysis conditions of each coding exon were carefully worked by a combination of computer-based melting profile predictions and empirical data that used available or specifically created positive controls. Results: We detected all known HFE mutations. Moreover, each melting domain of the HFE coding region without known mutation was investigated with, at least, one polymorphism as reference. As a consequence, DHPLC also gives a high probability of detecting unknown HFE mutations. Thus, scanning of the complete HFE gene in 54 HC probands from Brittany allowed us to find two new synonymous mutations, P303P (903 G->A) and G334G (1002 T->C), and a novel missense mutation, V295A (884 T->C), which is also considered to be a polymorphism. In addition, the amino-acid 295 of the HFE protein is not conserved between species: in humans amino-acid 295 is a valine, whereas in other species like mouse and rats it is an alanine. Conclusion: The DHPLC method can be used for an efficient scanning of the HFE gene in HC probands with, at least, one chromosome lacking both the C282Y and H63D mutations.

**Screening For Metabolic Disorders in Genetic Isolates in Manitoba: New Frontiers! New Challenges!** *C. Prasad, C.R. Greenberg.* Department of Biochemistry and Medical Genetics, University of Manitoba, Winnipeg, MB., Canada.

We describe our experience with the delivery of genetic services for three rare autosomal recessive metabolic disorders, hepatic CPT1 deficiency (CPT1A), sulfite oxidase deficiency (SUOX) and glutaric acidemia type 1 (GA1) in Manitoba. CPT1A occurs in the Hutterite community with a carrier frequency of 1 in 16. A pilot DNA based newborn screening program for a unique CPT1A Gly 710 to Glu (G710E) mutation has been offered to this community for 16 months, with one affected baby diagnosed. The prognosis is good with presymptomatic detection. The exceptional acceptance in this group has been made possible by direct liaison with a community representative and educational programs. A common 1347-1350delTTGT mutation has been identified to cause SUOX deficiency, a severe neurodegenerative disorder in a remote aboriginal community of Northern Manitoba with a population of 800 and a birth rate of 15/year. Three affected babies have been identified over past 10 years suggesting a high carrier frequency. An educational program on the genetic basis and the availability of carrier testing using video links, direct liaison with local health care providers and community members is planned. DNA-based newborn screening for the single homozygous mutation (GCDH IVS-1 +5g@t) that causes GA1 in the Oji-Cree of northeastern Manitoba has been ongoing for last 2 years. Four affected newborns have been identified. Despite early detection and treatment, prognosis for neurological outcome is suboptimal.

Numerous challenges need to be overcome when a screening program is offered to a particular community. Stigmatization, genetic discrimination, social constraints and lack of information about genetics often act as barriers to community and individual participation. Efforts to educate the community are paramount to the ultimate acceptance of a newborn or carrier-screening program. We discuss strategies that have made CPT1A newborn screening a success within the Hutterite community, and identify challenges with implementation of similar programs in the aboriginal communities of Northern Manitoba.

**Molecular analysis in newborns from Texas affected with Galactosemia.** *Y.-P. Yang, N. Corley, J. Garcia-Heras.*  
Genetic Testing Ctr, Texas Dept Hlth, Denton, TX.

We present data about the spectrum of mutations in the Galactose-1-phosphate uridyl transferase (GALT) gene in 39 galactosemia patients who were identified by the Texas Newborn Screening Program. There were 11 cases of classic type and 28 of Duarte-2. Twenty-four patients were White, 12 were Hispanic, 1 was Black, 1 was Asian and 1 was of unknown ethnic origin.

Blinded studies were done by DNA automatic sequencing of the 11 exons and all the exon-intron boundaries of the gene. Thirteen different mutations including 10 missense mutations, 2 nonsense mutations and 1 splicing mutation were detected in 74 of the 78 mutant alleles (diagnostic efficiency of 95%). The prevalent mutations were N314D (38%), Q188R (36%), K285N (5%), and IVS2nt-2a->g (4%). The other less frequent mutations were S135L and T138M (3% each), T23A, H184Q, Y251S, L195P, Q207X, L264X, and A345D (1% each). Three novel mutations, T23A, Q207X, and A345D, were identified. N314D was in linkage disequilibrium with the three intronic polymorphisms IVS4nt-27g->c, IVS5nt-24g->a, and IVS5nt+62g->a and the 5UTR deletion c.-119->-116delGTCA in Duarte-2 type. The 3 individuals with IVS2nt-2a->g were Hispanic, suggesting it is distinctive of Hispanics because it was not observed previously in other populations. S135L, a prevalent mutation in Blacks, was present in 2 Hispanic patients (genotypes Q188R/S135L and IVS2nt-2a->g/S135L). This finding may reflect a racial admixture or an independent origin of this mutation in Hispanics.

Most patients carried two different mutations (30/39). Four patients were homozygous for Q188R. Only 1 mutant allele was detected in 2 cases (1 classic and 1 Duarte-2 type) and no mutations were found in 1 Duarte-2 patient. Two unusual genotypes were observed in 2 patients homozygous for the Duarte-2 N314D allele and heterozygous for another novel mutation. One case was diagnosed as classic galactosemia (N314D+Q207X/N314D) while another one was diagnosed as Duarte-2 galactosemia (N314D+T23A/N314D).

**Choosing a novel strategy for point mutation detection in the dystrophin gene : DHPLC or BESS ? A preliminary comparison.** *S. Chambert, C. Saquet, M. Claustres, S. Tuffery-Giraud.* Lab Genetique Moleculaire, CHU montpellier, France.

In Duchenne and Becker Muscular Dystrophy (D/BMD), one third of the mutations are not detectable as intragenic deletions or duplications of the dystrophin gene. Because full gene sequencing (79 exons) would be laborious and time-consuming in order to identify point mutations occurring in this gene, we used an approach based on the analysis of dystrophin transcripts (RT-PCR) coupled with the protein truncation test (PTT) during these last years. As a result of these studies, the families of these patients are currently benefiting from accurate carrier-status assessment. Also, some patients carrying a point mutation have been selected for inclusion in clinical trials in view of therapy. However, this technique was limited to a detection rate of 86% in our series. In the aim at identifying point mutation in more patients, we set out to assess the sensitivity of Denaturing High-Performance Liquid Chromatography (DHPLC) and Base Excision Sequence Scanning (BESS) as an approach to mutation screening in DMD. We first assessed a cohort of 15 patients with previously identified mutations (frameshift or stop mutations) spread all over the gene. The comparison of the two methods was based on the analysis of the same amplified fragment of cDNA (~ 500bp) known to contain the mutation. A sequenced cDNA was used as control, and for heteroduplex formation in DHPLC. The sensitivities of DHPLC and BESS were very similar when respectively more than one column temperature was used for the detection of mismatches, and when BESS T and BESS G cleavage reactions were performed. Both allowed the rapid detection of single base substitutions as well as small deletions/insertions. From these findings, we conclude that these two methods provide a reliable alternative to the PTT. Up to now, we have not yet established which of these two technology (BESS or DHPLC) would be the most appropriate for the molecular diagnosis of DMD. We plan to analyze DMD patients (clinical diagnosis confirmed by immunohistochemical analysis of dystrophin) in whom extensive RT-PCR/PTT analysis failed to detect the mutation. Supported in part by a grant of Association Franaise contre les Myopathies (AFM).

**Mutational analysis of BRCA1 in familial breast cancer in Malaysia.** *P. Balraj<sup>1</sup>, A.S.B. Khoo<sup>1</sup>, Y.S. Choy<sup>2</sup>, S.K. Tan<sup>1</sup>, J.A.M.A. Tan<sup>1</sup>, H. Abdullah<sup>2</sup>, C.H. Yip<sup>3</sup>.* 1) Molecular Pathology, Institute of Medical Research, Kuala Lumpur, Malaysia; 2) Kuala Lumpur Hospital; 3) University Hospital, Kuala Lumpur.

Predictive genetic testing of BRCA1 and BRCA2 genes benefits women with family history of breast cancer as it enable medical and lifestyle decisions to be made while reducing the anxiety of not knowing the genetic background. However, the testing for both the BRCA1 and BRCA2 is tedious and expensive as both the genes are large without mutational hot-spots. Mutational testing using direct sequencing detects only 65% of the BRCA-1 linked families. Therefore, uninformative results would limit the benefits of testing in high risk families. In Malaysia, breast cancer is the commonest cancer death among women and it constitutes 7% of all cancers in the country with a prevalence of 150 per 100,000 individuals. Counseling of breast cancer for high risk individuals have been carried out in the breast cancer clinics. A pilot project on BRCA1 mutation analysis was carried out to evaluate the incidence of BRCA1 mutations in individuals at risk and to identify a cost effective methodology. Using direct sequencing of all splice sites and coding sequences, we have identified 2 mutations in two out of 12 Malaysian families (16%) comparable with Japanese families (20%). One of the mutation nt2754 G>A was novel and had been reported (Khoo A.S.B. et al, Human Mutation, 2000). The other mutation nt4693 del AA was found in a large families where 6 living individuals are involved. One frameshift mutation (nt5447 InsC) was detected in 1 out of 23 cases of early-onset breast cancer. Nine polymorphisms were identified and 5 of them were found in exon 11. More than half of the index cases have these polymorphisms. In another blinded study using heteroduplex analysis by conformational sensitive gel electrophoresis (CSGE), all the changes (100%) found by direct sequencing were identified. Therefore, we concluded that CSGE is a useful and equally sensitive method in mutation scanning as direct sequencing. It may be more cost effective to carry out CSGE before sequencing in our setting. But a comprehensive mutation detection strategy should include methodologies which cover large deletions and BRCA2 analysis.

**High throughput and specific newborn screening assay of 21-hydroxylase deficiency in dried blood spots using high performance liquid chromatography/electrospray ionization tandem mass spectrometry.** *C. Lai<sup>1</sup>, C. Tsai<sup>1</sup>, F. Tsai<sup>1</sup>, W. Hwu<sup>2</sup>, J. Wu<sup>1</sup>, S. Chu<sup>3</sup>.* 1) Department of Medical Genetics and Medical Research, China Medical College Hospital, Taichung, Taiwan,; 2) Department of Pediatrics and Medical Genetics, National Taiwan University Hospital, Taipei, Taiwan,; 3) Department of Pediatrics, Buddhist Tzu Chi General Hospital, Hualien, Taiwan,.

A specific, rapid, high throughput, and simple method based on high performance liquid chromatography/tandem mass spectrometry (HPLC/MS/MS) was applied to the screening of congenital adrenal hyperplasia (CAH) caused by 21-hydroxylase deficiency from dried blood spots on newborn screening cards. We used this new method to directly determine the 17OH-P levels in dried blood specimens with a detection limit of 20 ng/ml (~12 ml whole blood was used), to avoid the time-consuming derivatization steps required by gas-chromatography/mass spectrometry (GC/MS) method. The method is reproducible: the CVs were <6%. Dried blood specimens from 500 neonates include neonatal patients with classical 21-hydroxylase deficiency were random analyzed. Ten neonatal specimens had clearly elevated dried blood 17OH-P (>40 ng/ml) at the time that screening for 21-hydroxylase deficiency performed by LC/MS/MS and immunoassay, all were confirmed with true CAH and therefore a cut-off of 40 ng/ml for 17OH-P level was used for CAH newborn screening in our study. This suggested LC/MS/MS were compatible with immunoassay. We aimed at measuring the first dried blood specimens concentrations of 17-hydroxyprogesterone (17OH-P) determined by HPLC/MS/MS in term CAH neonates with 21-hydroxylase deficiency. This LC/MS/MS method is useful for screening infants with CAH due to 21-hydroxylase deficiency.

**VGT-SSCP: A highly sensitive and non radioactive mutation detection method based on vertical gradient temperature SSCP.** *H. Razzaghi, M.I. Kamboh.* Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA.

Single strand conformation polymorphism (SSCP) method is widely used for mutation detection. The sensitivity of the method depends on several factors, most importantly the temperature at which electrophoresis of single-stranded DNA (ssDNA) takes place. Temperature has a profound effect on the folded conformation of ssDNA. The temperature factor is predominantly determined empirically in conventional SSCP, which can be very tedious especially when a large number of different DNA samples need to be screened. We have devised a novel SSCP method based on a vertical gradient temperature (VGT), which automatically subjects ssDNA to various temperatures in the same electrophoresis. The theory behind VGT-SSCP protocol is that when ssDNA is subjected to run in a wide range of gradient temperature, it will automatically acquire optimal resolution at an optimal temperature to distinguish between the wild type and the mutant type ssDNA. The sensitivity level of mutation detection of VGT-SSCP depends on whether the corresponding optimal secondary structure of a mutant DNA strand is within the preset gradient temperature range. In summary, the VGT-SSCP is a simple and robust non-radioactive method that is more sensitive than constant-temperature SSCP in detecting unknown mutations.

**Establishment of stably transformed cell lines from residual clinical blood samples for use in performance evaluation and quality assurance in molecular genetic testing.** *T.T. Stenzel<sup>1</sup>, S.H. Bernacki<sup>1</sup>, J.C. Beck<sup>2</sup>, K. Snow<sup>3</sup>, V.M. Pratt<sup>1</sup>, K.G. Monaghan<sup>4</sup>, T.W. Prior<sup>5</sup>, K.J. Matteson<sup>6</sup>, L.M. Wasserman<sup>7</sup>, W.W. Noll<sup>8</sup>, E.C. Cole<sup>9</sup>.* 1) Duke Univ Medical Center; 2) Coriell Institute for Medical Research; 3) Mayo Clinic; 4) Henry Ford Hospital; 5) Ohio State Univ Hospital; 6) Univ Tennessee Medical Center; 7) Univ California San Diego; 8) Dartmouth-Hitchcock Medical Center; 9) DynCorp Health Research Services Division.

The demand for diagnostic molecular genetic testing (MGT) is continuously increasing as more mutations associated with genetic disorders are characterized. The development of new molecular genetic tests and the performance evaluation and quality assurance (PE/QA) of existing tests require the availability of good positive controls. Currently, these are difficult to obtain for many genetic diseases. We examined the feasibility of using residual blood originally collected for routine clinical MGT to establish stably transformed B lymphocyte cell lines that could supply reliable positive control material. Existing proficiency testing groups use lymphocyte cell lines extensively. In order to obtain the necessary samples, we established a network of 8 sample submitting labs. We used a standard EBV transformation protocol including PHA, and attempted transformation on 45 samples representing 7 genetic diseases. Successful transformation, defined as growth to  $1 \times 10^8$  cells, was achieved in samples up to 14 days old collected in either ACD or EDTA and from as little as 1 ml of residual blood. Tubes were either opened or unopened, and contamination was not a major problem. Acceptable storage conditions were either ambient or 4°C for samples  $\leq 7$  days old and 4°C only for samples 8-14 days old. Average time to transformation was  $43.1 \pm 1.8$  (SEM) days for ACD samples and  $61.3 \pm 10.8$  (SEM) days for EDTA samples. The historical average for samples freshly collected in ACD is  $35.7 \pm 0.3$  (SEM) days. Stability of the mutations was verified after five 10-fold expansions of the cell lines. We plan to pilot the cell lines to outside clinical MGT laboratories to determine their suitability for use as PE/QA material. (Funded by the Centers for Disease Control and Prevention).

**Simplified molecular diagnostic testing for fragile X syndrome using methylation-specific PCR (ms-PCR). Y.**

Zhou<sup>1</sup>, S.S. Chong<sup>1,2,3</sup>. 1) Pediatrics, Nat'l Univ Singapore & Hosp, Singapore; 2) Ob/Gyn & Lab Medicine, Nat'l Univ Singapore & Hosp, Singapore; 3) Pediatrics & Instit Genetic Medicine, Johns Hopkins Univ, Baltimore, USA.

Fragile X syndrome is the most common inherited form of mental retardation and accounts for about half of all X-linked mental retardation. It is caused by mutations in the *FMR1* gene, the overwhelming majority of which involve hyperexpansion and hypermethylation of a polymorphic CGG trinucleotide repeat in the 5' untranslated region of the gene. Currently, molecular analysis of the *FMR1* gene CGG repeat is performed using a combination of PCR and Southern blot analyses, neither of which can be used exclusive of the other to detect the full spectrum of *FMR1* alleles and genotypes. We explored the use of sodium bisulfite mediated selective modification of unmethylated versus methylated genomic DNA at the *FMR1* locus to develop a ms-PCR diagnostic testing strategy. Primers specific to sodium bisulfite modified unmethylated and methylated alleles were designed and tested on DNA samples from normal, premutation and full mutation males, as well as from normal, premutation carrier and full mutation affected females. For each sample, the sizes of the ms-PCR amplicons obtained using the unmethylated-specific and methylated-specific primers were compared to the corresponding results obtained by Southern blot analysis of *EcoRI/EagI* double-digested DNA. For most samples tested, ms-PCR amplicons of expected sizes from methylated and unmethylated alleles were clearly detectable by ethidium bromide staining on agarose gels. The assay also faithfully reflected methylation status of the respective alleles each sample, as confirmed by Southern blot analysis. Premutation and full mutation alleles in females, however, were consistently weaker in intensity than their corresponding normal allele, reflecting a lower amplification efficiency compared to the normal allele. Further modifications to improve detection of large premutation (> 100 repeats) and full mutation alleles are in progress, including the incorporation of fluorophore-tagged dNTPs during PCR, followed by automated fluorescence detection.

Program Nr: 1498 from the 2001 ASHG Annual Meeting

**A comprehensive molecular analysis of myotonic dystrophy in Iran.** *M.S.M.E. Mousavi, K. Kahrizi, S.S Hosseini Amini, H. Najmabadi.* Genetics Research center, University of Social Welfare and Rehabilitation Sciences, Tehran, Iran.

Myotonic dystrophy (DM) is the most common form of adult muscle dystrophies with varying frequencies in different populations. So far there has been no comprehensive population screening on this disease in Iran. DM has multisystemic manifestation including muscle weakness and myotonia. It has pattern of Trinucleotide (CTG) repeats, in 3' untranslated region of the serine Threonine protein kinase gene located on chromosome 19q13.3. Due to similarity in clinical picture with the other dystrophic patients and the lack of reliable diagnostics we decided to set up a molecular analysis technique for DM for the first time in Iran. PCR and southern blotting were performed using nonradioactive material. 100 patients were investigated. DM gene mutations were detected in 35% of the clinically diagnosed DM patients.

**Quality evaluation of data interpretation and reporting.** *E. Dequeker, J.-J. Cassiman.* Center for Human Genetics, KU Leuven, Leuven, Belgium.

Errors in any of the steps of a molecular genetic test may affect its results and conclusions, and can have potential consequences for prenatal diagnosis and carrier testing. Patients are usually tested only once and an incorrect result may not become apparent for many years. It is important that the error rate of genetic tests should be reduced to an absolute minimum. Over the past five years quality assessment schemes for cystic fibrosis (CF) were organised in Europe where 135 to 200 diagnostic laboratories participated. A significant improvement of the quality of the genotype results was obtained during subsequent QA schemes, coming from 65% of laboratories without errors in 1996 up to 90% in 2000. In addition to the evaluation of the genotype results, evaluation of the interpretation of the data in the report that is normally sent to the referral physician was done since 1999. The schemes demonstrated that the way of reporting laboratory results varied considerably, although the same request for genetic testing was addressed to all participants. A list of relevant items in the written reports was prepared. Based on the presence of the items of this list in the reports of 1999 versus 2000 we conclude that the standard of reports has improved in 2000. In particular, sample and patient information has improved, together with technical information. Unfortunately, more than 30% of the laboratories made at least one mistake in a submitted report (administrative errors, errors in risk calculation, a wrong interpretation of the results, or confusing genotype results of samples from patients and carriers). Taking into account the different reporting policies (country specific issues), this evaluation study also provided information on the large variation between laboratories in reporting genetic testing results for carrier testing of individuals with a positive family history of CF, or for genetic confirmation testing of the clinical diagnosis of CF. Overall, there is a high variation in the format, the content, and the quality of the written reports on molecular genetic tests. This could be further improved by preparing and using consensus guidelines for genetic test reporting (including the availability of model laboratory reports).

**A New Approach To Detect Gene Dosage At The *PMP22* Gene.** *S.M. Akrami, J.A.L. Armour.* Institute of Genetics, University of Nottingham , Nottingham, UK.

An increasing number of human disorders are known to be caused by micro-deletions/duplications, and gene dosage alterations are responsible for several categories of diseases. Examination of sub-microscopic changes is possible by using short probes flanked by the same primer pairs and such probes can be recovered and amplified quantitatively following hybridization to a genomic target. Multiplex Amplifiable Probe Hybridization (MAPH) is a simple, high-resolution method by which alterations of several hundred base pairs are detectable. DNA rearrangement is the molecular cause of most Charcot-Marie-Tooth (CMT1) disease by a gene dosage mechanism: the 1.5Mb duplication of chromosome 17p11.2-12 containing the *PMP22* gene accounts for about 70% of CMT1 patients. A deletion of the same region is detected in more than 85% of cases of hereditary neuropathy with liability to pressure palsies (HNPP). We are applying MAPH on the *PMP22* gene to develop an efficient and sensitive test for detecting gene dosage in CMT1A/HNPP patients. Work on genomic DNA of normal people shows reproducible results approximating to a normal distribution. A preliminary blind test of 99 samples gave the correct diagnosis in all but two cases; the method is currently being refined to investigate and eliminate cause of these two false-negative calls.

**Rapid detection of b-thalassemia mutations in the Italian population using a DHPLC system.** A. Colosimo<sup>1,2</sup>, V. Guida<sup>1,3</sup>, A. De Luca<sup>1</sup>, M.P. Cappabianca<sup>4</sup>, I. Bianco<sup>4</sup>, B. Dallapiccola<sup>1,3</sup>. 1) CSS-Mendel Institute, Rome, Italy; 2) Department of Biomedical Sciences, University "G.D'Annunzio" of Chieti, Italy; 3) Department of Experimental Medicine and Pathology, University "La Sapienza" of Rome, Italy; 4) Associazione nazionale per la lotta contro le Microcitemie in Italia.

b-thalassemia is the most common mendelian disease in the Mediterranean area, resulting from more than 200 different mutations in the b-globin gene. Prevention programs based on postnatal and prenatal molecular diagnosis of b-thalassemia carriers and patients require the use of a reliable mutation scanning method in at-risk populations. We have developed a rapid and highly specific mutation screening test based on the Denaturing High Performance Liquid Chromatography (DHPLC) system. The sensitivity and specificity of the method were tested on the full genomic region of the b-globin gene in 40 Italian healthy heterozygous carriers in which 25 different b-globin mutations had been previously characterized by ARMS-PCR technique. The entire gene, including 280 bp upstream of exon 1 and 200 bp downstream of exon 3, was amplified in 7 fragments of 300-500 bp using identical PCR parameters. The sensitivity and specificity reached 100% since all the 25 distinct sequence alterations were precisely identified by DHPLC. There were neither false positive nor false negative results. Both missense mutations and single or double base deletions were detected. In addition, several compound heterozygous and homozygous b-thalassemia patients were successfully subjected to DHPLC. To detect the mutations in homozygous patients the DHPLC analysis was preceded by a mixing step with a reference wild-type DNA. Overall, the method was able to unambiguously identify the most common b-thalassemia mutations, accounting for more than 95% of b-globin alleles in the Italian population. However, the presence of possible polymorphisms recommends to perform sequencing on DNA samples, whose DHPLC chromatograms differ from characterized elution profiles. In conclusion, compared to classical approaches of mutation screening, this method allows a rapid, highly sensitive, cost effective and semi-automated mutational screening of a large number of samples.

**Development and evaluation of a multiplexed, automated assay using a commercially available primer extension kit for determining the African American 3120+1G>A and the French Canadian I148T mutations in Cystic**

**Fibrosis.** *N.M. Brown<sup>1</sup>, S. Bernacki<sup>1</sup>, V.M. Pratt<sup>2</sup>, T.T. Stenzel<sup>1</sup>.* 1) Dept of Pathology, Duke University, Durham, NC; 2) Laboratory Corporation of America, Research Triangle Park, NC.

Cystic Fibrosis (CF) is an autosomal recessive disorder that is characterized by the triad of chronic broncho-pulmonary disease, pancreatic insufficiency and elevated sweat electrolytes (Welsh et al., 1995). Over 900 mutations in the CFTR gene have been found to cause CF and congenital bilateral aplasia of the vas deferens. The American College of Medical Genetics (ACMG) has recommended a core mutation panel for general population CF carrier screening (Grody et al., 2001). This panel contains 25 of the known CF mutations including 3120+1G>A and I148T. Commercially available kits (Roche, Applied Biosystems and Innogenetics) contain most of these 25 mutations but usually do not include 3120+1G>A and I148T. Therefore we developed a multiplex primer extension assay to rapidly detect these two CF mutations using the ABI prism Snapshot ddNTP primer extension kit. The kit uses a single fluorescently labeled dideoxynucleotide primer extension reaction in conjunction with the ABI genetic analyzer to detect the addition of a fluorescently labeled ddNTP to the 3' end of a sequencing primer, identifying the specific polymorphism or mutation. Seven samples were used to verify our assay's ability to identify normal and mutated alleles. From each sample, PCR amplified regions that included the mutations (3120+1G>A and I148T) were multiplexed into a single dideoxynucleotide primer extension reaction using two different sequencing primers of different lengths. Analysis was performed on the ABI 310 genetic analyzer, and five normal samples and two heterozygotes samples were identified. Multiplexing the single-plex ABI Prism SNaPshot ddNTP primer extension kit allows rapid identification of normal specimens and mutated specimens that carry the CF 3120+1G>A and I148T mutations. The successful development of this multiplex assay has enabled us to speculate that further manipulation of the assay could allow more than two mutations to be analyzed by using the single-plex kit resulting in a cost saving.

**Validated Standards for Genetic Testing.** *J.C. Beck, C.M. Beiswanger, L.H. Toji, P.K. Bender, J.C. Leonard, R.T. Johnson.* Coriell Cell Repositories, Coriell Inst Medical Research, Camden, NJ.

As the number of molecular genetic diagnostic tests offered continues to increase, there is a critical need for validated standards accessible to laboratories offering these tests. The Coriell Cell Repositories through the NIGMS Human Genetic Cell Repository and the NIA Aging Cell Repository have a collection of more than 600 cell lines and DNA samples representing 83 diseases with characterized mutations which could be used as standards. These include diseases caused by expansion of trinucleotide repeats, such as dentatorubral-pallidoluysian atrophy (for which three samples with known repeats are available); myotonic dystrophy (13); Friedreich ataxia (10); fragile X syndrome (26); Huntington Disease (13); SCA1 (2); and SCA3 (2). The collection also includes 40 different mutations in the *CFTR* gene, 20 unique mutations in the *BRCA1* gene, 6 mutations in the *BRCA2* gene, and 4 mutations in the *APC* gene. Samples from patients with hemochromatosis (19), muscular dystrophy (11), and spinal muscular atrophy (3) have also been molecularly characterized. In addition, specimens carrying the factor V Leiden mutation (4), the *MTHFR* thermolabile variant (3), and the 20210G-A polymorphism in the prothrombin gene (2) are also included in the collection. Standards are also available for apolipoprotein E and Rh D genotyping. Finally, the collections include five cell lines with mutations in multiple genes: two have mutations in three different genes, e.g., one with mutations in *MTHFR*, *F2*, and *F5*, and a second with mutations in *MTHFR*, *F2*, and *HFE*, and three cell lines have identified mutations in two genes, e.g., *MTHFR* and *DMPK*, *HFE* and *F5*, and *CFTR* and *HFE*. The samples in these resources, validated by certified expert molecular laboratories, are valuable reagents for laboratories performing molecular genetic testing and may also be useful for quality assurance programs. Detailed information about these samples, including ordering instructions, is available in an electronic catalog (<http://locus.umdj.edu/ccr>).

**Molecular Diagnosis of Five Spinocerebellar Ataxias by Capillary Electrophoresis.** *M.O. Dorschner<sup>1</sup>, D. Barden<sup>2</sup>, K. Stephens<sup>1,2</sup>*. 1) Division of Medical Genetics; 2) Department of Laboratory Medicine, University of Washington School of Medicine, Seattle, WA.

We have developed a single-tube, multiplex assay for the analysis of the CAG repeat expansions that cause the five most prevalent spinocerebellar ataxias, SCA1, 2, 3, 6, and 7. To facilitate multiplex amplification, an M13 -21 universal sequence was added to the 5' end of each SCA-specific primer, which is thought to mitigate differences in annealing and amplification efficiencies. By judiciously pairing fluorescent dyes with each SCA locus such that products of overlapping size ranges were labeled differently, only the three fluorescent dyes FAM, HEX, and NED were needed. All five loci amplified simultaneously using a *Pwo/Taq* polymerase blend. Both normal and expanded alleles were detected reproducibly, although expanded alleles amplified less efficiently as expected. The interassay variability is less than a single base. To assess the accuracy of fragment sizing by capillary electrophoresis (CE), we assayed samples that had been previously analyzed by conventional polyacrylamide gel electrophoresis (PAGE). Initial fragment sizes using CE were determined relative to a commercially available size standard. CE underestimated the fragment lengths for all five loci. This phenomenon is presumably caused by the secondary structure of amplicons and has been described previously for the trinucleotide repeat expansions of the Huntington and fragile X genes. Regression analysis of fragment length determined by PAGE versus CE was employed to calculate a size correction factor for each SCA locus. Size correction factors differed significantly among the five loci. The dominant spinocerebellar ataxias are a group of progressive neurodegenerative disorders that cannot be diagnosed accurately in the clinical setting. This assay will facilitate rapid, specific, and precise molecular diagnosis.

**The prevalence of mutations that cause Familial Dysautonomia and Mucopolysaccharidosis Type IV in the Ashkenazi Jewish Community.** *L. Edelmann, J. Dong, R.J. Desnick, R. Kornreich.* Dept Human Gen, Box 1497, Mt Sinai Sch Medicine, New York, NY.

Carrier screening among the Ashkenazi Jewish (AJ) population for a number of autosomal recessive mutations has provided an extremely effective method for identifying individuals at risk for having children with severely debilitating and often lethal diseases. For the majority of these diseases, there is currently no cure. Recently, the genetic lesions responsible for two additional recessive disorders that affect primarily AJ individuals were identified. They include, two mutations in the I $\kappa$ B kinase complex associated protein gene (*IKBKAP*), which are responsible for Familial Dysautonomia (FD), a severe congenital neuropathy, and two mutations in *MCOLN1*, which cause Mucopolysaccharidosis Type IV (MLIV), a severely debilitating lysosomal storage disease. To determine the frequency of carriers for both of these disorders and discern whether they should be added to the AJ panel, we anonymously tested DNA samples with informed consent from AJ individuals, living in the greater New York Metropolitan area, that were screened for other disorders in our current AJ panel. The use of a multiplex PCR method coupled with allele specific oligonucleotide hybridization (ASOH) facilitated a simultaneous search for mutation carriers for both disorders. For FD, 2500 AJ individuals were analyzed for the presence of the IVS20<sup>+6T>C</sup> splicing major mutation and the R696P missense minor mutation in *IKBKAP*. A carrier frequency of 3.2% or 1 in 31 was found for the splicing mutation, but we did not identify any carriers of the missense mutation, confirming that the IVS20<sup>+6T>C</sup> major mutation accounts for nearly all cases of FD in the AJ population. For MLIV, 1100 AJ individuals were screened for two founder mutations in *MCOLN1*, the major 5534A>G splicing mutation and the minor 511>6944del, a 6434 bp deletion. For the splicing mutation, a carrier frequency of 0.45% was found, and for the deletion, the frequency of carriers was 0.18%. These mutations have a combined frequency of 0.64% indicating that 1 in 157 AJ individuals is a carrier for MLIV. Based on these findings, we have added FD to our AJ screening panel and are in the process of including MLIV screening as well.

**Dutch approach to confirm the clinical diagnosis CADASIL, five new Notch3 gene mutations.** *E. Bakker<sup>1</sup>, S.A.J. Lesnik Oberstein<sup>1</sup>, M.J. Vollebregt<sup>1</sup>, J. Haan<sup>2</sup>, M.D. Ferrari<sup>2</sup>, M.H. Breuning<sup>1</sup>.* 1) Dept of Human and Clinical Genetics,; 2) Dept of Neurology, LUMC, Leiden, Netherlands.

The Dutch CADASIL Research Group uses a stepwise approach to confirm, molecular genetically, the clinical diagnosis in individual patients with CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy). Based on our earlier results, detecting a mutation in 11 out of 11 clinically well described CADASIL patients by sequence analysis of the Notch3 gene (1), we developed a stepwise approach making use of the Notch3 gene mutation spectrum (2), clinical and MRI data. For clinically suspected cases we start with sequence analyses of exon 4 (sequence round 1), which harbours a mutation hotspot (~65%; of all known mutations). When no mutation is detected in round 1 the referring physician is requested to send clinical and MRI data. If these proofs to support the diagnosis CADASIL, further analysis of the Notch3 gene (the remaining 32 exons) is performed. This proof could be detailed MRI data, because all genetically proven patients sofar showed prominent signal abnormalities on brain MRI -leukoencephalopathy on T2- and small subcortical infarcts on T1-weighted images. Or a positive pedigree, with several cases of late onset recurrent TIAs and strokes, vascular dementia, migraine with aura (35%; of patients), and psychiatric disturbances (30%; of patients). In those clinically highly suspected cases further analysis of the Notch3 gene is conducted in several rounds of sequencing. In round 2, exons 3, 5, 11, and 19 are sequenced. In round 3, the exons 2, 8, 14, 18, 20, 22 and 23 are sequenced. The last round harbours 16 of the remaining 18 exons, sequencing of exon 1 and 33 is not yet operational. Up to now 15 different mutations were detected, some of which recurrent and at least 5 which to our knowledge were not yet described: Cys134Trp, Cys446Phe, Arg544Cys, Cys1015Arg and Arg1076Cys. 1) SAJ Oberstein et al. (1999) Neurology 52;1913 2) A Joutel et al. (1997) The Lancet 350;1511-1515.

**Use of Invader assays to determine allele frequency of SNPs involved in lipid metabolism.** *B. Aizenstein, M. Baker, M. Brink, M. Maguire, R. Grygiel, K. Osterby, B. Neri, M. de Arruda.* Third Wave Technologies, Madison, WI.

The regulation of plasma lipid levels is the result of the complex interaction of the many gene products involved in their transport and metabolism. Genetic variations in these genes have been associated with a variety of diseases including hypercholesterolemia, hyperlipoproteinemia, and hypertriglyceridemia. The number of genes involved in lipid metabolism and the large number of variations that have been described in each gene, make their characterisation particularly important in accurately identifying the genetic basis of these diseases. We have used the Invader Assay to characterise over 20 allelic variations contained within 5 different genes involved in circulating plasma lipid metabolism: Low-Density Lipoprotein Receptor (LDLR), Lipoprotein Lipase (LPL), Cholesterol Ester Transfer Protein (CETP), ATP-Binding Cassette (A1 and C4 subfamilies), and Apolipoprotein E (ApoE).

The Invader® Assay is a signal amplification method for rapid and inexpensive identification of genetic variations directly from genomic DNA samples. Signal generation is based on the presence of an invasive specific structure formed by the hybridisation of two oligonucleotides, Primary Probe and Invader oligo, to the target DNA. The Primary Probe includes a 5'-flap that does not hybridize to the target DNA. This invasive structure is the substrate for the Cleavase enzyme, which in turn cleaves off the unpaired 5'-flap of the primary probe. The length of sequence specific region of the probe is designed to cycle on and off the target sequence at the reaction temperature thus allowing multiple cleaved flaps to be generated from a single target molecule. In a secondary concomitant reaction, the released flap serves as an Invader oligo on a synthetic target-probe complex, termed FRET Cassette, to recreate the invasive structure recognized by the Cleavase enzyme. Signal generation occurs when the Cleavase enzyme recognises and cleaves the invaded FRET cassette releasing the fluorescent dye.

We will present data on the allele frequency of each of the studied genes using a panel of 92 individuals.

**Comparison of methods for detection of mutations in the BRCA1 gene.** *B.A. Bove<sup>1</sup>, H. Ozcelik<sup>2</sup>, S. Neuhausen<sup>6</sup>, J. Boyd<sup>3</sup>, M. Southey<sup>9</sup>, R. Santella<sup>7</sup>, D. Venter<sup>9</sup>, J. Beck<sup>1</sup>, F. Li<sup>5</sup>, S. Buys<sup>4</sup>, I.L. Andrulis<sup>2</sup>, A.K. Godwin<sup>1</sup>, A. Whittemore<sup>8</sup> and CFRBCS.* 1) Fox Chase Cancer Ctr, Philadelphia, PA; 2) University of Toronto; 3) Memorial Sloan Kettering Cancer Center; 4) Huntsman Center; 5) Dana Farber Cancer Center; 6) University of Utah; 7) Columbia University; 8) Stanford University; 9) Peter MacCallum Cancer Institute.

The Cooperative Family Registry for Breast Cancer Studies (CFRBCS) was established in 1995 to create a resource that could be used to investigate genetic and environmental factors that influence the susceptibility to breast cancer and to exploit this information to aid in preventing the disease. Families in the CFRBCS have been identified through population-based registries in Northern California, Ontario and Australia and high-risk clinics in Pennsylvania, New York, Utah and Australia. Knowledge of the germline BRCA1 and BRCA2 status of individuals in the CFRBCS is an essential first step in utilizing the Registry for molecular epidemiological studies of genotype-phenotype correlations, gene-gene and gene-environment interactions. The purpose of the present study was to determine the sensitivity and specificity of molecular techniques to detect mutations in the BRCA1 gene. Twenty one coded lymphoblastoid cell line samples, whose BRCA1 mutation status had been determined previously by direct DNA sequencing analysis, were evaluated for DNA alterations using the following mutation detection assays: single-strand conformation polymorphism analysis (SSCP), two dimension (2-D) gene scanning, protein truncation test, and enzyme mutation detection (EMD). PTT correctly identified all truncation mutations. The EMD method correctly identified all truncation mutations, with the expected exception of a large deletion in exon 22, as well as two missense alterations. Two mutations were not detected by 2D gel scanning, and seven deleterious mutations were not detected by SSCP. A combination of techniques identified one additional truncation and one additional unclassified variant than was detected by direct sequencing, suggesting that complimentary methods for mutational analysis may be necessary.

**The relative contribution of mutations in the DFNB loci to congenital/early childhood non-syndromal sensorineural hearing impairment/deafness.** *N.C. Navarro-Coy<sup>1</sup>, T.P. Hutchin<sup>1</sup>, H.E. Conlon<sup>2</sup>, E.L. Coghill<sup>3</sup>, A. Middleton<sup>4</sup>, J.S. Rowland<sup>4</sup>, G.R. Taylor<sup>4</sup>, T. Bishop<sup>5</sup>, R.C. Trembath<sup>2</sup>, S.D.M. Brown<sup>3</sup>, R.F. Mueller<sup>1,4</sup>.* 1) Molecular Medicine Unit, University of Leeds, Leeds, UK; 2) Division of Medical Genetics, University of Leicester, UK; 3) MRC Mammalian Genetics Unit, Harwell, UK; 4) 4 Clinical Genetics, St James's University Hospital, Leeds, UK; 5) 5 ICRF Genetic Epidemiology Unit, St James's University Hospital, Leeds, UK.

Approximately 1 in 1000 children have congenital/early childhood onset sensorineural hearing impairment, of which 50% are genetic, two-thirds of which are non-syndromal with some three-quarters thought to be due to genes inherited in an autosomal recessive manner. Mutations in connexin 26 (CX26) have been identified as the most common cause, establishing CX26 gene mutation testing as a routine diagnostic investigation for a child sporadically affected with non-syndromal sensorineural hearing impairment/deafness. The relative contribution of the remaining recessive loci (DFNB) to autosomal recessive non-syndromal sensorineural hearing impairment/deafness (ARNSSNHI/D) is unknown. We analysed the contribution of the DFNB loci in a cohort of 118 sib pairs with ARNSSNHI/D. Cx26 mutations were found to be responsible in 28/118 (23.7%) of the sib-pairs. Analysis of the flanking linked polymorphic microsatellite markers for each of the remaining DFNB loci were analysed in the remaining sib pairs for concordance at each locus. All of the remaining loci were concordant for a minority of the sib-pairs, suggesting that none of the genes at the other DFNB loci appear to make a major contribution to ARNSSNHI/D. However, initial results of screening the DFNB genes which have been cloned revealed mutations in the PDS gene in 3 of the 10 sib-pairs concordant for the DFNB4 locus. The results of this study provides preliminary evidence for a rational clinical and molecular investigation of children sporadically affected with congenital/early childhood onset non-syndromal sensorineural hearing impairment.

**Denaturing high-performance liquid chromatography reliably detects ion channel mutations in Long QT syndrome.** *L. Ning<sup>1,2,3</sup>, A. Moss<sup>3</sup>, W. Zareba<sup>3</sup>, J. Robinson<sup>3</sup>, S. Rosero<sup>3</sup>, D. Ryan<sup>1</sup>, M. Qi<sup>1,2,3</sup>.* 1) Dept. of Pathology & Laboratory Medicine, University of Rochester, Rochester, NY; 2) Center for Cardiovascular Research, University of Rochester, Rochester, NY; 3) Dept. of Medicine, University of Rochester, Rochester, NY.

The hereditary long QT syndrome (LQTS) is a familial cardiac disorder that causes syncope, seizures, and sudden death from ventricular arrhythmias, specifically torsade de pointes. Multiple heterozygous mutations in several ion channel genes (KvLQT1, HERG, SCN5A, KCNE1, and KCNE2) have been shown to cause autosomal dominant LQTS. Due to their multiple loci and considerable sizes (2.8 kb of the coding sequence, represented by 16 exons for KvLQT1; 4 kb of the coding sequence, represented by 15 exons for HERG; 6.2 kb of the coding sequence, represented by 28 exons for SCN5A), mutation detection in these genes represents a challenge that is only partially met by the conventional screening method of single stranded conformational polymorphism (SSCP). The current technique is time consuming and labor intensive, requires specific expertise and is limited to a detection rate of 90%. In contrast, the recently introduced denaturing high performance liquid chromatography (dHPLC) offers a promising new method for a fast and sensitive analysis of PCR-amplified DNA fragments. To test the applicability of dHPLC in the molecular diagnosis of LQTS, we first assessed a cohort of 172 patients from our International LQTS Registry with 12 previously identified by SSCP and/or sequencing mutations (including 8 different missense mutations, 1-bp, 2-bp, 3-bp and 9-bp deletion mutations), and 2 polymorphisms in the LQTS genes. Eighty-two patients carry one or more mutation/polymorphism (s), and the remaining 90 patients are negative controls. Applying empirically determined exon-specific melting profiles, all mutations and polymorphisms were detected readily and reproducibly. One mutation undetectable by SSCP previously was also identified by dHPLC. From these findings we conclude that the dHPLC technology is a highly sensitive and efficient method for the molecular analysis of LQTS.

**Evaluation of DHPLC as a screening method for mutation detection in molecular diagnostics.** *L. Han<sup>1</sup>, A. Sekowski<sup>1</sup>, C. Wei<sup>1</sup>, Y. Qi<sup>1</sup>, T.L. Stockley<sup>1,2</sup>, P.N. Ray<sup>1,3</sup>.* 1) Paediatric Laboratory Medicine, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) Department of Laboratory Medicine and Pathobiology, University of Toronto, Ontario, Canada; 3) Department of Molecular and Medical Genetics, University of Toronto, Ontario, Canada.

The demand for efficient direct mutation detection in large genes for molecular diagnostics is rapidly increasing. Improved screening techniques to highlight regions of a gene that potentially contain mutations will be required to meet this demand. Denaturing high-pressure liquid chromatography (DHPLC) is a sensitive, automated screening method for heterozygote detection. In DHPLC DNA fragments are separated by HPLC at a temperature that results in partial denaturation of duplex DNA to distinguish heteroduplexes containing mutations from normal homoduplexes. The objective of this study is to evaluate DHPLC as a prescreening method prior to direct sequencing for molecular diagnostics, using analysis of Fabry disease, Retinoblastoma and Hunter syndrome as examples. Exons of the GLA gene (Fabry), RB-1 gene (Retinoblastoma) and IDS gene (Hunter) from patients and carriers with known mutations were analyzed with DHPLC at temperatures and buffer gradient conditions necessary for partial denaturation as predicted by WAVEMAKER® software (Transgenomics). Resulting chromatograms were analyzed and variants compared to normal control samples. Any exons that showed variants in DHPLC were sequenced in both directions to detect any sequence changes. 7 exons of GLA, 9 exons of IDS and 28 exons of RB-1 in 58 patient samples were screened by DHPLC for a total of 481 exon fragments analyzed. Of 74 fragments with known sequence changes, 72 were detected by DHPLC to give a sensitivity of 97%. 2 fragments with known sequence changes were not detected by DHPLC, to give a false negative rate of 2.7%. 23 of 407 fragments that did not have sequence changes were positive on DHPLC, to give a false positive rate of 5.6%. Therefore DHPLC has a high sensitivity and low false negative and false positive rates as indicated by the analysis of the GLA, IDS and RB-1 genes and is useful in expediting molecular diagnosis of these disorders.

**Complete Analysis of the PKD1 and PKD2 Genes Responsible for Polycystic Kidney Disease: a Clinical Testing Service.** *J.G. Jones<sup>1</sup>, J.A. Garces<sup>1</sup>, J. Wang<sup>1</sup>, J. Curran<sup>1</sup>, S. Allen<sup>1</sup>, K. Flynn<sup>1</sup>, A.N. Hennigan<sup>1</sup>, C.M. Sullivan<sup>1</sup>, N. Robichaud<sup>1</sup>, G.G. Germino<sup>2</sup>, T.J. Watnick<sup>2</sup>, S. Somlo<sup>3</sup>, W.K. Seltzer<sup>1</sup>, S. Hallam<sup>1</sup>, L. Kertiles<sup>1</sup>, C.M. Palatucci<sup>1</sup>, M.A. Boss<sup>1</sup>.* 1) Athena Diagnostics, Inc., Worcester, MA; 2) Johns Hopkins University School of Medicine, Baltimore, MD; 3) Yale School of Medicine, New Haven, CT.

Autosomal dominant polycystic kidney disease (ADPKD) is one of the leading causes of kidney failure. Mutations scattered throughout two genes, PKD1 and PKD2, cause about 95% of all ADPKD. Development of a DNA-based diagnostic tool for routine clinical use has been hindered by 3 factors: (1) 70% of the PKD1 gene is replicated as non-functional homologues with >95% sequence identity to PKD1, (2) portions of the gene are extremely GC rich, and (3) 15816 base pairs need to be analyzed. We developed a DNA testing service that comprehensively screens the coding sequence of both PKD genes to assist in the diagnosis and management of ADPKD. All 15816 bp of coding sequence as well as the invariant splice sites are evaluated. Genomic DNA extracted from whole blood is used for 8 highly specific long-range PCRs spanning the PKD1 replicated region. Primers for these LR PCRs are carefully designed to be PKD1-specific, being positioned at rare sites where the PKD1 sequence differs from the homologues. The 8 long range PCR products are diluted at least 1000 fold to minimize homologue sequence present in the residual genomic DNA, and are then used to amplify 52 nested fragments spanning the 34 PKD1 exons replicated in the homologues. These crucial steps prevent the spurious amplification of PKD1 homologues that would otherwise confound the analysis. Genomic DNA is used directly for 31 additional PCRs spanning the unique region of PKD1 and the entire PKD2 gene. All 83 PCR products are analyzed by denaturing HPLC (DHPLC) and those with variants are sequenced to identify the DNA alteration. Approximately 80 different PKD-specific variants were developed as positive controls for DHPLC analysis. Analytical sensitivity is derived from the analysis of over 120 different DNA variants scattered in all regions of the genes.

**Automated simultaneous analysis of 22 beta-globin mutations by reverse-hybridization.** *C. Oberkanins, A. Moritz, F. Kury.* ViennaLab Labordiagnostika GmbH, A-1110 Vienna, Austria.

More than 150 mutations in the human beta-globin gene have been identified to date, either causing structural abnormalities, such as hemoglobin S (sickle cell anemia), or leading to synthesis disfunctions (beta-thalasseмии). The resulting disorders are a major public health problem, in particular among Mediterraneans, Asians and Africans. Since for the large majority of affected individuals there is only supportive management but no definitive cure, emphasis is given to prevention programs based on heterozygous carrier screening and prenatal diagnosis. We have developed a reverse-hybridization assay (Beta-Globin StripAssay) for the rapid and simultaneous detection of 22 common beta-globin mutations. The test is based on a single, multiplex DNA amplification reaction and ready-to-use test strips containing oligonucleotide probes for each wild-type and mutated allele immobilized as parallel lines. It allows to discriminate between heterozygous ("minor"), compound heterozygous and homozygous ("major") individuals from one single test strip. The coverage with respect to the mutation spectrum is population-specific, reaching 80-99% in Mediterranean and Middle Eastern countries. The entire procedure from blood sampling to the identification of beta-globin mutations requires less than 6 hours, and may be carried out manually or essentially automated using existing instrumentation (e.g. TECAN profiBlot).

**Alpha thalassemia In Iran.** *M. Neishabury*<sup>1</sup>, *L. Abbasi Moheb*<sup>1</sup>, *A.A. Poorfathollah*<sup>2</sup>, *K. Kahrizi*<sup>1</sup>, *E. Keyhany*<sup>1</sup>, *W. Krugluger*<sup>3</sup>, *Ch. Oberkanins*<sup>4</sup>, *H. Najmabadi*<sup>1</sup>. 1) Genetics Research Center, University of Social Welfare and Rehabilitation Sciences, Tehran, Iran; 2) Blood Transfusion Services, Tehran, Iran; 3) Institute of Clinical Chemistry, Rodlfstiftung Hospital, Vienna, Austria; 4) Vienna lab, Labordiagnostka, Vienna, Austria.

The most common mutations of alpha thalassemia are the deletion mutations including single or double gene deletions. -a3.7 and -a4.2 are the most common single gene deletions. -a3.7 has a world wide distribution among all racial groups and -a4.2 is less common being most prevalent in South East Asia and Saudi Arabia. In Iran, a large number of patients with reduced MCV and MCH, normal HbA2 and F levels and normal iron level are being referred to molecular biology clinics all over the country as suspicious cases of alpha thalassemia. This causes a concern to determine the common alpha thalassemia mutations for Iranian population. This will greatly help us to do carrier identification and prenatal diagnosis for prevention of the deleterious forms of alpha thalassemia such as Hb H and Hb Barths's. In addition in a country like Iran with a considerably high prevalence of beta thalassemia, co inheritance of alpha and beta thalassemia is expected to occur in high frequency. In this study, the frequency of the two most common alpha thalassemia mutations in the region, -a3.7 and -a4.2 were determined in 60 alpha thalassemia suspicious cases. 33 % of the alpha thalassemia mutations in the studied population was -a3.7 while no -a4.2 deletion was identified.

Program Nr: 1515 from the 2001 ASHG Annual Meeting

**An automated multiplex detection system for detection of haemoglobinopathy mutations.** *Y.T. Liu, D.J. Weatherall, J.B. Clegg.* MRC Molecular Haematology Unit, Weatherall Institute of Molecular Medicine, University of Oxford, U.K.

The inherited disorders of haemoglobin - haemoglobinopathies are some of the most common single-gene disorders in humans. The World Health Organization has estimated that approximately 7 per cent of the world's population are carriers for these disorders, which include sickle cell anaemia and the thalassaemias.

Although common haemoglobinopathy mutations can now be routinely detected by PCR-based methods, like gap PCR, ARMS and reverse dot blotting, none of these methods easily lend themselves to an automated multiplexing approach. A method, which is based on the oligonucleotide ligation assay (OLA), that allows multiplex detection of non-deletion and deletional  $\alpha$  thalassaemia variants as well as  $\beta$  thalassaemia point mutations in a single reaction, will be presented. The method uses currently available automated DNA sequencing instrumentation and software. We envisage that it can form the basis of a fully comprehensive automated system which will be capable of detecting more than 99% of the  $\alpha$  and  $\beta$  globin gene mutations that underlie the major haemoglobinopathies.

**High-Through-Put SNP Detection and Haplotype Assessment in Human Melanoma Inhibitory Activity like Gene**

**(MIAL).** *P. Mouritzen<sup>1</sup>, A.T. Nielsen<sup>1</sup>, Y. Choleva<sup>1</sup>, L. Kongsbak<sup>1</sup>, N.D. Rendtorff<sup>2</sup>, N. Tommerup<sup>2</sup>, H. Vissing<sup>1</sup>.* 1) Euray, Exiqon A/S, Bygstubben 9, 2950 Vedbaek, Denmark; 2) Dept. of Medical Genetics, Inst. of Medical Biochemistry and Genetics, the Panum Inst., University of Copenhagen, 2200 Copenhagen N, Denmark.

The Human Melanoma Inhibitory Activity like Gene (MIAL) encodes a small extracellular protein that is preferentially expressed in the inner ear in humans. A frequent polymorphism exists in the translation initiation codon of the MIAL gene (+2 SNP), which abolishes the translation of the gene into protein. The restricted expression pattern and the inactivating polymorphism suggest that MIAL may contribute to inner-ear dysfunction in humans.

We have developed a high-through-put SNP detection technology, which potentially may genotype more than 35.000 patients for two SNPs in a single microarray experiment. Results will be presented using the +2 SNP and another upstream SNP (-31 SNP) of the MIAL gene as an example. MIAL amplicons containing the two SNPs are produced from each patient DNA sample with high fidelity PCR using LNA (Locked Nucleic Acid) containing primers. The amplicons are spotted on plastic slides followed by hybridization with four LNA containing probes each labeled with a different fluorophore. The LNA oligonucleotide probes complement the four possible sequences containing the two SNPs. A further development of the techniques allow us to perform haplotyping on chromosomal DNA. With the two MIAL SNPs we demonstrate haplotyping using a combination of allele specific PCR and hybridization of the resulting amplicons to arrayed capture probes on slides. Again the fidelity of the system relies on LNA in the allele specific primers and in the capture probes. The allele specific primers discriminate between the -31 SNP genotypes and capture probes discriminate between the +2 SNP genotypes. Hybridization of the different allele PCR amplicons are distinguished from each other by labeling the two allele specific primers with different fluorophores. The developed SNP detection technologies provide a highly reliable and cost-effective approach for SNP genotyping in large populations.

**Mutation analysis on Korean patients with tuberous sclerosis with the method of whole *TSC1* and *TSC2* cDNA sequencing.** *K.M. Hong*<sup>1</sup>, *Y.S. Kim*<sup>3</sup>, *Y.J. Woo*<sup>4</sup>, *W.Y. Jung*<sup>5</sup>, *C.H. Shin*<sup>2</sup>, *Y.B. Choi*<sup>2</sup>, *M.K. Paik*<sup>2</sup>. 1) Genetics Laboratory, Oregon Health Sciences University, Portland, OR 97201-3098; 2) Department of Biochemistry, Wonkwang University College of Medicine, Iksan, 570-749, Korea; 3) Department of Neurology, Wonkwang University College of Medicine, Iksan, 570-749, Korea; 4) Department of Pediatrics, Chonnam University College of Medicine, Kwang-Ju, 510-190, Korea; 5) Department of Neurology, Chosun University College of Medicine, Kwang-Ju, 501-759, Korea.

Tuberous sclerosis is an autosomal dominant neurocutaneous disorder with the prevalence of about 1:6,000. It is characterized by hamartomas in the skin, central nervous system, and the patients have epilepsy, mental retardation, facial angiofibromas, hypomelanotic patches and renal angiomyolipomas. It is a genetic disorder, but about 60% of the patients are sporadic form, apparently representing new mutations. This fact, along with the grave symptoms necessitates simpler screening methods. The disease is caused by the mutations in either of two large genes, *TSC1* and *TSC2*. These mutations are not clustered at some specific sites but are scattered over the entire gene. In this study, we have made a molecular diagnosis of tuberous sclerosis in five Korean patients by whole *TSC1* and *TSC2* cDNA sequencing. In each three patients, we found previously described mutations (R245X in *TSC1*, R611W and an exon 26 deletion in *TSC2*). In each of the other two patients, we found a 3-bp deletion in *TSC2* that might be a mutation. Additional studies will be performed to confirm the significance of these initial findings.

**A DHPLC protocol for detecting RET proto-oncogene mutations in MEN2 patients and medullary thyroid carcinoma.**

*I. Torrente<sup>1</sup>, A. De Luca<sup>1</sup>, C. Conte<sup>2</sup>, M. Mangino<sup>1</sup>, E. Chiefari<sup>3</sup>, F. Arturi<sup>3</sup>, S. Filetti<sup>3,4</sup>, G. Novelli<sup>2</sup>, B. Dallapiccola<sup>1,5</sup>.* 1) CSS-Mendel Institute, Rome, Italy; 2) Dept. of Biopathology and Imaging Diagnostic, University of Rome "Tor Vergata", Italy; 3) Dept. of Experimental and Clinical Medicine, University of Catanzaro, Italy; 4) Dept. of Clinical Science, University of Rome La Sapienza, Italy; 5) Dept. of Experimental Medicine and Pathology, University of Rome La Sapienza, Italy.

Germline activating mutations of the RET proto-oncogene cause three different dominantly inherited cancer syndromes, including multiple endocrine neoplasia type 2A (MEN 2A), type 2B (MEN 2B), and familial medullary thyroid carcinoma (FMTC). Mutations, involving the somatic cell lineage, are found in about 30% of sporadic medullary thyroid carcinomas (MTC). Early detection of mutations is mandatory for genetic counselling and risk assessment in family members allowing presymptomatic testing and improvement of the disease management. The majority of the activating RET mutations affect exons 10, 11, 13, 14, 15 and 16 and are currently detected by SSCP and restriction enzyme analysis. In order to improve sensitivity, time and cost of the RET mutation analysis, we have developed a Denaturing High Performance Chromatography (DHPLC)-based protocol. In this system mutations can be determined on the basis of the melting behaviour of heteroduplexes, which elute from the column by a combination of temperature and acetonitrile gradient. We performed DHPLC in 141 MTC patients with previously characterized mutations and 35 relatives. Heteroduplex peaks were detected for each mutation tested which produced a distinct and highly reproducible DHPLC elution profile. These results indicated that DHPLC methodology: a) displays a high level of sensitivity, approaching 100% for mutations in the RET proto-oncogene; b) is suitable for rapid genetic testing of members of the MEN2 affected families; c) provides a relatively simple and accurate screening technique by exhibiting advantages over conventional mutation methods, including semi-automated analysis of 96 PCR samples in less than 12 hours and low cost .

**Six novel point mutations in the Dystrophin gene identified in Brazilian Duchenne patients.** *D.N.F. Vagenas<sup>1,2</sup>, A. Cerqueira<sup>1</sup>, A. Torres<sup>1</sup>, R. Pavanello<sup>1</sup>, M.R. Passos-Bueno<sup>1</sup>, M. Zatz<sup>1</sup>.* 1) Centro de Estudo Genoma Humano, Universidade de So Paulo, So Paulo, S.P, Brazil; 2) Centro em Interunidades em Biotecnologia, Universidade de So Paulo, S.P. Brazil.

Duchenne (DMD) and Becker (BMD) type muscular dystrophies are allelic X-linked conditions caused by mutations in the gene encoding dystrophin. This gene contains 79 exons, which are distributed in approximately 2,400 Kb. The phenotype is caused in about 60% of the cases by deletions, 5 - 6% by duplications, while the remaining cases are due to point mutations or small deletions or rearrangements. We have ascertained so far 1010 families with DMD patients in our center. Among them 632 had deletions in the dystrophin gene. We are currently trying to identify the mutations in the non-deleted cases through SSCP, PTT (Protein Truncation Test) and sequencing of abnormal fragments. For PTT analysis, the dystrophin gene was divided in 10 fragments, each one with 8 exons, encompassing the 79 exons. In 99 patients, about 4 fragments were randomly analyzed leading to the identification of 10 mutations. Among these, six are novel mutations: one deletion of exon 38, three frameshifting involving the exons: 5 (494-497 delAGTA); 16 (2067 - 2068 del TG and 2080 - 2083 del ACAA); and two nonsense in the exons 17 (2345 C@T; Q 713 X) and 45 (6785 T@C; Q 2193 X). We are also assessing the intellectual capacity in our patients in order to verify what mutations/deletions are more commonly associated with mental impairment. CEPID-FAPESP, PRONEX, CNPq, IAEA.

**One step and reliable full HFE genotyping using DHPLC methodology.** *S. Pissard, L.T.A. Huynh, J. Martin, M. Goossens.* lab biochemistry and genetics, hop henri Mondor, Creteil, France.

In Caucasian populations, genetic hemochromatosis is a frequent autosomal recessive disorder which results in an increased absorption of dietary iron. Iron over storage leads to severe disorders which may result in serious complications and life expectancy shortening. The product of the HFE gene (chromosome 6) is one regulator of iron uptake through interaction with the transferrin receptor. Two mutations, C282Y (exon 4) and H63D (exon2) are strongly associated with the disease. C282Y homozygous or C282Y / H63D compound heterozygous genotypes are now stated to have a diagnostic value in genetic hemochromatosis . Therefor, in addition to biochemical determination of serum iron, iron storage (ferritin) and transferrin saturation, HFE genotyping is one step of the hemochromatosis diagnostic. In most laboratories, genotyping is done by means of conventional PCR restriction assays which are very sensitive and specific but time consuming and finally, costly through consumption of reagents and working time. DHPLC is a new powerful and automated method which is now a widely used tool for SNP detection. However, a main limitation of this method is that in some instance, it would not discriminate between homozygous wild type and homozygous mutant DNA. This makes its use difficult in genotyping for recessive disease. To override this limitation, we have designed a simple multiplex ARMS PCR which allowed to detect simultaneously these two mutations. Crude, unlabelled PCR products are run in non denaturing conditions (45C) giving unambiguous chromatogram patterns for wild type, mutant and heterozygous alleles. Primers were designed to bracket regions in HFE exon2 and exons 4 where other rare HFE mutations linked to hemochromatosis have been described, as the S65C mutation in exon 2. Running the same PCR products in denaturing conditions (58C) allows the diagnosis of these rare mutations even if the chromatogram pattern becomes more complex. This strategy greatly improve the usefulness of DHPLC making its advantages (full automation, low cost unlabelled PCR, fast method) available for genotyping in genetic diagnostic laboratories.

**Resolution of equivocal molecular genetic test results in the diagnosis of Facioscapulohumeral Muscular Dystrophy (FSHD).** *W.K. Seltzer<sup>1</sup>, K. Felice<sup>2</sup>, J. Durocher<sup>1</sup>, A.R. Yesley<sup>1</sup>, M.A. Boss<sup>1</sup>, S.E. Hallam<sup>1</sup>.* 1) Athena Diagnostics, Inc, Worcester, MA; 2) University of Connecticut Health Center, Farmington, CT.

Ninety to 95% of Facioscapulohumeral muscular dystrophy (FSHD) cases are associated with a deletion within a repeat array. Athena Diagnostics, Inc. performs FSHD analysis by EcoRI and EcoRI/BlnI restriction endonuclease digestions followed by Pulsed-Field Gel Electrophoresis to separate and resolve the 8 to > 48 kb sized DNA fragments. Southern analysis is then performed using probe, p13E-11, which hybridizes to repeat arrays at both 4q35 and 10q26. BlnI specifically digests the chromosome 10 repeat array to small fragments allowing discrimination between chromosome 10 and chromosome 4 arrays. Twenty percent of the general population carry a benign translocation resulting in either three chromosome 4q35 repeat arrays and a single 10q26 array, or alternatively, three 10q26 arrays and a single 4q35 array. This complicates result interpretation since it is the location of the repeat array deletion, and not its chromosomal origin, which determines the pathogenicity of the deletion. The presence of these translocations can potentially lead to false positive and false negative test results. We reviewed 275 cases of which 49 (18%) yielded findings that could not be unequivocally interpreted. In order to achieve a better understanding of the remaining equivocal results, we carried out XapI analyses which specifically digest the chromosome 4 repeat array. This provided significant utility in interpretation of these previously equivocal results.

**Frequency of Y-chromosome microdeletion in a non-selected population.** *G. Massazza, M. Poma, M. Iascone, U. Giussani, D. Chinaglia, A. Parma.* Clinical Pathology, Ospedali Riuniti di Bergamo, Bergamo, Italy.

Recent studies have indicated that microdeletions of AZF region in Yq could affect the normal expression of spermatogenesis factors. Every year we perform 1750 semen analysis most of which concerning men with fertility impairment. We decided to combine standard morphological analysis with PCR screening of microdeletions of the Y to assess if a sperm count  $< 5 \times 10^6$  spermatozoa /ml could be a parameter sufficient to justify the molecular analysis. We also wanted to correlate the clinical phenotype of infertile men with specific Yq-microdeletions. 2537 semen were analysed according to WHO guidelines (1999) indicating 90 azoospermic, 425 oligozoospermic and 2022 normozoospermic subjects. The patients mean age was 33 years (range 15-62). Genomic DNA was extracted from 193 azo-oligozoospermic and 15 normozoospermic semen samples and from peripheral blood lymphocytes (PBL) of 36 men enrolled in the protocol for assisted reproduction (mean age: 33yr range 25-38). Performing 2 multiplex-PCR in semen specimens we found microdeletions in 10,6% of azoospermic subjects and in 3,4% oligozoospermic men. An azoospermic patient showed deletion of AZFc region. Histological examination on testicular biopsy diagnosed a Dysgenetic Sertoli-cell only syndrome (SCOS). Another azoospermic patients had all three AZF loci missing. The following cytogenetic analysis revealed the presence of an isodicentric Y chromosome and the karyotype resulted 46,X, ish idic (y)(q11)(DYZ3++,DYZ1-). 34/36 azo-oligozoospermic men enrolled to assisted reproduction protocol had 46,XY karyotype, one was 46,XX male and one had a 46, XY (t13:14). Molecular analysis of specific Yq-STS on PBL revealed 4/5 oligozoospermic men deleted in AZFb regions. Our findings indicate that cytogenetic analysis and molecular screening of Y-chromosome microdeletions are necessary tools helping the diagnostic process in male infertility and they should be advise especially in those patients with sperm concentration  $< 5 \times 10^6$ /ml.

**Cytochrome P450 2D6 isoenzyme genotyping using derivative melting curve analysis on the LightCycler. A.**

*Millson<sup>1</sup>, E.L. Frank<sup>1, 2</sup>, E. Lyon<sup>1, 2</sup>.* 1) ARUP Laboratories, Salt Lake City, UT; 2) Department of pathology, University of Utah.

Genetic polymorphism of the cytochrome P450 superfamily results in phenotypic variation in drug metabolism that can affect therapeutic responses. CYP2D6 is an isoenzyme in this family that catalyzes the oxidative biotransformation of many commonly prescribed drugs including selective serotonin reuptake inhibitors, tricyclic antidepressants, antiarrhythmics,  $\beta$ -receptor blockers and neuroleptics. CYP2D6 polymorphism results in several phenotypes, including poor (PM), extensive (EM or wild type) and ultra (UM) metabolizers. Two variant alleles of the CYP2D6 gene, CYP2D6\*3 (A2637 deletion) and CYP2D6\*4 (splice site mutation G1934A) account for 70% of poor drug metabolizers. A deletion of the gene, CYP2D6\*5(del), also results in a poor metabolizer phenotype and occurs in approximately 2% of the Caucasian population. These polymorphisms are considered autosomal recessive inheritance.

Detection of the \*3, \*4, \*5 alleles has been developed using rapid PCR and melting curve analysis on the LightCycler®. Primer sets were designed to amplify two specific regions of the gene. The temperature at which hybridization probes dissociate from the template distinguish the wild type and polymorphic alleles. Comparison of derivative melting curve areas of CYP2D6 with the area of an internally amplified reference gene,  $\beta$ -globin, characterizes the gene. The normalized area ratio of  $\beta$ -globin to CYP2D6 for a normal gene dose ranges from 0.76-1.24 with a 99% confidence interval. Gene deletions have ratios >1.5. Allele frequencies determined using this method are 2.6% for CYP2D6\*3 and 22.8% for CYP2D6\*4 (n=114). Allele frequencies for CYP2D6\*5(del) are 0.9%. Gene dose analysis by derivative melting curves, represented by the CYP2D6\*5 system, is a methodology that can be widely applied to detect chromosomal duplications and deletions.

**Prenatally diagnosed neural tube defect rates before and after food fortification in California.** *L. Feuchtbaum, R. Currier, M. Kharrazi, F. Lorey, G. Cunningham.* Genetic Disease Branch, California Dept Health Services, Berkeley, CA.

Since 1992 when the Public Health Service announced that neural tube defects (NTDs) could be reduced by 50% if all women of reproductive age consume 400 micrograms of folic acid daily, there has been a public policy debate about how to achieve this goal. In 1996, the FDA mandated that by January 1, 1998 all cereals, breads, and other foods labeled as enriched be fortified with 140 micrograms of folic acid per 100 grams of cereal. In California, the impact of food fortification on NTD prevalence has yet to be examined. This study presents changes in the prevalence of newly diagnosed, prenatally detected NTDs, for the three-year period before and after the food fortification deadline.

The Genetic Disease Branch runs the California Expanded AFP Screening program to screen for NTDs and selected chromosome abnormalities in the 2nd trimester of pregnancy. The program diagnoses about 80% of all NTDs statewide. Women with screen-positive test results are referred for follow-up at a state-approved Prenatal Diagnosis Center that reports counts of diagnosed cases quarterly. This study presents quarterly NTD diagnosis rates (per 1000 referred women) from 1995 through 2001.

To date, 1,316 NTDs were diagnosed among 120,420 referred women including 680 anencephaly, 452 spina bifida, and 99 encephalocele cases. Overall, Hispanics had the highest anencephaly rate and Whites had the highest spina bifida rate. The overall NTD rate for the period after the fortification deadline declined by 24% ( $p < 0.01$ ). However, statistically significant declines were only observed among Whites. The anencephaly rate declined about 28% ( $p < 0.01$ ) and statistically significant declines were observed among Whites and Hispanics. The spina bifida rate declined about 12% ( $p = 0.17$ ) and the encephalocele rate declined about 11% ( $p = 0.55$ ). The regression line for NTD rates before the fortification deadline was much steeper than the line after the deadline indicating that rates appear to have leveled off in the past three years. The implications of these and other findings are discussed.

**Cost Effectiveness of tandem mass spectrometry (MS/MS) for neonatal screening: Medium chain acyl-CoA dehydrogenase (MCAD) as a model.** *D.N. Finegold<sup>1</sup>, E.W. Naylor<sup>2</sup>, D.H. Chace<sup>2</sup>, M. Kamlet<sup>3</sup>*. 1) Human Genetics, University of Pittsburgh, Pittsburgh, PA; 2) Neo Gen Screening, Inc, Pittsburgh, PA; 3) H. John Heinz III School of Public Policy and Management, Carnegie-Mellon University, Pittsburgh, PA.

Newborn screening is an accepted component of preventative public health measures. The acceptance of a test for newborn screening is dependent on incidence of disease, simplicity of testing, effective treatment for the disease to be tested, and considerations of economic costs. Recent technological advances such as MS/MS have provided alternative methods besides bacterial inhibition assays (BIA) to screen newborns for PKU and other metabolic diseases. MS/MS is able to rapidly detect over twenty inborn errors of metabolism in addition to PKU with little incremental cost. We performed a cost effectiveness analysis (CEA) of newborn screening assuming MS/MS as a screen for both PKU and MCAD, compared to using BIA to screen for PKU. Initial studies showed BIA for PKU alone, excluding the costs of follow-up for false positive tests, to be more cost effective than MS/MS for PKU. We then modeled MS/MS screening for MCAD since BIA testing will not detect MCAD. We included estimates of deaths caused by MCAD, children damaged by metabolic episodes caused by MCAD, children surviving to adulthood without an episode caused by MCAD, the estimated incidence of MCAD, costs of screening, as well as other factors. Based on dollars-per-quality-adjusted-life-years (\$/QALY), MS/MS is a cost effective screening tool to detect newborns at risk with MCAD. Since the added costs of screening for both MCAD and PKU are negligible, we concluded that MS/MS is a cost effective screening tool compared to BIA for PKU, and not screening for MCAD. MS/MS screening is able to detect many more disorders than MCAD and PKU. Further studies are ongoing to determine the overall cost effectiveness by \$/QUALY of MS/MS as a tool in newborn screening including all diseases detectable by MS/MS as well as cost of follow-up.

**Consequences for health care facilities if guidelines for healthy women with breast cancer in family history are applied.** *C.J. Asperen van*<sup>1</sup>, *R.A.E.M. Tollenaar*<sup>2</sup>, *E.M.M. Krol-Warmerdam*<sup>1</sup>, *F. Erp van*<sup>5</sup>, *C. Seynaeve*<sup>5</sup>, *P. Devilee*<sup>1,3</sup>, *C.J. Cornelisse*<sup>3</sup>, *C.T.M. Brekelmans*<sup>5</sup>, *J.G.M. Klijn*<sup>5</sup>, *G.H. Bock de*<sup>4</sup>. 1) Dept. Human and Clinical Genetics, Leiden University Medical Center Leiden, The Netherlands; 2) Dept. Surgery,; 3) Dept. Pathology,; 4) Dept. Medical Decision Making,; 5) Dept. Medical Oncology, Daniel den Hoed Cancer Center, University Hospital Rotterdam.

**Background** Many studies found an increased risk to develop breast cancer for first and second-degree relatives of breast cancer patients. This study analyzed the consequences for health care facilities if guidelines for advising healthy women with breast cancer in family history are applied.

**Methods** In a hospital based cohort of recently diagnosed breast cancer patients, 891 family histories were analyzed. These were obtained by interview and questionnaires and contained information about family size, first and second-degree relatives, age and cancer diagnosis. The schemes of the Dutch and British guidelines were applied on the family histories, by using SPSS 10.

**Results** In 891 families 3303 female first-degree relatives were reported 2021 (62%) were alive, above the age of 24, and unknown in a genetic department. Of this last group 672 (33%) women were between 35 and 50 years. When applying the guidelines for referrals, it was calculated that for each case of breast cancer 0.3 first degree female relative would be offered a consultation or a referral to a clinical genetic service. Likewise, per breast cancer case, 0.3 first-degree female relative will be offered a current advice for breast surveillance according to the Dutch guideline and 0.1 according to the British guideline.

**Conclusion** If available guidelines for healthy relatives of breast cancer patients are fully applied, this will lead to a sharp increase in the use of health care facilities. Scientific advances in breast cancer genetics combined with the growing public interest in breast cancer prevention could meet economic limitations. Further research is needed to focus on the cost-effectiveness of these guidelines.

**An individual and population-based framework for improving the public's health and wellbeing--with special emphasis on genetics and genetics-related issues.** *R.M. Fineman<sup>1</sup>, M. Puryear<sup>2</sup>, C. Crain<sup>3</sup>, P. Kyler<sup>2</sup>, J. Massad<sup>3</sup>, B. Oles<sup>3</sup>, C. Roeber<sup>3</sup>, N. Tashima<sup>3</sup>.* 1) Department of Health Services, UW School of Public Health, Seattle, WA; 2) GSB,MCHB,HRSA,DHHS,Rockville, MD; 3) LTG Associates,Takoma Park, MD.

Using a medical model in 1994, Evans and Stoddart proposed a relational framework to describe "the diverse determinants of health, as well as to permit a definition of health broad enough to encompass the dimensions that people--providers of care, policymakers, and particularly ordinary individuals--feel to be important." We have built upon this framework to create an updated version of this model that better defines and describes, from a public health (PH) genetics perspective, why some people enjoy good health and wellbeing, while others do not. Our model includes multiple health and health care determinants (e.g., the interaction of genetic, environmental and social risk and protective factors, access to care, etc.); the MCHB/HRSA/DHHS "pyramid" that includes direct patient services, enabling services, population-based services, and infrastructure/capacity-building services; governmental investment opportunities that influence health, health care, and wellbeing; and informed decision-making by individuals, families, and communities. Our model also connects PH genetics theory to practice, and it is analytical enough (e.g., goals, objectives, performance measures, guidelines, etc.) to measure health, wellbeing, and health promotion and disease prevention activities well into the 21st century--especially as they pertain to genetics and genetics-related issues.

**Results of a national survey re: retention and maintenance of clinical genetics records.** *W.S. Meschino.* Dept Genetics, North York General Hosp, Toronto, ON., Canada.

Issues related to the retention and maintenance of clinical genetics records may differ from those of the general health record because of the very nature of genetic information. Results of genetics consultations and tests relate not just to individuals, but to families, and have potential significance for future generations. Most genetics departments across Canada have been in existence less than 30 years. Over time, constraints of space and resources to maintain records may increasingly influence genetics departments to consider whether records should be destroyed as per provincial regulations for hospital/medical records, stored elsewhere or integrated into the main health record of the institution. A review of the relevant medical literature and provincial regulations in several provinces was conducted, and 21 genetic centres across Canada were surveyed. 18/21 centres returned completed questionnaires. Almost all centres (17/18) routinely maintain clinical genetics records indefinitely and believe that this practice should continue, assuming adequate space and resources. Some centres (4/18) destroy a portion of the record after the regulation time period (usually routine prenatal cases) or maintain only part of the chart (3/17) for longer than required. In most centres, clinical genetics records are maintained separately from the general health record, but in 2/17 centres, at least a portion of the genetics records (e.g. consultation) is copied to the general health record of the institution. The vast majority (17/18) believe that clinical genetics records should be maintained separately from the general health record for the following reasons: 1. To maintain confidentiality especially considering the sensitive nature of the information. 2. Most genetics records represent families, not just individuals, and detailed family information/records are not appropriate as part of an individual's health record. However, genetics units should be responsible for informing their institution's health records department of the existence of a patient record in genetics. Electronic data storage, microfilm etc. may be required to address ongoing space needs.

**Consumer interest in genetic testing for breast cancer susceptibility: Personal decision-making model. E.L.**

*Harris<sup>1</sup>, B. Stewart<sup>2</sup>, B. Valanis<sup>1</sup>, N. Vuckovic<sup>1</sup>.* 1) Kaiser Permanente Center Health Research, Portland, OR; 2) Oregon Health Sciences University, Portland, OR.

Genetic testing for breast cancer risk will soon extend beyond rare, high-risk genes, such as deleterious mutations in BRCA1/BRCA2. Also, there is evidence that risks associated with such mutations may be lower than estimated from high-risk families. Anticipating new knowledge about genetic susceptibility to breast cancer, we assessed consumer opinions about genetic testing for breast cancer risk from a broad perspective (rare, high-risk genes; more common, moderate-risk genes). A survey (Genetic Testing and Breast Cancer: Your Opinions) was completed by 303 adult female KP Northwest health plan members. Survey content was based on a personal decision-making model of genetic testing. Respondents were predominantly white non-Hispanic (77%); median age was 59 years. Factor analyses showed several factors for personal impact of testing, several related to breast cancer screening, and self risk perception. Univariate analyses of factor scores and interest in genetic testing suggest that interest is highly related to intention to change screening and prevention behaviors, greater personal control with knowledge of test results, importance of breast cancer screening, and open access to testing. Interest was not related to self risk perception, intended family disclosure or concerns, worry about test results, current breast cancer screening, or general mental health. Previously, we reported that gene and test characteristics were related to interest. Results from multivariate analyses, integrating information from all aspects of the personal model, will be available for presentation. Consumer preferences should be considered by policymakers when recommending strategies for genetic testing.

**Newborn Screening by Tandem Mass Spectrometry for Medium Chain Acyl-CoA Dehydrogenase Deficiency: Is**

**it Cost Effective?** *C.P. Venditti<sup>1</sup>, L.N. Venditti<sup>3</sup>, C.A. Stanley<sup>2</sup>, G.T. Berry<sup>1,2</sup>, P. Kaplan<sup>1</sup>, E.M. Kaye<sup>1</sup>, H. Glick<sup>3</sup>.* 1)

Division of Human Genetics and Molecular Biology and; 2) Department of Endocrinology, Childrens Hospital of Philadelphia,; 3) Department of General Internal Medicine, University of Pennsylvania School of Medicine, Philadelphia, PA.

Tandem mass spectrometry (MS/MS) has been advanced as a new technology that can be used to effectively screen for several classes of inborn errors of metabolism that are not detected by conventional newborn screening modalities. The cost-effectiveness of using this method has not been fully explored. To begin to address this problem, we have employed decision-analytic modeling to examine whether newborn screening by MS/MS for a relatively common and treatable fatty acid oxidation disorder, medium chain acyl-CoA dehydrogenase deficiency (MCAD), is cost-effective. We developed a computer model to evaluate the incremental cost per quality-adjusted life year (QALY) saved of newborn screening for MCAD compared to not screening. A hypothetical cohort of neonates was followed from birth using a Markov simulation model. In this model, subjects made transitions among a set of health states that reflected clinical status, morbidity, and cost. Outcomes were estimated for 3 time horizons, 10, 20 and 70 years. Transition probabilities were derived from empiric clinical data. Probabilities of clinical events and average Markov state costs were derived from chart reviews of a thirty-two patient cohort treated over the past thirty years, patient-family interviews, national cost surveys, and clinical experience with MCAD patient management. Estimates of the expected net changes in costs and life expectancy for MCAD screening were used to compute the incremental cost-effectiveness ratio (ICER) as compared to not screening. The 20-year incremental cost-effectiveness ratio (ICER) of newborn screening for MCAD is within the acceptable range of <\$50,000 US dollars per quality-adjusted life year gained; even with an overestimated screening cost and simulating only 10 years of life, the ICER is in the \$50,000/QALY zone. These results argue for the widespread implementation of newborn screening for MCAD.

**Detection of Rare FGFR3 alleles in sperm samples using the Invader Operating System.** ©. *M.W. Baker<sup>1</sup>, D. Lind<sup>2</sup>, D. Cox<sup>2</sup>, L. Wang<sup>1</sup>, B.P. Neri<sup>1</sup>, M. de Arruda<sup>1</sup>*. 1) Third Wave Technologies, Madison, WI; 2) Dept. of Genetics, Stanford University School of Medicine, Stanford, CA.

Mutations in the Fibroblast Growth Factor Receptor 3 (FGFR3) gene can cause Achondroplasia, the most frequent form of short-limb dwarfism. Achondroplasia is an autosomal dominant disorder; a majority of cases are sporadic, the result of a de novo mutation. It is estimated that more than 95% of the cases of Achondroplasia are associated with a G-to-A transition at nucleotide 1138 of the FGFR3 gene, while the second most common mutation is a G-to-C transversion at the same position. Based on previously published studies detailing prevalence (birth rate), it is predicted that the FGFR3 mutations occur at an estimated rate between 1.72 and  $5.57 \times 10^{-5}$  per gamete per generation.

Here we report the use of the Invader Assay to detect the presence of mutant G1138A and G1138C FGFR3 alleles in human sperm samples. The Invader Operation System is an isothermal, homogenous genotyping assay that uses fluorescence energy transfer (FRET) as a detection method. The unique specificity of the Invader Assay permits discrimination of mutant and wild type alleles at a resolution of at least 1:1,000.

We have used pools of about 1,000 sperm to amplify a region of 0.4 kb of the FGFR3 gene, which contained the 1138 locus. The amplification product was then used in the Invader Assay. Preliminary results from approximately 120 sperm pools, have detected the presence of mutant G/A allele in 5 pools and the presence of the G/C mutant allele in only of them. Combined together, the occurring frequency of the two mutants is very close to the birth rate of Achondroplasia in the general population. These results indicate that the Invader assay offers a simple and highly efficient method for screening sporadic mutations in a background of wild type sequence.

**Evaluation of the probe specificity used in INNO-LiPA CFTR12: No false positives with polymorphisms I506V, I507V, F508C, and I506M.** *P. Hendrix, C. Van Loon, I. De Canck.* Innogenetics, Gent, Belgium.

The INNO-LiPA CFTR12 and INNO-LiPA CFTR17 + Tn respectively identify 12 and 17 specific CF-related mutations and their wild-type sequences, as well as CBAVD-related polymorphism Tn in intron 8. The technology used is a simple reverse hybridization of an amplified product on a nitrocellulose strip carrying specific oligonucleotide probes as parallel lines. The amplified product is the result of an optimized multiplex amplification. Hybridization and stringent wash occur at the same temperature and can be performed either manually in a water bath or using the Auto-LiPA. Both assays were successfully validated in a European multicenter study and are suited for DNA extracted from whole blood and buccal brushes. Also, DNA extracted from amniotic fluid, chorionic villi, and dried blood spots has been shown to be compatible with the assays in exploratory evaluations. Individuals, homozygous for a mutant or a wild-type allele will only hybridize with the corresponding probe, whereas individuals heterozygous for a particular mutation will hybridize with both the mutant and wild-type probe for this mutation. The ACMG recommendations for General Population Carrier screening for CF emphasize the risk of unexpected homozygosity for DF508 and/or DI507, due to benign variants at codons 506, 507, and 508 in the CFTR gene. Therefore, we undertook to test the INNO-LiPA CFTR assay specificity for samples containing either the I506V, I507V, F508C, and even the I506M polymorphism. These sequence variants were introduced by mutagenesis and controlled by sequence analysis. In addition, three clinical samples with proven presence of F508C and linked with the S1251N mutation were included. None of the samples tested showed any false positive reactions with the mutant probe for DF508 and/or for DI507; in all cases, the wild-type probe for DF508/DI507 remained positive, allowing a correct clinical interpretation.

**Evaluation of a supratypic HLA-genetic marker for susceptibility to chronic beryllium disease: racial variation has no significant impact for pre-employment screening.** A. Weston, J. Ensey, K. Kreiss, C. Keshava, E. McCanlies. National Institute for Occupational Safety and Health, CDC, Morgantown, WV.

Codon 69 of *HLA-DPBI* is tri-allelic (AAG - lysine [K], GAG - glutamic acid [E] and AGG - arginine [R]), where the relative frequencies are K>E>R. The lysine allele is found in 54 of 88 known variants of this gene, glutamic acid is found in 29 and arginine in 5. Three published studies report an association of the supratypic marker *HLA-DPB1E69* with susceptibility to disease following occupational exposure to beryllium, where odds ratios range between 12 and 76 (95% CIs range = 2-322). Consequently, testing for *HLA-DPB1E69* is currently being considered as a pre-employment screening tool. This study investigates the prudence of this course of action in light of calculations of the positive predictive value, sensitivity and specificity of this supratypic marker in four racial populations. Polymerase chain reaction and restriction analyses were used to determine *HLA-DPB1E69* population frequencies. Calculation of positive predictive values assumed a disease frequency among beryllium workers of 5% for the workforce in general. Selection of an odds ratio for disease risk of 35 for the HLA marker was based on analysis of data previously reported in the literature by others. Allelic/carrier frequencies were found to be 0.21/0.33, 0.24/0.40, 0.27/0.47 and 0.38/0.59 for Caucasians, African-Americans, Latinas and Chinese respectively. Ranges of positive predictive values for a genetic test based on *HLA-DPB1E69* in these populations were calculated to be 8.3 - 14.3% for carriers with an assumed disease prevalence of 5%. These estimates suggest that using *HLA-DPB1E69* genotyping for general pre-employment screening in the beryllium industry has a low positive predictive value, regardless of the fact that there are significant differences in carrier frequencies among racial groups.

**Screening for the alpha 1-antitrypsin deficiency (a1ATD) mutation PiZ in Israeli Jewish populations. An apparent another frequent Ashkenazi-Jewish disorder.** . V. Adir, E. Golinker, E. Sachak, T. Falik-Zaccari, Z. Borochowitz. The Simon Winter Institute for Human Genetics, Bnai-Zion Medical Center, Technion-Rappaport Faculty of Medicine, Haifa, Israel.

a1ATD is a severe incurable hereditary autosomal codominant disorder. The homozygous PiZZ genotype accounts for all a1ATD childhood cases of liver disease and early onset of pulmonary emphysema. Being a hereditary fatal disorder with a known, simple to identify molecular genotype which accounts for all affected individuals, it thus fulfills the WHO criteria for population genetics screening tests. In order to justify a1ATD as a suitable disorder to be screened in our population, we needed to determine the frequency of the disease alleles responsible for all severe cases of a1ATD among the various ethnic groups in our targeted population. A total of 4226 Israeli Jews were divided into 3 ethnic groups: Ashkenazi (both parents are Ashkenazi n=2683), non-Ashkenazi (n=983) and 'mixed' origin (Ashkenazi with non-Ashkenazi, n=560), and were tested for the presence of the PiZ allele, using DNA-based analysis. Of 33 carrier individuals of the PiZ allele, 29 were Ashkenazi, and 4 were from the 'mixed' group, giving rise to a carrier frequency of 1:92. The frequency of the PiZ allele among the 'mixed' group was 1:140 which was higher than expected, however may be accounted to the small sample size. These results resemble the frequency of carriers found in European populations, however they are 6 fold higher than that shown by Nevo and Cleve (1). In their biochemical analysis of 550 Ashkenazi-Jews, only a single carrier was found. The discrepancy between our results and those determined by Nevo and Cleve can be explained by our larger sample size and the greater accuracy of DNA based techniques. Due to the higher prevalence of the PiZ allele found among the Ashkenazi Jewish population, along with the carrier frequency of 1 in 92 in that group, we strongly recommend screening the Ashkenazi Jewish population also for the PiZ allele. 1)Nevo S. and Cleve H: *Am. J. Med Genet* 1991; 15;39(4):399-403.

**A highly sensitive fluorescence-based maternal cell contamination test.** *W.C. Spence<sup>1</sup>, C.M. Kelly<sup>1</sup>, A. Maddalena<sup>1,2</sup>.* 1) Genetics & IVF Institute, Fairfax, VA; 2) Medical College of Virginia, Richmond.

The misinterpretation of a fetal molecular result can occur in pregnancies at high risk for a specific genetic disease if a significant percentage of maternal cells are present in the fetal specimen. Maternal cells in products of conception (POC) or other fetal cultures also have the potential to lead to an erroneous fetal interpretation when doing cytogenetic analysis. To aid in the interpretation of these molecular and cytogenetic cases, the GIVF molecular laboratory has modified a test that is being widely used in the paternity and forensics community for identity testing. The AmpFeSTR®Profiler Plus™ kit examines nine independent highly polymorphic loci. The primers are fluorescently labeled and the amplified product is analyzed by capillary electrophoresis on an ABI Prism® 310. Because of the polymorphic nature of the tested loci, the mother generally has two different alleles at many of the nine loci. One of these alleles is inherited by the fetus. If the second maternal allele is not shared by the fetus, this locus is considered to be informative. There is evidence of maternal cell contamination (MCC) if any amount of a second maternal allele in an informative system is detected in the fetal sample. Mixing experiments have been done to determine the sensitivity of this MCC fluorescent test. Contaminating DNA can begin to be detected at a level of approximately 1%. Conservatively, this fluorescent test can always detect contaminating DNA when it is present at a level of 10% or more. We have run mixing experiments on several of our molecular genetic tests and verified that 10% DNA contamination does not lead to a misinterpretation of the results. Therefore, this MCC test has the sensitivity needed to verify that a molecular test result is reliable in a fetal sample. It will also be useful in detecting MCC in fetal cytogenetic cases and may be particularly valuable when karyotyping POC.

**Minimization of the Time and Cost to Identify Unknown RB1 Mutations.** *K.E. Vandezande<sup>1</sup>, S. Richter<sup>1</sup>, N. Chen<sup>1,4</sup>, K. Zhang<sup>1</sup>, X.C. Tong<sup>1,3,4</sup>, B.L. Gallie<sup>1,2,3,4</sup>.* 1) Solutions by Sequence Inc, Toronto, ON; 2) Princess Margaret Hospital, Toronto, ON; 3) Ontario Cancer Institute, Toronto, ON; 4) Canadian Genetic Diseases Network.

Despite clear economic and clinical benefits, RB1 mutation detection is not widely implemented in care for retinoblastoma families. Testing for RB1 mutations is difficult and relatively expensive. The RB1 gene is large (180kb); as with other tumor suppressor genes (BRCA1, eg), a variety of mutations can disrupt function, including whole gene deletions, partial deletions and point mutations. There are no common founder mutations and no particular hotspots for mutations. Thus, a series of tests is required to attain high sensitivity in clinical mutation identification. We use 6 quantitative PCR multiplexes to detect deletions and insertions and 14 automated sequence runs (2 exons each) to detect substitutions. We developed general rules to find the most cost-effective order for molecular tests and applied them to the search for RB1 mutations. Based on mutations found for 302 of 349 retinoblastoma probands (86% sensitivity), we found the optimal order for finding RB1 mutations. Mutation discovery rates in sequencing exons are independent of test order, so sequencing tests rank optimally on a simple bang-for-buck measure. Mutation discovery rates from quantitative multiplex PCR depend on the order in which multiplexes are performed, so we examined all permutations of the 6 multiplexes to find the most effective. Last, all 20 tests were ordered by decreasing cost effectiveness to achieve an optimal test order. To find an unknown RB1 germline mutation, the naive strategy (all quantitative analyses before sequencing 14 duplexes) takes 125 hours and costs \$3,436(CAD). After optimization, the search is predicted to take an average of 117 hours and to cost \$2,951. Optimizing RB1 mutation detection decreases costs and turnaround time and increases the likelihood of clinical implementation. Our search algorithm is applicable to other genetic diseases and to general cost impact assessment of new techniques before implementation.

**Rapid and specific detection of b-thalassemia mutations in Malaysia using Combine-ARMS.** *J.A. Tan, K.L. Tan, Y.C. Wong, Y.C. Wee, S.F. Yap.* Allied Health Sci, Fac Med, University of Malaya Medical Centre, Kuala Lumpur, Malaysia.

The percentage of compound heterozygosity found in b-thalassemia major patients in the University of Malaya Medical Centre (UMMC) is about 47.62%. Thus, much time and effort is spent in the detection of two b-mutations per family in the event of a prenatal diagnosis. A Combined-ARMS (C-ARMS) technique was established for the detection of two to three b-mutations in a single PCR reaction. C-ARMS protocols for cd 41-42/IVSII #654 and -29/cd 71-72 detected b-mutations in 74.98% of the Chinese b-thalassemia patients in UMMC. C-ARMS for cd 41-42/IVSI #5/cd 17 detected b-mutations in 36.53% of b-thalassemia in the Malay patients. We conclude that Combine-ARMS, with the ability to detect two to three specific b-mutations in a single PCR reaction, provides a more rapid and cost-effective technique for prenatal diagnosis and molecular characterization of b-thalassemia in Malaysia.

**The experiences of a predictive testing programme for cancer genetics in South Africa.** *U.F. Algar<sup>1</sup>, P.A. Goldberg<sup>1</sup>, G.E. Pietersen<sup>2</sup>, J.A. Gilfillan<sup>2</sup>, R.S. Ramesar<sup>2</sup>.* 1) Colorectal Surgery, Groote Schuur Hospital, Cape Town, Western Province, South Africa; 2) Human Genetics, University of Cape Town, Cape Town, South Africa.

Research geneticists in South Africa have identified several novel mutations in the DNA mismatch repair genes underlying hereditary non-polytopic colon cancer (HNPCC). This has given clinical medicine an additional tool, namely predictive genetic testing, which can identify apparently healthy persons at high risk for developing predominantly colon cancer, later in life. Since 1990 genetic research bloods have been taken from 209 individuals of one HNPCC family (529 individuals on the pedigree). The majority of these family members live in a remote area in South Africa. As a result of a protocol of recruiting all individuals who are diagnosed with colon cancer under the age of 45 to an ongoing research programme, 10 families have been identified who have the identical genetic mutation. To date 440 predictive test results have been made known to these individuals, and of these, 21.36% are positive. Mutations detection in all these families has an impact on the psychosocial health of every individual involved, but it has also markedly reduced the burden of disease on the different health services (rural as well as urban, private and state) that are involved in delivering a service to these communities. Predictive testing in cancer genetics raises a number of questions for the spectrum of stakeholders associated with predictive testing: Are apparently healthy persons interested in knowing that they are at an increased risk of a particular cancer? How does this knowledge affect their wellbeing? Does knowledge of definitive risk status have an impact on society? What is the effectiveness of this "preventative" care? Does a tertiary health service have a duty to deliver health care? We will focus on these issues that have arisen in our service to HNPCC families in South Africa.

**What genetic issues do family physicians encounter?** *L.S. Acheson, S.J. Zyzanski, K.C. Stange.* Department of Family Medicine, Case Western Reserve Univ, University Hospitals of Cleveland, Cleveland, OH.

**Objective:** To describe the genetics-related clinical issues encountered by practicing family physicians (FPs), and which medical problems they are likely to refer to genetic consultants. **Methods:** Mailed questionnaire to a national, random sample of practicing FPs. FPs reviewed 18 categories of medical conditions and indicated how many times in the past year they had discussed genetic information about each of these conditions with patients, and what proportion of the families with each condition were referred for genetic consultation. **Results:** The response rate was 38%. Respondents were similar to nonrespondents except that more were women. 41% of the 190 physicians graduated from medical school before 1980. 47% practice in rural communities or small towns. 37% provide prenatal care. The majority of FPs had discussed the genetics of common cancers, cardiovascular disease (CVD), and Alzheimer's disease with 2 or more patients in the past year. 13% had referred patients for genetic counseling regarding breast-ovarian cancer but only 1 had referred a family because of CVD and 1 for Alzheimer's Disease. 25% to 50% of FPs had addressed genetic issues in at least one family with hemoglobinopathy, a blood clotting disorder, hemochromatosis, mental illness, vision loss or deafness, chromosome abnormality, infertility or pregnancy loss, congenital anomalies, mental retardation, and neurofibromatosis. Most cases where genetic issues were addressed were not referred for genetic consultation at that time. 23% of respondents said that genetic consultation is very difficult to obtain or unavailable. 17% listed ethical and social dilemmas that arose when considering whether to pursue genetic diagnosis. Lack of locally available consultants, worry about harms of testing, cost, and patients' opposition to abortion were the most frequently mentioned barriers to referral. **Conclusions:** Nationwide, family physicians are addressing a variety of genetic issues with patients. Genetic consultation is not currently used for some common adult disorders; it is more common for familial cancers and perinatal conditions. These data may be used in planning education and outreach to FPs.

**External Quality Assessment: A model scheme for Friedreich ataxia testing.** *D.E. Barton*<sup>1</sup>, *F. Ryan*<sup>2</sup>, *E. Sistermans*<sup>3</sup>, *M. Claustres*<sup>4</sup>, *L. Florentin*<sup>5</sup>, *S. Cocozza*<sup>6</sup>, *S. Patton*<sup>7</sup>, *R. Elles*<sup>7</sup>. 1) National Centre for Medical Genetics and University College Dublin, Ireland; 2) Dublin Institute of Technology, Dublin, Ireland; 3) University Hospital Nijmegen, Nijmegen, The Netherlands; 4) Institut de Biologie, Montpellier, France; 5) Lito Maternity Hospital, Athens, Greece; 6) University Federico II, Naples, Italy; 7) European Molecular Genetics Quality Network, Regional Molecular Genetics Laboratory, Manchester, UK.

Studies of the reliability of molecular genetic testing have indicated a significant level of inaccuracy, arising from errors in sample identification, genotyping or interpretation. The European Molecular Genetics Quality Network (EMQN) aims to raise and maintain the quality of molecular genetic testing by providing external quality assessment (EQA) schemes to diagnostic laboratories. EQA schemes are designed to test participants' ability in both genotyping and interpretation. EMQN has provided 15 EQA schemes in 6 disease-specific areas since 1997. We describe the results of an EQA scheme for Friedreich ataxia testing, and the development of best practice guidelines using the experience gained. Friedreich ataxia (FRDA) is the most common hereditary ataxia with an estimated prevalence of 1 in 50,000. The most frequent genetic abnormality seen in FRDA is the homozygous expansion of a GAA repeat in the FRDA gene. In 1998, EMQN organised a pilot EQA scheme for genetic testing for FRDA, with 10 participants from 10 different European Union countries. No genotyping errors were recorded, but a small number of errors of interpretation were identified. Accordingly, a workshop was organised to develop consensus best practice guidelines for FRDA testing. These guidelines are available at [www.emqn.org](http://www.emqn.org). An open FRDA EQA scheme was offered in 2000. Thirty-four laboratories including 3 from the USA participated. In contrast to the pilot scheme, this open EQA identified deficiencies in the tests in use in several laboratories, and revealed wide variation in the quality of interpretation of results. A clear need for reference samples for accurate sizing was also identified. Feedback from the scheme has been very positive; a further round of EQA will be carried out in 2001.

**The process of developing an educational pamphlet regarding hereditary breast cancer for un- and under-insured women.** *W.F. Cohn*<sup>1</sup>, *D. Brower*<sup>2</sup>, *J. Bauerle*<sup>3</sup>, *S.M. Jones*<sup>4</sup>, *S. Miesfeldt*<sup>3</sup>. 1) Health Evaluation Sci; 2) Curry School of Education; 3) Dept Internal Medicine; 4) Cancer Center; Univ Virginia, Charlottesville, VA.

Although cancer genetics services are increasingly available, access is limited among those who are un- or under-insured. We are developing an educational pamphlet to help un- and under-insured women understand and assess their potential risk for hereditary breast cancer (HBC). The pamphlet has two primary sections: (1) information on topics such as HBC risk and resources and (2) a workbook attachment that allows women to identify characteristics of their personal or family histories that may put them at risk for HBC. We followed an instructional design process to guide the development of the pamphlet. This involved several steps, including: goal development, instructional analysis, and analysis of learners and context. The educational goals of the pamphlet are to enable users to: (1) identify risk factors for HBC; (2) understand the importance of knowing if one is at risk for HBC; (3) determine one's potential risk for HBC; and (4) know available resources for women at risk for HBC. The instructional analysis involved identifying steps and subskills for each instructional goal, so that baseline knowledge needed for goal attainment would become evident and could be included in the pamphlet. The analysis of learners and context involved a small survey of the target population to determine baseline knowledge and learning preferences. Results indicated that most respondents understood the concepts of *hereditary* (19/20), *inherited* (15/20), *hereditary breast cancer* (19/20), and *inherited breast cancer* (15/20). A majority also understood the concepts of *risk* (12/20) and *risk factor* (15/20). Thus, these terms will be included in the pamphlet without extensive definition. Few women were able to define the phrase *early-onset* (4/20). This concept will be explained in the pamphlet. The pamphlet will enable women to self-assess potential risk for HBC and access appropriate resources. Future plans include a formative and summative evaluation of the pamphlet prior to wider distribution.

To be presented by L. P. ten Kate instead of L. Henneman.

Program Nr: 1542 from the 2001 ASHG Annual Meeting

**Preconceptional cystic fibrosis carrier screening: evaluation of a pilot study.** *L. Henneman<sup>1</sup>, L.P. Ten Kate<sup>1</sup>, G. Pals<sup>1</sup>, I. Bramsen<sup>2</sup>, H.M. Van der Ploeg<sup>2</sup>.* 1) Clinical and Human Genetics, VU Medical Center, Amsterdam, the Netherlands; 2) Medical Psychology, VU Medical Center, Amsterdam, the Netherlands.

The feasibility of preconceptional cystic fibrosis (CF) carrier screening in the Netherlands was evaluated using four different ways of inviting and educating couples. Invitations, by mail, were either by general practitioner (GP) or by municipal health services (MHS). Education was either individually at GP's consultation or at a predetermined general educational session. Participants' and non-participants' motives, reasons for (non-)attendance, knowledge, attitudes and sociodemographics were addressed using questionnaires. In total, 38,291 persons (20-35 years) received a first invitation. It turned out that only 20% of them formed part of an eligible couple. Of these, 559 couples consented to test. Participation of couples at the educational session invited by GP or MHS was 12% and 9% respectively. Uptake was higher when couples were educated at GP's consultation (25%). The main reason given for non-participation was lack of time to attend the educational session (53%) or GP's consultation (36%). Overall, other reasons given were that the couples did not want to know their results (28%), lack of concern (6%), and fear for results (5%). Sixty-nine percent of non-participants asserted that screening should be offered routinely to couples planning children. In two approaches, a second invitation was sent, one year after the first, and another 3-7% of eligible persons came forward. GP's did not report any negative experiences. Participating couples provided mouthwashes of both partners. Testing was, however, step-wise. Eighteen carriers were identified; their partners tested negative. Satisfaction among participants was high: 95% would make the same decision to be tested again, and 89% would recommend testing to others. Our results show that the primary care setting provides highest couple attendance, although knowledge of couples educated by the GP was lower than couples educated at the educational session. Furthermore, repetition of the invitation increased the uptake. Overall, these results suggest that preconceptional carrier screening is feasible in the Netherlands.

**Simple fluorescent PCR assay for discriminating FRAXA fully mutated females from normal homozygotes.** *J. Lourdaux<sup>1</sup>, C. Houdayer<sup>1</sup>, T. Billette de Villemeur<sup>2</sup>, G. Royer-Legrain<sup>3</sup>, M. Bahuaud<sup>1</sup>, JP. Bonnefont<sup>3</sup>, D. Feldmann<sup>1</sup>, R. Couderc<sup>1</sup>.* 1) Biochimie et Bio Moléculaire, Hospital Trousseau; 2) NeuroPédiatrie, Hosp. Trousseau; 3) Biochimie Génétique, Hosp. Necker; Paris, France.

Fragile X syndrome is the most common inheritable genetic disease accounting for mental retardation. Despite robustness, Southern blot-based diagnosis is not suitable for large-scale routine screening necessary for neuropediatric practice. PCR appeared as an interesting alternative and various protocols were successfully applied to molecular screening in mentally retarded boys and girls, in whom two alleles with one-repeat difference could be evidenced (CGG repeat heterozygosity among normal females is about 70%). Unfortunately, discriminating the remaining 30% normal homozygote females from full-mutated ones remains a difficult task. Indeed, failure of identification by PCR is accounted for by competition of the wild-type allele with the expanded one during the PCR process. Therefore, we opted for another approach in designing a semiquantitative PCR assay, based on the amplification of the wild type allele. This method allowed us to detect the presence of one or two normal alleles with the same sizes, thereby evidencing a FRAXA fully mutated female or a normal homozygote, respectively. A previously described protocol [Houdayer et al. Clin Chem Lab Med 1999; 37:397-402] was modified by using a limited number of cycles and a reduced amount of enzyme. As an internal control, DNA from a normal boy (with a different repeat number from the female sample studied) was added to the PCR mixture to monitor possible fluctuation in PCR reaction yield. PCR products were electrophoresed using an ABI 373A or 310 (Applied Biosystems). Mutational status was determined by the comparison of fluorescence intensity between peaks generated from the sample and peaks generated from normal or full-mutated female controls. After an optimization step, a preliminary trial on 50 female DNA samples allowed us to ascertain the mutational status in all patients. We believe this simple PCR assay is a powerful approach that would reduce the recourse to Southern-blotting in females with mental retardation of unknown etiology.

**Detection of trinucleotide repeat disease using micro-capillary electrophoresis chip.** *Y-E. Lee<sup>1</sup>, S-J. Baek<sup>1</sup>, H-J. Kim<sup>1</sup>, S-C. Jung<sup>2</sup>, J.K. Jeong<sup>1</sup>.* 1) Microarray Center, Biomedlab Institute, Biomedlab Co., Clinical Research Institute 5304, Seoul National University Hospital, Jongno-Gu, Yongon-Dong 28, Seoul 110-744, Korea; 2) Department of Biomedical Sciences, Division of Genetic Disease Research, Korea National Institute of Health, Eunpyong-Gu, Nokbun-Dong 5, Seoul, 122-701, Korea.

Several major human single gene disorders are attributed to the expansions of highly unstable trinucleotide repeat (TR) sequences. TR numbers are closely related to not only the onset age and severity but also diagnosis and prognosis of disease. Therefore, it is very effective and essential to estimate the accurate TR size for screening or confirmation of trinucleotide repeat disease (TRD). DNA testing such as southern blotting or polymerase chain reaction (PCR) has been commonly used in the diagnosis of TRD. However, such methods require laborious steps for the diagnosis and lack accuracy in detection of carriers and estimation of TR numbers. Therefore, we have developed a new method for the detection of TRD using micro-capillary electrophoresis chip (micro-CE chip). Amplified target sequence by PCR using specific primers designed for TR was separated in micro-capillary electrophoresis (CE) chip, having 15 mm deep, 60 mm width and 35.5 mm length separation channel. TR amplicon was detected by and the size of TR was determined by confocal detection method using the semiconductor diode laser (635 nm). We evaluated the method by analysis of samples from normal subjects, 9 HD patients, 13 SBMA patients, 2 DRPLA patients, 6 FX carriers and 3 DM carriers. Southern blotting method was simultaneously performed to confirm our results. The data obtained from the micro-CE chip and southern blotting were highly comparable. The estimated TR number was also confirmed by sequencing. This study suggests that micro-CE chip is very useful for the detection of TRD and the determination of TR numbers. This new method could be very helpful in early diagnosis, carrier testing, and proper genetic counseling.

**Molecular analysis of FRAXA mutations: advantages limits and diagnostic implications of an improved PCR-amplification method.** *R. Polli, F. Finco, M. Martella, L. Picci, F. Zacchello, A. Murgia.* Dept Pediatrics, Univ Padua, Padua, Italy.

Fragile X molecular testing is aimed at fully characterizing the extent of the FRAXA repeats expansions and the state of methylation of the FMR1 gene promoter and repeated sequences, and at defining the size of gray-zone alleles. Southern blot, which allows the complete analysis of these mutations, is considered the method of choice, even though not accurate in the resolution of small-size alleles and relatively labor-intensive. The attempts to simplify Fragile X analysis by several PCR amplification protocols, have not yielded convincing results, mainly due to the very high CG content and to the size these DNA stretches. A new PCR method that for the first time seems to efficiently amplify FRAXA full mutations has been recently developed and made available. We have been using this tool to retrospectively analyze samples of mutated individuals from 44 Fragile X families previously studied by conventional Southern blotting, to compare advantages and limits of the two different systems and verify the possibility of modifying our current molecular approach to routine FRAXA diagnosis. Preliminary results obtained from the analysis of 40 samples of FRAXA full and pre-mutations show amplification of fragments with a maximum of 700 repeats. It has been possible to identify, in a few samples, the presence of fragments of pre and full mutation that had not been detected by Southern blotting. These latter data could modify the final interpretation of the molecular analysis in those samples and increase the number of the observed mosaic cases. The use of Southern blot is definitely still necessary not only for a complete methylation analysis of the Fragile X region, but also for the reliable detection of extreme repeat expansions. On the other hand, the introduction of a FRAXA-specific PCR amplification system proved to be highly sensitive and efficient can contribute to improving the accuracy of Fragile X molecular testing and can increase our understanding of the molecular characteristics of these complex mutations. Cofinanziamento MURST 2000 MM06195974\_001.

**Screening of the CTG/CAG expansion at the Huntington's Disease-Like 2 locus (HDL2) in patients with Huntington's disease.** *G. Stevanin<sup>1</sup>, C. Julien<sup>1</sup>, S.E. Holmes<sup>2</sup>, C.A. Ross<sup>2</sup>, R.L. Margolis<sup>2</sup>, A. Brice<sup>1</sup>, A. Durr<sup>1</sup>.* 1) INSERM U289, Hopital de la Salpetriere, Paris, France; 2) Johns Hopkins University School of Medicine, Baltimore, MD, USA.

Huntington's disease (HD) is a neurodegenerative disorder resulting primarily from the loss of neurons in the striatum. Chorea is associated with cognitive impairment with a progressive and unremitting course. A CAG repeat expansion in the IT15 gene on chromosome 4 is responsible for the vast majority of cases with HD phenotypes and autosomal dominant transmission of the disease. Recently, a CTG/CAG repeat expansion in a new gene (HDL2 locus) was detected with the Repeat Expansion Detection method in patients from a large HD kindred without expansions in the IT15 gene (Holmes et al, ASHG 2001 abstract).

To verify the involvement of this new repeat expansion in unexplained HD cases and its frequency, we screened 95 controls and 83 patients with HD phenotypes, in whom expansions in the DRPLA and IT15 genes had previously been excluded. The number of repeats varied from 8 to 28 units in the controls. The distribution did not vary with geographical origin and was not significantly different in the patients (10 to 17 repeats). Only one Moroccan patient carried 50 uninterrupted CTG/CAG repeats.

The patient, a 44 year old woman, presents with a 2 years duration of mild choreic movements of the face and extremities associated with reduced Mini Mental Status (22/30). Neuropsychological evaluation revealed sub-cortical dementia similar to that found in HD caused by expansion in the IT15 gene. Enlargement of the anterior horn of the lateral ventricles was observed on cerebral MRI suggesting atrophy of the head of the caudate nucleus. The father died accidentally at age 54. No other affected individual is known in the paternal family.

In conclusion, this observation confirms the genetic heterogeneity of HD, but CTG/CAG repeat expansions at the HDL2 locus account for only 1% of our series of Huntington's disease-like patients without expansions in the IT15 gene.

**FRAXE screening among males with idiopathic mental impairment in Brazil.** *C.B. Santos, M.M.G. Pimentel.*  
Departamento de Biologia Celular e Genetica, Universidade do Estado do Rio de Janeiro , Rio de Janeiro, RJ, Brasil -  
cbs@alternex.com.br.

The FRAXE mutation is caused by an unstable expansion of a polymorphic CCG repeat within the 5' untranslated region of the FMR2 gene, located at Xq28, 600kb distal to FRAXA. As a consequence of the excessive number of triplet repeats, a nearby CpG island is hypermethylated and the FMR2 gene is turned-off, resulting in the phenotype features, such as, mental impairment or learning difficulties, speech delay, poor writing skills and hyperactivity. Based on size and methylation status, FRAXE alleles could be divided into four classes: normal (6-30 CCG), intermediate (31-60 CCG), premutated (61-200 CCG) and full mutated (over 200 CCG). In this study, a linear series of 226 special education-needs, developmentally delayed or language delayed male patients, aging from 2 to 18 years old, were screened for the FRAXE expansion. The subjects were previously referred for the Fragile X testing, but found to be negatives for full mutations across the FRAXA *locus*. We have developed a non-isotopic polymerase chain reaction (PCR)-based assay for the identification of FRAXE full mutation alleles among males. Amplification products were resolved by electrophoresis in nondenaturing 6% polyacrilamide gels stained by silver. None of the patients tested positive for the FRAXE expansion, suggesting that FRAXE is not a common aetiological factor among this group of patients. It is tempting to speculate that FRAXE full mutation bearers often escape ascertainment bias, due to the non-specific mild phenotype and the well adaptation to the environment. Therefore, it was postulated recently that the FRAXE full mutation prevalence is higher (1/23.423 males) than the estimated FRAXE prevalence of 1/50.000 males. In conclusion, once molecular analysis of FRAXE mutation is now available, further screening studies are needed for the purpose of identifying newly FRAXE patients and improving genetic counseling.

**Rapid HPLC Purification of Labeled and Unlabeled Oligonucleotides.** *K.R. Yardley<sup>1</sup>, P.D. Rainville<sup>1</sup>, M. Gilar<sup>1</sup>, E. Budman<sup>1</sup>, M. Berne<sup>2</sup>, R.J. Russell II<sup>1</sup>.* 1) Life sciences applications, Waters Corp., Milford, MA; 2) Physiology, Tufts University school of medicine, Boston, MA.

High purity oligonucleotides are essential for many types of genomic assays including detection of single nucleotide polymorphisms (SNPs) and quantitative PCR. Because the purity of synthetic oligonucleotides is typically ~ 70% (for 25-mer), purification is necessary to remove failure sequences and unlabeled target molecules. The current oligonucleotide purification methods include ion-exchange HPLC and PAGE purification, however, these methods suffer in recovery and/or purity of target product. We have developed a rapid, robust HPLC method for analysis and purification of unlabeled and fluorescently labeled oligonucleotides using ion-pair reversed-phase chromatography with the XTerra® 2.5mm MS C18 column. This single step HPLC separation is capable of purifying labeled and unlabeled oligonucleotides from failure sequences and unlabeled products. Results for unlabeled oligonucleotides are exceptional, typically > 95% purity, with >90% recovery. We have also used this method to purify oligonucleotides containing fluorescent labels including Cy5, FITC, TAMRA, and TaqMan™ to > 90% purity with > 85% recovery. This method far exceeds current purification technology in both recovery and purity for labeled and unlabeled oligonucleotides.

**Purification of synthetic oligonucleotides - Utilizing denaturing high performance liquid chromatography (dHPLC).** *S. Sheikhavandi*<sup>1</sup>, *J. Riviello*<sup>2</sup>, *L. Bao*<sup>2</sup>, *J. Adams*<sup>3</sup>, *M. Marino*<sup>4</sup>. 1) Applied Genomics and Molecular Genetics, Transgenomic, Inc., San Diego, CA; 2) Separations Research and Development, Transgenomic Inc., San Diego, CA; 3) Market Development, Transgenomic Inc., San Diego, CA; 4) Applied Genomics and Molecular Genetics, Transgenomic, Inc., Gaithersburg, MD.

The genomics revolution has rapidly increased the demand for highly purified synthetic oligonucleotides for PCR, cloning, genotyping, chip-based technologies, and various applications in the field of pharmacogenetics. Gel electrophoresis and high performance liquid chromatography (HPLC) have previously been the most commonly used techniques for oligo purification. Compared to both gel electrophoresis and typical IP-RP HPLC, dHPLC offers the advantages of higher resolution, larger size range for separation, purification chemistries, reproducibility, automation, and convenient data archiving. We describe the use of dHPLC for the analysis and purification of synthetic oligonucleotides. The unique separation chemistries of the OligoSEP® column combined with an elevated temperature of 70<sup>0</sup>C offer rapid and highly efficient separation and purification. The WAVE® OLIGO system is a fully automated dHPLC system specifically designed for the analysis and purification of synthetic oligonucleotides. Using thermally stable polymeric reversed phase columns in the reversed phase ion- pairing in fully denaturing mode, a broad range of synthetic oligonucleotides can be purified in less than 10 minutes. In addition, by changing the eluent chemistry, separations can be performed based either on oligo length alone, or a combination of length and base pair composition. The purification of unmodified, dye labeled, and biotinylated oligonucleotides have also been accomplished using this technique.

**Genomic approaches for identifying genes involved in auditory hair cell regeneration.** *D. Hawkins<sup>1</sup>, S.*

*Bashiardes<sup>1</sup>, N. Fukushima<sup>1</sup>, N. Saccone<sup>1</sup>, F. Li<sup>1</sup>, G. Stormo<sup>1</sup>, M. Warchol<sup>2</sup>, M. Lovett<sup>1</sup>.* 1) Washington University, St. Louis, MO; 2) Central Institute for the Deaf, St. Louis, MO.

In higher vertebrates sensory hair cell loss leads to permanent deficits in hearing and equilibrium. However, hair cells in the ears of many nonmammalian vertebrates can regenerate after injury. Replacement hair cells are produced by renewed proliferation of epithelial supporting cells. In the avian cochlea these cells are normally quiescent, but will proliferate in response to the death of hair cells. In contrast, supporting cells within the chick utricle are in a constant process of proliferation. We are measuring differences in gene expression between normal cochlea and utricle, and changes that occur in the cochlea during hair cell regeneration, by employing three custom cDNA microarrays. The first array consists of ~400 genes that previous studies have identified as being expressed in the inner ear. The second is an array of 10,000 genes from sequence verified human cDNA clones. The third is an oligonucleotide array of 50mers designed to detect the great majority of transcription factor genes. To derive expression profiles we have employed micro-cDNA synthesis methods to enable us to profile gene expression with less than 50,000 cells. In a comparative analysis of gene expression in the sensory epithelia of proliferative utricles and quiescent cochleas we have detected >4-fold increases in the utricle of the transcripts encoding tyrosinase-related protein, cadherin-4, neuregulin-1, and connexin 46.6, among others. Among the changes in the cochlea are higher levels of expression of the retinoic acid receptor responder 3, neurofibromatosis type 2, and dynein light chain genes relative to utricle. We are also enriching for differentially expressed genes in the utricle compared to the cochlea using a cDNA subtraction method. By applying this method through three rounds of subtraction we have reduced the level of common abundant cDNAs by >100-fold and have enriched for utricle-specific cDNAs. By a combination of these approaches we intend to identify key genes in the process of chick hair cell regeneration and to then explore their regulation in the mammalian inner ear.

**Molecular cloning of a human novel gene MLEL1 of a homologue of Drosophila Mle protein and its tissue expressive profile analysis.** *J. Fu, L. Li, G. Lu.* Laboratory of Human Reproductive Engineering, Central South University, Xiangya Medical College. Changsha, 410078 P. R. China.

The genome of *Drosophila Mle* has been sequenced, which is an ideal model organism for the study of structure genomics and function genomics. The maleless gene (*mle*) with RNA and DNA helicase function in *Drosophila*, is involved in gene expression post-translation regulation in the germline in *Drosophila*. The *mle* gene belongs to superfamily of DEAD/DEAH, and all possess of a conserved motif including Asp-Glu-Ala-Asp/His. The function of these proteins presents not only the splice, but also the cell functions including ribosome assemble, translation initiate, spermatogenesis and embryogenesis. In this paper, applying the strategy of homologue cloning from the beginning of MLE protein in *Drosophila*, the human novel gene, named MLE like 1 (MLEL1) has been cloned by combined with bioinformatic analysis and experience techniques (AF217190). MLEL1 gene have 3600 base pair (bp) long, contained a 3024 bp open reading frame with a longer DNA/RNA helicase box (DEAD/DEAH). The amino acid protein sequences of MLEL1 in human and MLE in *Drosophila* are 38% identical and 57% positive. Northern blotting showed a 3.8 kb single strong signal in testis, and others only very weak 3.8 kb hybridization pattern or not. MLEL1 gene has been mapped on chromosome 3q25.1-3q25.2 by chromosome localization analysis and 26 exons and 25 introns have been confirmed primarily by genomic structure analysis. MLEL1 may be involved in human spermatogenesis and male reproductive.

**Meta-learning for Combining Multiple Classifiers.** *X. Fang*<sup>1</sup>, *M. Xiong*<sup>2</sup>. 1) Statistics, Beijing University, Beijing, P. R. China; 2) Human Genetics Center, University of Texas - Houston.

Emerging advances in microarray technology and gene expression based classification are serving as precursors of whole genome functional analysis and revolutionizing disease diagnosis. There exist many classification methods. However, different classifiers may not only differ in their global performance, but they also may show strong local differences. Each classifier may have its own region in the feature space where it performs the best. To combine multiple classifiers will improve the accuracy of classification. Meta-learning is a technique that seeks to construct higher-level classifier that combine multiple classifiers based on different learning methods or different data sets. Due to the high cost of most microarray experiments, having the ability to utilize multiple data sets will be extremely valuable for biomarker identification and disease classification. In this report, we develop an adaptive boosting algorithm for meta-learning that seeks to compute a "meta-classifier" that integrates the separately learned classifiers to boost overall accuracy of classification. The proposed boosting algorithm will be applied to combine three classifiers based on linear discriminant analysis, logistic regression and support vector machines for classifying colon tumor tissues.

**Collection, storage, and distribution of data concerning DNA variations affecting human phenotypes.** *R.G.H. Cotton<sup>1</sup>, A.D. Auerbach<sup>2</sup>, P. Bork<sup>3</sup>, A. Brookes<sup>4</sup>, A.J. Cuticchia<sup>5</sup>, O. Horaitis<sup>1</sup>, H. Lehväsliho<sup>6</sup>, C.J. Porter<sup>5</sup>, C.R. Scriver<sup>7</sup>, C.C. Talbot Jr.<sup>9</sup>, G.R. Taylor<sup>8</sup>, S.A. Teebi<sup>5</sup> and members of the HUGO Mutation Database Initiative.* 1) Genomic Disorders Research Ctr, St Vincents Hospital Melbourne, Australia; 2) Rockefeller University, New York, U.S.A; 3) European Molecular Biology Laboratories, Heidelberg, Germany; 4) Karolinska Institute, Stockholm, Sweden; 5) Bioinformatics Supercomputing Centre, The Hospital for Sick Children, Toronto, Canada; 6) EMBL Outstation, European Bioinformatics Institute Wellcome Trust Genome Campus, Hinxton, UK; 7) McGill University, Montreal Children's Hospital Research Institute, Montreal, Quebec, Canada; 8) Imperial Cancer Research Fund, Mutation Detection Facility, Leeds, UK; 9) The Johns Hopkins University, Baltimore, USA.

We outline a plan to ensure that variation in genes, particularly mutations causing single gene disorders, is collected from laboratories worldwide, quality controlled, deposited for safe-keeping in a central database, and made readily available to the public. We plan to develop a community ethic in which mutation/variation submission is routine, to encourage and make such submission simple, and to develop a central database and appropriate systems to safeguard such data while making them available to the public and public databases. The collection of all variation (approximately 1/2 of known gene mutations now remain unpublished) will ultimately be important for human health as genomic disease causing alleles eventually affect 60% of the population in a lifetime. The MDI now proposes to develop a system to encourage and ensure variation capture. Receipt and capture of data will be enabled by a "WayStation" with Editorial review assisted by the MDI. A "Warehouse" will be established to store and distribute these data. Novel aspects of this system are its systematic involvement of the community, including worldwide collection of clinical mutations, the sophisticated Waystation entry point, acting as an electronic peer reviewed journal, and the Warehouse to act as the central database. See the MDI Website: [www.genomic.unimelb.edu.au/mdi/](http://www.genomic.unimelb.edu.au/mdi/).

**A comprehensive approach to whole genome SNP analysis and bioinformatics.** *A.M. Brower, D. Baranski, J. Baier, E. Beaty, B. Tremelling, V. Lyamichev, M. De Arruda Indig, M. Atilas, S. Law, B. Neri, R. Ganske, L. Fors.* Bioinformatics, Third Wave Technologies, Madison, WI.

As a result of the Human Genome Project (HGP), over 29 gigabytes of data is currently available in a number of public databases, and over 2.8 million candidate SNPs have been submitted to NCBI's SNP database (dbSNP). Twelve thousand entries describing human genetic disease have been submitted to the Online Mendelian Inheritance in Man database with over 9288 having a gene locus and 1124 of these identified as having allelic variants. It becomes clear that the ability to find and catalog SNPs has surpassed our capacity to validate and genotype these variants, and to describe the resulting genotype/phenotype correlation. We present a comprehensive, interactive sequence analysis pipeline designed to create synergy between sequence information of varying completeness, candidate SNPs, and disease genes. We created several BLASTable databases representing draft and finished sequence, mRNA sequences, and SNP sequences. We then developed a suite of computational tools and an *in silico* sequence analysis pipeline to mine and automatically harvest information to annotate the genomic landscape surrounding each SNP for 100 kilobases, resulting in a comprehensive and interactive database of SNPs grouped by their functional characteristics. The resultant SNP profiles include information relating to GC content, allele frequencies, population statistics, map location, amino acid change, protein motifs, and functional location (exonic/intronic). The SNPs can be easily grouped into blocks to create single multi-allelic loci for use in linkage disequilibrium studies as microsatellite replacements for gene mapping studies. In addition, SNPs in coding, splice sites, and regulatory regions of genes can be used in candidate gene studies and for fine mapping efforts. The SNPs are being used to populate panels of Invader assays targeted to address specific questions related to disease gene discovery, disease susceptibility, diagnosis and treatment. We will present a genome wide map of SNPs which incorporates allele frequencies from our genotyping of four distinct populations.

**Exclusion of SINEs from imprinted regions dates from the earliest mammalian lineages.** *J.M. Greally*. Department of Medicine (Hematology), Albert Einstein College of Medicine, Bronx, NY.

To test the hypothesis that regions undergoing genomic imprinting have unique genomic characteristics, a number of major parameters of sequence heterogeneity in the human genome were identified and used to compare imprinted with non-imprinted loci. Imprinted regions were found to be normally permissive to retroposition events in general, as judged by the similarity in frequency of recent L1 insertions in imprinted and non-imprinted regions. However, imprinted regions were found to have a universal and significant decrease in short interspersed elements (SINEs: both Alu and MIR elements). Paternally- and maternally-expressed imprinted genes were separately compared with the control sequence panel, each showing the same marked decrease in SINE content. Ongoing integration of SINEs occurs within the imprinted regions, as the distribution of Alu subclasses of different evolutionary ages is similar in imprinted and control loci. Further findings were that maternally- and paternally-expressed imprinted genes differed in terms of their GC, CpG and L1 content, indicating that they may segregate into separate genomic compartments, and that CpG islands were larger at promoters of imprinted than non-imprinted genes. Active selection against a level of SINE retroposition above a critical threshold may occur due to the property of certain SINEs to attract and spread methylation, which could cause functionally deleterious consequences in imprinted regions already undergoing methylation and silencing of one allele. As MIR elements are common to all mammals, including marsupials and monotremes, the paucity of MIRs in imprinted regions indicates that imprinting or the genomic conditions allowing it preceded the evolution of placental mammals. The low frequency of SINEs suggests that a function of imprinted regions may be to act as sentinels against high levels of potentially mutagenic transposon activity in the developing organism, by providing large, dispersed genomic targets in each germline that are critical for embryonic development and are sensitive to the presence of newly-retroposed and methylated SINEs.

**Automated Quality Analysis and Functional Annotation of Public SNP data.** *N.W. Brown<sup>1</sup>, J.J. DiStefano<sup>1</sup>, S.F. Nelson<sup>2</sup>.* 1) Computer Science, UCLA, Los Angeles, CA; 2) Human Genetics, UCLA, Los Angeles, CA.

The practical use of public genomic data requires assessing its accuracy, its integration with other genomic data and the qualitative and quantitative predictions of the functional implications of these data. This often requires the integration of data from many sources. This integration is problematic in that public genomics data sources are: 1) very often not well organized 2) of varying error rates 3) referenced/cross-referenced between or within the data source in poor or non-existent manner and 4) devoid of functional implications. Automatic approaches to retrieve, quality check, cross-reference and predict the functional consequence of these data is crucial to the practical use of genomic information. Here we present a scheme for the automated quality analysis and functional annotation of polymorphism data from dbSNP. Our approach uses heuristic rules and probabilistic models to integrate and predict the confidence of the existence of a single nucleotide polymorphism, its allele frequency and the functional severity of allelic differences from public SNP data.

**Parallelization of GENIGMA, a novel analytical tool for large-scale gene expression microarray studies.** *D. Bozinov, C.M. Burson, O. Spiegelstein.* Ctr Human Molecular Genetics, Univ Nebraska Medical Ctr, Omaha, NE.

Microarray experiments with two tissue samples labeled respectively with Cy-3 and Cy-5 can instantly produce datasets of tens of thousands of expression values. For computational purposes this data size seems still reasonable on modern computer workstations. However, many scientifically interesting questions can only be answered by analyzing multiple microarrays of this size. Such an extensive scientific study creates a multidimensional matrix with hundreds of thousands of data points. For such a vast amount of expression data sophisticated computational tools are critical in order to extract meaningful information. GENIGMA, a novel software tool for high-throughput analysis and interpretation of gene expression microarray data has been developed to manage and process up to one thousand arrays at a time. Various statistical methods are in place to offer a sophisticated means for advanced analysis of either the entire study or only a subset of arrays. Unfortunately existing algorithms for clustering characteristically show a time complexity of quadratic polynomial expansion. Therefore, the effective processing time increases dramatically for large data sets. New strategies for comprehensive gene clustering on massively parallel processor (MPP) systems are discussed, which result in substantial performance gain. Extensions for parallel processing of gene expression data as well as structural modifications of GENIGMA are described. The recent improvements of this software tool make it exceptionally powerful and well prepared for upcoming large-scale microarray studies.

**A Gene Expression Profile of Aging in Mice.** *Z. Chen, B.L Merriman, S.F. Nelson.* Human Genetics, UCLA, Los Angeles, CA.

The genetic basis of aging in mammals is poorly understood. At this early stage, it is desirable to take a broad, unbiased look at what is actually occurring at the genetic level during aging. DNA microarrays are a new technology that enable us to monitor gene expression in such a broad fashion. We apply this technology to a mouse model in order to directly look at age-related changes in mammalian gene expression on a genomic scale. Our approach is to measure gene expression levels in mice representing a variety of ages, from young adult to elderly, and to look for gene expression changes correlated with age. We monitor expression in a variety of tissues, to assess tissue-specific variations. The mice used were male BALB/c, at ages of 5, 8, 12, 17, 22, 25 months, and a pair of mice at each age level was used for replication. From each mouse we harvested multiple organs (brain, liver, kidney, muscle and heart) and expression in each was monitored separately. We use spotted cDNA microarrays containing 8600 mouse genes to measure gene expression in the tissue samples, and hybridizations were done in comparative fashion, using the young adult (5 month old) tissues as reference samples. Thus a total of 50 arrays were required for this study. We applied clustering methods to the resulting expression data to identify groups of genes with similar expression changes during aging, and similar behavior across multiple tissues. In this initial survey of 8600 genes, approximately 200 showed a clear up-regulation trend with age, while 100 showed a clear down regulation trend. Within these major groups are subgroups with more similar trends, including several "aging marker genes" that show dramatic change (up to 32 fold) at extreme ages, as well as subgroups containing genes connected to energy metabolism, biosynthesis, cell cycle regulation, and stress response. Overall the results suggest that the normal aging process in mammals has a moderate impact on the expression of hundreds of genes involved in many basic cell processes, while very few genes show striking alteration in expression levels.

**High throughput SNP analysis and drug target prioritization.** *J.P. Alsobrook II<sup>1</sup>, C. Burgess<sup>1</sup>, M. Grosse<sup>1</sup>, D. Lepley<sup>1</sup>, E. Szekeres<sup>2</sup>, L. Shien<sup>2</sup>, J. Bader<sup>2</sup>, R. Shimkets<sup>1</sup>.* 1) Internal Discovery, CuraGen Corp, New Haven, CT; 2) Bioinformatics, CuraGen Corp, New Haven, CT.

Genes differentially expressed between normal and diseased states offer attractive targets for drug-based intervention. CuraGens proprietary gene expression technologies (SNPCalling<sup>TM</sup>, SeqCalling<sup>TM</sup>, GeneCalling<sup>TM</sup>, PathCalling<sup>TM</sup>) employ an integrated bioinformatics platform for the rapid identification of potential human disease targets and pharmacogenetic markers. The GeneCalling<sup>TM</sup> and SNPCalling<sup>TM</sup> processes, respectively, compare the gene expression and polymorphism profiles of disease or drug-response models to appropriate controls. Identification of differentially expressed genes does not require prior knowledge of gene sequence, a direct contrast to conventional chip-based technologies. Downstream polymorphism analysis of these potential targets is supported by advanced automation and informatics technologies, as well as our proprietary human sequence database (SeqCalling<sup>TM</sup>) consisting of more than 4 million sequences. Target selection is further refined through the integration of the targets gene expression and polymorphism profiles with our extensive protein:protein interaction database (PathCalling<sup>TM</sup>) and high-throughput tissue distribution characterization. A complete profile of the selected target can be rapidly engineered, dramatically reducing the non-productive consumption of resources while increasing the efficiency of selection. Further laboratory validation efforts are thereby directed toward targets that have the highest potential for successful downstream drug development or therapeutic intervention.

**Post sequencing gene discovery; novel genes in human chromosome 21 (HC21).** *S. Deutsch*<sup>1</sup>, *A. Reymond*<sup>1</sup>, *R. Lyle*<sup>1</sup>, *S. Antonarakis*<sup>1</sup>, *A. Camargo*<sup>2</sup>, *S. de Souza*<sup>2</sup>, *A. Simpson*<sup>2</sup>, *B. Stevenson*<sup>3</sup>, *C. Iseli*<sup>3</sup>, *P. Bucher*<sup>4</sup>, *V. Jongeneel*<sup>3</sup>. 1) Group A: Division of Medical Genetics, University of Geneva Medical School, Switzerland; 2) Group B: Ludwig Institute for Cancer Research, Sao Paulo, Brazil; 3) Group C: Ludwig Institute for Cancer Research, Epalinges, Switzerland; 4) Swiss Bioinformatics Institute, Epalinges, Switzerland.

The initial annotation of the complete sequence of HC21 revealed 151 genes and 79 predicted transcripts identified by gene prediction programs and the presence of spliced ESTs (Nature 405: 311, 2000). However, the gene identification strategy pursued for chromosomes 21 and 22, and for the rest of the genome is probably biased against genes with small ORFs, and/or large 5 and 3 UTR. In our effort to refine HC21 sequence annotation, we have re-analyzed the entire chromosome sequence incorporating new ESTs (including the ORESTES database), and a new algorithm for stringently mapping 3 polyadenylation tags. 3 tags were extracted using raw chromatogram data from EST projects, and were quality controlled by considering multiple factors including polyadenylation signals, position of polyA in the sequence, and presence of artifactual genomic priming sites. These 3tags represent unambiguous and reliable markers for transcripts. We built an HC21 ACE database in order to visualize all potential transcripts together with the 3 tags, CpG islands, repeats and protein domains all of which contribute to the identification of putative genes. We thus defined a restrictive set of criteria that allowed the identification of 27 previously undescribed candidate transcripts, which are being experimentally confirmed by full EST insert sequencing, 5 and 3 RACE, and RT-PCR. More than a third of these putative transcripts have already been verified, and one maps within a previous sequencing gap of HC21. The revised HC21 transcriptome will have implications for the rest of the genome concerning the quality of previous annotations and the total number of transcripts. It will also provide new candidates for genes involved in Down Syndrome and other genetic disorders that map to HC21.

**Multiple Comparison Analysis Program: further analysis of GeneChip data.** *Y.V. Kotliarov<sup>1</sup>, S.E. Kotliarova<sup>2</sup>, N. Nukina<sup>2</sup>.* 1) Research into Artifacts, Center for Engineering, University of Tokyo Tokyo, Japan; 2) Lab for CAG Repeat Diseases; Brain Science Institute, RIKEN, Japan.

Transcriptome analysis using microarrays became a powerful tool in various areas of genetics and molecular biology. Usually researchers face the problem of multiple comparisons of several control data with several experimental data (e.g. several control animals versus several transgenic animals). The task is to fish out really affected genes (e.g. differentially expressed in transgenics vs controls) among the noise data (due to individual variation or experimental error). There is lack of software which allows to fulfil this task at present. We developed the program Multiple Comparison Analysis (MCA), which makes possible such analysis and, using the power of comparison analysis of multiple pairs, extracts additional information from the comparison data provided by Data Mining Tool and Microarray Suite softwares (Affymetrix).

MCA is written using VBA on MS Excel-2000 and therefore can run on both Windows and Macintosh computers. Briefly, the software groups the data from several pair-wise comparisons into one class by the same probe set, counts the members in the class, checks the presence of signal in all pairs, checks consistency of differential expression among the members of the same class. In addition, it averages several parameters (such as average difference, fold change, etc) in a class and, finally, makes decision of overall change in pairs of the same class. MCA, combined with the advanced features of MS Excel (Microsoft), brings additional power to microarray analysis using GeneChip (Affymetrix) to mine efficiently important information from the huge amount of biological data. The software was tested and used in practical analysis by researchers of RIKEN and of the University of Tokyo.

**Annotation of the Human Genome: Use of the Genome as an Organizing Principle for Data Integration.** *N.*

*Litchfield*<sup>1</sup>, *N. Tsinoremas*<sup>2</sup>. 1) Marketing & Communications, DoubleTwist, Inc, Oakland, CA; 2) Computational Genomics Group, DoubleTwist, Inc, Oakland, CA.

Analysis of publicly available human genomic sequences has yielded a range of gene predictions sorted by type and depth of evidence. As there is no single accepted algorithmic methodology to identify human genes, we have created an analysis pipeline based upon a combination of ab initio gene finders and mapping of additional experimental evidence onto the genome. This pipeline is executed in a parallel mode to optimize our ability to predict human genes. The first line of experimental evidence used in this study was clustered human and mouse expressed DNA sequences (ESTs). Mapping this information onto the genome provides very strong indication of the existence of genes when such information is available. The second line of experimental evidence includes mapping of all known proteins that share significant similarity with human genomic sequences. This powerful approach allows us to identify genes based on protein similarities where the other methods fail to provide evidence of a gene. Furthermore, we synthesize all this information using a rule-based system that combines each type of evidence and generates reports with varying confidence levels with respect to the existence of genes in a particular position on the genome.

**"SNP-Cruncher": A Perl Script Toolbox for Large-Scale SNP Data Mining and its application on 13q32.** *C. Liu, E.S. Gershon.* Dept Psychiatry, Knapp Res Ctr, Univ Chicago, Chicago, IL.

As the Human Genome Project comes to its final stages, more than 93% of the draft human genome sequence has been deposited into public databases, and millions of candidate SNPs (Single Nucleotide Polymorphisms) have been discovered. This data is essential for association analyses of complex disorders. In order to explore approaches required for a small lab to analyze all available genome data related to a region, we targeted the SNPs in chromosome 13q32 where a Bipolar Disorder susceptibility locus has been reported. "SNP-Cruncher" consists of 65 Perl programs, integrated by hyperlinks in a Microsoft PowerPoint file (or, alternatively, in a web page). Two categories of programs are provided. One group is standalone tools, providing functions including SNP restriction enzyme analysis, primer evaluation, and homology-based SNP mapping/annotation. Another group is "bridge tools," providing the input data preparation and output data interpretation for existing genomic analysis programs, as well as database contents preparation and update. With these "bridge tools," publicly available software (such as BLAST, RepeatMasker, Phrap, Primer3, Sim4, Vector NTI, and DNASTAR, etc.) can be used to analyze thousands of sequences easily. We analyzed 6349 SNPs on 13q32 from NCBI dbSNP. 21% of the SNPs were found to be duplicated or closely mapped. 40% of the SNPs were found to be suitable for PCR-RFLP analyses with inexpensive enzymes (one of the Perl programs of SNP-Cruncher). 57.5% of the SNPs analyzed contain more than 60% repeat sequences, and consequently may be unsuitable for use. 3.6% of the SNPs (226 SNPs) matched transcript sequences, and therefore may be potential cSNPs. A local database storing data for further systematic marker selection is generated as part of the analyses, and can carry annotation forward when new genomic or expressed sequence becomes available.

**Molecular dissection of the contribution of single genes to changes in global gene expression in Down syndrome.**

*R. Lyle<sup>1</sup>, R. Chrast<sup>1</sup>, C. Gehrig<sup>1</sup>, P. Chanson<sup>1</sup>, C. Hendrich<sup>1</sup>, H. Scott<sup>2</sup>, S. Antonarakis<sup>1</sup>.* 1) Department of Medical Genetics, Centre Medicaire Universitaire, Geneva, Switzerland; 2) Walter and Eliza Hall Institute, Melbourne, Australia.

Down syndrome (DS) or Trisomy 21 is the most common genetic cause of mental retardation, occurring in approximately 1/700 live births. In addition, there are other neurological phenotypes associated with DS, including brachycephaly, microcephaly and early onset Alzheimer's like disease. The presence of an extra copy of certain but not all of the approximately 250 genes on HC21 is likely to contribute to the DS phenotype. HC21 is largely syntenic with a region of mouse chromosome 16 and thus a partial trisomy 16, Ts65Dn, acts as a model of DS and shares many of the DS phenotypes. We have used Serial Analysis of Gene Expression (SAGE) and filter microarrays containing ~25,000 mouse genes and ESTs to analyse changes in gene expression in whole brains of Ts65Dn mice. Both analyses revealed complex changes in gene expression. Several lines of evidence suggest that dysregulation of the signal transduction cascades of Sim2 and Dyrk (Mnbh), a transcription factor and kinase respectively, are likely to be involved in development of DS phenotypes. To help dissect the contribution of the Sim2 and Dyrk to the Ts65Dn expression pattern, we have overexpressed their cDNAs in cell culture using adenoviral infection and analysed induced changes in gene expression using mouse filter arrays. A combination of these in vivo (Ts65Dn) and in vitro (Sim2 and Dyrk adenoviruses) data compared to controls should allow us to begin to decipher the molecular cascades leading from gene triplication to the complex DS phenotype.

**Molecular characterization of the human fovea using gene expression profiling and bioinformatic analyses.** *P.S. Lagali<sup>1</sup>, B.A. Wilton<sup>1</sup>, G.D. Lutzak<sup>1</sup>, D.K. Patterson<sup>1</sup>, K.R. Robson<sup>1</sup>, S.L. Bernstein<sup>2</sup>, P.W. Wong<sup>1</sup>*. 1) Department of Biological Sciences, University of Alberta, Edmonton, Alberta, Canada; 2) Department of Ophthalmology, University of Maryland, Baltimore, MD.

The human fovea is a small region of the retina containing the highest density of cone photoreceptor cells and is responsible for mediating fine visual acuity. Many inherited retinal disorders involve the dysfunction or degeneration of cells comprising the fovea, particularly diseases of the macula, which represent the most common cause of blindness in the developed world. To gain insight into the normal biology of the fovea, and to uncover potential contributing factors in the progression of retinopathies, several approaches were taken. A primary human fovea cDNA library was differentially screened to identify fovea-expressed genes that are associated with a particular tissue distribution, species specificity, and temporal expression pattern. Such analysis identified a number of genes characterized by neural tissue-enriched expression, sequence conservation across diverse species, or exhibiting age-related changes in expression level. These in turn represent genes that may be critical for fovea function and that are also possible candidate genes for retinal disorders affecting the foveal region. In addition, a macroarray containing 18,394 unique human ESTs was screened with human fovea total cDNA in order to identify fovea-expressed genes. 500 of the ESTs representing high to moderate abundance transcripts were further analyzed to determine their cytogenetic locations, thus enabling the creation of a primary transcript map of the human fovea. The genetic map locations of several of the corresponding putative genes coincide with chromosomal intervals to which retinal diseases have been mapped, thereby identifying potential candidate genes for these disorders. The methods utilized in this investigation have enabled molecular characterization of an understudied ocular tissue and have provided tools for the identification of possible disease genes that play a role in its dysfunction. [Supported by CIHR, AHFMR, the E.A. Baker Foundation of the CNIB, Foundation Fighting Blindness-Canada and NSERC].

**Enhanced Performance of SeqScape™ Software Version 1.1 for Comparative DNA Sequencing Analysis and**

**Mutation Detection.** *C. Kosman*<sup>1</sup>, *G. Chappell*<sup>2</sup>, *J. Sorenson*<sup>2</sup>, *Q. Doan*<sup>2</sup>, *P. Suri*<sup>2</sup>, *R. Paul*<sup>2</sup>, *B. Kshirsargar*<sup>2</sup>, *A. Sauve*<sup>2</sup>, *G. Mason*<sup>2</sup>, *P. Honebein*<sup>4</sup>, *G. Denisov*<sup>5</sup>, *M. Schoppe*<sup>3</sup>, *A. Pronayev*<sup>3</sup>, *V. Bawge*<sup>4</sup>, *L. Johnston-Dow*<sup>2</sup>. 1) Genetic Analysis, Applied Biosystems, Foster City, CA; 2) Informatics, Applied Biosystems, Foster City, CA; 3) Group Logic, Arlington, VA; 4) Systems Integration Solutions, San Francisco, CA; 5) Paracel, A Celera Company, Pasadena, CA.

SeqScape™ software is a Windows NT®- and 2000®-compatible program containing completely integrated base calling, sequence assembly, alignment and comparison tools which allow for the rapid and accurate analysis, and alignment of multiple sample sequences containing mixed-base positions against a reference sequence. Version 1.1 of this software contains several important feature enhancements to increase the quality of the analysis results and decrease user intervention. Specifically, the accuracy of base calling is increased through the use of TraceTuner™ Version 2.0 which supplies superior mixed-base calling and per-base confidence values. While the accuracy of consensus generation is significantly improved through the use of a novel comparative sequencing consensus caller with per-base confidence values and new algorithms for data trimming. Results from the performance evaluation of this new software tool on several challenging comparative sequencing data sets are shown. For these analyses, this new application produced superior results while providing substantial performance advantages over other similar assembly programs tested. In all cases, the innovative base calling and sequence assembly features included in SeqScape™ software Version 1.1 resulted in improved base calling and assembly accuracy, less manual data manipulation and shorter turnaround times for the complete analysis of comparative sequencing projects.

**Improved Quantitation of Affymetrix GeneChip Microarray Data.** *B.L. Merriman, Z. Chen, S. Nelson.* Human Genetics, UCLA, Los Angeles, CA.

The Affymetrix GeneChip is a commercially available DNA microarray system for large scale gene expression analysis in human, mouse and other organisms. The technology is based on the ability to synthesize short oligo DNA probes (25-mers) at high density (400,000 distinct probe spots on a 1.3 cm. square) on a glass substrate. In the GeneChip system, each gene being monitored is represented by many oligo probes---typically 32-40 probes per gene, with half of these being 25-mer sequences from the transcript, and the other half obtained by introducing a single base change into each of these sequences. The analysis software reduces these 40 hybridization signals per gene into a single measurement of gene expression level, the "Average Difference", which is the average of the differences in hybridization signal between the match and mismatch probes. There is little published data that validates this approach to producing a single gene expression number from the 40 measurements available. Moreover, in mammalian experiments, it can be seen that the oligo probes within an expressed gene are highly variable in how well they "work", i.e. in their binding affinities and specificities. For example, it is not unusual to see the match probe intensities vary by a factor of 10 within a gene, or to see a mismatch probe give more signal than the corresponding match probe. Also, the Average Difference measurement of gene expression typically does not show as large a range of variation as more direct experimental measurement techniques, such as SAGE or EST counting. This suggests that there may be more accurate ways of extracting gene expression information from the underlying oligo hybridization signals provided by the GeneChip System. We investigate this possibility in detail, based on the analysis of over 100 human GeneChip experiments. We show a variety of performance statistics for the oligo probes, and present several ways of obtaining more consistent and accurate expression measurements. We also compare these quantitation methods with SAGE and EST counting results. By creating a customized .CEL data file, these alternative gene expression measures can be input into the Affymetrix Analysis Suite software for data mining purposes.

**A complete mutation analysis panel of the 39 human HOX genes.** *K. Kosaki<sup>1</sup>, R. Kosaki<sup>2</sup>, K. Sasaki<sup>1</sup>, H. Yoshihashi<sup>1</sup>, M. Tomita<sup>3</sup>, N. Matsuo<sup>1</sup>.* 1) Department of Pediatrics, Keio University School of Medicine, Tokyo, Japan; 2) Department of Medical Genetics, Saitama Children's Medical Center, Iwatsuki, Japan; 3) Laboratory for Bioinformatics, Keio University, Fujisawa, Japan.

The HOX gene family consists of highly conserved transcription factors that specify the identity of the body segments along the anteroposterior axis of the embryo. Because the phenotypes of mice with targeted disruptions of Hox genes resemble some patterns of human malformations, mutations in HOX genes have been expected to be associated with a significant number of human malformations. Thus far, however, mutations have been documented in only 3 of the 39 human HOX genes (HOXD13, HOXA13, and HOXA11). In the present study we took advantage of the human and mouse draft genome sequences to determine the genome structure of 17 human HOX genes. When neither human nor mouse full coding cDNA sequences were available in the GenBank database, the phylogenetic footprints of the HOX clusters were delineated by comparison of the human genome sequence containing the HOX cluster with the corresponding mouse genome. In addition, the genomic region with coding potential was selected by probabilistic prediction method of the coding sequences. Based on this sequence information, we successfully developed a set of PCR primers to amplify the entire coding region of each of the 39 HOX genes from genomic DNA in 125 amplicons. Our results indicate the usefulness of bioinformatic analysis of the draft genome sequences for clinically oriented research projects. It is hoped that the mutation panel provided here will serve as a launchpad for a new discourse on the genetic basis of human malformations.

**An Independent Evaluation of the Human Genome Sequence.** *J.R. Lupski, K.C. Worley, N. Katsanis.* Baylor College of Medicine, Houston, TX, USA.

In June 2000, the completion of a draft version of the human genome comprised of multiple short contigs which encompass 85% or more of euchromatin was announced and the detailed findings of the sequencing consortium were reported several months later. The new information will allow global questions to be addressed, such as total gene numbers and a more accurate definition of gene families. Of equal importance, however, are positional questions such as local genome architecture, regional gene density, and location of transcribed units, the latter being critical for disease gene evaluation. We have performed a series of mapping and computational experiments using a non-redundant collection of 925 ESTs and the draft genome sequence available at different time points between April 2000 and May 2001. By comparing our EST mapping information obtained from two independent physical mapping methods to that obtained from sequence matches to draft genomic sequence, we estimated the percent of EST clones that could be mapped, and the ability to use genome information to map accurately any given EST. We have found substantial discrepancies in both the coverage of the human genome and the accuracy of mapping of genomic clones which suggests some limitations of the draft human genome sequence in providing positional information and detailed characterization of chromosomal subregions.

Program Nr: 1570 from the 2001 ASHG Annual Meeting

**Mouse Genome Database: Curation Strategies for Alleles and Phenotypes in the Mouse.** *C.L. Smith, J.A. Blake, J.E. Richardson, J.A. Kadin, J.T. Eppig and the Mouse Genome Informatics Group.* Mouse Genome Informatics, The Jackson Laboratory, Bar Harbor, ME. (<http://www.informatics.jax.org/>).

The Alleles and Phenotypes section of The Mouse Genome Database (MGD) seeks to represent mouse mutants and models of human genetic disorders and associated phenotypic characteristics in a robust yet easily searchable format. In addition, MGD provides integrated access to extensively curated data on the genetics, comparative genomics and mapping of these mouse mutants as well as gene expression data from the Gene Expression Database (GXD) and tumor biology from the Mouse Tumor Database (MTB).

A major effort is underway to create a structured, controlled vocabulary to describe phenotypic abnormalities in the mouse. In addition to facilitating computational data curation and mining, this set of terms will expedite curation of and queries for phenotypic information in MGD. The terms will also enhance integration between phenotypes and other relevant information, such as genes, expression data, and comparative maps. Furthermore, the vocabularies will be structured to allow complex queries involving multiple characteristics or expression and mapping data that are difficult to retrieve by plain text searches. Standard vocabularies are especially important due to the rapid production of phenotypic mutants generated at the distributed ENU mutagenesis centers.

A further refinement in allele curation is the adoption of standardized allele and transgene nomenclature in curated data sets, providing databases and investigators a mechanism to name and differentiate similar mutations. Allele nomenclature guidelines are set by the International Committee on Standardized Genetic Nomenclature for Mice.

MGD is supported by NIH/NHGRI grant HG00330.

**A Tabu Search Algorithm for Gene Selection in Whole Genome Functional Analysis.** *M. Sun*<sup>1</sup>, *M. Xiong*<sup>2</sup>. 1) Business, University of Texas at San Ant, San Antonio, TX; 2) Human Genetics Center, University of Texas - Houston, Houston, TX 77225.

Completion of the human genome sequence marks a switch from a genome sequence era to an age of functional genomics and will have a profound impact on biomedical research. Currently, the major tools for mapping disease genes are based on meiotic mapping within the paradigm of positional cloning. A road less traveled is functional analysis. How to systematically and efficiently identify disease-associated genes and biomarkers of drug action using whole genome gene expression profiles obtained from DNA chip has not been fully explored. In this report, we will propose to use classification as a general framework and to develop feature wrappers and filters as major statistical methods for gene selection. Since whole genome gene expression profiles, in general, involves thousands or even ten thousands of genes, both feature wrappers and filters, incurs the high computational cost of conducting a search through the huge space of feature subsets. To develop efficient algorithms to search subsets of genes with the optimal criterion values is essential to the success of disease-associated genes and biomarker discovery. In this talk, we will present a novel search algorithm for feature selection which is computationally less expensive and is able to search global optimal subsets of genes and biomarkers. Unlike traditional feature selection algorithms which search only an optimal subset, the search algorithms in our biomarker and gene identification problem should be adapted to finding all possible optimal subsets of genes.

**The Generalized T2 test for Biomarker Identification Using Gene Expression Data.** *J. Zhao, M. Xiong.* Human Genetics Ctr, Univ Texas Houston, Houston, TX.

The identification of specific targets for diagnostic or therapeutic use has been a principle goal for both clinicians and biomedical researches. So far, in biomedical research, major methods for identification of disease genes is based on positional cloning, and linkage and linkage disequilibrium analysis. Alternative approach to the discovery of disease genes and biomarkers for diagnosis of disease and measuring of drug efficacy and toxicity is whole genome functional analysis, which incorporates feature selection into gene expression pattern recognition. However, pattern recognition methods, in general, do not provide p-values to evaluate the significant evidence for biomarker identification. In this report, we propose a generalized T2 test and a sequence forward floating search algorithm for biomarker discovery. The proposed method not only can identify single biomarker, but also can identify a composite biomarker which consists of several genes. In this report, we will also reveal a close connection of the proposed T2 test statistic with the discriminant analysis. The proposed method will be applied to the real gene expression data sets.

**In Silico Cloning: the identification of genes within the CLN6 critical region.** *R.B. Wheeler<sup>1</sup>, J.D. Sharp<sup>1</sup>, R.A. Schultz<sup>2</sup>, S.E. Mole<sup>1</sup>, R.E. Williams<sup>1</sup>, R.M. Gardiner<sup>1</sup>.* 1) Dept Paediatrics, RFUCMS, The Rayne Institute, London, England; 2) Eugene McDermott Center for Human Growth and Development, University of Texas SouthWestern Medical Center, Texas, USA.

CLN6, the gene for variant late infantile neuronal ceroid lipofuscinosis, maps to a 1cM region on chromosome 15q22-23 between microsatellite markers D15S988 and D15S1000. A physical map of the region has been constructed and two PAC clones from the region have been fully sequenced at the University of Texas. A total of 316,633 base pairs of sequence have been deposited at <http://gestec.swmed.edu>. A set of overlapping BAC clones which span the entire 1 Mb CLN6 critical region have been identified by virtual STS content mapping using NIX (<http://menu.hgmp.mrc.ac.uk/Nix>) and the Human Genome Browser (<http://genome.ucsc.edu>). Using this data we identified additional simple repeats in silico using the program Tandem Repeat Finder (<http://c3.biomath.mssm.edu/trf.html>). Marker typing in informative families enabled us to reduce the critical region from 14 to only 9 BACs. Gene prediction and homology searches were performed on all sequences in the critical region and to date 10 genes have been identified. Of these 7 transcripts have homology to known genes and 3 represent novel transcripts. The coding sequences of 7 of these genes have been fully sequenced in a subset of the CLN6 patient resource and to date no mutations have been identified. We are using a variety of methods to identify further genes within the region including NIX gene predictions, Unigene homologies and ORF predictions from the Human Draft Browser Sequence. This has allowed us to identify a number of potential genes and we are currently testing these predictions in the laboratory.

**Microarray analysis of changes in skeletal muscle gene expression in response to insulin.** *G.P. Page<sup>1</sup>, V. So<sup>2</sup>, J. Ding<sup>2</sup>, L. Mainous<sup>1</sup>, J. Rosinski<sup>2</sup>, B. Rhees<sup>2</sup>, M. Martin<sup>2</sup>, W.T. Garvey<sup>1</sup>.* 1) Medical Univ. South Carolina, Charleston, SC; 2) Dept. Genomic and Info. Sci., Hoffmann-La Roche, Inc., NJ USA.

Insulin is one of the most important and powerful hormones in the human body. The binding of insulin to the insulin receptor causes a cascade of reactions including protein phosphorylation through the PI-3-kinase pathway and de novo transcription through the ras transcription activation complex. We have analyzed skeletal muscle biopsies from 55 individuals pre and post euglycaemic insulin clamp using the Affymetrix Hu95A-E microarrays to look for alterations in gene expression. We have identified 1009 genes (at  $p < 0.05$ ) as being differentially expressed in response to insulin many of which have interconnected functions. For example, in polyamine metabolism SLC7A5 (+1.8 Standard deviations) and SLC7A6 (+0.7 SD) transport arginine into the cell. ARG1(+0.57 SD) metabolizes arginine into ornithine and urea. ODC1 (+1.1 SD) converts ornithine into putrescine. AMD1 (+1.4 SD) metabolizes s-adenosylmethionine into decarboxylated s-adenosylmethionine, which is the primary substrate for converting putrescine into spermidine and spermidine into spermine. ODC1 degradation is inhibited by Antizyme inhibitor (+0.9 SD). The combined increased expression of SLC7A5, SLC7A6, ARG1, ODC1, AMD1, and antizyme inhibitor would be expected to greatly increase the intracellular levels of polyamines which are known to affect DNA methylation levels. S-adenosylmethionine also will donate a methyl group during DNA methylation via DNMT1 (+0.4 SD) and becomes S-adenosylhomocysteine, which may be metabolized into homocysteine and adenosine by AHCYL1 (+1.3 SD). Elevated homocysteine levels are common in type 2 diabetics and are a risk factor for cardiovascular disease. AHCYL1 expression is significantly elevated in insulin sensitive, insulin resistant, and type 2 diabetic individuals in response to insulin. The high levels of insulin seen in diabetics and insulin resistant individuals may induce the elevated plasma homocysteine levels seen in these conditions. Using DNA microarrays with proper experimental design can provide important insights into the pathophysiology of insulin action and diabetes.

**Developing an automated tool for characterizing EST sequences from a human cartilage-specific cDNA library.**

*D. Wheeler<sup>1</sup>, P. Hermanns<sup>1</sup>, C. Johnson<sup>1</sup>, M. Lee<sup>1</sup>, C. Stelzer<sup>2</sup>, B. Zabel<sup>2</sup>, A. Winterpacht<sup>3</sup>, R. Gibbs<sup>1</sup>, B. Lee<sup>1</sup>.* 1) Dept. of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Dept. of Pediatrics, University of Mainz, Mainz Germany; 3) Institute of Human Genetics, University of Hamburg, Hamburg, Germany.

Despite the huge number of EST sequences in the public domain, it is very likely that there are still some genes found in rare tissues that are under-represented. In order to find and characterize cartilage-specific genes, a pilot study was performed. A previously-generated human cartilage cDNA library derived from fetal 16 week to 2 year costochondral cartilage was prescreened for clones known to be abundantly expressed in this tissue. Five hundred "negative" clones were sequenced by the Human Genome Sequencing Center at Baylor College of Medicine and the output was used to develop an automated tool for identifying novel genes, which are specific for or predominantly expressed in cartilage. A limitation of single pass sequencing is that the sequence quality is highly variable and the reads may be error prone. The best available model for assessment of sequence quality comes from the program PHRED. A 2 pole Tschebysheff low pass filter was employed to improve precision and predictability of identification of the high quality region. This enabled simplified processing of the quality scores and assessment of high quality regions and lead to demonstrably more efficient detection of overlap sequences in EST data sets. Based on this trimming a search pipeline against public databases (mainly NCBI) was developed to divide the cartilage EST sequences into different groups. One group contains all ESTs which match already known and characterized genes. In another one group all ESTs are sorted to match sequences in the public EST databases, but whose gene identity is unknown. The last and most interesting group of ESTs do not match sequences in the public domain and may represent putative novel and/or cartilage-specific genes. In order to minimize false positives in the last group of ESTs, we have studied and optimized the effects of differing search parameters in each of the search steps.

**An equivalence test for comparing DNA sequences.** *H. Thijs<sup>1</sup>, K. Van Steen<sup>1</sup>, G. Molenberghs<sup>1</sup>, M. De Wit<sup>2</sup>, M. Peeters<sup>2</sup>*. 1) Center for Statistics, Limburgs Universitair Centrum, Diepenbeek, Belgium; 2) Tibotec-Virco, Mechelen, Belgium.

All genetic instructions of an organism are stored in code in its DNA. It is a linear molecule that can be seen as a necklace of simple building stones, called nucleotides and represented by the letters A (adenine), C (cytosine), T (thymine) and G (guanine). Recently lots of effort is put in the comparison between sequences of DNA and more specifically one is interested in testing equivalence between two or more sequences by means of statistical methodology. These statistical methods were first developed in the context of pharmacokinetics and later extended to the field of clinical trials (e.g., Dunnett and Gent, 1977). Nowadays, (bio)-equivalence tests are well-known in the drugs testing field, but less frequently used in other fields. Mc Bride (1999) claims that there appear to be few reported applications of equivalence tests in environmental science and management. We feel that also in statistical genetics, testing of interval hypotheses via equivalence test procedures needs a push forward.

Two different DNA sequences can be considered as ratings on several characteristics (loci). From this perspective, we are interested in the closeness or similarity of ratings as a measure of agreement. Closely linked to the concepts of similarity of ratings is the idea that the level of disagreement between any two ratings might be represented by some sort of distance measure. Here, distance should be seen as a measure in an abstract space that has the same mathematical properties as that used for the more familiar 3-dimensional physical world (Dunn, 1989). We therefore propose a Mahalanobis-type index which enables us to recognize a certain degree of uncertainty in the measurements. This uncertainty may be caused by missing observations, inaccurate measurements or ambiguity. After defining this new distance measure we will construct a proper testing procedure through simulation studies which validates the new procedure.

Program Nr: 1577 from the 2001 ASHG Annual Meeting

**Nomenclature: The language of Genomics.** *H.M. Wain, E.A. Bruford, R.C. Lovering, M. Lush, M.W. Wright, M.S. Povey.* HUGO Gene Nomenclature Committee, The Galton Laboratory, Department of Biology, University College London Wolfson House, 4, Stephenson Way London NW1 2HE.

"One gene, one name" is an important concept for accurate communication in genetic research. The HUGO Gene Nomenclature Committee (HGNC) has so far been responsible for naming one third of the genes estimated from the draft of the human genome sequence. With around 20,000 more genes to name we are investigating new initiatives that will give the greatest benefit to the scientific community, specifically recognising that flexibility is required and that names are no substitute for functional annotation. Recent discoveries have increased our understanding of the variety of functional molecules which can be generated from the human genome. Therefore, in line with recent requests, we propose to update our guidelines and policies, increasing the range of genomic features named. These include families of genes with constant or variable regions, which generate alternative proteins depending on their splicing assembly e.g. protocadherins. Better ways are also needed to identify untranslated mRNAs, antisense RNAs, ribosomal RNAs and genes only found within subsets of the population (usually formed by different duplication events). We are also considering nomenclature for other structures in the genome such as LINEs, SINEs and transposable elements. Decisions will be made on an individual basis, so that we can provide a nomenclature which fits the need researchers have to discuss these features. A first draft of the new guidelines will be found on the HUGO Gene Nomenclature Committee webpage at URL <http://www.gene.ucl.ac.uk/nomenclature/> from October 1st 2001. They will be discussed at the pre-ASHG Nomenclature workshop and made available at the ASHG meeting. We can be contacted by email at [nome@galton.ucl.ac.uk](mailto:nome@galton.ucl.ac.uk).

**A comprehensive online human genomic catalog.** *P.S. White<sup>1</sup>, E.P. Sulman<sup>1</sup>, E.P. Katz<sup>1</sup>, S. Sabuktagin<sup>2</sup>, C.J. Porter<sup>3</sup>, T.C. Matisse<sup>2</sup>.* 1) Dept Pediatrics, Children's Hosp Philadelphia, Philadelphia, PA; 2) Department of Genetics, Rutgers University, Piscataway, NJ; 3) Genome Database, Toronto, ON, Canada.

The identification of loci contributing to complex disease remains a central challenge of biomedical genetics. Upon assignment of a candidate disease locus to a specific chromosomal region, determination of the causal gene currently requires extensive bioinformatics and data mining skills, as available genomic and functional genomic datasets are often poorly integrated. To address this, we have developed a genomic data integration method and resource (eGenome) that comprehensively combines publicly available physical, genetic linkage, sequence, and functional genomic-based data sets into a unified data structure accessible via straightforward Internet queries. Utilizing a relational database, eGenome incorporates data sets from a large number of diverse sources, including GenBank, RHdb, the CEPH Genotype database, dbSNP, UniGene, LocusLink, cytogenetic data from the Genome Database, and large-insert clone data. These data were localized to specific chromosomal locations by three mechanisms: 1) construction of high-resolution, high-confidence radiation hybrid maps; 2) construction of all-inclusive genetic linkage maps; and 3) identification of exact sequence coordinates in human draft and finished sequence contigs. Genomic elements representing genes, markers, and polymorphisms were then normalized to remove redundancies and to identify and annotate discrepancies and errors in localizations. The eGenome process was applied to each human chromosome, resulting in placement and annotation of over 2.5 million elements. This resource has been made available to the general public through a website that provides keyword and positional queries using marker names, cytogenetic band positions, and sequence position. In addition to positional information, eGenome provides element-specific links to a large number of online databases and utilities, including Ensembl, UCSC/Golden Path, GenBank, OMIM, and BLAST. In this way, eGenome serves as a primary portal and data mining entry point for all position-oriented human genetic and genomic research. Access eGenome at <http://genome.chop.edu>.

**Automated classification of SNP genotyping results.** *J. Studebaker<sup>1</sup>, S. Alfisi<sup>1</sup>, W. Ankener<sup>1</sup>, D. Morris<sup>2</sup>, M. Phillips<sup>1</sup>.*  
1) Orchid BioSciences, Princeton, NJ; 2) GeneScreen, Inc., Dayton, Ohio.

High throughput, cost effective, and accurate SNP genotyping is a key to the study of diversity in genomes. We have created a prototype program that reduces the time consuming, costly effort required for human review of the genotyping data. We have used this program on 1.2 million individual assays run over a four-month period using the SNPIT™ single base extension technology on SNPstream 25K systems.

The final step in analyzing results from SNPIT genotyping is human review of a scatter plot with the results for multiple samples and a single SNP. The reviewer checks for low signals in samples, high standard deviations in the clusters (two homozygous and one heterozygous) and other features of the plot. The end result of the review is a grade of Pass or Fail for the results presented in the plot. To increase reviewing throughput, we developed a program that compiles statistics for each assay and classifies it on the basis of the statistics.

Our program groups the scatterplots into classes in a hierarchical method. Some classifications, like PCR failure, reflect operational characteristics, and others reflect characteristics of the SNPs themselves. We chose three classifications as automatic Fails, because the reviewers marked 100% of the results in these classifications as Fail. Accordingly, the program now automatically marks results in these classifications as Fail.

Major benefits from the program have been:

- 1) Elimination of the need to review plots in the classifications automatically marked as Fail
- 2) Presentation of all available plots in a particular classification consecutively, an approach that has proven to speed review

Our next goals are automatic grading of 90% of the plots and extension of the program to other systems that use the SNPIT genotyping technology.

**Analysis and validation of cDNA microarray expression data.** *D.N. Stivers<sup>1</sup>, H.G. Sung<sup>1</sup>, M.D. Story<sup>2</sup>, T. Burrows<sup>2</sup>.*  
1) Dept Biostatistics, U.T. M.D. Anderson Cancer Ctr, Houston, TX; 2) Experimental Radiation Onc, U.T. M.D. Anderson Cancer Ctr, Houston, TX.

The quality of data produced by cDNA microarray assays of gene expression can be uncertain. Issues include differentiating true signal from background noise, error whose variance varies non-monotonically as a function of signal level, and estimating the significance of differences in expression level. We describe a set of microarray experiments and statistical analyses testing the ability of microarray technology to resolve true differences between expression levels without finding spurious difference. We estimate background level parametrically, and combine this with non-parametric estimation of error in signal measurement in order to sort differences in expression levels according to their statistical significance. This includes the case when a gene is found to be "off" (i.e., below threshold) in some experiments, but "on" in others.

**The BiSC WayStation: A Centralized Structure for the Collection of Genetic Variations.** *S.A. Teebi<sup>1</sup>, C.J. Porter<sup>1</sup>, C.C. Talbot Jr<sup>2</sup>, A.J. Cuticchia<sup>1</sup>*. 1) Bioinformatics Supercomputing Centre, The Hospital for Sick Children, Toronto, ON, Canada; 2) The Johns Hopkins University School of Medicine, Baltimore, MD, USA.

The BiSC WayStation is a web-accessible centralized structure for the submission, peer-review, publication and release of genetic variation data. Backed by the HUGO-Mutation Database Initiative, it provides a consistent, flexible interface through which researchers anywhere in the world can report novel variations (both disease-causing mutations and silent polymorphisms such as SNPs) in any gene. Submission comprises a series of streamlined forms that closely follow MDI's recommendations for the content and quality control of variation reporting. Data relating to the variations source (reference), genomic context, DNA and quality are required for submission. Other, optional sections gather data on RNA, protein, populations, clinical features, and database cross-links. CGI scripts for verification of submission integrity are embedded into the submission forms and act as a first rudimentary validation step. Definitive validation is provided by the WayStation Review Network. This structure is made up of locus-specific database (LSDB) curators and orphan gene editors for genes not associated with an existing LSDB. Each member of the Review Board is appointed by the MDI to review submitted variations in a specific gene; they do so via a Reviewer module on the website. Coordinated by MDI, recruitment of a complete Review Board has begun and is ongoing.

It is our intention to make submission via the WayStation equivalent to peer-reviewed publication. To this end, we are currently in discussion with the journal *Human Mutation* and the National Library of Medicine to issue *Human Mutation* IDs and PubMed IDs to WayStation submissions. If implemented, these IDs would act as a record and proof of a valid submission, and, significantly, as an incentive to submit to the WayStation. After validation, the WayStation releases published submissions to the appropriate LSDB, HGBASE, and other databases such as dbSNP and OMIM. A demonstration version of the WayStation may be accessed at <http://www.centralmutations.org/>.

**Characterization of Alu distribution in the working draft sequence of the human genome.** *J.E. Stenger, H. Xu.*  
Center for Human Genetics, Duke University Medical Center, Durham, NC.

We have characterized all Alu pairs on each of the human chromosomes using the December 12, 2000 freeze of the human genome draft sequence at UCSC as the data source. Alu data was incorporated into a MySQL database. By querying our database, we identified inverted Alu pairs that were closely-spaced (<20 bp), full length (> and shared high sequence identity as experiments in a yeast model system demonstrated that such Alu pairs were unstable and thus could be a source of genomic instability in humans. Of the 523, 772 Alus pairs in the human genome that were separated by less than 650 bp, 243 were potentially unstable; many of which were intergenic and thus had the potential to cause Alu mediated rearrangements that could result in genetic disease. We also looked at the relationship between Alu content and gene content. Chromosome 19 had by far the greatest number of Alus per bp (756 vs. 195 Alus per bp in the genome). Although chromosome 19 has 2.8 times the gene density of the average chromosome and 3.9 times the number of alu pairs averaged over the genome, there was not a strict correlation between Alu content and gene density. Chromosomes 19, 7 and 16, respectively, had the greatest density of Alus per gene content of the chromosome, while chromosome 7 has less genes per Mb than the average. When we looked at the frequency of particular groups of subfamilies in GC rich regions we observed that the FLA\* subfamily was least represented among regions containing more than 46% GC content, followed by the Y\* subfamily, the J\* subfamily, and the S\* subfamily, while uncharacterized Alus were the most represented. The order was inverted when the GC content fell beneath 38% GC. Interestingly, among individual subfamilies, Alu-Sbcg was by far the most abundant in regions containing greater than 54% GC content.

**Integration of rat, mouse and human EST and comparative maps.** *T.E. Scheetz<sup>1</sup>, M.R. Raymond<sup>2</sup>, A. McClain<sup>2</sup>, M.B. Soares<sup>3</sup>, T.L. Casavant<sup>1</sup>, V.C. Sheffield<sup>2</sup>.* 1) Electrical and Computer Engineering, Univ Iowa, Iowa City, IA; 2) Pediatrics and HHMI, Univ Iowa, Iowa City, IA; 3) Physiology, Univ Iowa, Iowa City, IA.

We have created a set of integrated EST and comparative maps for the human, mouse and rat. These maps consist of almost 60,000 radiation hybrid mapped genes and ESTs across all three species. Specifically, they consist of over 14,000 RH-mapped rat ESTs generated locally at The University of Iowa (1), 12,000 RH-mapped mouse ESTs available from the mouse RH map site at MIT (2), and more than 30,000 mapped human ESTs and genes from GeneMap99 (3). This mapping data was used to identify syntenic segments between each pair of species separately, as described in (4). At least two elements from each species must co-localize before a syntenic segment is defined.

The results of this comparative analysis were then integrated into a comprehensive database with a dynamic, web-accessible interface that is publicly accessible via <http://ratEST.uiowa.edu/>. This resource is expected to be useful in better utilizing the available animal models of human diseases.

Planned extensions to this research include integration of disease interval annotation, and the integration of genomic sequence for all three species as it becomes available.

**Integration of draft sequence data into the Genome Database (GDB).** *W. Zhu<sup>1</sup>, C.C. Talbot Jr.<sup>2</sup>, C.J. Porter<sup>1</sup>, K. Li<sup>1</sup>, S. Murthy<sup>1</sup>, A.J. Cuticchia<sup>1</sup>.* 1) Bioinformatics Supercomputing Centre, The Hospital for Sick Children, Toronto, ON, Canada; 2) Genome Database, The Johns Hopkins University School of Medicine, Baltimore MD, USA.

For the past ten years, the Genome Database (GDB) has presented human genome mapping data to the research community. During this period, as the resolution of the available maps has increased, GDB moved from providing only cytogenetic localizations to displaying linkage, radiation hybrid and contig maps. Further developments allowed us to display our own integrated comprehensive map, and more recently sequence feature maps that position markers on the evolving draft sequence contigs by electronic PCR.

We are now working to integrate positional data from the draft sequence more closely with the mapping data already in GDB. We have created a draft sequence database that stores the positions of GDB objects on the sequences of the Golden Path and NCBI contigs. A browser application allows the contigs to be searched for specific markers, and extensive links between the browser and GDB allow rapid retrieval of additional information. This allows the user to move easily and rapidly from the sequence data to GDB's extensive curated information. The contigs can also be searched with positional queries, or browsed on a chromosome-by-chromosome basis.

When moving from GDB to the sequence browser, or searching the browser for a particular marker, the user can choose to compare positions within the two contig assemblies currently stored. The database makes it possible for further assemblies to be displayed alongside.

The integration of this new resource into GDB provides a site where researchers can compare mapping results based on sequence, and on more traditional mapping methods. We are investigating ways of displaying these comparisons to researchers in a meaningful way.

**The skeletal genome anatomy project (SGAP).** *T.M. Teslovich<sup>1</sup>, D.P. McKeane<sup>1</sup>, K.E. Pearson<sup>1</sup>, C. Francomano<sup>2</sup>, R. Hotchkiss<sup>3</sup>, D.A. Stephan<sup>1</sup>.* 1) Research Center for Genetic Medicine, Children's National Medical Center, Washington, D.C. 20010; 2) National Institute of Aging, NIH, Bethesda, MD 20892; 3) OrthoGene, Inc. and the Hospital for Special Surgery, NY, NY 10021.

Diseases pertaining to skeletal tissue affect millions of Americans. Most notable is osteoporosis, which afflicts 8 million women and 2 million men in the United States; an additional 18 million Americans have low bone mass and are at risk of developing the disease. Osteoporosis is responsible for more than 1.5 million fractures annually, including 300,000 hip fractures. Within one year of hip fracture, up to 20% of victims will die, 25% of survivors will be confined to long-term care facilities, and 50% will experience long-term loss of mobility. Osteoporosis-related health care costs are estimated at \$14 billion annually, and osteoporosis-related injuries significantly decrease the quality of life for millions of people. While factors such as diet, exercise, and smoking have great influence, research at the National Institutes of Health indicates that genetics may determine up to 80% of a person's risk for osteoporosis. To facilitate the identification of genes involved in osteoporosis and other skeletal diseases, cDNA libraries have been constructed for the purpose of generating full-length coding sequence for skeletal genes. The RNA source for the libraries is fracture-related tissue undergoing healing, which presumably contains most skeletal cell lineages and will allow us to capture the majority of expressed genes. We have clustered 3' reads, identified clones containing full-length inserts via 5' sequencing and informatics, and these unique clusters will be used to construct a custom Affymetrix expression array. The array will be used as a template to screen clinical disease samples. It is hypothesized that novel, highly-differentially regulated genes will be identified which predispose to osteoporosis. In addition, our information platform will be applied to understand why younger patients heal bones faster than older patients and to gain insight into other skeletal disease processes for which there is a known genetic component. The end goal is the design of diagnostics and therapeutics.

**Development of a microarray-based assay for imprinting in the CNS.** *V.L. Buettner<sup>1</sup>, M.E. Barish<sup>2</sup>, J.R. Mann<sup>1</sup>, J. Singer-Sam<sup>1</sup>*. 1) Division of Biology, Beckman Research Institute, Duarte, CA; 2) Division of Neuroscience, Beckman Research Institute, Duarte, CA.

Although imprinted genes play a role in CNS development, and certain genetic disorders of the CNS show a pattern of inheritance demonstrating that imprinted genes are involved, there is no effective screening method for imprinted gene expression. We are therefore focusing on the establishment of a high-throughput assay that would allow the discovery of novel imprinted genes as well as the interrogation of multiple genes in different regions of the CNS and at various developmental stages. The method relies on crosses of mouse strains carrying balanced translocations of chromosomal regions of interest. The resulting progeny include a subset carrying only maternal or paternal copies of the chromosomal regions; the gene expression profile of these two sets of progeny can then be compared by use of high density DNA microarrays. As a model system, we are analyzing RNA from neonates carrying only maternal or paternal copies of proximal chromosome 7, including the chromosomal region corresponding to the human Prader-Willi/Angelman Syndrome domain. To establish the validity of the assay and optimize conditions, we have designed a custom oligonucleotide microarray. In addition to probes for housekeeping genes and known imprinted genes expressed in the CNS, the microarray contains 300 probes for other genes relevant to CNS function, including ~40 that map to proximal chromosome 7. We have thus far demonstrated the reproducibility of the method, and confirmed imprinting of two genes expressed in cerebellum, *Ndn* and *Snrpn*. To establish the limits of sensitivity of the technique, we are currently using the custom microarray to analyze imprinted gene expression in different regions of neonatal brain, and comparing the results with those obtained by quantitative RT-PCR.

**Identification of novel AAA genes as candidate genes for neurologic disorders.** *P. Hedera<sup>1</sup>, X. Zhao<sup>1</sup>, J.K. Fink<sup>1,2</sup>.*  
1) University of Michigan, Department of Neurology, Ann Arbor, MI; 2) Geriatric Research Education Clinical Center, Ann Arbor Veterans Affairs Medical Center.

AAA (ATPases Associated with various cellular Activities) is a diverse superfamily of proteins characterized by the presence of highly conserved AAA motif, including Walker homology sequences and ATP binding consensus. AAA proteins have been shown to play a role in different functions, including protein degradation, organelle biogenesis, vesicle mediated protein transport and regulation of the cell cycle. Recently, two novel AAA genes have been shown to cause autosomal recessive (AR) hereditary spastic paraplegia (HSP) linked to chromosome 16q24.3 (paraplegin) and autosomal dominant (AD) HSP linked to chromosome 2p22-p21 (spastin). Homology between these two new AAA-family members was limited to the AAA domain. At least 11 additional genes have been mapped as a cause of AR or AD HSP. Phenotype of HSP is typically stereotypical with spastic weakness of lower extremities. We hypothesized that genes causing other types of HSP may also belong to the AAA family. To test our hypothesis, we designed degenerated PCR primers based on the conserved 120 amino acids motif containing the ATP binding consensus domain to systematically clone and characterize genes of the AAA family from the human brain. cDNA from both adult and fetal brain cDNA libraries were first amplified with vector primers and used for amplification with the degenerated primers. PCR products of expected size (about 320 bp) were cloned and analyzed. We analyzed a total of 649 clones by hybridization and DNA sequence analysis and identified several known AAA genes, which include proteasome 26 and delta subunits, peroxisomal biogenesis factor 6, spastin and paraplegin-like protein AFG3. Known genes accounted for 90% of all clones. We also identified 25 unique DNA inserts representing novel AAA genes. None of these novel genes mapped to identified HSP loci. These novel AAA genes, expressed in the fetal and adult brain, may be potential candidates for unidentified HSP loci and other neurological disorders.

**Gene Expression Mapping of Various Regions of the Adult Human Brain.** *M.A. Vinores, M.H. Polymeropoulos, C. Lavedan.* Pharmacogenetics, Novartis Pharma Corp, Gaithersburg, MD.

Despite recent advances in Neurogenetics, and in particular the discovery of genes involved in common neurodegenerative disorders such as Alzheimer's and Parkinson's disease, our understanding of the genetic influence and the molecular mechanism of neurological disorders is still limited. The purpose of this study was to determine gene expression profiles of various regions of the adult human brain and to identify genes specifically expressed in these regions. This information would be helpful in better understanding neuronal molecular pathways and the etiology of various neurological disorders and to aid in designing new therapies. Six different regions from the adult human brain were analyzed: cerebellum, thalamus, corpus callosum, caudate nucleus, hippocampus and amygdala. The samples were hybridized to the Affymetrix U95A array containing approximately 12,000 probe sets. Gene expression profile of these various brain samples were compared to each other as well as to a variety of different human tissues. Comparisons of profiles were performed using the in-house Novartis Pharmacogenetics Network (NPGN) database. Gene expression profiles were also analyzed using GeneSpring 4.0.1a software to identify clusters of co-regulated genes within each of the six brain regions. Approximately 300 genes were found to be expressed at a significantly higher level in the human brain than in a variety of other normal human tissues. The number of genes expressed specifically in a single brain region did not exceed 40. These findings provide a global atlas of gene expression in distinct regions of the brain. This gives a new insight into the molecular mechanisms implicated in brain functions, as well as candidate genes that may be involved in common diseases such as Alzheimer's disease, schizophrenia or other psychiatric disorders.

**Expression profiling of the cardiovascular system by the microarray technology.** C.-H. Yi<sup>1</sup>, M. Schinke<sup>1</sup>, J.-H. Kim<sup>2</sup>, P. Jay<sup>1</sup>, T. Shioi<sup>1</sup>, M. Wripple<sup>2</sup>, A. Butte<sup>2</sup>, L. Riggi<sup>1</sup>, D.I.-B. Chen<sup>1</sup>, I.S. Kohane<sup>2</sup>, S. Izumo<sup>1</sup>. 1) Cardiovascular Div, BIDMC, Harvard Medical School, Boston, MA 02215; 2) Children's Hospital Informatics Program, Harvard Medical School, Boston, MA 02215.

We have initiated applying the DNA microarray technology to the expression profiling of the cardiovascular system in various developmental, physiological and pathological states. The gene expression levels of the mouse hearts have been measured by cDNA microarray (Incyte) and oligonucleotide array (Affymetrix). For more reliable signal intensity values and gene identities, various low-level analyses and corrections of raw data from microarray hybridization have been performed. Based upon these refinements, the transcriptomal analysis that utilizes two-point and multiple-point analyses both in combinatorial or novel ways was schematized and performed for the framework of data analysis and interpretation, which are informative of global cellular states or changes, and are harmoniously connected to the follow-up studies with the hypotheses generated. The dataset from the heart undergoing transition from embryonic stage to adulthood and that of a mouse dilated cardiomyopathy model induced by a dominant negative H-Ras in the heart were arbitrarily chosen. The mouse heart undergoing the transition showed a comparatively large transcriptomal alteration, confirming the initial prediction that the cell-division related genes, for example *Cdc2*, *Cdc28*, *Pcna*, be significantly down-regulated. The negative H-Ras mouse model showed a comparatively small change both in gene numbers and in the extent of expression changes, revealing the up-regulation of conventional hypertrophy marker genes, *ANF* and *BNP*. Many new genes that have never been characterized and uncharacterized, up to now, in the cardiovascular system showed significant changes in expression levels. *Cbfa1*, a transcription factor characterized in osteogenesis, was implicated both in the late heart development and the dilated cardiomyopathy. The transcriptomal analysis also revealed that interferon gamma signaling is likely to play important roles both in the cardiac development and in the dilation/hypertrophy process of the negative H-Ras mouse model.

**Identification of noise factors in expression profiling.** *M.A. Bakay, R. Borup, Y. Chen, E.P. Hoffman.* Research Center for Genetic Medicine, Children's National Medical Center, Washington DC.

Expression profiling is increasingly utilized as a genome-wide approach for defining the downstream effects of biological variables on gene expression. We investigated Duchenne dystrophy by comparing expression profiles for 2 groups of DMD patient: 5-6 and 10-12 year old to define the source of variability (experimental, intra-patient (tissue), inter-patient (SNP noise) and disease progression). The analysis group was 34 MuscleChip profiles from 8 controls and 10 dystrophin-deficient patients (5 patients in each age group). Each MuscleChip array contained 4,601 probe sets corresponding to 3,369 distinct genes and ESTs expressed in human muscle. Variables tested included 2 different regions of the same biopsy on duplicate MuscleChip (20 profiles), and mixed patient hybridization cocktails (10 profiles). Unsupervised hierarchical clustering of the 34 profiles showed that the greatest source of variability often originated from different regions of the same patient muscle biopsy. This suggests tissue heterogeneity is a major confounding variable in interpretation of expression profiling data. Mixed patient samples showed the highest concordance of duplicate profiles, showing that tissue heterogeneity and SNP noise variability could be normalized by experimental design. We used a two-sample t-test in GeneSpring software to analyze individual profiles and specify differentially expressed genes that could distinguish between group 5-6 and 10-12 year old DMD patients. We also used our four-fold iterative survival method to obtain fold changes for mixed profiles. Both methods showed patient age was not a predictable variable in expression profiles, despite the fact that this was a progressive disease. In conclusion, we showed by using the custom skeletal muscle-specific GeneChip that variables effecting expression profiles were: tissue heterogeneity>>inter-patient variability>>age of patient. Furthermore, our data showed mixing of patient samples prior to profiling is a valid method for normalizing both inter- and intra-patient variation when studying disorders of known primary etiology preserving most significant and specific gene expression changes.

**Global Analysis of Gene Expression in Inherited Human Craniosinostosis.** *T.S. Zorick<sup>1</sup>, A.Y. Fernandes<sup>4</sup>, P. Turma<sup>2</sup>, H. Matsushita<sup>3</sup>, S. Zanini<sup>5</sup>, A. Palhares<sup>6</sup>, M.R. Passos-Bueno<sup>1</sup>.* 1) Biology, University of Sao Paulo, Sao Paulo, Sao Paulo, Brazil; 2) Plastic Surgery, Hospital das Clinicas, Sao Paulo, Brazil; 3) Neurosurgery, University of Sao Paulo, Sao Paulo, Brazil; 4) Neurosurgery, USP-Bauru, Sao Paulo, Brazil; 5) Craniofacial Surgery, USP-Bauru, Sao Paulo, Brazil; 6) Plastic Surgery, USP-Botucatu, Sao Paulo, Brazil.

Inherited human craniosynostoses are one of the most common inherited human birth defects, occurring in about 1 in every 2500 births. Recently, many craniosynostotic syndromes have had their causative mutations mapped to genes for Fibroblast Growth Factor Receptor (FGFRs) 1-3. However, despite extensive knowledge about the primary genetic changes responsible for the conditions, considerable overlap and clinical variability exists with regards to clinical outcome and phenotypic severity even among individuals possessing identical mutations. We are using fibroblasts cultured from surgical specimens taken during normally scheduled corrective surgeries to perform the SAGE technique in order to understand the pattern of gene expression among the various conditions. We have found some preliminary differences in gene expression between normal human fibroblastic cultures and cultures taken from a patient with nonsyndromic craniosynostosis. We hope to extend this study to other samples taken from patients with identifiable mutations and typical syndromic clinical conditions in the future.

**Evidence for interchromosomal recombination errors as a factor in the duplications of chromosome 15q.** *D-H. Liu, S. Mann, N. Wang, N. Dorrani, C. Schanen.* Dept. Human Genetics, UCLA, Los Angeles, CA 90095.

A common cytogenetic abnormality associated with autism is a supernumerary chromosome derived from chromosome 15, idic(15). Both idic(15) and interstitial duplications [int dup(15)] within 15q11-q13 are thought to arise because of nonhomologous meiotic recombination, usually involving a series of repeated sequences on proximal 15q. In order to analyze the mechanism of formation of these duplications, we genotyped 20 families with duplications of proximal chromosome 15q. Using 9 microsatellite markers flanking the critical region 15q11-q13 (from proximal marker D15S541 to distal marker D15S1031), we found all the duplications were of maternal origin. Among 20 cases, twelve clearly resulted from interchromosomal exchanges, with three distinct alleles from proximal down to distal region. These findings suggest that similar to the deletion events found in Prader-Willi patients, the duplication events often arise due to unequal meiotic exchanges between nonsister chromatids in the maternal meiosis I. Thus, duplications that lead to trisomy for the involved region may involve either maternal heterodisomy or isodisomy, depending upon the origin of the normal maternal chromosome 15. Since the correlation between phenotypic features resulting from duplications appears more complex than simply the amount of involved chromatin, it will be interesting to determine whether different duplication mechanisms might link a clustering of clinical features in AD with a variety of proximal 15q anomalies. Supported by HD 35470.

**Detection of Trisomy 21 using Single Nucleotide Polymorphisms.** *G.A. Pont-Kingdon<sup>1</sup>, E. Lyon<sup>1, 2</sup>*. 1) ARUP Laboratories, Salt Lake City, UT; 2) Department of Pathology, University of Utah.

Numerous SNPs have been mapped along chromosome 21. Using a panel of these SNPs, we have developed a quantitative molecular assay with the LightCycler and hybridization probes for the detection of trisomy 21. This approach should allow fine molecular detection of partial chromosomal duplication. The use of heterozygous SNPs provides an internal control in the assay. Derivative melting curves differentiate two alleles of a given SNP by their different thermodynamic stability with a fluorescently labeled hybridization probe. The temperature ( $T_m$ ) at which the probe denatures from the template and fluorescence signal is lost, identifies the alleles. Hybridization probes were selected to provide a difference in  $T_m$  between both alleles of 7 to 10°C. Alleles are quantified by analyzing the relative area of derivative melting curves. The relative area in non-trisomy 21, heterozygous at a SNP locus should reveal two curves of near equal area, while in heterozygous trisomy 21 samples, one peak should be twice the other. Several SNPs, heterozygous in at least 30% of a random population were selected to provide a test that includes at least two heterozygous SNPs per individual in a large percent of the population. Additional SNPs, in the region believed to be critical for the syndrome are currently being investigated. A consistent difference in peak area ratio between non-trisomy 21 and trisomy 21 samples was observed and indicates the feasibility of the approach. After normalizing to a heterozygous control, non-trisomic samples had a melting curves ratio around 1.0 while trisomy 21 samples had ratios of 1.8 or 0.6 depending on which allele was duplicated. This study opens application of melting curve analysis and can be extended to other chromosomal dosage defects.

**Is a novel fragile site on chromosome 18q22.1 associated with in vivo chromosome breakage? B.MH.**

*Winnepenninckx<sup>1</sup>, I. Naessens<sup>1</sup>, J. Wauters<sup>1</sup>, D. FitzPatrick<sup>2</sup>, F. Kooy<sup>1</sup>.* 1) Center for Medical Genetics, University of Antwerp, Wilrijk, Antwerp, Belgium; 2) Human Genetics Unit, Molecular Medicine Centre, Western General Hospital, Crewe Road, Edinburgh EH4 2XU, UK.

At the moment, approximately 30 fragile sites have been described. The majority of them is expressed when cells are grown in folic acid deficient medium, whereas others are induced by the addition of BrdU or distamycin A to the culture medium. After induction of cultured cells with these specific chemical agents, fragile sites appear as non-staining regions, chromatid gaps or sometimes even breaks on metaphase spreads. Only a single fragile site has been observed that also causes in vivo chromosome breakage: FRA11B. Apart from FRA11B, there has been no direct evidence of chromosomal breakage occurring in vivo in carriers of fragile sites. Yet, recently, a novel fragile site was postulated on chromosome 18q22.1 of the father of an infant with an apparent 18q22.1 deletion. In addition, the child has features of Beckwith-Wiedemann syndrome and biallelic IGF2 expression [Brewer et al., 1998]. The fact that the putative fragile site in the father was found on the same location as the chromosome deletion breakpoint in the infant, suggests that the deletion in the infant is associated with the inheritance of the paternal fragile site expressing chromosome 18 and its subsequent in vivo breakage. The current contribution aims at presenting our results on the testing of a possible association between this fragile site and the chromosome deletion in the infant by identifying the chromosome breakpoint and cloning the 18q22.1 fragile site. As a first step, we confirmed the presence of this novel fragile site and showed that the infant has actually a terminal deletion, not due to a translocation. The candidate region of the breakpoint was refined to minimum size. Genes in the region were identified and the region was searched for expanded repeats. The finding that apart from FRA11B also another fragile site is known to cause in vivo chromosome breakage, would make it obvious to implicate fragile sites in a common mechanism of chromosome breaks. Brewer CM et al. 1998. *J Med Genet* 35: 162-164.

**Multiple pathogenic and benign rearrangements arise from an ancient 35-kb genomic duplication involving the *NEMO* and *LAGE2* genes.** S. Aradhya<sup>1</sup>, T. Yamagata<sup>2</sup>, T. Bardaro<sup>3</sup>, P. Galgoczy<sup>4</sup>, T. Esposito<sup>3</sup>, S. Kenwrick<sup>5</sup>, M. Platzer<sup>4</sup>, M. D'Urso<sup>3</sup>, D.L. Nelson<sup>1</sup>. 1) Molecular & Human Genetics, Baylor College of Medicine, Houston, USA; 2) Jichi Medical School, Tochigi, Japan; 3) Int'l Institute of Genetics and Biophysics, Naples, Italy; 4) Institute of Molecular Biotechnology, Jena, Germany; 5) University of Cambridge, Cambridge, UK.

Incontinentia pigmenti (IP) is an X-linked dominant, male-lethal disorder caused by mutations in *NEMO* (*IKK-g*). We recently showed that most IP patients carry the same genomic deletion, due to rearrangement between two identical repeats. Analysis of the IP deletion in male abortuses had suggested the existence of a second, incomplete copy of *NEMO*. Clones containing this truncated copy (*DNEMO*) have now been identified and incorporated into a BAC contig in distal Xq28. *DNEMO* lies in an inverse orientation telomeric to *NEMO* and lacks exons 1 and 2, confirming our hypothesis. Interestingly, the *LAGE2* gene has also been duplicated along with part of *NEMO*. However, a similar, but single-copy, *LAGE1* gene lies telomeric to the two *NEMO/LAGE2* duplicons. Sequencing the entire 120 kb from *NEMO* to *LAGE1* showed that the duplication spans 35.5 kb, with a single-copy 22-kb sequence separating the two copies. Analysis of great apes indicated that the *NEMO/LAGE2* duplication occurred before divergence of the human-chimp-gorilla lineages, around 10-15 million years ago. Despite this substantial evolutionary history, only 22 single nucleotide differences were found between the two duplicons, making them >99% identical. We have detected evidence of sequence exchange between the two duplicons, possibly pointing to gene conversion events. The homology and physical orientations of the two duplicons, and of smaller sections within each copy, lead to various alterations. We have detected four types of rearrangements that involved one or both of the *NEMO/LAGE2* copies or *LAGE1* as well. Together, these data describe an unusually complex genomic region that predisposes to various rearrangements, including one that causes the lethality associated with IP. These findings also emphasize that polymorphic duplications may be more common in the genome than currently perceived.

**Organization of LINE 1 sequences on human chromosome 21.** *H.D. Beris<sup>1</sup>, M.J. Roy<sup>1</sup>, K.A. Davis<sup>1</sup>, C. Lucero<sup>1</sup>, S.L. Carnahan<sup>1</sup>, A.E. Burket<sup>1</sup>, M.R. Cummings<sup>2</sup>, J.L. Doering<sup>1</sup>.* 1) Dept. of Biology, Loyola University Chicago; 2) Dept. of Biological Sciences, University of Illinois at Chicago.

LINE-1 (L1) sequences are retrotransposons distributed throughout the human genome. There are about  $5 \times 10^5$  copies of L1 constituting 17% of the genome. Evidence suggests that L1 elements preferentially insert into A-T rich regions which are abundant in the heterochromatin of acrocentric p arms. Organization of L1s in heterochromatin and chromosome specific L1 structures are not well characterized. Southern blots of genomic and HC21 hybrid cell DNAs probed with the four L1 sub-fragments show HC21 specific patterns of L1 organization. Reverse Southern to L1 sub-fragments show that L1s on HC21 are more truncated than in the overall genome. Blots of HC21 hybrid cell mapping panel DNAs probed with the four L1 sub-fragments reveal L1s are highly under-represented on 21p. Most 21p copies are full length, polymorphic in number and organization, with substantially more full length L1s on 21p than 21q. We find that there may be as many as 40 full length L1s on 21p. HC21q represents 1.05% of the genome, and proportionately, should contain about 1% of all L1 elements. However, genomic sequence analysis shows that about 2% of all L1s are on 21q, suggesting that L1 is over-represented on this chromosome. Similarly, about 30 of the genome's 3000 full length L1s should be found on 21q. Sequence analysis shows only four full length elements on 21q. All four have target site duplications, and none belong to the recently active Ta subset of L1. L1s on 21q tend to be truncated at a limited number of different sites. Pulsed field mapping shows no full length L1s in the centromere region, but some 5' truncated L1s are contiguous to the D21Z1 alphoid cluster. Functional constraints may prevent L1 integration into the centromere. Since most full length L1s are in 21p heterochromatin, this suggests preferential integration sites, or lack of selection against such L1s in this region, resulting in their preferential accumulation on 21p. This concentration of full length L1s on 21p may facilitate p arm interactions among acrocentric chromosomes, increasing the risk of translocations and non-disjunction.

**The Human Genome: Never a dull chromosome, Never a dull band, Never a dull moment.** *X-N. Chen<sup>1</sup>, P. Bhattacharyya<sup>1</sup>, SY. Zhao<sup>2</sup>, M. Sekhon<sup>3</sup>, J. McPherson<sup>3</sup>, M. Wang<sup>4</sup>, U-J. Kim<sup>4</sup>, H. Shizuya<sup>4</sup>, M. Simon<sup>4</sup>, J.R. Korenberg<sup>1</sup>.* 1) Dept Medical Gen, Ste 2069, Cedars-Sinai Med Ctr, UCLA, Los Angeles, CA; 2) TIGR, Rockville, MD; 3) Washington Univ Genome Sequencing Ctr, St Louis, MI; 4) Caltech, Pasadena, CA.

The story of metazoan evolution is a story of genomic duplication. Primates are not an exception and the human genome reflects a rich history of recent duplication events that are a source of contemporary genomic variability and instability. We now link these duplicated regions to the draft sequence and show that they are located throughout chromosome arms, reflect regions of instability and represent gaps in the current draft sequence of the human genome. To avoid biases in sequence sets introduced by unstable regions, we have defined at random a subset of BACs for putatively duplicated regions and integrated them with the draft sequence. They provide anchor points for sequencing centromeres, pericentromeres and duplications in chromosome arms. These include a total of 6,000 BACs mapped by FISH, 3,500 defined at random, 184 from screens with alpha satellite, 346 with telomeric oligos and ~2,000 from other screens of the Caltech BAC libraries A and B. About 957 are STS linked. Out of 6,000 BACs, 373 mapped to centromeric regions, 192 to single centromeres, 150 to multiples and 20 to all human centromeres. Of 990 multisite BACs, 350 were defined at random suggesting a minimum of 10% of the genome was duplicated and interspersed. A total of 489 were fingerprinted, 33 with 5-29 bands showed no database match and suggested a minimum of 8% of duplications (non centromeric) were not represented in the fingerprint database. Of the 434 end sequenced BACs, 134 or 30% had no match in the draft sequence; 145 had hits of over 98% homology and 147 had hits of 80-98%. Three were located on orphan contigs. This suggested that at least 65% of the multisite clones detected repeated regions which were not included in the draft sequence. These BACs provide anchors for defining hotspots of genomic instability, for sequencing centromeric regions containing genes and for filling gaps in the draft sequence.

**Ancient Duplication: Chromosome 21 is paralogous to chromosome 11 in regions associated with DS phenotypes.**

*J.R. Korenberg, P. Bhattacharyya, G.M. Barlow, X.N. Chen.* Div Medical Gen, Cedars-Sinai Medical Ctr, Los Angeles, CA.

Genomic Duplication is the sustaining force of evolution. The emergence of the draft sequence of the human and other genomes provides the opportunity to trace these evolutionary events with respect to phylogenetic changes in metazoan evolution. We present evidence from in silico analyses to suggest that much of chromosome 21 is paralogous to chromosome 11 bands q23-q25 and results from genomic duplications that occurred during early vertebrate evolution before the emergence of Amphibians but after the emergence of bony fishes (Osteichthyes). At least four paralogous pairs were duplicated prior to and three after this period. Analyses of 127 cDNAs with accession numbers assigned to chromosome 21 yielded a total of 42 with homology to chromosome 11 (40/42 hits-1-3) and 20 with homology to cDNAs mapping to other genomic regions, 9 to second loci on 21, and no other region having more than 8 matches. Of the 127, 17 were detected by BLASTN, 24 by BLASTP and three to genomic draft sequence only. Eleven of the 17 detected by BLASTP shared domains. Clear homologs to both members were defined in all mammalian species examined. To evaluate the likelihood of duplication in Zebrafish, 27 chromosome 21/ chromosome 11 paralogous pairs were used to search the EST database. Of these, 18 of the HSA21 and 15 of the HSA11 members revealed homology with  $\geq 1$  EST. Of the 12 pairs with independent hits, 9 matched the same EST and two of the three with different hits were accounted for by clear preceding duplications. Although synteny is only locally maintained (2 Mb regions), paralogous regions are largely restricted to three bands on 11 and 21q11.2-22.3. These results illustrate a myriad of genomic mechanisms operating over about 400 million years of evolutionary change, provide evidence for high degree of expressed sequence preservation and an approach to determining the genes responsible for the successful rise of the tetrapods.

**Annotation of Human Chromosome 7 for Disease Research.** *S.W. Scherer, J. Cheung, K. Nakabayashi, J. Vincent, E. Petek, J.A. Herbrick, M. Li, J. Skaug, D. Kolozsvari, P. Deb-Rinker, A. Carson, A. Hudek, A. Paterson, L. Osborne, J. Rommens, A. Boright, L.C. Tsui.* Department of Genetics and The Centre for Applied Genomics, The Hospital for Sick Children, Department of Molecular and Medical Genetics, University of Toronto, Ontario, M5G 1X8, Canada.

The aim of our project is to establish a fully annotated genetic, physical, DNA sequence, and gene map of human chromosome 7. As part of this annotation we are also collecting and characterizing all clinical, functional, and biological information relevant to chromosome 7. Through analysis of DNA sequence data in the public and Celera databases we could detect corresponding genomic fragments for over 98% (6,500 of 6,579) of our collection of STSs known to map to chromosome 7. Initially, 65 large (>100 kb) DNA sequence contigs could be established covering >145 Mb of DNA. The average length was 1.68 Mb and the largest was 14 Mb on 7p. Our analysis indicates there are 10 known physical gaps not bridged by any clones and 55 sequence gaps spanned by known clones which are being sequenced (the statistics do not include the immediate 1-2 Mb flanking the centromere which require additional work). We are estimating the sizes of the physical gaps using FISH analysis and attempting to close them through screening additional cosmid, PAC, and BAC libraries and by performing long PCR. Moreover, a 100-200 kb duplicon at 7p11.1 was identified to be present in 30 copies elsewhere in the genome and another 200 kb segment was found in 3-4 copies at 7q11.23 and 7q22, further complicating assemblies. We have also identified genomic polymorphism on the long arm of chromosome 7. With the current DNA sequence map we have, so far, identified over 720 full-length genes and 1382 additional transcriptional units (total > 2000) on chromosome 7. Five genes larger than 1.0 Mb have been identified. Also, 150 rearrangement breakpoints, 700 FISH mapped clones, 3 fragile sites, and 3 imprinted regions could be accurately placed on the DNA sequence-based map. The integration of all biological information around the DNA sequence map will facilitate disease research.

**Alpha-Satellite Organization In Great Apes.** *M. Rocchi, C. Spalluto, S. Piccininni, L. Anelli, N. Archidiacono, R. Marzella, L. Viggiano.* DAPEG - Sezione Di Genetica, Univ Di Bari, Bari, Italy.

We have previously reported the comparative mapping of human alphoid sequences in great apes (Archidiacono et al., 1995). The unexpected results showed that the large majority of human probes do not recognize their corresponding centromeres, revealing a very rapid evolution of these sequences. Furthermore, these studies indicated that the suprafamily organization of alphoid sequences in great apes does not necessarily match that found in HSA. This suggests that alphoid centromeric sequences underwent a very rapid evolution. These findings prompted us to undertake a systematic cloning of alphoid probes in great apes to investigate their suprafamily organization and evolutionary history. Very few alphoid sequences from these species, have been characterized before. A further appealing reason to study the organization of alphoid sequences in great apes is the elucidation of their evolutionary relationship with pericentromeric regions, which we have shown to be extremely plastic (Jackson et al., 1999-2000; Eichler et al. 1999). We undertook the systematic cloning of alpha-satellite DNA sequences in the great apes for the following reasons: 1) to establish the suprafamily organization of alpha-satellite DNA in great apes; 2) to investigate the evolutionary history of this type of sequence in primates; 3) to establish the correlation between alpha-satellite DNA sequences and the distribution of NF-1 pseudogenes in primates. We report here the cloning of 36 alphoid probes derived from PTR centromeres using three different experimental approaches. These probes have been used in FISH experiments at high and low stringency hybridization conditions to investigate their suprafamily organization. We are able to group these alpha-satellite DNA sequences into two, not so clearly separated, large groups, as is also found in orang-utan (Haaf et al., 1998). In conclusion we think the suprafamily organization of alpha-satellite DNA in great apes is equidistant between the human suprafamily organization (every chromosome has at least one specific subset) and the suprafamily organization of Old World Monkey (OWM) (only one alpha-satellite DNA sequence).

**Genomics and Evolution of the Human X Chromosome Centromere.** *M.G. Schueler, H.F. Willard.* Case Western Reserve University, Cleveland, Ohio.

Pericentromeric regions of human chromosomes are largely uncharacterized but contain sequences involved in centromere function. Genomic analysis of these regions may reveal evolutionary events that have led to current mammalian chromosome structure and detect DNA elements common to functional centromeres. We report a BAC/PAC contig joining the X chromosome-specific alpha satellite array, DXZ1, with the most proximal expressed gene in Xp11.21, ZXDA. Our contig spans ~ 500 kb represented in 19 clones. The region consists of monomeric alpha satellite, gamma satellite, interspersed repeats and a novel 35 bp repeat, but lacks large segments of unique or paralogous sequences. The junction between arm-specific sequences and centromeric satellites is located 149 kb from the ZXDA gene and is marked by an L1M1 LINE element adjoining a partial alpha satellite monomer. This unique map resource allows us to test and formulate hypotheses regarding pericentromeric structure and evolution. The most distal alpha satellite in this region lacks higher-order structure and CENP-B boxes; however, we have identified diverged higher-order sequences at the border of the DXZ1 array that provide direct evidence of unequal crossover as a mechanism of evolution of alpha satellite arrays. Second, DXZ1 and diverged DXZ1 sequences within this ~ 20 kb transitional region at the array border are phylogenetically distinct from the monomeric alpha satellite that adjoins the chromosome arm. Third, L1 dating predicts that monomeric alpha satellite in the region has resided at this location since early in primate evolution. Further, in a screen of ~ 4.5 Mb of DXZ1 DNA, only the currently active L1Hs element was identified, indicating a more recent origin for the DXZ1 array. Functional studies indicate that DXZ1 alpha satellite can form active, de novo centromeres (see abstract by Rudd). It is our hypothesis, therefore, that monomeric alpha satellite is a remnant of the ancestral primate X centromere and that the sequences currently functioning as the X centromere have evolved recently. Conservation of X chromosome content through evolution makes our contig an excellent model upon which to conduct comparative analysis of centromere evolution.

**Alpha satellite organization in chimpanzee (*Pan troglodytes*, PTR).** *L. Viggiano, C. Spalluto, S. Piccininni, L. Anelli, N. Archidiacono, R. Marzella, M. Rocchi.* Genetics, Univ of Bari, Bari, Italy.

We have recently reported the comparative mapping of human alphoid sequences in Great Apes (Archidiacono et al., *Genomics* 25:477-484 1995). The unexpected results showed that the large majority of human probes do not recognize their corresponding centromeres, revealing a very rapid evolution of these sequences. Furthermore, these studies indicated that the suprafamily organization of alphoid sequences in Great Apes does not necessarily match that found in HSA. These findings prompted us to undertake a systematic cloning and characterization of alphoid probes in Great Apes to investigate their suprafamily organization and evolutionary history. Very few alphoid sequences from these species have been indeed cloned and characterized so far. A further reason to study the organization of alphoid sequences in great apes is the elucidation of their evolutionary relationship with pericentromeric regions, which we have shown to be extremely plastic (Jackson et al. *Hum.Mol.Genet.* 8:205-215, 1999; Eichler et al., *Genome Res.* 9:1048-1058, 1999). We report here the cloning of 36 independent alphoid probes derived from PTR centromeres using three different experimental approaches. These probes have been used in FISH experiments at high and low stringency hybridization conditions to investigate their suprafamily organization. Moreover the most representative clones have been sequenced and compared against the human alpha-satellite DNA consensus sequence (Romanova et al., 1996). Our analysis have shown that a distinct and strict suprafamily organization, as found in humans, does not exist in PTR. We hypothesize that the chromosomal organization of alphoid sequences in this species is intermediate between the highly chromosome-specificity and strict suprafamily distinctions as occurs in humans, and the simple organization of Old World Monkey (OWM) where one alpha-satellite DNA sequence is supposed to be shared by all chromosomes.

**The map problem: a comparison of genetic and sequence-based physical maps.** *A.T. DeWan<sup>1</sup>, A.R. Parrado<sup>1</sup>, T.C. Matisse<sup>2</sup>, S.M. Leal<sup>1</sup>.* 1) Laboratory of Statistical Genetics, The Rockefeller University, New York, NY; 2) Department of Genetics, Rutgers University, Piscataway, NJ.

The genetic order of autosomal markers from Marshfield panel 10 was compared to their physical order based upon the assembled non-redundant human genome sequence from the Human Genome Project - Santa Cruz (HGP-sc) and Celera (CEL) databases. The likelihoods were calculated for the minimum recombination maps for each of the 22 autosomes and compared to the likelihoods for alternative map orders, to determine which markers could be placed on the genetic maps based upon a likelihood ratio criterion of 1000:1. Of the 380 autosomal panel 10 markers which are spread across the genome at ~10cM intervals, a total of 254 (67%) and 265 (70%) markers could be found in the HGP-sc and CEL databases, respectively. Through the use of e-pcr, an additional 42 (11%) of the markers could be placed on the assembled genome sequence from the HGP-sc database for a total of 296 (78%) markers. E-pcr could not be performed on CEL sequence data, due to unavailability. A total of 210 (55%) of the markers could be found in both databases. There was an inconsistency in the order of 9 (3%) and 15 (6%) of the markers when the genetic order was compared to their order in HGP-sc and CEL, respectively. Only two of these inconsistent markers were redundant in HGP-sc and CEL. For all of the inconsistent markers only 1/9 of the HGP-sc markers and 1/15 of the CEL markers was the genetic order not supported by a likelihood ratio of 1000:1. In addition, for 2/9 HGP-sc and 2/15 CEL markers the physical chromosomal assignment did not match the genetic chromosomal assignment. Of the 15 inconsistent CEL markers, 10 were located in the HGP-sc database. The HGP-sc physical order and genetic order were consistent for 8 of these 10 markers. Likewise 6/9 of the inconsistent HGP-sc markers were identified in the CEL database. The CEL physical order and genetic order were consistent for 4 of these 6 markers. In conclusion, the majority of the inconsistencies between the physical and genetic map order point to errors in the physical map order.

**Haplotype analyses of the HLA-DRB1 region suggest a high mutation rate in the DRB1 gene.** *H. Hohjoh, J. Ohashi, K. Tokunaga.* Human Gen/Grad School Medicine, Univ Tokyo, Tokyo, Japan.

Phylogenetic trees for the HLA-DRB1 alleles suggest that DRB1\*0701 may have diverged from other DRB1 alleles before the separation of human and chimpanzee. However, based on nucleotide changes in the PRKRA pseudogene specifically present in the HLA-DR53 group, the divergence times of the DRB1\*0701 and DRB1\*04 alleles linked with PRKRA pseudogene were estimated to be 0.38~0.3 million years (Myr) ago. To settle this issue, here we study haplotypes with the centromeric flanking region of DRB1, DRB1, and PRKRA pseudogene. Results indicate that the haplotypes carrying DRB1\*0701 and DRB1\*04 have been derived from a common ancestral haplotype, and that the divergence of the haplotypes may have occurred 0.92~0.37 Myr ago. In addition to the above results, the haplotypes further reveal that the number of selectively neutral (synonymous) substitutions in DRB1 is significantly higher than those in the centromeric flanking region and PRKRA pseudogene, although the balancing selection may have acted equally throughout the haplotypes. This suggests that DRB1 has a significantly high mutation rate. Such a high mutation rate as well as the balancing selection may contribute to the highly complex polymorphism in DRB1.

**A panel of somatic cell hybrids specific for the Olive baboon (*Papio anubis*, Old World Monkeys).** *R. Marzella, V. Miolla, P. Chiarappa, C. Carrozzo, M. Rocchi, N. Archidiacono.* DAPEG Sezione di Genetica, Univ Bari, Bari, Italy.

A draft of the human genome sequence has been accomplished moving the Human Genome Project into its postgenomic era. It is becoming evident, however, that the understanding of our humanness will be achieved only by comparing our genome and its functional aspects with those of our closest relatives: the primates. Unfortunately the dearth of primate resources for molecular analyses is very serious. In recent years we have investigated the plasticity of the pericentromeric regions of human chromosomes (Jackson et al. *Hum.Mol.Genet.* 8:205-215, 1999; Eichler et al., *Genome Res.* 9:1048-1058, 1999). This task have been primarily achieved by comparative mapping of appropriate human probes on cytological preparation of primates. Molecular aspects of these studies, however, are severely handicapped by the lack of appropriate molecular tools, chromosome-specific resources in particular. For this reason we have initiated the construction of a panel of somatic cell hybrids specific for a selected primate species. Here we report the preliminary characterization of a panel of somatic cell hybrids specific for the Olive baboon (*Papio anubis*, Old World Monkeys). This is one of the few primate species for which a public available BAC library exists (P. de Jong, <http://www.chori.org/bacpac/>). The B14-150 CHO cell line (TK-) was used as a rodent parental cell line. The characterization of the baboon chromosomes retained in each hybrid was first obtained by banding analysis. The DNA from each hybrid was selectively amplified by dual-Alu primers and the amplified products were then used as a probe in FISH experiments on both baboon and human metaphases. The reverse-painting characterization also allowed the identification of chromosomal fragments, that are a non rare occurrence in somatic cell hybrids. The work is in progress. At present the following chromosomes have been found to be retained in various combinations: Whole chromosomes 6, 10, 12, 20, 17, 19 , 13 , and Y; fragments of chromosomes: 1, 2, 5, 7, 8, 10, 13, 17.

**Construction and application of BAC libraries constructed using sheared DNA.** *K. Osoegawa, C.-L. Shu, P.J. de Jong.* Children's Hospital Oakland Research Institute, Oakland, CA.

Bacterial artificial chromosome (BAC) libraries have initially been developed for use in genome mapping and sequencing. After completion of the human draft sequence, mapped and sequenced BACs have become important tools for disease diagnostics and functional genomics. Nevertheless, there is a need for additional human clones to facilitate genomic gap closure. We developed procedures for cloning sheared DNA in a modified BAC vector with the expectation to avoid cloning bias due to aberrant levels of the restriction sites in specific genomic regions. BACs created from sheared DNA will also be useful to determine more random end sequences to assist in scaffolding sequence contigs derived from whole genome shotgun sequencing. BAC libraries with different average insert sizes and random ends support the now accepted hybrid approach based on a combination of whole genome shotgun and clone-by-clone sequencing. To create the required BACs, HMW DNA is sheared by multiple cycles of freezing and thawing. The fragment ends are blunted by subsequent treatments with Mung Bean nuclease and T4 DNA polymerase, and are then ligated to the blunt-end side of an adapter that also has a 3' overhang (ACAC). The ligation products are size-fractionated to remove the excess adapter and to obtain the clones in the desirable size range. The new vector (pTARBAC6) has two BstXI restriction sites flanking a replaceable stuffer fragment. Upon BstXI digestion, a vector fragment with two 3' overhangs (GTGT) is generated, complementary to the genomic DNA. We have been able to construct several BAC libraries from *Drosophila*, *Ciona savignyi* and mouse with different average insert sizes to fit the applications. Provisional results with the new libraries indicate random clone distribution and a very low level of undesirable chimeric clones. Initial screening results for the fly BAC library indicate a possible extension of contigs towards the telomeres. Information on our libraries can be obtained at: [www.chori.org/bacpac](http://www.chori.org/bacpac). Library construction was supported either directly or indirectly by grants from the NHGRI. The US DOE specifically funded the technology development of sheared BAC libraries.

Program Nr: 1607 from the 2001 ASHG Annual Meeting

**A new resource of chimpanzee biomaterials: gender determination and genotyping data.** *R. Robledo, C.M. Beiswanger, P.K. Bender, W. Beggs, J.C. Leonard, R.Z. Goldman, M.J. Manduka, J. Coccia, J.C. Beck.* Coriell Inst Medical Research, Camden, NJ.

Recognizing the need for resources to permit genetic comparisons of closely related species, the Coriell Cell Repositories, in collaboration with the Yerkes Regional Primate Research Center, have begun the establishment of a collection of biomaterials from chimpanzees (*Pan troglodytes*). Lymphoblastoid cell lines were established from blood collected in ACD tubes using standard protocols with Epstein-Barr virus and phytohemagglutinin (PHA). Fibroblast cell lines were established from skin biopsies. All established lines are viable and contaminant-free. Karyotype analyses confirm that the lines are chimpanzee. In addition, the chimpanzees were genotyped using primers from the ABI PRISM Linkage Mapping Set, version 2 and probes discriminating gender based on X chromosome amelogenin alleles. Even though the markers tested were developed for analysis of human loci, all markers successfully amplified chimpanzee DNA. Some markers show no overlap in allele size between chimpanzees and humans, while others show a substantial overlap with humans tending to have larger allele sizes than chimpanzees. Only one marker (D22S539) proved to be mono-morphic in these chimpanzees, a finding not surprising in view of the low heterozygosity reported in humans. The amelogenin probes correctly identified the gender of all samples and the microsatellite data are consistent with the proposed pedigrees derived from behavioral studies. These data show that it is possible to use the ABI PRISM Linkage Mapping Set for a wide genome screening for genetic mapping, evolutionary studies and paternity testing. Detailed information about these samples, including ordering instructions, is available in an electronic catalog (<http://locus.umdj.edu/ccr>). Supported in part by NIH/NCRR, RR-000165.

**BAC Libraries From Non-human Primates and Other Model Organisms for Comparative Genome Analysis.** *B. Zhu, K. Osoegawa, C. Shu, P. deJong.* BACPAC Resources, CHORI, Children's Hospital Oakland, Oakland, CA.

With the increasing interest in comparative genomics, BAC libraries have become important resources permitting the isolation of regions of syntenicity between species through BAC contigs. Intraspecies comparisons do not rely on BACs but can also be derived by long PCR. Interspecies comparisons cannot be done by PCR - except for very closely related species. Genomic comparison for syntenic regions thus relies on selective cloning approaches or by selecting clones from total-genome libraries. We have recently developed hybrid BAC/YAC vectors ("pTARBAC") to create the newer BAC libraries. BAC clones created in the hybrid vectors through cloning in *E. coli*, can be deleted individually with restriction enzymes. The deleted clones can be repaired to original size by homologous recombination in yeast between uncloned high molecular weight DNA from the same species and the linear deleted BAC. This process occurs following co-transformation of the linear vector and the deleted BAC DNA and has therefore been labeled as "Transformation Associated-Recombination" by Larionov & Kouprina. To permit this application, we constructed new BAC libraries in pTARBAC vectors for rhesus macaque, chimpanzee, baboon, rat and zebrafish. Preliminary characterization showed that the Rhesus Macaque (CHORI-250) and Chimpanzee (CHORI-251) BAC libraries have at least 10-fold genome redundancy with average inserts of about 175 Kb. The Baboon BAC (RPCI-41 male) library has already been arrayed into 384-well plates and represents 10-fold genome coverage, with insert size of 174 Kb. The zebrafish BAC library (CHORI-211) has been arrayed into 384-well plates at about 10-fold genome coverage with an average insert size of 165 Kb. A 10-fold redundant new rat (BN/SsNHsd/MCW) BAC library has just been completed. Characterization of the first 5-fold redundancy part of the rat library indicates average inserts of 214 kb. Information about BAC libraries, vectors and procedures is available from our website: [www.chori.org/bacpac](http://www.chori.org/bacpac). The new BAC libraries constructed have been supported by grants from NHGRI, the US DOE and through sub-contracts.

**An integrated physical map of the human and chimpanzee genomes.** *M. Sekhon.* Genetics/GSC, Washington University, Saint Louis, MO.

The genomes of Chimpanzee (*Pan troglodytes*) and Humans (*Homo sapiens*) are believed to be 98% identical at the nucleotide level. In order to further investigate the similarities and differences between the two organisms, we attempted 68,721 fingerprints of a Male Chimpanzee BAC library ([www.chori.org/bacpac/](http://www.chori.org/bacpac/)) and integrated the fingerprint data into our BAC fingerprint physical map of the Human genome ([http://genome.wustl.edu/gsc/human/human\\_database.shtml](http://genome.wustl.edu/gsc/human/human_database.shtml)). To date, we have been able to position ~67% of the chimpanzee clones to corresponding mapped BACs of the human genome with identical or highly similar restriction digest fingerprint patterns. The correct placement of the chimpanzee BAC clones in the human physical map is being assessed by sequence analysis and fluorescence in situ hybridization (FISH) of a subset of the mapped clones. The Chimpanzee mapping data is a valuable resource for selecting clones of interest for sequence comparison with Human draft and finished data. Human disease regions in the physical map can be identified and corresponding chimpanzee clones can be selected for sequencing and further analysis. In addition, chimpanzee clones that cannot be placed on the human physical map are being further investigated to see if they represent regions not present in the human genome.

**Using DAML format for representation and integration of complex gene networks: implications in novel drug discovery.** *K. Baclawski*<sup>1,2</sup>, *E. Neumann*<sup>2,3</sup>, *T. Niu*<sup>1,4</sup>. 1) College of Computer Science, Northeastern University, Boston, MA; 2) Jarg Corporation, Waltham, MA; 3) Beyond Genomics, Inc., Waltham, MA; 4) Program for Population Genetics, Harvard School of Public Health, Boston, MA.

Great strides have been made in understanding the complex molecular networks underlying biological systems. Advances in high-throughput microchip-based assays are providing us with global gene activity profiles characterizing the output of the gene regulatory network. The eXtensible Markup Language (XML) is becoming a key component in data exchange in biology and currently there are over a dozen XML DTDs and schemas for bioinformatic applications, including BioML, CellML, RNAML, DDBJ-ML and BSML. However, there are intrinsic limitations of using XML in representing biopathways because of its hierarchical nature. To address this problem, we introduced a new way of knowledge representation using DARPA Agent Markup Language (DAML) schemas through ontology-based models for integration of complex genetic networks. This new approach has overcome the restriction of the use of hierarchical data structure, and can facilitate automatic retrieval and update of gene network-related data and can be transformed into other XML dialects. Our prototype is expected to shed novel insights on genetic networks that will help our efforts towards better understanding of complex disease etiology, which in turn, can have significant expectations in clinical pharmacogenomics.

**Reproducibility and Selection of Probe Sets Across Generations of Microarrays.** *A. Nimgaonkar<sup>1</sup>, D. Sanoudou<sup>2</sup>, A. Butte<sup>1</sup>, J.N. Haslett<sup>2</sup>, L.M. Kunkel<sup>2</sup>, A.H. Beggs<sup>2</sup>, I.S. Kohane<sup>1</sup>.* 1) Informatics Program, Children's hospital, Harvard Medical School, Boston, MA; 2) Genetics Division, Children's Hospital, Harvard Medical School, Boston, MA.

The availability of massively parallel expression profiling is changing the scientific paradigms of biological investigation, yet the rapidity of change of these technologies present large challenges. Commercial microarrays are regularly modified with new sets of genes and improved target sequences. Comparing datasets across generations is crucial for any long-term research project. However, to date, there are no means to allow comparisons across generations. We measured the reproducibility of gene expression level across two generations of microarrays (HuGene FL and HG-U95A, 7129 and 12,626 probe sets respectively) produced by Affymetrix. Four normal muscle samples were hybridized on one HuGene FL and one HG-U95A chip each. The 7,129 HuGeneFL probe sets were compared to the 8,075 probe sets on the HG-U95A chips that represent the same gene. The four transcriptome correlations ( $r^2$ ) across the two microarray generations varied from 0.58 to 0.70. Probe sets with 3 or more probe pairs in common had a correlation greater than 0.75, and considering those with 13 or more probe pairs in common improved the correlation to over 0.90. Probe sets with no probe pairs in common decreased the correlation to 0.27. When particular types of probe sets were considered (e.g. probe sets for which Affymetrix was not possible to pick a full set of unique probes), the correlation changed statistically significantly. Considering each gene's four measurements across the two generations, around 20% of probe sets were negatively correlated. That is, the expression level of these genes changed in opposite directions when measured across the two chip generations.

Our results support limited comparability between microarray generations, and introduce computational methods that will enable such comparisons. Further study of more samples and tissue types could establish a widely applicable analytical model to make the most of current datasets, and accelerate work with future microarray generations and platforms.

**Using Genetic, Radiation Hybrid, and Sequence Maps Comparisons to Analyze Recombination and Gene Density.** *J.E. Stajich, E.R. Hauser, J.M. Vance.* Center for Human Genetics, Duke Univ Medical Center, Durham, NC.

The completion of a rough draft assembly of the human genome provides many opportunities to revisit established observations of genomic trends. We have compared the recently completed sequence maps with established genetic and RH maps to investigate relationships of map distance and sequence properties. Our research studied the human genome on a 100kb scale, and compared gene density and repetitive elements with recombination rates.

The sequence based marker comparisons were constructed using e-PCR on the Golden Path of the human genome as constructed by UCSC. Repeat density was calculated by RepeatMasker and tandemrepeatfinder on each segment of genomic sequence. Confirmed genes from Project Ensembl were used to score the number of genes in a given segment to assess number of genes in a location.

Comparisons of genetic and sequence distances across a chromosome can be used to infer variation in recombination rates. A model relating genetic distance to sequence distance was developed to find correlations in recombination and sequence statistics such as gene and repetitive element density. We found strong positive correlation of SINE elements to gene density and moderately negative correlation of LINE content to gene density in a region.

The application of the map integration aspect of this project is useful in aiding candidate gene discovery from linkage analysis results. Software was developed to automate the integration of genetic and radiation hybrid markers onto a single map to provide researchers with a simple interface for locating candidate sequence regions. Ultimately with this approach genes can be easily mined automatically from databases such as Ensembl using only markers from linkage analysis studies to identify the regions.

**Methods for Completion of a Human Physical Map.** *S. Jaeger.* Genetics/GCS, Washington University, Saint Louis, MO.

As part of the Human Genome Project, we have constructed a physical map of the human genome comprised of greater than 400,000 bacterial artificial chromosome (BAC) clones, primarily from the RPCI-11 library (BAC/PAC Resources). Each clone was digested using HindIII and the fragments were separated by gel electrophoresis. Bands were identified using IMAGE software (Sanger Centre), and the resulting fingerprint was put into a Fingerprint Contig (FPC) database (Sanger Centre). Clones binned and initially ordered using the FPC software tools were manually edited to form contigs. Contigs were localized to the 24 chromosomes using various marker data, hybridization assays, FISH, and *in silico* PCR. Currently, the BAC map contains ~750 contigs. Many clones for the working draft of the human genome were selected using this map and the entire working draft sequence has been aligned to it. Remaining gaps in the map are likely due to biases in the BAC libraries and repetitive regions. We are using several techniques to close the gaps, and complete the map. One method for sizing a gap is FISH. Clones from both ends of the gap are fluorescently labeled and hybridized to chromosome fibers. The gap can be sized by measuring related signal lengths. If the gap is <~30kb, primers can be selected using end, draft, or finished sequences (TIGR database, NCBI) from clones flanking the gap, and a PCR-based method can be used to bridge the gap. A method for closing a larger gap is endwalking. BAC end, draft or finished sequence is used to develop probes. Radioactively labeled probes are hybridized to filters containing clones from RPCI-13 and RPCI-11 Segment 5. Clones identified from the hybridization are fingerprinted, incorporated into FPC, and used to extend the ends of the contig. Some clones extend the contig without filling the gap. In this case, those clones are chosen for end sequencing by the Physical Mapping Group. Those sequences are used to develop probes and do further walking. Yeast artificial chromosome (YAC) clones are chosen that span gaps that are not readily closed by walking. The spanning YACs are used to generate further probes and may also be used directly for sequencing templates.

**The identification of disease genes by genomic sequencing analysis of 8q22-q24.** *N. Shimizu, A. Shimizu, T. Sasaki, A. Shintani, K. Kawasaki, J. Kudoh, S. Minoshima, S. Asakawa.* Dept Molecular Biol, Keio Univ Sch Medicine, Tokyo, Japan.

Recently, the initial draft sequence was reported by the international human genome sequencing consortium including us, but further efforts will be needed to extract the full information contained in the human genome. For this task, we have focused on the human chromosome 8q22-q24 in which at least five disease genes responsible for developing glaucoma, Cohen syndrome, Klippel-Feil syndrome, Langer-Giedion syndrome, and myoclonic epilepsy have been mapped. The 8q22-q24 (D8S1822-D8S1826) region is about 30 Mb, which we covered with 7 contigs of Keio BAC clones. These BAC clones have been processed for shotgun sequencing in combination with primer walking. We have finished sequencing of 82 BAC clones, covering about 40% of the 8q22-q24 region (~ 10 Mb) with the longest continuous sequence of 2.1 Mb. Genomic sequence was subjected to homology search with the database. We have so far identified 112 genes, including 73 known genes (PGCP, LC27, MATN2, RPL30, UK114, POP1, PRO1097, KRS1, GEM, CDH17, PABP, HTPHLP, P53R2, HYD, ODFPG, TIEG, DPYS, ST7, OXR1, INT6, ANGPT1, DC6, EBAG9, TRPS1, EXT1, EIF3S37 etc.) and 15 novel genes (C8orfK1, C8orfK2, C8orfK3, C8orfL4 etc.) in addition to 24 pseudogenes (SMT3H2P, LETM1P, GAPDP, MLF2P, RPL30P, RPL39P, SMT3H2P, EEF1A etc.). Initial characterization of these genes including mutation search for the patients of epilepsy and Cohen syndrome will be presented.

**Genome Database, GDB, post-sequence advances.** *A.J. Cuticchia<sup>1</sup>, C.J. Porter<sup>1</sup>, W. Zhu<sup>1</sup>, C.C. Talbot Jr.<sup>2</sup>.* 1) Bioinformatics Supercomputing Centre, The Hospital for Sick Children, Toronto, ON, Canada; 2) Genome Database, The Johns Hopkins University School of Medicine, Baltimore MD, USA.

Since its inception in 1990, the Genome Database (GDB) has provided free access to curated mapping and marker information generated by scientists worldwide. With the accelerated timetable of the Genome Project and subsequent publication of the draft sequence in 2001, GDB has, in parallel, increasingly developed sequence-based tools and techniques to incorporate sequence information with its traditional, e.g. linkage, RH, and FISH, mapping data. GDB now uses e-PCR to create maps comprising amplimers and SNPs that have been computationally positioned on both finished and draft sequence contigs, and updates these maps as their source contigs change. We can thereby integrate positional data from sequence more directly with other mapping data to update and refine our Comprehensive Maps.

A GDB-BLAST tool returns any GDB objects (clones, amplimers, and genes) associated with the returned sequence hits, and our e-PCR tool analyzes query sequences against GDB's many amplimers. The use of Toronto's Bioinformatic Supercomputing Centre's supercomputers has enabled GDB to develop a novel e-PCR Database. Our e-PCR Database Lookup tool essentially reverses the conventional e-PCR process and allows users to enter query amplimers and search GenBank for sequences that should, based on computation, serve as their templates.

We have recently devised a new method to link data from heterogeneous databases and incorporate them within the display of the associated GDB objects. Another new database has been created to store sequence position data for presentation either via this new technique or independently in its own browser. This new display method is used to access sequence context and position information, and to incorporate data from external databases of genome annotation with a GDB record. These links will also be used to present additional functional, expression, and proteomic data as they become available. Links have been put in place between amplimers and the GDB e-PCR Database to allow users to find sequences overlapping the markers' positions.

***MutationView* : A Graphical Database System for Mutations and Polymorphisms in Human Disease Genes.** S.

Minoshima<sup>1</sup>, M. Ohtsubo<sup>1</sup>, S. Mitsuyama<sup>1</sup>, S. Ohno<sup>1</sup>, T. Kawamura<sup>1</sup>, S. Ito<sup>2</sup>, F. Ito<sup>3</sup>, N. Shimizu<sup>1</sup>. 1) Dept Molec Biol, Keio Univ Sch Medicine, Tokyo, Japan; 2) Dept Environ Health Science, Setsunan Univ, Osaka, Japan; 3) Dept of Biochem, Setsunan Univ, Osaka, Japan.

More than 1000 disease-causing genes have been reported. Databases for mutations in these disease-causing genes are indispensable for the diagnostics, therapeutics and basic research of the diseases. At present, mutation data are maintained as individual Locus-specific Databases (LSDBs) for some 200 diseases and therefore more comprehensive database system with common graphical user-interface is required. We have established the *MutationView* as an integrated graphical mutation databases. Currently, the *MutationView* has collected 5563 entries of mutations/polymorphisms from 1091 literatures dealing with 183 genes involved in 173 distinct diseases. The characteristic features of the *MutationView* are as follows:

(1) Several ways to access are available through the chromosomal map of the gene or disease, anatomical chart of disease-associated organ or tissue, and diagram of causative gene product.

(2) Various data display and analysis functions are available such as genomic/cDNA structure of normal gene; functional domain structure of protein; zooming-in and -out of the nucleotide and amino acid sequences; plotting mutations with the histogram of case number; changes in the nucleotide sequence and restriction sites; classification based on mutation type, case number, dominant/recessive and symptom; experimental information such as PCR primers and reaction conditions.

(3) Mutation data can be put in any web server and therefore *MutationView* system is ideal to link global mutation databases managed by LSDB curators.

The user ID and password are issued upon formal applications through the URL <http://mutview.dmb.med.keio.ac.jp>. Computer demonstration will be performed at the meeting.

**Comprehensive setting of 30,000 polymorphic microsatellite markers throughout human genome.** *K. Okamoto<sup>1,2</sup>, S. Makino<sup>1</sup>, T. Endo<sup>3</sup>, H. Hayashi<sup>1</sup>, A. Oka<sup>1</sup>, K. Fujimoto<sup>1</sup>, A. Denda<sup>1</sup>, H. Watanabe<sup>1,2</sup>, E. Tokubo<sup>1</sup>, R. Sato<sup>1,2</sup>, A. Takaki<sup>1</sup>, Y. Sakurai<sup>1</sup>, Y. Nagatsuka<sup>1</sup>, T. Imanishi<sup>3</sup>, T. Gojobori<sup>3</sup>, K. Tokunaga<sup>4</sup>, G. Tamiya<sup>1</sup>, H. Inoko<sup>1</sup>.* 1) Sch Medicine, Tokai Univ, Isehara, Japan; 2) Chugai Pharmaceutical Co., Ltd, Gotemba, Japan; 3) National Institute of Genetics, Mishima, Japan; 4) Grad Sch Medicine, Univ Tokyo, Tokyo, Japan.

The aim of this study was to identify novel polymorphic microsatellite markers throughout human genome.

Our previous data indicated that microsatellite markers showed a linkage disequilibrium with disease-related alleles spanning from 100 to 200 kilobases (kb). Based on this evidence, we made a plan to identify a total of 30,000 polymorphic markers throughout human genome with 100 kb intervals. In addition to approximately 10,000 markers that were previously registered in GenBank, we identified 20,000 novel markers. First, we identified all available microsatellite sequences from the human genome draft sequence. In order to investigate the microsatellite polymorphism, we performed genotyping using pooled DNA from 100 healthy Japanese individuals. Approximately 30,000 markers were identified as a polymorphic in Japanese pool. Furthermore, we investigated the characteristics of these polymorphic markers, including heterozygosity, allele number, and length of repeated unit. Mean heterozygosity and allele number were approximately 0.65 and 6.3 respectively. These data strongly suggest that we did obtain highly informative genetic markers. Next, we have mapped newly identified polymorphic markers into chromosomes, composed of the assembled genomic sequences from the repository of International Human Genome Sequencing Consortium. With these mapping data, we plan to submit the our novel the polymorphic markers to the public genomic repository.

A total of 30,000 markers will aid the construction of a useful marker map of the human genome and will be a powerful tool for fine mapping of disease-susceptibility genes in genome-wide association studies. In addition, they should be applied for other purposes such as population studies.

**Identification of 140,000 cSNPs in the human genome.** *T. Tanaka*<sup>1,2</sup>, *Y. Ohnishi*<sup>1,2</sup>, *R. Yamada*<sup>1,2</sup>, *Y. Nakamura*<sup>1,2</sup>. 1) Human Genome Center, Institute of Medical Science, University of Tokyo, Tokyo, Japan; 2) SNP Research Center, RIKEN, Tokyo, Japan.

SNP is the simplest and the most common form of DNA polymorphism. Owing to these characteristics, it is expected to be of great use in association studies on common diseases or drug sensitivities. In particular, those within promoter regions, exons and introns, which we call cSNPs, are much more valuable than others, since cSNPs have much higher probability to directly modify functions of genes or their spatial and temporal patterns of expression. On April 2000, we have launched a national project in Japan to identify 150,000 SNPs in two years. Our method is as follows; human genomic sequences are extracted from GenBank database and PCR primers are synthesized to amplify exons, promoter regions and introns. Genomic DNA from three independent individuals are mixed into one and used as templates for direct sequencing of PCR products. In total, 24 individuals are examined in eight sample tubes. Computer program Polyphred is used to assist verification of SNPs by eye inspection, followed by construction of SNP database open to public via world wide web (<http://snp.ims.u-tokyo.ac.jp>). We have already discovered 140,000 cSNPs in one and a half year. Approximately 20% of them are within exons. At present, only 25% of our SNPs were identical to those in dbSNP database. In addition, we have already identified 3676 cSNPs on chromosome 22, whose result is different from that of the previous report of 2730 SNPs on that chromosome. These may reflect the strategic differences to identify SNPs, problem on the reliability of the public database, or ethnic differences. With our catalog of 150,000 cSNPs in the human genome when completed, we believe further investigation should be much easier to identify genes related to common diseases or drug sensitivity.

**New labeling method for microarray hybridization detection.** *C. Xiang, M. Chen, M. Brownstein.* Lab of Genetics, NIMH/NIH, Bethesda, MD.

The methods that have been developed for routine labeling of cDNA probes for microarray studies require a minimum of 20 ug of total RNA or 2 ug of poly(A)RNA. Many of the tissue samples that one would like to study are small and hard to obtain. Consequently it has been difficult, if not impossible, to use them for expression profiling. Recently, methods for amplifying RNA and then labeling probes have been published. These multistep procedures are tedious and expensive to perform, however. Here we describe a new technique for preparing fluorescent probes from total RNA. It is based on random hexamer priming with oligonucleotides having bases with free amino groups along with incorporation of amine-modified bases into the cDNA produced by reverse transcription. Fluorescent dyes are added to the cDNA products chemically after they are formed. This addition is quite efficient, and the dyes are much cheaper to purchase than dye-labeled bases. The proprietary method described herein can be used to label as little as 0.5 ug of total RNA. When a single-stage RNA amplification procedure is employed in tandem with our method, it can be used to label RNA from 1000 or fewer cells.

**Potential for genetic factors in General Clinical Research Center (GCRC) studies.** *J.A. Phillips III<sup>1</sup>, D. Robertson<sup>2</sup>.*  
1) Dept Pediatrics, Vanderbilt Univ Sch Medicine, Nashville, TN; 2) Dir Clinical Research Center, Vanderbilt Univ Sch Medicine, Nashville, TN.

Genetics is relevant to virtually all human diseases. While the genome sequence can be used to identify genes that may contribute to a disease, it cannot predict all possible genotype- phenotype correlations. Thus phenotype mapping will be needed to identify the genes that contribute to diseases. Many diseases are rare but some such as hypertension are common. Currently, little is known about genes that cause, or could be used to diagnose and treat such common diseases. We hypothesize that most diseases, phenotypes or clinical trials being studied in General Clinical Research Center (GCRC) research projects can be related to one or more known genes. To determine the proportion of GCRC projects for which a potential genetic factor could be identified, we reviewed 32 consecutive projects submitted to the Vanderbilt GCRC from 2/09-5/01/01. The phenotypes and/or medication(s) being studied were examined to identify candidate genes (major, modifying or multifactorial) or those which metabolize the medication being studied. We used the following databases: 1) NCBI (OMIM, LocusLink and SNP) at <http://www.ncbi.nlm.nih.gov/Sitemap/index.html> and 2) Human P450 Metabolism at [http://www.gentest.com/human\\_p450\\_database/srchh450.asp](http://www.gentest.com/human_p450_database/srchh450.asp). Of these 32 projects 59, 22, 6, 6 and 3% were medication trial, phenotyping, vaccine trial, gene identification and device testing. We identified genes which could potentially affect the phenotype being studied in 30/32 (94%) of the projects. The genes identified were of major effect, modifier/multi factorial or metabolized medications in 14, 43 or 43%, respectively of these 30 projects. Our data indicate that: 1) 94% of GCRC projects studied related to genes and 2) the most common study type (59%) is a medication trial for which gene(s) that metabolize the medication or modify the phenotype and have known variation were identified. Our data suggest that: 1) most GCRC projects are studies of phenotypes for which genes that could cause variation are known and 2) GCRCs have great potential to map phenotypes and become clinical arms of the Human Genome Project.

**A semi-automated data-processing system for large-scale determination of SNP allele frequency by SSCP. T.**

*Tahira<sup>1</sup>, K. Higasa<sup>1</sup>, A. Suzuki<sup>1</sup>, Y. Kukita<sup>1, 2</sup>, S. Baba<sup>1</sup>, K. Hayashi<sup>1</sup>.* 1) Division of Genome Analysis, Research Center for Genetic Information, Medical Institute of Bioregulation, Kyushu University, Fukuoka, Japan; 2) Human Genome Center, Institute of Medical Science, University of Tokyo, Tokyo, Japan.

Millions of candidate SNPs accumulated in public database are valuable resource for medical and biological studies, and technique to characterize these SNPs is required. We have developed a cost-effective and streamlined technique, PLACE-SSCP, in which the PCR products are fluorescently labeled and applied to capillary electrophoresis for SSCP-separation of SNP-alleles. SNPs are identified after sequencing of individuals who have different SNP-alleles and are correlated with the corresponding peaks of SNP-alleles. Allele frequencies of SNPs in the pooled DNA can be precisely determined from the peak heights of alleles in PLACE-SSCP analysis. To enable large-scale characterization of candidate SNPs with minimal human intervention, we have developed a laboratory information management system, dbQSNP, which works on the Unix server and can be accessed from client machines. This system designs experimental projects, analyses data of SSCP and sequencing, and stores relevant information. Genotyping results of SSCP and sequencing are checked for consistency to avoid errors coming from data handling. Software dedicated for capillary array-based SSCP analysis has been developed and integrated in this system. It performs SNP typing and SNP allele frequency determination in the following steps. 1) Peak detection in raw data of SSCP electrophoresis, and normalization of inter-capillary variation of mobility. 2) Allele definition of polymorphic STS and SNP identification. 3) Allele frequency determination of pooled samples. Allele frequencies are calculated automatically using data of pooled DNA and heterozygote. SNPs that cause subtle mobility shift can be quantified semi-automatically using a tool for peak separation. Hundreds of SNP data have already been processed using this database system.

**Primate Genome Evolution Analyses with BAC End Sequences.** *S. Zhao*<sup>1</sup>, *E. Eichler*<sup>2</sup>, *A. Shvartsbeyn*<sup>1</sup>, *M. Krol*<sup>1</sup>, *J. Cheng*<sup>3</sup>. 1) Dept of Mamalian Genomics, Inst for Genomic Research, Rockville, MD; 2) Dept of Genetics, Case Western Reserve University, Cleveland, OH; 3) Lawrence Berkeley National Laboratory, Berkeley, CA.

Random and targeted BAC clones of primates human, chimpanzee, baboon and lemur were electronically placed onto the human genome through the paired BAC end sequence matches. By examining the sequence conservations and long range variations, we analyzed human evolution of 60 million years. BACs that were targeted to hypervariable duplicated regions showed extensive structural rearrangement between closely related species as well as potential structural polymorphism within the human population. In contrast, unique region of the human genome were remarkably stable over evolutionary time and very little evidence of structural polymorphism (inversion, deletion or translocation) could be found within these regions. Duplicated regions present problems for human genome assembling, our data are therefore likely to facilitate the finishing of the human genome.

**Novel Human Ancient Sequence Genes Defined by *D. Melanogaster* Homology.** G.A. Bruns<sup>1,2</sup>, R.E. Eisenman<sup>1</sup>. 1) Genetics Division, Children's Hosp, Boston, MA; 2) Dept of Pediatrics, Harvard Medical School, Boston, MA.

More than 45 novel human genes that have significant homology in the *D. Melanogaster* genome but do not recognize known proteins or motifs have been identified by cross phylum database search. These genes are members of a small subset of loci that encode ancient conserved sequences of as yet unknown function. They define new protein families, some of which can be expected to have fundamental roles in cellular processes. BLAST searches of the *D. Melanogaster* EST database were carried out using human unique Unigene sequences as bait. Any high scoring retrieve that recognized a homolog of known function, a member of a function family, or an identified motif was excluded. The E values of the novel human ancient sequence genes ranged from  $e^{-131}$  to  $e^{-010}$  with the vast majority having scores of at least  $e^{-015}$ . In numerous cases, the extensive homology extended throughout the protein. Nearly all of these retrieves recognized the corresponding *C. elegans* homolog and many, the *S. cerevisiae* relative as well. RNA expression data for these novel human ancient sequence genes is being compiled.

In this study, human ESTs and mRNAs were used as bait for cross phylum database search. From our prior analysis of chromosome 22 and 21, a rich source of additional novel human ancient conserved sequence loci may be the category of "predicted genes" from the genomic sequence.

**Development of a system for parallel genotyping of human P450 single nucleotide polymorphisms: The CodeLink P450 Bioarray.** *J.D. Winick, A. Zilbergleyt, M.R. Bonner, B. Chui, P. Gwynne, K.R. Luehrsen, M. Gaskin, G.L. Kiser, T. Peters, T. Peck, T.J. Raich, Y. Jia, A. Gandhi, M. Hernandez, T. Perez, E. Pestova, D. Fermin, T.-C. Cheah, J. Gu, C.T. Yamashiro.* Motorola BioChip Systems, Tempe, AZ.

The Cytochrome P450 gene family is involved in drug metabolism and mutations in family members are indicative of an individual's response to many drugs. P450 genotyping will form the basis of pharmacogenomic studies in drug metabolism that relate to: systemic drug metabolism, inter-individual variability in drug metabolism, explanation of some specific toxic effects of drugs and explanation of multi-drug interactions. The CodeLink P450 Bioarray assay system developed at Motorola Life Sciences can detect 75 single nucleotide polymorphisms (SNPs) for 7 human P450 genes (CYP1A1, 1A2, 1B1, 2D6, 2C19, 2E1, and 3A4). The CodeLink SNP platform utilizes DNA polymerase-mediated, allele-specific extension of anchored oligonucleotide probes attached to a three-dimensional activated matrix. Each pair of allele-specific oligonucleotide probes is complementary at their 3' ends to the polymorphic position of a SNP. The P450 gene family is highly homologous between sub-family members at the nucleotide level and the inter-gene homology represents a challenge to developing a genotyping assay. PCR primer pairs were designed to amplify P450 DNA gene fragments without the amplification of highly related pseudogenes or homologous family member sequences. The CodeLink P450 Bioarray assay is a three step process: first, gene-specific target DNA is amplified by PCR from genomic DNA using CodeLink P450 Primer plates; second, the Allele Specific Extension assay is performed on the chip with CodeLink SNP genotyping reagents; and third, genotype data analysis is performed on scanned chip images using our proprietary CodeLink SNP calling algorithm. The data is tabulated and exported to a database using CodeLink Analysis software. Using DNA samples derived from known tissue culture lines the CodeLink P450 Bioarrays perform with a 99% call rate and a 99% accuracy as confirmed by conventional sequencing methods.

**Ultra-High Throughput Genotyping Platform using Arrayed Glass Plates and Primer Extension.** *P.A. Bell, X. Zhao, E. Huang, C. Emerich, R. Zhao, J.C. Wu, S. Varde, D. Kahn, K.E. Scott, C.A. Gelfand, M. Ruben, F. Jones, K. Chokshi, P. Farnsworth, V. Bogdanov, R. Kopla, F. Modica, A. Recber, A. Yasseen, J. Tarantino, M. Kochersperger, A. Huang, F.S. Kuo, M. Pohl, G. Schnerr, M. Boyce-Jacino.* Dept Biochemical Development, Orchid Biosciences, Inc, Princeton, NJ.

The success of the human genome project has increased interest in single nucleotide polymorphism (SNP) genotyping as the key measure of genetic diversity. Assays designed to score these polymorphisms are playing an increasing role in genome mapping and pharmacogenetic studies. To date, genome wide scans, and studies involving thousands of SNPs and patient samples have been hampered by the lack of a system that can perform genotyping with the needed throughput, reliability and cost. To address this need, we have developed an automated, ultra-high throughput system; SNPstream UHT™, which uses SNP-IT™, our proprietary single base extension technology. Assay design for the UHT system is performed with Orchids AutoPrimer™ software. The system uses microarrays manufactured in a 384-well format using a novel glass-bottomed plate and disulfide coupling chemistry. >10-plex PCR and genotyping are performed in homogeneous reactions, and assay results are read by direct fluorescence with our two-color SNPscope™ imager. We present here results of UHT genotyping on a panel of SNPs derived from The SNP Consortium database and human DNA samples from the Coriell repository. Using the UHT system, we have demonstrated the feasibility of analyzing 100,000 SNP genotypes per 8hr day.

**A high throughput SSCP method for large-scale analysis of SNPs/mutations using capillary-array electrophoresis system.** *Y. Kukita<sup>1,2</sup>, K. Higasa<sup>1</sup>, S. Baba<sup>1</sup>, M. Nakamura<sup>1</sup>, S. Manago<sup>1</sup>, A. Suzuki<sup>1</sup>, T. Tahira<sup>1</sup>, K. Hayashi<sup>1</sup>.* 1) Division of Genome Analysis, Research Center for Genetic Information, Medical Institute of Bioregulation, Kyushu University, Fukuoka, Japan; 2) Human Genome Center, Institute of Medical Science, University of Tokyo, Tokyo, Japan.

Characterization of human genome diversity is a major task of the genome project at the post-sequencing stage, and the technique to detect SNPs/mutations with low running cost is awaited for, by many researchers in medical science, who are ready to analyze their samples to elucidate genetic background of various human traits. We previously developed a cost-efficient mutation/SNP detection method, PLACE-SSCP, which is a combination of post-amplification fluorescent labeling of PCR products and automated capillary-electrophoretic SSCP analysis. We present here, a high throughput version of PLACE-SSCP, which uses commercially available capillary-array electrophoresis system, i.e., MegaBACE1000, ABI3100 and ABI3700. The main obstacle in the development had been the unavailability of sieving matrix and absence of the software suitable for the analysis. We first synthesized two different polymers, which were polyacrylamide for coated capillaries used by MegaBACE1000 and polydimethylacrylamide for uncoated capillaries used by ABI machines, respectively. The SSCP software, which can process raw electropherograms from instruments, was also developed in our laboratory. All instruments using the polymers described above showed high reproducibility between capillaries after alignment of sample peaks by internal markers, when analyzed by the software described above. We observed improved separation of alleles in buffers of lower pH and higher ion concentration. Analyses of more than 100 SNPs showed that the detection rate of polymorphic alleles was more than 90% in one electrophoretic condition. We conclude that the capillary-array based PLACE-SSCP is suitable for large-scale analysis of SNP/mutation detection because of its high sensitivity, high throughput and low running cost.

**SNPStream® MT, a microsphere-based, Primer Extension System for the Analysis of Single Nucleotide Polymorphisms.** *T.M. Mulcahy, M.A. Kunkel, D. Greeny, R. Liberchuk, A. Camisa, J. Studebaker, C.A. Gelfand, P.A. Bell, M. Boyce-Jacino.* Dept Development, Orchid Bio Sciences, Princeton, NJ.

The increasing interest in single nucleotide polymorphism (SNP) genotyping and the pharmacogenomic implications of correlating SNPs to phenotypes have resulted in the need for simple, highly efficient and accurate genotyping methods. Orchid BioSciences has developed SNPstream MT, an adaptation of Orchids SNP-IT primer extension genotyping technology to Luminexs microsphere-based assay platform. Validation of this system for multiplex genotyping was performed using 48 human DNA samples on a broad SNP panel. The SNP panel was chosen to include all possible biallelic SNPs (i.e. AG, TC, TA, TG, GC, AC) and to yield polymorphic data. The results of these experiments demonstrate that SNPstream MT is a highly efficient genotyping system that facilitates the analysis of multiplexed solution phase SNP-IT assays with a high degree of accuracy. The advantages of this microsphere-based system will be described along with details of multiplex genotyping and data on the accuracy and reproducibility of the results that have been achieved with the system.

**Development of the first Center for Genomic Medicine in Mexico.** *G. Soberon*<sup>1</sup>, *JP. Laclette*<sup>2</sup>, *A. Serrano-Perez-Grovas*<sup>3</sup>, *R. Tapia-Conyer*<sup>4</sup>, *JC. Valdes-Olmedo*<sup>1</sup>, *G. Jimenez-Sanchez*<sup>5,1</sup>. 1) Mexican Health Foundation (FUNSALUD); 2) National Autonomous University of Mexico (UNAM); 3) National Council for Science & Technology (CONACYT); 4) Secretary of Health (SSA), Mexico; 5) Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD, USA.

The Human Genome Project made evident the molecular bases of human individuality. Population analyses have identified polymorphisms associated with susceptibility and resistance to common multifactorial diseases. This information along with development of new genomic technologies has led to Genomic Medicine (GM), a more predictive and preventive medicine, with important social and financial implications. Mexico has over 50 different ethnic groups that contribute to the unique genomic makeup of the Mexican population. The first polymorphisms related to common diseases in our population have been identified. These findings, along with Mexico's long tradition of excellence in medicine and genetics, have provided bases for the first Mexican Center for Genomic Medicine (CEMEGEN). This national reference center for GM, will develop basic and clinical investigation contributing to the knowledge of the human genome, with particular reference to several Latin American populations. The unique horizontal structure of the CEMEGEN will stimulate continuous interactions with other academic centers in Mexico and the rest of the world. CEMEGEN will generate human resources and establish strong links with industry to capitalize new information through services and products for Latin America. In preparation for the foundation of CEMEGEN, on October 3, 2000, our initiative was funded through an official agreement signed by the heads of the National Autonomous University of Mexico, the Secretary of Health, the National Council for Research and Technology and the Mexican Health Foundation, to develop a feasibility study. This analysis has been completed and provides strong data to support scientific, technological, social, academic, political and economical feasibility to develop the CEMEGEN. This new institution will ensure high quality scientific research and production of human and material resources to develop GM in Mexico.

**Bench-top genotyping using a 96 strip-well primer extension SNP-IT™ assay.** *B.C. Sundaresan, M. Xu, K. Davis-Fleischer, M. Phillips, P.A. Bell, M. Boyce-Jacino.* Application Research, Orchid Biosciences, Inc., Princeton, NJ.

With the increasing availability of genomic DNA sequences, single nucleotide polymorphisms (SNPs) are fast becoming a powerful tool for genetic research, gene mapping and pharmacogenetics. While there are a number of tools available for SNP scoring, all of them require time consuming optimization and can require expensive instrumentation. We have adapted single base primer extension (SNP-IT) technology into an easy to use 96 well format that specifically overcomes these issues. The SNPware™ 96 Kit provides a cost effective, flexible and high quality solution to low or moderate volume SNP genotyping. DNA primers for the assay are designed using Orchids proprietary primer design software, through Orchids web site Autoprimer™.com. The DNA region that includes the SNP of interest is PCR amplified using one un-modified and one phosphorothioate modified primer. The addition of phosphorothioate groups to one of the primers enables single strand generation during the process. Single strand target DNA is hybridized to a SNP-IT oligonucleotide immobilized on the surface of a 96-well microtiter plate. Following hybridization, single base primer extension occurs by the addition of DNA polymerase and labeled terminators. The incorporated base is detected by an ELISA based colorimetric detection scheme. Results are readable by eye, or with a standard microplate reader. In a demonstration of the approach, 60 different SNPs with a genome-wide distribution were selected from The SNP Consortium database for testing with 20 Coriell DNA samples. SNPware 96 data analysis software, developed at Orchid, was used to visualize the data and facilitate genotype calling. This study demonstrates the utility of the SNPware 96 kit to perform genotyping studies without requiring costly instrumentation.

**TempliPhi™, F29 DNA polymerase based Rolling Circle Amplification of templates for DNA sequencing.** *T.L. Giesler, Y.C. Cai, J.W. Farchaus, J.R. Nelson.* Genomics Reagents, Amersham Pharmacia Biotech, Piscataway, NJ.

We have developed a DNA amplification kit that employs rolling circle amplification to generate high quality templates for DNA sequencing reactions. The TempliPhi™ kit takes advantage of the fact that cloned DNA is typically located in circular vectors. These are readily replicated *in vitro* using F29 DNA polymerase. This single subunit, proofreading DNA polymerase utilizes excellent processivity and strand displacement properties to generate multiple, tandem double stranded copies of the input circular DNA. High amplification levels (2-3 mg) can be obtained in a short time (4 hours) using random hexamer primers to initiate rolling circle amplification on very small amounts of input circular DNA. Input templates can be as little as 0.01 ng of purified plasmid DNA, a single bacterial colony or a small aliquot of a saturated overnight culture. After an initial denaturation step (3 minutes at 95°C), the amplification reaction proceeds at 30°C. F29 DNA polymerase can initiate synthesis from many primers on each circle, simultaneously advancing multiple replication forks around the circle in a highly processive fashion, generating as much as 10<sup>7</sup>-fold amplification of the input circular DNA. Once completed, the product can be added directly into sequencing reactions. This novel workflow can be completed in less than 5 hours with only two simple manipulations and eliminates the need for liquid cell cultures and template purification prior to DNA sequencing. Results obtained using this isothermal method of amplification to prepare sequencing templates from clones in M13, plasmid and cosmid vectors are presented. \*Address all correspondence to J.R. Nelson. E-mail: john.nelson@am.apbiotech.com.

**Isolation of the full-length cDNAs for "predicted genes" and finding "novel genes" on human chromosome 21.** *J. Kudoh, K. Shibuya, J. Wang, I. Obayashi, M. Tatsuyama, M. Takahashi, K. Kawasaki, A. Shintani, T. Sasaki, A. Shimizu, S. Asakawa, S. Minoshima, N. Shimizu.* Department of Molecular Biology, Keio University School of Medicine, Tokyo, Japan.

The chromosome 21 mapping and sequencing consortium including us finished 33.83-Mb genomic sequencing of chromosome 21 and identified 225 genes including 98 predicted genes (Nature, 405:311-319, 2000). We are now performing full-length cDNA isolation of "predicted genes" which were identified by sequence similarities to known genes and/or spliced EST matches and/or exon prediction programs. Putative exon sequences were used to amplify cDNA fragments by PCR using cDNAs from various human tissues. We identified nearly full-length cDNAs for predicted genes including DSCR6, C21orf20, C21orf21, C21orf22, ANKRD3 (ankyrin repeat domain 3), ZNF298, C21orf25, ZNF295, TMPRSS3 (transmembrane protease, serine 3), TSGA2 (testis specific gene 2), and SNF1LK (SNF1-like kinase), and a cluster of keratin-associated protein (KAP) genes on 21q22.3. Among these, TMPRSS3 was found to be responsible for the autosomal recessive nonsyndromic deafness DFNB8/DFNB10 (Nature Genet. 27:59-63, 2001). Furthermore, we recently identified another cluster of KAP genes on 21q22.11. Thus chromosome 21 may contain more than 40 KAP genes including pseudogenes in addition to the previously identified 225 genes. Because of difficulties in finding novel KAP genes, which are short single-exon genes and are hardly found by any exon prediction programs, we estimate that there may be hundreds of KAP genes in the human genome. The detailed transcript map and sequence information are available through our Web site (<http://www.dmb.med.keio.ac.jp>). These information and resources will be useful for identification of disease related genes, especially those responsible for a particular phenotype of Down syndrome or bipolar affective disorder, and structural and functional analysis of each of these genes.

**Pyrophosphorolysis activatable oligonucleotides have a high sequence specificity throughout their lengths.** *Q. Liu, S.S. Sommer.* Dept Molecular Genetics, City of Hope Natl Medical Ctr, Duarte, CA.

Pyrophosphorolysis activated polymerization (PAP) was initially developed to enhance the specificity of allele-specific PCR for detection of known mutations in the presence of a great excess of wild type allele. The high specificity of PAP derives from the serial coupling of pyrophosphorolysis-mediated activation of a pyrophosphorolysis activatable oligonucleotide (P\*) followed by extension of the activated oligonucleotide. Herein, we demonstrate that AmpliTaqFS or ThermoSequenase DNA polymerases greatly improve the efficiency of PAP, making it a practical technique for detection of rare mutations. We also show that pyrophosphorolysis activatable oligonucleotides (P\*) have the novel and unexpected property of high sensitive to mismatches throughout at least the sixteen 3' terminal nucleotides. PAP constitutes a technology platform of potential utility whenever high specificity is required along the length of an oligonucleotide, e.g. rapid microarray-based scanning for unknown mutations or analysis of chromatin structure.

Program Nr: 1633 from the 2001 ASHG Annual Meeting

**Human chromosome 21 updated annotation and additional resources at RIKEN GSC.** *T.D. Taylor.* RIKEN Genomic Sciences Center, Yokohama, Japan.

Chromosome 21 is the smallest human chromosome and is a model for physical mapping and sequencing of the entire human genome. Three copies of this autosome cause Down syndrome, the most frequent genetic disorder associated with significant mental retardation. The complete sequence of chromosome 21 provides a unique resource for understanding the molecular pathophysiology of Down syndrome, as well as all other monogenic and complex disorders that map to this chromosome, including Alzheimer's disease, leukemia, autoimmune disease, epilepsy and manic-depressive psychosis. It also stands as a structural framework from which the complete molecular architecture of the chromosome can be determined.

In an on-going effort to improve the quality of the sequence, several minor changes have been incorporated and are now available from our web site (<http://hgp.gsc.riken.go.jp/>) and in the public databases. The annotation data has been significantly enhanced, with more types of analyses having been performed. Of note is the inclusion of new genes, SNP information from clone overlaps and other sources, cross-species comparison analysis, additional gene-finding predictions, and homology information. Tables with summary information about the chromosome and statistical findings (i.e., frequency of alternatively-spliced exons) are also available on our web site. Several corrections have also been made to the annotation, thanks in part to feedback from the community. Of the remaining gaps, one clone gap has been partially filled, and all the sequencing gaps have now been sized.

We will continue to make updates, to make more views of the data available, to layer additional analyses and information on top of the existing data such as gene confirmation/expression data, and to include any additional genes or regulatory elements that are subsequently identified.

Program Nr: 1634 from the 2001 ASHG Annual Meeting

**From SNPs to Medical Utility.** *A. Braun.* Genomics, Sequenom, Inc., San Diego, CA.

The completion and availability of the entire human genome sequence is enabling for the discovery of genes and gene products involved in human complex disorders. The successful identification of these genes is dependent on available sample sets, a high-throughput scoring technology and an underlying scientific hypothesis on how to use the samples and the technology. Sequenom has developed a chip-based mass spectrometry approach for the analysis of single nucleotide polymorphisms (SNPs) the most abundant genetic variations, which is complemented by a fully automated SNP assay development procedure and the rapid assessment of allele frequencies in sample pools. This allows the cost effective testing of virtually all gene-based genetic variations and the association of the results with a variety of different phenotypes. We are currently developing the worlds most comprehensive set of reagents to test for SNPs. A scientific strategy using this reagent set for elucidating the major genetic factors involved in human diseases will be presented.

**Identification of disease associated genes and tumour class prediction by genome wide microarray-based DNA methylation scanning.**

*B. Genc<sup>1</sup>, P. Adorjan<sup>2</sup>, J. Distler<sup>1</sup>, E. Lipscher<sup>1</sup>, F. Model<sup>2</sup>, J. Mueller<sup>3</sup>, C. Pelet<sup>1</sup>, A. Braun<sup>3</sup>, D. Guetig<sup>3</sup>, G. Grabs<sup>1</sup>, R. Lesche<sup>1</sup>, E. Leu<sup>1</sup>, A. Lewin<sup>2</sup>, S. Maier<sup>1</sup>, V. Mueller<sup>2</sup>, T. Otto<sup>2</sup>, H. Ziebarth<sup>1</sup>, K. Berlin<sup>3</sup>, C. Piepenbrock<sup>2</sup>, A. Olek<sup>1</sup>.* 1) biomedical R&D, Epigenomics AG, Berlin, Germany; 2) information sciences, Epigenomics AG, Berlin, Germany; 3) technology development, Epigenomics AG, Berlin, Germany.

Class prediction is of crucial importance for most therapeutic decisions in cancer. Recent studies have shown that classification of cancers can be achieved by mRNA expression monitoring. However, due to difficulties with handling mRNA samples, expression analysis is not widely used for large-scale analyses or clinical settings. Here we present a novel, more robust approach to classify human cancers based on analysis of characteristic DNA methylation patterns. Information on methylation status was obtained for many sites in parallel using a DNA-based microarray. Methylation patterns were then presented to a learning algorithm to perform class predication. In addition, hierarchical clustering methods were used to show that class discovery is also possible. Our results demonstrate that analysis of methylation patterns combined with supervised and unsupervised learning techniques constitutes a powerful tool to classify human cancers.

**A real-time PCR assay for detection of disease susceptibility in an hereditary oxyradical overload condition.** *J. Fuchs, M. Podda.* Dept. of Dermatology, University of Frankfurt, Germany.

Hemochromatosis gene (HFE) linked hereditary hemochromatosis (HH), an autosomal recessive disorder, is one of the most common inherited diseases among individuals of Northern European ancestry. Two sites of point mutations in the HFE gene-C282Y and H63D-are associated with greater than 90% of HH cases. HH is a classic example of chronic iron toxicity with production of oxidative stress. In homozygotes and compound heterozygotes the massive iron overload may cause dysfunction of the liver, heart, and pancreas, finally leading to hepatic cirrhosis, liver cancer, diabetes and cardiac insufficiency among other sequelae. 10% of the Northern European population appears to be heterozygous for the hemochromatosis gene and most of these persons have elevated body iron levels, but are otherwise asymptomatic. Although it is commonly believed that the high frequency of heterozygotes may be related to a selective advantage in the past because of their slightly increased iron stores, in present times these individuals may be less in favor because of chronic co-exposure to oxidizing environmental pollutants leading to supra-threshold oxidative stress. Thus heterozygotes may be more likely to develop pathologic sequelae such as atherosclerosis, carcinogenesis and aging. If this hypothesis is true, HH heterozygotes may constitute an antioxidant responsive subpopulation that may benefit from preventive strategies and antioxidant supplementation therapy. We describe a rapid and reliable mutation analysis method for detection of the HFE mutations C282Y and H63D in mutant homozygous, wild-type, and heterozygous samples. This robust real time PCR assay is ideal for the clinical setting and for mass screening programs and will be employed for studies investigating the association of hemochromatosis heterozygosity and disease susceptibility.

**Performance Assessment of the Serial Analysis of Gene Expression (I-SAGE™) Molecular Biology Kit.** *P.N. Gilles<sup>1</sup>, Y. Zhang<sup>1</sup>, C. Stalder<sup>1</sup>, S. Roach<sup>1</sup>, A. Waters<sup>1</sup>, S.Y. Wong<sup>1</sup>, D. Mehta<sup>1</sup>, B. Cook<sup>2</sup>, S. Madden<sup>2</sup>, D. Brown<sup>1</sup>, M. Gleeson<sup>1</sup>.* 1) Genomics, Invitrogen Corp, Carlsbad, CA; 2) Genzyme Molecular Oncology, Framingham, MA.

SAGE™ or Serial Analysis of Gene Expression (Velculescu et al., Science 270, 484, 1995) is an established method for generating quantitative genome-wide expression profiles. The technique is based on the acquisition of 10-bp sequence tags, which identify each unique mRNA transcript, independent of prior sequence information. Ligations of two tags (ditag) serve as short uniform sized templates for PCR amplification with minimal bias and sensitivity for low copy transcripts. The SAGE library is constructed by the serial concatenation of ditags into elongated molecules which allows for the rapid sequencing and digital enumeration of 20 to 60 transcripts per sequencer lane. Importantly, SAGE experimental results are directly comparable to existing libraries in the public SAGEmap expression database (SAGEmap:<http://ncbi.nlm.nih.gov/>). A traditional molecular biology kit (I-SAGE™) has recently been developed and is commercially available from Invitrogen Corp. In this study, the I-SAGE™ Kit was evaluated for the representative expression of three housekeeping genes, elongation factor -1a, b-actin and glyceraldehyde 3-phosphate dehydrogenase, in the human lung carcinoma A549 cell line. The quantified expression of these housekeeping genes was evaluated in libraries generated from the manufactured I-SAGE™ Kit and compared to Beta test lots and to libraries generated with conventional SAGE methodology by an independent laboratory. The above analysis validated that the libraries generated using the I-SAGE™ Kit reflect conventional SAGE expression profiles and can be used to perform comparative analysis with other databases. The I-SAGE™ Kit facilitates the generation of complex and comprehensive expression profiles (>100,000 tags), which will contribute to the identification, cloning and characterization of genes involved in normal physiologic and pathologic states.

Program Nr: 1638 from the 2001 ASHG Annual Meeting

**Rapid analysis of biochemical modifications in DNA fragments - Visualisation of phosphorylation and cytosine deamination in single 15 minute analyses.** *M. Daniels<sup>1</sup>, M. Dickman<sup>2</sup>, D. Hornby<sup>2</sup>*. 1) Transgenomic Ltd, Crewe Hall, Crewe, Cheshire, UK; 2) Transgenomic Research Laboratory, Krebs Institute, University of Sheffield, Sheffield, UK.

The analysis of biochemical modifications in nucleic acids is often difficult, requiring multiple steps including enzymatic or chemical reactions, the need for fluorescent or radioactive labels, and the use of agarose or polyacrylamide gel electrophoresis with subsequent blotting and/or autoradiography. In addition, the interpretation of data from these analyses can be demanding in order to discern the presence of artefacts and correctly identify reaction products. A single analysis may reasonably be expected to run over two to three days. In order to overcome these limitations we have utilised the WAVE® Nucleic Acid Fragment Analysis System as an analysis platform to visualize a phosphorylation reaction catalysed by polynucleotide kinase and a cytosine deamination repair reaction catalysed by uracil DNA glycosylase. These analyses could equally be used to assay the respective enzyme activities, or to assay the quality of DNA with respect to phosphorylation or cytosine deamination. The WAVE® System readily resolved both phosphorylated from non-phosphorylated oligonucleotides and uracil containing from apyridinic oligonucleotides. The analysis required less than 15 minutes per sample and no radioactivity was required.

**Cross species hybridization of human microarrays to study diseases and mechanisms of drug action. L.M.**

*Barnes*<sup>1</sup>, *F. Staedtler*<sup>2</sup>, *J. Liebman*<sup>3</sup>, *M.H. Polymeropoulos*<sup>1</sup>, *C. Lavedan*<sup>1</sup>. 1) Novartis Gaithersburg, USA; 2) Novartis Basel, Switzerland; 3) Novartis Summit, USA.

DNA microarray technology provides the opportunity to look at the genome wide expression of disease processes and mechanism of drug action. Utilizing this technology to examine animal models of disease as well as studies that cannot be done in cell culture or in humans would be very useful. Microarrays have been developed for human, mouse, rat, yeast, and the fruit fly. The purpose of this study is to evaluate whether samples of other species can be analyzed by cross-hybridization to human DNA microarrays. We hybridized samples from various tissues of dog, cow, and monkey to Affymetrix human microarrays which interrogate ~ 6,000-12,000 genes and ESTs. Because of sequence differences between species, we anticipated that cross-hybridization to human arrays would result in a decreased hybridization of some of the perfect match probes and a increased hybridization to some of the mismatch probes; consequently there would be a decrease in the number of genes called "present" by the Affymetrix algorithm. Using standard protocols, we found that the average number of genes called "present" on the cross-hybridized arrays varied between ~ 11%; in dog, ~ 12% in cow, and ~ 35% in monkey, compared to ~ 40% in human. We observe that when hybridization intensity is significant, the pattern of expression for a specific gene across the 20 probe pairs of a set is remarkably similar between species. This indicates that data obtained on probes sets not called "present" can also be used by taking into account the non-specificity of the probe set across gene family members. Furthermore, clustering of microarray data, independent of the Affymetrix "present" or "absent" call, from various human and monkey tissues indicates that gene expression profiles generated by cross-hybridization to human arrays still provides useful information such as tissue-specific gene expression patterns. We conclude that, while cross-hybridization to human microarray is not as robust as same species hybridization, it is possible and offers an opportunity to generate very valuable information on gene expression profiles.

**Optimization of an External Standard for the Normalization of Affymetrix GeneChip® Array Data.** K.J.

Antonellis<sup>1</sup>, Y. Beazer-Barclay<sup>1</sup>, M. Elashoff<sup>1</sup>, S. Peres-da-Silva<sup>1</sup>, S. Jelinsky<sup>2</sup>, M.Z. Whitley<sup>2</sup>, E.L. Brown<sup>2</sup>, U. Scherf<sup>1</sup>.  
1) Gene Logic, Inc., Gaithersburg, MD; 2) Genetics Institute/Wyeth-Ayerst Research, Cambridge, MA.

Expression profiling using nucleic acid hybridization-based methods have become prevalent in medical and biotechnological research and development, diagnostic testing and drug development. It allows the researcher to screen thousands of genes on a single chip thus making this a time efficient technique. The reliability and utility of nucleic acid hybridization-based methods depends on accurate and reliable methods for accounting for variations between analyses. For example, variations in hybridization conditions, label intensity, reading and detector efficiency, sample concentration and quality, background effects, and imaging processing effects each contribute to hybridization signal heterogeneity. One of the challenges with the use of microarrays is identifying the optimal approach for normalizing one chip to another. One approach currently utilized is the use of global scaling for chip normalization. However, this analysis has significant limitations when comparing chips with different number of expressed genes. Here, we introduce the optimization strategy that utilizes 11 external spiked-in cRNAs for the use of generating the best standard curve to normalize chips to each other. We performed *in silico* and wet lab experiments to identify, from the 40,000,000 possible combinations of the 11 cRNAs, the best assignments for the individual concentrations of the external cRNAs. The generated standard curve is then used to convert gene expression intensity values into frequency numbers. We have demonstrated sensitivity of the external cRNAs down to 0.5 pM, 95% of the time. This external normalization has been validated on numerous GeneChip® arrays, like human, rat, mouse, yeast and *Arabidopsis* with  $R^2$  of approximately 0.985. We showed that external normalization has improved the data by allowing for comparison between genes on different chip types, higher accuracy in fold change analysis, as well as more powerful multivariate analysis.

**Technologies for generating, normalizing and subtracting cDNA libraries from small quantities of mRNA.** S. Bashiardes, Y. Korshunova, R. Tidwell, D. Hawkins, M. Lovett. Genetics, Washington University, St. Louis, MO.

An increasing number of expression-based studies focus upon generating accurate profiles from small amounts of RNA. We have modified several cDNA techniques to derive a method that allows for the construction of a representative cDNA library from as little as 5ng of mRNA without overt skewing in sequence representation. First strand cDNA is synthesized on a solid matrix and a modified SMART oligo is added to this. The cDNA is then PCR amplified through 15 cycles using nested primers and is cloned by ligation-independent methods. We have used this method to construct ten different cDNA libraries from microdissected tissues. In this method first stand cDNAs are retained on the solid matrix and can be used to derive targets for gene chip hybridizations by linear run-off amplifications. The method thus allows one to build cDNA libraries and conduct expression profiles from one small RNA sample. We have also developed new modifications to cDNA normalization and subtraction methods that are compatible with these libraries. These involve using PCR amplified and biotinylated inserts in a hybridization with very pure single stranded libraries of cDNAs. We have employed these methods in the generation of 8 normalized and two subtracted cDNA libraries. In a separate project we are also developing methods for building full length cDNA libraries. These are not immediately applicable to small amounts of RNA, but have great utility in extending parts of genes or ESTs. We have developed a method (double capture) that targets both the 5' and 3' ends of the mRNA:cDNA duplex following first strand synthesis (through the 5' CAP and 3' polyA tail). The 5' capture is achieved by binding to a synthetic aptamer. This yields approximately 10% of the synthesized first strand cDNA. The 3' capture is achieved using a specially designed Digoxigenin labelled capture oligo. Using a combination of this oligo and RNase treatment, we select against cDNA molecules synthesized through mispriming events. cDNAs synthesized from bone fide poly(A) tails are bound to anti-Dig magnetic beads. The resulting cDNAs are cloned and then evaluated by DNA sequence analysis.

**PCR device for highly parallel sample preparation for multiplex SNP genotyping platforms.** *M.T. Cronin, E.S. Mansfield, D. Dutta, M. Pho, J. Wu, M. Liu, B. Chen, A. Nguyen, D. Albagli, G. Bogdan, B. Silver, M. Tang, R. Anderson.* Applied Genomics, ACLARA Biosciences, Inc, Mountain View, CA.

The focus of human genomic research is rapidly shifting away from acquiring primary sequence data to cataloging and characterizing sequence variability. Mendelian and complex genetic disorder mapping is accelerating as dense genetic maps of common sequence polymorphisms evolve. The resulting sharp increase in demand for high throughput genotyping is being addressed with highly parallel analysis technologies such as hybridization arrays, bead arrays, mass spectrometry and capillary array electrophoresis. However, sample preparation remains a bottleneck effectively limiting access to these parallel readout methods. Generally, widely dispersed informative sequence polymorphisms, including SNPs and STRs are analyzed as pooled products from multiple single-plex PCR reactions, limited multiplex PCR reactions, or higher levels of multiplex PCR that require extensive assay development. This is to prevent primer interaction or allelic dropouts that complicate analysis and may lead to typing errors or decrease the yield of genotyping results. Amplification and labeling steps done in low multiplicity tend to be inefficient since it adds sample processing steps and leads to substantial reagent waste. We have developed a novel LabCard™ device to simultaneously amplify 960 PCR reactions using standard thermocyclers. More consistent representation of allelic products and better signal-to-noise were observed when the multiplex PCR was carried out in the prototype LabCard device than conventional multiplex tube reactions. Samples prepared using this device are compatible with a wide range of multiplex genotyping methods. Representative analytical data from primer extension based genotyping of informative SNPs in drug metabolizing enzyme genes using SNaPshot™ biochemistry and ABI 3100 analysis will be presented, as will additional data from samples prepared using LabCard devices for multiplex target amplification followed by primer extension labeling analyzed by array hybridization or MALDI-TOF detection.

**Perioperative Genomic Profiles With the Invader® Flap Endonuclease System.** *R.W. Kwiatkowski<sup>1</sup>, R. Selzer<sup>2</sup>, D. Green<sup>2</sup>, E. Rasmussen<sup>1</sup>, K. Hogan<sup>2</sup>.* 1) Third Wave Technologies, Madison, WI; 2) University of Wisconsin-Madison, WI.

Over 40,000,000 patients undergo anesthesia and surgery per year in North America. Despite profound heritable differences in response to potent drugs and stress of surgery, genetic factors are at present unaccounted for in advance. Here we compare the analytical validity of the novel Invader genotyping system with conventional PCR-based RFLP and sequencing methods for a panel of alleles, each with specific and well-established clinical utility. Genomic templates (blood, cheek swab) from 213 patients having outpatient, peripheral vascular, neurosurgical or solid organ transplant procedures were assayed for 690 genotypes using both PCR/RFLP and Invader assay techniques for 31 pathologic alleles in the BChE, RYR1, CACNA1S, CYP2D6, FV, FII, MTHFR, MTR, MTRR, CBS, TNF and genes. Overall concordance was 99.6% (687/690). The three discordant samples all appeared in the BChE locus (G1615A). The Invader assay reproducibly called all three heterozygote while PCR/RFLP results revealed wild type status, which was confirmed by PCR-sequencing. Invader assays are typically run directly on genomic DNA without prior target amplification using PCR. In an effort to resolve the discrepancies, the Invader assay was also run on PCR product for the three discordant samples. In that case the Invader assay results agreed with the wild type call made by the PCR based assays. The reason for the difference when this locus was tested directly on genomic DNA is unknown. DNA preparation or storage is suspect, the three discordant samples had been prepared using non-standard methods and stored over 10 years. We conclude that the Invader genotyping system is capable of high precision in the detection of SNPs, insertions, and deletions in both non-coding and coding regions underlying traits of clinical significance that may be genetically heterogeneous. Advantages in operator efficiency, cost, and safety, coupled with avoidance of PCR-based cross-contamination and mis-incorporation point to important advantages of Invader-based methods in genotyping many millions of patients for hundreds of alleles in the perioperative interval.

**Making DNA microarrays optimization and comparison of various DNA immobilization strategies.** *S. Kmoch<sup>1,2,3</sup>, L. Ondrová<sup>1,2</sup>, M. Nová<sup>1</sup>, M. Jebková<sup>1,2</sup>, M. Hřebíček<sup>1,2,3</sup>*. 1) Inst Inherited Metabolic Dis, Charles Univ 1st Sch Medicine, Prague 2, Czech Republic; 2) Center for Integrated Genomics, Prague; 3) GeneAge Technologies, Prague.

Efficient and uniform immobilization of target DNA molecules onto a glass surface is one of the critical steps in making DNA microarrays and is central to the quality of the resulting data. We have adopted and compared immobilization of amino-modified DNA onto a poly-L-lysine and 3-glycidoxypropyltrimethoxysilane-modified glass surfaces, disulphide-modified DNA onto a 3-mercaptopropyltrimethoxysilane-modified glass surface and a disulphide-modified DNA covalently cross-linked to 3-mercaptopropyltrimethoxysilane onto unmodified glass surface. Individual chemistries were tested with Cy5 and Cy3 labeled PCR products or Cy5 labeled oligonucleotides. Target DNA was spotted by GeneSurfer arrayer (GeneAge Technologies) and individual reaction steps were followed by IVL laser scanner (Genomic Solution). Our experience showed that published immobilization protocols were usable only after careful optimization. Poly-L-lysine chemistry is useful for binding of amino-modified and even of non-modified DNA. However, blocking procedure limits its application only for hybridization experiment. Disulphide chemistry is applicable for both hybridization and primer extension experiments. Procedure is fast, effective and cheap what makes it preferable for high-throughput array production.

Program Nr: 1645 from the 2001 ASHG Annual Meeting

**Detection of Cytokine Induction in Cell Lysates Using a Biplex mRNA Invader® Assay.** *M.C. Olson, S.M. Olson, W. Iszczyszyn, P.S. Eis, T. Takova, M.L. Curtis, L. Chehak, B.T. Argue, R.W. Kwiatkowski.* Third Wave Technologies, Madison, WI.

The Invader technology is a flexible, isothermal, easy to use method that can accurately quantitate mRNA without target amplification. Low variability (3-10% coefficient of variation) provides accurate quantitation of less than two-fold changes in mRNA levels. A biplex FRET-based detection format enables simultaneous quantitation of expression from two genes within the same sample. One of these genes can be an invariant housekeeping gene that is used as the internal standard. Normalizing the signals from the gene of interest with the internal standard provides accurate results and obviates the need for replicate samples. A simple and rapid cell lysate sample preparation method can be used with the mRNA Invader assay. The combined features of biplex detection and easy sample preparation make this assay readily adaptable for use in high-throughput applications. Results will be presented demonstrating biplex detection of cytokine and housekeeping gene expression levels with automated 96- and 384-well microplate formats.

**A multiplex solution for SNP interrogation using fifth-dye labeled short size standard and single-tube primer extension reaction.** *S.S. Kuo, G. Ayanoglu, D. Wei, M. Johnson, D. Bishop, A.B. Tomaney, P. Dong.* Applied Biosystems, Foster City, CA.

A variety of methods may be used to characterize and to screen single nucleotide polymorphisms. Analysis platforms include microarray scanning, real-time PCR analysis (TaqMan), and MALDI-TOF. In addition, electrophoresis-based techniques include OLA analysis, dideoxy sequencing, and single-nucleotide primer extension (SNE). SNaPshot is a single-tube SNE reaction designed for elucidation of individual loci within known sequence contexts for the purpose of SNP screening and validation.

The completed reaction identifies one nucleotide located 3' relative to the primer site. We have reformulated our SNaPshot reagent mix to enable robust multiplex SNP interrogation against multiple templates in varying amounts. The resulting multiple products can then be analyzed by electrophoresis in the presence of a size standard, labeled with a 5th dye. Evaluations on ABI Prism Models 310, 3100, and 3700 have been successful.

We describe the development of a 5th-dye labeled short size standard for analyzing small fragments on fluorescent detection systems. This standard contains 9 fragments ranging from 15 to 120 nucleotides. During evaluation on various capillary electrophoresis platforms, we are able to achieve excellent precision and curve-fitting. The fifth dye is spectrally well-resolved from other dyes. The 5th-dye size standard is designed in particular to enable automated data analysis in methods for SNP detection. In our poster, we will demonstrate its utility in SNE assays. With the combination of different primer lengths and four-color sample chemistry, the potential for multiplexing SNP loci exists for high-throughput genotyping with minimal optimization.

**GeneJumper<sup>TM</sup>-oriV Transposon: A valuable tool for retrofitting BACs/PACs with an amplifiable origin of replication in genome sequencing.** *U. Matrubutham<sup>1</sup>, J. Liu<sup>1</sup>, D.M. Brown<sup>1</sup>, W. Szybalski<sup>2</sup>, M.A. Gleeson<sup>1</sup>.* 1) Gene Discovery, R&D, Invitrogen Corporation, Carlsbad, CA; 2) McArdle Laboratory for Cancer Research, University of Wisconsin Medical School, Madison, WI.

Invitrogen's GeneJumper<sup>TM</sup> transposon is an artificial mini-Mu transposon used in *in vitro* transposition reaction to randomly insert primer-binding sites into target DNA. The transposon enables rapid generation of DNA templates for bi-directional sequencing without the need for shotgun cloning or primer walking of large plasmids such as BACs and PACs. We have subcloned the DNA element of the origin of replication oriV, from plasmid RK2, into the GeneJumper<sup>TM</sup> transposon (called GeneJumper<sup>TM</sup>-oriV) in order to retrofit BACs/PACs with this ori via *in vitro* transposition. This ori becomes amplifiable in the presence of a copy-up mutant of the replication initiation protein TrfA. We have validated the GeneJumper<sup>TM</sup>-oriV transposon for efficient retrofitting of BACs, increased plasmid yield upon amplification (2 to 6 ug ml<sup>-1</sup>), and stable maintenance of large plasmid upon prolonged amplification. We have also shown the applicability of the transposon for high-throughput sequencing. GeneJumper<sup>TM</sup>-oriV transposon is available from Invitrogen Corporation, Carlsbad, CA in a kit format, which consists of reagents for *in vitro* transposition, the suitable *E. coli* competent cells for oriV amplification and the primers for bi-directional sequencing.

**Application of a DNA microarray-based comparative genomic hybridization (Array-CGH) method to the study on the genetic effects of Atomic bomb radiation.** *N. Takahashi<sup>1</sup>, K. Sasaki<sup>1</sup>, N. Tsuyama<sup>1</sup>, M. Kodaira<sup>1</sup>, M. Itoh<sup>1</sup>, I. Danjo<sup>1</sup>, S. Kyoizumi<sup>2</sup>, N. Niikawa<sup>3</sup>, A. Fujiyama<sup>4</sup>.* 1) Lab Biochem Genet/Dept Genet, RERF, Hiroshima, Japan; 2) Dept Radiobiol, RERF, Hiroshima, Japan; 3) Nagasaki Univ Sch Med, Nagasaki, Japan; 4) Nat Inst Genet, Mishima, Japan.

For over 50 years, the Foundation has conducted a study on the effects of A-bomb radiation on human germ cells. For the study at the genome-level, it is essential to efficiently collect a large volume of genetic information from a sufficient number of subjects. It is also important to accurately detect a gene deletion which occurs on an autosome (in most cases, radiation-induced mutations appear to be about 1 Mb deletion type), since the deletion appears as a change from 2 allele copies to a single copy. Comparative genomic hybridization (CGH) was developed for genome-wide analysis of DNA copy number in a single experiment. However, conventional CGH limits detection of events involving small deletion (of less than 20 Mb). On the other hand, there are reports that Array CGH can detect single-copy decrease and increase from normal diploidy, and have higher resolution power than conventional method. Thus, the Array CGH is considered to be an effective method for our study. We therefore tested the effectiveness in an experimental system. Cosmid DNA clones containing DNA fragments from either autosomes or X chromosomes, and Pac DNA containing the fragments, which were deleted in Prader-Willi syndrome (PWS) patients, were immobilized on a glass. The DNA from females labeled with Cy5 was used as internal control, and the DNAs of females, males, or PWS patients were separately labeled with Cy3 and used as a test sample. A mixture of labeled DNAs was hybridized and quantified. We demonstrated that female-DNAs contain 2 copies, and male-DNAs contain 1 copy from the fluorescence ratio on the spots of X chromosome's clones. We also found that there was a single copy decrease in DNAs from the PWS patients on the spots of the corresponding clone spots. These results indicate that the Array CGH can detect changes in the copy number of specific loci in genome-DNA. Thus, this method should prove most useful for our study.

**SNP Detection on Solid Surface Using the Invader® Assay.** *P. Wilkins Stevens<sup>1</sup>, J. Hall<sup>2</sup>, V. Lyamichev<sup>2</sup>, B. Neri<sup>2</sup>, D. Kelso<sup>1</sup>.* 1) Biomedical Engineering, Northwestern University, Evanston, IL; 2) Research & Development, Third Wave Technologies, Inc., Madison, WI.

We have demonstrated that the invasive cleavage reaction can be performed on a solid phase. The solution-phase invasive cleavage assay, a signal-amplification method capable of distinguishing nucleic acids that differ by only a single base, is already an effective tool for many genomic applications such as scoring single nucleotide polymorphisms, tracking genotypes of viruses and microorganisms, and monitoring gene expression. The method positions two overlapping oligonucleotides, the probe and upstream oligonucleotide, on the target nucleic acid to create a complex recognized and cleaved by a structure-specific 5-prime nuclease. In the solid-phase experiments, both the probe and upstream oligonucleotide were attached to the surface of microparticles, which served as the solid-phase platform. The probe, configured with a 5-prime terminal dabcyl molecule and an internal fluorescein, was fluorescence-quenched until target-directed cleavage released the dabcyl quencher. Targets based on the ApoE 158 Cys and Arg alleles were tested with particles coated with Cys- or Arg-allele probes, and target-specific probe cleavage was documented. The particle-bound Cys probes were enzymatically cleaved only when the target was based on the Cys allele, while the particle-based Arg probes were cleaved only when the target corresponded to the Arg allele. Effective cleavage of the probe oligonucleotide occurred when probe and upstream oligonucleotides were positioned away from the particle surface via long tethers; a number of different tether lengths were tested.

Three different methods for reading fluorescent signal from the particles are being investigated: real-time monitoring of the fluorescence of a suspension of particles with a fluorometer, measuring the fluorescence of individual particles on a fluorescence-activated cell scanner, and reading the fluorescence of particles immobilized on a microscope slide.

**Whole genome amplification with a highly frequent degenerated oligo pair (HFDOP).** *K. Zhang<sup>1</sup>, L. Jin<sup>2</sup>.* 1) Human Genetics Center, UTHHSC-SPH, Houston, TX; 2) Department of Environmental Health, University of Cincinnati, Cincinnati, OH.

Whole genome amplification has its wide application in a variety of genetic analysis wherever the amount of DNA available is limited. Several techniques have been proposed for the whole genome amplification, including inter-IRS PCR, IRS-Bubble PCR, tagged PCR and DOP PCR. It has been shown that DOP PCR not only produce a good coverage, but also is technically simple and robust. However, based on the recently published human genome draft sequence, our analysis shows that approximately 20 percent of the human genome do not have a primer pair in proper orientation within the range of 5Kb, which is the upper size limit for normal PCR amplification, and hence is not accessible for DOP PCR amplification. Here we report a pair of primers for whole genome amplification designed with a novel strategy. Firstly, we established an oligo distribution database based on the human genome draft sequence for the oligos between 6 mers to 12 mers. Highly frequent probabilistic "contigs" were assembled from those 10mers that have more than 10,000 copies in the haploid genome, and totally twenty seven primers were designed based on four selected contigs. Secondly, the priming capability and the genome coverage of these primers and their combinations was tested both electronically and experimentally, then a degenerated primer pair, term as highly frequent degenerated oligo pair (HFDOP), was selected for whole genome amplification. Electronic PCR indicates that the inaccessible region of the human genome can be reduced 3 percent, which is also supported by gel electrophoresis that shows much more bands for PCR with our primer pair than that for DOP PCR. Finally, we labeled the PCR products with fluorescent dyes, hybridized them with a human cDNA expression array containing 2764 genes. By comparing the number of spots, which have pixel distribution significantly different from that of the local background, we found that the coverage of the PCR product with HFDOP is approximately 43% higher than that with DOP. In summary, HFDOP PCR is a robust and simple whole genome amplification method with much higher genome coverage than other WGA methods available.

**An efficient application of MALDI-TOF/MS coupled with micorarray for detection of microsatellite**

**polymorphism.** *Y. Yoshikawa*<sup>1</sup>, *K. Nakajima*<sup>4</sup>, *N. Kimura*<sup>1</sup>, *M. Gonda*<sup>2</sup>, *K. Okamoto*<sup>4</sup>, *M. Ota*<sup>3</sup>, *G. Tamiya*<sup>4</sup>, *H. Inoko*<sup>4</sup>.  
1) Nisshinbo Industries, INC, Chiba, Japan; 2) Shimadzu Corporation, Kyoto, Japan; 3) Sch Medicine, Shinshu Univ, Matsumoto, Japan; 4) Sch Medicine, Tokai Univ, Isehara, Japan.

The analysis of microsatellite polymorphisms mainly depends on the electrophoretic separation of fluorescently labeled PCR products. There is an increasing demand for genotyping method that can provide large amount of genetic information in a time-efficient and cost-effective manner.

To address this request, we have been developed an alternative method by matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF/MS). MALDI-TOF/MS offers unprecedented speed for analysis with excellent accuracy in measuring DNA fragment size. However, the conditions for DNA detection using MALDI-TOF/MS has not been considered, especially when a large DNA fragment is analyzed. In order to optimize the conditions for large DNA fragment, we first examined matrices, small organic molecule, which is a key part of mass spectral method. We have screened 147 compounds as potential matrices, and we find that several of these compounds were useful for the preparation and analysis of samples. Among them, the best results were obtained with 2,4-dihydroxyacetophenone. With this matrix, we successfully detected 100- and 102- nucleotide samples with extremely high-resolution that sufficient to distinguish single-nucleotide difference. Next, we examined carbodiimide-coated glass plate instead of expensive stainless-steel plate that commonly used to MALDI-TOF/MS. As a result, we clearly detected PCR products of 200 bp on this glass plate. Moreover, microarray-based hybridization assay is verified using the glass plate. Conditions for hybridization were optimized, and we were able to detect the DNA fragment hybridized on the glass plate using MALDI-TOF/MS without any non-specific signals.

These results indicate that MALDI-TOF/MS coupled with microarray technology is now emerging as a powerful approach of high-throughput and cost-effective alternative to gel electrophoresis for precise determination of polymorphic microsatellites.

**New tools to study proteins involved in disease: FSHD as paradigm.** *S. van Koningsbruggen*<sup>1</sup>, *H. de Haard*<sup>2</sup>, *R.W. Dirks*<sup>1</sup>, *J.T. den Dunnen*<sup>1</sup>, *G.W. Padberg*<sup>3</sup>, *G.J. van Ommen*<sup>1</sup>, *C.T. Verrrips*<sup>2</sup>, *R.R. Frants*<sup>1</sup>, *S.M. van der Maarel*<sup>2</sup>. 1) Center for Human & Clinical Genetics and Dept. of Molecular Cell Biology, LUMC Leiden, Leiden, Netherlands; 2) Unilever Research, Vlaardingen, Netherlands; 3) Dept. of Neurology, UMCN Nijmegen, Nijmegen, The Netherlands.

Facioscapulohumeral muscular dystrophy (FSHD) is caused by a complex genetic rearrangement. Likely, partial deletion of the subtelomeric D4Z4 repeat on 4qter causes the transcriptional deregulation of nearby genes by a position effect variegation-like mechanism. Consequently, there are no obvious structural mutations within the FSHD candidate genes, complicating their positive identification.

Next to expression profiling of candidate genes, we have embarked on protein profiling employing llama-derived phage-display single (heavy) chain antibody fragments. *Camelidae* carry apart from a conventional antibody repertoire, a unique repertoire of heavy-chain antibodies that only consist of two heavy chains and are devoid of light chains. Using this antibody repertoire as source for phage-display libraries circumvents the in vitro combination of heavy and light chains, one of the major drawbacks of conventional phage-display libraries. Moreover, these antibodies have unique properties regarding affinity and stability. Current strategies are directed in optimizing high-throughput selection and screening protocols and design of phage-display vectors allowing uniform arraying, visualization, and intracellular expression. Due to their small size (14kDa) and high affinities, autofluorescent heavy-chain antibody fragments will be eminently suited for a variety of applications.

As proof of principle, we successfully generated immune-libraries raised against cocktails of proteins and whole human skeletal muscle homogenate. We selected high-affinity antibody fragments against FRG1P, the gene product of one of the candidate genes for FSHD. These antibody fragments perform well in a series of immunological techniques: for example, co-localization was observed for EGFP-tagged FRG1P and selected heavy-chain antibody fragments.

**Full-length cDNA cloning of tissue specific expressed sequence tags.** *Z. Xu<sup>1</sup>, L. Jia<sup>2</sup>, K. Eng<sup>1</sup>, C. Xia<sup>1</sup>, D. Jablons<sup>1</sup>.*  
1) Cancer Ctr, Univ California, San Francisco, San Francisco, CA; 2) Medical Genetics Branch, NHGRI/NIH, Bethesda, MD.

One of the ultimate goals of high through-put EST sequencing is the development of resources for study on functional genomics of different tissues. A large number of tissue specific expressed sequence tags (EST) have been isolated. Because of short sequences for ESTs, it is important to isolate full-length cDNA clones for functional analysis of the tissue-specific ESTs. We have developed a library-free method for rapid full-length cDNA cloning. The method involves ligating an anchor sequence to 3 ends of the first strand cDNA using T4 DNA ligase after reverse transcriptase reaction. An oligo-nucleotide primer specific to tissue related ESTs was biotinylated and hybridized with the first strand cDNA pool. EST-specific first strand cDNA was captured by streptavidin-coated magnetic beads and eluted. The purified EST-specific first strand cDNA was then amplified using high fidelity thermal stable DNA polymerase and cloned into plasmid vectors. We have successfully cloned full-length cDNAs for several known human genes including p53 (2.5 kb), transferrin receptor (5 kb) and CFTR (6.2 kb) using this approach. Four bone tissue specific ESTs (453, 467, 509, 835) were tested using this method. Full-length cDNA fragments were successfully amplified and cloned from three of the four ESTs tested and the complete inserts were under sequence analysis. The results demonstrate that this library-free method is more efficient for cloning full-length cDNAs than conventional method and should be useful for generating full-length clones for tissue specific ESTs. (Supported in part by NIH grant R21CA85172).

**Generation of high specificity cRNA Probes from 1 ug of total RNA for Hybridization onto DNA Microarray Glass Slides.** *J. Tajbakhsh, S.F. Nelson.* Human Genetics, UCLA, Los Angeles, CA.

DNA microarray technology is a powerful method to simultaneously monitor the activity of thousands of genes thus allowing the parallel analysis of gene expression changes in a given biological context. Since its introduction as a high-throughput method DNA-microarrays have been used to address questions in a variety of biomedical fields. Typical gene expression analyses using glass arrays require relatively large quantities of total RNA (up to 100 ug) or poly A+ RNA (5ug). However in a number of application fields the amount of starting material is very low. For instance, samples prepared by microdissection of small tissue regions or collected from patient biopsies or embryonic material often contain only a few cells and therefore yield relatively little RNA. To date several approaches have been reported to circumvent probe limitation either by an enzymatic amplification of the poly A+ message, involving PCR, or by a post-hybridization signal amplification step. In order to rule out the possibility of introducing biases via non-linear amplifications, we have developed a simple, reproducible, and representative method which allows us to perform gene expression profiling on DNA microarrays from 1ug of total RNA. In this approach double-stranded cDNA is synthesized from total RNA including a promoter for the T7 RNA polymerase on its upper strand, followed by one round of T7 based in vitro transcription (IVT) in which modified UTP molecules (aminoallyl-UTP or Cy3/Cy5-UTP) can be incorporated into nascent antisense RNA (aRNA) products. In this way enough RNA can be amplified (up to 600 fold) to sensitively probe a spotted array while maintaining the relative abundance of mRNA species. We have experienced that the combination of RNA amplification and cRNA labeling in one step is time saving and cost effective and therefore offers an attractive way to generate hybridization probes for a large number of microarray analyses with limiting samples.

**Single Label, Single Reaction, Single Nucleotide Polymorphism Genotyping.** *S.A. Varde, M.A. Kunkel, C.A. Gelfand, M.T. Boyce-Jacino.* Assay Research, Orchid BioSciences, Inc., Princeton, NJ.

For correlating molecular markers (single nucleotide polymorphisms or SNPs) with disease states, either to diagnose a disease or to identify a drug target, it is imperative to have assays that are robust and simple to use. Orchid has developed a bi-allelic SNP-IT<sup>TM</sup> single nucleotide primer extension technology that will facilitate a single SNP genotyping reaction that uses only a single color. This SNP-IT assay involves using multiplex PCR as a template and is carried out in solution phase as a multiplex reaction in a single well using a single label on each of the allelic terminating nucleotides for detection. The analysis can be performed on various platforms and its simplicity enables it to be easily automated. Furthermore, the requirement of only one labeled terminator makes the assay cost-effective. The same assay scheme can be applied to our more traditional two-label assay with redundant data that makes possible even higher confidence genotype scoring, and enabling all four base identities to be genotyped in multiplexed reactions with only two labels. Assay results using a variety of platforms using both the single- and dual-label variations of this SNP-IT assay are presented.

**The 1.4 Mb CMT1A duplication/HNPP deletion genomic region reveals unique genome architectural features and provides insights into the recent evolution of new genes.** *J.L. Badano<sup>1</sup>, K. Inoue<sup>1</sup>, K. Dewar<sup>2</sup>, N. Katsanis<sup>1</sup>, L.T. Reiter<sup>1</sup>, E.S. Lander<sup>2</sup>, K.L. Devon<sup>2</sup>, D.W. Wyman<sup>2</sup>, B. Birren<sup>2</sup>, J.R. Lupski<sup>1</sup>.* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Whitehead Institute for Biomedical Research, Cambridge, MA.

Duplication and deletion of the 1.4 Mb region in 17p12 that is delimited by two 24 Kb low copy number repeats (CMT1A-REPs) represent frequent genomic rearrangements resulting in two common inherited peripheral neuropathies, Charcot-Marie-Tooth disease type 1A (CMT1A) and hereditary neuropathy with liability to pressure palsy (HNPP). A gene within the 1.4 Mb region, *PMP22*, is responsible for these disorders through a gene dosage effect in the heterozygous duplication or deletion. However, the genomic structure of the 1.4 Mb region, including other genes contained within the rearranged genomic segment, remains essentially uncharacterized. To delineate genomic structural features, investigate higher order genomic architecture, and identify genes in this region we constructed PAC/BAC contigs and determined the complete nucleotide sequence. This genomic segment contains 1,421,129 bp of DNA. A low copy number repeat was identified, with one copy inside and two copies outside the 1.4 Mb region. Comparison between physical and genetic maps revealed a striking difference in recombination rates between the sexes with a lower recombination frequency in males (0.67 cM/Mb) versus females (5.5 cM/Mb). Hypothetically, this low recombination frequency in males may enable a chromosomal misalignment at proximal and distal CMT1A-REPs and promote unequal crossing over, which occurs 10 times more frequently in male meiosis. In addition to three previously described genes, five new and 13 predicted genes were identified. Analyses of the genomic region adjacent to proximal CMT1A-REP indicated an evolutionary mechanism for the formation of proximal CMT1A-REP and the creation of novel genes by DNA rearrangement during primate speciation. In addition, using this finished genomic sequence a set of 15-STR markers that can detect >99% of CMT1A duplication was developed for potential diagnostic use.

**Smith-Magenis syndrome repeat gene clusters - structure, evolution, and breakpoints of genomic rearrangements in human and gorilla.** *P. Stankiewicz*<sup>1</sup>, *S.-S. Park*<sup>1</sup>, *W. Bi*<sup>1</sup>, *L. Potocki*<sup>1</sup>, *J. Lehoczyk*<sup>3</sup>, *K. Dewar*<sup>3</sup>, *B. Birren*<sup>3</sup>, *J.R. Lupski*<sup>1,2</sup>. 1) Depts. of Molecular & Human Genetics; 2) Pediatrics, Baylor College of Medicine, Houston TX; 3) Whitehead Institute for Biomedical Research/MIT Center for Genome Research, Cambridge, MA.

Over 90% of SMS patients are deleted for an identical ~4Mb 17p11.2 genomic region, whereas in the remainder both smaller and larger sized deletions were identified. Our studies demonstrated the presence of three large, complex low-copy repeat gene clusters: proximal SMS-REP (progenitor, ~260Kb) is in the same orientation as distal SMS-REP (~190Kb), whereas middle SMS-REP is inverted. These architectural features enable substrates for non-allelic homologous recombination resulting in both deletions and reciprocal duplications of the same region within 17p11.2. This chromosome segment is also associated with breakpoints of the *idic(17)(p11)* chromosome (CML, PNETs) and with the breakpoint of an evolutionary chromosome *t(4;19)* in gorilla. These observations suggest that it is susceptible to mitotic and meiotic rearrangements and that higher order genomic architecture involving low-copy repeats plays a significant role in the genome evolution during primate speciation. To delineate the genomic structure and evolution of SMS-REPs we constructed a complete BAC contig, are determining the genomic sequence, and performed FISH and Southern hybridization studies in several primate species. We identified that SMS-REPs are absent in mice and were duplicated after the divergence of New World Monkeys from pre-monkeys, >40Mya. In addition to a strong signal on 17p11.2, BACs containing SMS-REP showed in FISH studies weaker signals on 17q11.2, 17q12q21, and 17q24. BLAST analysis revealed that SMS-REPs shares ~25Kb fragments of 99% homology with NF1-REPs. To further investigate the relevance of SMS-REPs structures to chromosome rearrangements, we analyzed the breakpoints of unusual sized deletions in SMS patients. The SMS critical region was narrowed to ~1Mb. All 5 patients with a smaller sized deletions have their proximal breakpoints mapping within the middle SMS-REP and their distal breakpoints within or adjacent to distal SMS-REP.

**Identification of genes involved in susceptibility to bipolar affective disorder using GeneChips.** *L.J. Adams, P.R. Schofield.* Neurobiology, Garvan Institute, Sydney, Australia.

Bipolar affective disorder (BD) is a major psychiatric condition characterized by severe mood disturbances. BD is treated by anti-manic drugs such as lithium and anti-epileptic/anti-manic drugs such as valproate, although we still know little about how these drugs exert their therapeutic mood stabilising effects. We are using the mouse as a model to investigate the expression of genes that are modulated by anti-manic drugs through the use of microarray studies. Our premise is that since the currently used drugs take several days to effect therapeutic benefit, they must cause changes in gene expression in the brain as an essential prerequisite to the onset of clinical effectiveness. Genes found to be commonly modulated by more than one of the anti-manic drugs are candidates that may have a role in the etiology of BD. We have validated treatment doses in mice for both lithium and valproate to achieve the equivalent of human therapeutic serum levels of these drugs. We have obtained brains from mice treated for 7 days with either valproate (400 mg/kg/day, n = 10); lithium (340 mg/kg/day), separated into those with high (0.8-1.2 mM; n = 10) or medium (0.4-0.7 mM; n = 10) serum levels of lithium; or saline controls (n = 10). Our initial experiments were undertaken using Affymetrix Murine U74A GeneChips, each containing approximately 12,000 transcripts, and mice (n = 5) with high lithium serum levels (meanSD = 0.940.03 mM) or saline controls (n = 5). Analysis of these GeneChips identified 20 transcripts expressed at least two-fold more, and two genes expressed at least two-fold less in the lithium treated animals compared to the controls. These represent members of different gene families, including protein kinases, transcription proteins, and integral membrane proteins. These studies may help to elucidate the underlying cellular events that ultimately lead to the onset of bipolar disorder, and the biological pathways that are involved in disease pathogenesis.

**Construction of a microarray on 5q31-q33 region array to identify genes controlling resistance or susceptibility to parasitic diseases as schistosomiasis and malaria.** *C. Chevillard<sup>1</sup>, N. Haribou<sup>1</sup>, R. Tagett<sup>2</sup>, B. Lorient<sup>2</sup>, R. Houlgatte<sup>2</sup>, C. NGuyen<sup>2</sup>, A. Dessein<sup>1</sup>.* 1) INSERM U399, faculty of medicine, Marseille, 13385, france; 2) INSERM U136, parc scientifique de luminy, case 906, Marseille, 13288, france.

Schistosomiasis affects 200 million people and is a major public health problem in many southern countries. Our group performed studies on the causes of high infections in an endemic area of Brazil. Certain subjects appeared to be predisposed to high infections whereas others always exhibited low infection in spite of high exposure. This suggested that host-specific factors were important in the control of infection. Using segregation and linkage analysis, it was shown that there was strong evidence for the control of infection by a major locus (SM1) which was located in the 5q31-q33 region which contains a number of gene that encode cytokines that play an important role in the regulation of immune response against parasites. Immunological studies performed on the same population showed that SM1 control is linked to the differentiation of the T helper cells into Th1 or Th2 lymphocytes. Furthermore, it was also reported that blood parasitemie in *Plasmodium falciparum* are controlled by a locus located in the same region. This region is containing a large number of genes. In order to facilitate the analysis of this locus we have developed a systematic expression level analysis of all the coding regions of the 5q31-q33 interval by microarray technology. The target will be a I.M.A.G.E. clone set (approximately 800) arrayed on nylon support. The probe will be labeled with 33P. Indeed combination of nylon array with 33P labeled radioactive probes provides 100 fold better sensitivity, making it possible to perform expression profiling experiments using submicrogram amounts of unamplified total RNA from small biological samples. Generation of a 5q31-q33 region specific array will be essential for study of several others diseases as asthma familial hypereosinophilia. The results obtained in the analysis of mRNA expression in subjects with schistosomiasis will be presented.

**Functional analysis of promoter SNPs.** *B. Hoogendoorn, K. Smith, S. Coleman, C. Guy, P.R. Buckland, M.C. O'Donovan.* Dept Psychological Medicine, Univ Wales Col Medicine, Cardiff, Wales.

Single nucleotide polymorphisms (SNPs) in the regulatory regions of genes may affect transcription by altering binding or recognition sites for transcription factors or RNA polymerase. Consequent variation in gene expression may be implicated in inherited psychiatric disorders. We have developed a rapid and simple method for detecting promoter activity of putative gene promoters and for comparing the effect of promoter region polymorphic variants on the expression of genes. To date, we have selected 1050 putative gene promoters identified from a variety of publicly available databases. To date, we have designed PCR primers for 630 of these promoters. The primer pairs spanned the DNA sequence 500bp immediately upstream of, and including, the start of transcription. PCR conditions were optimised for 400 of the 630 promoters, which were subsequently amplified from DNA of 16 unrelated subjects. Amplimers were screened for heteroduplex formation by DHPLC. To date, 207 out of 400 promoters were found to be polymorphic. SNPs were confirmed and characterised by sequencing. Allelic pairs of promoters were cloned into a modified pGL3 luciferase expression T-vector, and transfected into 3 cultured cell lines (HEK293T, TE671, JEG3) before measuring levels of luciferase by luminometry. By utilising 96 well plate technology and an internal control plasmid expressing secreted alkaline phosphatase, each of these allele pairs can be tested for relative promoter activity in each of three cell lines. Significant differences in activity were detected between alleles in many of the pairs assayed. This work is ongoing and the relevant numbers are likely to change considerably.

**Complete transcript map of the Wolf-Hirschhorn syndrome critical region (WHSCR) by comparative sequence analysis between man and mouse, expression analysis and functional studies.** *N. Pfarr*<sup>1,2</sup>, *S. Ende*<sup>2</sup>, *S. Schlickum*<sup>2</sup>, *C. Steglich*<sup>2</sup>, *M. Oswald*<sup>1</sup>, *B.U. Zabel*<sup>1</sup>, *J.-H. Bebermeier*<sup>2</sup>, *A. Winterpacht*<sup>2</sup>. 1) Childrens Hospital, University of Mainz, Mainz, Germany; 2) Institute of Human Genetics, University of Hamburg, Hamburg, Germany.

Wolf-Hirschhorn syndrome (WHS) is a complex and variable malformation syndrome resulting from the absence of the distal segment of one chromosome 4 short arm. Clinical and cytogenetic data indicate that WHS is a contiguous gene syndrome with an undefined number of genes contributing to the phenotype. The WHS critical region (WHSCR) has been confined to a 165 kb gene rich region on chromosomal subband 4p16.3. From clinical data (Rauch et al., 2001) and from mouse experiments (Naf et al., 2001) it is known that deletion of the WHSCR alone results in mild WHS features. Nevertheless, deletion of this region seems to be necessary (but not sufficient) for the complete WHS phenotype in man and mouse. Our studies aim at the identification of all genes and regulatory regions in the WHSCR (including flanking regions) as well as the functional characterization of the gene products. We and others have previously identified novel genes in the WHSCR and flanking region. Here, we report the reinvestigation of the WHSCR using comparative sequencing of the corresponding chromosomal region in the mouse genome (chromosome 5) and interspecies sequence comparison to identify evolutionary conserved and therefore functionally important sequences. The study was accompanied by detailed expression analysis of the resulting transcripts and by functional studies of selected genes. On the basis of these data we present a novel, complete transcript map of the Wolf-Hirschhorn syndrome critical region in man and mouse. Besides the known genes LETM1, WHSC1, WHSC2 and POL4P we identified additional putative transcribed sequences which may represent alternatively spliced exons and/or additional genes. One of these transcripts shows specific expression in several adult and fetal organs affected in WHS patients. Further activities will concentrate on the functional analysis of the transcribed sequences and on conserved non-coding regions.

**Identification of human genes specifically expressed in retina.** *S. Schultz*<sup>1</sup>, *T. Leveillard*<sup>2</sup>, *J. Sahel*<sup>2</sup>, *C. Lavedan*<sup>1</sup>. 1) Pharmacogenetics, Novartis, Gaithersburg, MD; 2) INSERM/ULP/HUS EMI 99-18, Strasbourg France.

Retinal degenerative diseases affect millions of people all over the world. Unfortunately, there are few effective treatments for retinal degenerative diseases, such as Retinis Pigmentosa and Age Related Macular Degeneration. Most retinal degenerative diseases are inherited. Several genes such as RHO and PDE6B have been shown to be mutated in some patients. The identification of other genes specifically expressed in human retina may provide new clues in understanding the development of these diseases. It may also aid in designing more specific and effective treatments. The purpose of this work was to identify genes specifically expressed in the human retina and more precisely, genes expressed in the periphery containing rod photoreceptors and genes expressed in the macula containing cone photoreceptors. Retina samples were obtained from two male individuals. From each retina, the periphery and macula were separated and RNA was extracted. The 4 samples were individually hybridized to an oligonucleotide microarray containing ~12,000 probe sets. Retina specific genes were found by comparing gene expression profiles obtained from these 4 retina samples to profiles of more than 50 different normal adult and fetal tissue samples. Comparisons of profiles were performed using our in-house Novartis Pharmacogenetics Network (NPGN) database. The comparison of the two macula samples with the two periphery samples allowed us to determine in which type of retinal cells (rod or cone) these genes were expressed. The gene expression profiles were also analyzed using GeneSpring software to identify clusters of co-regulated genes. The identification of rod and cone specific genes, combined with mapping information of disease loci, is providing a new list of candidate genes potentially mutated in patients with retinal degenerative diseases. Furthermore, clusters of genes co-expressed in different regions of the retina are providing a greater understanding of the pathways involved in the development and function of the human retina. These results should help in initiating new experiments designed toward the discovery of better therapeutics for retinal diseases.

**Validation of SNPs in asthma candidate genes on chromosome 2q from public data bases using pooled DNA samples and the MALDI TOF technique.** *T. Immervoll, H. Gohlke, M. Wjst.* Inst. of Epidemiology, GSF Research Ctr, Neuherberg, Bavaria, Germany.

During asthma inflammation many mediators are released and involved in tissue damage. A key element in the inflammatory response is the prompt production of proinflammatory cytokine IL-1 $\beta$ . Exogenous administration of IL-1 $\beta$  creates airway responsiveness. On the other hand IL-1Ra has anti-inflammatory properties. Therefore the imbalance between these proinflammatory and inhibitory cytokines may be an important determinant of asthma. These genes as well as the corresponding receptors have all been mapped to the same chromosomal region 2q12-21, where linkage with asthma and allergy genes has been detected. We therefore looked for SNPs from public available databases located in these genes (<http://www.ncbi.nlm.nih.gov/LocusLink>). Up to now 64 of 97 SNPs in genes of the IL1 gene cluster have been analysed in 94 probands of a German population study where DNA concentration was measured with cyber green and pooled into one tube. A pool of equimolar amounts of DNA of each proband was then PCR amplified in the regions of interest and the corresponding SNPs were analysed with the MALDI TOF technique (Buetow et al., 2001). Comparing mass peaks of the two possible SNP variants we calculated the frequencies of the analysed SNPs. 24 of the 64 SNPs could not be found in our population as they all had frequencies lower than 10%. 20 SNPs showed a frequency of 10 - 20% in this population, 14 SNPs from 20 -30% and six between 30 and 50%. These SNPs are now tested in the individual proband DNA samples. First results indicate that the results of the individual and the pooled DNAs do not differ more than 5 %, which should be sufficient for the association analysis of a complex diseases like asthma. -Buetow KH, Edmonson M, MacDonald R, Clifford R, Yip P, Kelley J, Little DP, Strausberg R, Koester H, Cantor CR, Braun A (2001) High-throughput development and characterization of a genomewide collection of gene-based single nucleotide polymorphism markers by chip- based matrix-assisted laser desorption/ionization time-of-flight mass spectrometry. *Proc Natl.Acad.Sci U.S.A* 98:581-584.

**Leaky imprinting in the Prader-Willi Syndrome region.** *C.I. Brannan, S.J. Chamberlain.* Department of Molecular Genetics and Microbiology and the Center for Mammalian Genetics, University of Florida, Gainesville, FL.

Prader-Willi syndrome (PWS) appears to be a contiguous gene syndrome resulting from mutation of two or more imprinted genes. Previously, we described a mouse model for PWS in which paternal transmission of a 35 kb PWS Imprinting Center (PWS-IC) deletion mutation resulted in complete loss of local paternal gene expression. On the (C57BL/6J x 129/Sv)F1 genetic background, these PWS mice exhibit severe growth retardation, hypotonia and neonatal lethality. Our long-term goal is to rescue these neonatal phenotypes via genetic complementation in an effort to functionally identify the causative genes in PWS. Our strategy has been to create multiple lines of transgenic mice on the FVB/NJ genetic background using bacterial artificial chromosomes (BACs) that contain either individual or groups of PWS candidate genes. We have then bred transgenic females with males harboring the PWS-IC deletion mutation and genotyped and observed the resulting offspring. In the course of these experiments, we have found that the (FVB/NJ x 129/Sv)F1 mice harboring the PWS-IC deletion mutation are able to survive to adulthood provided the majority of the wild-type sibs are removed within a few days after birth. While these surviving mice are smaller than normal, they do not get obese and both males and females have proven to be fertile. To determine why these mice survive, we assayed expression of the PWS candidate genes at birth, 1 week, 2 weeks, and 3 weeks of age. We found that expression of multiple PWS candidate genes was detectable at low levels (only detectable by RT-PCR, but not by Northern blot) by 1 week of age. Even more surprising is that based on analysis of *Snrpn* we have determined that this expression is derived from the maternal FVB/NJ allele. These results lead to two conclusions. First, it appears that certain mouse strains do not silence imprinted genes as completely as other strains. This suggests that either the machinery of imprinting or the cis-elements have diverged among strains, resulting in leaky imprinting. Second, to rescue the majority of PWS phenotypes, it appears that only low levels of expression of PWS candidate genes may be required.

**Disruption of the imprinting center on human chromosome 15q11-q13 region using the DT40 cell shuttle system.**

*M. Meguro, M. Haruta, M. Oshimura.* Dept Molecular Cell Genetics, Tottori Univ Sch Life Sci, Yonago, Tottori, Japan.

Human chromosome 15q11-q13 harbors multiple imprinted genes that are involved in Prader-Willi (PWS) and Angelman (AS) syndromes, two distinct mental retardation disorders caused by paternal and maternal deficiencies, respectively. Several PWS and AS patients have been found to have microdeletions in a region of upstream of the SNRPN gene referred to as the imprinting center (IC). The IC is proposed to regulate initiation of imprint switching for all genes in a 2 Mb imprinted domain during gametogenesis. Recent studies of a rare PWS family and chimeric mice with imprinting mutations showed clearly that de novo IC deletion on the paternal chromosome results in postzygotic acquisition of a maternal epigenotype in somatic cells. Certainly the IC is therefore the region of mechanistic importance in the process of genomic imprinting of 15q11-q13. However, how the IC performs this function is unknown.

Previously, we demonstrated that the targeting experiments using the DT40 cell shuttle system demonstrate that the human *LIT1* locus can act as a negative regulator *in cis* for the coordination of imprinting at the chromosomal domain. This system can be used to define regulatory elements that confer long-range control of gene activity within chromosomal domains. Thus, we are generating modified human chromosomes carrying a targeted deletion of the PWS/AS IC using the DT40 cell shuttle system to the role of IC in maintenance of parental imprint in this region.

**Transcribed single nucleotide polymorphisms as markers for screening genomic imprinting.** *G. Zhu, R.H. Lipsky, K. Xu, L.A. Akhtar, G.L. Jenkins, D. Goldman.* Laboratory of Neurogenetics, NIAAA, NIH, Rockville, MD.

Single nucleotide polymorphisms (SNPs) in transcribed regions are ideal markers for detecting allele-specific patterns of gene expression. To facilitate rapid identification of imprinted genes and to perform large scale screening of RNA samples for quantitation of gene imprinting patterns, a method for measuring allele-specific differential expression was developed and applied to two known imprinted genes: Small nuclear ribonucleoprotein polypeptide N (SNRPN) and Insulin-like growth factor 2 receptor (IGF2R) expressed in human lymphoblast cell lines. Relative allele-specific mRNA levels were determined using a reverse transcriptase (RT)-coupled 5 nuclease fluorescence assay. Genomic imprinting was determined by pair-wise comparison of SNRPN or IGF2R allele expression in mRNA from individuals heterozygous for a coding region SNP. These expression patterns were confirmed by RT-PCR based RFLP method. The parental origin of the expressed allele was confirmed by pedigree analysis.

For SNRPN, only one allele was expressed in 11 heterozygous lymphoblastoid cell lines, consistent with complete genomic imprinting, and the origin of the expressed allele was in each case paternal, as predicted. In contrast, only one of 10 heterozygous cell lines showed mono-allelic expression (maternal) of IGF2R, the other 9 heterozygotes showed bi-allelic expression of IGF2R. These results suggest that IGF2R is polymorphically imprinted. The RT-coupled 5 nuclease fluorescence assay appears to be a reliable approach for large scale screening of imprinted genes. This approach can be extended to detect unknown functional polymorphisms in promoter regions and to determine the influence of SNPs in 5' and 3' untranslated regions on gene expression.

**LD, FRAX and sequence-based maps.** *S. Ennis*<sup>1</sup>, *A. Collins*<sup>1</sup>, *A. Murray*<sup>2</sup>, *G. Brightwell*<sup>2</sup>, *N.E. Morton*<sup>1</sup>. 1) Wessex Human Genetics Inst., Duthie Building (Mp 808), Southampton General Hospital, Southampton, Hampshire, U.K; 2) Wessex Regional Genetics Laboratory, Salisbury District Hospital, Wiltshire, U.K.

The FRAX region at Xq27-28 is one of the most intensively studied areas of the genome by virtue of its associated syndromes. Our studies on over 7000 independent haplotypes, one of the largest collections in the world, have revealed extensive linkage disequilibrium (LD) across the region (Ennis et al, 2000). We have also demonstrated that LD may be applied to evaluate the accuracy of alternative sequence assemblies within the region. Using the  $r$  (rho) parameter as the measure of association and estimating  $M$ ,  $e$  and  $L$  in the Malecot equation, where  $E(r) = Me^{-ed}$ , we compared a sequence-based map (<http://genome.ucsc.edu/>) to our older map which was based on linkage, radiation hybrid and physical mapping [Location DataBase (LDB) [http://cedar.genetics.soton.ac.uk/public\\_html/](http://cedar.genetics.soton.ac.uk/public_html/)]. The value of  $M$  remains stable and there is no evidence against  $L=0$  for either map. Evidence against the non sequence-based map is stronger than  $c^2_1 = 28$ . The swept radius (the value at which LD falls to  $\sim .37$  of its original value) increases from 420 kb for our older LDB map to 1000 kb for the sequence-based assembly, reflecting the greater length of the new map.

Our current project is designed to extend our understanding of LD in the region. We are genotyping selected subsets of our independent chromosomes for single nucleotide polymorphisms (SNPs) covering a region of approximately 4.5 Mb from 1.5 Mb proximal to FRAXA to 1.5 Mb distal to FRAXE at a density of 1 SNP per 100kb. We employ SNPs which have been first characterised in chromosomes with a clinically interesting FRAXA repeat number. These data will be used to better determine localised recombination hot and cold spots, test map order integrity and investigate any SNP associations with the dynamic mutation which causes the fragile X syndrome.

**The mouse orthologue of the glutamate receptor-like gene *GRINL1A* maps to mouse chromosome 9.** K.S.

Wydner<sup>1</sup>, B.K. Mohan Raj<sup>2</sup>, S.W. Finkernagel<sup>3</sup>, L.J. Sciorra<sup>3</sup>, R.S. Roginski<sup>2</sup>. 1) Biology, Saint Peter's College, Jersey City, NJ; 2) Anesthesiology, University of Medicine and Dentistry of New Jersey, Robert Wood Johnson Medical School, New Brunswick, NJ; 3) Obstetrics and Gynecology, University of Medicine and Dentistry of New Jersey, Robert Wood Johnson Medical School, New Brunswick, NJ.

An intron capture strategy involving use of polymerase chain reaction was used to identify and map the mouse orthologue of *GRINL1A*, a human glutamate receptor-like gene. Oligonucleotides complementary to adjacent exons in the rat orthologue of *GRINL1A* were used to amplify the corresponding segment from mouse genomic DNA. Sequencing of the resulting mouse DNA fragment of approximately 2 kb revealed that the exon sequences at the ends of the amplified fragment are highly homologous (96% nucleotide identity) to both the rat orthologue and the human *GRINL1A*. A *BstXI* restriction site polymorphism within the mouse intron was used to map the mouse glutamate receptor-like gene (*Grinl1a*) to mouse chromosome 9 in a region that shares linkage conservation with human chromosome 15q21-q22, to which *GRINL1A* was recently mapped by in situ hybridization. *GRINL1A* is a functional and positional candidate gene for autism susceptibility. *Grinl1a* cosegregates with several genes that are expressed in neural tissues, including *Adam10*, *Foxb1b*, *Gnb5*, *Myo1e*, and *Tcf12*.

**Do expression patterns correlate with genetic linkage regions?** *A.M. Valdes, K. Jones, A. Schafer, D. Townley.*  
Incyte Genomics, Cambridge, England.

We have investigated whether a gene expression pattern-recognition searching tool termed Guilt -by-Association (GBA) could be used to identify genes which predispose to osteoporosis. GBA (Walker et al Genome Res 1999; 9:1198) finds transcripts with similar expression patterns by reducing expression data to a binary variable (present or absent). A gene is considered to be present if cDNA corresponding to the gene is detected in the sample from that library and absent when no cDNA for that gene is detected in the library. To determine whether two genes have significantly similar expression patterns their occurrences in a large number of cDNA libraries are examined, a contingency table is built and the probability of the table under the assumption of independent expression is computed. Using GBA, we examined the gene expression in 1176 cDNA libraries, and analyzed the transcripts that mimic the expression pattern of four genes known to affect the risk of osteoporosis: vitamin D receptor (VDR), estrogen receptor alpha (ESRA), transforming growth factor beta-1 (TGFB1) and collagen type I alpha 1 (COLIA1). 219 transcripts were found to have significantly similar patterns to one or more of the above genes. Only one gene (LMP7) had a significantly similar expression pattern to all four candidate genes. The map locations of the 219 transcripts were derived by mapping their sequences to the Santa Cruz genome assembly contigs and extracting the map positions of the contigs. Of the 219 transcripts, 29 fell within the linkage regions reported in published genome-wide linkage scans for bone mineral density (BMD; Koller et al. J Clin Endocrinol Metab 2000 85:3116; Niu et al. Hum Genet 1999 104:226). These regions are: 1q21-23,11q12-13, 5q33-35,6p11-12,2p21-24 and 13q34. To assess the relevance of this finding, the mapping location of 400 random genes was derived. Only 19 of these 400 mapped to any of the above mentioned linkage regions. The proportion of sequences falling within linkage regions derived from GBA (13.2%) is significantly higher than the one derived from random genes (4.7%) with  $p < 0.0001$ . Our results suggest that GBA can be a valuable tool in the search for genes involved in susceptibility to complex diseases.

**High-resolution human genome-wide integrated radiation hybrid and linkage maps.** *T. Matisse<sup>1</sup>, S. Sabuktagin<sup>1</sup>, E. Sulman<sup>2</sup>, E. Katz<sup>2</sup>, C. Porter<sup>3</sup>, P. White<sup>2,4</sup>.* 1) Genetics, Rutgers Univ, Piscataway, NJ; 2) Oncology, Children's Hospital of Philadelphia, PA; 3) Genome Database, Toronto, ON, Canada; 4) Pediatrics, University of Pennsylvania, Philadelphia, PA.

Even as complete genomic sequence is becoming available, high-resolution maps of the human genome continue to serve many important roles in sequence assembly, disease gene and comparative mapping, disease risk prediction, and understanding mechanisms of recombination. As part of our eGenome data integration project, we have constructed a novel set of high-resolution linkage and radiation hybrid (RH) maps, using publicly available data. Although other groups have used overlapping subsets of the same data to construct similar maps, our approaches are different, more comprehensive, and provide a unique and complementary resource. Combined with including the most comprehensive sets of markers, these unique maps can play very useful roles for the ongoing functions of linkage and RH maps and can assist in more accurate draft sequence assemblies.

We first constructed a novel set of RH maps using all publicly available markers (> 54,000) scored in the GB4 panel and obtained from the Radiation Hybrid Database (RHdb). A stringent mapping approach was employed using the MultiMap, RADMAP, and CRI-MAP computer programs. Polymorphic markers within this set were identified and given priority for placement on the map, to improve integration with our linkage maps. We then constructed novel meiotic linkage maps using all publicly available polymorphic markers (> 12,000) genotyped in the CEPH reference pedigrees and obtained from the CEPH Genotype Database, the Marshfield Center for Medical Genetics, and the CHLC. The subset of polymorphic markers present on our backbone RH maps were used as initial skeletal maps for the construction of meiotic linkage maps using procedures similar to those used for RH mapping. The average resolution (Mb/map interval) is 0.96 and 1.5 and density (markers/Mb) is 10 and 4 for the RH and linkage maps, respectively. These maps have been integrated into our eGenome database (<http://egenome.chop.edu>).

Program Nr: 1671 from the 2001 ASHG Annual Meeting

**A Higher Resolution Genetic Map.** *A. Kong, D.F. Gudbjartsson, G.M. Jonsdottir, M. Frigge, S.A Gudjonsson, J. Sainz, T.E. Thorgeirsson, B. Hallbeck, S. Sigurdardottir, J. Gulcher, K. Stefansson.* Decode Genetics, Reykjavik, Iceland.

By genotyping 146 Icelandic nuclear families with over 6000 polymorphic markers, we have constructed a genetic map based on 1257 meioses, 658 male and 659 female, or more than six times the number of meioses upon which the Marshfield map is based. In addition to providing a more accurate map for linkage analysis, the larger sample size provides substantially higher resolution for studying the variation of recombination rates across the genome, the relative recombination rates between sexes, the correlation between recombination rates and linkage disequilibrium, and the relationship between recombination rates and sequence parameters including G+C content, density of genes, density of SINEs, LINEs, LTR and DNA elements and other repeated elements. Previously unknown local patterns of recombination rates have been detected throughout the genome. We have also used the data to identify and correct some problems in the current assembly of the public sequences.

**Human physical map version 05 and discrepancies with the UCSC sequence draft assembly.** *J. Sainz, S. Gudjonsson, K. Agnarsson, O. Atladottir, U. Benitez, S. Einarsson, E. Gonzalez, O. Traustason, S. Palsson, G. Sigurdsson, D. Gudbjartsson, G. Jonsdottir, M. Frigge, A. Kong, K. Stefansson, J. Gulcher.* Decode Genetics Inc, Reykjavik, Iceland.

We have developed an automatic method to integrate data from different sources to rapidly construct genomic physical maps. We used the method to generate five consecutive versions (V01 to V05) of human genome physical maps. In version05 we integrate experimental and in silico data with data from the public domain including the working draft assembly from the 12 December 2000 freeze released by UCSC. The experimental data includes hybridization of 10,388 microsatellite markers versus the RPCI-11 BAC library. We also integrated a high resolution genetic map generated at Decode. Map V05 includes among other data, 71,670 UniGene clusters in 82,740 locations, 10,932 RefSeqs in 20,512 locations, 5,847 expressed sequences containing trinucleotide repeats with a total of 7,644 repeats, 164,669 STSs and 11,610 microsatellite polymorphic markers. Comparison among the order of markers in our map and in the UCSC sequence revealed some strong discrepancies. We are currently modifying the draft sequence assembly according to our physical and genetic maps.

**On PREDs and ORFs of human chromosome 21.** *M. Friedli, C. Henrichsen, F. Chapot, M. Guipponi, R. Lyle, A. Reymond, S. Antonarakis.* Division of Medical Genetics, Univ. of Geneva Medical School, Geneva, GE, Switzerland.

An extra copy of chromosome 21 causes Down Syndrome (DS), the major genetic cause of mental retardation, which affects approximately 1 live born child in 700. To understand the molecular pathogenesis of DS, it is necessary to identify all Human Chromosome 21 (HC21) genes. The sequence of the entire human chromosome 21 identified 151 genes, while 79 novel anonymous genes solely identified by gene prediction and/or spliced ESTs still need to be confirmed as *bona fide* transcripts. Experimental documentation of full-length transcripts is of importance since bioinformatic analyses do not always accurately predict the full genomic structure of a gene, or provide detailed information about the pattern of expression, alternative splicing and the 5 and 3 extremities of the transcript. To identify candidate genes for DS phenotypes we are systematically sequencing human ESTs mapping to chromosome 21 and murine ESTs mapping to the syntenic regions on mouse chromosomes 16, 17 and 10, and corresponding to the published PREDs and C21ORFs. This allowed to refine the gene models by combining two predicted genes in one (e.g. C21orf11 and PRED44), by splitting a predicted gene in two (e.g. PRED54), by showing that the predicted gene does not correspond to a transcript as another gene is present at this locus (e.g. PRED56), or by showing that the predicted gene correspond to a pseudogene (e.g. PRED31); the analogous gene mapping elsewhere on the human genome. The revision of the HC21 transcriptome will have implications for the rest of the genome in terms of the quality of previous annotations and the total number of the transcripts, as well as providing new candidates for genes involved in Down Syndrome.

**Dissecting the genomic patterns of methylation status by novel melting curve based methods.** *D.T. Akey, J.M. Akey, K. Zhang, L. Jin.* Environmental Health, University of Cincinnati, Cincinnati, OH.

DNA methylation is the covalent modification of cytosine to 5-methylcytosine at CpG dinucleotides and may have a myriad of functional consequences such as mediating tissue and developmental-specific gene expression and providing a mechanism to control endogenous parasitic mobile genetic elements. Moreover, aberrant regulation of DNA methylation can lead to various types of cancer and neurodegenerative diseases. The two most common methods to determine methylation status are Methylation Specific PCR (MSP) and COBRA. Both of these assays require initial modification of DNA by sodium bisulfite, which converts unmethylated cytosines to uracil. MSP relies on PCR primers specific for methylated versus unmethylated DNA whereas COBRA employs restriction enzymes to differentiate methylated and unmethylated DNA. Although these methods are powerful and conceptually straightforward, in practice MSP and COBRA are not amenable to high-throughput analyses because they are labor intensive and expensive. To address these limitations, we have adapted MSP and COBRA to a melting curve analysis (MCA) platform (which we denote as  $M^C$ MSP and  $M^C$ COBRA) that eliminates the need for gel-electrophoresis. MCA is performed by slowly heating DNA fragments in the presence of the double stranded DNA specific fluorescent dye SYBR Green I. As the sample is heated, fluorescence rapidly decreases when the melting temperature of a particular fragment is reached. Our data suggests that MCA is at least 10 times as sensitive compared to gel-electrophoresis. In addition,  $M^C$ MSP and  $M^C$ COBRA are well suited for high-throughput applications because 96 samples can be analyzed and automatically scored in under 15 minutes. Furthermore, preliminary data suggests that  $M^C$ MSP and  $M^C$ COBRA allow quantitative estimates of methylation status. We demonstrate the use of  $M^C$ MSP and  $M^C$ COBRA by assessing the methylation status in the promoter region of two important tumor suppressor genes, p16 and p15 from normal tissue and bladder tumors. In conclusion,  $M^C$ MSP and  $M^C$ COBRA allow the methylation status of CpG dinucleotides to be determined in a simple, inexpensive, and high-throughput manor.

Program Nr: 1675 from the 2001 ASHG Annual Meeting

**Rapid, High Precision Analysis of DNA and RNA Footprinting Reactions Utilising the WAVE® Nucleic Acid Fragment Analysis System.** *M. Dickman<sup>1</sup>, M. Piff<sup>1</sup>, M. Daniels<sup>2</sup>, D. Hornby<sup>1</sup>*. 1) Transgenomic Research Laboratory, Krebs Institute, University of Sheffield, Sheffield, UK; 2) Transgenomic Ltd, Crewe, UK.

The analysis of footprinting reactions is a highly involved process, normally requiring the use of a radioactive label, polyacrylamide gel electrophoresis and autoradiography. This method of analysis may take two to three days before results are available and requires skilled interpretation to avoid errors. By utilising the WAVE® Nucleic Acid Fragment Analysis System we developed an automated protocol for DNA and RNA footprinting reactions with a 15 minute run-time without the requirement for radioactive labels. Comparison of previously published analysis of an RuvA/Holliday junction complex using conventional polyacrylamide gel electrophoresis and X-ray crystallography with the WAVE® System gave predictions of a protected region extending over 13 bases, 8 bases and 9 to 10 bases, respectively. We demonstrate that the greater accuracy and precision of the WAVE® System in comparison to gels in separating the footprinting reaction products results in a more accurate prediction of the protected region. Footprinting of a hairpin ribozyme complex gave results in agreement with previously published data. This analysis is quantitative and interpretation is assisted by automatic integration of peak areas with graphical display to assist in identification of protected bases.

**Use of fluorescein-labeled probes as a quality control tool for cDNA microarrays.** *M.J. Hessner, K. Dowling, O. Kokanovic, L. Meyer, S.H. Nye, X. Wang, J. Waukau, S. Ghosh.* Pediatrics, Medical College of Wisconsin, Milwaukee, WI.

DNA microarrays enable expression analysis of thousands of genes simultaneously making them a tool of growing popularity in the genetics research community for identification of candidate genes involved in human disease. Generation of quality arrays depends on a number of steps that are difficult to measure, especially when dealing with potentially thousands of cDNA amplicons. Recent reports have identified probe quality and quantity as critical control points. We have developed a means of quality control for probe amplification, array/element morphology and post-process probe retention, and potentially normalization of inter-element variation by generation of probes with fluorescein-labeled primers. This approach eliminates the need to evaluate probe quality by gel electrophoresis as well as the need to visualize arrays with a DNA stain to evaluate probe retention and element morphology. Visualization of the entire array at any point from printing through hybridization is possible with no spectral interference when evaluating Cy3 or Cy5-labeled hybrids. The use of fluoresceinated probes for microarrays necessitates purification of amplified PCR products prior to printing in order to remove unincorporated dye-labeled oligonucleotide primers. We have evaluated high-throughput methods for probe purification and have found Promega's MagniSil system an effective, high-recovery, automatable alternative to column-based purification products. By titrating purified labeled probes, we have demonstrated that a significant percentage (>75%) of probe printed in 50% water/50% DMSO is not retained by poly-L-lysine coated glass slides. Smaller array elements and greater probe retention is observed when printing is performed in 3X SSC/1.5 M trimethylglycine as reported by Diehl et al. [NAR, 29(7):e28]. We conclude that the use of labeled probes is affordable and can greatly facilitate methods optimization and array quality control.

**Comparison of spotted cDNA arrays and Affymetrix oligonucleotide arrays: High concordance under stringent analysis parameters.** *F. Martinez-Murillo, E.P. Hoffman.* Research Center for Genetic Medicine. Center III. Children's National Medical Center. Washington, DC.

We present a systematic comparison of data obtained from the two commonly used expression profiling experimental platforms: spotted cDNA arrays, and Affymetrix oligonucleotide GeneChip arrays. Using murine tissues expected to be highly discordant in expression profiles (brain and liver), we processed aliquots of the same RNA samples for hybridization to multiple replicates of each microarray type (6 arrays with 4,600 murine gene cDNAs printed in duplicate, and 2 Affymetrix GeneChip arrays with 12,600 murine probe sets for U74A and U74B, respectively). Both experimental platforms gave highly reproducible results, with replication of experiments showing Pearson correlation coefficients of 0.96-0.98 for absolute analyses for Affymetrix arrays, and 0.95-0.99 for ratio analyses for cDNA arrays. Fold-change analysis of Affymetrix arrays (comparison analyses of brain versus liver expression profiles) showed almost as high a correlation, with  $r$  values between 0.93-0.98. In both methods the gene expression comparisons showing the greatest variability corresponded to those where one RNA sample showed expression of a specific gene near background levels and where the other showed high level expression, leading to the expected volatility of the resulting ratio. We were able to compare a total of 257 significantly differentially expressed probe sets common to both platforms. Comparison of the fold-changes for these shared genes showed that some of the most discordant results were those where the denominator approached background hybridization levels. Additional discordances were seen with saturation on specific probes and with low-level transcripts. Overall, when considering all sources of experimental error and ratio volatility, we excluded 41 outlier calls from the total 257 compared probe sets and we observed an outstanding correlation between the two methods, with  $r = 0.90$  and an  $t$ -test showing an overall  $p < 0.001$ . In conclusion, we have found that both methods are comparable and sensitive, although intrinsic properties of each system requires some user intervention in data analysis.

**Optimization of SBE-TAGS technology for the rapid and cost-effective genotyping of single nucleotide polymorphisms in ADHD.** *J.L. Stone, M.N. Ogdie, V. Kustanovich, L. Crawford, J. Kimura, S. Nelson.* Department of Human Genetics, UCLA, Los Angeles, CA.

In the sphere of human genetics where SNP markers have now become plentiful, the key issues in large-scale implementation of single nucleotide polymorphism (SNP) typing strategies revolves around the cost, accuracy, and speed of SNP genotyping. The genetic elucidation of complex traits is demanding the genotyping of large numbers of markers on hundreds of individuals per study both to follow up linkage studies and to identify association/linkage disequilibrium. In an effort to extend current genotyping methods, we have further optimized a method for high-throughput SNP genotyping, which is both cost effective and accurate.

The method is based on single nucleotide primer extension of tagged oligonucleotides (SBE-TAG). Each tagged SBE primer has a unique tag at its 5' end. Up to 100 such tagged SBE primers extension reactions can be multiplexed such that a single fluorescently labeled ddNTP is incorporated into each tagged SBE primer to score the allele. Which allele has been extended with which ddNTP is decoded by hybridization to a standard array of the 100 different reverse complements of the tags. In order to make this reaction simpler and more robust, we have created inexpensive spotted oligonucleotide arrays on standard glass slides that allow 16 different individuals in discrete wells to be genotyped per slide using standard multichannel pipettors. Second, we have introduced a two-dye system utilizing only cy3 and cy5, which simplifies the assay and make it readily compatible with existing microarray scanner technologies. We have developed software for the direct computation of SNP types from image data in a batch process mode.

As a stringent test of the system, we are applying this assay to genotyping candidate alleles and candidate regions in 250 multiplex families with attention deficit and hyperactivity disorder.

**Mapping genes for human mitochondrial ribosomal proteins.** *T.W. O'Brien*<sup>1</sup>, *H.-R. Graack*<sup>2</sup>, *N. Fischel-Ghodsian*<sup>3</sup>, *E.B. Mougey*<sup>4</sup>, *B.A. Maguire*<sup>4</sup>, *B. Wittmann-Liebold*<sup>5</sup>, *D.P. Nierlich*<sup>6</sup>, *J.E. Sylvester*<sup>4</sup>. 1) Biochemistry & Molec Biol, Univ Florida Hlth Sci Ctr, Gainesville, FL; 2) Max Planck Institute for Infection Biology, Berlin, Germany; 3) Cedars-Sinai Medical Center, Los Angeles, CA; 4) Nemour's Children's Clinic, Jacksonville, Fl; 5) Max-Delbruck-Center for Molecular Medicine, Berlin, Germany; 6) UCLA, Los Angeles, CA.

Mitochondrial DNA encodes tRNAs and rRNAs, but the other genes for the mitochondrial translation system are found in nuclear DNA. Upward of 85 mammalian mitochondrial ribosomal proteins (MRPs) are imported into mitochondria where they assemble into ribosomes that are responsible for translating the 13 mRNAs for essential proteins of the oxidative phosphorylation system. Since mutations in mitochondrial tRNA and rRNA can cause various pathological states, we hypothesize that mutations in MRP genes are also candidates for human disorders. Our approach is to use N-terminal and internal amino acid sequence data obtained from purified bovine MRPs (O'Brien, et al. (2000) J Biol Chem. 275: 18153) to search EST databases. Chromosome map positions for the MRP genes are ascertained by *in situ* hybridization (FISH) with genomic sequences and/or by using *in silico* methods to search Genbank and GeneMap through NCBI. At present, we have over 45 different human MRPs at various stages of characterization. We are currently investigating one MRP as a potential candidate for Russell-Silver Syndrome (RSS), a dwarfism characterized by low birth weight and lateral asymmetry, characteristics that are consistent with reduced mitochondrial function. DNA from RSS patients is being analyzed for possible mutations in MRPs. In addition to studying their clinical relevance, long term characterization of MRP genes should lead to important insights into mammalian evolution, coordinate regulation of nuclear and mitochondrial gene expression, and ribosome function. This work is being done as part of the Mammalian Mitochondrial Ribosomal Consortium and is supported by NIH/NIDCD grant RO1DC04092 and the Nemours Research Program.

**Misexpression of 50 uncharacterized *Drosophila* homologs to human disease genes reveals insight into gene function.** *D. Huffman, L.T. Reiter, E. Bier.* Biology, UCSD, La Jolla, CA.

We conducted a large scale BLAST analysis of human disease genes associated with known mutant alleles against the complete *Drosophila melanogaster* genome. This analysis, available as a searchable database called [Homophila](#), revealed that 77% of these genes have *Drosophila* counterparts. A goal of creating this database was to identify disease gene homologs in flies which might be studied effectively using powerful molecular genetic tools available in *Drosophila*. We were interested in determining the consequences of misexpression on a select group of 50 of these *Drosophila* genes, which have no known mutant alleles. These genes were selected due to their proximity to *p*-elements called an enhancer promoter elements (EP) which contains 14 copies of the yeast GAL4 upstream activating sequences (UAS). Using these stocks it is possible to misexpress the gene of interest by crossing the EP line to a stock expressing the GAL4 transactivator protein in one of many available patterns. Each of the 50 selected EP lines were crossed to a set of representative GAL4 driver stocks expressing GAL4 in various patterns during development: GMR drives expression in the eye; MS1096 and *dpp*<sup>disk</sup> in the wing; and *paired* drives expression in every other embryonic body segment. The progeny of these UASxGAL4 crosses were then scored for visible phenotypes or lethality that would be suitable for use in screens for identifying second site enhancer or suppressor mutations. Of the 50 EP lines screened, two showed moderate to severe phenotypes with one or more of the four GAL4 drivers. One example is the *Drosophila* homolog of the human disease gene ATR-X, which causes X-linked alpha-thalassemia. Overexpression of this gene in the wing causes mis-shaped wings with ectopic bristle formation while its overexpression in the eye results in a rough eye phenotype. The human counterpart of this gene is thought to be a member of the SNF2 subfamily of ATPase helicases. We anticipate that through misexpression and loss of function studies of human disease associated genes in *Drosophila* we will rapidly gain insight into disease gene function..

**High-Speed Detection of  $\alpha$ 1-Antitrypsin Deficiency Alleles PiZ, PiS and Adjacent Sequence Variations with Hybridization Probes and Real-Time PCR on the LightCycler.** C. Aslanidis, G. Schmitz. Inst Clinical Chem/Lab Med, Univ Regensburg, Regensburg, Germany.

$\alpha$ 1-Protease inhibitor I ( $\alpha$ 1-antitrypsin,AT) is the main serum inhibitor of proteolytic enzymes. In AT deficiency, enzymes like neutrophil elastase can damage the lung tissues leading to pulmonary emphysema. More than 90 different alleles have been identified so far for the  $\alpha$ 1-protease inhibitor I (PI) gene. The three most important variants are type M (90% of population), and type S (Pi\*S) and Z (Pi\*Z), two of the commoner abnormal variants. Homozygotes of type Z may develop pulmonary emphysema or hepatic cirrhosis. SZ-heterozygotes are less severely affected. The underlying mutations are a GAG to AAG (Glu342Lys) for Pi\*Z and a GAA to GTA (Glu264Val) for Pi\*S.

To date different phenotypes have been characterized by isoelectric focusing, or lately, by DNA-based technologies like PCR-RFLP. These technologies are time consuming and cumbersome. We have used PCR in glass capillaries in combination with hybridization probes capable of fluorescence resonance energy transfer (LightCycler) and melting curves for mutation detection in Pi\*Z and Pi\*S. Amplification and allele characterization is completed within 25-30 min. The melting peaks in both applications are 6 °C and 7 °C apart and allow unequivocal identification of the genotypes. In addition, using one hybridization probe for the PiZ allele (Glu342Lys), unambiguous identification of an adjacent polymorphism (one nucleotide apart) is facilitated. A C to G transversion leads to a Asp341Glu amino acid change. The resulting C-C mismatch in the hybridization probe leads to a T<sub>m</sub>-shift of 10 °C. The protocol used here does not involve the digestion of PCR-products with restriction enzymes followed by gel electrophoresis. PCR contamination concerns due to sample handling are eliminated.

**A high through-put mutation detection technique for identification of genes implicated in cancer.** *H.R. Molloy<sup>1</sup>, G.R. Bignell<sup>1</sup>, C.J. Cox<sup>1</sup>, P.J. Stephens<sup>1</sup>, M.J. Dronsfield<sup>2</sup>, P.A. Futreal<sup>1</sup>, M.R. Stratton<sup>1</sup>, R. Wooster<sup>1</sup>.* 1) The Cancer Genome Project, The Sanger Centre, Wellcome Trust Genome Campus, Hinxton, Cambridge, England; 2) Applied Biosystems, Warrington, UK.

In the search for genes involved in the development of cancer we are using the human genome sequence to systematically screen all coding exons in the genome for somatic mutations. The current estimate of the number of genes in the genome is 33,000 and an average gene will require 12 STSs to cover all the coding exons. Therefore, to analyse the entire genome from one primary tumour, together with its corresponding normal DNA control, will involve screening around 800,000 PCR fragments. We have developed a high through-put mutation detection technique capable of detecting base substitutions and small insertions and deletions for this work. The technique termed Conformation Sensitive Capillary Electrophoresis (CSCE), is based around heteroduplex analysis of fluorescent labelled PCR fragments analysed by capillary electrophoresis on an ABI PRISM 3100 Genetic Analyser. Heteroduplex peaks are detected by a shift in the migration of the peak relative to homoduplexes. To assess the sensitivity of this technique we have screened 43 STSs containing known SNPs against a panel of 24 normal DNAs. The results were compared to direct sequencing of all the STSs. CSCE analysis detected all insertion/deletion polymorphisms and 83 out of the 88 base substitutions present in the fragments screened, giving a sensitivity of greater than 94%. Using this technique a number of different fragments can be analysed simultaneously by multiplexing on both size and fluorescent label. We estimate that using 25 3100 machines it will take 10 days to screen the entire genome of one tumour sample. In addition to cancer genetics, this method is also applicable to large-scale mutation screening for other diseases, both in situations where there is a well localised disease gene and where the disease alleles can only be mapped to large genomic intervals.

**SNP analysis from ultra low levels of human genomic DNA using a homogeneous Invader®/PCR assay.** A.A. Lukowiak, J.G. Hall, V.I. Lyamichev, B.P. Neri. Third Wave Technologies, Madison, WI.

The Invader assay allows for the direct scoring of single nucleotide polymorphisms (SNPs) using as little as 10's of nanograms of human genomic DNA without any target amplification. Although this limit of detection is sufficient for many applications, studies with limited genomic samples or which require large scale SNP scoring may demand pre-amplification of DNA prior to SNP analysis. Pre-amplification of genomic targets using PCR would not only provide improvements in detection, but would furnish a flexible format for the discrimination of pseudogenes and the identification of haplotypes during SNP detection as well. Here we describe a novel method for using PCR in combination with the Invader assay in a homogeneous format. This system provides significant improvements in sensitivity and is readily adaptable to high throughput applications using 96 and 384 well formats. In addition, we have investigated the possibility of using multiplex PCR in combination with the Invader assay for the pre-amplification of multiple targets from a single genomic sample.

**High-throughput mutation detection and screening using MegaBACE™ Capillary Array Instrument for Genetic Analysis.** *M. Minarik*<sup>1</sup>, *J. Bjørheim*<sup>2</sup>, *P.O. Ekstrøm*<sup>2</sup>, *K.M. Dains*<sup>1</sup>. 1) R&D, Molecular Dynamics, Sunnyvale, CA; 2) Dept. of Surgical Oncology, The Norwegian Radiumhospital, Oslo, Norway.

Over the past decade, DNA mutation detection and screening has become a valuable tool for genetic testing and clinical diagnostics. A number of point mutations within genes are being used as markers indicating the occurrence of diseases such as breast cancer, colorectal cancer, cardiovascular disease and others. Detection of low-level point mutations is a key factor for disease prevention through early diagnosis. The current methods of testing widely accepted in the clinical community are based on DNA sequencing and allele-specific PCR, but these methods are expensive and often lack sufficient sensitivity. Other techniques, such as denaturing HPLC (dHPLC), restriction fragment length polymorphism (RFLP) or single-stranded conformation polymorphism (SSCP) are currently low throughput assays, prohibiting large-scale prevention screening. Here, we demonstrate a high-throughput approach for mutation detection using a technique based on modified heteroduplex analysis. Using the MegaBACE, a capillary electrophoresis instrument for genetic analysis, we apply temporal temperature gradients to resolve heteroduplexes of multiple point mutations for up to 384 samples in a single run. We will present data from colorectal carcinoma patients screened for k-ras and p53 mutations using this new, high-throughput.

**Characterisation of Cytochrome p450 Polymorphisms Using the Invader System ®.** *M. Neville<sup>1</sup>, R. Walton<sup>2</sup>, B. Aizenstein<sup>1</sup>, M. Maguire<sup>1</sup>, R. Seltzer<sup>3</sup>, K. Hogan<sup>3</sup>, B. Neri<sup>1</sup>, M. de Arruda<sup>1</sup>.* 1) Third Wave Technologies, Inc, Madison, WI; 2) Oxford University, Oxford, UK; 3) University of Wisconsin, Madison, WI.

The cytochrome p450 (CYP) superfamily comprises a group of enzymes that play an essential role in the biotransformation of medically relevant compounds. Approximately 40% of CYP isoforms are polymorphic, including CYP1A2, 3A4, 2B6, 2D6, 2C9, AND 2C19. Accurate genotyping of patients for these and other p450 loci is of increasing interest because allelic variants may lead to loss of efficacy or toxic accumulation. These consequences are particularly pronounced in the perioperative interval with multiple low therapeutic ratio substrates competing for shared CYP pathways.

The Invader genetic analysis system developed by Third Wave Technologies, is a homogeneous, isothermal, FRET based assay. The technology employs a 3' invading oligonucleotide and a partially overlapping 5' primary probe oligonucleotide that form a specific ensemble when hybridised to a complementary DNA template. Upon recognition of this invasive structure, a Cleavase enzyme cleaves off the 5' flap from the primary probe oligonucleotide. In a simultaneous reaction, the cleaved flaps hybridise to a FRET cassette generating the substrate to the Cleavase Enzyme. Cleavage of the FRET cassette generates fluorescence, which is easily detected by standard plate readers. The Invader assay is highly specific and able to resolve single nucleotide polymorphisms with exquisite accuracy. ®

Here, we describe the analytical validity of a panel of CYP genetic assays comparing the Invader system to PCR-RFLP, and present allele frequency data from a panel of ethnically diverse individuals.

**High throughput multiplex genotyping using chimeric LNA (Locked Nucleic Acids)/DNA oligos immobilized on a polymer microchip.** *H. Vissing, A.T. Nielsen, M. Noerholm, P. Mouritzen, P.E. Hojby, S. Pedersen, Y. Choleva, M.S. Andersen, J.G. Kolberg, K.H. Haagesen, L. Kongsbak.* Bioinformatics/Genomics, Euray, EXIQON A/S, Vedbaek, Denmark.

A new approach for nucleic acid variation detection has been developed by taking advantage of three novel technologies: 1) LNA (Locked Nucleic Acids) 2) anthraquinones for photoactivated cross-linking and 3) a polymer microchip platform. LNA, a bicyclic DNA analogue, has proven very useful in hybridizations due to the exceptional high specificity and affinity. Short chimeras of LNA and DNA with the length of 12 nucleotides allow discrimination of single base mutations in microchip-based hybridizations. The anthraquinone phosphoramidites facilitate an efficient and robust polarised coupling of the capture probes or target to the polymer platform, which generates high quality hybridization spots with a diameter of less than 50 nm and a high-density homogeneous distribution. The use of chimeric LNA and DNA oligos as PCR primers facilitates specific multiplex PCR target amplification as well as allele specific amplification for haplotype assessment.

We have applied these technologies for two different designs of microchips. The first one is a direct multiplex SNP detection targeting more than 100 SNPs related to MODY (Mature Onset Diabetes Mellitus) and obesity. The second is a reverse format in which multiplex gene target amplicons are spotted on microchips and assayed for multiple SNPs. More than 10.000 patients can be genotyped on a single microchip and also allows for haplotype assessment. An example of this is SNP detection and haplotype assessment in Human Melanoma Inhibitory Activity like Gene (MIAL). In order to optimize the design of microchips, we have developed a software package integrating microchip design, database and neural network analysis.

**Single Nucleotide Polymorphism Typing Using Dual-Color AlphaScreen Technology.** *L. Beaudet<sup>1</sup>, J. Lian<sup>1</sup>, B. Breton<sup>1</sup>, M.-E. Caruso<sup>1</sup>, M.L. Budarf<sup>2</sup>.* 1) BioSignal Packard Inc., 1744 William #600 Montreal, QC, Canada, H3J 1R4; 2) Division of Human Genetics, Department of Pediatrics, University of Pennsylvania School of Medicine, Philadelphia, PA 19104.

In AlphaScreen homogeneous assays, a highly amplified signal is generated when donor and acceptor beads are brought into proximity. The coupling of AlphaScreen to PCR product detection has allowed the development of a high-throughput SNP analysis platform (Beaudet et al., *Genome Research* 2001, **11** (4): 600). In SNP assays, AlphaScreen beads and probes are combined with the PCR reagents prior to amplification. The genotypes are analyzed after amplification without the need to purify the PCR products or to perform additional enzymatic reactions.

Recently, a second donor bead has been developed, which is activated at 780 nm, compared to 680 nm for the original donor bead. When this bead is used in conjunction with the original donor and acceptor beads, two different targets can be detected in a single well. For SNP analysis, the use of two different donor beads allows the detection of the two SNP alleles in the same well. This approach increases throughput, reduces significantly genotyping costs and, and increases the accuracy of genotyping.

We have developed several homogeneous genotyping assays using dual color AlphaScreen and results will be presented on the late onset Alzheimer marker APOE and on CYP3A polymorphisms that may be implicated in altered drug metabolism.

**High Throughput SNP scoring using the Invader® Operating System.** *M.W. Atilas, S. Law, R. Roeven, K. Lockwood, J. Koebel, R. Grygiel, B. Neri, M. de Arruda.* Third Wave Technologies, Madison, WI.

Sequencing the Human Genome has opened many opportunities to understand diseases and improve patient care. SNP discovery and disease association studies are important steps to achieve the ultimate goal of personalized medicine. To help accelerate this process, Third Wave Technologies, Inc. provides dried generic reagents necessary for SNP genotyping using the Invader® Operation system. This highly flexible system allows users to increase their genotyping throughput by direct detection of nucleic acids without the need of previous target amplification. The Invader assay is homogenous and isothermal, and is based on the specificity of the Cleavase® enzyme, which recognizes a specific structure formed when two allele specific oligonucleotides hybridize to a given target. Signal detection is based on Fluorescence Resonance Energy Transfer (FRET), and uses two reporter dyes with non-overlapping fluorescence spectra, which allows detection of both alleles in a single well using standard fluorescent plate readers. The simplicity of the assay permits the reactions to be set up either manually or in a fully automated system. The generic Invader reagents (Cleavase enzyme, detection cassettes, and buffer) are provided dried in microtiter plates (96- or 384-well). The assay entails a short set-up, which requires the addition of allele specific oligonucleotides,  $MgCl_2$  and pre-denatured DNA, a 4 H incubation at 63°C and an additional 10-15 minutes of data acquisition and analysis. The 96-well format requires 75-100 ng of DNA in a 15ml reaction, and the 384-well format requires as little as 20-40 ng of DNA in a 6ml reaction. The different formats provide users flexibility in terms of throughput and equipment required. Results obtained from fully automated assays will be shown using 96- and 384-well biplex assays.

Program Nr: 1689 from the 2001 ASHG Annual Meeting

**Simultaneous Genotyping of More Than 1000 SNPs with the SNPcode™ Platform.** *M.A. Donaldson, J.A. Lathrop, W.M. Ankener, J.F. Studebaker, S.V. Alfisi, M.S. Philips, C.A. Gelfand, M.T. Boyce-Jacino.* Assay Research, Orchid BioSciences, Inc., Princeton, NJ.

The task of elucidating the human genome sequence has led to a dauntingly wide range of projects that use the genome sequence as a starting point, such as genotyping of single nucleotide polymorphisms (SNPs). Many SNP studies, for example correlating genotype to medically relevant conditions, require detection systems enabling thousands of SNPs per sample to be genotyped in a low cost, robust fashion. The SNPcode™ system developed by Orchid BioSciences, Inc. couples SNP-IT™ genotyping technology with the Affymetrix GenFlex™ platform to create a versatile high-density SNP scoring system. The inherent generic design of the chip allows the user to adapt any SNP loci of interest to this platform. In the assay, multiplex PCR is followed by solution phase SNP-IT primer extension. The SNP-IT products are then hybridized to the GenFlex chip, the sorting mechanism for the multiplexed reactions. During SNPcode product development we demonstrated that greater than 98% of all validated assays result in a genotype call with greater than 99% reproducibility.

Currently Orchid is developing panels of SNPs using the SNPcode system. PCR and SNP-IT reactions are routinely tested in 12-plex with 96 reactions pooled together for analysis on a single chip. Each reaction tests 12 unique SNPs for a single sample thereby enabling analysis of over 1100 SNPs for a single sample in one assay. Primer sets are individually designed for each SNP and panels are assembled into functional families based on the needs of the individual project. Results of various 1100-plex assays will be presented. At mid-year, more than 12 panels have been tested resulting in nearly 10,000 functional assays. By the end of 2001, Orchid plans to have more than 50,000 SNPs validated across three ethnically diverse populations, as part of Orchid's collaboration with The SNP Consortium. Orchid expects to develop SNP panels for chromosome mapping, drug metabolism (ADMET), and disease correlation.

**SNP Identification, Validation, and Scoring with the Multi-Functional CEQ™ 2000XL DNA Analysis System.**

*H.H. Wai, R.M. Oda.* Bioresearch Sys. Dev. Ctr., Beckman Coulter, Inc., Fullerton, CA.

The study of genetic variations in individual genomes is critical to understanding the biological mechanisms that lie behind susceptibility and predisposition to many diseases. Finding markers that are closely linked to these genetic predispositions could enhance the success of diagnosis and treatment of diseases that have a significant genetic component. Single Nucleotide Polymorphisms (SNPs) are located throughout the genome. Depending on the level of detail required, SNPs can be finely mapped with regular interval on different chromosomes. These finely mapped SNPs can then be used as molecular markers to establish accurate linkage of polymorphisms to genes and possible diseases. It is this accurate linkage aspect that can catapult SNP analysis into an extremely powerful and fast tool for many systematic studies of genes, diseases, and etc. Beckman Coulter's CEQ 2000XL is a multi-functional DNA Analysis System that can be used in SNP identification, validation, and scoring. The CEQ 2000XL can sequence different individual or pooled samples to identify potential SNPs. Sequencing the same genetic region of additional related and unrelated individuals can validate or invalidate any potential SNP. Once the biological importance of a SNP has been established, the CEQ 2000XL can be also used to accurately and efficiently score the validated SNPs in different individuals.

**Detection of Single Nucleotide Polymorphisms by MALDI-TOF Mass Spectrometry.** *P.M. Vallone, J.M. Butler.*  
Biotechnology Division, Natl Inst Standards/Technology, Gaithersburg, MD.

Single nucleotide polymorphisms (SNPs) are the most frequent form of DNA sequence variation in the human genome and are becoming increasingly useful as genetic markers for genome mapping studies, medical diagnostics, and human identity testing. The primer extension reaction is a commonly employed molecular biology assay for genotyping a known single nucleotide polymorphism marker in genomic DNA. In a basic primer extension assay a short (less than 30 bases) DNA oligonucleotide or primer is extended by a single nucleotide unit. The identity of the extended base allows the sample to be accurately genotyped.

One technique for SNP detection currently employed relies on the mass resolution between a primer and its single base extension product(s) utilizing Matrix Assisted Laser Desorption Ionization Time-of-Flight Mass Spectrometry or MALDI-TOF MS. The speed of data collection by this technique is on the order of 5 sec per sample and has the potential for high throughput when interfaced with a robotic system and automated data collection/analysis. Genotyping results obtained from the basic primer extension assay, the GOOD assay and primer extension using a chemically cleavable primer will be presented. Comparisons of the primer extension assays will be addressed as well as issues pertaining to high throughput MALDI-TOF MS data collection and interpretation. Genotyping examples will be illustrated using human identity genetic markers located on the Y chromosome and in the mitochondrial genome.

**Improved genotyping of SNPs by double-discrimination allele-specific real-time PCR.** *J. Zhang, J. Li, R.M. Myers.*  
Dept. of Genetics, Stanford University School of Medicine, Stanford, CA 94305-5120.

While the Human Genome Project has made the initial identification of single nucleotide polymorphisms, or "SNPs", very efficient, robust methods for genotyping in a large number of genomic DNA samples are still in a state of development. The requirements for a useful technique are a high degree of accuracy, reproducibility, ease of use, and a reasonable cost per genotype. One of the difficulties in genotyping is accurately distinguishing heterozygotes from both homozygotes, and special attention must be paid to each SNP assay to be sure these conditions are met when the technique is applied on a large scale. In this study, we have developed a variation on the allele-specific PCR (AS-PCR) method, a commonly used technique in which one of the PCR primers in a pair contains the variable base at its 3' end. Standard AS-PCR is rapid and inexpensive to use, but is often unreliable for heterozygote detection. In the improvement we developed, two distinct pairs of regular primers are used. In one pair, both forward and reverse primers immediately match one allele at their 3' terminal bases, such that the two 3' ends of the primers actually overlap by one base pair. The second pair is similar, but the two primers match the other allele at their 3' terminal bases. We combine this "double discrimination" set of oligonucleotids with the use of real-time PCR, monitoring the progress of the amplification reaction with the inexpensive intercalating dye, SYBR-Green. Genotypes were correctly determined in 25 different SNPs by differences in the threshold cycle numbers of the two alleles. Without requiring the expensive fluorescent probes or extensive handling, this method provides an accurate, inexpensive and high throughput method to genotype SNPs in the scale suitable for the lab or median size research project.

**Microarray transcriptional profiling of the adaptive response in human lymphoblastoid cells..** *M.A. Coleman<sup>1</sup>, E. Yin<sup>1</sup>, B.J. Marsh<sup>1</sup>, L.E. Peterson<sup>2</sup>, K. Sorensen<sup>1</sup>, J. Tucker<sup>1</sup>, A.J. Wyrobek<sup>1</sup>.* 1) Biology and Biotechnology Research Program. Lawrence Livermore National Laboratory, Livermore, CA; 2) Department of Medicine, Baylor College of Medicine, Houston, TX.

Exposure to a low dose of ionizing radiation is known to protect against a subsequent higher dose of radiation. This phenomenon, known as adaptive response (AR), has been attributed to DNA repair and stress response functions, yet the responsible pathways and genes are not well understood. Our project investigated variation in AR across lymphoblastoid cells from unrelated individuals (Corriel Repository) and compared their transcription profiles of cells using RNA sampled 4 hours after they were treated under non-adapting (2Gy exposure only) or adapting conditions (5cGy priming dose followed 6hrs later by 2Gy). AR was confirmed by the frequencies of first-division micronuclei. Significant adaptation was detected in 60% of experiments, synergism in 15%, and no effect in 25%. Using Affymetrix oligonucleotide arrays, ~2700 genes showed differences in transcription levels between adapting and nonadapting conditions. Of these, 211 genes showed consistent and significant responses across both cell lines, including 101 genes that were up-regulated and 110 that were down-regulated. Genes associated with adaptation include PKC and MAP kinase as well as several heat shock genes (HSP70 and DNAJ). Several genes involved in the adaptive response are also known as cell cycle control and DNA repair genes (e.g., ATM, RAD51C, PCNA, E2F1, p130 and G-cyclins), indicating that AR is linked to induced changes in these functions. Several of these changes have been confirmed by real-time PCR. In addition, numerous novel non-annotated genes were identified, warranting future investigations. These findings suggest that AR is not a reproducible genetic trait for individual cell lines, but when it occurs in cells from unrelated individuals, it appears to involve similar transcriptional changes across hundreds of common genes. [This work was conducted under the auspices of DOE by the University of California, LLNL under contract W-7405-ENG-48 with support from NIH (ES09117-02) and DOE (KP110202).].

**Factorial moments analysis of intermittency in gene expression on cDNA microarrays.** *L.E. Peterson*<sup>1</sup>, *K. Lau*<sup>2</sup>. 1) Dept. of Medicine, Baylor College of Medicine, Houston, TX; 2) Dept. of Physics, University of Houston, Houston, TX.

Intermittency occurs when quantities depend more on physical fluctuations than statistical fluctuations. The method of factorial moments has been used in high energy physics to search for intermittency. This paper describes use of factorial moments to search for intermittency in gene expression on cDNA microarrays which contain expression levels for thousands of genes under given experimental and disease conditions. Data used in this investigation included log expression ratios (*LERs*) for (a) 2,466 genes of the bacteria *S. Cerevisiae* on 79 microarrays representing different experiments and time periods [Eisen et al., PNAS. 95(25):14863-14868 (1998)] and (b) 9,706 genes on 60 microarrays representing 60 cancer cell lines [Ross et al., Nat. Genetics. 24:227-235 (2000)]. Results indicate that, as the number of bins increases in the frequency distribution of *LER*, gaps become visible within the tails and peaks. This suggests the possibility of intermittency. Calculation of scaled factorial moments, which remove Poissonian noise, also reflected varying amounts of intermittency on most of the arrays. This may suggest that certain environmental stressors or cancers result in clustering (self-similarity) of genes and their expression levels. That intermittency changed across the arrays may suggest the existence of long-range correlations whereby one or more regulating signals affected expression of a large number of genes. An implicit property of scaled factorial moments is that there is no contribution from frequency bins with less than two genes, since bins with a single gene cannot contain any correlates. In light of the above, our results may suggest the presence of one or more unique regulating signals causing self-similarity of genes whose expression are fractal-like. (L.E.P. supported by NCI grant CA-78199-04).

**L1 suppression display: a genomic approach to the isolation and characterization of young L1s.** *R.M. Badge, J.V. Moran.* Human Genetics, University of Michigan, Ann Arbor, MI.

The most active L1 retrotransposon subfamily in the human genome, Ta, comprises a small number of sequences (~550). A significant proportion (~25%) of Ta subset L1s are full length and ~50% can encode potentially functional polypeptides. Up to 90% of Ta insertions are polymorphic, so that genomic sequence databases contain only a fraction of extant diversity. In contrast older L1 sequences (pre-Ta and non-Ta) are extremely abundant (~850,000 copies). These sequences generally are fixed, 5' truncated, rearranged and mutated, and rarely encode open reading frames. To evaluate the impact of Ta L1s on genomic diversity, subfamily specific methods are required. Such a method, allele specific PCR (using Ta specific SNPs) requires sequence variation data, so a database of full-length L1 sequences was constructed. The non-redundant database comprises 242 full-length L1 sequences from the human genome working draft sequence, annotated for target site duplication, polyadenylation, transduction and coding potential status, as well as diagnostic sequence variants. While limited to high frequency and fixed insertions, the database provides an extensive collation of L1 sequence variation, and is informative with respect to phylogenetic and mechanistic relationships. Primers designed using this database allowed the specific isolation and characterization of Ta subfamily insertions by multiplex suppression PCR display. The method requires only small amounts of genomic DNA and generates individual specific displays of both 5' truncated and full-length Ta insertions. Several Ta insertions were characterised and their polymorphic status confirmed by locus specific PCR. The use of methylation sensitive restriction enzymes also enables this technique to probe genomic epigenetic variation associated with L1. In combination these approaches (database and display) have identified a novel non-Ta subfamily that carries a SNP associated with the most active (in cell culture) Ta sequences. This finding emphasizes the importance of studying active L1 retrotransposons in the context of human populations and the synergy possible between molecular biological and bioinformatic methods.

**Discovery and analysis of a new polymorphic human-specific family of LINE-1 retrotransposons.** *I. Ovchinnikov, G.D. Swergold.* Dept. Medicine, Columbia U., New York, NY.

Here we describe a new, polymorphic, human-specific LINE-1 subfamily that we call Tb. The youngest and most active autonomous retrotransposons in the human genome are members of a family called Ta (L1Hs-Ta). They are defined by the nucleotides ACA + G at diagnostic positions in the 3' UTR. L1s that amplified in the human genome during the primate radiation have GAG + A at these positions. Of the 14 known de novo human L1 insertions, one had nucleotides ACG + G. Elements with the ACG sequence have not been previously investigated in detail. We identified 117 ACG L1 elements in the Genbank NR database including 86 with the sequence ACG + G (previously called "pre-Ta") and 31 with the sequence ACG + A (herein named Tb). From this we calculate that the haploid human genome contains 311 pre-Ta and 98 Tb elements. A sequence alignment of Ta, pre-Ta, Tb, and primate (GAG) L1s revealed that Tb elements shared 7 of 27 diagnostic sites with GAG elements while pre-Ta elements shared only 2. Autosomal Tb elements had an average pairwise sequence divergence of 1.4% compared with 0.9% for pre-Ta elements. We calculated the time of maximal amplification of Tb elements to be 2.5 MYA compared with 2.0 MYA for pre-Ta elements. Only 14% of Tb elements were polymorphic in the present-day human population compared with 26% of pre-Ta elements. None of the Tb or pre-Ta insertions were found in chimpanzees, gorillas, or orangutans indicating that both of these subfamilies arose after the separation of humans and apes. Several other characteristics of the elements confirmed that Tb elements were older than pre-Ta elements. These include a shorter poly(A) tail, more frequent degradation of the polyadenylation signal, and more frequent existence of microsatellites in 3' flanking DNA. Phylogenetic analyses using neighbor joining, maximum parsimony, and maximum likelihood methods all yielded tree topologies that separated Tb and GAG elements into separate branches but grouped the Ta and pre-Ta elements together. In summary, Tb elements represent a newly defined subfamily of polymorphic retrotransposons that are, at present, the oldest known human-specific LINE-1 subfamily.

**Insights into the mechanism of human LINE-1 retrotransposition.** *G.D. Swergold<sup>1</sup>, I. Ovchinnikov<sup>1</sup>, H.H. Kazazian, Jr.<sup>2</sup>, E. Ostertag<sup>2</sup>.* 1) Dept. Medicine, Columbia Univ, New York, NY; 2) Dept. Genetics, University of Pennsylvania, Phil. PA.

The currently accepted model of human L1 (L1Hs) transposition is called Target Primed Reverse Transcription (TPRT) and is derived from detailed investigations of the R2Bm element in the silkworm. Evidence to support TPRT in L1Hs transposition is lacking. We analyzed the structure of a large number of L1Hs insertions in order to define important molecular details about L1Hs retrotransposition. Our findings are: 1) A polymorphic L1-Hs insertion bearing a 3' flanking DNA transduction was discovered by L1 display. Detailed analysis of the polymorphic transduction revealed that internal priming by the nicked target site was used for first-strand cDNA synthesis, and supports the use of TPRT in L1Hs transposition. 2) Analysis of 117 human-specific L1 insertions revealed that 26% were full-length, 43% had 5' terminal truncations, and 31% had both 5' terminal inversions and truncations. The length of the truncated elements were not random and favored short insertions. For insertions with inversions, both the 5' terminal inverted segments, and the 3' terminal non-inverted segments were also consistently short. These data suggest that the L1 reverse transcriptase is a non-processive enzyme. 3) Relatively few inversion events (11%) resulted in perfect ends without gaps or overlaps between the segments. Duplications were more common (31%) and were short (avg. 19 bp). Gaps were most common (58%), and while most were short, some were > 500 bp long. 4) For inversions, analysis of the target site sequences immediately 5' of the insertions revealed a statistically significant similarity to the minus strand of the L1 consensus sequence immediately downstream of the 5' terminal inverted segments. These data suggest that separate cDNA priming events are involved in the reverse transcription of the 3' terminal and 5' inverted segments. We present a modified model of TPRT that explains our results. The model predicts that L1Hs TPRT differs in important molecular details from R2Bm TPRT, and raises the possibility that L1Hs insertions may occur into locations of pre-existing double strand DNA breaks.

**Gene dosage-dependent effects in YAC transgenic mice carrying expanded alleles at the Machado-Joseph disease**

**locus.** *C.K. Cemal<sup>1</sup>, C. Carroll<sup>1</sup>, L. Lawrence<sup>2</sup>, M. Lowrie<sup>2</sup>, F. Scaravilli<sup>3</sup>, PK. Thomas<sup>3</sup>, C. Huxley<sup>1</sup>, S. Chamberlain<sup>1</sup>.*

1) Cell and Molecular Biology, Imperial College of Medicine, South Kensington, London, SW7 2AZ, England; 2) Cellular and Integrative Biology, Imperial College of Medicine, South Kensington, London, SW7 2AZ, England; 3) National Hospital for Neurology and Neurosurgery, Queen Square, London, England.

Machado-Joseph disease or spinocerebellar ataxia 3 (MJD/SCA3) is a progressive neurodegenerative disorder caused by pathological expansion of a CAG trinucleotide repeat motif located within exon 10 of the MJD1 gene. The generation of a representative mouse model for the disease should give a greater understanding of the role of repeat length, tissue specificity and level of expression on the associated pathology. We have generated a number of YAC transgenic lines differing with respect to transgene copy number and pathological allele size. The animals demonstrate a progressive cerebellar deficit, with reduced pelvic elevation accompanied by motor and sensory loss and hypotonia. Detailed phenotype analysis in the transgenic lines has resulted in the detection of a number of gene dosage-dependent abnormalities including reduced body weight, hypoactivity, reduced grip strength, incoordination and abnormal limb clasping reflexes. Disease severity is proportional to both the level of expression of the expanded protein and the size of the expanded repeat. In contrast, transgenic animals carrying the wild-type (CAG)<sub>15</sub> allele at the MJD1 locus appear completely normal at 24 months. The YAC transgene is transmitted to the predicted 50% of offspring and expressed in the appropriate manner. Further expansion of the CAG repeat is only detected on paternal transmission and contraction of the repeat is observed on maternal transmission, concurring with the human condition. The model therefore is representative of MJD with respect to pathology, gene dosage effects and repeat instability and should be a good system to test future therapeutic strategies for this disorder.

**Strategies for the identification of non-integer repeats in the automated Short Tandem Repeat (STR) genotyping.**

*M.D. Dobbs, H. Gull, D. Campbell.* Bioresearch Sys Dev Ctr, Beckman Coulter, Inc, Fullerton, CA.

A number of variables are known to contribute to the accuracy of sizing DNA fragments using gel electrophoresis, suggesting that absolute fragment lengths reported by different instrument systems, or reported on the same instrument system using different separation parameters may not be comparable (see ABRF poster at <http://162.129.76.21/Posterhtml/title.html>). Under constant conditions, it is therefore necessary to establish average observed sizes and their spacing for each genetic marker of interest. Using Beckman Coulters CEQ™ 2000XL DNA Analysis System, we genotyped 90 individuals from the Coriell Cell Repositories DNA Polymorphism Discovery Resource Collection (M90PDR) for the following nine human STR markers: D1S1679, D3S2387, D9S938, D9S2157, D11S1884, D14S599, D22S683, DXS7132 and GATA193A07. The markers were selected for previously documented high heterozygosity and the presence of non-integer repeats. Data sorting, filtering, and linear regression analysis were performed using Microsoft<sup>1</sup> Excel to model software enhancements for the current CEQ 2000XL. For complex allele patterns, automatically ignoring all but the tallest peaks in the traces facilitated the interpretation of both simple and complex allele patterns. Linear regression analysis was used to infer which alleles were true non-integer repeats versus fragments that belonged in integer repeat bins. The rules developed proved useful in reducing large fragment lists of STR genotype to data sets that represented primarily evenly spaced alleles, with smaller numbers of alleles that were in between repeats, but at unit nucleotide intervals. Based on the wide array of fragments observed at these STR loci, we developed a graphical user interface that provides a reliable way of identifying true alleles when they differ from the expected integer repeat size.

**A New Approach To Genotype Deconvolution Based On Experimental Studies Of PCR Slippage.** *D. Shinde*<sup>1</sup>, *Y. Lai*<sup>2</sup>, *F. Sun*<sup>2</sup>, *N. Arnheim*<sup>1</sup>. 1) Program in Molecular Biology; 2) Dept. of Mathematics, University of Southern California, Los Angeles, CA 90089.

Microsatellite DNA sequences are highly polymorphic and a useful source of genetic markers for genotyping, individual identification and detection of genomic instability. During microsatellite PCR, insertion and deletion mutations produce stutter products differing from the main PCR product by multiples of the repeat size often leading to problems in allele identification. To more fully understand the mutation process, we analyzed the PCR slippage products of dinucleotide repeats (dC.dA)<sub>n</sub>-(dG.dT)<sub>n</sub> and mononucleotide repeats (dA)<sub>n</sub>-(dT)<sub>n</sub> cloned in a pUC18 vector. Template sizes varied from 2-21 CA repeats and 4-16 A repeats. Data was generated on ~10 independent single molecules of each of the 19 different clone types using two rounds of nested PCR. The size and peak areas of the unchanged and stutter products were obtained by capillary electrophoresis. We built a mathematical model for PCR slippage assuming the mutation rate of a template at any cycle depends on the number of repeats. A maximum likelihood approach is used to estimate the mutation rate per repeat per PCR cycle, the expansion to contraction ratio and the threshold repeat number for stutter. The "per repeat" mutation rate for the CA tracts was  $1.9 \times 10^{-3}$ , and contractions were ten times more frequent than expansions. For A tracts the rate was  $1.26 \times 10^{-2}$  and contractions outnumbered expansions by 5 fold. The threshold for 'stutter' products was 5 repeats for poly-CA and 8 repeats for poly-A. In both cases, tracts containing less than or equal to 8-10 bp had undetectable per repeat mutation rates and may be related to the fact Taq DNA polymerase makes contacts with approximately the same number of nucleotides in the active site. This experimentally derived threshold value is consistent with estimates based on in silico analysis of microsatellite allele size distributions in the genomes of human and other organisms. Because the model was found to fit the data well, the ability of the model to deconvolute the stutter profiles generated from mixtures of alleles of similar sizes will be tested.

**Microarray expression analysis supports upregulation of genes on the single active X chromosome, as compared to autosomal genes.** *C.M. Disteche, T. Holzman, D.K. Nguyen, R. Bumgarner.* Depts Pathology, Microbiology and Molecular Biotechnology, Univ Washington, Seattle, WA.

S. Ohno predicted that "to escape a great peril" genes on the active X chromosome would have been upregulated during mammalian evolution to allow for X inactivation and to maintain balance of expression with the autosomes. We have previously shown that the *Clc4* gene located on the X chromosome in some species of mice and on an autosome in other species of mice was expressed from the active X locus at twice the expression level of the autosomal locus. To extend these findings to additional genes and to another species we have explored microarray expression data, which provide an overview of genome expression from each human chromosome. Studies done by others in yeast and in human have shown that an increase in copy number of a given gene or chromosome is generally accompanied by increased gene expression that can be detected by microarray analysis. Therefore, we reasoned that, if genes located on the X chromosome had indeed been upregulated to compensate for their hemizygous expression due to X inactivation, the average expression of X-linked genes versus autosomal genes would be equal on microarray expression data. Human cDNA microarrays were examined in terms of expression from the X chromosome clones versus the autosomes. Genes that were expressed at a low level were eliminated from the analysis. Our studies indicate that the level of expression from 36 genes located on the X chromosome does not differ on average from the expression of 1,028 genes located on autosomes. These findings support the notion of evolutionary upregulation of the single active X chromosome in mammals.

**Catechol-O-methyl transferase inhibitors in the treatment of inherited dopamine deficiency.** *A. Ponzone, S. Baglieri, G. Battistoni, L. Sorasio, A. Martini, S. Ferraris, M. Spada.* Pediatrics, University of Torino, Torino, Italy.

Most patients suffering from inborn errors of aromatic amino acid hydroxylation have to be treated with L-dopa, the hydroxylated precursor of dopamine. They include all the recessive and dominant forms of tetrahydrobiopterin deficiency and tyrosine hydroxylase deficiency. The limiting factor in this therapy depends on the short plasma half-life of the administered L-dopa and on the production of methylated catabolites after long treatments. Some benefit can be obtained by the administration of inhibitors of peripheral decarboxylases, sustained-release preparations, monoamine oxidase inhibitors. With this aim, we attempted the concurrent administration of entacapone, a reversible inhibitor of catechol-O-methyl transferase. Six patients suffering either from 6-pyruvoyl tetrahydropterin synthase or from dihydropteridine reductase deficiency were given entacapone, in addition to their standard therapy, at the dose of 15mg/Kg/day. The evaluation of the efficacy was based on the assessment of neuromotor performances and included the analysis of dopamine and prolactin blood profiles and of L-dopa kinetics. The use of entacapone resulted in a substantial improvement of neurotransmitter therapy, with prolonged L-dopa half-life and reduced methyl-dopa production, also allowing a 30% reduction of the daily dosage and number of administrations of L-dopa.

**Molecular analysis of two patients with 3-hydroxy-methyl-glutaric aciduria: identification of three novel mutations including one de novo mutation.** *J.Y. Wu<sup>1,2</sup>, C.F. Yang<sup>1,2</sup>, F.J. Tsai<sup>1,2,3</sup>*. 1) Dept Medical Research, China Medical Col Hosp, Taichung, Taiwan; 2) Dept Medical Gen, China Medical Col Hosp, Taichung, Taiwan; 3) Dept Pediatrics, China Medical Col Hosp, Taichung, Taiwan.

3-hydroxy-3-methylglutary-CoA lyase (HMG-CoA lyase, HL) deficiency gives rise to 3-hydroxy-3-methylglutaric aciduria. This disorder is one of the many inborn errors of CoA ester metabolism, and is of particular interest because the deficient enzyme (HL) plays a key role in ketone body, fatty acid and leucine metabolism. The disease is fatal in about 20% of cases. HL deficiency is transmitted as an autosomal recessive trait. In this study, two unrelated patients with HMG-CoA lyase deficiency are screened by direct sequencing of cDNA and genomic DNA. We identified three novel mutations in HL gene in these two patients. Patient 1 was characterized to have a deletion of exon 3 in direct sequencing of HL cDNA. Direct sequencing of genomic DNA indicated a G-to-A change at the first nucleotide in intron 3, which leads to aberrant splicing. The other mutation was not identified despite rigorous sequencing of all exons of HL gene. Patient 2 was found to carry a missense mutation in one allele and splicing mutation on the other allele. In segregation analysis, this patient was found to inherit the splicing mutation from the mother while the father did not carry the other identified missense mutation. Fraternity test indicated the father was indeed this patient's biological father. Several polymorphism markers around the HL locus were selected to confirm that this patient did inherit one allele from the mother and the other allele from the mother. This data indicated that this patient carry a de novo mutation in HL gene in the allele from the father.

**Parent mastery of heel/finger stick skills in PKU as a predictor of outcome.** *G.L. Arnold, J. DeLuca, E. Blakely.* Div Pediatric Genetics, Univ Rochester Sch Medicine, Rochester, NY.

Cognitive outcomes in children with Phenylketonuria (PKU) are strongly related to plasma phenylalanine (phe) concentrations, particularly in the first decade of life. Thus, outcome for affected children potentially might be improved by early identification of families at risk for the development of poor PKU management skills. We studied the ability of parents to master performance of the required weekly heel/finger stick for phe concentrations in the first year of life as a predictor of later phe control. We reviewed the charts of children with early and continuously treated classic PKU from the University of Rochester Inherited Metabolic Disorders Clinic. The group whose parents had achieved home heel/finger stick measurements in the first year of life were compared to those whose levels were performed by a medical professional instead of a parent.

There were 44 children who met study criteria. The group whose parents mastered the home draws was composed of 13 boys and 9 girls with mean age 8.2 yrs, and the group whose parents did not master this skill was composed of 17 boys and 5 girls with mean age 7.5 yrs. Median phe concentration from the prior year in the parent drawn group was 4.5 mg/dl and in the professional drawn group was 8.6 mg/dl ( $p < 0.05$ ). This relationship was even stronger for children under ten years old, where mean phe in the parent drawn group was 4.0 mg/dl, and was 6.9 mg/dl in the health professional drawn group ( $p < 0.002$ ). Further, six children from the professional drawn group required Child Protective Referrals for medical neglect, compared to none in the parent drawn group ( $p < 0.05$ ).

Parent mastery of heel/finger sticks for phe concentrations appears to be a strong predictor of outcome, particularly in the first decade. This is likely an indirect measure of family functioning including parental limit-setting, coping strategies, organization or other issues. Further studies are planned to determine which aspects of family functioning are impaired in families who fail to master this skill and if earlier intervention can improve outcome.

**Mutation analysis in families with X-linked metabolic disorders: adrenoleukodystrophy (X-ALD), ornithine carbamoyltransferase (OTC) deficiency and hypoxanthine-guanine phosphoribosyltransferase (HPRT) deficiency.** *L. Dvorakova, E. Tietzeova, G. Storkanova, J. Zeman, E. Hrubá, E. Kostalova, I. Sebesta, S. Kmoch, M. Hrebíček.* Inst inherit Metabol Disorders, Prague 2, Czech Republic.

In families with gonosomal recessive disorders a reliable detection of carriers is important. To identify heterozygotes in affected families we have set up methods for mutation analysis in ABCD1 (gene for X-ALD), OTC and HPRT genes. As the mutations are usually private, we start the analysis by direct sequencing of PCR or RT/PCR products amplified from genomic DNA or cDNA of probands or obligatory heterozygotes. Subsequently, family members are genotyped by specific PCR-RFLP assays. X-ALD patients with all common phenotypes (5 ccALD, 4 AMN, 2 ADO, 3 asymptomatic) came from 12 unrelated families. We have found 12 mutations, 9 of them being novel. No genotype - phenotype correlation was found. We have analyzed mutations in 10 families with OTC deficiency. In 3 families with neonatal form two nonsense mutations and one missense mutation were found. In one OTC family the only patient is a symptomatic female heterozygous for a novel nonsense mutation. In 4 out of 6 families with late onset form of the disease we have identified a previously reported mutation, R277W. Up to now we have examined only one family with a partial HPRT deficiency. The proband is a symptomatic female. She is a heterozygote for previously described missense mutation V53A. Her father, who has symptoms of partial HPRT deficiency, is hemizygous for the mutation. In total we screened 65 family members from all affected families and identified 4 presymptomatic boys and 24 heterozygotes. In one X-ALD family mutation analysis served for prenatal diagnosis. Interestingly, we did not detect the mutation in 3 out of 18 examined mothers - obligatory heterozygotes. As the examined DNA is isolated from leukocytes, we cannot exclude the possibility of gonadal mosaicism, a phenomenon described in literature. Therefore, in the case of these mothers we strongly recommend genetic counseling and prenatal diagnosis in future pregnancies. (Supported by IGA MH grants NE5770-3-99 and NE 6557-3-01).

**Characterization of the human gene encoding Alpha-aminoadipate Aminotransferase (AAAT).** *D.L. Goh<sup>1</sup>, A. Patel<sup>2</sup>, G.H. Thomas<sup>2</sup>, M.T. Geraghty<sup>1</sup>.* 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 2) Kennedy Krieger Institute, Baltimore, MD.

In mammals, the degradation of L-lysine is a multi-step process that ends in the formation of acetyl-CoA. An intermediary step in this pathway involves the transamination of alpha-aminoadipate to alpha-ketoadipic acid. The rat gene encoding alpha-aminoadipate aminotransferase (KAT/AadAT) was previously identified. Using the BLAST algorithm, we identified a human EST contig homologous to the rat KAT/AadAT gene. The full length cDNA contains an open-reading frame of 1275 bp, predicted to encode 425 amino acids which contains a mitochondrial targeting signal as well as the expected pyridoxal-phosphate binding site. The human protein is 64% identical to the rat protein and 29% identical to its yeast counterpart. In Northern blot analysis, the cDNA hybridized to two transcripts, a major signal at ~2.9 kb and a minor signal at ~4.7 kb. Expression was highest in liver but was also seen in heart, brain, kidney, pancreas, prostate and testis. We further identified a human genomic BAC clone containing the AAAT gene, and using FISH confirmed the localization of this gene to chromosome 4q32.2. Using the BLAST alignment tool, we characterized the genomic structure of the gene, which consists of 12 exons spanning 40kb. Bacterial expression studies are currently underway to confirm the predicted function of this gene. Finally, while it has been suggested that patients with B6 responsive seizures might have a defect in this enzyme, we sequenced the cDNA of two patients and were unable to find any mutations in the AAAT gene.

**Human Cystathionine b-Synthase Gene is Coordinately Regulated with Proliferation by a Synergistic Interaction Between Sp1 and Sp3.** *K. Maclean, E. Kraus, J.P. Kraus.* Dept Pediatrics, C-233, UCHSC, Denver, CO, 80262.

Cystathionine b-synthase (CBS; L-serine hydro-lyase (adding homocysteine), EC 4.2.1.22) catalyzes the condensation of serine with homocysteine to form cystathionine, which is subsequently converted to cysteine. Homozygous CBS deficiency is the most common cause of classical homocystinuria, whilst partial deficiency of CBS has been proposed to cause mild hyperhomocysteinemia, considered an independent risk factor for arteriosclerosis. We have previously identified two separate promoters in the human CBS gene designated -1a and -1b, and have shown that they are coordinately regulated with proliferation. Deletion analysis and promoter assays in HepG2 cells using luciferase reporter constructs were used to define both the basal and minimal CBS -1b promoter regions. This promoter was found to be serum and fibroblast growth factor inducible and is down regulated by growth arrest and differentiation. Examination of CBS promoter activity in Sp1 negative *Drosophila* SL2 cells indicated that both CBS promoters have an obligate need for the redox sensitive transcription factor Sp1. Deletion analysis of the CBS -1b basal promoter indicated the presence of at least 3 key Sp1 sites that contribute to basal promoter activity. The CBS -1b minimal promoter contains one Sp1 binding site and when this site is mutagenized CBS promoter activity is abolished. Co-transfection of SL2 cells with the CBS -1b basal promoter with either Sp1 or Sp3 expression constructs leads to CBS promoter activity approximately 10-fold over background. However, co-transfection of the CBS -1b promoter with both Sp1 and Sp3 lead to a 70-fold increase of CBS activity indicating that regulation of the human CBS -1b promoter involves a positive synergistic interaction between these two transcription factors. When this transfection is repeated using the CBS-1b minimal promoter, the synergistic interaction is lost indicating that not all Sp1 sites in the CBS -1b promoter are functionally equivalent. Several key Sp1 sites in the -1b promoter have been identified and this regulation has been shown to be sensitive to intracellular redox as a function of cellular proliferation status.

**Identification of the gene encoding hydroxyproline oxidase and delineation of mutations responsible for hyperhydroxyprolinemia.** C. Hu<sup>1</sup>, W-W. Lin<sup>1</sup>, G. Steel<sup>1</sup>, H. Levy<sup>2</sup>, D. Valle<sup>1</sup>. 1) Inst Genetic Medicine, Johns Hopkins Univ Sch Med, Baltimore, MD; 2) Children's Hospital, Boston, MA.

Using the sequence of yeast and *Drosophila* proline oxidase to probe mammalian EST and genomic databases, we identified two homologous human genes: the first, *POX*, located at 22q11.2, encodes proline oxidase; the second, located at 19q13.1, by elimination, became a candidate for the gene (*HPOX*) encoding hydroxyproline oxidase. The protein products of these two genes have 33% amino acid identity. Hydroxyproline oxidase (HPOX) is a mitochondrial enzyme that catalyzes the first step in hydroxyproline degradation. Deficiency of HPOX is presumed on the basis of metabolite studies to be the primary defect in hyperhydroxyprolinemia (HHP), an autosomal recessive biochemical disorder characterized by a 10-fold accumulation of plasma hydroxyproline. The putative *HPOX* cDNA has a 1608 bp ORF encoding a protein of 536 residues with a predicted molecular weight of 58 kDa. Northern analysis showed expression in liver, kidney and heart. The *HPOX* gene has 12 exons distributed over 17 kb of genomic DNA. To confirm identity of the putative *HPOX* cDNA, we expressed it in Chinese hamster ovary cells and showed that it conferred hydroxyproline oxidase activity. To determine if HPOX mutations cause HHP, we surveyed the gene in a previously reported patient with HHP (Kim et al J Pediatr 130: 437, 1997). The proband, a 16 year old girl with a plasma hydroxyproline of 360mM (normal 0-50) and normal proline levels, is clinically asymptomatic. We amplified all 12 HPOX exons and their flanking splice sites from the proband and found that she is a compound heterozygote for a 1 bp deletion allele [H289fs(-1)] inherited from her father and an allele with an altered splice site in intron 6 (In6dnrG-1T) inherited from her mother. Both alleles are predicted to result in the loss of the C-terminal half of the protein. Our results confirm the identification of the human gene encoding hydroxyproline oxidase and show that mutations in this gene cause hyperhydroxyprolinemia.

**Mutational spectrum in the genes SLC3A1 and SLC7A9 in early manifesting cystinuria.** *C. Schmidt<sup>1</sup>, E. Botzenhart<sup>1</sup>, U. Vester<sup>2</sup>, P. Hoyer<sup>2</sup>, K. Zerres<sup>1</sup>, T. Eggermann<sup>1</sup>.* 1) RWTH Aachen, Institute of Human Genetics, Aachen, Germany; 2) Department for Pediatric Nephrology, Essen.

Cystinuria (OMIM 220100) is an inherited hyperaminoaciduria. The defective cystine transport across the renal brush border membrane leads to recurrent kidney stone formation. While mutations in the SLC3A1 gene cause type I cystinuria, patients with non-type I cystinuria harbour mutations in the SLC7A9 gene. Both gene products form a renal amino acid transporter. The different types can be distinguished biochemically by urinary amino acid profiles. Until now it has been assumed that type I patients show a more severe phenotype with earlier manifestation than non-type I patients. Goodyer et al. (*Kidney International*, Vol. 54, 56-61, 1998) demonstrated that patients with mutations in SLC3A1 form stones in their first decade of life while non type I patients only show increased urinary cystine values at this age. In this study we collected blood, plasma and urine samples of 22 cystinuria patients from 17 families. Patients' age ranged from nine months to 21 years, they and their relatives were classified biochemically by ion exchange chromatography. Genomic DNA was used for molecular genetic analyses (SSCA, restriction assays, sequencing) of both cystinuria genes. Our results indicate that the mutational spectrum in younger patients is similar to that in a previously studied group of unclassified patients with an older age of onset: 2/3 of the patients had mutations in SLC3A1, 1/3 in SLC7A9. In both groups M467T is the most frequent mutation. The study population also includes a sibship showing homozygosity for the same SLC3A1 mutation but with ages of onset of nine and 22 years. We conclude that stone formation depends on further modifying factors like urinary citrate or calcium concentration.

**Argininemia: A prospective study and two new cases.** *P.L. Plotner, H. Northrup.* Division of Medical Genetics, Department of Pediatrics, The University of Texas Medical School at Houston, Houston, TX.

Defects in any of the five urea cycle enzymes lead to disease and are collectively known as urea cycle defects. Urea cycle defects occur in about 1 in 30,000 live births. Argininemia is an autosomal recessive disease caused by a deficiency of the enzyme arginase, the last enzyme in the urea cycle. A deficiency of arginase leads to a build up of arginine and its metabolic by-products. Argininemia is the least frequently diagnosed urea cycle defect and its population incidence and prevalence are unknown. The most common clinical features of argininemia are neurologic: motor control and intellectual functioning. The presentation of motor deficits ranges from ataxia to spastic tetraplegia with spastic diplegia being, by far, the most common presentation (>90%).

To date 36 cases, representing 30 families, have been reported in the medical literature with Hispanic patients representing the largest ethnic group (46%). We report 2 unrelated patients, also of Hispanic ethnicity, that were diagnosed in our cerebral palsy clinic within the same year.

Identifying these two patients prompted a prospective search for others with argininemia within the same cerebral palsy clinic population. Including our two patients, 661 charts were reviewed with 136 (20%) included in the study. A plasma arginine level was obtained on 86 (63%) of the 136 study participants. No plasma arginine levels were diagnostic for argininemia except for those described above (1%). Based on this information, and a reported U.S. prevalence of cerebral palsy of 2/1000, we hypothesize that the population prevalence of argininemia is less than 1 per 350,000.

**PET scans abnormalities in adults with early-treated PKU.** *M.P. Wasserstein, S.E. Snyderman, C. Sansaricq, M.S. Buchsbaum.* Mount Sinai School of Medicine, NY, NY.

Classical phenylketonuria (PKU) may cause subtle neurocognitive defects despite early, adequate treatment. Understanding which regions of the brain are adversely affected may provide insight about the pathophysiology of these abnormalities. We used positron emission tomography (PET) with  $^{18}\text{F}$ -deoxyglucose in 12 adults (4 women, 8 men; ages 23 to 36) with early-treated PKU to evaluate if abnormalities exist in cerebral metabolic rate, if the abnormalities are related to concurrent plasma phenylalanine (Phe) levels, and if relationships exist between age-specific Phe levels and particular regions of abnormality. SPGR MRI with 1.2 mm slice thickness were reoriented to standard atlas position and PET coregistered. Relative metabolic rate at the center of positions identified in the atlas were assessed in all subjects. Repeated measures MANOVA was used to assess regional metabolic differences. Lifelong, age-specific phe levels were available for 9 patients. 10 patients had day-of-scan Phe levels  $>17$  mg/dl. Patients with PKU in comparison to normal, age- and sex-matched controls had lower relative metabolic rates in the executive area of the prefrontal cortex, but higher relative metabolic rates in the lateral temporal lobe and hippocampus (group by region interaction,  $F=8.46$ ,  $df=1,31$ ,  $p=0.006$ ). Patients had higher relative metabolic rates than normals in the putamen and the thalamus, and lower rates in the right caudate (group by structure by hemisphere interaction,  $F=6.05$ ,  $df=2, 62$ ,  $p=0.004$ ). Day-of-scan Phe correlated only with abnormalities in the globus pallidus (lower in patients than normals,  $r=0.75$ ,  $p<0.05$ ). An association was found between lower relative metabolic rates in Brodman's area 45, a late developing area involved in higher cognitive function, and Phe level during adolescence ( $r=-.78$ ,  $p<0.05$ ). These regional abnormalities correlate with some of the clinical features of early treated PKU, such as abnormal executive function (prefrontal cortex), and mood swings(temporal lobe). The finding of abnormalities in Brodman's area 45 suggest that the brain remains sensitive to the effects of phe longer than previously thought.

**Maple Syrup Urine Disease: Identification of a Novel Ashkenazi Jewish Mutation.** *S.E. Snyderman, M.P. Wasserstein, C. Sansaricq, R. Kornreich, G.A. Diaz.* Human Genetics, Mount Sinai School of Medicine, New York, NY.

Maple Syrup Urine Disease (MSUD) is a rare, autosomal recessive disorder of branched chain amino acid metabolism. The clinical course in classic MSUD is characterized by episodic metabolic decompensations that can result in severe neurologic damage or death. The disease is genetically heterogeneous and is caused by deficient activity of the mitochondrial multienzyme complex, branched chain A-keto acid dehydrogenase (BCKAD). Mutations in the E1 (composed of two E1A and two E1B subunits) or E2 components of BCKAD result in classic, intermediate, or intermittent MSUD. Whereas the frequency of MSUD in the general population is estimated to be approximately 1 in 185,000, its frequency in the Mennonite population is 1 in 176 due to a founder effect. We noted that a large percentage of MSUD families (10 of 34) followed in our clinic are of Ashkenazi Jewish descent, leading us to search for a common mutation within this group. A haplotype flanking the E1B subunit was found in homozygosity in two of five Ashkenazi Jewish patients screened, and in heterozygosity in three additional individuals. Additionally, 9 of 10 MSUD chromosomes studied shared a common allele at marker D6S251. Sequencing of the gene in a patient homozygous for the conserved haplotype revealed a novel homozygous 538G->C missense mutation in exon 5 predicted to result in a non-conservative substitution, R183P. Screening of the remaining patients for this mutation revealed that all chromosomes with the common allele at D6S251 carried the R183P mutation. This arginine residue has been completely conserved in the homologous proteins from bacteria through mammals and is located in a B strand that forms part of a K<sup>+</sup> ion-binding pocket close to the interface of the E1A and E1B subunits. The structural changes introduced by the mutation may thus interfere with the proper formation of the ion-binding pocket and/or with subunit interaction. In summary, we have identified a novel missense founder mutation in the E1B subunit causing MSUD in the Ashkenazi Jewish population. These findings enable the determination of allele frequency in this group and may facilitate carrier screening.

**Carnitine Metabolic Defects in Saudi Arabia.** *A.I. Al-Aqeel<sup>1</sup>, M.S. Rashed<sup>2</sup>, J.P.N. Ruiten<sup>3</sup>, L. Ijst<sup>3</sup>, R.J.A. Wanders<sup>3</sup>.*  
1) Dept Pediatrics, Riyadh Military Hosp, Riyadh, Saudi Arabia; 2) Departement of biological & medical research, King faisal Hospital, Riyadh Saudi Arabia; 3) Laboratory of Genetic Metabolic Diseases University of Amsterdam, Amsterdam. The Netherland.

Some 13 different inherited defects of mitochondrial fatty acid -oxidation have been described. Four of these affect the carnitine shuttle for the transport of long-chain fatty acids into the mitochondria, either intracellular uptake of carnitine of the enzymes carnitine palmitoyltransferase (CPT) I and II or carnitine acylcarnitine translocase (CACT). We report 5 affected Saudi patients, a product of first cousin marriage, with CPT I deficiency who presented with typical Reye-like syndrome with unconsciousness, hepatomegaly, hypoglycemia, hyperammonemia, very high liver enzymes and typical acylcarnitine profile. In one of these patients the disease was fulminant with hemophagocytic syndrome. With CACT deficiency we also report a five-month-old patient who presented on the second day of life with nystagmus and hyperammonemia and typical acylcarnitine profile. These patients had a unique molecular defect with a homozygous 1950 G-A transition in the cDNA encoding CPT1A, (G650D) and 713 A-C transversion (Q238R) in the CACT deficiency patient, which is conserved in other organisms. Expression studies in yeast has to be done to investigate the consequences of these mutations for the function of the enzymes. In conclusion, carnitine metabolic defects are treatable disorders with unique molecular defects in our Saudi patients.

**Impaired inducibility of superoxide dismutases in Friedreich's ataxia.** *V. Geromel<sup>1</sup>, K. Chantrel-Groussard<sup>1</sup>, H. Puccio<sup>2</sup>, M. Koenig<sup>2</sup>, A. Munnich<sup>1</sup>, A. Rotig<sup>1</sup>, P. Rustin<sup>1</sup>.* 1) INSERM U393, Hosp Necker, Paris, Paris, France; 2) Institut de Genetique et de Biologie Moleculaire et Cellulaire, INSERM, CNRS, 1 rue Laurent Fries, BP 163, 67404 Illkirch, France.

Friedreich's ataxia (FRDA) is an autosomal recessive neurodegenerative disease causing limb and gait ataxia and cardiomyopathy. The disease gene encodes a protein of unknown function, frataxin. In the vast majority of the patients, the loss of frataxin is due to a large GAA trinucleotide expansion in the first intron of the gene, which hampers the gene transcription by causing the formation of a sticky DNA structure. Decreased frataxin content results in a generalized deficiency of mitochondrial iron-sulfur protein activity that has been previously ascribed to mitochondrial iron overload. However, iron overload appears as a late event in the disease and in a mouse model as well. Here we show that neither superoxide dismutases nor the import iron machinery were induced by an endogenous oxidative stress in FRDA patient's fibroblasts as compared to control cells. Superoxide dismutase activity was not induced in heart of conditional frataxin-KO mice either. This suggests that continuous oxidative damages to iron-sulfur clusters, resulting from a impaired superoxide dismutase signaling, are causative of the mitochondrial deficiency and the long term mitochondrial iron overload occurring in FRDA.

**Deletion pattern of the STS gene and flanking sequences in Mexican patients with XLI.** *S.A. Cuevas<sup>1</sup>, A.L. Jimenez<sup>1</sup>, M. Valdes<sup>2</sup>, M.R. Rivera<sup>1</sup>, S.H. Kofman<sup>1</sup>.* 1) Genetica, Hospital General de Mexico, Mexico, D.F., Mexico; 2) Centro Nacional de Rehabilitacion (INO)Mexico, Mexico, D.F.

X-linked ichthyosis (XLI) is an inherited disorder due to steroid sulfatase deficiency. Most XLI patients (>90%) have a complete deletion of the STS gene and flanking sequences. The presence of low copy number repeats (G1.3 and CRI-S232) on either side of the STS gene, promoting unequal crossing over, seems to play a role in the high frequency of these interstitial deletions. In the present study, we analyzed 80 Mexican patients with XLI and complete deletion of the STS gene. STS activity was measured in the leukocytes using 7-[3H]-dehydroepiandrosterone sulfate as a substrate. Amplification of the regions telomeric-DXS89, DXS1139, DXS1130, 5'STS, 3'STS, DXS1133, DXS237, DXS1132, DXF22S1, DXS278-centromeric was performed through PCR. No STS activity was detected in the XLI patients (0.00 pmoles/mg protein/h). We observed 3 different deletion patterns. 57 patients showed a deletion at the sequence DXS1139 (5'end of the STS gene) that corresponded to the probe CRI-S232A2. 32 out of these patients presented the 3 rupture site at the sequence DXF22S1 (probe G1.3) and the rest 25 patients had the 3 breakpoint at the sequence DXS278 (probe CRI-S232B2). 23 patients had the breakpoints at several regions on either side of the STS gene as follows: 5'-3' ends, 2 patients; 5'end-DXS1131, 3 patients; 5'end-DXS1133, 1 patient; 5'end-DXS237, 1 patient; 5'end-DXF22S1, 1 patient; DXS1130-DXS1131, 2 patients; DXS1130-DXS237, 1 patient; DXS1130-DXF1132, 1 patient; DXS1130-DXF22S1, 3 patients; DXS1130-DXS278, 1 patient; DXS1139-DXS1131, 4 patients; DXS1139-DXS1133, 1 patient; DXS1139-DXS237, 2 patients. Although there was an important participation of low copy number repeats in the etiology of the 70% of our patients, we also had a high percent (30%) in which this low copy number repeats were not involved. These data indicate that more complex mechanisms, apart from homologous recombination, are participating in the ruptures sites of the STS gene in XLI patients in Mexican population.

**Chronic PDGF signaling in glioma cells modulates expression of multiple genes encoding receptors, signal transduction components, and pro-angiogenic factors, and may promote reciprocal paracrine communication between glioma cells and endothelia.** *M.A. Dressman<sup>1</sup>, E.C. Holland<sup>2</sup>, O. Grenet<sup>3</sup>, S.D. Chibout<sup>3</sup>, C. Lavedan<sup>1</sup>, M.H. Polymeropoulos<sup>1</sup>.* 1) Pharmacogenetics, Novartis Pharmaceuticals Corporation, Gaithersburg, MD; 2) Neurosurgery, Neurology, and Cell Biology, Memorial Sloan Kettering Cancer Center, New York, NY; 3) Toxicology, Novartis Pharmaceuticals Corporation, Basel, Switzerland.

Chronic autocrine loop stimulation by platelet derived growth factor (PDGF) has been proposed as a major contributor to glioma cell proliferation and induction of angiogenesis. Therefore, PDGF induced gene expression in glioma cells may provide insight into the molecular mechanisms of gliomagenesis. We have used expression profiling to identify genes that are regulated by PDGF signaling in the glioma cell line U373. Similarly, we generated expression profiles of VEGF signaling in cultured endothelial cells. A PDGFR specific regulated expression profile of 112 genes was identified providing a global snapshot of a dynamic process including successive stages of the tyrosine kinase signaling pathway, angiogenic genes and numerous receptor genes most likely involved in paracrine stimulation. The tyrosine kinase inhibitor PTK787 reversed the profile of 111 of these genes. Studying expression profiles of PDGFR signaling in parallel with VEGFR profiles suggested that chronic PDGFR signaling induces paracrine loops of glioma proliferation and induction of new blood vessel formation. Key members of this expression profile reside at the nodes of numerous signaling pathways and should be considered as therapeutic targets for diseases including cancer, stroke, hyperplasias, pulmonary fibrosis, psoriasis, and disorders of angiogenesis and wound healing.

**Tetrahydrobiopterin deficiency due to defective 6-pyruvoyl-tetrahydropterin synthase: negative charges at amino acid position 19 modulate enzyme activity.** *W. Leimbacher, N. Blau, B. Thony.* Dept Ped, Div Clin Chem/Biochem, Univ Zurich, Zurich, Switzerland.

We previously identified in a 6-pyruvoyltetrahydropterin synthase (PTPS)-deficient patient an inactive PTPS allele with an Arg16 to Cys codon mutation. Arg16 is located in the protein surface exposed phosphorylation motif Arg16-Arg-Ile-Ser-Phe, with Ser19 as the identified phosphorylation site for the cGMP protein kinase II, a serine/threonine protein kinase. Purification of recombinant PTPS-S19A from bacterial cells yielded an active enzyme that was kinetically (kcat/kM) indistinguishable from the wild-type enzyme. Adversely, upon transient transfection into COS-1 cells, the PTPS-S19A allele was stably expressed but not phosphorylated and had a reduced activity of 33% in comparison to wild-type PTPS (1). Since in vivo modification appears to be essential for normal activity, we investigated the function of phosphoserine19 of human PTPS in more detail by substitution of the Ser19 not only by alanine but also by an acidic residue. Replacement of Ser19 by aspartic acid mimics the kinase-modified PTPS-phosphoserine by replacing two negative charges from the phosphate group by one negatively charged side chain from Asp. Transient transfection into COS-1 cells of the PTPS mutant resulted not only in rescuing wild-type activation to 100%, but in hyperactivation of the Asp19 mutant to 146+18%. This demonstrates that alanine or acidic residues at position 19 in human PTPS modulate enzyme activity. (1) Scherer-Oppliger T, Leimbacher W, Blau N, and Thony B: Serine 19 of human 6-pyruvoyltetrahydropterin synthase is phosphorylated by cGMP protein kinase II, *J Biol Chem* 1999; 274:31341-31348.

**Gene expression profiling of renal cortex from STZ-induced diabetic rats.** *L.A. McLean<sup>1</sup>, D.L. Feldman<sup>2</sup>, L.M. Barnes<sup>1</sup>, T.C. Mogelesky<sup>2</sup>, W. Chen<sup>2</sup>, M.A. Dressman<sup>1</sup>.* 1) Pharmacogenetics, Novartis, Gaithersburg, MD; 2) MCD, Novartis, Summit, NJ.

The purpose of this study was to evaluate the molecular mechanisms associated with diabetic nephropathy by utilizing oligonucleotide microarray technology. RNA was extracted from renal cortex of three rats two weeks after treatment with streptozotocin (STZ) (a model of early diabetes) along with five untreated control animals. Subsequently synthesized and labeled cRNAs were hybridized to Affymetrix microarrays that represent over 8,000 full length genes and expressed sequence tags (ESTs). Several genes that have previously been demonstrated to be upregulated in diabetes were confirmed to have significantly increased gene expression levels in this study, including: mitochondrial 3-hydroxy-3-methylglutaryl-CoA synthase, gene 33 (mitogen-inducible gene-6), glucose transporter GLUT2, insulin-like growth factor binding protein 1 (IGFBP-1), and the diabetes-inducible cytochrome p450RLM6. Tamm-Horsfall protein, which is typically decreased in patients with diabetic nephropathy, was shown to have significantly lower expression levels in the STZ-treated rats, as were several other genes not previously associated with diabetes. Altered gene expression levels were found for several metabolic enzymes such as 2-hydroxyphytanoyl-CoA lyase; betaine homocysteine methyltransferase (BHMT); lipoprotein lipase; acetyl-CoA acyltransferase, 3-oxo acyl-CoA thiolase A; malic enzyme 1; and glutathione synthetase. Expression of several solute transport proteins were also differentially expressed in the diabetic animal model, including: kidney band 3 anion exchange protein, taurine/beta-alanine transporter, organic cation transporter 2 (OCT2), organic anion transporter (OATP), and the anion exchange protein 2 (AE2). Examination of expression levels of extracellular matrix (ECM)-associated genes revealed a significant ( $p < 0.05$ ) increase in laminin chain beta-2, the proteoglycan decorin, and the serine protease inhibitor leuserpin-2 in the STZ-treated animals. Enhanced gene expression of these ECM-related proteins may correlate to the hallmark ECM deposition seen later in STZ-induced diabetic nephropathy.

**Sub-cellular localization of tetrahydrobiopterin biosynthetic enzymes: nuclear localization of GTPCH and PTPS.** *B. Thony*<sup>1</sup>, *S. Laufs*<sup>2</sup>, *A. Resibois*<sup>3</sup>, *W. Leimbacher*<sup>1</sup>, *N. Blau*<sup>1</sup>. 1) Dept Ped, Div Clin Chem/Biochem, Univ Zurich, Zurich, Switzerland; 2) DKFZ, Im Neuheimer Feld, D-69120 Heidelberg, Germany; 3) Biological Chemistry Laboratory, Faculte de Medicine, Universite Libre de Bruxelles, Belgium.

Tetrahydrobiopterin cofactor deficiency comprises a heterogeneous group of disorders caused by mutations at one of the genes encoding enzymes involved in the biosynthesis or regeneration. The biosynthesis of tetrahydrobiopterin requires the enzymes GTP cyclohydrolase I (GTPCH), 6-pyruvoyl tetrahydropterin synthase (PTPS), and sepiapterin reductase (SR). Upon studying the distribution of GTPCH and PTPS with polyclonal immune sera in cross-sections of rat brain and peripheral organs, strong nuclear staining was observed in neurons and cells of the kidney convoluted tubules. Cytoplasmic and nuclear staining at least for PTPS was also observed in transiently transfected COS-1 cells that do not have this enzyme (and GTPCH) endogenously present. To study the nature of this nuclear localization in more detail, we generated plasmids expressing recombinant Flag-tagged fusion proteins for the three human biosynthetic enzymes Flag-GTPCH, Flag-PTPS, and Flag-SR. Flag-peptide (DYKDDDDK) epitope-tagged enzymes can be specifically detected by a commercially available monoclonal antibody. Transiently transfected COS-1 cells expressing individual Flag-fusion proteins were fractionated into cytoplasmic and nuclear extracts, and analyzed for enzyme activity and cross reactivity by Western blot. All three enzymes were found in the cytoplasmic fraction, whereas only the Flag-GTPCH and Flag-PTPS were also located in the nucleus. Unexpectedly, enzymatic activity in the nuclear fraction was observed for Flag-GTPCH but not for Flag-PTPS. Furthermore, since no canonical nuclear localization signal is present in PTPS (and also in GTPCH), a series of amino acid alterations, and C- and N-terminal deletions of Flag-fusion proteins were tested to identify residues that may target the PTPS protein to the nucleus. Preliminary results suggest that correct folding and/or stable expression of PTPS is essential for nuclear localization.

**A novel heteroplasmic mtDNA mutation in a family with heterogeneous clinical presentations.** *M. Zeviani<sup>1</sup>, F. Carrara<sup>1</sup>, P. Corona<sup>1</sup>, E. Lamantea<sup>1</sup>, M. Greco<sup>1</sup>, M. Mora<sup>2</sup>, C. Mariotti<sup>3</sup>*. 1) Molecular Neurogenetics, Istituto Nazionale Neurologico, Milano, Italy; 2) Neuromuscular Disorders, Istituto Nazionale Neurologico, Milano, Italy; 3) Biochemistry & Genetics, Istituto Nazionale Neurologico, Milano, Italy.

The proband, a 36 year-old man, showed isolated, severe spastic paraparesis. One of his brothers had died at age 24 years of heart failure due to hypertrophic-dilative cardiomyopathy. Another brother, now 34 years old, is presently healthy. The proband's mother, aged 64 years, showed truncal ataxia, spastic paraparesis, slurred speech, severe hearing loss, and mental regression. A muscle biopsy performed in the proband failed to show the morphological abnormalities typical of mitochondrial disorders and the activities of respiratory chain complexes were normal. However, complex I and IV activities were 38% and 50% of controls' mean in the muscle homogenate of the mother, and 44% and 4% in that of the affected brother deceased of cardiac failure. In this sample, reduction to 54% of controls' mean was also found for complex V (mitochondrial ATPase). Sequence analysis of mtDNA from muscle tissue of the proband revealed a heteroplasmic mutation of the tRNA<sup>ile</sup> gene (G4284A). Allele-specific RFLP analysis and densitometry showed 55%, 80%, and 95% mutant heteroplasmy in the muscle mtDNA of the proband, his mother and affected brother, respectively. A lesser but still clearly detectable mutation load was present in other tissues of the affected members of the family, including urinary and oral mucosa, hair follicles, and blood. Mutation was absent in mtDNA from several tissues of the healthy brother, as well as in 100 lymphocyte mtDNA samples from Italian controls. Ten 143B.206 cybrid clones containing 100% mutant mtDNA were compared with ten cybrid clones containing 100% wt mtDNA, both derived from the proband. A significant reduction of complex IV activity normalized to that of citrate synthase was demonstrated in the mutant cybrids ( $20 \pm 7$ ) compared to the wt cybrids ( $33.8 \pm 7.6$ , Student's *t* test  $p < 0.0005$ ). These results indicate that the G4284A change in the tRNA<sup>ile</sup> gene is a novel pathogenic mutation of mtDNA.

**The Pathogenesis of Joint Disease in the Mucopolysaccharidoses.** *C.M. Simonaro<sup>1</sup>, M.E. Haskins<sup>2</sup>, E.H. Schuchman<sup>1</sup>*. 1) Dept Human Genetics, Mount Sinai School of Medicine, New York, NY; 2) Dept of Pathobiology, University of Pennsylvania School of Veterinary Medicine, Philadelphia, PA.

Mucopolysaccharidosis Type VI (MPS VI; Maroteaux-Lamy Disease) is the lysosomal storage disorder due to the deficient activity of arylsulfatase B (N-acetylgalactosamine 4-sulfatase). A major feature of this and other MPS disorders is abnormal cartilage and bone development leading to short stature, dysostosis multiplex, and degenerative joint disease. To investigate the pathogenesis of joint disease in MPS VI, primary cultured articular chondrocytes and articular cartilage were examined from MPS VI rats and cats. Increased numbers of apoptotic chondrocytes were identified by TUNEL staining and anti-PARP immunocytochemistry in several joints from the MPS animals. Cultured chondrocytes from these animals also released more nitric oxide and TNF- $\alpha$  into the culture media than normal cells. Notably, dermatan sulfate induced nitric oxide release from normal articular chondrocytes to a degree greater or equal to LPS, a structurally related, pro-apoptotic polysaccharide. Marked proteoglycan and collagen depletion also was observed in the MPS epiphyses by Safranin-O and/or Alcian Blue staining. A model of MPS VI joint pathology is proposed in which dermatan sulfate accumulation leads to an enhanced propensity for chondrocyte cell death, either as a direct effect of the glycosaminoglycan itself or due to generalized lysosomal dysfunction. In turn, the homeostasis of the MPS cartilage matrix is abnormal and the matrix becomes depleted of proteoglycans and collagen. This leads to abnormal articular cartilage function and degenerative joint disease, which is exacerbated by the abnormal mechanical stress placed on the MPS joints and the release of inflammatory cytokines.

**Conditional transgenic over expression of  $\alpha$ -L-Iduronidase.** *C.S. Russell<sup>1</sup>, C.G Lobe<sup>4</sup>, A. Borowski<sup>2</sup>, S.M Gibson<sup>1</sup>, K.E Yip<sup>1</sup>, A. Nagy<sup>3</sup>, F.R. Jirik<sup>2</sup>, L.A. Clarke<sup>1</sup>.* 1) Dept Medical Genetics, Univ British Columbia, Vancouver, Canada; 2) Center for molecular Medicine and Therapeutics, Univ British Columbia, Vancouver, Canada; 3) Samuel Lunenfeld Research Institute, Mount Sinai Hospital, Toronto, Canada; 4) Cancer Research Division, Sunnybrook Health Science Center, Toronto, Canada.

MPS I is an autosomal recessive genetic disorder resulting from deficiency of alpha-L-iduronidase. MPS I presents as a clinical spectrum of disease ranging from severe skeletal disease, mental degeneration, cardiomyopathy, and death in the first decade (Hurler Syndrome), to milder forms of MPS I with minimal skeletal disease, normal mentation, and viability into adulthood (Scheie syndrome). Treatment options for MPS I include bone marrow transplantation and most recently enzyme replacement therapy (ERT). We have attempted to generate transgenic mice that over express human IDUA for use in BMT and other transplantation studies. Over expression of IDUA appears to be lethal to the developing embryo. Four rounds of pronuclear injection with either myeloid specific (CD11B promoter/enhancer) or ubiquitously expressing (Beta actin promoter/CMV enhancer) transgene constructs produced no transgenic offspring. An approach using embryonic stem cells was employed, one of the lines lead to generation of chimeric animals. We have interpreted this data to suggest that over expression of IDUA severely impairs early embryogenesis. To circumvent this problem we have used a conditional transgene expression approach to generate transgenic ES lines. This conditional expression is mediated by expression of CRE recombinase. Using the expanding repertoire of transgenic mice that express CRE recombinase, we hope to be able to regulate where and when IDUA will be over expressed. This will allow for further studies related to the lethal effects of IDUA over expression as well as the provision of an over expressing murine line for therapeutic studies. The effect of over expression of IDUA indicates that care may need to be taken in relation to the appropriate dose of IDUA for ERT or gene therapy trials.

**Identification and characterization of disease-causing mutations in Type II sialidosis patients.** *S. Pattison*<sup>1</sup>, *C.A. Rupa*<sup>2</sup>, *S.A. Igdoura*<sup>1,3</sup>. 1) Dept. of Biology, McMaster University, Hamilton, Ontario, Canada; 2) Division of Clinical Biochemistry, University of Western Ontario, London, Canada; 3) Dept. of Pathology and Molecular Medicine, McMaster University, Hamilton, Ontario,.

Sialidosis is a disease of hereditary sialidase deficiency with various clinical phenotypes. The most severe form, type II (congenital) sialidosis is characterized by hydrops fetalis, hepatosplenomegaly, severe psychomotor retardation and death usually before 1 year of age. Our objective is to identify mutations that cause disease, and to investigate the impact of these mutations on disease phenotype. We report the identification of 5 novel disease-causing mutations from three type II sialidosis patients. Using sialidase specific intron-based primers, PCR of patient derived genomic DNA was performed. Mutations were determined by sequencing and confirmed by restriction enzyme diagnostic. One homozygous nonsense mutation produced a premature stop codon in exon 1. The other four are missense mutation in exons one, four and five. We examined how each of the mutations exert their pathogenic effect by impairing the folding of the sialidase enzyme, or disturbing the assembly of b-galactosidase, cathepsin A and sialidase (GCS) complex. The impact of mutations on enzyme activity toward natural substrates such as GM3 was also assessed in determining disease phenotype, particularly when differences in tissue sialoglycoconjugate accumulations between type II patients are considered. The expression studies of mutant sialidase cDNAs in human primary cell lines provided insights into structurally sensitive protein domains that may be involved in enzyme activity and intercellular localization. Genotype/phenotype correlation of the sialidase mutations will provide a better understanding of the molecular pathology of the disease.

**Urinary glycosaminoglycan excretion quantified by an automated semi-micro method in specimens conveniently transported from around the globe.** *C.B. Whitley, R. Spielman, G. Herro, S. Severson.* Gene Therapy Program, Univ Minnesota Medical Sch, Minneapolis, MN.

Current and future treatments for children with mucopolysaccharidosis diseases require early, presymptomatic diagnosis, yet existing diagnostic methods to quantitate urinary glycosaminoglycan (GAG) are labor-intensive, and thus not applicable for newborn screening. Direct and rapid quantification of GAG excretion with 1,9 dimethylmethylene blue (DMB) is applicable to small volumes of urine collected, dried, and mailed on a paper matrix. To determine if this assay could be automated, a robotic instrument (Biomek 1000) was programmed to accomplish the procedure; the pilot method simultaneously determines GAG and creatinine concentrations in 10 specimens. Each analyte is measured in 4 dilutions thus increasing the operating range to cover a broad spectrum of normal and pathologic levels. Samples and reagents are mixed in 96-well tray format in approximately 20 minutes, and densitometric measurements are recorded in less than 60 seconds. Optical density measurements are electronically transmitted to a desktop computer to select optimal dilutions, identify values above or below the level of reliability, make calculations, and print reports. This automated method was applied to 255 specimens from 101 subjects representing each of the MPS diseases specifically, types I (n=126), II (47), III (48), IV (17), VI (14), VII (3). This method discriminated pathologic elevations of GAG excretion of MPS patients particularly when multiple specimens are available. In contrast to other lysosomal storage disorders, a patient with fucosidosis was found to have markedly elevated levels. Automation of the direct DMB method provides the key technology necessary for newborn screening for MPS diseases.

**MODELING DIFFERENTIAL BINDING OF NF-kB P50 TO A CYP2D6 PROMOTER VARIANT BY INFORMATION THEORY.** *I. Hurwitz, S. Svojanovsky, S. Leeder, P. Rogan.* Clinical Pharmacology, Children's Mercy Hospital, Kansas City, MO.

We determined the functional consequence of the C-1496G promoter variant that has been reported to modulate CYP2D6 activity *in vivo*. *In vitro*, transient transfection assays with the C variant exhibited 4-fold lower activity than -1496G. This SNP falls within an "NF-kB-like" binding motif. EMSAs demonstrate that NF-kB p50/p65 heterodimers do not bind to this region of the CYP2D6 promoter, whereas binding of p50 homodimers to -1496C is ~10-fold greater than to -1496G. These results were analyzed with information theory-based ( $R_i$ , in bits) models of NF-kB binding sites. Model weight matrices derived from published EMSA studies distinguish p50 from p65 homodimers and from p50/p65 heterodimer binding sites, based on their respective average information contents and nucleotide weights at each position. The p50/p65 model ( $R_{\text{sequence}}$ , average information = 11.45 bits) was validated by EMSA with nuclear extracts containing p50/p65 heterodimers and a series of probes with single nucleotide mutations within the commercially available optimal NF-kB binding motif. This sequence (5'-AGTTGAGGGGACTTTCCCAGGC-3') contains a strong 13.3 bit site that is weakened to 5.3 bits (equivalent to  $3^{256}$ -fold decreased binding) in the corresponding commercially available negative control probe (...GGCGACTTTC...). The -1496C allele contains a weak p50/p65 site (-1495 to -1508;  $R_i = 3.3$  bits) that is abolished ( $R_i < 0$ ) in the G variant. These alleles each also contain p50 homodimer binding sites on opposite strands; however, the C allele is predicted to bind with greater affinity (3.5 vs. 2.7 bits;  $3^{1.6}$  fold difference). Given the role of p50/p50 as a negative regulator of gene expression, the higher CYP2D6 activity observed for the -1496G allele may be due to reduced binding and repression by NF-kB p50 homodimers.

*Supported by grant ES10855-01 from NIEHS.*

**Cerebral hypometabolism detected by positron emission tomography (PET) in a patient with complex glycerol kinase deficiency and mental retardation.** *K.M. Dipple<sup>1</sup>, K.M. Venisnik<sup>2</sup>, D.H.S. Silverman<sup>2</sup>, J. Czerin<sup>2</sup>, E.R.B. McCabe<sup>1</sup>.* 1) Department of Pediatrics; 2) Department of Molecular and Medical Pharmacology, Univ California Los Angeles, Los Angeles, CA.

Complex glycerol kinase deficiency (GKD) is due to deletions of the glycerol kinase gene on Xp21 and the classical phenotype involves metabolic acidosis and central nervous system decompensation. In addition, many of the patients with GKD have mental retardation (MR) and seizures. To better understand the MR in these patients, we performed PET using fluoro-deoxyglucose (FDG) to assess glucose metabolism in the brain of a patient with complex GKD. This patient has a deletion involving part of IL1RAPL1, all of DAX1 and GK, and part of DMD (Niakan et al., abstract this meeting). PET has not previously been used to assess the regional brain metabolism in GKD patients. The patient was injected with FDG, and glucose and radioactivity were measured in arterial blood throughout the scan to allow molar quantitation of glucose uptake into brain tissue using compartmental modeling. Region of interest (ROI) analysis was performed by individualized region delineation and by standardized regions drawn on a template to which the patients scan was spatially transformed. Absolute quantitative values of glucose utilization, as well as internally normalized values, were compared to corresponding measurements in control subjects. Both visual interpretation and ROI analyses demonstrated relative and absolute hypometabolism in the parietal, temporal, and basal ganglia regions compared to normal individuals. There was hypermetabolism in the sensorimotor regions, and normal levels of metabolism in the thalamus, cerebellum, and remaining cortex. This is the first study on brain glucose metabolism in a patient with GKD with mental retardation. Parietal and temporal hypometabolism has been noted in several neurodegenerative diseases producing cognitive impairment and reflects a decrease in function of associative cortex. PET in patients with differing breakpoints will help us understand the neurobiological significance of the changes observed and their relationship to the genes in this region.

**Are type 2 and type 3 Gaucher disease a continuum? An intermediate phenotype.** *O. Goker-Alpan<sup>1</sup>, J.K. Park<sup>1</sup>, R. Schiffmann<sup>2</sup>, E. Orvisky<sup>1</sup>, B.K. Stubblefield<sup>1</sup>, N. Tayebi<sup>1</sup>, E. Sidransky<sup>1</sup>.* 1) NSB/NIMH/NIH, Bethesda, MD; 2) DMMP/NINDS/NIH, Bethesda, MD.

Gaucher disease is the inherited deficiency of lysosomal glucocerebrosidase which results in the deposition of glucosylcerebroside in various organs. The disease is classified into three major groups depending on whether the nervous system is involved (type 2 and 3) or not (type 1). The distinction between type 2 and type 3 has been made based upon the age and rate of progression of symptoms, with type 2 being considered acute and type 3 chronic. However, we have identified and genotyped 9 children with neuronopathic Gaucher disease who appear to have an intermediate phenotype. The children were all diagnosed after age 6 months and lived more than one year, but shared acute and rapidly progressive neurologic deterioration. Most died between age 2 and 4 years. Five of the children had been considered type 3 and four type 2, although there was an overlap in their age at diagnosis and their level of residual enzyme activity. Six of the children received enzyme replacement therapy, which had little effect on the progression of the neurologic manifestations. No genotype was common to all of these patients, although most had at least one allele with mutation L444P. Interestingly, 2 patients shared genotype L444P/G202R, but one was considered a type 2 patient and the second a type 3 patient. Thus, it appears that neuronopathic Gaucher disease may actually be a continuum with this intermediate phenotype contributing to the difficulty in distinguishing between type 2 and type 3 Gaucher disease.

**Evaluation of patients with X-linked adrenoleukodystrophy using next generation internet.** *M.L. Ingeholm<sup>1</sup>, B.A. Levine<sup>1</sup>, F. Eichler<sup>2</sup>, G. Raymond<sup>2</sup>, H.W. Moser<sup>2</sup>, G. Jimenez-Sanchez<sup>3,2</sup>.* 1) ISIS Center, Georgetown University Hospital, Washington, DC; 2) Kennedy Krieger Institute, Baltimore, MD; 3) Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD.

X-linked adrenoleukodystrophy (X-ALD) affects mainly the nervous system white matter, adrenal cortex and testis. It has an estimated frequency of 1:21,000 in the male population. We have developed a multicenter therapeutic trial in which patients from over 15 countries will participate, including most Latin American countries. Magnetic resonance imaging (MRI) permits early detection of nervous system damage and is a sensitive indicator of disease progression. Initial results from an Internet-1 based network between Baltimore and Minneapolis has shown the important benefits of electronically transmitted MRI in the evaluation of patients with X-ALD. Recently, a new generation Internet (NGI) was developed. This version offers significant advantages over the previous generation, including better image quality, since non-compressed images can be transmitted rapidly, and higher transmission speed of complex MRI and MR spectroscopy images, reducing time to seconds rather than hours. This latter feature makes possible a real-time interaction between site of origin and a central reading site, so that image acquisition can be monitored and modified as the image is being produced. A pilot study compared 78 data transfer trials using standard Internet to 83 data transfer trials using NGI. The NGI showed significant advantages in the overall, among which, the mean transmission time of the NGI (242.5 secs) showed to be nearly an order of magnitude faster than the mean transmission time of the standard Internet (2062.5 secs). Our preliminary results suggest that this will be a valuable aid for the evaluation of disease severity and effects of therapeutic interventions in a multicenter therapeutic trial for X-ALD and may have application in other disease states.

**Glu274Lys/Gly309Arg mutation of the tissue-nonspecific alkaline phosphatase gene in neonatal hypophosphatasia associated with convulsions.** *O. Reish*<sup>1,3</sup>, *I. Litmanovitz*<sup>2,3</sup>, *T. Dolfin*<sup>2,3</sup>, *S. Arnon*<sup>2,3</sup>, *R. Regev*<sup>2,3</sup>, *M. Yamazaki*<sup>4</sup>, *K. Ozono*<sup>4</sup>. 1) Genetic Inst, Assaf Harofeh Medical Ctr, Zerifin, Israel; 2) Department of Neonatology, Meir Medical Center, Kfar Saba, Israel; 3) Sackler School of Medicine Tel-Aviv University, Israel; 4) Department of Environmental Medicine, Osaka Medical Center and Research Institute for Maternal and Child Health, Izumi, Osaka, Japan.

We describe a patient diagnosed with lethal perinatal hypophosphatasia with a unique clinical presentation of convulsions that responded to vitamin B6. Genomic DNA sequence analysis of the tissue-nonspecific alkaline phosphatase (TNSALP) gene revealed two missense mutations: a G to A transition resulting in a Glu to Lys at codon 274 (E274K), and a G to C transversion resulting in a Gly to Arg at codon 309 (G309R). The first mutation was maternally transmitted and was previously characterized as a moderate one, while the latter was paternally transmitted and has not been previously reported. Phenotype/genotype correlation suggests that G309R is a deleterious mutation that may lead to seizures and a lethal outcome, as was demonstrated in our patient.

**Prosaposin Deficient Mice: Threshold Rescue and Lack of *In Vivo* GrossMorphologic Effects of The Saposin C "Neurotogenic" Region.** Y. Sun, X. Qi, E. Ponce, B. Quinn, G.A. Grabowski. Dept Human Genetics, Children's Hosp Research Fndn, Cincinnati, OH.

Prosaposin, a multifunctional protein, is a precursor of four glycoprotein activators (saposins) for lysosomal hydrolases. The intact prosaposin has lipid transfer properties *in vitro* as well as neurotrophic effects *ex vivo* and *in vivo* when exogenously supplied. Using a transgene (Tg)/knockout (PS<sup>-/-</sup>) strategy, transgenic mice were created to contain the full-length normal (wt) or a mutated (CBC) mouse prosaposin cDNA driven by the PGK (3-phosphoglycerate kinase) promoter. The mutated prosaposin cDNA has the "neurotrophic" region of saposin C replaced by the homologous sequence from saposin B. *In vitro* and *ex vivo* this "saposin CBC" did not promote neurite outgrowth whereas saposin C did. In PS<sup>-/-</sup>;Tg mice the highest levels of transgene expression were consistently in central nerve system (CNS). No major reversal of pathology was appreciated in the visceral tissues of PS<sup>-/-</sup>;Tg (wt or CBC). Compared to PS<sup>-/-</sup> mice, these mice bearing either transgene had delayed onset of neurologic signs and significant extension of life span (up to 5-fold) that were dependent on the level of Tg expression. Similarly, the rate of progression of neuropathology (neuronal storage of glycosphingolipids, hypomyelination, Purkinje cell loss and lipids accumulation) was less in mice with higher levels of Tg expression. For all PS<sup>-/-</sup>; Tg mice neuropathological abnormalities substantially preceded the onset and progression of neurologic abnormalities. PS<sup>-/-</sup>;Tg-CBC had partial rescue but normal brain and spinal cord neuronal migration. These studies show an *in vivo* threshold effect of prosaposin expression and neuropathologic abnormalities. Also, very low steady state levels of prosaposin expression are needed to significantly improve, but not eliminate, the CNS phenotype. Finally, these studies do not support the presence of a significant gross trophic effect of saposin C on CNS development.

Program Nr: 1731 from the 2001 ASHG Annual Meeting

**Modulator Genes in Lesch Nyhan Disease: Microarray Studies.** *D.W. Smith, L. DeGregorio, T. Friedmann.*  
Pediatrics, UC San Diego, La Jolla, CA.

The mechanisms by which mutations in the hypoxanthine guanine phosphoribosyltransferase (HPRT) gene in humans leads to the devastating neurological phenotype of the Lesch Nyhan syndrome are not well understood. It seems likely that the immediate cause for the neurological dysfunction involves developmental damage to dopaminergic pathways in the brain, but the biochemical and molecular connections between purine pathways affected by HPRT and the dopamine systems are not well characterized. The hypothesis underlying these studies is that the primary defect in HPRT expression results in altered expression of genes that in turn modulate the dopamine pathway. To search for genes and families of genes whose expression is altered in HPRT deficiency, we are using microarray methods to analyze gene expression in the affected brain regions in wild type and HPRT-deficient mice over the post-natal period during which the dopamine defect is established. We shall describe technical aspects of the microarray approach to this disorder and present a description of some candidate modulator genes. These studies were supported by grant HD39250 from the National Institute for Child Health and Human Development and a grant from the Lesch Nyhan Syndrome Children's Research Foundation.

**Cloning and partial characterization of human Agmatinase - concrete evidence for an alternate pathway for polyamine biosynthesis in mammals.** *R.K. Iyer<sup>1,2</sup>, J.H Kim<sup>1</sup>, R.M. Tsoa<sup>3</sup>, W.W. Grody<sup>1,2,4</sup>, S.D. Cederbaum<sup>2,3,4</sup>.* 1) Department of Pathology & Laboratory Medicine, University of California, School of Medicine, Los Angeles, CA; 2) The Mental Retardation Research Center, University of California, School of Medicine, Los Angeles, CA; 3) Department of Psychiatry, University of California, School of Medicine, Los Angeles, CA; 4) Department of Pediatrics, University of California, School of Medicine, Los Angeles, CA.

Polyamines (Spermine and Spermidine) are crucial participants in DNA replication, transcription and protein synthesis, among other functions, and are absolutely essential for cell growth and differentiation of normal cells as well as the proliferation of cancer cells. In mammalian cells Arginine is converted to putrescine, the diamine precursor of polyamines, by the coordinated action of Arginase and ODC; whereas, in *Escherichia coli* and plants, putrescine is synthesized by the enzymes Arginine decarboxylase (ADC) and Agmatinase. Until recently, neither agmatine nor ADC, the enzyme that synthesizes it or Agmatinase the enzyme that is responsible for its metabolism and the synthesis of putrescine were known to exist in man or other mammals. We describe here the cloning and partial characterization of the human Agmatinase gene and the tissue distribution of its transcription product. Human Agmatinase contains 351 amino acid residues and has a calculated molecular weight of 37,688 kD. It has 56% homology to *E. coli* Agmatinase and 42% to human Arginases I and II, sharing highly conserved substrate binding domains. The identification of mammalian Agmatinase supports the possibility of an alternative pathway of arginine metabolism whose products such as agmatine and polyamines can exert powerful and pleiotropic effects in cell growth and function. Possession of this alternate route may help to explain continued polyamine synthesis, and growth in some cancers in which the classic pathway is not present, or is blocked by specific inhibitors.

**Transcriptional regulation mechanisms of holocarboxylase synthetase (HLCS) and biotin dependent carboxylases in multiple carboxylase deficiency (MCD).** *S. Solorzano Vargas, D. Pacheco Alvarez, A. Leon-Del-Rio.* Department of Molecular Biology and Biotechnology, Universidad Nacional Autonoma de Mexico, Mexico, DF, Mexico.

Holocarboxylase Synthetase (HLCS) catalyzes the biotinylation and activation of three mitochondrial and two cytoplasmic biotin dependent carboxylases in humans. Inherited deficiency of HLCS activity causes a disorder known as multiple carboxylase deficiency (MCD), characterized by a blockage of carbohydrates, lipids and amino acid metabolism. MCD is potentially lethal if not treated promptly with pharmacological concentrations of biotin. It has been shown recently that biotin may be involved in other cellular processes in the cells. In this work we show that biotin activates the transcription of Holocarboxylase Synthetase, Acetyl Coa Carboxylase I, and Propionyl CoA Carboxylase. We present here that transcription regulation by biotin is mediated by activation of the soluble form of guanylate cyclase (sGC). Activation of sGC requires a functional HLCS since cells from patients with MCD do not show activation of these genes in response to biotin. These results suggest that the active form of biotin responsible for transcriptional activation is the HLCS biotinylation derivative 5-AMP-biotinyl. Our observations may help to explain the phenotype of patients with MCD. Some of the clinical and biochemical manifestations of the disease cannot be attributed to the individual carboxylase deficiencies and may be the result of a transcription regulation impairment on these patients.

**Photosensitivity in patients with the Smith-Lemli-Opitz Syndrome (SLOS).** *E.R. Elias<sup>1</sup>, I.E. Kochevar<sup>2</sup>, C.R. Taylor<sup>2</sup>.* 1) Special Care Clinic, Children's Hosp, Box 365, Denver, CO; 2) Wellman Laboratories of Photomedicine, Mass Gen'l Hosp, Boston, MA.

Patients with SLOS have an inborn error in the cholesterol metabolic pathway, resulting in severe cholesterol deficiency, and accumulation of the cholesterol precursor, 7-dehydrocholesterol (7-DHC). About one third of SLOS patients manifest severe photosensitivity. A study was designed to evaluate the mechanism of this photosensitivity, by exposing SLOS patients to UV light, and by studying fibroblasts exposed to UV light in the laboratory.

Eight children (ages 2-17 years) with biochemically confirmed SLOS, and pretreatment cholesterol levels ranging from 20-124 mg/dl, were treated with timed exposures to both UVA and UVB light. The reaction was graded by a trained dermatologist to establish the minimum erythema dose (MED), or lowest amount of light exposure necessary to produce an erythematous response. Although only three of the eight patients had shown clinical photosensitivity, all eight had an exaggerated response to timed UVA exposure. The response to UVB was normal in all patients. Treatment with cholesterol reduced clinical photosensitivity, but did not normalize the response to UVA exposure.

Normal fibroblasts were incubated in delipidized medium with AY9944, an inhibitor of the reductase enzyme that is defective in SLOS. The cells were then treated with either 7-DHC or a solvent control, and exposed to varying doses of UVA (2.5-30 J/cm<sup>2</sup>). Cytotoxicity was assessed, and PGE2 release (a mediator of UV-induced inflammation) was measured. Cytotoxicity and PEG2 release were greater in the 7-DHC treated cells. This response was inhibited by the antioxidant, N-acetylcysteine.

These results suggest that the photosensitivity seen in patients with SLOS is caused by UVA light, and may be at least partially due to altered UVA-induced oxidative processes involving 7-DHC in cell membranes. Treatment with cholesterol can reduce clinical photosensitivity in SLOS patients.

**Evidence that *rab27a* mutations are associated with neurological involvement, not simply the hemophagocytic syndrome, in patients with Griscelli syndrome.** *D.L. Fitzpatrick*<sup>1</sup>, *M. Huizing*<sup>1</sup>, *Y. Anikster*<sup>1</sup>, *H. Hurvitz*<sup>2</sup>, *A. Klar*<sup>2</sup>, *E. Gross-Kieselstein*<sup>2</sup>, *W.A. Gahl*<sup>1</sup>. 1) HDB, NICHD, NIH, Bethesda, MD; 2) Ped, Bikur Cholim, Jerusalem.

Griscelli syndrome (GS) is a rare autosomal recessive disorder characterized by pigmentary dilution of the skin and silvery gray hair due to pigment clumping. GS patients have been separated into two subgroups on the basis of clinical and molecular findings. GS1 is defined by severe neurologic impairment and mutations in the *myoVa* gene, coding for myosin Va, a protein functioning with actin in the intracellular movement of vesicles. GS2 is characterized by immune abnormalities and the hemophagocytic syndrome which leads to death in the absence of bone marrow transplantation. GS2 patients have mutations the *rab27a* gene, which codes for a small GTPase involved in vesicle trafficking. Both *myoVa* (mutant mouse: *dilute*) and *rab27a* (mutant mouse: *ashen*) are on chromosome 15q21, < 1.6cM apart. In vitro, *rab27a*-deficient T cells exhibit reduced cytotoxicity and impaired cytolytic granule exocytosis, processes required for immune homeostasis. In vivo, all GS patients with mutations in *rab27a* have developed the hemophagocytic syndrome. However, no GS patient with *rab27a* mutations has manifested neurological features. Our patient, a member of a highly consanguineous Moslem-Arab family with 3 other affected individuals, had silver-gray hair but no tendency to infections. He did suffer from progressive neurological impairment which proved fatal at 10 years of age. Therefore, we screened our patient for mutations in *myoVa*. No mutations were found on cDNA sequencing and a northern blot demonstrated the expected length and signal size for *myoVa*. We next examined the *rab27a* gene. A northern blot of the patient's mRNA, using *rab27a* as a probe, gave no signal. Repeated attempts to amplify the 6 exons of *rab27a* on genomic DNA failed, while two flanking genes (*Loc51187* and *Pigb*) were well-amplified in our patient. These data point to a genomic deletion in the *rab27a* gene of our patient. We propose that a large deletion in *rab27a* may cause neurological involvement in our GS patient, and perhaps in others as well.

**SEQUENCE ANALYSIS OF THE GLUCOSE 6-PHOSPHATE TRANSLOCASE GENE IN PATIENTS WITH GLYCOGENOSIS TYPE IB.** *T. Podskarbi*<sup>1</sup>, *Y.S. Shin*<sup>2</sup>, *A.R. Janecke*<sup>3</sup>. 1) Molec Gen & Metabolism Lab, Munich, Germany; 2) University Childrens Hospital, Munich, Germany; 3) Institute of Human Genetics, Innsbruck, Austria.

Glycogen storage disease type Ib (GSD Ib), characterized by hypoglycemia, hepatomegaly, neutropenia, generalized convulsion and neutrophil dysfunction among others is caused by deficiency of glucose 6-phosphate translocase (G6PT) which catalyses the transport of G6P from the cytoplasm into the endoplasmic reticulum. We report here sequence analysis of the G6PT gene in 15 Caucasian patients whose diagnosis of GSD Ib was secured biochemically either using liver biopsy or analysing glucose transport in PMN cells. All these patients revealed biallelic mutations in the G6PT gene which include five novel mutations. Most of the mutations were frameshift yielding aberrant proteins and others revealed two stopcodon mutations, one large intragenic deletion and missense mutations. The common mutations in exon 8, 1211-2delCT and G339C comprised about 53% of disease alleles. Clinical symptoms of all patients in this study are compatible to those of GSD Ib including neutropenia. No correlation between the genotype and the phenotype could be observed. These data indicate that the molecular analysis of the G6PT gene is an effective mean for the non-invasive and efficient diagnosis GSD Ib.

Program Nr: 1737 from the 2001 ASHG Annual Meeting

**Mutation analysis for mucopolysaccharidosis disorders.** *L. Peterson, E.L. Aronovich, D. Pan, C.B. Whitley.* Gene Therapy Center, University of Minnesota, Minneapolis, MN.

Molecular genetic diagnosis of mucopolysaccharidosis (MPS) disorders is important for a number of clinical applications. Such discrimination of pseudodeficiency states, genotype-phenotype correlation (e.g., early differentiation of relatively attenuated forms of a condition, from more "severe" or classic outcomes). Methods refined over the past decade have allowed us to accomplish complete sequencing of the coding region of several genes, thus establishing a database of common and rare mutations, as well as polymorphisms. Such relatively complete sequence analysis is also necessary to accomplish the experimental procedure known as preimplantation genetic diagnosis (PGD). For PGD, the causative mutations are identified in the proband, and also in both parents. With this information, PGD providers have the information needed to design mutation-specific PCR assays applicable to material derived from the fertilized ovum thus allowing implantation of an unaffected embryo. Although this laboratory has assisted in mutation analysis for 3 families who have contemplated this procedure, we are unaware a pregnancy "at risk" for MPS that has been conceived by this means.

**Succinyl CoA-3-keto Transferase (SCOT) deficiency in a Panamenian patient.** *C.S. Canton<sup>1</sup>, R. Garcia<sup>2</sup>, M. Pasquali<sup>3</sup>, R.H. Sing<sup>3</sup>, K.M. Gibson<sup>4</sup>, N. Longo<sup>3</sup>.* 1) Dept Genetics, Complejo Hospitalario Metropolitano de la Caja de Seguro Social Panama, M.D; 2) Dept Pediatrics, CHMCSS Panama, M.D; 3) Dept Genetics, Emory University, M.D; 4) Bioch Genet Lab, Oregon Health Sciences, University, PhD, FACMG.

Succinyl CoA acetoacetate Transferase is a mitochondrial enzyme which forwards the transfer of Coenzyme A from Succinyl CoA to acetoacetate. Subsequently, mitochondrial acetoacetyl-CoA thiolase converts acetoacetyl to acetylCoA, which can be oxidized in the Krebs cycle. This deficiency is a rare autosomal recessive disorder. We present a female patient with young consanguineous parents. She initially presented at 8 months of age with tachypnea, vomiting, and lethargy. Laboratory testing indicated severe metabolic acidosis with low CO<sub>2</sub> (<5 mEq/L), pH of 6.98, hypokalemia (1.4-2 mEq/L), with elevated anion gap (22-27 mEq/L). Serum ammonia and liver function tests were normal. Urine analysis indicated a pH of 8, negative glucose, and very abundant ketones. There was no evidence of hypoglycemia. Dialysis normalized the acidosis and the anion gap. However, acidosis reappeared when dialysis was discontinued. Biochemical genetic testing indicated abnormal urine organic acids with excess ketones without abnormal metabolites or excess lactic acid on two separate occasions while the child was stable (not acidotic). Ketonuria increased during the acute attack, and very mild lactic aciduria became evident. Plasma and urine amino acids were normal, excluding generalized Fanconi syndrome. A skin biopsy was obtained and the results of enzyme assay on fibroblasts of the patient were absent succinyl CoA: 3-oxoacid CoA transferase (SCOT) activity (normal 4.1-8.1 nmol/min/mg protein). These results confirmed a diagnosis of SCOT deficiency. The treatment consists in a diet poor in fat (25 percent of total calories) and enriched in protein and carbohydrates. The effect of this diet on the anion gap was substantial. At the present she has 2 years and 11 months, psychomotor and physical development are in normal limits. The report is important because this inborn error of the metabolism is very rare (low frequency) and the good neurologic state of the patient is the result of early diagnosis and treatment.

**Gaucher disease and parkinsonism: clinical, molecular and neuropathological findings.** *E. Sidransky*<sup>1</sup>, *R. Schiffmann*<sup>2</sup>, *N. Tayebi*<sup>1</sup>, *D. Krasnewich*<sup>1</sup>, *B.K. Stubblefield*<sup>1</sup>, *A.O. Vortmeyer*<sup>3</sup>, *K. Wong*<sup>4</sup>. 1) NSB/NIMH/NIH, Bethesda, MD; 2) DMMB/NINDS/NIH, Bethesda, MD; 3) SNB/NINDS/NIH, Bethesda, MD; 4) AFIP, Washington, DC.

Among the many phenotypes associated with Gaucher disease, the inherited deficiency of glucocerebrosidase (GC), are reports of patients with parkinsonian symptoms. These patients have an early onset, treatment-refractory form of parkinsonism and often have mild Gaucher manifestations. Sequencing of the GC gene in 12 of such patients revealed no shared genotype and no mutations in the gene for parkin were identified. One patient, studied in great detail, was first diagnosed with Gaucher disease at age 19 because of mild anemia, and was splenectomized at age 34. Her genotype was D409H/L444P, but in addition she carried a duplication resulting from a recombination between the gene and pseudogene for metaxin. She developed a tremor at age 42, followed by rapid deterioration of her gait, and an unsuccessful pallidotomy was performed at age 47. She had impaired horizontal eye movements, tremors, and developed myoclonic jerks, but few systemic manifestations of Gaucher disease. Her neurological symptoms and cognition deteriorated dramatically despite enzyme replacement therapy, and she died at age 52 from aspiration pneumonia. At autopsy, the neuropathological findings were dramatic. She had marked neurodegeneration with demyelination and loss of neurons involving the hippocampus, substantia nigra, dentate and cerebellar Purkinje cell layers. Moreover, there were multiple classic brain-stem-type Lewy bodies, inclusions typically seen in Parkinson disease, found in the hippocampus, pyramidal neurons, substantia nigra and other midbrain structures including the red and oculomotor nuclei which were immunoreactive with anti-ubiquitin and anti-synuclein. However, cortical-type Lewy bodies were not identified in the cerebral cortex. Clusters of Gaucher cells were seen in the leptomeninges although intraparenchymal Gaucher cells were absent. The specific pattern of hippocampal and midbrain involvement observed in this case may provide insight into the pathogenesis of this unique Gaucher phenotype.

**Towards cloning the copper toxicosis gene in Bedlington terriers.** *B. van de Sluis*<sup>1</sup>, *J. Rothuizen*<sup>2</sup>, *P.L. Pearson*<sup>1</sup>, *B.A. van Oost*<sup>2</sup>, *C. Wijmenga*<sup>1</sup>. 1) Department of Medical Genetics, UMC, Utrecht, Utrecht, The Netherlands; 2) Department of Clinical Sciences of Companion Animals, Faculty of Veterinary Medicine, Utrecht University, the Netherlands.

Copper is an essential trace element for the survival of all organisms, although it is highly toxic above a certain threshold. A well-regulated copper metabolism is required to ensure a cellular process for copper homeostasis. Only two genetic defects of copper metabolism in man, Menkes and Wilsons diseases have been described. A copper overload disorder, copper toxicosis (CT), is also seen in the Bedlington terrier. CT in Bedlington terriers is an autosomal recessive disorder characterized by an accumulation of copper in the liver leading to chronic hepatitis and, ultimately, cirrhosis. Recently, we assigned the CT locus in Bedlington terriers to the canine chromosome region CFA 10q26, which is homologous to HSA 2p13-21. A radiation hybrid map of the CFA 10q21-26 region was constructed containing 13 DNA markers, 8 genes and 3 ESTs. Moreover, a BAC contig covering the CT region has been finished to facilitate positional cloning of the CT gene. Using homozygosity mapping, the CT locus has been confined to a region less than 5 cR3000 estimated to be 1 Mb, which is entirely contained in a BAC contig. Currently we are in the process of shotgun sequencing the CT-candidate region, in order to obtain a transcript and comparative map of this region. In addition, the draft sequence data of HSA2p13-21 will complement the search for coding sequences. So far, 7 genes from HSA2p13-21 could be mapped back to the CT BAC contig. Sample sequencing revealed 5 additional genes. These genes are currently screened for mutations in affected Bedlington terriers. Isolating a gene for CT will be an important addition to the limited knowledge of the genetic regulation of copper metabolism in mammals.

**A novel, autosomal-recessive form of cardioskeletal myopathy and neutropenia with iron deficiency and Parkinsonism.** *D.G. Brooks<sup>1</sup>, G. Lech<sup>2</sup>, K. VandenBorne<sup>3</sup>, R.B. Wilson<sup>4</sup>, D. Stambolian<sup>5</sup>, B. Chance<sup>2</sup>, R.I. Kelley<sup>6</sup>.* 1) Medical Genetics, Univ. of Pennsylvania, Philadelphia, PA; 2) Dept of Biochemistry and Biophysics; 3) Dept of Physiology; 4) Dept of Pathology; 5) Depts of Genetics and Ophthalmology,; 6) Kennedy-Krieger Institute, Johns Hopkins University, Baltimore, MD.

X-linked cardioskeletal myopathy with neutropenia, and 3-methylglutaconic (3MGC) aciduria (MIM302060), or Barth syndrome (BTHS), is caused by mutations in the Xq28-linked gene, G4.5. G4.5 encodes a fatty acyl transferase-like protein with a probable role in synthesis of cardiolipin, a mitochondrial phospholipid (PL) that is very low in BTHS patients. We report here a non-X-linked form of Barth syndrome with CNS abnormalities and abnormal PL metabolism. Two males and a female born to consanguineous parents were studied. The boys presented with myopathy and neurological regression at ages 5 and 2 years and had increased urinary levels of 3MGC and citric acid cycle intermediates, neutropenia, anemia, and a Parkinsonian tremor. After a 6 month old sister presented with severe dilated cardiomyopathy both older brothers were found to have mild dilated cardiomyopathy and therefore all features of BTHS. Linkage to the G4.5 locus was excluded defining a BTHS variant. Investigating the iron-resistant microcytic anemia revealed increased levels of soluble and lymphoblast transferrin receptor, suggesting intrinsic cellular iron deficiency. Because of evident mitochondrial disease, the children were treated with coenzyme Q and vitamin E, which stopped neurological regression. Later addition of lipoic acid caused improved growth. All three supplements are known to protect cardiolipin from free radical damage. Two Xq28-linked BTHS patients had normal 31P MR muscle spectroscopy whereas two variant-BTHS patients had absent phosphodiester peak which is composed largely of the PL metabolites, glycerophosphorylethanolamine and glycerophosphorylcholine. Infrared spectroscopy showed prolonged recovery time from exercise-induced desaturation in one boy. We speculate that this apparently autosomal recessive BTHS variant is caused by disordered PL metabolism.

**DNA Analysis of Puerto Rican Patients with Albinism Demonstrates that the HPS1 16 bp Duplication Does Not Cause the Majority of Cases.** *A.E. Maldonado<sup>1</sup>, P.J. Santiago-Borrero<sup>2</sup>, J.Y. Rentá<sup>1</sup>, Y. Rodríguez<sup>1,2</sup>, L. Del Fierro<sup>1</sup>, D. Muñoz-Acaba<sup>1</sup>, I. Ortíz<sup>2</sup>, E. Rivera-Caragol<sup>2</sup>, M. Castro<sup>1</sup>, J. Flores<sup>1</sup>, C.L. Cadilla<sup>1</sup>.* 1) Dept. of Biochemistry, UPR School of Medicine, P.O. Box 365067, San Juan, PR 00936-5067; 2) Dept. of Pediatrics, UPR School of Medicine, San Juan, PR.

Albinism is commonly found in the island of Puerto Rico (PR). Previous studies have concluded that the most common form of albinism in PR is the Hermansky Pudlak Syndrome (HPS). Most PR HPS patients examined have a frameshift mutation consisting of a 16 bp duplication in exon 15 of the HPS1 gene, discovered by Spritz and collaborators in 1996. Locus heterogeneity for HPS in PR has been reported in a small number of cases. We have screened 117 Puerto Rican patients with albinism for the HPS1 16 bp duplication and found that only 47% of the patients were homozygous for the duplication, 47% were negative, and 6% were heterozygous for the HPS1 PR mutation. The carrier frequency of HPS in Northwest Puerto Rico was estimated in 1990 to be 1:25, and the prevalence of HPS 1:1800. These estimates were made when no molecular diagnostic test was available. We have preliminary evidence from DNA analysis of PR newborns that the HPS1 16 bp duplication is not as frequently found in the general and Northwest PR populations as previously thought. Out of 326 PR newborns, only five were carriers of the duplication mutation, and only 2/147 came from the Northwest PR region. We have examined HPS1 duplication-negative albino patients for tyrosinase mutations by SSCP and DNA sequencing. We found 5 out of 55 duplication-negative patients homozygous for the G47D mutation in exon 1 of the TYR gene. Some of the duplication-negative patients have evidence of a bleeding diathesis by clinical history, and the results of hematological tests such as platelet aggregation studies, bleeding time and coagulation factor levels. We conclude that the PR HPS1 16 bp duplication accounts for less than half of the albinism cases in PR, and the G47D tyrosinase mutation only accounts for 9% of the albinism cases among HPS1 duplication-negative patients. This study was supported in part by NIH-NIGMS grants S06-GM08224, R25-GM61838 and RCMI grant NCRR G12-RR08051.

**Recombinant adenoviruses mediate doxycycline regulable expression of glycerol kinase in culture.** *K. Nagano, J.J. Chang, Y.-H. Zhang, K.M. Dipple, E.R.B. McCabe.* Department of Pediatrics, UCLA School of Medicine, and Mattel Children's Hospital at UCLA, Los Angeles, CA.

Isolated X-linked glycerol kinase deficiency (GKD) may be either symptomatic or asymptomatic, and we have previously shown that GK genotype does not predict phenotype. A mouse model of GKD will permit improved understanding of pathogenesis and the influence of modifier genes on phenotype. The early death of affected murine males has interfered with characterization of pathogenesis. The purpose of this work was to develop doxycycline regulable adenoviral constructs with the eventual goal of using wild type (wt) and mutant GK expression to rescue and to investigate mice with GKD. We constructed E1/E3 deleted adenoviral vectors (Adeno-X: CLONTECH, Palo Alto, CA) with wt and mutant GKs under control of a tetracycline (tet) response element (TRE) for use in concert with the tet transactivator (tTA) (Adeno-X Tet-Off: CLONTECH). Mutations from symptomatic patients including R413X, R405Q, and D440V, and from asymptomatic patients including A305V and Q438R. We infected HeLa, HepG2, Cos7 and A549 cells, measured GK activity by a radiochemical assay of lysed cells two days after infection, and observed expression in all four cell lines. In HeLa cells, expression required the presence of both Adeno-X Tet-Off and Adeno-X TRE-GK, and was reduced in a dose-dependent manner to negligible GK activity (<1% with MOI of 10) by culture with 10ng/ml doxycycline. Similar to observations in Cos7 cells after transfection with mutant plasmid constructs, the symptomatic R405Q mutation had the highest residual activity when expressed in HeLa cells, again showing an absence of correlation between genotype and phenotype. We conclude that wt and mutant adenoviral GK constructs are expressed in cell culture in a Tet-Off system, and are downregulated effectively by doxycycline. We speculate that in vivo investigations with these constructs in a GKD mouse model will permit rescue and regulable GK expression to investigate pathogenesis and influences on phenotype.

**L-cells lack the ability to convert desmosterol to cholesterol due to a defective *dhsr24* gene.** *P.J. Wightman*<sup>1</sup>, *N. McGill*<sup>1</sup>, *H.R. Waterham*<sup>2</sup>, *D.R. Fitzpatrick*<sup>1</sup>. 1) MRC Human Genetics Unit, Edinburgh, Midlothian, United Kingdom; 2) Departments of Paediatrics and Clinical Chemistry, Division Emma Children's Hospital, Academic Medical Center, University of Amsterdam, The Netherlands.

L-cells are a mouse fibroblasts cell line that can be transfected easily with exogenous DNA and are, thus, widely used for gene expression studies. L-cells exhibit disordered cholesterol biosynthesis which results in the accumulation of desmosterol as the major sterol when grown in the absence of cholesterol. In the 1970's the desmosterol-to-cholesterol converting enzyme (DCE, OMIM 125650) was mapped to human chromosome 20 by complementation using L-cell somatic cell hybrids. Recently human DCE has been shown to be a 3 $\beta$ -hydroxysterol D<sup>24</sup>-reductase now named *DHSR24* and mutations in this gene have been found in two patients with desmosterolosis, an autosomal recessive inherited disorder of cholesterol biosynthesis that results in severe congenital and skeletal anomalies (Waterham et.al. submitted). We have subsequently identified the mouse *dhsr24* gene by homology to the human cDNA sequence. We have isolated mouse genomic BAC clones which contain the entire coding region and have shown the genomic structure to consist of 9 exons and 8 introns. Amplification of each *dhsr24* exon suggested that the first exon was deleted in L-cells. We have stably transformed L-cells using mammalian expression constructs containing the mouse and human *DHSR24* cDNAs, transfection of the expression vector alone and a mutated form of the cDNA were used as negative control. Cells were then grown in media containing delipidated serum. Sterol extraction was performed and the extracts analysed by HPLC. This revealed that the wild type mouse and human *DHSR24* cDNAs restored desmosterol to cholesterol conversion, whereas no restoration was seen with the negative controls. This confirms that the mouse *dhsr24* gene defect is responsible for the desmosterol accumulation in L-cells and are thus a good model for studying the cellular defects in desmosterolosis.

**Rapid Mutation Scanning of the Glucocerebrosidase Gene using Denaturing High Performance Liquid**

**Chromatography.** *P.E. McAndrew<sup>1</sup>, P. Bauer<sup>2</sup>, M. Noyer-Weidner<sup>3</sup>, A. Rolfs<sup>2</sup>, M.A. Marino<sup>1</sup>.* 1) Applied Genomics & Molecular Genetics, Transgenomic Inc, Gaithersburg, MD; 2) Department of Neurology, University of Rostock, Rostock, Germany; 3) Transgenomic Ltd., Berlin, Germany.

Gaucher disease is the most common lysosomal storage disease. The basic defect is a deficiency of glucocerebrosidase, an enzyme required for the lysosomal degradation of glycolipids. Type 1 Gaucher is the most common of the 3 clinical subtypes and is associated with hepatosplenomegaly, anemia, nosebleeds, and bones which break easily. The disorder occurs in all ethnic groups, but has the highest prevalence in the Ashkenazi Jewish population. Type 2 is much less prevalent but is associated with severe neurological symptoms and is often fatal by the age of 18 months. Type 3 Gaucher is similar to Type 2, but the disease progression is less rapid and has a later age of onset. A genetic test to detect five common mutations has ~97% sensitivity in the Ashkenazi Jewish population, and ~70% sensitivity in the general population. An efficient, high-throughput method to screen all Glucocerebrosidase gene (GCB) exons would increase the sensitivity of genetic testing and provide further information about the genotype/phenotype relationships for this disorder. In addition, Type I Gaucher patients with less common mutations who would benefit from the highly effective enzyme replacement therapy can be identified.

We developed denaturing high-performance liquid chromatography (dHPLC) methods to screen all GCB exons using the WAVE® Nucleic Acid Fragment Analysis System. DHPLC uses an ion-pair reversed-phase column to separate heteroduplex molecules from homoduplex fragments in the presence of any base changes, and has become a method of choice for mutation screening. We analyzed a panel of Gaucher patients with common mutations and demonstrate that dHPLC is an efficient method to rapidly screen the GCB gene for known mutations, and we are currently extending our analysis to screen for less common gene alterations which cause Gaucher disease.

**Functional characterization of MCC mutations associated to methylcrotonylglycinuria.** L.R. Desviat<sup>1</sup>, C. Perez-Cerda<sup>1</sup>, J. Esparza-Gordillo<sup>2</sup>, B. Perez<sup>1</sup>, P. Rodriguez-Pombo<sup>1</sup>, J.M. Rodriguez<sup>2</sup>, S. Rodriguez de Cordoba<sup>2</sup>, M.A. Peñalva<sup>2</sup>, M. Ugarte<sup>1</sup>. 1) Centro Biología Molecular, Univ Autónoma, Madrid, Spain; 2) Centro de Investigaciones Biológicas, CSIC, Madrid, Spain.

Methylcrotonylglycinuria (MCG; OMIM 210200) is an autosomal recessive inherited human disorder caused by the deficiency of 3-methylcrotonyl-CoA carboxylase (MCC), involved in leucine catabolism. MCC is a heteromeric enzyme composed of a and b subunits, encoded by the genes *MCCA* and *MCCB*, respectively, which we recently characterized at the cDNA and genomic level. A total of two *MCCA* mutations and 4 *MCCB* mutations were identified in seven patients. Two novel mutations (exon 3 skipping and Q372P in the *MCCA* gene) have now been identified in two additional MCG patients. We have expressed the missense changes in the *MCCA* and *MCCB* genes showing they are clearly pathogenic as they cause reduction or loss of enzyme function. MCC activity was found to be restored to normal levels only when both wild-type *MCCA* and *MCCB* cDNAs are cotransfected in the mutant cell lines, suggesting that coordinated overexpression of both cDNAs is necessary to fully correct the enzyme deficiency. In the *MCCA* gene, the M325R mutation showed low activity (7% of controls) while the residual activity of R385S was undetectable. Both missense mutations C167R and A218T in the *MCCB* gene result in very low levels of residual activity (<2%). No clear genotype-phenotype correlation is evident in this disease newly characterized at the molecular level.

**Effect of *PCCB* gene mutations on the heteromeric and homomeric assembly of propionyl-CoA carboxylase.** S. Muro, B. Perez, L.R. Desviat, R. Rodriguez-Pombo, C. Perez-Cerda, M. Ugarte. Centro de Biología Molecular, Universidad Autónoma de Madrid, Madrid, Spain.

Propionic Acidemia is an inherited metabolic disorder caused by deficiency of propionyl-CoA carboxylase, composed of a-PCC and b-PCC subunits (encoded by genes *PCCA* and *PCCB*) that have been associated to a number of mutations responsible for this disease. After the analysis of the patients' genotypes, the functional characterization of the mutations is an important research area, in order to improve the knowledge of the genotype-phenotype correlations. In the present study 12 *PCCB* gene mutations were analyzed for their involvement in a-b heteromeric and b-b homomeric assembly. For this purpose we performed two-hybrid assay in mammalian COS-7 cells using different cultivation temperatures to distinguish between mutations directly involved in interaction and those probably affecting polypeptide folding and consequently the correct assembly. Mutations R512C, L519P, W531X and N536D, located at the carboxyl-terminal end of the *PCCB* gene, were found to inhibit a-b heteromeric and/or the b-b homomeric interaction independently of the cultivation temperature, reflecting their primary effect on the assembly. Two changes A497V and R165Q did not affect either heteromeric or homomeric assembly. The remaining mutations (R67S, S106R, G131D, R165W, E168K and G198D), located in the amino-terminal region of the b-polypeptide, resulted in normal interaction levels only when expressed at the lower temperature, suggesting that these changes could be considered as folding defects. From these results and the clinical manifestations associated to patients bearing the mutations described above, several genotype-phenotype correlations may be established.

**A Deletion-Insertion Mutation in the Phosphomannomutase 2 Gene in 2 African American Siblings with Congenital Disorders of Glycosylation Type-Ia(CDG-Ia).** *E. Orvisky<sup>1</sup>, N. Tayebi<sup>1</sup>, D. Andrews<sup>1</sup>, J. Park<sup>1</sup>, J. McReynolds<sup>2</sup>, E. Sidransky<sup>1</sup>, D. Krasnewich<sup>3</sup>.* 1) NIH/NIMH, Bethesda, MD; 2) Nemours Children's Clinic, Orlando, FL; 3) NIH/NHGRI, Bethesda, MD.

Congenital Disorders of Glycosylation (CDG) are a group of metabolic disorders with multisystemic involvement characterized by abnormalities in the N-glycosylation of proteins. The most common form, CDG-Ia, resulting from mutations in the gene encoding the enzyme phosphomannomutase2 (PMM2), manifests with severe abnormalities in psychomotor development and multisystemic involvement. While these disorders is panethnic, we present the first cases of CDG-Ia identified in an African American family with two affected sisters. The proband had failure to thrive in infancy, hypotonia, ataxia, cerebellar hypoplasia, and developmental delay. On examination, she also exhibited strabismus, inverted nipples and atypical perineal fat distribution, all features characteristic of CDG-Ia. Direct sequencing demonstrated that the patient had a unique genotype, T237M/c.565-571delAGAGT ins GTGGATTTC. The novel deletion-insertion mutation, which was confirmed by subcloning, introduces a stop codon 11 amino acids downstream from the site of the deletion. The presence of this deletion-insertion mutation at a cDNA position 565 suggests that this site in the PMM2 gene may be a hotspot for recombination.

**Phenylketonuria:genotype-phenotype correlations based on expressed activity of 18 mutant proteins.** *B. Perez, A. Pey, A. Gamez, L.R. Desviat, M. Ugarte.* Centro Biologia Molecular, Universidad Autonoma, Madrid Spain.

Phenylketonuria (PKU) results from the deficiency of phenylalanine hydroxylase (PAH), that catalyses the hydroxylation of phenylalanine to tyrosine. After the identification of more than 400 different PAH gene mutations worldwide, the present research aim is to elucidate their pathologic role in order to gain further insight in the genotype-phenotype correlations. When analysed in the context of the PAH three-dimensional structure, only a minority of the mutations affect catalytic residues, and consistent with these observations, recent data point to defective folding and subsequent aggregation/degradation as predominant disease mechanism for several missense mutations. In this work we use a combined approach of expression in a prokaryotic system with co-expression of chaperonins, in eukaryotic cells at different temperatures and pulse-chase experiments after in vitro synthesis to characterize and confirm structural consequences for 18 PKU mutations localized in the regulatory and catalytic domains of the protein. Four mutations were found to abolish the specific activity in all conditions, the remaining are clear folding mutations causing altered oligomerization, reduced stability, and accelerated degradation although, in addition, some of them affect residues probably involved in regulation. The results derived provide an experimental framework to define the mutation severity relating genotype to phenotype, and allowing to explain the observed inconsistencies for some mutations.

**Characterization of the Human Glycerol Kinase Promoter.** *S.V. Stepanian, K.M. Dipple, E.R.B. McCabe.* Dept Pediatrics, UCLA School of Medicine, Los Angeles, CA.

Isolated glycerol kinase deficiency (GKD) is an X-linked inborn error of metabolism characterized by hyperglycerolemia and glyceroluria which is either symptomatic (episodic metabolic and CNS decompensation) or asymptomatic (pseudo-hypertriglyceridemia). We have been unable to correlate genotype with phenotype in isolated GKD and hypothesize that phenotypic variability might be due to factors influencing GK expression. To test this hypothesis, we characterized the GK promoter, identified potential transcription factors, and analyzed promoter regions for their influences on expression. Computer analysis of the promoter region identified potential HNF-4 consensus binding sites. HNF-4 is involved in the expression of liver-specific genes as well as genes involved in carbohydrate and fat metabolism. Plasmid constructs containing 100, 250, 500, 750, 1500, and 2000 bp (relative to the translation start site) of the GK 5' UTR controlling the expression of a luciferase reporter gene (e.g., GK100LUC) were transiently transfected into human hepatocellular carcinoma (HepG2) cells. Luciferase activity was determined and normalized to beta-galactosidase activity. Three independent experiments showed that GK100LUC was sufficient to activate transcription. GK250LUC and GK500LUC consistently had higher activity than GK100LUC and GK250LUC, respectively, suggesting that transcriptional activators bind between -101 to -250 and -251 to -500 bp. Interestingly, there is an HNF-4 consensus binding site between -433 and -451 bp. GK750LUC, GK1500LUC, and GK2000LUC had less activity than the smaller constructs suggesting that transcriptional repressors may bind between -501 and -2000 bp. These results suggest that the binding of transcription factors, such as HNF-4, may be important for GK expression. Identification of these transcription factors will permit us to examine possible interindividual variations in their response elements in the GK 5' UTR or in their levels of expression. These investigations will allow us to examine the hypothesis that influences on transcriptional activity may mediate phenotypic variability in isolated GKD.

**Clinical features, response to treatment, prognosis, and molecular characterization in Korean patients with inherited urea cycle defects.** *H.W. Yoo, G.W. Kim, E.J. Seo.* Medical Genetics Clinic & Laboratory, Asan Medical Center, Ulsan University College of Medicine, Seoul, Korea.

The urea cycle, consisting of a series of six enzymatic reactions, plays key roles to prevent the accumulation of toxic nitrogenous compound and synthesize arginine de novo. Five well characterized diseases have been described, resulting from an enzymatic defect in the biosynthesis of one of the normally expressed enzyme. This presentation will focus on two representative diseases; ornithine transcarbamylase(OTC) deficiency and citrullinemia(argininosuccinate synthetase deficiency). Ornithine transcarbamylase deficiency is one of the most common inborn error of urea cycle, which is inherited in X-linked manner. We identified 16 different mutations in 20 unrelated Korean patients with OTC deficiency; L9X, R26Q, T44I, R92X, G100R, R141Q, G195R, M205T, H214Y, D249G, R277W, F281S, 853 delC, R320X, V323M and 10 bp del at nt. 796-805. These mutations occur at well conserved nucleotide sequences across species or CpG hot spot. The L9X and R26X lead to the disruption of leader sequences, required for directing mitochondrial localization of the OTC precursor. Their phenotypes are severe, and neonatal onset. The G100R, R277W and V323M mutations were uniquely identified in patients with late onset OTC deficiency. The other genotypes are associated with neonatal onset. Out of 20 patients with OTC deficiency, only 6 patients are alive; two were liver transplanted, and normal in growth and development at 2, 4 years after transplantation respectively. Citrullinemia is an autosomal recessive disease, caused by the mutations in the argininosuccinate synthetase(ASS) gene. We identified in 3 major mutations in 10 unrelated Korean patients with citrullinemia; G324S, IVS6-2 A to G, and 67 bp ins at nt 1125-1126. Among these, the 67 base pair insertion mutation is novel. The allele frequency of each mutation is; G324S(45%), IVS6-2 A to G(40%), and 67 base pair insertion(10%). All patients are diagnosed at neonatal or infantile age. Interestingly, two patients presented with stroke like episode. All patients except one are surviving on dietary management.

**Pheno-genotypic studies of childhood neuronal ceroid lipofuscinoses.** *N. Zhong*<sup>1,2,4</sup>, *D. Moroziewicz*<sup>1,2</sup>, *W. Ju*<sup>1,2</sup>, *K.E. Wisniewski*<sup>3,4</sup>, *S.S. Brooks*<sup>2</sup>, *W.T. Brown*<sup>2</sup>. 1) Molecular Neurogenetic Diagnostic Laboratory, NYS Inst Basic Res, Staten Island, NY; 2) Dept. Human Genetics, NYS Institute for Basic Res, Staten Island, NY; 3) Dept. Neuropathology, NYS Institute for Basic Res, Staten Island, NY; 4) Dept. Neurology, SUNY-Health Science Center at Brooklyn, Brooklyn, NY.

Neuronal ceroid lipofuscinoses (NCLs) are a group of common childhood neuronal degenerative disorders. A common feature of the rapid progression of psychomotor and cognitive deterioration characterizes the NCLs, however, affected individuals differ in clinical presentation. To better characterize phenotypes and genotypes and to obtain a better understanding of NCL pathogenesis, we analyzed age-at-onset, initial symptoms/signs, and clinical progressive course; electron microscope (EM) examination for lipofuscin storage profiles; lysosomal enzyme assays for PPT1 and TPP1; and molecular analyses for gene mutations. A total of 392 clinically diagnosed subjects affected with NCL were studied. Among these, INCL accounts for 20.6%, LINCL for 40.6%, and JNCL for 38.9%. The initial symptoms/signs of seizures, speech/learning disabilities, vision loss, motor dysfunction, dementia, and behavioral changes were determined to be 11.1, 33.3, 36.1, 19.4, 0, and 0% in INCL; 39.4, 33.8, 14.1, 5.6, 2.8, and 4.2% in LINCL; and 5.9, 22.1, 57.4, 1.5, 7.4, and 5.9% in JNCL. The predominant EM profile in the INCL was pure GR (51.2%), followed by GR+CV/FP (17%) and GR+CV+FP (9.7%). However, FP and FP+CV (59.4%), followed by CV (16.7%), were the common profiles in JNCL and CV (66.2%), followed by CV+FP (16.9%) and CV+FP+GR (13.8%), in LINCL. Mutation analyses showed that common mutations in both alleles usually associate with typical clinical courses, however, uncommon mutations in one or both alleles may result in atypical progression. A small portion of NCL families has been found could not be classified with known NCL variant forms in our studies, which we grouped as NCL9. We propose that NCL9 is underlied by a yet-unidentified gene CLN9. Currently, searching for the gene CLN9 is being undertaken.

**Genotype-Phenotype correlations in cystathionine beta synthase deficiency.** *M.T. Steen<sup>1</sup>, R.H. Singh<sup>1</sup>, M. Pasquali<sup>1</sup>, L.J. Elsas II<sup>1</sup>, W.D. Kruger<sup>2</sup>.* 1) Div Medical Genetics, Emory Univ, Atlanta, GA; 2) Div Population Genetics, Fox Chase Cancer Center, Philadelphia, PA.

We evaluated genotype-phenotype relationships among twelve patients from 11 families with cystathionine beta synthase (CBS) deficiency. Using DNA sequencing, we identified 21 of 22 possible mutant CBS alleles, and characterized both clinical and biochemical phenotypes. Each missense mutation in CBS was engineered into a recombinant *S. cerevisiae* strain containing an expressed human CBS cDNA as its sole source for CBS activity, and bioassayed for the correction of cysteine auxotrophy. Crude cell extracts were then prepared and enzymatic activities were determined. Previously described mutations and their CBS activities (in parentheses, expressed in nanomoles/mg protein/hr) were: wild type (350), G307S (0), I278T (20), V320A (90), T353M (6), and L101P (2). Six novel mutations first identified in this study were: A226T (26), N228S (22), A231L (12), D376N (0), and Q526K (8). One splice site mutation was found (G<sub>736</sub>-1 C). The I101P, V228S, V320A, T353M, and D376N mutations demonstrated clinical B6-nonresponsiveness, while the A226T mutation was B6-responsive. The T353M mutation was found exclusively in each of four American Black patients. Five I278T and five T353M alleles accounted for 45% of the 22 alleles in this patient cohort. We conclude that there is a genotype-phenotype relationship in CBS deficiency.

**NDUFV2 mutation in a case of hypertrophic cardiomyopathy and mitochondrial complex I deficiency.** *P. Benit<sup>1</sup>, M. Corral-Debrinsky<sup>2</sup>, P. de Lonlay<sup>1</sup>, J.P. Issartel<sup>3</sup>, D. Chretien<sup>1</sup>, A. Munnich<sup>1</sup>, P. Rustin<sup>1</sup>, A. Rotig<sup>1</sup>.* 1) Dept Genetics, INSERM U393, Hosp Necker, Paris, France; 2) UMR 8541, Ecole Normale Suprieure, 75005 Paris, France; 3) Laboratoire de BioEnergétique Cellulaire et Pathologique, Dpartement de Biologie Molculaire et Structurale, CEA, 38054 Grenoble Cedex 9, France.

NADH:ubiquinone oxidoreductase (complex I) is the largest complex of the mitochondrial respiratory chain. This complex accounts for most cases of respiratory chain deficiency in human. Only seven mitochondrial DNA genes but more than 35 nuclear genes encode complex I. Among them, the NDUFV2 gene encodes the 24 kDa subunit which contains a Fe-S-binding site. In an attempt to elucidate the molecular bases of complex I deficiency, we studied the NDUFV2 gene in a series of 40 patients with isolated complex I deficiency. The full length NDUFV2 mRNA extracted from cultured skin fibroblasts was reverse transcribed and tested by Denaturing High Performance Liquid Chromatography (DHPLC). Abnormal fragments were then directly sequenced. We identified a NDUFV2 mutation in a patient born to first cousin parents of West African origin. He presented a severe hypertrophic cardiomyopathy, hypotonia, growth retardation and profound isolated complex I deficiency in skeletal muscle. Accordingly, oxidation of malate-pyruvate was decreased in his cultured skin fibroblasts. Three older sibs had previously deceased from cardiomyopathy. Sequencing of NDUFV2 cDNA and genomic sequence revealed a deletion of exon 2 due to a 4 bp deletion in intron 2 (IVS2 120+5D4bp) in the intron splice site. The resulting protein is predicted to lack amino acids 19-40 thus removing part of the mitochondrial targeting signal peptide and its cleavage site. Western blot analysis of mitochondria from cultured skin fibroblasts of the patient revealed that the amount of NDUFV2 protein was decreased to 30-40% as compared to control. This is the first report of a NDUFV2 mutation in a case of complex I deficiency.

**2-Methyl-3-hydroxybutyryl-CoA dehydrogenase: purification of the enzyme, cloning of the cDNA and resolution of the molecular basis of 2-methyl-3-hydroxybutyryl-CoA dehydrogenase deficiency.** *R.J.A. Wanders<sup>1</sup>, R. Ofman<sup>1</sup>, M. Feenstra<sup>1</sup>, J.P.N. Ruiten<sup>1</sup>, J. Zschocke<sup>2</sup>, H.R. Waterham<sup>1</sup>.* 1) Clinical Chemistry, Laboratory for Genetic Metabolic Diseases, Academic Medical Centre, University of Amsterdam, The Netherlands; 2) Universität Kinderklinik, Heidelberg, Germany.

We recently identified a new defect in the isoleucine breakdown pathway, 2-methyl-3-hydroxybutyryl-CoA dehydrogenase (MHBD/SCHMAD) deficiency, in a boy showing progressive infantile neurodegeneration. The normal activity of other mitochondrial 3-hydroxyacyl-CoA dehydrogenases including the short-(SCHAD) and long-chain (LCHAD) enzyme, suggested the existence of a distinct 3-hydroxyacyl-CoA dehydrogenase. We now report the purification of this enzyme from bovine liver using several different column chromatography steps. The candidate protein band was excised from the SDS/PAGE gel and subjected to MALDI-TOF mass spectrometry after in gel digestion with trypsin. Screening of several databases resulted in a positive identification. The authenticity of its cDNA was established by expressing this cDNA in *E. coli* followed by enzyme activity assays. Molecular studies in the index patient as well as other patients with MHBD/SCHMAD-deficiency revealed distinct mutations.

**Two-Dimensional Electrophoresis, The Best Screening Method for Mucopolysaccharidoses: Comparing the Reliability With Acid Turbidity Test and Berry Spot Test.** *C. Chuang, S. Lin.* Medical Research Dept, MacKay Memorial Hosp, Taipei Taiwan, Republic of China.

Because of the differences in glycoaminoglycan (GAG) contents and quantities in various mucopolysaccharidoses (MPS), the MPS screening tests including acid turbidity test and Berry spot test are not specific and sensitive enough for the preliminary diagnosis of MPS. A false-negative interpretation resulted in a mistaken diagnosis happens frequently. We analyzed urine samples collected from 33 MPS patients (2 with MPS I, 15 with MPS II, 9 with MPS III, 5 with MPS IV, and 2 with MPS VI) and 24 control children using acid turbidity (qualitative and quantitative) and Berry spot tests, respectively. All the samples were confirmed by the dimethylmethylene blue method (DMB) for GAG quantitation, and two-dimensional electrophoresis (2-D EP) for MPS differential diagnosis. With the exception of MPS I, II, and VI, patients with MPS III and IV showed 44.4% and 60% false-negative results, respectively, in which the concentrations of uronic acid in the urine samples were all less than 1.5 mg/mL and the spot test showed very faint metachromatic pattern. Conclusively, the DMB ratio (GAG mg/mmol creatinine) is not correlated to the results obtained from acid turbidity test and Berry spot test, on the contrary, the latter two have good correlation to each other. Therefore, a misdiagnosis of MPS by using both tests is possible. For an accurate diagnosis of MPS, the 2-D EP method is recommended. The 2-D EP method provides a good separation of GAG contents, high sensitivity, specificity, and efficiency, in addition, a false-negative interpretation of MPS is rarely happened.

**VALIDATION OF GLUCOSE TETRASACCHARIDE AS A BIOMARKER FOR DIAGNOSIS AND MONITORING ENZYME REPLACEMENT THERAPY FOR POMPE DISEASE.** *Y. An, D.S. Millington, P. Kishnani, A. Amalfitano, Y.T. Chen.* Division of Medical Genetics, Department of Pediatrics, Duke Univ Medical Center, Durham, NC.

Glycogen storage disease type II (GSD-II), also known as Pompe disease, results from lysosomal acid  $\alpha$ -glucosidase (GAA) deficiency. Clinically, GSD-II encompasses a range of phenotypes from the infantile form with hypotonia, muscle weakness, cardiac hypertrophy and culminating in early death, to the juvenile and adult-onset forms characterized by progressive respiratory and limb muscle involvements. The objective of this research was to validate a tetraglucose oligomer, Glc1-6Glc1-4Glc1-4Glc, designated (Glc)4, as a biomarker for monitoring the disease state and therapeutic response in GSD-II patients. (Glc)4 levels in blood and urine samples collected from either animal models of GSD-II, or GSD-II patients were measured by a newly developed HPLC test method. Validation for (Glc)4 as a biomarker included measuring the glycogen content and (Glc)4 level in the muscles of GSD-II quails and normal quails. The (Glc)4 levels in GSD-II quail muscles were 0.01-0.02 mg/mg protein. In normal quails, the (Glc)4 levels were undetectable. The ratio of (Glc)4 to total glycogen content in Pompe quail muscles was 2-3%. Moreover, in vitro tests suggested that the (Glc)4 is likely derived from partial digestion of glycogen by neutral glucosidases. The (Glc)4 levels correlated well with the clinical forms of the disease with infantile and early juvenile patients having higher (Glc)4 levels than the later-onset adult patients. In addition, (Glc)4 levels were inversely related to the serum GAA activity levels measured in infantile patients receiving recombinant enzyme therapy. As a further validation of the utility of the (Glc)4 biomarker to monitor GSD-II therapies, we found that the (Glc)4 levels increased in patients that began mounting anti-rhGAA antibody responses, and that the (Glc)4 levels decreased after therapeutic maneuvers were initiated (increased frequency of enzyme infusions, or immune-suppressive strategies). Our results indicate that (Glc)4 is a promising biomarker for monitoring the disease state and therapeutic response in Pompe disease.

**Phenotypic differences between sialidosis and galactosialidosis mouse models.** A. D'Azzo<sup>1</sup>, E. Bonten<sup>1</sup>, L. Mann<sup>1</sup>, N. DeGeest<sup>2</sup>. 1) Department of Genetics, St. Jude Children's Research Hospital, Memphis, TN; 2) Department of Genetics, Katholieke Universiteit, Gasthuisberg Campus, Leuven, Belgium.

Neuraminidase initiates the hydrolysis of sialo-oligosaccharides, -glycolipids and -glycoproteins by removing their terminal sialic acid residues. In humans, primary or secondary deficiency of this enzyme leads to two clinically similar neurodegenerative lysosomal storage disorders, sialidosis and galactosialidosis. Mice nullizygous at the *Neu 1* locus develop clinical abnormalities reminiscent of early onset sialidosis in children, including severe nephropathy, progressive edema, splenomegaly, kyphosis and urinary excretion of sialylated glycoproteins. As observed in patients with these diseases, the sialidosis mouse model share clinical and histopathological features with GS mice. However, we have identified phenotypic abnormalities that are exclusively present in sialidosis mice. Progressive deformity of the spine, high occurrence of early death, age-related extramedullary hematopoiesis, and lack of apparent degeneration of Purkinje cells appear diagnostic for this disease model only. Thus the differences and similarities between the two mouse models may help to better understand the pathophysiology of these diseases in children and to identify more target therapies.

Supported in part by NIH grants GM60950, DK52025, and CA21765, Assisi Foundation of Memphis, and the American Lebanese Syrian Associated Charities (ALSAC).

**Correction of lysosomal PPCA and neuraminidase in mouse deficient macrophages after uptake of recombinant baculovirus-expressed proteins.** *E. Bonten, A. d'Azzo.* Department of Genetics, St. Jude Children's Research Hospital, Memphis, TN.

Galactosialidosis (GS) is a lysosomal storage disorder caused by combined deficiency of protective protein/cathepsin A (PPCA), b-galactosidase, and neuraminidase (neur). Patients develop a multi-systemic disease mostly accompanied by severe neurological deficit and early death. Their clinical symptoms are similar to those of sialidosis patients and have been mainly attributed to the secondary deficiency of neur. The dependence of neur to PPCA for intracellular targeting and activation underscores the need for therapeutic modalities that would supply the patients with both enzymes. Recombinant PPCA precursor is secreted efficiently from normal and over-expressing mammalian cells, and can be taken-up by deficient fibroblasts and other cells via the M6P receptor, correcting the enzyme deficiency. In contrast, neur, although secreted, lacks a functional M6P recognition marker and is internalized poorly by mammalian cells. With the intent to investigate the potential of ERT for the treatment of GS we have used recombinant baculovirus-expressed proteins (BV-neur and BV-PPCA) as source of the corrective enzymes. The recombinant proteins are biologically functional, and can be produced in large quantities at low cost. BV-expressed neur and PPCA were tested in uptake experiments on cultured BM macrophages. Both BV-PPCA and BV-neur, either alone or mixed, were efficiently taken up by PPCA-deficient mouse macrophages, and capable of restoring cathepsin A and neuraminidase activities. Maximum correction of neuraminidase activity (>10 fold control values) was established with a mixture of PPCA and neur. Uptake was blocked by the addition of yeast mannan, indicating that the proteins were taken up via the macrophage-specific mannose receptor. These results set the basis for ERT trials in PPCA and neur deficient mouse models, using BV-derived recombinant proteins. The use of BV-produced proteins may be applicable to other lysosomal disorders.

Supported in part by NIH grants GM60950, DK52025, and CA21765, Assisi Foundation of Memphis, and the American Lebanese Syrian Associated Charities (ALSAC).

**Characterization of a canine model of mucopolysaccharidosis IIIB.** *N.M. Ellinwood<sup>1</sup>, P. Wang<sup>1</sup>, T. Skeen<sup>2</sup>, N. Sharp<sup>2</sup>, M. Cesta<sup>2</sup>, W. Bush<sup>1</sup>, E. Hardam<sup>1</sup>, M.E. Haskins<sup>1</sup>, U. Giger<sup>1</sup>.* 1) Univ. Pennsylvania, Philadelphia, PA; 2) North Carolina St. Univ., Raleigh, NC.

Mucopolysaccharidosis III (MPS III) has been documented in numerous species, including mice (MPS IIIA and IIIB), dogs (MPS IIIA), emus (MPS IIIB), and goats (MPS IIID). We now report on a canine form of MPS IIIB; on the clinical, biochemical and pathologic features, and the preliminary genetic characterization of the canine N-acetyl-a-D-glucosaminidase (NAGLU) locus.

Two 3-year-old Schipperke dogs were evaluated by the Metabolic Screening Laboratory of the Veterinary Hospital of the University of Pennsylvania. The affected dogs had progressive, severe neurological signs consistent with diffuse cerebellar disease. Both animals were confirmed to have heparan sulfaturia. Assays of fibroblast cultures for eleven lysosomal enzymes indicated a deficiency of NAGLU activity, making the diagnosis of MPS IIIB. Pedigree analysis and levels of NAGLU activity of family members supported autosomal recessive inheritance, as expected for MPS IIIB. Due to neurological deterioration, both dogs were euthanized, and complete post-mortem examinations were performed. Biochemical studies of tissues from both animals confirmed a lack of NAGLU activity, storage of sulfated glycosaminoglycans, and secondary elevations of other lysosomal enzymes, including b-glucuronidase and total b-hexosaminidase. Pathology of the brain included severe cerebellar atrophy and lysosomal storage in neurons and perithelial cells.

The use of canine MPS IIIB offers an opportunity to further assess the pathogenesis of MPS IIIB and to evaluate possible therapies. To this end, an obligate male carrier was used to establish a research colony. Initial genetic analysis of the normal canine NAGLU locus has begun with the production of canine specific NAGLU sequence, comprising one third of the predicted canine cDNA. Completed investigations will include the characterization of the entire canine NAGLU locus and confirmation of the causative mutation responsible for canine MPS IIIB.

Supported by NIH Grant RR02512.

**A Fluorescence-Based, High Performance Liquid Chromatographic Assay to Determine Acid Sphingomyelinase Activity and Diagnose Types A and B Niemann-Pick Disease.** *X. He, F. Chen, E.H. Schuchman.* Department of Human Genetics, Mount Sinai School of Medicine, New York, NY.

Acid sphingomyelinase (ASM, sphingomyelin phosphodiesterase, E.C. 3.1.4.12) is the lysosomal enzyme that hydrolyzes sphingomyelin (SPM) to phosphorylcholine and ceramide. An inherited deficiency of ASM activity results in Types A and B Niemann-Pick disease (NPD). In this study we report a new assay method to detect ASM activity and diagnose NPD using the fluorescent substrate, Bodipy C12-SPM (B12SPM, Molecular Probes Inc.), and reverse-phase high performance liquid chromatography (HPLC). The reaction product, Bodipy C12-ceramide (B12Cer), could be clearly and efficiently separated from the substrate (B12SPM) within 4 min using a hydrophilic column (Aquasil C18, Keystone Scientific Inc.). Femtomol quantities of the reaction product, B12Cer, could be detected in as little as 0.1 ml of human plasma, providing a sensitive measure of ASM activity. Mean ASM activity in human plasma from NPD patients (36 pmol/ml/h) was only 2.7% of that in normal plasma (1334 pmol/ml/h), confirming the specificity and diagnostic value of this new assay method. Importantly, mean ASM activity in human plasma from NPD carriers (258.3 pmol/ml/h) was also significantly reduced (19.5% of normal). The ranges of ASM plasma activities in NPD patients (N=19), carriers (N=11), and normal subjects (N=15) were 2.5-97.4, 108-551, and 1030-2124 pmol/ml/h, respectively. Based on these results, we suggest that this fluorescence-based, HPLC assay method is a reliable, rapid, and highly sensitive technique to determine ASM activity, and that plasma is a very reliable and simple source for the accurate diagnosis of NPD patients and carriers based on ASM activity. This new method may also serve as a prototype for assaying various other biologically important sphingomyelinases and may be useful in a wide range of experimental circumstances where the in vitro detection of ASM activity is necessary.

**A first successful bone marrow transplantation case of galactosialidosis.** *J. Hwang<sup>1</sup>, D. Im<sup>1</sup>, J. Lee<sup>1</sup>, E. Kwon<sup>1</sup>, J. Kim<sup>1</sup>, J. Kim<sup>2</sup>, D. Jin<sup>1</sup>.* 1) Pediatrics, Samsung Medical Center, Seoul, Korea; 2) Clinical Pathology, Samsung Medical Center, Seoul, Korea.

Galactosialidosis is a lysosomal storage disease associated with a combined deficiency of b-galactosidase and neuraminidase, secondary to a defect of another lysosomal protein, the protective protein/cathepsin A (PPCA). Although a transgenic mouse model demonstrated a promising outcome of bone marrow transplantation (BMT), there was no reported case of BMT in the literature. Here we report a first successful BMT results in a Korean patient whose enzyme assay confirmed galactosialidosis. The index case of the family was his younger sister who showed typical coarse face, scoliosis, mental retardation, myopia, generalized tonic clonic seizure and cherry red spot. There was a progressive aggravation of her neurologic symptom and eventually she was bed-ridden, and enzyme assay for lysosomal storage disorders was evaluated. The enzyme assay of her fibroblast revealed combined deficiency of b-galactosidase and neuraminidase which confirmed the galactosialidosis. Incidentally, her brother showed the similar morphologic manifestation which prompted us to evaluate him. He also had cherry red spot and abnormal increase of glycosaminoglycan, but there was no hepatosplenomegaly. Several months after diagnosis, he also showed gait disturbance and neurologic deterioration. Thus he was treated with bone marrow transplantation with haploidentical donor, his mother. One hundred days after BMT, b-galactosidase activity in his leukocyte were normalized and his neurologic derangement was stationary. However, his post-BMT course was complicated at 9 months after BMT by severe varicellar infection and he succumbed to pulmonary hemorrhage due to uncontrolled infection. We concluded that his neurologic deterioration was halted before he succumb at least. Here we report a first BMT case of galactosialidosis.

**Mutation analysis of iduronate-2-sulfatase gene in 20 Korean families with mucopolysaccharidosis type II. H.**

*Kim<sup>1</sup>, C. Kim<sup>2</sup>, H. Hwang<sup>2</sup>, S. Song<sup>1,2</sup>, J. Kim<sup>1,2</sup>, J. Lee<sup>1</sup>, J. Kim<sup>3</sup>, D. Jin<sup>1,2</sup>.* 1) Pediatrics, Samsung Medical Center, Seoul, Korea; 2) Medical Genetics, Samsung Biomedical Research Institute, Seoul, Korea; 3) Clinical Pathology, Samsung Medical Center, Seoul, Korea.

Mucopolysaccharidosis(MPS) II is an X-linked recessive lysosomal storage disorder caused by a deficiency of the lysosomal enzyme iduronate-2-sulfatase (IDS) because of several different types of mutations in the IDS gene. Two forms of MPS II are distinguishable clinically. A severe form has progressive mental retardation and physical disability and death before age 15 years in most cases. A mild form has a slower progression of somatic deterioration and retention of intelligence. The responsible IDS gene consists of 9 exons and 8 introns structurally. It is sequenced a 2.3-kb cDNA clone coding for the entire sequence of human IDS. The IDS cDNA detected structural alterations or gross deletions of the IDS gene in many of the clinically severe form of MPS II patients studied. In Korea, MPS type II is the most prevalent form among MPS. In our Genetic clinic of Samsung Medical Center, we are following up 30 families of MPS type II. Among these,sequencing analysis with a total 20 families of MPS II was performed in order to identify the primary genetic lesion and to find the novel mutation. Seventeen different mutation of IDS gene were detected.: 1 splicing mutation, 3 missense mutation, 5 nonsense mutation, 6 deletion mutation and 2 insertion mutation. The nine of them were novel and unique.: 1 novel missense mutation: Leu259Pro, 2 novel nonsense mutations: Glu177X(GAA->TAA) and Lys213X (AAA->TAA), 4 novel deletion mutations: 121-123bp(c41,CTC), 69-88bp(c23-c30, TGC^GTGGCctcgcgatccgaaacgcagCCAAC), c263(GCC->-CC), 1042-1049(c348-c350, GCC^AAAtacagcaaTTTGAT), 2 novel insertion mutations: c8G(CGA->GCGA), c228(CCC->CCCA). We can expect that new mutation detection contributes to the level of heterogeneity for in MPS II.

**Mutation analysis of the acid ceramidase gene in Japanese patients with Farber disease.** *K. Inui, T. Muramatsu, N. Sakai, Y. Yamada, H. Tsukamoto.* Dept Pediatrics, Fac Medicine, Osaka Univ, Osaka, Osaka, Japan.

Farber disease is a rare lysosomal storage disease, characterized by the accumulation of ceramide in tissues due to the acid ceramidase deficiency. Here we report the identification of three novel mutations in the acid ceramidase gene in two Japanese patients. Patient 1 showed joint problems around 10 months old and she is now emaciated with multiple nodules at 9 years old and mild neurological problems. Patient 2 was the product of consanguineous parents and showed joint contracture around 8 months old. She showed neurological symptoms around 2 years old and died at 6 years old due to respiratory failure. The diagnosis was made by clinically and confirmed by enzymatic assay of acid ceramidase. In molecular analysis using cultured skin fibroblasts, normal mRNA levels were expressed in both patients. By direct sequencing of cDNAs, missense mutations of V97E in exon4 and G235R in exon 9 were detected in patient 1 and 96delV in exon 4 was homozygously identified in patient 2. These mutations were also confirmed in genomic DNAs. Expression of the mutated acid ceramidase cDNAs in COS-1 cells and subsequent determination of acid ceramidase residual enzyme activity demonstrated that each of these mutations was the direct cause of the acid ceramidase deficiency in the respective patients. We also found a new polymorphism V369I in exon 14 in the allele from the mother of the patient 1. Until now only several mutations were reported in Farber disease. These mutations including our new identified mutations show genetically privates in Farber disease.

**Biochemical and molecular analysis of infantile free sialic acid storage disease (ISSD) in a North American child.**

*R. Kleta*<sup>1</sup>, *M. Huizing*<sup>1</sup>, *E. Strovel*<sup>1</sup>, *Y. Anikster*<sup>1</sup>, *E. Orvisky*<sup>2</sup>, *D.J. Aughton*<sup>3</sup>, *D. Krasnewich*<sup>4</sup>, *W.A. Gahl*<sup>1</sup>. 1) HDB, NICHD, NIH, Bethesda, MD; 2) NSB, NIMH, NIH; 3) William Beaumont Hosp., Royal Oak, MI; 4) MGB, NHGRI, NIH.

Our patient was born at 38 weeks of gestation after an uneventful pregnancy. Neither her parents nor grandparents were of Finnish origin. Her growth and development appeared normal at 4 weeks of age. Subsequently, the child showed progressive growth retardation and developmental delay. A seizure disorder was diagnosed at the age of 6 months. Facial features appeared course at 7 months of age. Muscular tone decreased gradually and respiratory difficulties became a major medical issue. The child died at the age of 33 months. Elevated urinary sialic acid was documented by thin layer chromatography at 17 months of age. Fibroblast studies confirmed this finding, with levels of 54 and 89 nmol free sialic acid/mg protein (normal, 1). Most of the free sialic acid (62%) was within the lysosomal, or granular, fraction. Recently, Salla disease and ISSD were shown to be allelic disorders involving mutations in SLC17A5 and, consequently, defective sialin. This lysosomal membrane transporter is responsible for the egress of free sialic acid out of lysosomes. We performed mutation analysis of the SLC17A5 gene using the patient's cDNA and genomic DNA. On the cDNA level, the patient was compound heterozygous for a 148-bp deletion of exon 9 and a 15-bp deletion (del 801-815) in exon 6 of the SLC17A5 gene. The 148-bp deletion (del 1112-1259), which encompassed the entire exon 9, was due to a GA splice site mutation in position 1 of intron 9. In summary, we demonstrate the biochemical diagnosis of ISSD by showing increased free sialic acid within fibroblast lysosomes, and the molecular diagnosis by confirming a new example of compound heterozygosity for SLC17A5 gene mutations in a North American child. The differential diagnosis of developmental delay and growth retardation in early childhood is difficult, and is particularly challenging in infancy. ISSD and Salla disease are important members of the differential diagnosis in children who show developmental delay of postnatal onset.

**The E326K mutation and Gaucher disease: Mutation or Polymorphism?** *M.E. LaMarca<sup>1</sup>, J.K. Park<sup>1</sup>, D. Stone<sup>1</sup>, J.J. MacKenzie<sup>2</sup>, N. Tayebi<sup>1</sup>, E. Sidransky<sup>1</sup>*. 1) NSB, NIMH/NIH, Bethesda, MD; 2) Queens University, Ontario, Canada.

Gaucher disease is caused by mutations in the gene for human glucocerebrosidase, a lysosomal enzyme involved in the intracellular hydrolysis of glucosylceramide. While over 150 different glucocerebrosidase mutations have been identified in patients with Gaucher disease, not all mutations have been fully characterized as being causative. One such mutation is the E326K mutation, which results from a G→A nucleotide substitution at genomic position 6195. There are several cases of patients with Gaucher disease and the E326K mutation; however, in each instance, the E326K change was found as a second mutation on an allele with another glucocerebrosidase mutation. Utilizing PCR screening and restriction digestions of both patients with Gaucher disease and normal controls, we identified the E326K allele in both groups. Of the 216 alleles screened from patients with Gaucher disease, the E326K mutation was detected in 4 alleles (1.9%). Each carried another known glucocerebrosidase mutation. In addition, screening for the E326K mutation among normal controls revealed that 3 alleles among 130 screened (2.3%) also carried the E326K change. In the normal controls with the E326K allele, the glucocerebrosidase gene was completely sequenced but no additional mutations were found. Therefore, we believe that the E326K mutation may not be a causative change and stress that a careful examination of any allele with this mutation should be performed to check for the presence of another glucocerebrosidase mutation.

**Tissue specific expression and regulation of CTNS.** *A. Helip Wooley, J. Thoene.* Hayward Human Genetics Center, Tulane University School of Medicine, New Orleans, LA 70112.

Cystinosis results from defects in the CTNS gene which encodes the lysosomal cystine transporter cystinosin. The mouse homolog of CTNS (Ctns) encodes a protein that is 92.6% similar to human cystinosin. Tissue specific expression of Ctns in the mouse was examined using the mouse Rapid-Scan Gene Expression Panel consisting of 96 well PCR plates of first strand cDNAs in 4 serial dilutions representing 24 different tissues or embryonic stages (Origene). Each cDNA is normalized to contain equivalent amounts of B-actin cDNA, then PCR amplified using primers for either Ctns or B-actin as a control. Ctns is expressed in all tissues and embryonic stages examined, with the highest levels of expression seen in liver, kidney, lactating breast and testis. Upregulation during lactation may reflect increased proteolysis to facilitate milk protein production. Adrenal, the only tissue not found to store cystine in cystinotic humans, had the lowest level of Ctns expression in the panel. Cultured cells treated with cystine di-methylester (CDME) accumulate high concentrations of cystine in their lysosomes. Human embryonic kidney (HEK293) cells were cultured in the presence or absence of 0.2 mM CDME for 1, 3, or 7 days. RNA was harvested on the indicated day and analyzed by northern blot using PCR radio-labeled probes for either CTNS or B-actin. Similar levels of CTNS expression in CDME treated and untreated cells were seen on day 1. On days 3 and 7, however, CTNS message is almost absent in the untreated cells but the CDME treated cells continue to express high levels of CTNS. Levels of B-actin were similar for all samples. This difference in CTNS expression is attributed to the untreated cells entering a stationary phase as they reach confluence with minimal transcription of CTNS, while the CDME treated cells, though also reaching confluence, are stimulated by lysosomal cystine to maintain expression of CTNS at high levels. These studies indicate cystinosin expression is somewhat tissue specific in the mouse and may be influenced by lysosomal cystine content in cultured human cells.

**Subcellular localization and correction of CTNS gene mutations.** *R. Lemons, M.A. Park, A. Helip-Wooley, J. Thoene.* Hayward Human Genetics Center, Tulane University School of Medicine, New Orleans, LA. 70112.

Mutations of the CTNS gene resulting in intermediate or nephropathic cystinosis have been described. A splice site mutation (IVS11+2 T ® C) that eliminates the GYDQL lysosomal targeting sequence of cystinosin yields an intermediate phenotype, but can produce cystine depletion when transfected into CTNS null fibroblasts. The possibility of an alternate lysosomal targeting sequence was evaluated by constructing plasmids with N-terminal GFP fused to either normal CTNS or CTNS with the splice site mutation. The normal CTNS-GFP fusion product was found to co-localize with the lysosomal marker lysosensor red almost exclusively, while the splice site CTNS-GFP fusion product was found in the plasma membrane and cytoplasm as well as lysosomes. This finding was supported by Cherqui, et al who recently described a second, less efficient, lysosomal targeting sequence, YFPQA, in CTNS which is retained in the truncated protein resulting from the splice site mutation. A nonsense mutation in CTNS (753 G ® A) encoding a premature termination codon (PTC) at amino acid 138 (W138X) has been described. Gentamicin is known to induce PTC read-through and hence full length protein production. We have demonstrated that gentamicin treatment (300 mg/ml) leads to depletion of intracellular cystine in cell strains with a premature termination codon, but not in those with large deletions or a deletion leading to a frame shift mutation. Plasmids with GFP as a C-terminal fusion to CTNS or PTC-CTNS were constructed allowing GFP to serve as a reporter. The normal CTNS-GFP fusion co-localized with lysosomes. No significant fluorescence was observed in PTC-CTNS transfected cells in the absence of gentamicin but green fluorescence was demonstrated and shown to co-localize with lysosomes in its presence. These findings were confirmed by immunofluorescence labeling with anti-GFP antibodies. Using GFP fusion proteins we have demonstrated lysosomal targeting of normal CTNS, partial lysosomal targeting of a CTNS splice site mutation using an alternate targeting sequence, and aminoglycoside induced PTC read-through of a PTC-containing CTNS mutation.

**Site-specific recombination of the NPC1-gene in human cells - a model for the analysis of biochemical consequences of different mutations.** *R. Oheim, P. Bauer, R. Knoblich, M. Zschesche, C. Bauer, A. Rolfs.* Dept. of Neurology, University of Rostock, Rostock, M/V.

Niemann Pick Type C (NPC) disease is a rare, autosomal recessive lipid storage disorder involving the nervous system. In at least 95% of all NPC-patients mutations can be identified in NPC1 gene, which encodes for a lysosomally targeted transport protein. NPC is characterized by moderate to severe hepatosplenomegaly, pronounced neonatal jaundice, supranuclear gaze palsy and movement disorders such as ataxy and cognitive impairment. Biochemically, the translocation of LDL-derived unesterified cholesterol from the lysosomes to the Golgi is blocked. In order to study phenotypical consequences of different mutations within the NPC1 gene and to develop a genetically based therapeutic treatment we have produced a knock-out cell-line as NPC-model. For this reason a knock-out vector was constructed, which is based on the pBSbluescript, including two regions of homology to the NPC gene, namely LA (ca. 1,8 kb) and RA (ca. 4,0 kb). These fragments are interrupted through a neomycin-box, which causes the exon-knock-out in the genom of the cells and is necessary for positive selection. For negative selection with ganciclovir the vector was designed with a herpes simplex virus thymidin kinase box 3' from the RA-fragment. The homologous fragments were constructed using long distance PCR and cloned into the vector using restriction enzymes. We chose XbaI and SalI for the LA-fragment and XhoI and BamHI for the RA-fragment. Two different cell lines were transfected by electroporation, first the haploid CHO-KI to avoid problems of generating homozygous knock-out in diploid cells and to control the functionality of the vector and second 1321LN, a human astrocytoma cell line, to establish a NPC1-model related to the nervous system. Genetic and biochemical analyses including microarray studies of the homozygously NPC1 knocked-out cells will follow.

**Site-specific recombination of the glucocerebrosidase-gene in human cells - a model for the analysis of biochemical consequences of different mutations.** *K. Heintze<sup>1</sup>, P. Bauer<sup>1</sup>, R. Knoblich<sup>1</sup>, C. Bauer<sup>1</sup>, M. Horowitz<sup>2</sup>, A. Rolfs<sup>1</sup>.* 1) Dept. of Neurology, Univ. of Rostock, Germany; 2) Dept. of Cell Res. and Immunology, Tel Aviv Univ., Israel.

Gaucher disease (GD) is a lipid storage disorder characterized by impaired activity of the lysosomal enzyme glucocerebrosidase (GBA), which involves the nervous system in a variable manner. Its clinically heterogeneity is attributed to a large number of mutations in the GBA-gene but also depends on the given cellular environment within the neuronal and glial cells or fibroblasts. In a prospective study we have analyzed more than 300 patients for mutations within the GBA-gene by sequencing the entire GBA-gene. The data demonstrate a relative low prevalence of the well known mutations 370Asn>Ser and 444Leu>Pro which account for only 40% of the GD-producing alleles. Additionally, we have identified 37 new mutations, e.g. 809C>T (231Thr>Ile), 827C>T (237Ser>Phe), 882T>G (255His>Glu), 1028A>G (304Tyr>Cys), 1208G>A (364Ser>Asn), 1227C>A (370Asn>stop), 1296G>A (393Trp>stop). In order to study the biochemical crosstalk between those GBA-mutations (444Leu>Pro, 393Trp>stop) found mainly in the neuronopathic forms of the disease and the consequences in the given cell population we underwent a targeted disruption of the GBA-gene. The targeting vector, as a replacement construct, contained two regions of homology genomic fragments (1,5 kb containing exon 1-3 and 4 kb containing exon 5-10) of the GBA-gene on either side of the positive selectable marker neomycin. Furthermore, a negative selectable marker, the herpes simplex virus thymidine kinase, was introduced into the targeting vector outside the region of homology to GBA. The 1,5 kb genomic fragment (left arm, LA) was generated by PCR with oligonucleotides which contains the Restriction-sites SalI (sense Primer) and XbaI (antisense Primer). The 4 kb fragment (right arm, RA) was generated by long-distance PCR and contains XhoI/ClaI. The recombination will be done in human neuronal cell lines in comparison to fibroblasts. A detailed biochemical and genetic analysis of the homozygously GBA-knocked-out cells is followed by micro-array studies.

**Abnormal regulation of genes encoding lysosomal and cytoskeletal proteins in fibroblasts from patients with lysosomal disorders.** *P.R. Hunt*<sup>1</sup>, *C.R. Bouton*<sup>2</sup>, *J. Pevsner*<sup>1,2,3</sup>. 1) Doctoral Program in Human Genetics and Molecular Biology, The Johns Hopkins University, Baltimore, MD; 2) Department of Neuroscience, The Johns Hopkins School of Medicine, Baltimore, MD; 3) Department of Neurology, Kennedy Krieger Institute, Baltimore, MD.

Although individually rare, lysosomal storage disorders share many clinical characteristics, and as a group, have an estimated frequency of about 1 in 5,000 births. Clinical symptoms are progressive, and often include mental disturbance and regression, characteristic facies, enlarged liver and spleen, and respiratory and cardiac problems. While most lysosomal storage disorders are characterized by defects in genes encoding specific lysosomal enzymes, several are characterized by defects in lysosomal or endosomal transport, e.g. mucopolysaccharidosis types II (MLII) and IV (MLIV), Chediak-Higashi Syndrome (CHS), and Niemann Pick Disease Type C (NPC). We hypothesized that, since trafficking to lysosomes is perturbed in these disorders, the diseased cells may respond by differentially regulating the expression of genes encoding lysosomal proteins. By cDNA microarray analysis we measured the expression of 9,000 genes in fibroblasts from patients with MLII, MLIV, CHS, NPC, and in chloroquine-treated fibroblasts in which swollen endosomal compartments are induced. Data analysis employed the DRAGON database to identify changes in 200 groups of functionally related genes. In MLII, MLIV, CHS, and chloroquine-treated fibroblasts, but not in NPC, we found increased expression of genes encoding lysosomal proteins. Surprisingly, we also found a group of genes encoding cytoskeletal elements to be down-regulated in MLIV. Findings are confirmed at the protein level by Western analysis and immunofluorescence microscopy. These studies provide insight into the cellular response to lysosomal disorders.

**A biliary phenotype of Type 1 Gaucher disease(GD): high prevalence of cholesterol gallstones(GS)associated with abnormal lipid metabolism.** *P.K. Mistry<sup>1</sup>, H. Hyogo<sup>2</sup>, K. Lim<sup>1</sup>, W. Lomazow<sup>1</sup>, H. Chung<sup>1</sup>, H. Deng<sup>2</sup>, A. Stancato-Pasik<sup>1</sup>, G. Hermann<sup>1</sup>, S. Wallenstein<sup>1</sup>, D.E. Cohen<sup>2</sup>.* 1) Dept Human Genetics, Mount Sinai Sch Medicine, New York, NY; 2) Liver Research Center, Albert Einstein School of Medicine, Bronx, NY.

Type 1 GD is due to a recessive deficiency of acid b glucosidase, which leads to widespread accumulation of macrophages laden with lysosomal glucosylceramide. Consistent with the finding of efficient biliary secretion in rats, gcosylceramide does not accumulate in heptocytes of GD patients. Nevertheless, a biliary phenotype of GD has not been described. **AIM:** To assess the prevalence and determinants of GS (asymptomatic GS plus previous cholecystectomy). **METHODS:** The study cohort comprised 322 consecutive patients with type 1 GD,171 females, 151 males, aged <sup>3</sup> 10 yrs (mean 48±17)and 230 had intact spleens while 90 were asplenic. **RESULTS:** Compared to the general population overall prevalence of GS was more than 5-fold higher, increasing from 5% in 10-19 yrs to 67% in >70 yrs age group (mean prevalence 35%). GS were more frequent in asplenic patients compared to those with intact spleen: 53% vs 32%, p<0.001. Patients with GS had higher body mass index(p<0.001) and higher LDL cholesterol(p<0.001) than those without. On multivariate analyses, significant correlates of GS were older age(p<0.001, splenectomy(p<0.001), female sex(p=0.005) and HDL cholesterol(p=0.027). Overall, cholesterol levels and body mass index of GD patients was below 95th percentile. Cholesterol GS were identified in three patients and pigment stones in the other. Biliary lipid composition in biles of 4 GD patients was markedly altered containing high concentration of glucosylceramide(334-1068 mM) compared to normal approximately 1mM(Pentchev et al, BBA, 665,615,1981). GD biles also contained glucosylsphingosine 1.5-4.8mM. **CONCLUSIONS:** Low body mass index, extremely low plasma cholesterol, abnormal biliary lipid secretion associated with marked propensity to cholesterol GS represent a hitherto undescribed metabolic syndrome of GD. We speculate that in GD, glucosylceramides profoundly affect biliary lipid secretion and cholesterol solubility in bile.

**Chiari type 1 malformation in three unrelated patients affected with Fabry disease. P. HALIMI<sup>1</sup>, D.P. GERMAIN<sup>2</sup>.**

1) Department of Radiology; 2) Department of Genetics, European Hosp Georges Pompidou, Paris, France.

Fabry disease (FD) (OMIM 301500) is an X-linked recessive disease resulting from deficiency of the lysosomal hydrolase alpha-galactosidase A. The enzymatic defect leads to the widespread deposition of uncleaved neutral glycosphingolipids in the plasma, and lysosomes of many cell types, especially in vascular endothelial and smooth muscle cells. Initial clinical signs include skin lesions (angiokeratoma), excruciating acral pain, and benign corneal opacities. Progressive glycosphingolipid deposition in the microvasculature of hemizygous males subsequently leads to ischaemic complications involving kidneys, heart and brain, and to failure of target organs. Among neurological symptoms, strokes and transient ischaemic attacks have been reported. A 29-year-old male patient, with a confirmed diagnosis of FD, was referred to us for evaluation of a sudden episode of dizziness with disequilibrium and diplopia, in agreement with the diagnosis of transient ischaemic attack. Magnetic resonance imaging showed minimal cerebrovascular involvement. In particular, no sign of stroke, vertebral arteries abnormalities, or bulbar infarction was evidenced. However, sagittal MRI revealed Chiari type 1 malformation (CM1). CM1 is a pathological continuum of hindbrain maldevelopments, characterized by downward herniation of the cerebellar tonsils. CM1 is defined as tonsillar herniation of more than 5 mm below foramen magnum. Following the ascertainment of this first patient, we systematically performed cerebral magnetic resonance imaging in a cohort of 15 male patients affected with FD, and identified two additional cases of association between FD and CM1 in two unrelated patients. This survey is the first report on the association between FD and CM1. Our data emphasize that CM1 malformation should be considered in the differential diagnosis of cerebrovascular manifestations of FD. In addition, since both conditions are rare, the association may possibly not be coincidental.

**Cystinotic fibroblasts display aberrant apoptosis.** *M.A. Park, A.H. Wooley, J.G. Thoene.* Human Genetics, Tulane University, New Orleans, LA.

Cystinosis is a lysosomal storage disorder characterized by abnormally high lysosomal cystine levels due to a defect in the lysosomal cystine transporter cystinosin. Patients with the disorder manifest failure to thrive, the renal Fanconi syndrome, progressive renal failure, hypothyroidism, retinopathy and keratopathy. The proximal cause of cell, tissue and organ death is not known, nor is it easily inferred, given that the cystine accumulation remains partitioned in the lysosomal compartment. The lysosomal cysteine and aspartic proteases, cathepsins B and D respectively, are newly characterized effectors in the apoptotic response pathway. Cathepsin D translocates from the lysosomes to the cytosol in response to a pro-apoptotic signal. There it activates pro-apoptotic caspases. Cathepsin B acts as an inhibitor of cathepsin D. Examination of cystine inhibition of purified human hepatic cathepsin B using a fluorogenic substrate found that 10 uM cystine inhibited 0.1uM cathepsin B by 87%. Direct measurement of cathepsin B activity in cystinotic and normal fibroblast lysates showed that the cystinotic cells demonstrated only 65% of normal activity per milligram cell protein, and that this activity was restored to normal by addition of DTT to the lysates. Apoptosis was induced in cystinotic and normal cell lines, and the cells were analyzed by TUNEL or Annexin V staining followed by fluorescence microscopy. Cystinotic fibroblasts (cell line GM00008), were found to undergo apoptosis about 4 - 20 times more readily than normal fibroblasts (GM00010) when microinjected with cytochrome C. A similar response was observed in cystinotic and normal fibroblasts treated with anti-Fas antibodies, thapsigargin, and etoposide. We hypothesize that cystine-induced inhibition of cathepsin B leads to aberrant apoptosis, and may be responsible for inappropriate cell death in cystinosis, leading to the phenotype.

**Patients with Gaucher disease and myoclonic epilepsy.** *J.K. Park<sup>1</sup>, R. Schiffmann<sup>2</sup>, N. Tayebi<sup>1</sup>, E. Orvisky<sup>1</sup>, C. Kaneski<sup>2</sup>, M.E. LaMarca<sup>1</sup>, E. Sidransky<sup>1</sup>.* 1) NSB, NIMH, Bethesda, MD; 2) DMNB, NINDS, Bethesda, MD.

Gaucher disease, resulting from the inherited deficiency of the lysosomal enzyme glucocerebrosidase, is divided into three clinical types based upon the presence and rate of progression of neurological symptoms. Type 1 is the most common form and has no associated neurological symptoms, whereas type 2 presents with acute and progressive neurologic involvement. Type 3, by definition, includes those patients with chronic neurologic involvement who have survived past the first few years of life, but the associated neurological symptoms can be quite variable. One rare subgroup of patients with type 3 Gaucher disease are those that develop myoclonic epilepsy. We evaluated the phenotypes and genotypes of 14 patients with Gaucher disease and myoclonic epilepsy utilizing molecular techniques including PCR, long template PCR, direct sequencing and Southern blot analysis. Generally, this group of patients had severe visceral involvement with the onset of seizures by adolescence. All of the 14 patients had involvement of the horizontal saccadic eye movements. Twelve different genotypes were encountered. Shared alleles included G377S, V394L and N188S, each seen in 2 alleles, and L444P and recNciI, each seen in 4 alleles. Two patients each shared the genotypes V394L/RecNciI and N188S/RecNciI. In addition, another patient had the genotype N188S/c.84insG. Both V394L and N188S are mutations that have previously been described as associated with non-neuronopathic Gaucher disease. As this group of patients with a rare phenotype does not share a specific genotype, the possibility of modifying genes is being considered. Since genotype alone cannot accurately predict phenotype, the focus on patients with unique phenotypes, such as patients with myoclonic epilepsy, may lead to a greater understanding of the molecular complexity encountered in Gaucher disease.

**Gene conversion events in patients with Gaucher disease.** *N. Tayebi, B.K. Stubblefield, M.E. LaMarca, J.K. Park, B.M. Martin, E. Sidransky.* NSB, NIMH, Bethesda, MD.

Gaucher disease is the autosomal recessively inherited deficiency of the lysosomal enzyme glucocerebrosidase (GC). The human GC gene, located on chromosome 1q21, has a pseudogene that shares 96% sequence homology and is located 16kb downstream of the functional gene. The presence of this pseudogene increases the possibility of recombination within this locus. Patients with Gaucher disease are divided into three types, based upon the presence and rate of progression of neurological manifestations: type 1, non-neurologic, type 2, acute neurologic, and type 3, subacute neurologic. We examined the genotypes of patients with Gaucher disease utilizing PCR, long template PCR, direct sequencing, Southern blots and polymorphism analyses. We found 55 alleles carrying a recombination between the GC gene and its pseudogene in 205 patients with Gaucher disease. Thirty-two of the recombinant alleles resulted from gene conversion events, the majority of which occurred within an 830 nucleotide sequence extending from the end of intron 8 to the beginning of exon 10 of the GC gene. Moreover, in the 17 recombinant alleles identified in a subgroup of 32 patients with type 2 Gaucher disease, we found 11 gene conversion alleles. Several possible sites of gene conversion were identified. In one of the gene conversion alleles, the shortest length of homology between the acceptor and donor sequence was only 23 nucleotides. Comparison of the sequences at the identified sites of gene conversion revealed a shared pentamer motif sequence (CACCA) that may be a hot spot for gene conversion. These findings substantiate the premise that the 3' end of the GC gene has a great proclivity for recombination events. Therefore, genotypic analysis of patients with Gaucher disease, especially type 2, should be performed with attention to molecular detail to enable more accurate studies of genotype-phenotype correlation.

**Cholelithiasis in patients with Gaucher disease.** *H. Rosenbaum*<sup>1</sup>, *E. Sidransky*<sup>2</sup>. 1) Dept. of Hematology, Rambam Medical Center and Rappaport Faculty of Medicine, Haifa, Israel; 2) NSB, NIMH, Bethesda, MD.

Gaucher disease, the inherited deficiency of the lysosomal enzyme glucocerebrosidase, manifests with a wide range of clinical features. We noted that a number of adult patients with type 1 Gaucher disease also had gallstones. The clinical records of 65 adult patients evaluated at the National Institutes of Health with type 1 Gaucher disease were reviewed and 19 patients were identified who either had gallstones or a history of a cholecystectomy. Of the 19 patients, six were male. The age at which stones were noted ranged from 19 to 70 years (mean 35 years). Thirteen of the patients had a cholecystectomy performed. Several different factors may contribute to the development of gallstones in these patients. Eleven of the patients were found to have chronic anemia, including 3 with autoimmune hemolytic anemia. Fifteen of the patients underwent splenectomy. To determine whether our findings were specific to our referral population, the medical records of a second series of 80 adult patients of Ashkenazi Jewish ancestry with type 1 Gaucher disease followed in Northern Israel were reviewed. Sixteen of these patients (5 male, 11 female) were also noted to have gallstones. To our knowledge this is the first report of gallbladder involvement in Gaucher disease.

**Gaucher Disease: Creation of point mutations in mouse acid b-glucosidase (GCase).** *Y.H. Xu, T. Leonova, E. Ponce, G.A. Grabowski.* Dept Pediatrics, Div Human Gen, Children's Hosp Medical Ctr, Cincinnati, OH.

Gaucher disease is an autosomal recessively inherited disease caused by the mutations in the GCase locus leading to disruption of the enzyme's structure and function. Toward understanding the molecular bases of Gaucher disease, using the cre-lox system, 5 point mutations (N370S, V394L, D409H, D409V, or D399N) were introduced into mouse GCase to mimic the mutations in human disease with differential phenotypes. The mutations were confirmed by sequencing of both genomic DNA and RT-PCR products. Compared with wild type (WT), the V394L homozygotes (>160 day survival) showed a reduced GCase in liver ( $5.6 \pm 1\%$  of wt), spleen ( $19 \pm 0.6\%$ ) and brain ( $50 \pm 1\%$ ). N370S homozygosity is lethal and these mice died shortly after birth. To study the expression of the mutant GCases *ex vivo*, skin fibroblasts were established from FVB-WT<sup>+/+</sup>, V394L<sup>+/-</sup>, V394L<sup>-/-</sup>, N370S<sup>+/-</sup>, N370S<sup>-/-</sup>, V394L<sup>-/null</sup>, N370S<sup>-/null</sup>, null/null, and Neo-N370S<sup>-/-</sup>. GCase activities in these fibroblasts were 61.2%, 24.4%, 59.8%, 13.5%, 13.4%, 5.8%, 2.4%, and 0.59% (n=2-7) of WT (FVB strain), respectively. In parallel, the tTA-off or rtTA-on system (tetracycline transactivator and human GCase TARGET gene) has been developed for conditional rescue of GCase mutant mice. In the Lap-tTA-off system, GCase expression was increased to 250% in liver and to 200% in spleen in absence vs presence of tetracycline. Studies in these point-mutant and conditionally expressing mice will facilitate understanding of the pathophysiology of Gaucher disease.

**Molecular analysis of GM1-gangliosidosis: identification and characterization of four novel mutations in two Taiwan Chinese patients.** *F.J. Tsai<sup>1,2,3</sup>, C.F. Yang<sup>2,3</sup>, J.Y. Wu<sup>2,3</sup>*. 1) Dept Pediatrics, China Medical Col Hosp, Taichung, Taiwan; 2) Dept Medical Research, China Medical Col Hosp, Taichung, Taiwan; 3) Dept Medical Gen, China Medical Col Hosp, Taichung, Taiwan.

GM1-gangliosidosis is an autosomal recessive lysosomal storage disease caused by a deficiency of acid beta-galactosidase (GLB1; EC3.2.1.23). By use of direct sequencing, mutation screening of the GLB1 gene was performed in two Taiwan Chinese patients with severe form of GM1-gangliosidosis. Patient 1 carries a G-to-T change at nucleotide position 1481 (exon 15) on one allele, which converts glycine into valine (Gly494Val), and a three-nucleotide deletion on the other allele, resulting in an in-frame deletion of one leucine residue (c.945-947del). Patient 2 was characterized to have three different nucleotide changes. She carries a C-to-G change at nucleotide position 304 (exon 3) on one allele, which converts histidine into aspartic acid at residue 102 (His102Asp). She also has a C-to-T transition at nucleotide 902 (exon 8) on the other allele, which converts alanine into valine at residue 301 (Ala301Val). In addition to Ala301Val, this patient also has a G-to-A change at nucleotide position of 67 in exon 1 on the same allele, leading to the substitution of serine for glycine at residue 23 (Gly23Ser). Transient overexpression in COS-1 cells with cDNA encoding Ala301Val, Gly494Val, His102Asp, c.945-947del, Gly23Ser mutant b-galactosidases produced products with activities of 0, 0, 14, 2.9, 94.7 % compared with the cDNA clone for wild-type b-galactosidase. The transient overexpression in COS-1 cells allows us to discriminate mutations affecting catalytic activity from those that did not. In conclusion, we have identified four novel mutations and one polymorphism in two Taiwan Chinese patients with severe form of GM1-gangliosidosis.

**Barriers to successful dietary control among pregnant women with phenylketonuria (PKU).** *A.S. Brown<sup>1</sup>, P. Fernhoff<sup>2</sup>, S. Waisbren<sup>3</sup>, D. Frazier<sup>4</sup>, R. Singh<sup>2</sup>, F. Rohr<sup>3</sup>, J. Morris<sup>1</sup>, A. Kenneson<sup>1</sup>, P. MacDonald<sup>1</sup>, M. Gwinn<sup>1</sup>, M. Honein<sup>1</sup>, S. Rasmussen<sup>1</sup>.* 1) CDC, Atlanta, GA; 2) Emory University, Atlanta, GA; 3) Children's Hospital, Boston, MA; 4) University of North Carolina, Chapel Hill, NC.

Despite the known and preventable risks associated with maternal PKU, affected babies continue to be born, emphasizing the need to identify barriers to successful dietary control among pregnant women with PKU. To investigate these barriers, a questionnaire was used to interview women with PKU known to metabolic disease clinics in three states who were pregnant during 1998-2000. Of 24 women in the study, 22 (92%) followed the phenylalanine-restricted diet during pregnancy; only 8 (33%) initiated the diet prior to pregnancy. Of 22 medical records received, only 12 (55%) indicated control of blood phenylalanine levels prior to 10 weeks gestation. Women who achieved metabolic control after 10 weeks gestation were five times as likely to be younger than 25 years of age (RR= 5.1, 95% CI = 1.4, 18.9) and believe that treatment costs complicated the diet (RR= 5.0, 95% CI = 1.3, 18.6). All of the women expressed confidence in the metabolic clinic staff, but only 8 (33%) perceived their obstetricians were familiar with maternal PKU pregnancy risks. Of 13 women enrolled in state-based assistance programs, 9 (69%) reported proof of pregnancy was required for eligibility. Many women using private insurance reported their insurer was unwilling to pay for medical foods. When the data were stratified according to state of residence, differences were observed in the live birth rate, pre-pregnancy formula use, average travel time to the metabolic clinic, and gestational week when metabolic control was achieved. These findings suggest that women with PKU need more education about the importance of dietary control before conception. Obstetric knowledge of maternal PKU needs further evaluation. Discrepancies should be resolved between maternal PKU medical recommendations and the policies of third party-payers. The disparities in financial assistance and services available to pregnant women with PKU residing in different states should be examined further.

**Evaluating the Dose Response in Maternal Phenylketonuria.** *A.E. Kanaga, J.D. McDonald.* Dept of Biological Sciences, Wichita State University, Wichita, KS.

In the human inborn error of metabolism, phenylketonuria, there is an important maternal effect syndrome; namely maternal phenylketonuria. In this syndrome, a fetus being gestated in the uterus of a phenylketonuria female is damaged due to her metabolic defect. We are using the *BTBR-Pah<sup>enu2</sup>* mouse phenylketonuria model and a synthetic diet (Teklad Research Diet #97152, Harlan-Teklad, Madison, WI) to study the relationship between maternal hyperphenylalaninemia and birth defects among offspring. By varying maternal genotype between mutant and non-mutant and by varying the concentration of phenylalanine in the diet, we can investigate the dose response between maternal blood phenylalanine level and fetal birth defect incidence. A number of differing dietary conditions are used to produce a range of maternal blood phenylalanine levels between normal and classical phenylketonuria levels. To monitor the incidence of birth defects, fetuses are assessed at term for three gross morphometric parameters known to be affected in human maternal phenylketonuria offspring: body weight (BW), crown-to-rump length (CRL), and head circumference (HC). Fetal blood samples are collected and a quantitative spectrofluorometric assay is used to determine fetal blood phenylalanine levels. Other pregnancy complications thought to be a part of the human maternal phenylketonuria syndrome are increased rates of spontaneous abortion and stillbirth. Therefore, these birth defects will also be scored in the mouse model, as well as the point in gestation at which they occur. Further, all fetuses will be analyzed for both genotype and sex in order to determine if any subset of animals is more severely affected, experience a higher incidence of birth defects, or is more susceptible to lethality. The dose response will be evaluated for each individual birth defect as a function of maternal blood phenylalanine level. Continuous variables (i.e., BW, CRL, and HC) will be assessed using regression analysis, with the goal of ultimately accepting or rejecting linearity of the dose response curve. Discrete variables (i.e., spontaneous abortion and stillbirth) will be assessed through chi-square analysis.

**Prevention of Maternal PKU: What is an adequate phenylalanine level for adolescent females and other women of childbearing age?** *G. Pridjian<sup>1,2,3</sup>, A. Cunningham<sup>1</sup>*. 1) Hayward Genetics Center; 2) Department of Pediatrics; 3) Division of Maternal and Fetal Medicine, Department of Ob/Gyn, Tulane University School of Medicine, New Orleans, LA.

Maternal PKU continues to be a devastating disease. Conception and pregnancy in the metabolic milieu of uncontrolled PKU leads to microcephaly, developmental delay/retardation, congenital anomalies (in particular congenital heart disease), and growth delay. Maternal PKU embryopathy can be prevented by maintaining maternal phenylalanine levels in a normal range (2 to 6 mg/dL). To assure normal levels of phenylalanine in the first trimester, excellent preconception metabolic control is advocated. However, 40 to 65% of pregnancies are unplanned, often discovered late in the first trimester. Statements of the NIH Consensus Development Conference include maintenance of phenylalanine values between 2 and 15 mg/dL in PKU individuals after 12 years of age, with individual consideration for gender and childbearing status. In the last 6 years alone 8 pregnancies of 4 mothers with PKU were followed in the Hayward Genetics Center. All mothers were consistently instructed regarding the teratogenesis of uncontrolled plasma phenylalanine and encouraged to plan pregnancy with prepregnancy control. Of the 8 pregnancies, 7 were unplanned. The mean gestational age at the time of pregnancy diagnosis was 9.3 menstrual weeks (range 6.5 to 16.0). The mean phenylalanine level at the time of diagnosis was 14.4 mg/dL (range 9.2 to 25.9). Of the 8 pregnancies, three have signs of maternal PKU embryopathy. Their initial values after pregnancy was discovered were 25.9, 18.7, and 16.6 mg/dL. However, all had some dietary modification prior to the initial level. Two pregnancies with no sign of maternal PKU are still ongoing. While 2 to 15 mg/dL may be an acceptable range for male adolescents with PKU, it may not be for females. While the data in this report are small in number, the outcomes are convincing to suggest female adolescents with PKU, and in general, all females with PKU of childbearing age should maintain phenylalanine levels closer to the normal range (2 to 6 mg/dL) as pregnancy is often not a planned phenomenon.

**Impact of apo E genotype on familial combined hyperlipemia (FCHL) expression.** *O. Guardamagna<sup>1</sup>, C. Bondone<sup>1</sup>, C. Sacchetti<sup>1</sup>, A. Gomez<sup>3</sup>, G. Mercadante<sup>2</sup>, E. Cocco<sup>3</sup>, C. Allora<sup>1</sup>, M. Bo<sup>2</sup>, R. Bonardi<sup>4</sup>, S. Bosso<sup>3</sup>, G. Restagno<sup>3</sup>.* 1) Pediatria, University of Torino; 2) Medicina Interna, University of Torino; 3) Molecular Genetics Service, AOOIRM-S.Anna, Torino; 4) Malattie dell'Apparato Digerente e Nutrizione, University of Torino, Italy.

The apo E gene represents a major determinant in lipoprotein metabolism. The e2, e3 and e4 alleles, which originate six different apolipoproteins, are differently related to total cholesterol (TC), triglycerides (Tg), and apo B levels. Furthermore the relationship between the familial combined hyperlipemia (FCHL, a complex inherited disorder of lipoprotein carrying apo B) and apo E haplotypes is poorly questioned. Aim of the study is to examine in the Italian FCHL kindreds the correlation between common haplotypes E2/E3, E3/E3, and E3/E4 and lipoprotein profiles. Methods: 35 affected children, 63 adults patients and 6 healthy sibs from 27 FCHL kindreds were submitted to biochemical analysis and DNA collection. The diagnosis was based on TC and/or Tg exceeding the 90<sup>o</sup> percentile, on at least a first degree related affected patient and on kindreds phenotype variability. The apo E isoforms were detected by DNA RFLPs after cleavage with CFoI enzyme. Statistical evaluation was based on ANOVA one-way method. Results: Alleles frequencies in FCHL and control kindreds were not significant. TC resulted 140, 224, 272 mg%, LDL-C 70, 149, 196 mg %, apo B 74, 109, 141 mg% and Tg 182, 89 and 142 mg% in E2/E3, E3/E3 and E3/E4 respectively. A statistically significant result (p<0.001 and p<0.05) was obtained on TC, LDL-C and apo B respectively on adults and children. Conclusions: TC, LDL-C and apo B higher levels were observed in subjects carrying the E3/E4, followed by subjects with E3/E3 and E2/E3 haplotypes. In contrast the higher Tg levels are observed in the E2/E3 haplotype. These results confirm a correlation between apo E alleles and the biochemical expression of FCHL phenotype. Moreover the atherogenic phenotype related to e4 allele is here evidenced since pediatric age, while the involvement of e2 is still doubtful.

**Detection of Hartnup's Disorder in an Alkaptonuria Sibship.** *I. Bernardini, W. Introne, R. Kleta, D.L. Fitzpatrick, W.A. Gahl.* HDB, NICHD, NIH, Bethesda, MD.

Our investigations into alkaptonuria include collecting histories and assessing routine physiological parameters of the patients enrolled. These data will yield a composite natural history of this rare disease, and provide us with a baseline against which to evaluate the effects of NTBC therapy on homogentisic acid excretion, renal glomerular function, and plasma and urine amino acid patterns. NTBC, currently used to treat type I tyrosinemia, inhibits the production of homogentisic acid, which accumulates in alkaptonuria and destroys joints and other cartilage-containing tissues. In the 44 alkaptonuria patients assessed so far, we have found normal renal glomerular function except for one patient with end-stage renal disease due to insulin-dependent diabetes mellitus. Plasma and urine amino acids have been within normal limits, except for one family in which two of the three sibs with alkaptonuria also had plasma and urine amino acid patterns consistent with Hartnup's disorder. Remarkably, all 3 sibs also carried a diagnosis of documented sucrase-isomaltase deficiency. The theoretical probability of finding these three conditions in a single individual by chance alone would be approximately one in 4 trillion. However, in this case the family history revealed a coefficient of inbreeding of 1/8 (Garnica, 1981). Hartnup's disorder is an abnormality of renal tubular and gastrointestinal mucosal transport of neutral amino acids at the plasma membrane level. The main symptoms result from niacin deficiency, since this vitamin/cofactor is synthesized from tryptophan, one of the amino acids that fails to be absorbed properly in the gastrointestinal tract. In our two affected siblings, neutral amino acids were low in plasma and high in urine, resulting in elevated fractional excretions. The patients had histories of gastrointestinal and neuropsychiatric symptoms consistent with symptomatic Hartnup's disorder. After confirmation of this abnormality, a trial of niacin supplementation will be attempted. This case emphasizes the possibility that multiple rare disorders can occur in a single individual, especially when consanguinity is involved.

**Misconceptions and Concerns Regarding the Use of Tandem Mass Spectrometry in Newborn Screening.** *D.H. Chace, S.M. Beatty, E.W. Naylor.* Neo Gen Screening, Bridgeville, PA.

Tandem Mass Spectrometric (MS/MS) analysis of dried blood specimens for acylcarnitines and amino acids is clearly one of the most significant advances in newborn screening since Robert Guthrie introduced BIA's in the early 60s to detect PKU. As quoted by Harvey Levy in a Clinical Chemistry editorial, MS/MS analysis represents a sea-change in how newborn screening is approached. No longer is one method used to analyze one metabolite to detect one disorder. The new approach is to use one method to analyze multiple metabolites to detect multiple disorders. With future applications of molecular diagnostics, this concept will be clearly established as the norm. As the use of MS/MS is rapidly growing throughout the US and other nations. What began as a research/clinical screening tool for an analysis of a few samples averaging 10-20 infants per day in the early 1990s has grown to 1000+ samples per week in one laboratory. Today, more than 15% of the infants born in the US now have at least one metabolite measured using MS/MS. Clearly, the benefit of MS/MS screening is being born out with statistics now being obtained. However, there still remains much confusion and misinformation regarding the appropriate use of MS/MS as well as the research that is still required to validate and educate physicians about this extraordinarily comprehensive, complex tool. Issues with regard to the diseases that may be detectable by MS/MS, the differences between screening programs using this technology, the numerous alterations of a method to suite individual laboratory needs, the early stages of implementation of QA, challenges of interpretation, disease treatability and challenges in implementation will be discussed. MS/MS is clearly an important system for enhanced newborn screening and raises issues that will have to be discussed and solved as more complex comprehensive diagnostic methods are developed. MS/MS provides us with an early opportunity to consider new approaches, programs and issues that must be solved such as QA, informed consent, education, follow-up and treatment of more than 100 diseases affecting newborns that may be analyzed in some laboratories.

**Neutral lipid storage disease with mild ichthyosis, hepatopathy, developmental delay and skeletal anomalies (Chanarin-Dorfman disease).** *E. Morava*<sup>1</sup>, *T. Decsi*<sup>2</sup>, *L. Szonyi*<sup>3</sup>. 1) Department of Clinical Genetics, Pecs University, Medical Faculty, Pecs, Hungary; 2) Department of Pediatrics, Pecs University, Pecs, Hungary; 3) Department of Pediatrics, Semmelweis University, Budapest, Hungary.

Neutral lipid storage in liver, muscle and other tissues is a rare metabolic condition. It may be present due to lysosomal acid lipase deficiency which is rapidly fatal in Wolmann's disease but may also be compatible with long term survival in Chanarin-Dorfman disease. Characteristic clinical features are developmental delay with muscle hypotonia, hepatomegaly with increased liver enzyme activities and ichthyosis. Lipid laden leukocytes (Jordan's anomaly) are commonly observed. We report on a male infant with severe muscle hypotonia and liver steatosis in whom mild ichthyosis rose the suspicion of Chanarin-Dorfman disease. The diagnosis was corroborated by detecting elevated hexacosanoic acid (C26:0) values in plasma lipids. We also report multiple skeletal anomalies which represent a hitherto unreported finding in this syndrome.

**Early retinal and MRI changes in a neonate with homocystinuria and methylmalonic aciduria(*cb1C*).** P. Jayakar<sup>1</sup>, E. Vasconsellos<sup>1</sup>, D.S. Rosenblatt<sup>2</sup>. 1) Miami Children's Hospital, Miami, FL; 2) McGill University, Montreal, Canada.

AA, a girl born of non-consanguineous Mexican parents was doing well on breast feeds till the age 3 weeks, when she presented with respiratory infection, progressive lethargy, poor feeding and bilateral retinal hemorrhages. The brain CT and the bone survey were normal. At age 1 month she had low plasma methionine(4umoles/L), elevated free plasma homocystine(46 umoles/L) and normal serum vitamin B12. Urine organic acids showed elevated methylmalonic acid (MMA) (177.4mmol/molcr) and methylcitric acid. The uptakes of C14-propionate and C14-methyltetrahydrofolate by cultured fibroblasts were low with a good response to hydroxycobalamin in culture medium; complementation studies confirmed the (*cb1C*)defect. On starting hydroxycobalamin(1mg/day)and carnitine, plasma free homocystine decreased (9umoles/L), plasma methionine (14umoles/L)normalized and urine MMA decreased(10.9mmol/molcr) within 2 to 5 days. A brain MRI at 1 month showed lateral and third ventriculomegaly, cerebral atrophy, spongiform changes and increased signal in the periventricular white matter extending to the subcortical U fibers, normal basal ganglia and cerebellum. Ophthalmic exam showed subtle pigmentary macular changes, several small faded blot hemorrhages in the mid periphery along the veins and temporal arcade, 2 tiny linear dark and fresh hemorrhages bilaterally in the macula with absent macular reflex. At age 3 months, ophthalmic exam showed optic atrophy, no new hemorrhages and MRI showed progressive ventriculomegaly, prominent basal cisterns, increased signal and thinning of periventricular white matter in the right hemisphere, mild cerebellar atrophy, with normal basal ganglia. At 5 months, she is globally delayed with no metabolic crisis, normal plasma methionine and plasma free homocystine but mildly elevated urine MMA (15.2mmol/molcr). The neonatal presentation of lethargy and retinal hemorrhages is unusual for (*cb1C*) and needs to be differentiated from non-accidental trauma. The diagnostic difficulties are further compounded by the early white matter spongiform changes typically seen in other neurodegenerative disorders; these progressed despite early treatment.

**Biochemical and molecular analysis of 12 patients with thiamine-responsive pyruvate dehydrogenase complex deficiency.** *E. Naito, M. Ito, I. Yokota, T. Saijo, Y. Ogawa, K. Shinahara, S. Yamamoto, Y. Kuroda.* Department of Pediatrics, School of Medicine, University of Tokushima, Tokushima, Japan.

We report biochemical and molecular analysis of 12 patients with thiamine-responsive pyruvate dehydrogenase complex (PDHC) deficiency. PDHC activity was assayed using two different concentrations of thiamine pyrophosphate (TPP) in cultured lymphoblastoid cells or cultured fibroblasts from 12 patients. These 12 patients displayed very low PDHC activity in the presence of a low ( $1 \times 10^{-4}$  mM) TPP concentration. These PDHC activities increased at a high (0.4 mM) TPP concentration. Especially, PDHC activity of six patients increased within normal range. Therefore, PDHC deficiency in 12 patients was due to a decreased affinity of PDHC for TPP. Treatment with a high dose of thiamine resulted in a reduction in lactate and clinical improvement in these patients, suggesting that these 12 patients have a thiamine-responsive PDHC deficiency and a high dose of thiamine is very effective for patients with this type of PDHC deficiency. The DNA sequence of these patients' X-linked E1a subunit revealed a point mutation in all 12 patients, including 6 patients in exon 3, one patient in exon 4, two patients in exon 7, and three patients in exon 8. Five mutations (V71A, R88C, C101F, L216F, and L260Q) of them were novel. Two mutations (L216F and R263G) were found in the genomic DNA of two mothers, and the PDHC activity of these two mothers was decreased in the presence of a low TPP concentration. Half of 12 patients with thiamine-responsive PDHC deficiency were caused by mutations in exon 3 of E1a subunit gene. Therefore, exon 3 in the E1a subunit gene appears to be important in thiamine-responsive PDHC deficiency.

**Biochemical, behavioral and pathologic analysis of an animal model of glutaric acidemia type I.** *D.M. Koeller<sup>1</sup>, L.S. Crnic<sup>2</sup>, M. Wootner<sup>2</sup>, B.K. DeMasters<sup>3</sup>, J. Stephens<sup>3</sup>, E.L. Hunt<sup>3</sup>, S.I. Goodman<sup>2</sup>.* 1) Depts Pediatrics and Molecular & Medical Genetics, Oregon Health Sci Univ, Portland, OR; 2) Dept Pediatrics, Univ of Colorado Health Sci Ctr, Denver, CO; 3) Dept of Pathology, Univ of Colorado Health Sci Ctr, Denver, CO.

Glutaric acidemia type I (GA-I) is an autosomal recessive disorder of organic acid metabolism resulting from a deficiency of glutaryl-CoA dehydrogenase (GCDH). Patients accumulate glutaric acid (GA) and 3-OH glutaric acid (3-OHGA) in their blood, urine and CSF. Clinically, GA-I is characterized by macrocephaly, progressive dystonia and dyskinesia. Degeneration of the caudate and putamen of the basal ganglia, widening of the Sylvian fissures, fronto-temporal atrophy and severe spongiform change in the white matter are also commonly observed. To study the pathophysiologic basis for the neurologic damage seen in GA-I we made a mouse model via targeted deletion of the *Gcdh* gene in embryonic stem cells. *Gcdh*<sup>-/-</sup> mice accumulate both GA and 3-OHGA at levels similar to those seen in GA-I patients. The affected mice have a mild motor deficit but do not develop the progressive dystonia seen in human patients. Subjecting the *Gcdh*<sup>-/-</sup> mice to a metabolic stress, which often precipitates symptoms in patients, failed to have any neurologic effect on the mice. Pathologically, the *Gcdh*<sup>-/-</sup> mice have a diffuse spongiform myelinopathy similar to that seen in GA-I patients. However, unlike in human patients, there is no evidence of neuron loss or astrogliosis in the striatum.

**Study of two phosphate transporters of the Anion/Cation Symporter family in GSD1c.** *D. Melis<sup>1</sup>, G.M.S. Mancini<sup>2</sup>, A. Havelaar<sup>2</sup>, A. Benedetti<sup>3</sup>, G.P.A. Smit<sup>4</sup>, F.W. Verheijen<sup>2</sup>.* 1) Dept of Pediatric, Federico II University, Naples, Italy; 2) Department of Clinical Genetics, Erasmus University, Rotterdam; 3) Department of Pathology, University of Siena; 4) University Hospital, Groningen.

The Anion/Cation symporter (ACS) family is a relatively large group of phylogenetically conserved transporter genes. Recently two phosphate transporters of the ACS family, NPT3 and NPT4, have been identified; northern blot analysis and RT-PCR revealed that they are expressed in liver, kidney and intestine. Aim of the present study was to analyze the intracellular localization and the genomic structure of human NPT3 and NPT4. Human NPT4 was expressed from the vector pcDNA3.1/GS (Invitrogen). The expression in COS-1 cells and the immunofluorescence study showed an endoplasmic reticulum (ER) localization. The high homology of NPT3 and NPT4 and the analysis of the putative aminoacid sequence points to an ER localization also for NPT3. The genomic structure showed 11 exons in NPT3 and 10 exons in NPT4. The deficiency of a microsomal phosphate transporter in liver, kidney and intestine has been suggested as the biochemical basis of glycogen storage disease type Ic (GSDIc), but mutations in phosphate transporters have not been found yet. We sequenced NPT3 and NPT4 in DNA from six patients affected by GSDIc in whom mutations in both glucose-6-phosphatase (G6Pase) and G6PT genes had not been found. One patient was heterozygous for a G to A transition at nucleotide 920 determining the glycine 307 be replaced by an arginine, in NPT4. In NPT3, a different patient was heterozygous for a C to T transition at nucleotide 1527 determining the serine 509 be replaced by a leucine and two alterations were also detected in the intronic regions in three patients. These alterations were not detected in 10 controls. These results are not conclusive to confirm or exclude the involvement of NPT3 and NPT4 in GSDIc. However, our studies suggest a role of NPT3 and NPT4 in the regulation of phosphate availability in the ER. Presumably, high concentration of phosphate inhibits the G6Pase. The existence of GSDIc patients with mutations in NPT3 and NPT4 suggests a regulatory function of these transporters on G6Pase system.

**Determination of the complete DNA sequence of the human phenylalanine hydroxylase gene.** *D.S. Konecki, U. Lichter-Konecki.* Medical Genetics Branch, NHGRI/NIH, Bethesda, MD.

Classical phenylketonuria (PKU), an inborn error of amino acid metabolism, is inherited in an autosomal recessive manner and usually results from a deficiency of the enzyme phenylalanine hydroxylase (PAH). A cDNA encoding the human PAH enzyme was isolated and characterized in the laboratory of S.L.C. Woo at Baylor College of Medicine in 1983. The PAH gene structure was also determined in the Woo laboratory and published in 1986. Since that time more than 300 mutations in the PAH gene have been documented to result in PKU and a number of studies have been published increasing the understanding of the regulation of this gene. An obvious absence from this research landscape has been the complete sequence of the human PAH gene. We first began generating and collecting PAH gene sequences in 1984. During the last two years we have been involved in a dedicated effort to determine the complete sequence of the human PAH gene through the use of random and directed sequencing approaches applied to isolated human lambda and BAC genomic recombinants containing the gene. More than 1000 sequence reads from subcloned genomic fragments and sequences directed by 426 PAH gene-specific primers are included in the ~79kbp PAH gene sequence. The entire length of the finished genomic sequence encompassing the human PAH gene is ~171kbp in length and extends ~27kbp upstream of the transcription initiation site in the first exon and terminates ~64.5kbp downstream of the poly(A) addition site located in the last exon of the gene (exon 13). Also included are PAH genomic sequences obtained from the NCBI sequence databases. It is anticipated that the completed sequence of the human PAH gene will be of value to the PAH/PKU research community and to investigators studying genetic diversity through variations in the human PAH gene.

**Mitochondrial Trifunctional Protein Defects and Sudden Infant Death Syndrome.** *Z. Yang, P. Lantz, Y. Zhao, J.A. Ibdah.* Wake Forest University School of Medicine.

Background: Infants with fatty acid oxidation (FAO) disorders may die suddenly and unexpectedly, and, if appropriate investigations are not conducted, may meet the criteria for sudden infant death syndrome (SIDS). Biochemical studies have suggested that »5% of all SIDS cases have FAO defects. The objective of this study is to characterize the association between defects in the mitochondrial trifunctional protein (MTP) and SIDS in families with documented MTP mutations and in SIDS cases with fatty infiltration of the liver. MTP is the enzyme complex that catalyzes the last 3 steps of long chain FAO. Methods: We analyzed the pediatric history and genotypes in 34 families with documented MTP mutations. We also reviewed the histopathological changes in 120 SIDS cases certified by the regional Medical Examiner. Cases with fatty infiltration of the liver were screened for mutations in MTP. Results: In families with MTP defects, 13/34 (38%) of the affected children died. Four deaths were sudden, and initially unexplained at 4-8 months of age. Autopsy revealed diffuse micro- and macro-vesicular hepatic steatosis. All were homozygous for the common G1528C (E474Q) mutation. In five families there was a history of sudden and unexplained death in a sibling of an unknown genotype. Our retrospective analysis in SIDS cases revealed diffuse micro- and macro-vesicular hepatic steatosis in 13/120 (»11%) cases. Molecular analysis identified 1/13 (»8%) with compound heterozygosity for MTP defects. The first mutation was the common G1528C mutation. The second mutation was a 1-bp deletion at position 1967 (1967T) in exon 18, which causes a stop codon and a premature termination. Additional screening for the common G985A mutation in medium chain acyl-CoA dehydrogenase (MCAD) revealed homozygosity in another case and heterozygosity in two. Conclusions: MTP defects cause sudden unexpected death and account for a significant proportion of SIDS cases with fatty infiltration of the liver. We recommend screening for FAO defects in SIDS cases with fatty infiltration of the liver. (Supported by a grant #6-FY99-376 from March of Dimes).

**Molecular basis of autosomal recessive desmosterolosis.** R. Waterham<sup>1,2</sup>, J. Koster<sup>1</sup>, G.J. Romeijn<sup>1</sup>, P. Vreken<sup>1</sup>, R.C.M. Hennekam<sup>2</sup>, H.C. Andersson<sup>3</sup>, D. FitzPatrick<sup>4</sup>, R.I. Kelley<sup>5</sup>, R.J.A. Wanders<sup>1,2</sup>. 1) Lab Gen Metabolic Dis (FO-224), Acad Med Center/Univ Amsterdam, Amsterdam, Netherlands; 2) Dept. of Pediatrics, Acad Med Center, Amsterdam, Netherlands; 3) Tulane University School of Medicine, New Orleans, USA; 4) MRC Human Genetics Unit, Western General Hospital, Edinburgh, UK; 5) Kennedy Krieger Institute, Baltimore, USA.

Recent years, several inherited disorders have been linked to enzyme defects in the isoprenoid (cholesterol) biosynthetic pathway by the finding of abnormally increased levels of intermediate metabolites in patients followed by the demonstration of disease-causing mutations in genes encoding the implicated enzymes [refs 1-4 for reviews]. Most currently known enzyme defects in the pathway specifically affect cholesterol biosynthesis and lead to multiple congenital anomalies, and/or skeletal and skin abnormalities underlining cholesterol's pivotal role in embryogenesis/morphogenesis. We now report the molecular basis of autosomal recessive desmosterolosis (MIM 602398), a severe multiple congenital anomaly syndrome. Affected patients have elevated levels of desmosterol in tissues, plasma and cultured cells, indicating a deficiency of 3 $\beta$ -hydroxysterol D<sup>24</sup>-reductase (DHCR24), the enzyme catalysing the reduction of the C24-C25 (D<sup>24</sup>) double bond of cholesterol precursors including desmosterol. By similarity searching using a candidate gene of the plant *Arabidopsis thaliana*, we identified the gene encoding human DHCR24 (*DHCR24* at chr. 1) as demonstrated by expression in yeast. Sequence analysis of *DHCR24* in genomic DNA of two patients with desmosterolosis identified four different missense mutations confirmed to be disease-causing by expression in yeast and revealing a clear genotype-phenotype correlation. Our results demonstrate that mutations in *DHCR24* cause desmosterolosis. {Supported by a fellowship of the Royal Netherlands Academy of Sciences to HRW}

**Biochemical and molecular analysis of a patient with Congenital Disorder of Glycosylation type Ia.** *T.C. Wood<sup>1</sup>, D. Flannery<sup>2</sup>, J. Kottra<sup>3</sup>, J. Longshore<sup>1</sup>, H. Taylor<sup>1</sup>.* 1) Greenwood Genetic Ctr, Greenwood, SC; 2) Department of Pediatrics, Medical College of Georgia, Augusta, GA; 3) Eisenhower Army Hospital, Augusta, GA.

Congenital disorder of glycosylation (CDG) comprise a group of inherited disorders caused by defects in N-glycosylation. The most common type, CDG Ia, results from a deficiency of phosphomannomutase (PMM) that normally converts mannose-6-phosphate to mannose-1-phosphate. Clinically CDG Ia patients can present with strabismus, psychomotor retardation, retinitis pigmentosa, dysmorphic features, inverted nipples, and abnormal fat pads. Screening for CDG is usually performed with serum transferrin and diagnosis of CDG Ia is made by measuring PMM activity. The phosphomannomutase gene (PMM2) has been isolated and mutational analysis has been performed on a number of patients. We report on a patient referred because of growth failure, strabismus, muscle spasms, inverted nipples, and an accumulation of fat above the hips. Capillary electrophoresis of the patients serum showed a change in the transferrin sialoform pattern, consistent with CDG. Sequencing analysis of the PMM2 gene identified three changes in the coding region: G42R, I153T, and E197A. The latter two changes have been identified as causative mutations in other CDG Ia patients, however G42R has not been previously reported. The glycine involved in the G42R mutation is conserved between the human and *Drosophila melanogaster* PMM proteins, and this change has not been noted in the other CDG Ia patients in which the PMM2 gene has been sequenced. Studies are currently underway in an attempt to determine if this change is a polymorphism. Analysis of the patients parents found the father to carry the I153T allele while the mother carries both the G42R and E197A alleles. Because both the G42R and E197A alleles were passed from the mother, and because she is healthy, we suggest that they are located on the same chromosome, in cis position, in the proband.

**Kelley-Seegmiller syndrome as a novel cause of gout in a female patient.** *I. Sebesta<sup>1,2</sup>, L. Dvorakova<sup>1</sup>, M. Kumsta<sup>2</sup>, B. Stiburkova<sup>1</sup>, S. Kmoch<sup>1</sup>, J.A. Duley<sup>3</sup>, H.A. Simmonds<sup>3</sup>.* 1) Inst.Inher.Metab.Dis; 2) Inst.Clin.Biochem., 1st Fac.Med., Charles Univ., Prague, Czech Republic; 3) Purine Research Unit, Guy's Hospital, London, UK.

Partial deficiency of hypoxanthine-guanine phosphoribosyltransferase (HPRT) described as Kelley-Seegmiller (KS) syndrome is an X-linked recessive genetic defect associated with overproduction of uric acid. Complete HPRT deficiency (Lesch-Nyhan syndrome) results in severe neurological symptoms and urate overproduction. KS syndrome generally presents later with gout and/or urolithiasis and has been reported exclusively in males. Female carriers have somatic cell mosaicism of HPRT activity, and are healthy. We have found a girl with partial HPRT deficiency. She presented at the age of 9 years with gouty arthritis of big toe and hyperuricaemia. No evidence of neurological involvement was found. At the age of 16 years she was referred for purine metabolic investigation. Activity of phosphoribosylpyrophosphate synthetase in erythrocytes was normal. Absence of HPRT activity, together with raised activity of adenine phosphoribosyltransferase in lysed erythrocytes and raised concentration of nicotinamide adenine dinucleotide in erythrocytes confirmed partial HPRT deficiency. The loss of HPRT activity was found in the girl's father, who has suffered renal colic and gout since the age of 18 years. The father's brother also has the same clinical and biochemical findings. Molecular genetic analysis revealed a missense mutation in the patient and her father. It is a T→C transition at position 158 of the cDNA that changes codon for valine to alanine (V53A). This mutation has also been described in a male patient with partial HPRT activity (K.Sege-Peterson et al,1992, Hum.Mol.Gen. 1:427-32). X chromosome inactivation studies are in progress. This unusual and first description of partial HPRT deficiency in a female enlarges the differential diagnosis of hyperuricaemia and/or gout in females and underlines the need to perform purine metabolic investigations in such findings. Gout in the young should always be investigated.(Supported by grants:EC BMH4-CT98-3079;MSM - 111100005, Czech ME and IGA MH NE 6559-3-01).

**Pediatric reference ranges for delta-aminolevulinic acid(ALA), porphobilinogen(PBG), and fractionated porphyrins in urine.** *D. Salazar, L. Guerrero, J.E.S. Lee.* Dept Biochemical Genetics, Quest Diagnostics Nichols Inst, San Juan Capist, CA.

**Introduction:** Most genetic forms of porphyria are inherited as autosomal dominant, leading to a heterozygous state in the majority of patients. Individuals most often manifest at or after puberty; thus, porphyrias are generally thought of as adult disorders. Since individuals do sometimes present during childhood, we developed pediatric reference ranges based on random urine specimens rather than the more-difficult-to-collect 24-hour urine specimens.

**Methods:** Random urine samples were collected from 95 apparently healthy, ambulatory children: 47 females, 48 males, ages 1-17.9 years. Children with chronic illness or an acute illness of longer than 2 weeks duration were excluded from the study. Samples were light protected and frozen at -70°C prior to analysis. ALA and PBG were analyzed using kits from Bio-Rad Laboratories (Hercules, CA). Porphyrins were fractionated by HPLC and detected by fluorescence.

**Results:** ALA, PBG and fractionated porphyrin levels were independent of sex, but not age. The ALA reference range is 2.3-6.2 mg/g Cr for 1.0-8.9 years and 1.5-5.3 mg/g for 9.0-17.9 years. The PBG reference range is 0.9-2.8 mg/g Cr for 1.0-8.9 years and 0.5-2.0 mg/g Cr for 9.0-17.9 years. The fractionated porphyrin reference ranges are 4.3-16.2 mg/g Cr for uroporphyrin, <4.6 mg/g for heptaporphyrin, not detected for hexaporphyrin, <3.2 mg/g for pentaporphyrin, 10.1-254.7 mg/g for coproporphyrin and 17.0-269.7 mg/g for total porphyrins at 1.0-10.9 years. The reference ranges for 11.0-17.9 years are 4.6-18.9 mg/g Cr for uroporphyrin, <4.6 mg/g for heptaporphyrin, not detected for hexaporphyrin, <3.0 mg/g for pentaporphyrin, 11.8-107.2 mg/g for coproporphyrin, and 16.4-121.5 mg/g for total porphyrins.

**Conclusion:** Concentrations in the pediatric population are generally higher than in the adult population. Thus, these reference ranges will be useful for diagnosing porphyria in the pediatric population.

**A novel common mutation in OCTN2, carnitine transporter gene, in Southern Chinese patients with primary carnitine deficiency.** *N.L.S. Tang<sup>1</sup>, W.L. Hwu<sup>2</sup>, R.T. Chan<sup>3</sup>, S.L.M. Fung<sup>1</sup>, L.K. Law<sup>1</sup>.* 1) Department of Chemical Pathology, The Chinese University of Hong Kong, Hong Kong; 2) Department of Medical Genetics, National Taiwan University Hospital, Taiwan; 3) Department of Pediatrics and Neonatology, Centro Hospitalar Conde S. Januario, Macau.

Mutations in OCTN2, encoding for the plasma membrane carnitine transporter cause primary carnitine deficiency. After our first report of mutations in Chinese, we collected other Chinese families with the disease for mutation analysis. Two families were recruited from Taiwan and one family was from Macau. All patients are Southern Chinese, originating from Canton Province. The parents of these families were non-consanguineous and unrelated. Mutation analysis was performed by PCR of all ten exons and PCR products were directly sequenced. Two novel truncating mutations were detected. A single base mutation (C to T) was found at cDNA position 981 of codon 254 (CGA->TGA). Another mutation was at codon 387 (TAT->TAG). Two probands, one each from Taiwan and Macau, were homozygote for R254X. The other proband from Taiwan carried R254X and Y387X. Analysis of samples from parents or siblings indicated that the mutations were inherited but not sporadic mutation. Two heterozygote carriers of R254X were also identified among 250 control subjects, while none was detected from Y387X. It suggests that the population carrier rate for R254X was around 1/125. Haplotype of R254X was determined with three intragenic polymorphisms, including silent polymorphisms of codon 95 and 269, and an intron polymorphism, ivs4+13C/T. All five chromosomes carrying R254X showed the same haplotype on these markers. Analysis of population allele frequencies of these markers indicates the chance of these five chromosomes with R254X arising independently was less than 0.05. This study revealed novel mutations in OCTN2 found in the Southern Chinese population. The R254X may be a founder mutation and its carrier frequency in the general population may be about 1 in 125. The predicted disease prevalence due to R254X alone would be 1 in 60,000 suggesting primary carnitine deficiency is a relatively common inherited metabolic disease in the locality.

**A novel defect of N-glycan synthesis.** *F. Scaglia<sup>1</sup>, J.L. Northrop<sup>1</sup>, C.N. Ou<sup>2</sup>, D.G. Patel<sup>3</sup>, M.A. Gilger<sup>3</sup>, S.J. Karpen<sup>3</sup>, V. Westphal<sup>4</sup>, H.H. Freeze<sup>4</sup>.* 1) Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX; 2) Dept Pathology, Baylor Col Medicine, Houston, TX; 3) Dept Pediatrics, Baylor Col Medicine, Houston, TX; 4) The Burnham Institute, La Jolla, CA.

The congenital disorders of glycosylation (CDGs) are autosomal recessive disorders, with a spectrum of neurologic and multisystemic manifestations caused by defective N-glycosylation. Different types of CDGs can be recognized by altered isoelectric focusing patterns of serum transferrin. We report a 10 month-old male infant with protein losing enteropathy, liver disease, coagulopathy and developmental delay. He initially came to medical attention at 6 weeks of age with the symptoms of diarrhea and hypoalbuminemia. During his hospital course he developed protein losing enteropathy, hypotonia and liver disease. His condition was complicated by anasarca, seizures, and severe coagulopathy. In addition, he developed hypothyroidism, cataracts and decreased bone mineralization that led to fractures. Due to onset of seizure activity, a brain MRI was obtained and it revealed brain volume loss and a diffuse leukoencephalopathy with no cerebellar hypoplasia. Genetics was consulted and a congenital disorder of glycosylation was considered. A diagnosis of CDG type I was made on an abnormal serum transferrin isoelectric focusing pattern. Normal phosphomannomutase and phosphomannose isomerase activities in leukocytes ruled out CDGs type Ia and type Ib. CDG type Ic was excluded based on the sequencing of the ALG6 gene. CDGs type Id and type Ie were ruled out based on biochemical analyses and sequencing of the DPM1 gene respectively. Evaluation for the cause of CDG type If is currently underway with cDNA sequencing analysis of MPDU1 and *in vitro* studies of the synthesis of N-linked glycans in fibroblasts to identify the defective enzyme. It is important to increase awareness of these disorders since many patients with glycosylation defects probably remain undiagnosed. This case report shows that the association of protein losing enteropathy, coagulopathy and liver dysfunction is not necessarily associated only with CDG type Ib and that the spectrum of this type of disorders continues to expand.

**A NOVEL MUTATION OF THE ALPHA-GALACTOSIDASE A GENE IN A FAMILY WITH A JUVENILE-ONSET FORM OF FABRY DISEASE.** *Y.S. Shin*<sup>1</sup>, *T. Podskarbi*<sup>2</sup>. 1) Pediatrics, University of Munich, 80337 Munich, Germany; 2) Molecular Genetics and Metabolism Laboratory, Munich, Germany.

Fabry disease is an X-linked metabolic disease which is caused by deficiency of the lysosomal alpha-galactosidase A. The disease results in the progressive globotriaosylceramide (GL-3) accumulation primarily in vascular endothelium. We report here a German male with typical changes of Fabry disease mainly in the skin and eyes. Even though leading cardio-, vaso-, reno-, oculo- and cutaneous symptoms were there since early childhood, the diagnosis of Fabry disease has been delayed until his first visit to the hospital at the age of 22 years. The alpha-galactosidase A activity in leukocytes was significantly decreased (0.02 nmol/min/mg protein; mother: 0.35; normal range: 0.4-1.2). The sequence analysis of the alpha-galactosidase A gene revealed the hemizygous transition in the position c.1038T>C yielding the amino acid exchange of cysteine to arginine in the codon 347 (C347R) in the patient as well as in the mother. This missense mutation possibly encodes the slight residual activity found in the patient. The molecular genetic analysis provides the definitive diagnosis of female carriers, since some heterozygotes are symptomatic and the enzyme activity values of leukocytes are not always clearly distinguishable from those of normal controls.

**Missense model of MPS VII produced by targeted mutagenesis: Genotype/phenotype correlation and immune tolerance.** *S. Tomatsu*<sup>1,2</sup>, *K. Orii*<sup>1,2</sup>, *J.H. Grubb*<sup>1</sup>, *E.M. Snella*<sup>1</sup>, *C. Vogler*<sup>3</sup>, *W.S. Sly*<sup>1</sup>. 1) Department of Biochemistry and Molecular Biology, Saint Louis University School of Medicine, St. Louis, MO; 2) Department of Pediatrics, Gifu University, Gifu, Japan; 3) Department of Pathology, Saint Louis University School of Medicine, St. Louis, MO.

MPS VII is an autosomal recessive disease caused by b-glucuronidase deficiency, leading to a wide range of clinical phenotypes from the most severe hydrops fetalis type to mild types without mental retardation. To study missense mutant MPS VII models with phenotypes of varying severity, we produced L176F (the commonest human mutation) and E540A and E540Q (active site nucleophile replacement) mouse models. The E540A mouse has no GUSB activity and displays a severe phenotype like the original MPS VII mouse. Both L176F and E540Q show levels of residual activity below 0.5% and milder phenotypes. All three revealed progressive vacuolar storage in many tissues, with rate and extent of accumulation correlating with severity. These missense models should be useful in studying pathogenesis due to specific point mutations. Cellular and humoral immune responses have been recognized as impediments to enzyme replacement and gene therapy strategies. To solve this issue for evaluating long-term effectiveness and side effects of therapies for MPS VII, we introduced both the hGUSB E540A cDNA transgene into intron 9 and the active site E540A mutation into the endogenous GUS gene. These mice have no b-glucuronidase activity, and show the full MPS VII phenotype. However, ubiquitous expression of the inactive hGUSB produced tolerance to immune challenge with hGUSB. This provides a model to study long-term administration of hGUSB, the likely form of enzyme for human clinical trials, and for gene therapy with vectors expressing hGUSB.

**Medium-chain acyl Co-A dehydrogenase deficiency: identification and characterization of three novel mutations.**

*B-Z. Yang, M.R. Mysliwiec, J-H. Ding, C.R. Roe.* Inst Metabolic Disease, Baylor Univ Medical Ctr, Dallas, TX.

Medium-chain acyl-CoA dehydrogenase (MCAD) deficiency is the most common inherited defect of fatty acid oxidation characterized by fasting intolerance, which may lead to hypoglycemia, coma, and sudden death. Most children present with acute illness between three and 15 months of age. A common mutation A985G has been identified among patients with MCAD deficiency, which accounts for 88.9 percent of the mutant allele. In this study, we report three novel mutations identified in three unrelated patients with MCAD deficiency. The diagnoses were based on plasma acylcarnitine profile, which showed highly elevated octanoyl carnitine, indicating MCAD deficiency. Using our Multiple Specific Fluorescent Primer Extension (MSFPE) assays to screen all known-mutations, only one A985G mutant allele was identified in each patient. To investigate the second mutant allele, all of MCAD exons from patients' DNA were amplified and sequenced. Sequence analysis revealed a novel A503G mutation in patient 1 and his mother, resulting in an Aspartic Acid to Glycine substitution at codon 158 (D158G) in one allele. Patient 2 was compound heterozygous for the common mutation A985G and a novel mutation, a single T insertion at nucleotide position 245. Patient 3 was also compound heterozygous for the A985G mutation and a novel mutation C250T, which results in a Leucine to Phenylalanine substitution at codon 84 (L84F). In addition, the frequency of the A985G mutant allele as well as other mutations in 35 new patients with MCAD deficiency are briefly discussed.

**Mutations in BCS1, a mitochondrial respiratory chain assembly gene, are responsible for complex III deficiency in patients with tubulopathy, encephalopathy and liver failure.** *P. de Lonlay<sup>1,5</sup>, I. Valnot<sup>1</sup>, A. Barrientos<sup>2</sup>, M.*

*Gorbatyuk<sup>2</sup>, A. Tzagoloff<sup>2</sup>, J.W. Taanman<sup>3</sup>, D. Chretien<sup>1</sup>, N. Kadhom<sup>1</sup>, A. Lombes<sup>4</sup>, H. Ogier de Baulny<sup>6</sup>, P. Niaudet<sup>5</sup>, A. Munnich<sup>1</sup>, P. Rustin<sup>1</sup>, A. Rotig<sup>1</sup>.* 1) INSERM U393, Hosp Necker-Enfants Malades, Paris, France; 2) Department of Biological Sciences, Columbia University, New-York, USA; 3) Royal Free and University College Medical School, Department of Clinical Neurosciences, London, UK; 4) INSERM U523, Institut de Myologie, Paris, France; 5) Departement de Pediatrie, Hosp Necker-Enfants Malades, Paris, France; 6) Service de Neuropediatrie, Hosp Robert-Debre, Paris, France.

Complex III (CIII, ubiquinol cytochrome c reductase) of the mitochondrial respiratory chain catalyzes electron transfer from succinate and NAD-linked dehydrogenases to cytochrome c. CIII is made up of 11 subunits of which all but one (cytochrome b) are encoded by nuclear DNA (nDNA). CIII deficiencies cause a variety of clinical symptoms including myopathy, cardiomyopathy and tubulopathy. Although pathogenic mutations in the mitochondrial cytochrome b gene have been occasionally described, no mutations in the nuclear DNA-encoded catalytic subunits have been hitherto reported in CIII deficiency. This suggests that most non-maternally transmitted disease-causing mutations lie in gene products affecting assembly of the complex. Various nuclear genes have been involved in assembly of yeast CIII. Up till now however only one such gene, BCS1, has been identified in the human genome. BCS1 represents therefore an obvious candidate gene in CIII deficiency. Here, we report BCS1 mutations in six patients, from four unrelated families, presenting neonatal proximal tubulopathy and hepatic involvement. Complementation studies in yeast confirmed the deleterious nature of these mutations. In addition to being the first reported nuclear gene responsible for isolated CIII deficiency, this gene is apparently a frequent cause of CIII deficiency, as one third of our complex III-deficient patients carried BCS1 mutations.

**A mutation in mitochondrial DNA encoded cytochrome c oxidase II gene in a child with Alpers-Huttenlocher - like syndrome.** *S. Finnila*<sup>1,2,5</sup>, *J. Uusimaa*<sup>2,3,5</sup>, *L. Vainionpää*<sup>3</sup>, *R. Herva*<sup>4</sup>, *H. Rantala*<sup>3</sup>, *I.E. Hassinen*<sup>2</sup>, *K.*

*Majamaa*<sup>1,2,5</sup>. 1) Department of Neurology, University of Oulu, Oulu, Finland; 2) Department of Medical Biochemistry, University of Oulu, Oulu, Finland; 3) Department of Pediatrics, University of Oulu, Oulu, Finland; 4) Department of Pathology, University of Oulu, Oulu, Finland; 5) Biocenter, University of Oulu, Oulu, Finland.

Defects in mitochondrial oxidative phosphorylation are common causes of unexplained childhood encephalomyopathies, but the common mitochondrial DNA mutations are rarely found in these patients. We detected a combined defect in respiratory chain complexes I and IV in a girl with psychomotor retardation, hypotonia, fatty liver, cardiomyopathy and lactic acidosis. The disease proved fatal at the age of 6 years 8 months. Postmortem histological examination revealed a marked loss of neurons in the olivary nuclei and a spongy change in the calcarine cortex, fatty infiltration and micronodular cirrhosis of the liver and atrophic ovaries. Determination of the sequence of the entire coding region of mitochondrial DNA showed a novel heteroplasmic 7706G>A mutation in the cytochrome c oxidase subunit II. The median degree of the mutant heteroplasmy in five tissues was 90 %. The degree of the mutant heteroplasmy was 87 % in the blood of the proband, 72 % in the blood of probands asymptomatic mother and 66 % in the blood of probands asymptomatic grandmother. The 7706G>A mutation converts a hydrophobic alanine in a highly conserved transmembrane segment to hydrophilic threonine. We suggest that the 7706G>A mutation is pathogenic and leads to defective assembly of cytochrome c oxidase by disrupting a hydrophobic-hydrophobic interaction between subunits II and VIc. The clinical phenotype of this patient resembled that in Alpers-Huttenlocher disease suggesting that analysis of mitochondrial DNA may be worthwhile in patients with a progressive cerebrohepatic disease.

**Comparison studies in four different mutations located in the ATPase 6 gene.** *R. Carozzo<sup>1</sup>, O. Capuano<sup>1</sup>, M.E. Vazquez-Memije<sup>2</sup>, G. Chichierchia<sup>1</sup>, F.M. Santorelli<sup>1</sup>.* 1) Molecular Medicine Unit, Bambino Gesù Hosp, Rome, Italy; 2) Unidad de Investigación Genética Humana, Hospital de Pediatría, Centro Médico Nacional-IMSS, Mexico City, Mexico.

The F1F0 ATP Synthase is present in the bacterial plasma membrane, chloroplast thylakoid membrane and mitochondrial cristal membrane, this enzyme is responsible for most of the ATP cellular production. In mammals, two subunits of the F0 portion, A6 and A6L, are mtDNA encoded. Mutations in the ATPase 6 gene have been associated with MILS (maternally inherited Leigh syndrome) and with NARP (neuropathy, ataxia, retinitis pigmentosa). Evidence from family studies suggest that the T8993G (resulting in L156R) and T9176G (resulting in L217R) mutations result in more severe clinical phenotype than their allelic mutations, T8993C (L156P) and T9176C (L217P), respectively. To obtain clues as for the different pathogenic mechanisms leading to diverse clinical severity, we compared cellular ATP production, cell growth and entity of cellular response upon use of metabolic stressors (i.e., galactose, with or without oligomycin) in primary cell cultures obtained from patients harboring either the L156R, or L156P, or L217R, or L217P. We also analyzed clonal cells obtained after fusion of the abovementioned primary cultured cells with an osteosarcoma cell line, experimentally devoided of mtDNA. Clones harboring different percentage of mutated mtDNA molecules were selected for our studies. Our preliminary data suggest various levels of ATP production in the four cell lines, in agreement with the different clinical phenotype. Cell growth data showed a more severe effect in the mutations in which arginine substituted for leucine. The L156P mutation did not seem to be significantly affected after 5 days of treatment when galactose (+/- oligomycin) was substituted for glucose. This was not the case of L156R mutation.

**A mouse model of mitochondrial encephalopathy.** *W.J. Craigen, E. Weeber, M.J. Sampson, K. Anflous, M. Levy, D. Armstrong, J.D. Sweatt.* Dept Molec/Human Gen, Dept Path, and Div Neuroscience Baylor Col Medicine, Houston, TX.

The molecular basis for heritable mental retardation is poorly understood and undoubtedly multifaceted. In the case of mitochondrial disorders, mental retardation is common and not amenable to therapy. Possible mechanisms include reduced ATP production, alterations in calcium homeostasis, increased reactive oxygen species, or abnormal nitric oxide formation, amongst others. There is a paucity of animal models of mental retardation, regardless of the cause, yet animal models are needed to investigate and validate novel therapies for such complex phenotypes. We have generated mice lacking the major pathway across the mitochondrial outer membrane, the porin proteins VDAC1 and VDAC3, either as single locus or double locus mutants, and characterized the behavioral phenotypes of these mice. Two forms of learning were investigated using a standardized battery of tests; associative and spatial learning. All sensory parameters were normal. Each mouse strain exhibited distinct abnormalities in fear conditioning, a measure of associative learning, while all mutant mice failed to navigate the Morris water maze, reflecting defects in higher order learning and memory. To search for molecular correlates of these deficits, aspects of synaptic plasticity were measured in hippocampal slices using standard electrophysiologic protocols. Again, distinct abnormalities were found. By measuring paired pulse facilitation (PPF), VDAC3 deficient mice were demonstrated to have a pre-synaptic defect in neuronal plasticity. In contrast, VDAC1 deficient mice exhibited normal pre-synaptic function but abnormal post-synaptic function, as reflected in a reduction in the ability to generate long term potentiation (LTP). Double mutant slices demonstrated more pronounced defects in both PPF and LTP. These results demonstrate that there are distinguishable neuronal functions associated with each VDAC isoform, and that VDACS play an important role in learning, memory, and synaptic plasticity. These mice may serve as a model for mental retardation associated with mitochondrial dysfunction.

**Feasibility of using paraffin blocks for mitochondrial DNA mutation analysis.** *S.H. Kim<sup>1</sup>, S.H. Yoo<sup>1</sup>, J.G. Chi<sup>2</sup>*. 1) Dept.of Biology, College of Natural Sciences, Taegu Univ, Kyungsan 712-714, South Korea; 2) Dept.of Pathology, Seoul National University College of Medicine, Seoul 110-799, South Korea.

We investigated feasibility of using the formalin-fixed and paraffin-embedded tissue to study mitochondrial DNA mutations in the case that the fresh or frozen tissue, or blood samples are not available. 10 paraffin blocks of muscle biopsies in patients who had previously shown to have symptoms of mitochondrial disorder were chosen at random. These blocks had been processed between 1988-1996. Total DNA was extracted from these blocks and PCR amplification was carried out using the 24 standard DNA primer pairs for whole mitochondrial genome amplification used by other investigators and another primer pairs made by us. The size of the PCR product was between 800-1,600 bp. We could detect PCR products more than 800bp in length in many instances, although some investigators have reported the existence of limits to the size of fragments that can be amplified from such materials. The mitochondrial genome of our paraffin blocks is presumably in good condition (i.e. not much degraded than expected), since we could amplify up to 80% of whole mitochondrial genome in many cases. We could not confirm the presence of uncharacterized inhibitors of PCR reported by other investigators. The 3243 A to G MELAS mutation was confirmed in two PCR-amplified fragments by RFLP and sequencing. Our results are in accordance with the previous findings by other investigators that PCR allows molecular genetic analysis of paraffin-embedded tissues stored in most histopathology laboratories.

**Mitochondrial Myopathies: a South African perspective.** *A. Olckers<sup>1</sup>, D. Prosser<sup>1</sup>, D.C. Wallace<sup>2</sup>, M.D. Brown<sup>2</sup>, I. Smuts<sup>1</sup>.* 1) University of Pretoria, Pretoria, South Africa; 2) Emory University, Atlanta, USA.

Mitochondrial myopathies are the most frequent cause of metabolic abnormalities in the paediatric neurology population (Zeviani et al., 1996). Two recent studies estimate the prevalence of mitochondrial myopathies to be 1:15 000 in the adult English (Chinnery et al., 2000) and 1:11 000 in the paediatric Swedish (Darin et al., 2001) populations respectively. In this study a group of 42 paediatric patients who presented with phenotypes suspected to be due to a mitochondrial aetiology, were included. Patients were screened for ten of the most frequent mtDNA mutations that cause MELAS, MERRF or Leigh Syndrome. RFLP or Single Stranded Sequence analyses were utilised to detect the presence of the respective mutations. In 21 patients all twenty-two mitochondrial tRNA encoding genes were sequenced. Full-length mtDNA sequences were generated for six patients. The presence of one reported mutation (A3243G) has been verified in a single proband. Upon investigation this mutation was also detected in her mother and sister, but was found to be absent in her other maternal relatives. In the three individuals harbouring this mutation different levels of heteroplasmy was observed. To date, none of the other reported mtDNA mutations have been observed in this group of South African paediatric patients who have been well characterised on the clinical level.

**Antenatal manifestations of mitochondrial respiratory chain deficiency.** *J.C. Von Kleist-Retzow<sup>1,2</sup>, P. de Lonlay-Debeney<sup>1</sup>, V. Cormier-Daire<sup>1</sup>, G. Viot<sup>1</sup>, J. Amiel<sup>1</sup>, P. Rustin<sup>1</sup>, A. Rötig<sup>1</sup>, A. Munnich<sup>1</sup>.* 1) INSERM U393, Hosp Necker, Paris, France; 2) Pediatric Clinic, University Cologne, Germany.

Antenatal manifestations of respiratory chain deficiency have not been hitherto described. Reviewing the clinical features of 300 patients with proven respiratory chain deficiency, we found that 20% had intrauterine growth retardation (IUGR). Most children were born at (or close to) term and macrosomia, hydramnios or oligoamnios with fetal immobility were rarely noted. Hydrops fetalis was frequently observed during pregnancy of children who further developed Pearson syndrome. Interestingly, a number of malformations of various types were noted namely cerebral malformations (agenesis or hypoplasia of the corpus callosum, cerebellar hypoplasia), gastrointestinal malformations (duodenal atresia, duplication of the choledochus, agenesis of the gallbladder), renal malformations (dilatation of pyelocalicial cavities and the bladder) and craniofacial dysmorphism. Round face, high forehead, flat philtrum, low set ears, short neck, ear dysplasia characteristic for CHARGE association and an incomplete VATER association were occasionally observed in our series. Other malformations included cardiomegaly and supraventricular tachycardia in the third trimester. Similarly, echo doppler may occasionally provide important information. Indeed, a boy with complex I deficiency had IUGR, hypertrophic cardiomyopathy and Leigh syndrome in his first year of life. Retrospective analyses revealed the presence of enlarged ventricles with bilateral porencephalic cysts in the germinal matrix and reduced cerebral blood flow in the brainstem consistent with vascular injury at 22 weeks of gestation. This study suggests that the antenatal manifestations of respiratory chain deficiencies have been largely overlooked and give strong support to the early intrauterine expression of the disease-causing genes in mitochondrial diseases.

Program Nr: 1809

**Molecular analysis of the SURF-1 gene associated with Leigh syndrome within the South African paediatric population: a pilot study.** *D. Prosser<sup>1</sup>, I. Smuts<sup>1</sup>, M.D. Brown<sup>2</sup>, D.C. Wallace<sup>2</sup>, A. Olckers<sup>1</sup>.* 1) University of Pretoria, South Africa; 2) Emory University, Atlanta, USA.

Leigh syndrome (LS) is a devastating neurological disorder which has onset during the first two years of life. The clinical manifestations of LS include psychomotor regression, brainstem abnormalities and lactic acidosis. To date three modes of inheritance have been described to be associated with LS. Maternal inheritance with mutations in the ATP6 gene of the mitochondrial genome, X-linked inheritance associated with mutations in the PDHA1 gene encoding the E1a subunit of the pyruvate dehydrogenase complex and autosomal inheritance. The latter is associated with mutations in the SURF-1 gene, localised to chromosome 9q34. The SURF-1 protein is responsible for maintenance of cytochrome c oxidase (Tiranti et al., 1998, and Zhu et al., 1998) Twelve patients diagnosed on both a clinical and biochemical level were included in this study. The mtDNA mutations T8993G/C and T9176C have been excluded as the cause of the phenotype observed in these patients. The SURF-1 analysis was performed via PCR of the nine exons, followed by SSCP and Heteroduplex (HEX) analyses. Aberrant fragments observed via SSCP-HEX were investigated via single stranded sequence analyses.

**Studies of pathogenesis in Farber disease.** *T. Muramatsu*<sup>1</sup>, *Y. Yamada*<sup>1</sup>, *N. Sakai*<sup>1</sup>, *H. Tsukamoto*<sup>1</sup>, *K. Isahara*<sup>2</sup>, *Y. Uchiyama*<sup>2</sup>, *K. Inui*<sup>1</sup>. 1) Dept of Pediatrics, Osaka Univ, Suita, Osaka, Japan; 2) Dept of Anatomy, Osaka Univ, Suita, Osaka, Japan.

Farber disease is a rare autosomal recessive sphingolipidosis caused by a deficiency of acid ceramidase, a lysosomal enzyme that normally catalyzes the hydrolysis of ceramide to sphingosine and free fatty acids. The disease is clinically characterized by swollen joints with limitation of movements, disseminated subcutaneous nodules and progressive cachexia. The storage material, ceramide, has attracted a great attention as an intracellular effector molecule in apoptosis. In this study we measured inflammatory cytokines in patients plasma and histologically examined the nodules. We found the slight increase of IL-6 but normal level of TNF-, and TUNEL positive staining cells in the nodules. The cells were co-stained with activated caspase-3 and CD68, and were identified as macrophages. The apoptotic changes were due to the activation of caspase 3 systems. We also screened gene expression in subcutaneous nodules and found expression several genes including caspase3, TGF-1, THF-, and MCP-1. Using cell lines derived from macrophage, mRNA expressions of NF-kB, TNF- and MCP-1 were increased with dose dependently by C2-ceramide addition into the culture medium. In Farber disease ceramide accumulation occur in lysosome and some ceramide escape to cell membrane, which induces production of some cytokines and apoptotic changes in macrophages. These events may partly explain the pathogenesis of Farber disease by the ceramide function as a second messenger.

**Expression of Arginase Isozymes in Mouse Brain.** *H. Yu*<sup>1,2</sup>, *R.K. Iyer*<sup>1,3</sup>, *R. Kern*<sup>2</sup>, *W. Rodriguez*<sup>1,2</sup>, *W.W. Grody*<sup>1,3,4</sup>, *S.D Cederbaum*<sup>1,2,4</sup>. 1) Mental Retardation Research Center; 2) Dept of Psychiatry; 3) Dept of Pathology and Laboratory Medicine; 4) Dept of Pediatrics; UCLA School of Medicine, Los Angeles, CA.

The two forms of arginase in man, identical in enzymatic function, are encoded in separate genes and are expressed differentially in various tissues. AI is expressed predominantly in the liver cytosol and is thought to function primarily to detoxify ammonia as part of the urea cycle. AII, in contrast, is predominantly mitochondrial and is more widely expressed, and is thought to function primarily, to produce ornithine. Ornithine is a precursor in the synthesis proline, glutamate and polyamines. Both forms of arginase are expressed at similar levels in both human and mouse brain. This study was undertaken to explore the cellular and regional distribution of AI and AII expression in brain using immunohistochemistry and in situ hybridization. It is the first step in a longer-term project to explore the perturbations of AII in the AI knockout mouse and those of AI in the AII knockout animal, and the biochemical implications of hyperargininemia on neural cell injury and apoptosis, nitric oxide synthesis and excitotoxic injury. AI and AII are detected only in neurons and are generally co-expressed in most cells studied. Expression is particularly high in cerebellar, brainstem and spinal cord neurons. Minor regional differences in AI and AII distribution may exist but are not dramatic. GAD (glutamic acid decarboxylase) 65 and GAD 67, postulated to be related to the risk of glutamate excitotoxic injury are similarly ubiquitous in their expression and generally parallel arginase expression patterns. Neither AI nor AII was seen in astrocytes, oligodendrocytes or white matter. Understanding differential arginase expression in brain is critical to understanding the function of the two isozymes, the pathogenesis of human AI deficiency and hence its treatment. The co-expression of the two isozymes, if present in different cellular compartments, may not necessarily represent overlapping and hence redundant function. The AI knockout mouse should provide an important additional tool in our quest and allow a more thorough dissection of the function of each isozyme.

***SUTAL* gene mutations causing Hermansky-Pudlak Syndrome Type-3 in a non-Puerto Rican family.** P. Anderson, D.L. Fitzpatrick, M. Huizing, Y. Anikster, W.A. Gahl. Section on Human Biochemical Genetics, HDB, NICHD, NIH, Bethesda, MD.

Hermansky-Pudlak syndrome (HPS) is a rare autosomal recessive disorder characterized by oculocutaneous albinism and a storage pool deficiency due to absence of platelet dense bodies. Lysosomal ceroid lipofuscinosis, pulmonary fibrosis, and granulomatous colitis are occasional manifestations of the disease. Patients can have HPS due to mutations in one of several different genes. *HPS1* mutations cause HPS-1 disease, with a relatively severe phenotype and a risk of pulmonary fibrosis. *ADTB3A* mutations cause HPS-2 disease, with relatively mild disease plus neutropenia. HPS-3 disease is caused by mutations in *SUTAL*, isolated after linkage mapping in a genetic isolate of mildly affected HPS patients from central Puerto Rico. *SUTAL* is a 3015-bp gene coding for a 113.7 kD protein of unknown function. Central Puerto Rican HPS-3 patients are homozygous for a 3094-bp deletion that involves exon 1 and part of intron 1 of *SUTAL*, plus 2874-bp of upstream sequence. We screened non-Puerto Rican HPS patients for *SUTAL* mutations by northern blot analysis and cDNA sequencing. In one 5-year old boy with mild oculocutaneous albinism and a minimal bleeding diathesis, we found a heterozygous C1329T (Arg/Trp) mutation in exon 6, in addition to a splice site mutation (G2729+1C) causing deletion of exon 14. Screening of family members of the HPS proband revealed that the proband's affected sister also possessed the C1329T mutation, as did his unaffected father. The proband's unaffected sister, half-sister and mother did not possess the C1329T mutation. The splice site mutation was found in the mother, both sisters and the half sister, but not the father. This case illustrates the occurrence of HPS-3 in a non-Puerto Rican family presenting with mild disease, and segregation of *SUTAL* mutations with the disease phenotype. It emphasizes the importance of screening non-Puerto Rican patients with Hermansky-Pudlak syndrome for *SUTAL* mutations other than the founder mutation present in central Puerto Ricans.

***PEX6* Mutation Identification in 20 Patients with Peroxisome Biogenesis Disorders.** *N.E. Braverman<sup>1</sup>, C. Obie<sup>1</sup>, P. Lin<sup>1</sup>, D. Valle<sup>1</sup>, A.B. Moser<sup>2</sup>, H.W. Moser<sup>2</sup>, S.J. Steinberg<sup>2</sup>.* 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins Univ, Baltimore, MD; 2) Dept of Neurogenetics, Kennedy Krieger Institute, Baltimore, MD.

Peroxisome biogenesis disorders (PBD) are a heterogeneous group of autosomal recessive diseases associated with failure to assemble mature peroxisomes. The patients are divided into 12 complementation groups (CGs) based on recovery of peroxisomal functions after cell fusion. Each CG reflects a defect in a different *PEX* gene. 80% of PBD patients belong to CGs affecting *PEX1* (CG1) and *PEX6* (CG4). *PEX1* and *PEX6* proteins are interactive, partially redundant AAA ATPases whose role in peroxisomal matrix protein import involves recycling of the receptors. To further characterize these proteins and to determine phenotype-genotype relationships, we performed a comprehensive mutation analysis in CG4 probands.

*PEX6* has a 2.9 kb ORF encoded by 17 exons that span 16kb of genomic DNA on 6p21.1. We amplified genomic DNA by multiplex PCR and directly sequenced the amplicons. This process identified mutations in 31/40 alleles (77.5%). We found 16 missense mutations, 2 small insertions, 3 single base pair deletions and 10 large intragenic deletions that involve direct repeat sequences. The majority of the mutations were unique. We did ASO analysis to determine the frequency of the missense alleles in the general population. None were present except one, P285A, which was found once in 150 control genes. In addition, we identified six polymorphic changes, the most common were V133V (19 alleles) and P939Q (14 alleles). Consistent with results from other PBD CGs, alleles predicted to have the most severe effect on protein function were associated with Zellweger syndrome, the most severe phenotype.

The high frequency of CG1 is due partly to the presence of 2 *PEX1* founder alleles. However, the high frequency of CG4 cannot be explained this way. Interestingly, one of our probands is cousin to a patient in CG1. We propose that some CG4 patients might be compound heterozygotes for defects in both *PEX6* and *PEX1*.

**A common mutation and a novel mutation in the *ORNT1* gene of Japanese patients with mitochondrial ornithine transporter deficiency (HHH syndrome).** *T. Miyamoto*<sup>1</sup>, *N. Kanazawa*<sup>1</sup>, *S. Kato*<sup>2</sup>, *M. Kawakami*<sup>3</sup>, *T. Inoue*<sup>4</sup>, *K.*

*Takeshita*<sup>5</sup>, *I. Yoshida*<sup>6</sup>, *C. Hayakawa*<sup>7</sup>, *S. Tsujino*<sup>1</sup>. 1) Inherited Metabolic Diseases, National Inst Neuroscience, Tokyo, Japan; 2) Department of Internal Medicine, Shinfuji hospital, Shizuoka, Japan; 3) Department of Neurology, St. Marianna University School of Medicine, Kanagawa, Japan; 4) The Department of Pediatrics; Western Shimane Medical and Welfare Center for the Handicapped; Gohtsu, Japan; 5) Division of Child Neurology; Institute of Neurological Sciences; Faculty of Medicine; Tottori University; Yonago, Japan; 6) Department of Medical Education and Pediatrics, Kurume University School of Medicine, Fukuoka, Japan; 7) Department of Pediatrics, Central Hospital, Aichi Welfare Center for Persons with Developmental Disabilities, Aichi, Japan.

Mitochondrial ornithine transporter Deficiency (HHH syndrome) presents with various neurological symptoms, including mental retardation, spastic paraparesis with pyramidal signs, cerebellar ataxia. We previously described three mutations (R179X, G27E, and 228/229 insAAC) in the *ORNT1* gene in three Japanese patients with HHH syndrome. In this report, four additional Japanese patients (52-year-old woman, 10-year-old man, 15-year-old man, and 46-year-old woman; ages are at diagnosis) were tested. At first, we screened these patients for the three mutations with the PCR-RFLP or ARMS method as described. As a result, 3 of the 4 patients were homozygous for R179X. Together with our previous results, 4 of 7 Japanese patients (8 of 14 alleles) had R179X, suggesting that this is a common mutation in Japanese patients with HHH syndrome. Therefore, detecting this mutation may be feasible for diagnosis in Japanese patients. As one patient had none of the three mutations, we amplified exonic fragments containing the entire coding region of the *ORNT1* gene by PCR with intronic primers, and revealed a novel mutation, C-to-G transition resulting in a change of CCC to CGC at codon 126 (P126R) in exon 3. The patient was homozygous for P126R. Mutations so far reported in the *ORNT1* gene are distributed throughout most exons, and there appears to be no "hot spot" for mutations.

**Identification of novel mutations and three most common mutations in the human ATP7B gene of Korean patients with Wilson disease.** *G.H. Kim, E.J. Seo, H.W. Yoo.* Medical Genetics Clinic & Laboratory, Asan Medical center, Ulsan University College of Medicine, Seoul, Korea.

Wilson disease is an autosomal recessive disorder of copper transport, which is probably the most common inherited metabolic disorder in Korea. In Wilson disease, synthesis of a defective copper transporting enzyme leads to the accumulation of copper in the liver, brain and kidney. The product of the Wilson disease gene is a copper transporting P-type ATPase(ATP7B). In this study, efforts have been made to identify novel mutations and investigate a frequency of the common mutations in Korean patients with Wilson disease. This study includes 37 patients from 33 unrelated Korean families with Wilson disease. Genomic DNA from peripheral leukocytes or skin fibroblasts and cDNA from liver tissue were PCR amplified exon by exon, subsequently analyzed using heteroduplex or SSCP analysis. Specimen showing mobility shift on those studies were directly sequenced. We identified 12 different mutations in 33 Korean families with Wilson disease; Arg778Leu(R778L), Asn1270Ser(N1270S), Ala874Val(A874V), 2304 del C, 27bp deletion in exon 11, 2461 ins C, Cys656Stop(C656X), Pro768His(P768H), Leu1083Phe(L1083F), Ala1168Ser(A1168S), Leu1255Ile(L1255I), and Asp1267Ala(D1267A). Among these, 6 mutations(27 bp deletion in exon 11, 2461 ins C, C656X, P768H, A1168S, and L1255I) are novel, the R778L mutation has been known to be highly prevalent in Asian patients. The allele frequency of the R778L in Korean patients with Wilson disease was 37.9%, which was slightly higher than those of Japanese and Taiwanese. Interestingly, the N1270S, originally described in an Italian patient, was the next common mutation in Korean patients with Wilson disease with the allele frequency of 12.1%, which was presumed to disrupt ATP hinge domain of the ATP7B protein. The A874V mutation was the thirdly common mutation with the allele frequency of 9.4%, which was presumed to disrupt Td domain of the ATP7B protein. R778L, N1270S, and A874V mutation are three major mutations covering upto nearly 60% of mutated alleles, though Korean patients with Wilson disease are genetically heterogeneous.

**The *CTNS* promoter and its mutations causing cystinosis.** C. Phornphutkul, Y. Anikster, M. Huizing, J. Chou, W. Gahl. HDB, NICHD, NIH, Bethesda, MD.

Cystinosis is a rare autosomal recessive storage disease resulting from impaired transport of the disulfide amino acid cystine out of cellular lysosomes. The cystinosis gene, *CTNS*, contains 12 exons and codes for a 367-amino acid peptide that appears to be an integral membrane protein functioning as the lysosomal cystine transporter. Although more than 55 mutations in the *CTNS* coding sequence have been reported, no regulatory mutations have been found because the promoter region has not been identified. By using CAT (chloramphenicol acetyltransferase) reporter constructs of sequences 5' to the *CTNS* coding sequence, we identified the *CTNS* promoter as the region from nucleotides -316 to +1 with respect to the transcription start site. Several predicted transcription factors exist in this region, including an Sp-1 motif at nucleotide -299 to -293, verified by gelshift assays. In studying patients who were not homozygous for the common 57-kb deletion in *CTNS*, we identified three patients who exhibited mutations in the *CTNS* promoter region. All three had only one mutation in the *CTNS* coding sequence. One nephropathic cystinosis patient carried a -295 G->C substitution that disrupted the Sp-1 motif, while two patients with ocular cystinosis displayed a -303 G->T substitution and a -303 T insertion, respectively. Each mutation drastically reduced CAT activity when inserted into a reporter construct. Moreover, each failed to cause a mobility shift when exposed to nuclear extract or to compete with the normal oligonucleotide's mobility shift. On both clinical and functional grounds, all three mutations are considered severe, explaining the patients' clinical manifestations. The *CTNS* promoter also shared 41 nucleotides with the promoter of an adjacent gene of unknown function, *CARKL*, whose start site is 501 base pairs from the *CTNS* start site. However, the patients' *CTNS* promoter mutations had no effect on *CARKL* promoter activity. These findings suggested that the *CTNS* promoter region should be examined in cystinosis patient having fewer than two coding sequence mutations.

**Congenital erythropoietic porphyria: Identification, characterization and genotype/phenotype correlations of novel gene mutations.** A.A. Shady, B. Colby, K.H. Astrin, R.J. Desnick. Human Genetics, Mount Sinai School of Medicine, New York, NY.

Congenital erythropoietic porphyria (CEP) is an autosomal recessive disorder which results from the markedly deficient activity of uroporphyrinogen III synthase (UROS), the fourth enzyme in the heme synthetic pathway. Clinical manifestations range from hydrops fetalis to lifelong transfusion dependency to mild cutaneous photosensitivity. To investigate the genetic heterogeneity underlying CEP, we determined the UROS mutations in seven unrelated patients whose clinical manifestations varied from moderate to severe. All 10 exons, the adjacent intron/exon boundaries, and the housekeeping and erythroid promoters of the UROS gene were PCR-amplified and sequenced on an ABI Prism 377 sequencer. Three previously documented mutations (C73R, T228M and -86C→A) and seven novel mutations were detected: four missense (A69T, E81D, G188W and I219S), one single-base deletion (21G), a large 28-base insertion (672ins28), and one complex mutation (6276ins39). While both E81D and G188W are adjacent to the exon/intron boundary, RT-PCR analysis showed that only E81D altered splicing by deleting exon 4. Each novel missense mutation was expressed in *E. Coli*, and its residual enzymatic activity was determined. With the exception of E81D, residual enzymatic activity was markedly reduced for the A69T, G188W and I219S missense mutations. Expression of the E81D allele showed relatively high residual activity; however, it was less heat stable than the wild type ( $T_{1/2}$  at 37°C was 40 min vs. 90 min, respectively.) The total enzyme activity from both alleles in each patient correlated with disease severity. These findings document the molecular heterogeneity and provide genotype-phenotype correlations in CEP.

**Hypoglycemia and dicarboxylic aciduria as the presenting biochemical findings in a patient with Barth syndrome.** *D.J. Waggoner, R.L. Brown, J. Hedrick.* University of Chicago, Department of Human Genetics, Chicago, USA.

Barth syndrome is a rare but well described X-linked metabolic disorder characterized by cardiomyopathy, neutropenia, growth retardation, skeletal myopathy, and 3-methylglutaconic aciduria. Affected males usually die due to complications of cardiomyopathy in the first year of life; although phenotypic variability exists and there are reports of males who have survived into adulthood. The gene responsible for Barth syndrome, G4.5, was reported in 1996 and encodes a novel protein whose function remains unknown. Studies have been unable to show a genotype/phenotype correlation with the various mutations reported. Barth syndrome is suspected in patients with 3-methylglutaconic aciduria, cardiomyopathy, and neutropenia but the differential diagnosis includes defects of the mitochondrial respiratory chain. Patients with mitochondrial dysfunction typically have additional metabolites, which serve to differentiate them. We report an 11-month-old boy with a history of hypotonia who presented in heart failure secondary to cardiomyopathy and was found to have significant hypoglycemia and acidosis. There was no history of increased infections or neutropenia. Initial results of urine organic acid studies showed 3-methylglutaconic acid, large amounts of C6-C10 saturated and unsaturated dicarboxylic acids and 3-hydroxycarboxylic acids. The patient was eventually found to have the deleterious mutation Arg93Gly in the G4.5 gene confirming the diagnosis of Barth syndrome. These findings broaden the biochemical presentation of patients with Barth syndrome to include hypoglycemia and dicarboxylic aciduria often seen as the presenting biochemical findings in fatty acid oxidation disorders or mitochondrial defects. Molecular testing for mutations in G4.5 is a valuable component of the evaluation of these complicated patients with multiple diagnostic possibilities.

**Hyperoxaluria type 1: a novel 2 bp deletion in AGXT resulting in loss of the peroxisomal targeting signal.** *M.B. Coulter-Mackie<sup>1,2</sup>, J.R. Toone<sup>1,2</sup>, D.A. Applegarth<sup>1,2,3</sup>*. 1) Department of Pediatrics, University of British Columbia, Vancouver, BC; 2) Department of Pathology and Laboratory Medicine, University of British Columbia, Vancouver, BC; 3) Biochemical Diseases Lab, B.C. Children's Hospital, Vancouver, BC.

Primary hyperoxaluria type I, PH1, results from a deficiency of alanine glyoxylate aminotransferase (AGT) activity. AGT is a peroxisomal enzyme in humans. A common polymorphism, P11L, provides an N-terminal mitochondrial targeting signal in the so-called minor allele. The most common PH1 mutation, G170R, when in *cis* with P11L, results in mis-targeting of AGT to mitochondria. A patient with pediatric onset PH1 was assessed biochemically and at the level of her DNA. Her liver AGT enzymic activity was 4.7% of normal controls but she had an almost normal level of AGT-specific CRM at 80% compared to normal liver. DNA analysis demonstrated that she was homozygous for the major allele indicating she was not a candidate for mis-targeting. She was found to carry one copy of the mutation, G82E, on her maternal allele. This is a previously documented recurrent mutation reported to result in a normally-targeted inactive protein. On the paternal allele she carried a 2 bp deletion in the final exon of the AGT gene. Because the resultant frameshift occurs in the last exon, it is expected that the allele would be translated. Such an allele, along with the G82E allele, would account for the high level of immunoreactive material. However, the C-terminal peroxisomal targeting signal would be lost from the protein product of the deletion allele. The AGT produced from this allele would un-targeted rather than mis-targeted and would be expected to remain in the cytoplasm.

This work was supported in part by a grant from the Garrod Association of Canada.

**Intermediate phenotype of rhizomelic chondrodysplasia punctata.** *P.K. Chakraborty<sup>1</sup>, N. Braverman<sup>2</sup>, J.T.R.C. Clarke<sup>1</sup>.* 1) Department of Clinical & Metabolic Genetics, Hospital for Sick Children, Toronto, ON, Canada; 2) McKusick-Nathans Institute for Genetic Medicine, Johns Hopkins Medical Center, Baltimore, MD.

Rhizomelic chondrodysplasia punctata (RCDP) is a genetically heterogeneous disorder that classically presents with congenital cataracts, rhizomelia, epiphyseal calcifications, contractures, dysmorphic facial features, and severe psychomotor and growth retardation with early demise. We present the case of a 3-year-old boy with an intermediate clinical and biochemical phenotype of RCDP. He had congenital cataracts surgically removed at 1 month of age. At 20 months of age, multiple joint contractures and epiphyseal stippling were noted. He is not rhizomelic, but has mild facial dysmorphisms seen in patients with RCDP including a Binder's nose and prominent forehead. He was slightly delayed in reaching early milestones, and now has mild global delay with speech being most affected. Investigations of peroxisomal function demonstrate defects of phytanic acid catabolism and plasmalogen synthesis, with normal very long chain fatty acid and cholesterol synthesis. Plasma phytanic acid is markedly elevated at 365 mM, while RBC plasmalogens are moderately decreased (C16:0 DMA / C16:00 fatty acid = 0.031 [normal control: 0.051-0.09, RCDP control: 0.001-0.05], C18:0 DMA / C18:00 fatty acid = 0.109 [normal control: 0.137-0.255, RCDP control: 0.001-0.05]). Skin fibroblast peroxisomal plasmalogen synthesis (3H/14C incorporation = 3.037 [mean normal control: 0.67, mean RCDP control: 33.67]) is intermediately impaired. Fibroblast phytanic acid oxidation (18% control) is in the range of classical RCDP. The biochemical profile in this patient is characteristic for defects in the peroxisome receptor, Pex7. Pex7 targets a subclass of matrix enzymes to the peroxisome, including phytanyl CoA hydroxylase (PAHX) and alkyl-dihydroxyacetone phosphate synthase. Only a small number of mild RCDP variants are reported and the clinical spectrum is unknown. In all of these, plasmalogen biosynthesis is moderately affected, but PAHX activity remains severely defective. These patients support a major role for plasmalogens in determining the RCDP phenotype. PEX7 mutation analysis for this patient is in progress.

**Peroxisomal biogenesis: Study of protein-protein-interactions of early peroxins by fluorescence resonance energy transfer (FRET) analysis.** *A.C. Muntau<sup>1</sup>, A.A. Roscher<sup>1</sup>, W.-H. Kunau<sup>2</sup>, G. Dodt<sup>2</sup>.* 1) Dr. von Hauner Children's Hospital, Clinical Chemistry and Biochemical Genetics, Ludwig-Maximilians-University, Munich, Germany; 2) Physiological Chemistry, Ruhr-University, Bochum, Germany.

Peroxisomal biogenesis disorders (PBD) are characterized by an impairment of multiple peroxisomal functions phenotypically presenting as Zellweger syndrome, neonatal adrenoleukodystrophy, infantile Refsum disease or rhizomelic chondrodysplasia punctata. Proteins involved in peroxisomal assembly are termed peroxins and are encoded by *PEX* genes. Organelle biogenesis requires the formation of a lipid bilayer, the insertion of membrane proteins, and the import of matrix proteins. Defects in most *PEX* genes result in impaired peroxisomal matrix protein import, whereas the ability to import membrane proteins is often retained. Fibroblasts from patients with defects in *PEX3*, *PEX16* or *PEX19*, however, display a cellular phenotype characterized by a lack of even residual peroxisomal membrane structures. A protein-interaction between *PEX3* and *PEX19* has been shown to be a crucial functional component of early peroxisomal assembly. However, the intracellular site of this interaction is still unclear.

To address this issue by fluorescence resonance energy transfer (FRET) analysis, we tagged *PEX3* and *PEX19* to yellow fluorescent protein (YFP) and cyan fluorescent protein (CFP), respectively. Coexpression of fully functional *PEX3*-YFP and *PEX19*-CFP fusion proteins in *PEX3*-deficient fibroblasts revealed a FRET signal not only at the peroxisomal membrane, but also in the cytosol. Control coexpression of *PEX3*-YFP and CFP-N1 yielded only a weak background signal. Our data show that FRET analysis is able to reveal quantitative spatio-temporal information about the physical interaction of peroxins during the process of peroxisomal assembly in single living cells. This may contribute to unravel some basic aspects of peroxisome biogenesis.

**Molecular diagnosis of Refsum Disease, a disorder of the peroxisomal phytanic acid  $\alpha$ -oxidation.** *G.A. Jansen<sup>1</sup>, H.R. Waterham<sup>1</sup>, D.M. van den Brink<sup>1</sup>, S. Ferdinandusse<sup>1</sup>, E.M. Hogenhout<sup>1</sup>, O.H. Skjeldal<sup>2</sup>, O. Stokke<sup>3</sup>, R.J.A. Wanders<sup>1</sup>.* 1) Dept. Clinical Chemistry, Laboratory for Genetic Metabolic Diseases, Academic Medical Centre, University of Amsterdam, The Netherlands; 2) Dept. Pediatrics, Neurological section, Rikshospitalet, Oslo, Norway; 3) Institute of Clinical Chemistry, Rikshospitalet, Oslo, Norway.

Refsum disease is a rare inherited disorder of lipid metabolism with retinitis pigmentosa, peripheral neuropathy, cerebellar ataxia and elevated protein levels in the cerebrospinal fluid as main manifestations. Patients with Refsum disease accumulate phytanic acid, an unusual branched chain fatty acid (3,7,11,15-tetramethylhexadecanoic acid) in tissues and body fluids, which is the biochemical hallmark of this disorder used to confirm the clinical diagnosis. The accumulation of phytanic acid is the result of a deficient activity of phytanoyl-CoA hydroxylase (PhyH), a peroxisomal enzyme which catalyses the conversion of phytanoyl-CoA to 2-hydroxyphytanoyl-CoA, one of the four steps of the phytanic acid  $\alpha$ -oxidation degradation pathway. PhyH deficiency is caused by mutations in *PHYH*, the gene encoding this enzyme. Until recently, only cDNA mutation analysis was available as a tool for diagnosing the genetic defect in Refsum disease. After resolving the structure of the *PHYH* gene, we now have developed a method for rapid mutation analysis at the genome level, using the PCR technique to amplify the nine exons of the 21 kb *PHYH* gene in eight fragments, followed by sequence analysis. Using this method, we have analysed genomic DNA from a large number of Refsum patients, and have found more than 20 different mutations, including missense mutations, insertions, deletions, some of which lead to missplicing events. Most mutations were located in exons six and seven of the *PHYH*-gene, but the most frequent mutation with a allele frequency of about 20% was present in the splice acceptor site of IVS2, resulting in skipping of exon 3.

**Large 5' deletions in the X-linked adrenoleukodystrophy gene, *ABCD1*, in two patients with a novel neonatal phenotype.** *S.J. Steinberg*<sup>1</sup>, *D. Corzo*<sup>2</sup>, *W.T. Gibson*<sup>3</sup>, *G.A. Mitchell*<sup>3</sup>, *G. Cox*<sup>2</sup>, *G. Cutting*<sup>4</sup>, *C. Boehm*<sup>4</sup>, *H. Tyson*<sup>4</sup>, *P.A. Watkins*<sup>1</sup>, *G.V. Raymond*<sup>1</sup>, *A.B. Moser*<sup>1</sup>, *H.W. Moser*<sup>1</sup>. 1) Kennedy Krieger Inst, Baltimore, MD; 2) Children's Hosp, Boston, MA; 3) Medical Genetics Service, Ste-Justine Hosp, Montreal, Canada; 4) Johns Hopkins Univ, Baltimore, MD.

Adrenoleukodystrophy (X-ALD) is caused by mutations in the ALD gene, *ABCD1*, which encodes a peroxisomal integral membrane protein (ALDP). All previously described X-ALD patients have been asymptomatic at birth, the earliest onset of neurologic symptoms being 2.75 years. We now report the molecular genetic basis of X-ALD in two patients with a presentation more typical of a peroxisomal biogenesis disorder. Both were hypotonic and had cholestatic liver disease. In addition, Patient (Pt) 1 (Corzo, D et al., *Am J Hum Genet* 65, 4 (suppl):A1295) had sensorineural hearing loss, seizures and died at 4 months. Pt 2 had bilateral polar cataracts, neurological deterioration and died of failure at 12 months. Plasma very long chain fatty acids were characteristic of a peroxisomal  $\beta$ -oxidation defect in both patients. Additional biochemical studies in blood and cultured cells did not reveal additional peroxisomal metabolic defects. Immunofluorescence microscopy of cultured fibroblasts from these patients showed that they had normal appearing peroxisomes that lacked ALDP. Based on these results, mutation analysis of all 10 *ABCD1* exons was initiated by PCR and direct sequencing of genomic DNA. Exon 1-5 failed to amplify in Pt 1 and exons 1-10 failed to amplify in Pt 2. Southern blot analysis confirmed the absence of these exons, but the precise breakpoints have not been defined. Of 230 non-recurrent *ABCD1* mutations 5% involve a deletion of at least 1 exon. Only one previously reported patient had a deletion involving exon 1, a 0.5kb deletion at the 3' end of the 1.286kb exon. Further studies to determine if the deletions in these boys extend beyond the 5' end of exon 1 are in progress. Once the deletion breakpoints are defined we can initiate investigations that would shed light on the pathogenetic mechanism of this new X-ALD phenotype and perhaps on the function of ALDP itself.

**Genetic Variation in the Human Organic Cation Transporter hOCT2.** *M.K. Leabman<sup>1</sup>, J. DeYoung<sup>2</sup>, C. Huang<sup>3</sup>, S.J. Johns<sup>3</sup>, K.M. Giacomini<sup>1</sup>*. 1) Department of Biopharmaceutical Sciences, School of Pharmacy, University of California, San Francisco, San Francisco, CA; 2) Neurogenetics Laboratory, Program in Human Genetics, University of California, San Francisco, San Francisco, CA; 3) Sequence Analysis and Consulting Service, Computer Graphics Laboratory, Department of Pharmaceutical Chemistry, University of California, San Francisco, San Francisco, CA.

Membrane transporters play a critical role in drug response, affecting the pharmacokinetics and/or pharmacodynamics of drugs. The organic cation transporter, hOCT2, is thought to play a major role in the renal elimination of a variety of structurally diverse basic drugs (e.g., cimetidine, metformin). Therefore, genetic variation in this transporter may contribute to variability in renal clearance. We recently conducted denaturing HPLC analysis followed by automated sequencing on an ethnically diverse, 250 sample collection of genomic DNA to identify variants of hOCT2. Twenty eight variants, 16 coding and 12 non-coding, were identified and their frequencies in each ethnic population were determined. Three common, non-synonymous coding region variants have been constructed and functional studies in *Xenopus laevis* oocytes have shown that they transport the prototypical organic cation MPP<sup>+</sup>. In RNA dose response studies, the uptake of a saturating concentration of MPP<sup>+</sup> in variant 1 and variant 3 expressing oocytes was lower than that of wild type at all doses of RNA ( $p < 0.05$ ), suggesting that the  $V_{max}$  of MPP<sup>+</sup> in the variant expressing oocytes differs from that in oocytes expressing the wild type transporter. Potency of inhibition of MPP<sup>+</sup> uptake of tetrabutylammonium (TBA) differed in oocytes expressing two of the variants. These data demonstrate that the three common polymorphisms of hOCT2 are functional, but differ from the wild type hOCT2 in terms of their kinetic characteristics and interactions with hydrophobic organic cations.

This work was supported by a grant from the National Institutes of Health (GM61390).

**Characterization of a carbohydrate response element (ChoRE) regulating the gene for human galactose-1-phosphate uridylyltransferase (hGALT).** *L.J. Elsas II, A. Webb, S.D. Langley.* Dept Pediatrics, Medical Gen, Emory Univ, Atlanta, GA.

We previously found that D-galactose stimulated hGALT in HepG2 and OVCAR-3 cells and that a four bp deletion (-119 to -116delGTCA) in the hGALT promoter region was linked to the Duarte mutation in galactosemia, disrupted the spatial relationship between two E-box motifs (CANNTG) and reduced a positive regulatory response (*Molec. Genet. Metab.* 27:297-305, 2001). In the wild type promoter there are three sequential GTCA repeats in this positive regulatory domain. Here we define the effects of altering the 22 bp spacing and number of GTCA repeats between the -145 to -140 CAGGTG and -117 to -112 CACGTG E-box motifs on *trans* nuclear protein binding and function. We compare electrophoretic mobility shift assays (EMSA) and dual luciferase reporter constructs transfected into HepG2 cells. Radiolabeled oligonucleotide probes representing wild type (WT)(38 bp), WT-GTCA (34 bp) and WT+GTCA (42 bp) encompassed both E-box motifs and specifically bound c-myc and at least one other nuclear protein. Unexpectedly, the 42 bp probe bound more *trans* factor ( $1010 \pm 50$ ) than the WT 38 bp probe ( $450 \pm 29$ ) and the WT-GTCA probe bound the least ( $360 \pm 32$  CPM) ( $p < 0.05$ ). These structural binding studies correlated with functional studies of hGALT promoter constructs containing the WT, WT-GTCA and WT+GTCA sequences where dual luciferase ratios were  $5.8 \pm 2$ ,  $3.6 \pm 1$  and  $12 \pm 2$ , respectively. When HepG2 cells were incubated in 5mM galactose before and during transfection, promoter activity increased ten-fold. We conclude that the hGALT promoter contains a ChoRE contained within two E-box motifs whose spatial relationship determines the degree of positive response to galactose stimulation by specific *trans* nuclear proteins.

**Coarse face, dysostosis multiplex, progressive laryngeal obstruction and severe psychomotor retardation - a new type of autosomal recessive storage disease?** *R. Shenhav<sup>1</sup>, E. Sayag<sup>1</sup>, L. Basel<sup>1</sup>, G. Halpern<sup>1</sup>, A. Rotchild<sup>2</sup>, M. Frydman<sup>3,4</sup>, M. Shohat<sup>1,4</sup>.* 1) Medical Genetics, Rabin Medical Center, Beilinson Campus, Petah Tikva, Israel; 2) Medical Genetics, Hadassah Medical Center, Ein Kerem, Jerusalem, Israel; 3) Medical Genetics, Sheba Medical Center, Tel Hashomer, Israel; 4) Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel.

We describe an extended consanguineous Israeli Arab family - a brother and sister are married to their first cousins, who are themselves brother and sister. The two couples had together five affected daughters out of nine children. All those affected had similar clinical features: short stature, severe psychomotor retardation, mild microcephaly, coarse and dysmorphic face with depressed nasal bridge, wide nose, full lips, macroglossia, protruding ears, strabismus, and short and broad neck. Other features were small hands and feet with brachydactyly, hyperlaxity of the joints, hirsutism, mild hepatomegaly, but no splenomegaly. There was progressive narrowing of the larynx and trachea, resulting in serious airway compromise, and one girl has already died from this, aged 11 years. Laboratory findings: urinary examination showed normal levels of mucopolysaccharides and oligosaccharides, and no sialic aciduria. Serum arylsulfatase A level and sulfate incorporation by cultured fibroblasts were normal. Skull X-ray revealed a thick calvaria and "J" shaped sella turcica. Skeletal radiological survey showed dysostosis multiplex, platyspondyly, broad ribs, coarsely trabeculated long bones with hypoplastic and irregular epiphyses and broad metaphyses, dysplasia of the hands with hypoplasia and tapering of the distal phalanges, bullet-like proximal phalanges, and acetabular dysplasia. CT and MRI of the skull revealed no specific changes. On rectal biopsy, ultrastructural examination showed no findings specific for mucopolysaccharidosis. Echocardiography was normal. Linkage analysis excluded linkage to the mucopolipidosis 2 gene located on chromosome 4q21-q23. This family represents a previously undescribed type of storage disease that is probably transmitted by autosomal recessive inheritance, and we are currently undertaking linkage analysis.

**Coding region mutations in the MCAD and VLCAD genes may have unforeseeable consequences due to disruption of potential splice enhancer sequences.** *B.S. Andresen<sup>1,2</sup>, K.B. Nielsen<sup>1,2</sup>, T.J. Corydon<sup>1</sup>, L.D. Schroeder<sup>1,2</sup>, N. Gregersen<sup>2</sup>.* 1) Inst Human Genetics, Aarhus Univ, Arhus C, Denmark; 2) . Research Unit for Molecular Medicine, Aarhus Univ. Hospital.

It is becoming clear that coding region mutations do not always exert their effect by simply changing the amino acid sequence of the encoded protein. Instead, the main effect can be a lowering of the amounts of mutant mRNA (mediated by nonsense mediated decay (NMD)) or missplicing of the mRNA. We have monitored the amounts of medium-chain acyl-CoA dehydrogenase (MCAD) mRNA from alleles with >20 different disease-causing mutations using allele specific quantitation in LightCycler based mutation specific assays. All alleles with mutations that generated premature termination codons (PTC)'s upstream of the last exon resulted in low levels of mRNA. Surprisingly, one of the missense mutations (362C>T), located in exon 5, far from both splice junctions, also resulted in low MCAD mRNA amounts. Analysis of patient MCAD cDNA showed that this was caused by complete skipping of exon 5 resulting in a shifted reading frame ending with a PTC in exon 6, thus triggering NMD. Using transfection studies in COS-cells with wild-type and mutant (362C>T) MCAD mini-gene constructs we could reproduce the exon 5 skipping from the mutant construct. Mutagenesis of pos. 362, the neighboring positions, and the suboptimal 3'splice site of intron 4, indicated that exon 5 skipping is probably caused by disruption of an exonic splice enhancer (ESE) sequence. Studies aimed at identifying the relevant splice factor is underway. Similarly, we have identified a potential ESE sequence in exon 12 of the very-long-chain acyl-CoA dehydrogenase (VLCAD) gene, which when disrupted by a missense mutation (1213G>C) leads to exon skipping in patient cells. Studies employing mutagenesis of pos.1213, the neighboring positions and the suboptimal 3'splice site of intron 11 of our VLCAD mini-gene is underway. We conclude that disruption of ESE sequences, which are necessary for correct splicing of exons with a suboptimal 3'splice site, may lead to unpredictable consequences of simple coding region mutations.

**Function-Structure Relationship of Saposin B: An Ex-Vivo Study.** *M. Wang, X. Qi.* Dept. and Program of Human Genetics, Children's hospital, Cincinnati, OH.

Saposin B, a physiologic activator of arylsulfatase A, is essential for the hydrolysis of sulfatide by arylsulfatase A in lysosome. Patients lacking saposin B show variant forms of metachromatic leukodystrophy. In order to investigate the function-structure relationship of saposin B, an ex-vivo system was established. Lissamin-rhodamin labeled sulfatide (LRh-CS) was synthesized as a fluorescent substrate of arylsulfatase A. The characterization of this fluorescent substrate was analyzed by TLC, spectrometer and mass spectroscopy. Liposomes containing LRh-CS and entrapping normal or mutant saposin Bs were used for delivery to cells. The degradation of LRh-CS was activated by external saposin Bs. Degradation was quantified by comparing the fluorescence intensity measured using Laser Screen Microscope. Acriflavin, a lysosomal marker, was used as an internal standard. The staining of acriflavin per sq.mm. cell section was equal in wild type and saposin B mutant cells. Our experiments showed co-localization of LRh-CS and acriflavin in human saposin B mutant cell. In addition, The recombinant saposin B was localized mainly in lysosomes with immune-fluorescence study. By co-loading of recombinant human saposin B, the amount of LRh-CS accumulated in human saposin B mutant cells was significantly reduced by 85%. A substantial accumulation of the loaded substrate LRh-CS was present in granular vesicles in cytoplasm in mouse total saposin (*sap-/sap-*) deficient cells and human saposin B mutant cells. In contrast, this staining pattern was not observed in loaded cells from prosaposin transgenic (*sap-/sap-*) mice and wild type cells. The pattern in these cells was a crescent-shape around the nucleus. Variety of chimeric and mutant saposin Bs was generated to identify the bioactive sites essential for its function.

**Molecular, biochemical, and phenotypic analysis of a male with X-linked dominant Conradi-Hunermann-Happle syndrome (CDPX2).** *J.M. Milunsky<sup>1</sup>, T.A. Maher<sup>1</sup>, A.B. Metzenberg<sup>2</sup>, R.I. Kelley<sup>3</sup>.* 1) Center for Human Genetics and Dept Pediatrics, Boston Univ Sch Medicine, Boston, MA; 2) Dept Biology, California State Univ, Northridge, CA; 3) Kennedy Krieger Inst, Baltimore, MD.

X-linked dominant Conradi-Hunermann-Happle syndrome (CDPX2; MIM 302960) is a rare chondrodysplasia punctata primarily affecting females. CDPX2 is presumed lethal in males, although a few affected males have been reported. CDPX2 is a cholesterol biosynthetic disorder due to 3 $\beta$ -hydroxysteroid-d8,d7-isomerase deficiency caused by mutations in the emopamil binding protein (EBP) gene. A two-year-old Caucasian male was followed from the age of six weeks and noted to have significant developmental delay, hypotonia, seizures, and patchy hypopigmentation. Multiple congenital anomalies included a unilateral cataract, esotropia, crossed renal ectopia, stenotic ear canals, failure to thrive requiring G-tube placement, and microcephaly. Multiple dysmorphic features and ptosis were noted. No skeletal asymmetry or chondrodysplasia punctata were noted on skeletal survey at six weeks and thirteen months. An extensive genetic workup including cholesterol (126-176 mg/dl) and 7-dehydrocholesterol was unrevealing. However, the levels of 8(9)-cholestenol and 8-dehydrocholesterol were mildly increased in plasma which was confirmed in cultured fibroblasts. This prompted molecular analysis of the EBP gene which revealed a novel hemizygous (non-mosaic) mutation in exon 2 (L18P). Expression studies on skin fibroblasts are in progress. Two restriction digests were developed that confirmed this mutation in skin fibroblasts, blood, and buccal cells (all non-mosaic). We determined that the patient's mother (adopted) also has the L18P mutation enabling future prenatal diagnosis. She has normal stature, no asymmetry, no cataracts at this time, and has a patch of hyperpigmentation on her chest best appreciated on Woods lamp exam characteristic of CDPX2. The mild maternal phenotype has been described previously. However, this missense mutation has resulted in a severe phenotype in our surviving male.

**Female carriers of adrenoleukodystrophy show skewed patterns of X inactivation but no favorisation of the mutant allele.** *E.M. Maier<sup>1</sup>, A.C. Muntau<sup>1</sup>, S. Kammerer<sup>2</sup>, A.A. Roscher<sup>1</sup>*. 1) Dr. von Hauner Children's Hospital, Clinical Chemistry and Biochemical Genetics, LMU, Munich, Germany; 2) SEQUENOM Inc., San Diego, CA.

X-linked adrenoleukodystrophy (X-ALD) is the most frequent genetically determined peroxisomal disorder, which is biochemically characterized by an accumulation of very long chain fatty acids (VLCFA) in tissues and body fluids. It is caused by mutations in the *ALD* gene encoding a peroxisomal membrane protein, that is a member of the superfamily of ATP-binding cassette transporters. X-ALD leads to a progressive demyelination of the central nervous system with a wide range of phenotypic expression. Unlike most carriers of X-linked disorders, the majority of X-ALD carriers develop neurological abnormalities at later ages. In the past, this had been explained by skewing of X inactivation favoring the mutant allele.

We analyzed X-chromosome inactivation in peripheral blood cells of carriers and noncarriers from 18 ALD families as well as of healthy controls, using a PCR-based assay at the human androgen receptor locus (HUMARA). Highly skewed patterns (>80:20) were found in 7 of 22 carriers, but were not observed in 7 related noncarriers and 35 unrelated controls. The distribution of X inactivation patterns in X-ALD carriers was clearly different from the bell-shaped normal distribution with predominant random X inactivation demonstrated by both noncarriers and unrelated female controls. The differences were statistically highly significant. Skewing of X inactivation in peripheral blood did not correlate with plasma VLCFA levels. Among the X-ALD carriers with skewed patterns of X inactivation we found association with either favoring the mutant or the wildtype allele. No clear favorisation of the mutant *ALD* allele as the preferentially active one could be delineated. Thus, the results of this study challenge the so far postulated hypothesis of favorisation of the mutant allele. The finding that both favorisation of the mutant or the wildtype allele can be observed in X-ALD carriers might reflect the influence of modifying factors affecting postinactivation selection mechanisms.

**Variation in three SNPs in the calpain-10 gene not implicated in conferring susceptibility to type 2 diabetes in a large Finnish cohort.** *T.E. Fingerlin<sup>1</sup>, M.R. Erdos<sup>2</sup>, R.M. Watanabe<sup>3</sup>, T.T. Valle<sup>4</sup>, J. Tuomilehto<sup>4</sup>, R.N. Bergman<sup>3</sup>, M. Boehnke<sup>1</sup>, F.S. Collins<sup>2</sup> for the FUSION Study Group.* 1) University of Michigan, Ann Arbor, MI; 2) NHGRI, NIH, Bethesda, MD; 3) USC Keck School of Medicine, Los Angeles, CA; 4) National Public Health Institute, Helsinki, Finland.

In recent study of Mexican Americans (MA) Horikawa et al. found that an intronic SNP, UCSNP-43, in the calpain-10 gene showed evidence for linkage and association with type 2 diabetes (T2D), with the common G allele the at-risk allele. Further analyses identified a pair of three-SNP (UCSNP-43, 19, 63) haplotypes that in combination were strongly associated with T2D. Homozygotes for either of the two haplotypes were not at increased risk. We genotyped UCSNP-43, 56, and 63 (UCSNP-56 is in complete linkage disequilibrium with UCSNP-19 and was more easily typed) in 906 Finnish subjects from the FUSION study: 506 index cases with T2D, 179 non-diabetic spouses of index cases or their siblings, and 221 normal glucose tolerant elderly control subjects. We found no significant differences in allele or genotype frequencies between cases and spouses and elderly controls for any of the three SNPs (all p-values > 0.25). We also estimated haplotype frequencies for cases and spouses and elderly controls using the three SNPs. Preliminary results suggest that the high-risk haplotype combination identified by Horikawa et al. is rare in our sample. Within each study group, we compared T2D-related traits (insulin secretion and sensitivity measures, lipid profiles, age-of-onset, and BMI) between subjects with and without the common G allele and among subjects with each of the three genotypes (GG, GA, AA) at UCSNP-43 after adjusting for age and gender. We found no important differences. These results suggest that in this Finnish population 1) UCSNP-43 neither confers susceptibility to T2D nor strongly influences several T2D-related traits and 2) the high-risk haplotype combination identified in the MA population cannot play a substantial role in conferring susceptibility to T2D due to the low frequency of that haplotype combination in Finnish T2D families.

**Linkage disequilibrium in the genes of the renin-angiotensin system; Findings from the Family Blood Pressure**

**Program.** *R.S. Cooper*<sup>1</sup>, *D. Yan*<sup>2</sup>, *X. Zhu*<sup>1</sup>, *A. Luke*<sup>1</sup>, *A. Weder*<sup>3</sup>, *A. Chakravarti*<sup>2</sup>. 1) Preventive Medicine & Epid, Loyola University Chicago, Maywood, IL; 2) McKusick-Nathans Institute of genetic Medicine, Johns Hopkins University, Baltimore, MD; 3) Division of Hypertension, School of Medicine, University of Michigan, Ann Arbor, MI.

Association studies of candidate genes for complex traits like hypertension conducted thus far have relied primarily on information from only one nucleotide polymorphism or an alu element. Variation in the extent of linkage disequilibrium in the gene or region being examined markedly influences the sensitivity and precision of association studies, however, and it has not been adequately described for most candidate genes. In a sample of 415 whites and 477 blacks we estimated intragenic linkage disequilibrium in the 4 genes of the renin-angiotensin system by typing 21 single nucleotide polymorphisms. All but one of the sets of markers were spaced between 1 and 20,000 kb, thus providing resolution at relatively a small scale. Strong linkage disequilibrium existed across all the pairs of markers in whites, with the exception of one polymorphism in the angiotensin I receptor gene. Among blacks there was substantially less linkage in renin, angiotensin-converting enzyme, and the angiotensin receptor, but not angiotensinogen. The average half-length of linkage disequilibrium was about 60 kb in whites and 8 kb in blacks, with the correspondingly greater number of haplotypes among blacks. These findings have implications for fine mapping of candidate genes and suggest that variation between populations of European and African origin in haplotype diversity is characteristic of most genes.

**Genome-wide association study to identify genes related to myocardial infarction.** *K. Ozaki<sup>1</sup>, Y. Ohnishi<sup>1</sup>, A. Iida<sup>1</sup>, R. Yamada<sup>1</sup>, T. Tsunoda<sup>1</sup>, A. Sekine<sup>1</sup>, Y. Nakamura<sup>1,2</sup>, T. Tanaka<sup>1</sup>.* 1) SNP Research Center, The Institute of Physical and Chemical Research (RIKEN), Tokyo, Japan; 2) Laboratory of Molecular Medicine, Human Genome Center, Institute of Medical Science, University of Tokyo, Tokyo, Japan.

To clarify genetic backgrounds in the pathogenesis of acute myocardial infarction (MI), we have launched a genome-wide association study in a Japanese population using 100,000 cSNPs. As a first step, we are now genotyping 94 MI patients and 564 general population by high-throughput multiplex PCR-Invader assay method. We temporarily chose p value of 0.01 to be threshold to select SNPs for further verification by expanding sample size. At present, we have screened 2,609 SNPs and 96% of them did not meet this threshold. When the rest of the SNP loci were re-examined with additional 1,000 MI patients and 1,000 general population, almost all of them did not show statistically significant association. However, one SNP locus showed a tight association, with a  $\chi^2$  value of 21.52 ( $p=0.0000035$ ) and odds ratio of 1.74 (95% confidence interval 1.38-2.21). We are now making a dense SNP map of this locus for linkage disequilibrium mapping, followed by functional analyses of gene products.

**A novel locus for autosomal dominant non-syndromic deafness (DFNA41) maps to chromosome 12q24-qter.** X.Z. Liu<sup>1,2</sup>, S.H. Blanton<sup>1,3</sup>, C.Y. Liang<sup>2</sup>, M.W. Cai<sup>2</sup>, A. Pandya<sup>1</sup>, B. Landa<sup>1</sup>, S. Mummalanni<sup>1</sup>, K.S. Li<sup>2</sup>, L.L. Du<sup>2</sup>, X.N. Qin<sup>2</sup>, Y.F. Liu<sup>2</sup>, W.E. Nance<sup>1</sup>. 1) Dept Human Genetics, VCU, Medical Col Virginia, Richmond, VA; 2) Dept Otolaryngology, West China University of Medical Sciences, Chengdu, China; 3) Dept Pediatrics, University of Virginia, Charlottesville, Virginia.

Hearing impairment is the most common sensory disorder in humans, and genetic factors are a major cause. Approximately 80% of hereditary hearing loss is non-syndromic without associated abnormalities. It is estimated that 15-25% of these cases exhibit an autosomal dominant pattern of transmission. At least 40 autosomal dominant loci have been mapped to date, and of these, 13 have been cloned. We have mapped a novel locus for autosomal dominant non-syndromic hearing loss, DFNA41, to chromosome 12q24-qter in a large multigenerational Chinese family with progressive hearing impairment. Most affected individuals noticed hearing impairment after their teens with subsequent gradual progression from moderate to profound loss. All affected individuals had bilateral sensorineural hearing loss involving all frequencies. There were no obvious vestibular dysfunction and other associated abnormalities. Following a genome wide scan performed by CIDR, a maximum multipoint lod score of 8.97 was obtained at marker D12S343. While multipoint analysis places the DFNA41 locus distal to D12S1609, there was no recombination with other more distal markers to permit identification of a distal flanking marker. Another deafness locus, DFNA25, has been mapped to 12q21-q24. We excluded linkage of the markers surrounding this locus to our family. The DFNA41 interval begins approximately 35 cM distal to DFNA25. Numerous genes are known to map to the region, and among the positional candidate genes, those functionally related to hearing or expressed in the inner ear are being screened for deafness-causing mutations. This work was supported by NIDCD grants DC04530, DC02530, and DC 04282.

**Linkage of autosomal dominant hearing impairment to a locus in 19q13.3-q13.4 and exclusion of BAX, a BCL2-related apoptosis regulator expressed in the cochlea.** *M. Pfister*<sup>1</sup>, *F. Mirghomizadeh*<sup>1,6</sup>, *M. Devoto*<sup>2</sup>, *B. Bardtke*<sup>6</sup>, *J. Oeken*<sup>4</sup>, *S. Koenig*<sup>4</sup>, *E. Vitale*<sup>3</sup>, *A. Riccio*<sup>5</sup>, *A. de Rienzo*<sup>5</sup>, *HP. Zenner*<sup>1</sup>, *N. Blin*<sup>6</sup>. 1) Otolaryngology, University of Tuebingen, Tuebingen, Germany; 2) AI duPont Hospital for Children, Dept. of Research, Wilmington, DE, USA & Department of Oncology, Biology, and Genetics, University of Genoa, Italy; 3) Dept. Until now, 32 loci have been identified by linkage analysis of affected families that segregate with non-syndromic and dominantly inherited form of hearing impairment (DFNA). Based on these data, 11 genes for DFNAs were cloned and their majority was characterized. A German family with a non-syndromic progressive hearing impairment transmitted in autosomal dominant modus was linked to 19q13.3-q13.4 by a genome-wide scan. Due to the low lodscore (1.85 at  $q=0.05$ ) for APOC2-locus we extended the fine mapping attempt with further markers in the same chromosomal region. This resulted in significant evidence for linkage to the markers D19S246 and D19S553 (two-point lodscores of 4.05 and 3.55 at  $q=0.0$ ) and a candidate critical region of 14 cM between markers D19S412 and D19S571. This region shows partial overlap with the previously reported DFNA4 critical region. The human gene BAX is orthologous to rodent Bcl2-related apoptosis gene that is temporally expressed in postnatal period of the developing inner ear of the mouse. BAX maps at a distance of no more than 0.73 cM distally to marker D19S553, and thus it appeared a likely candidate in our pedigree. Genomic sequencing of coding regions and exon/intron boundaries resulted in no indication for disease-related mutations, hence, most likely excluding BAX as a candidate gene. However, additional ESTs in the same region remain to be tested.

**Evidence that Connexin 26 35delG does not represent a mutational hotspot.** *C.R. Rothrock<sup>1</sup>, A. Murgia<sup>4</sup>, E. Leonardi<sup>4</sup>, E. Sartorato<sup>5</sup>, L. Bean<sup>1</sup>, R. Fisher<sup>2</sup>, J. Elfenbein<sup>3</sup>, K. Friderici<sup>1</sup>.* 1) Microbiology & Mol. Gen; 2) Peds & Hum. Dev; 3) Audiology and Speech Path., Michigan State University, East Lansing, MI; 4) Dept Pediatrics, Univ. Padua, Padua, Italy; 5) CBMEG, Laboratorio de Genetica Humana, Universidade Estadual de Campinas, Campinas, SP, Brazil.

Non syndromic hearing impairment (NSHI) is the most common form of deafness and presents with no other symptoms or sensory defects. Mutations in the gap junction gene GJB2 account for a high proportion of recessive NSHI. The GJB2 gene encodes connexin 26 that forms plasma membrane channels between cochlear cells. In Caucasian populations a single mutation, 35delG, accounts for most cases of NSHI. This mutation appears to be most prevalent in individuals of Mediterranean European descent, with carrier frequencies estimated as high as one in thirty. Because the 35delG mutation arises from the deletion of one G in a stretch of six guanines, and also because microsatellite markers previously tested show little evidence for linkage disequilibrium, it is possible that this may be a mutational hotspot. However, we believe that 35delG is an old mutation in a chromosomal region of high recombination. To distinguish between an old or recurring mutation, the genetic context of the 35delG mutation was examined. We identified two single nucleotide polymorphisms (SNP) immediately upstream of the first exon of GJB2. PCR-RFLP analysis determined the SNP genotype of 35delG containing chromosomes from various populations, including North America, Italy and Brazil. We find the same relatively rare polymorphism associated with the 35delG mutation in all populations studied. We have also examined microsatellite markers D13S175, which is 80 kb centromeric to GJB2, and D13S1316, which is 80 kb telomeric to GJB2. D13S175 appears to be in strong linkage disequilibrium with 35delG, while D13S1316 shows less linkage disequilibrium. This indicates there has been substantial recombination around the 35delG mutation, especially telomeric to the gene. Our data suggests the 35delG mutation is not a recurring mutation at a mutational hotspot, but is more likely an older mutation that has been maintained in the Caucasian population.

**Development of a laboratory information management system for high throughput SNP genotyping.** *A.A. Chen, K. Embree, J. Bryce, G. Lichtman, A. Mailman, K. Munnely, J.S. Rennich, R. Stanton, T. Yamartino, A. Parker.* Millennium Pharmaceuticals, Cambridge, MA.

The completion of the Human Genome Project has made available to geneticists a vast number of candidate SNPs. Seeking to discover SNPs associated with neuropsychiatric disease, we studied 2251 individuals drawn from a population characterized by an elevated incidence of schizophrenia. In this sample we genotyped a large number of polymorphisms closely spaced in a region known to exhibit linkage to the disease using TaqMan assays. We attempted to configure markers for 78 SNPs, with 92% success; these 72 markers were typed in the study sample with an average of 95% completeness and greater than 99% accuracy. The design and implementation of a comprehensive Laboratory Information Management System (LIMS) is a prerequisite for successful high throughput SNP genotyping on this scale. We have designed and implemented a LIMS permitting us to generate and analyze up to 23,000 SNP genotypes per day.

The LIMS has four fully modular components. The first module is a database system that inventories SNP markers including oligonucleotide sequences, PCR reaction conditions, and physical storage locations. The second module is an allele-calling program that graphically displays data points and allows the user to assign allele calls to the data. A third module directs automated assembly of the PCR reactions on a Tecan Genesis liquid-handling robot. The fourth module is an information management system that inter-connects the other modules, providing barcode label control over disposable labware, and implementing a secondary QC analysis of scored genotypes prior to final storage.

**Integrated genotype/phenotype analysis of complex genetic disorders using the Discovery Manager™ Database.**

*C. Lopez-Correa*<sup>1</sup>, *E. Legius*<sup>2</sup>. 1) Genomica Corporation UK, Ltd Berkhamsted; 2) Center of Human Genetics KULeuven, Belgium.

Now, more than ever, there is an increasing need to handle genetic and population studies due to the overwhelming volume of data and variety of sources. One of the present challenges in genetic research is the study of complex genetic disorders using data from different sources including clinical data, genotype data and mapping data. For those researchers that want to perform genotype/phenotype correlations in complex genetic disorders from multi-disciplinary and multi-site projects this task is even more difficult. Discovery Manager™, a software solution from Genomica, provides an integrated, flexible, easy-to-use database and analysis environment in which genetic, phenotypic, molecular and population-derived information can be stored. This data may be visualized, manipulated and mined with simple and intuitive data management tools specifically designed for genetic and molecular studies. All stored information can be rapidly transformed and exported in the rich formats required for further research and analysis using third party programs such as CRIMAP, MULTIMAP, GENEHUNTER 2.0, LINKAGE, DISEQ, HAPLO, MAPMAKER/SIBS, SAGE/SIBPAL, SIMWALK 2, GAS and SAS. Here we show an example using NF1 microdeletion patients (*Am J Hum Genet.* 2000 ;66(6):1969-74 and *Hum Mutat.* 1999;14(5):387-93). All the genotype and phenotype data from the patients was stored and analyzed in Discovery Manager™. Physical mapping from the deletion region as well as sequence analysis from the sequences involved in the deletion process could also be analyzed using DMTM. Using Discovery Managers analysis tools, the subject population can be stratified based on the severity of the phenotype, and correlation between the particular phenotype and the genotype (markers/ deletion size) can be performed. The sequence analysis tools could also be used to identify new genes located in the deletion region that might be implicated in the phenotype. Aside from this application, Discovery Manager supports a wide range of workflows such as genome-wide linkage scan, association studies and pharmacogenomics.

**Improved design of genetic studies using computer generated data.** *F. Sievers, E. Kelly.* Hitachi Dublin Laboratory, Trinity College, Dublin, Ireland.

Any gene hunting study, be it association or family based, requires an initial design of experiment. This design is usually hampered by uncertainties concerning the dimensioning of the study. For example, how big a stretch of the genome to span, what density of markers, which kind of markers and how many patients or families? Is the total population big enough to support a meaningful analysis or does one have to move to a different population? We propose to use computer generated genetic data to furnish at least approximate answers to these questions. Our population generator traces a set of loci for a whole population over a specified number of generations. We simulate target genes (associated, for example, with diseases or traits) and markers. The number of loci, allele frequencies and recombination ratios between loci can be selected by the designer of the experiment to simulate all possible and impossible scenarios. At different time steps the generated genetic data can be analysed to see if the experiment design is capable of detecting the desired signal (e.g., linkage disequilibrium). We have chosen the Transmission Disequilibrium Test (TDT) as an example to demonstrate the benefits of our technique. A disease gene was initially introduced among microsatellites and SNPs. The population was evolved over 50 generations, at each step guaranteeing random mating but avoiding consanguinity. After a number of generations a signal emerged due to recombinations of the more remote marker loci, confirming the location of the introduced disease gene. As time elapsed an exponential decay of linkage was observed due to recombinations in the vicinity of the disease locus. To assess the accuracy of the TDT results we bootstrapped the population data. Varying the patient sample size was clearly reflected in the size of the error bars observed, thus giving an estimate for the smallest possible population size required to give a reliable signal. We also studied the effect of marker spacing and type of marker (SNP/microsatellite) on the ability to detect linkage.

**An association between an aggrecan gene polymorphism and idiopathic scoliosis.** *T.I. Axenovich<sup>1</sup>, I.V.*

*Zorkoltseva<sup>1</sup>, A.M. Zaidman<sup>2</sup>, O.A. Lubinsky<sup>1</sup>, R.N. Sharipov<sup>1</sup>, G.M. Dimshits<sup>1</sup>.* 1) Institute of Cytology and Genetics, Russian Academy of Sciences, Novosibirsk, Russia; 2) Novosibirsk Research Institute of Traumatology and Orthopaedics, Novosibirsk, Russia.

Idiopathic scoliosis (IS) is defined as a lateral curvature of spine and is a complex inherited disease of unknown etiology. We have performed a segregation analysis of IS on 101 families from Siberian population and found evidence for autosomal major-gene control of the disease with incomplete gender- and age-dependent penetrance. The next step is the mapping of the disease predisposing gene. For that purpose we have used the candidate gene approach, with the aggrecan gene as the candidate gene for IS. Due to the different number of tandem repeats in the alleles of this gene, the aggrecan core proteins are of different length, which may lead to changes in the functional properties of the cartilage. As has been demonstrated, aggrecan gene polymorphism is related to some bone malformations, for example, lumbar disc degeneration. We have performed TDT test on 33 unrelated simplex families (i.e. proband and his/her parents), selected from the sample used in the previous segregation analysis. We have found 9 alleles of aggrecan gene in the sample analyzed, of which three (containing 25, 26 and 27 tandem repeats) were most frequent. We did not detect preferential transmission of any of these alleles to the affected offspring (TDT statistics for an allele vs. all the others varied from 0.0 to 0.71). The global TDT test of marginal heterogeneity did not reveal any association, either. No correlation has been found between the number of tandem repeats and the degree of spine deformation. Thus, either the number of tandem repeat polymorphism of the aggrecan gene is irrelevant to the development of idiopathic scoliosis in the families under consideration, or the effects of this polymorphism are too small to be detected given the sample size chosen.

**Linkage of femoral neck bone mineral density to a quantitative trait locus on chromosome 1p36 by variance component analysis.** *M. Devoto*<sup>1,2</sup>, *C. Specchia*<sup>1,3</sup>, *H-H. Li*<sup>1</sup>, *J. Caminis*<sup>4</sup>, *A. Tenenhouse*<sup>4</sup>, *H. Rodriguez*<sup>5</sup>, *L.D. Spotila*<sup>5</sup>. 1) Dept. Research, AI duPont Hospital for Children, Wilmington, DE; 2) Dept. Oncology, Biology, and Genetics, University of Genoa, Genoa, Italy; 3) Dept. Health Science, University of Genoa, Genoa, Italy; 4) McGill Bone Centre, Montreal, Canada; 5) Dept. Bioscience and Biotechnology, Drexel University, Philadelphia, PA.

Osteoporosis is a common condition characterized by reduced skeletal strength and increased susceptibility to fracture. Eight million Americans over the age of 50 have osteoporosis of the femoral neck. The most important risk factor for osteoporosis is low bone mineral density (BMD), and several epidemiological studies have shown the importance of genetic factors in determining variability of BMD. Our initial genome screen in seven large pedigrees produced suggestive evidence for a candidate region conferring susceptibility to low bone mineral density of the femoral neck located on chromosome 1p36. We have now confirmed and extended this finding by typing nine microsatellite markers spanning a 40 cM interval across our candidate region in a total of 42 Canadian families. Heritability of femoral neck BMD was estimated as  $0.51 \pm 0.13$  in our families, after accounting for the effects of age, sex, BMI, height and weight. Variance component linkage analysis by means of the SOLAR computer program yielded a maximum multipoint lod-score of 3.5 for linkage of femoral neck BMD to a QTL located near marker D1S214, with an associated empirical p-value by simulation analysis of less than 0.00015. More than 50% of the total phenotypic variance was explained by this locus, with no residual additive genetic variance. Our results strongly support the hypothesis that a QTL controlling femoral neck BMD is located on chromosome 1p36, and further analysis of candidate genes in this region is warranted.

**ASSOCIATION BETWEEN TNFR2 AND FAMILIAL BUT NOT SPORADIC RHEUMATOID ARTHRITIS PROVIDES EVIDENCE FOR GENETIC HETEROGENEITY.** *P. Dieude<sup>1</sup>, E. Petit<sup>1</sup>, S. Cailleau-Moindrault<sup>1</sup>, J. Osorio<sup>1</sup>, S. Lasbleiz<sup>2</sup>, B. Prum<sup>1</sup>, T. Bardin<sup>1,2</sup>, F. Cornelis<sup>1,2</sup>.* 1) Laboratoire de recherche Européen pour la Polyarthrite Rhumatoïde, Genopole, for ECRAF, EVRY, FRANCE; 2) Centre Viggo-Petersen, Hôpital Lariboisière, PARIS, FRANCE.

**Background.** Tumor necrosis factor alpha (TNF $\alpha$ ) involved in rheumatoid arthritis (RA) binds TNFR1 and TNFR2 receptors. Genome scans have suggested the TNFR2 locus as a candidate RA locus. A case-control study in a United Kingdom (UK) Caucasian population has shown an association between a TNFR2 genotype (196R/R in exon 6) and familial, but not sporadic RA. **Objective.** To test this association in the French Caucasian population. **Methods.** To test for an association in sporadic RA, 100 families were genotyped for the 196M/R polymorphism and analyzed using the transmission disequilibrium test and the haplotype relative risk (HRR). To test for an association in familial RA, RA index cases from affected sib pair (ASP) families (n = 100) were genotyped for 196M/R. Linkage analysis was performed with 3 TNFR2 microsatellite markers. **Results.** The TNFR2 196R/R genotype was not associated with sporadic RA (odds ratio [OR]: 0.59, P= 0.72), but with familial RA (OR: 4, P= 0.026). The association was most marked in the context of TNFR2 twin-like RA sibs (affected sibs sharing both TNFR2 haplotype) (OR: 9.73, P= 0.0017). Linkage analysis was consistent with the association, the subgroup of families with 196R/R ASP index cases provided most of the TNFR2 linkage evidence. **Conclusion.** This study represents the first replication of the involvement of TNFR2 in RA genetic heterogeneity. Our data refine the initial hypothesis, to suggest that a TNFR2 recessive factor, in linkage disequilibrium with the 196R allele, plays a major role in a subset of families with multiple RA cases.

**Genome Scan for Hand Osteoarthritis: The Framingham Study.** *S. Demissie*<sup>1</sup>, *L.A. Cupples*<sup>1</sup>, *R.H. Myers*<sup>2</sup>, *P. Aliabadi*<sup>2</sup>, *D. Felson*<sup>2</sup>. 1) School of Public Health, Boston University, Boston, MA; 2) School of Medicine, Boston University, Boston, MA.

Osteoarthritis (OA) is the most common form of arthritis and is among the leading causes of disability. As part of the complex etiology of this disease, there is an increased recognition that a genetic component plays an important role, 20-50% heritability. Our objective was to search for markers that are linked to hand OA using radiographic data in the Framingham Heart Study. The sample included 684 original cohort members (parents) and 793 offspring in 296 pedigrees. The average age at which the hand radiographs were taken was 62 years for the original cohort and 54 years for the offspring. Radiographs were read by one expert reader, and OA features evaluated included Kellgren and Lawrence (K/L) grade, osteophytes (OST), and joint space narrowing (JSN) scores (0-3 scale). Four quantitative hand OA phenotypes were computed from these measurements: sum of KL scores across hand joints, sum of OST scores, sum of JSN scores, and proportion of affected joints. Prior to linkage analysis these phenotypes were adjusted for age and sex using a linear regression analysis from which standardized residuals were computed. The variance component model (SOLAR) was then applied to the normalized scores of the residuals. Linkage was considered significant if the LOD score exceeded 3.0 and suggestive if it exceeded 1.5. Fifty percent of the original cohort members and 30% of their offspring had at least one affected joint defined as K/L grade<sup>3</sup>. Heritability of hand OA ranged between 28% ± 6% for the proportion of joints affected with OA to 34% ± 6% for the sum of KL grades. Eight chromosomal regions indicated suggestive linkage for at least one of the four phenotypes. For these chromosomal regions LOD scores were highest for JSN, with a LOD=2.96 on 1p at D1S1665. Chromosomes 7, 9, 13, and 19 indicated consistent LOD score elevation for multiple phenotypes. The results of this study suggest that there are several chromosomes that may harbor osteoarthritis susceptibility genes. Further investigation of these regions using larger studies and finer maps will be important to confirm linkage.

**Association of Fcγ receptor gene polymorphisms in the Japanese patients with systemic lupus erythematosus: Independent contributions from *FCGR2B* and *FCGR3A*.** C. Kyogoku<sup>1</sup>, H.M. Hashimoto<sup>4</sup>, J.G.J. van de Winkel<sup>3</sup>, C.G.M. Kallenberg<sup>2</sup>, K. Tokunaga<sup>1</sup>. 1) The University of Tokyo, Japan; 2) University Hospital Groningen, Netherlands; 3) University Medical Center Utrecht, Netherlands; 4) Juntendo University, Japan.

Human low affinity Fcγ receptors (FcγRs) constitute a clustered gene family located on chromosome 1q23, that consists of FcγRIIA, IIB, IIC, IIIA and IIIB genes. FcγRIIB is unique in its ability to transmit the inhibitory signals through ITIM in its cytoplasmic domain, and recent animal studies demonstrated the role of FcγRIIB in the regulation of autoimmunity. The association of genetic variants of FcγRIIA, IIIA and IIIB with systemic lupus erythematosus (SLE) has been extensively studied, but the results have been inconsistent in various populations. To examine the possibility that another susceptibility gene of primary significance exists within the Fcγ receptor loci, we screened for the polymorphisms of human *FCGR2B* gene. A single nucleotide polymorphism, c.695T>C, was detected, presenting two alleles coding for Ile (232I) and Thr (232T) within the transmembrane domain. The case-control association study using 193 Japanese patients with SLE and 303 healthy individuals demonstrated that 232T/T genotype was significantly increased in the patients (10.9%) compared with the healthy individuals (5.3%,  $c^2=5.6$ ,  $P=0.018$ ). Genotyping was also carried out for *FCGR2A*-131H/R, *FCGR3A*-176F/V and *FCGR3B*-NA1/2 polymorphisms, among which *FCGR3A*-176F/F showed significant association ( $c^2=5.8$ ,  $P=0.016$ ). The two-locus analyses revealed that, while the association of 3A and 2B was independent, the previously reported association of 3B was considered to derive from strong linkage disequilibrium with 2B. In conclusion, our present findings strongly suggested that *FCGR2B* and 3A independently contribute to the genetic susceptibility to SLE in the Japanese population. The role of FcγR region genes for the genetic background of SLE appears to be highly complicated, with multiple genes associated with different aspects of the disease in different populations.

**Evidence for a novel locus for human malignant infantile osteopetrosis on chromosome 6q21.** A. Ramirez<sup>1</sup>, J. Faupel<sup>1</sup>, C. Stoeckle<sup>1</sup>, C. Hasan<sup>2</sup>, U. Bode<sup>2</sup>, P. Propping<sup>1</sup>, C. Kubisch<sup>1</sup>. 1) Institute of Human Genetics, University of Bonn, Germany; 2) Department of Pediatrics, University of Bonn, Germany.

Malignant infantile osteopetrosis (OMIM 259700) is a rare autosomal recessive disease. The clinical findings including osteosclerosis, hepatosplenomegaly and pancytopenia normally become apparent during the first months of life. The disease is thought to be due to an inadequate bone resorption caused by osteoclast dysfunction. Mutations in the human subunit  $\alpha 3$  of the  $H^+$ -ATPase and the voltage-gated chloride channel CLCN7 are known to cause malignant infantile osteopetrosis by impairing osteoclast function. In a small inbred family with malignant infantile osteopetrosis, no mutation in the  $\alpha 3$  subunit of the  $H^+$ -ATPase nor in CLCN7 were found. To identify a novel osteopetrosis locus and to try to unravel the causative gene defect in this family, a candidate locus approach was pursued by homozygosity mapping. We excluded homozygosity for regions harboring several candidate genes which cause severe osteopetrosis in mice, among them c-FOS on 14q24, c-SRC on 20q11, OPGL on 13q14, and CSF-1 on 1p13. We then analyzed a region on human chromosome 6q21 syntenic to mouse chromosome 10 where the causative gene for the osteopetrotic mouse "grey-lethal" has been mapped. The murine critical locus is flanked by Fyn and Ros1, yet, the responsible gene has remained elusive. We detected homozygosity in a region spanning at least 15cM between microsatellite markers D6S1717 and D6S287. In this region several candidate genes, like Fyn-related-kinase (FRK), BET3, and MARCKS are located. We are currently conducting systematic mutation screening for several candidate genes. In summary, we provide evidence for a novel locus for human malignant infantile osteopetrosis on chromosome 6q21 probably representing the human ortholog of the murine "grey-lethal" locus.

**A new syndrome of hereditary sensory and cerebellar ataxia with muscle atrophy, SCA18: linkage to chromosome 7q31-7q32.** Z. Brkanac<sup>1</sup>, M. Fernandez<sup>4</sup>, M. Matsushita<sup>2</sup>, H. Lipe<sup>5</sup>, T.D. Bird<sup>2,3,5</sup>, W.H. Raskind<sup>1,2,6</sup>. 1) Depts of Psychiatry; 2) Medicine and; 3) Neurology, University of Washington, Seattle, WA; 4) Dept of Neurology, Ohio State University, Columbus OH; 5) GRECC and; 6) MIRECC, VA PSHCS, Seattle, WA.

The autosomal dominant (AD) spinocerebellar ataxias (SCAs) are a heterogeneous group of disorders characterized by variable clinical, electrophysiological, imaging and neuropathological profiles. This clinical heterogeneity is paralleled by molecular genetics studies that have so far implicated 13 loci in the etiology of the disease; 7 genes have been identified. There is a substantial clinical overlap between SCAs, and often they cannot be differentiated on the basis of clinical or neuro-imaging studies. We have identified a four generation American family of Irish ancestry with a unique neurological disorder displaying an AD pattern of inheritance. The proband presented with gait ataxia. Onset of symptoms is usually in adolescence, progression is slow and life span normal. There was variable expressivity of symptoms and severity, including ataxia, sensory loss, pyramidal tract signs and proximal weakness. EMG and NCV studies were consistent with sensory axonal neuropathy. Muscle biopsy revealed neurogenic atrophy and brain MRI has shown mild cerebellar atrophy. To identify the responsible locus we pursued a whole genome linkage analysis with ABI PRISM Linkage Mapping Set, Version 2. Two-point linkage was performed with the LINKAGE-MLINK program. After analyzing 114 markers, linkage to D7S486 was identified with a two point LOD score of 4.79 at Q=0.00. Evaluation of additional markers in the region provided a maximum LOD score of 6.36 at Q=0.00 for marker D7S2554. Haplotype analysis delimited an approximately 14 cM region between markers D7S2418 and D7S1804 containing the gene for this novel SCA. The locus was assigned the symbol SCA18 by the Genome Nomenclature Committee. Our latest query of the NCBI database revealed 52 genes mapped to the region. Interestingly, PMPCB, a gene which was identified as a frataxin protein partner and would be an excellent candidate gene, lies 10 cM proximal to the critical region.

**Genetic analysis of an Italian family with dominant focal dystonia adds further evidence for genetic splitting .**

*F. Brancati*<sup>1,2</sup>, *V. Caputo*<sup>1</sup>, *G. De Fazio*<sup>3</sup>, *E.M. Valente*<sup>1</sup>, *A. Ferraris*<sup>1,2</sup>, *A. Pizzuti*<sup>1,2</sup>, *A. Berardelli*<sup>2</sup>, *B. Dallapiccola*<sup>1,2</sup>.

Primary Torsion Dystonia (PTD) is a neurological disorder characterized by involuntary twisting movements and abnormal posture, in absence of any recognizable secondary cause. Most cases are sporadic, but several PTD families have been reported with autosomal dominant inheritance, reduced penetrance, and variable expression. Four PTD loci (DYT1, DYT6, DYT7 and DYT13) have been mapped, DYT1 being the only gene cloned so far. A unique mutation (GAGdel) in the DYT1 gene is responsible for most cases of early limb-onset generalised dystonia, usually with sparing of the cranial-cervical region. DYT6, DYT7 and DYT13, on chromosomes 8p, 18p and 1p36, have been mapped in single PTD families with adult onset and cranial-cervical involvement. Linkage analysis of the DYT6, DYT7 and DYT13 regions was carried out in a three generation family (15 members) from Southern Italy with 6 patients affected by purely focal dystonia. Age of onset was between 20 and 50 years. Furthermore, the DYT1 gene on 9q34 was screened for the GAGdel mutation. In this family, linkage of dystonia with all known PTD loci was excluded, and the DYT1 mutation was not detected. These data suggest that, in this family, dystonia is linked to a novel unassigned gene, and confirm the genetic heterogeneity of adult-onset PTD. The small size of this kindred does not allow a genome-wide search. The clinical features are clearly distinct from those observed in the families linked to the excluded PTD loci. A detailed evaluation of the phenotype in newly recognized PTD families is crucial to identify clinically homogeneous families to be pooled together, in order to assign novel PTD loci. The present study supports that pure focal dystonia with variably affected body parts among family members is a distinct clinical and genetic disorder.

**5-HT6 receptor gene polymorphism and Parkinson's disease.** *G. Annesi<sup>1</sup>, I.C. Ciro Candiano<sup>1</sup>, P. Serra<sup>1</sup>, A.A. Pasqua<sup>1</sup>, F. Annesi<sup>1</sup>, C. Tomaino<sup>1</sup>, P. Spadafora<sup>1</sup>, S. Carrideo<sup>1</sup>, D. Civitelli<sup>1</sup>, E.V. De Marco<sup>1</sup>, L. Mangone<sup>2</sup>, G. Nicoletti<sup>1</sup>, D. Messina<sup>1</sup>, A. Quattrone<sup>1,2</sup>.* 1) Inst Exp Med & Biotech, National Research Council, Cosenza, Italy; 2) Inst Neurol, Dept Med Sci, Univ Catanzaro, Italy.

Parkinson's disease (PD) is neurodegenerative disease characterized by a triad of rigidity, resting tremor and bradykinesia. These symptoms result predominantly from the dysfunction and loss of nigrostriatal dopaminergic neurons. Damage to dopaminergic nigrostriatal neurons in the unifying neuropathology and neurochemical feature of the disease. Studies have reported reduced 5-HT concentration in patients with PD, and evidence suggests that serotonin (5-HT) may modulate dopaminergic activity in the striatum. The effects of 5-HT in the brain are mediated through several receptor subtypes. 5-HT6 gene maps to human chromosome region 1p35-36 and encodes for a receptor protein that positively links to adenylyl cyclase. In this study we conducted a genetic association analysis to verify whether the allelic variant C267T of the human 5-HT6 gene contribute to the risk of developing PD. To test this hypothesis, we studied the C267T polymorphism in 243 patients with PD (142 men and 101 women; mean age  $66.7 \pm 8.8$ ) and 234 healthy control subjects (117 men and 117 women; mean age  $68.0 \pm 15.9$ ) all coming from the same geographical area. Both populations were in Hardy-Weinberg equilibrium. Allele and genotype distribution were significantly different between patients and controls. Patients carried the C allele less frequently than controls and subjects who were homozygous (CC) or heterozygous (CT) for the C267T polymorphism were at reduced risk of PD (OR=0.60; CI= 0.40-0.89;  $p=0.013$ ). The functional significance, if any, of this polymorphism is unknown and this association, although interesting, needs to be replicated.

**Systematic Genome Scan of Alcoholism using Genetic Linkage Analysis in Multiplex British Families supports the presence of susceptibility loci on chromosome 1p and 16p.** *I. Guerrini<sup>1</sup>, C.C.H. Cook<sup>3</sup>, W. Kest<sup>1</sup>, A. Devitgh<sup>1</sup>, A. McQuillin<sup>1</sup>, G. Kalsi<sup>1</sup>, D. Curtis<sup>2</sup>, H.M.D. Gurling<sup>1</sup>.* 1) Molecular Psychiatry Laboratory, Windeyer Institute for Medical Science, Department of Psychiatry and Behavioural Sciences, Royal Free and University College London Medical University of London, 46 Cleveland Street, London W1P 7PN; 2) Joint Academic Department of Psychological Medicine, St Bartholomew's and Royal London School of Medicine and Dentistry, 3rd Floor Alexander Wing, Turner Street, London E1 1BB; 3) Kent Institute of Medicine and Health Science, University of Kent at Canterbury, Canterbury, Kent CT2 7PD.

Previous genome-wide scan studies have reported suggestive evidences of linkage to alcoholism on chromosome 11p, near the tyrosine hydroxylase and the DRD4 loci, on chromosome 4, in two loci, near the locus for the b1-GABA receptor unit and near the ADH gene cluster (Long et al., 1998) and also on chromosomes 1p, 2q, 4p, 7q and 16p (Reich et al., 1998). We carried out a genome scan on medium to large sized British families, densely affected by alcoholism, by using a set of 360 polymorphic microsatellite markers. Linkage analysis was performed out using model-free and a model based lod scores methodologies. Linkage analyses with two point and multipoint analyses have shown positive lod scores on chromosome 1p at D1S1588 (MLOD: 1.8), D1S3723 (MLOD: 1.1) D1S1591 (MLOD: 0.9), D1S532 (MLOD: 1.23), D1S1675 (MLOD: 1.23) and at the locus D16S2622 on chromosome 16p (MLOD: 1.16). These results are supportive of linkage at two regions previously implicated by the USA COGA study on chromosome 1p and on chromosome 16p. Long JC, et al. (1998), *Am J Med Genet*, 81, 216-21; Reich T., Edenberg HJ et al. (1998), *Am. J. Med. Gen.*, 81, 207-215. **Clinical and genetic study of a family with autosomal recessive Charcot-Marie-Tooth (CMT2AR) from southern Italy mapping to 1q21.2-21.3.** A.L. Gabriele<sup>1</sup>, M. Muglia<sup>1</sup>, A. Patitucci<sup>1</sup>, A. Magariello<sup>1</sup>, R. Mazzei<sup>1</sup>, F.L. Conforti<sup>1</sup>, L. Mangone<sup>2</sup>, R. Nistico<sup>2</sup>, P. Valentino<sup>2</sup>, A. Quattrone<sup>2,1</sup>. 1) Institute of Experimental Medicine and Biotechnology, CNR, Cosenza-Italy; 2) Institute of Neurology, School of Medicine, Catanzaro-Italy.

Charcot-Marie-Tooth (CMT) disease is the most common inherited motor and sensory neuropathy. The axonal form of the disease is designated as CMT type 2 (CMT2) and has been divided into autosomal dominant CMT2 AD and autosomal recessive forms CMT2 AR. Five loci are implicated in autosomal dominant CMT2 and have been mapped on 1p35-p36 (CMT2A), 3q13-q22 (CMT2B), 7p14 (CMT2D) and most recently on 8p21 (CMT2E). A fifth CMT2 type (CMT2C) has not been linked to any known locus. Only two genes responsible for the CMT2A and the CMT2E have been identified as the Microtubule Motor KIF1Bb and neurofilament light (NFL) respectively. Until now, two loci have been associated with the autosomal recessive axonal form: the first has been mapped on chromosome 1q21.2-21.3 in a consanguineous Moroccan family, the second locus has been identified in a Costa Rican family on chromosome 19q13.3. So far only one family has been reported to be linked to the chromosome 1q21.2-21.3, making it difficult to compare clinical features and severity of the disease. In this study we report a pedigree from southern Italy with autosomal recessive CMT2. By analysis of the family we detected linkage to the 1q21.2-21.3. Our data likely locate the CMT2AR gene in a region of approximately 1.7cM between markers D1S303 and D1S506, confirming the previous report that the CMT2AR is genetically linked to the 1p21.2-21.3 region.

**Results of a high resolution genome screen in 443 Alzheimer's disease families: the NIMH Genetics Initiative.** *D. Blacker*<sup>1</sup>, *L. Bertram*<sup>1</sup>, *A.J. Saunders*<sup>1</sup>, *T.J. Moscarillo*<sup>1</sup>, *M.S. Albert*<sup>1</sup>, *H. Wiener*<sup>2</sup>, *R. Perry*<sup>2</sup>, *R.C.P. Go*<sup>2</sup>, *A. Mahoney*<sup>3</sup>, *T. Beaty*<sup>3</sup>, *M.D. Fallin*<sup>3</sup>, *S.S. Bassett*<sup>3</sup>, *E.W. Pugh*<sup>4</sup>, *K.F. Doheny*<sup>4</sup>, *R.E. Tanzi*<sup>1</sup>. 1) Massachusetts General Hospital/Harvard Medical School, Boston, MA; 2) University of Alabama School of Public Health, Birmingham, AL; 3) Johns Hopkins University Medical School/School of Public Health, Baltimore, MD; 4) Center for Inherited Disease Research, Baltimore, MD.

A 9 to 10 centimorgan genome screen of 443 affected sibpairs and other mostly small families with Alzheimer's disease from the National Institute of Mental Health Genetics Initiative sample (n = 1453: 700 affected, 419 unaffected, and 34 with phenotype unknown) was performed at the Center for Inherited Disease Research. Families in which any sampled affected onsetted prior to age 50 were excluded: the mean age of onset in this sample is 72.5 years (s.d. = 7.7), typical for late-onset Alzheimer's disease. The resulting genotypes and up-to-date clinical information--the highest resolution screen of the largest sample collected to date for this disease--were subjected to parametric two-point lod score analyses in LINKAGE, non-parametric two-point identity by descent analyses in Sibpal, and non-parametric multipoint analyses in GENEHUNTER, with additional efforts at localization using the novel multipoint program Genefinder. These analyses were performed for the total sample, and then separately for the late-onset (all sampled affecteds onsetting at or beyond age 65) and the remaining early/mixed strata. There were two peaks that gave strong evidence of genetic linkage (including chromosome 19q13 [the location of APOE], with ZLR = 3.8 in GENEHUNTER), and five additional areas with more modest evidence for linkage (ZLR > 2.5). Each of these peaks was observed across the various methods, and included evidence for linkage at several adjacent markers. Additional work is underway to follow-up on these peaks with flanking markers, and to test promising candidate genes within these regions.

**The A80G polymorphism in the reduced folate carrier (RFC-1) gene as risk factor for NTDs.** *P. De Marco*<sup>1</sup>, *M.G. Calevo*<sup>2</sup>, *L. Arata*<sup>1</sup>, *A. Moroni*<sup>1</sup>, *E. Merello*<sup>1</sup>, *L. Andreussi*<sup>1</sup>, *A. Cama*<sup>1</sup>, *R. Finnell*<sup>3</sup>, *V. Capra*<sup>1</sup>. 1) Lab.Servizio di Neurochirurgia, Istituto Scientifico G.Gaslini, Genova, Genova, Italy; 2) Servizio di Epidemiologia e Biostatistica, Istituto G. Gaslini, Genova, Italy; 3) Center for Human Molecular Genetics, Nebraska Medical Center, Omaha, NE.

Moderate hyperhomocysteinemia in women has been associated with an increased risk of pregnancies affected by neural tube defects (NTDs). Folate supplementation may normalize homocysteine metabolism and decrease NTD risk. The C677T polymorphism of the MTHFR enzyme is an important genetic risk factor. Furthermore, compromise of internalization of folate may be involved in pathogenesis of NTD. Folate transport system is mediated by a low affinity and high capacity membrane protein encoded by the newly discovered RFC-1 (reduced-folate carrier) gene. A common polymorphism, A80G, in exon 2 of RFC-1 gene could be an additional risk factor, since that doubly homozygous 80GG/677TT subjects have moderate increase in homocysteine levels. In a case-control study, we examined the genotype frequencies of A80G polymorphism in the Italian population and evaluated its impact on NTD individuals and their relatives. By means of restriction enzymatic analysis, we determined that the frequency of the G allele was 0.46 among control individual suggesting that the A80G mutation is a common polymorphism, at least among Italian population. Significantly higher frequencies were found among NTD cases (0.57), mothers (0.59) and fathers (0.50). OR and 95% CI for heterozygous 80AG and homozygous 80GG NTD cases were 1.84 (0.97-3.51;  $P < 0.045$ ) and 2.43 (1.18-5.06;  $P < 0.009$ ), respectively. A similar risk was found for homozygous mothers: OR=2.83 (0.93-8.83;  $P < 0.04$ ). The odds ratio were also calculated for heterozygous A80G genotype of the mothers and for heterozygous and homozygous genotype of the fathers, but the results were not statistically significant. These results demonstrate that the RFC-1 80G polymorphism may play a role in NTD risk, at least in the Italian population. Further studies should evaluate of the level of risk conferred by interaction between the A80G mutation and other polymorphisms, especially the C677T of the MTHFR gene.

**Linkage and candidate gene analysis of Idiopathic Epilepsies.** *M.E.S. Bailey<sup>1</sup>, S.A. Carter<sup>1</sup>, E.S. Tobias<sup>2</sup>, P. Kwan<sup>3</sup>, R. Sutton<sup>1</sup>, G.J. Sills<sup>3</sup>, M.J. Brodie<sup>3</sup>, K.J. Johnson<sup>1</sup>.* 1) Div Molecular Genetics, IBLs, Univ Glasgow, Glasgow, U.K; 2) Dept Medical Genetics, Yorkhill Hosp., Glasgow, U.K; 3) Epilepsy Unit, Univ. Dept Medicine and Therapeutics, Western Infirmary, Glasgow, U.K.

The idiopathic epilepsies (IE) are a complex set of common disorders of the brain characterised by the occurrence of unprovoked seizures of unknown aetiology as the main or only symptom. In familial cases, a range of seizure phenotypes may co-exist in different family members and within individuals. It is thought that major genes underlie aspects of seizure susceptibility, while modifier loci of varying effect contribute to seizure type specificity and severity. Recently, progress has been made in mapping and identifying genes involved in IEs, particularly the most clearly familial forms, all of which have turned out to be ion channels, making these the current candidate genes of choice. One recently described syndrome, GEFS+, is caused in a few families by mutations in genes encoding subunits of neuronal sodium channels, *SCN1A*, *SCN2A* and *SCN1B*. Other phenotype combinations are caused by mutations in members of the calcium channel and GABA<sub>A</sub> receptor subunit gene families. Another common form IE, juvenile myoclonic epilepsy (JME), can exist either alone, or with other IEs in the syndrome idiopathic generalised epilepsy (IGE). Recent genome scans of JME and IGE families have implicated several novel chromosomal regions. We have collected both families with IE phenotypes and JME triads with full clinical investigation. In familial cases, we have conducted linkage analyses using markers spanning chromosomal regions harbouring known IE loci. Results to date have shown evidence for lack of linkage across large regions of these chromosomes. We have found a significantly positive score in non-parametric linkage analysis in a GEFS+ family in a novel region of chr.2p. JME patients and the affected individuals from the familial cases have been screened by SSCP and dHPLC for variant mobility fragments in *SCN1A*, *SCN1B*, *CACNB4*, *GABRG2* and several other candidate genes. No variants segregating consistently with affected status have been observed. Candidate gene mutation and association studies are ongoing.

**Clinical and genetic heterogeneity in Joubert syndrome: exclusion of loci on 9q and 17p.** A. Badhwar<sup>1,2,6</sup>, E. Andermann<sup>1,2</sup>, F. Andermann<sup>1,3</sup>, E. Uyama<sup>4</sup>, J. Kamei<sup>5</sup>, S. Bourgoin<sup>6</sup>, M. Labuda<sup>6</sup>, B. Rosenblatt<sup>1,3</sup>, M. Shevell<sup>1,3</sup>, A. Lortie<sup>7</sup>, L. Carmant<sup>7</sup>, M. Pandolfo<sup>1,6</sup>. 1) Depts. of Neurology and Neurosurgery; 2) Human Genetics and; 3) Pediatrics, McGill University, Montreal, Canada; 4) Dept. of Neurology, Kumamoto University School of Medicine, Japan; 5) Dept. of Neurology, Iwate Medical College, Japan; 6) CRLCS, Notre Dame Hospital, Montreal, Canada; 7) Dept. of Neurology, St. Justine Hospital, Montreal, Canada.

Four French-Canadian siblings with agenesis of the cerebellar vermis, episodic alternating hyperpnea and apnea, developmental delay, ataxia, hypertonia, and oculomotor abnormalities were described by Joubert et al. (Neurology 1969;19:813-825). Subsequently, Joubert syndrome (JS) has been recognized as a common autosomal recessive disorder of brain development with variable phenotype (Curr Opin Pediatr 2000;12:523-528). To date, the molecular basis of JS is unknown. Linkage to chromosome 9q34.3 was reported in one consanguineous Arabian-Iranian family (Am J Hum Genet 1999;65:1666-1671). More recently, the description of a patient with the JS phenotype and an unusual Smith-Magenis syndrome (SMS) deletion (del 17p11.2-12) suggested the presence of a JS gene in close proximity to the SMS locus (Am J Med Genet 2000;95:467-72). In the present study, we recruited ten JS families, including the original sibship described by Joubert et al. Seven of these families were of French-Canadian origin, and three of Japanese descent. Significant clinical heterogeneity was found within and among the JS sibships. Genealogical study of the French-Canadian families resulted in a pedigree of 425 people spanning 11 generations, and tracing back to a founder who immigrated to Quebec, Canada from the province of Perche, France in 1634. We genotyped nine families using polymorphic markers (D9S164, D9S1818, D9S114, D9S1826, D9S158, and D9S1838) on the 9q34.3 locus and markers that define the possible JS locus on 17p11.2-12. Haplotype analysis in these families showed no evidence of homozygosity relevant with linkage to either the 9q or 17p loci, suggesting genetic heterogeneity in JS. A genome-wide scan is underway.

***Mvb1* Suppresses Neurodegeneration in the *vibrator* Mouse.** J.A. Floyd<sup>1</sup>, D. Concepcion<sup>2</sup>, E.J. Ward<sup>2</sup>, B.A. Hamilton<sup>1</sup>,  
<sup>2</sup>. 1) Program in Biomedical Sciences, UC San Diego, La Jolla, CA; 2) School of Medicine, UC San Diego, La Jolla, CA.

*Vibrator* mice have a five-fold decrease in *phosphatidylinositol transfer protein a (PITPa)* gene expression which is caused by an insertion of an endogenous retrovirus into intron 4. The resulting phenotype of the mouse is an early-onset tremor with decreased longevity and neurodegeneration in the brainstem and spinal cord. The CAST-Ei allele of the gene *Modifier of vibrator1 (Mvb1)* was found to suppress these phenotypes in the *vibrator* mice. Specifically, life span of the mice is increased, neurocytology is improved, and *PITPa* expression is increased two-fold. This locus has been mapped to chromosome 19 through 10,000 meioses. The *Mvb1* interval contains nine genes, three of which are expressed in tissues that show *Mvb1* effects on *PITPa* RNA levels and are polymorphic between the two strains. As *Mvb1* affects *PITPa* expression in fibroblasts cultured from *vibrator* mice, *Mvb1* will be identified by *in vitro* complementation.

**Association studies of multiple candidate genes for Parkinson's disease by using single nucleotide**

**polymorphisms.** *Y. Momose<sup>1,2</sup>, M. Murata<sup>2</sup>, K. Kobayashi<sup>1</sup>, M. Tachikawa<sup>1</sup>, N. Hattori<sup>3</sup>, M. Yamamoto<sup>4</sup>, I.*

*Kanazawa<sup>2</sup>, T. Toda<sup>1</sup>.* 1) Div. Functional Genomics, Dept. Post-Genomics and Diseases, Osaka Univ. Grad. Sch. Med., Osaka; 2) Dept. Neurology, Grad. Sch. Med., Univ. Tokyo, Tokyo; 3) Dept. Neurology, Juntendo Univ. Sch. Med., Tokyo; 4) Dept. Neurology, Kagawa Pref. Central Hospital, Kagawa, Japan.

Parkinson's disease (PD) is a complex genetic disorder, with multiple genetic and environmental factors influencing disease risk. Although several causal genes of familial parkinsonisms have recently been identified, certain genetic factors associated with pathogenesis of idiopathic PD have not yet been clarified. On the other hand, clinical course and effects or side effects to antiparkinsonian drugs are different between each patient. To identify susceptibility genes for PD and to establish tailor-made medicine for PD, we started association studies by using single nucleotide polymorphisms (SNPs) in candidate genes. 236 patients with PD and 249 normal controls were examined in this study. We studied 20 SNPs of 18 candidate genes for association with PD, namely, (1) dopamine-related genes: AADC, COMT, DBH, DRD3, DRD5, DAT; (2) nerve growth factor-related genes: BDNF, CNTF, NGFB, NTRK1; (3) genes for metabolism or transportation of toxins: CYP1A2, CYP2E1, CYP2C9, PON1, MTHFR, DIA4, ABCB1; (4) genes of familial PD; UCH-L1. We found that homozygosity for the V66M polymorphism of the BDNF(brain derived neurotrophic factor) gene occurs more frequently in PD patients than in unaffected controls ( $c2=5.59$ ,  $p=0.018$ ). In addition, we confirmed that homozygosity for the S18Y polymorphism of the UCH-L1(ubiquitin carboxy-terminal hydrolase L1) gene are less frequent ( $c2=5.87$ ,  $p=0.015$ ). For the tailor-made medicine for PD, we further examined the association between each SNP and susceptibility to subsequent levodopa-associated adverse effects such as dyskinesia, wearing-off type motor fluctuation, and neuroleptic malignant syndrome. However, we saw no significant associations. Our results provide genetic evidence supporting a role for BDNF in the pathogenesis.

Program Nr: 1857 from the 2001 ASHG Annual Meeting

**The amyloid precursor protein locus and very-late-onset Alzheimer's disease.** *J.M. Olson, K.A.B. Goddard, D. Dudek.* Epid/Biostat, MetroHlth Med Ctr, Case Western Reserve Univ, Cleveland, OH.

Although mutations in the amyloid-beta precursor protein (APP) gene are known to confer high risk of Alzheimer's disease (AD) to a small percentage of early-onset families, convincing evidence of a major role for the APP locus in late-onset AD has not been forthcoming. Using data collected through the NIMH AD Genetics Initiative, we analyzed the chromosome 21 genome scan data using the covariate-based methods of affected-sib-pair (ASP) linkage analysis described in Goddard et al. [AJHG 68:1197-1206, 2001] and now available in S.A.G.E. By including covariates in the linkage model, one allows for possible locus heterogeneity due to the covariate. Using the number of E4 alleles in the ASP as a covariate, we confirmed an earlier finding using these data that ASPs lacking E4 alleles show some increased evidence for linkage (lod score = 1.13 vs baseline lod score = .02). More importantly, we obtained strong evidence for linkage when age-at-onset (lod=2.27, p=.0032), age-at-exam/death (lod=5.54, p=.000002) or age-at-onset plus disease duration (lod=5.63, p=.000006) were included as covariates in the linkage analysis. These results support a hypothesis that APP mutations are involved in familial AD in the most elderly patients (age-at-exam/death > ~88). Removal of potential outliers does not substantially change the results. These results also highlight the usefulness of covariate-based model-free linkage methods in complex human disease.

**A large family with pure autosomal dominant hereditary spastic paraplegia from southern Italy mapping to chromosome 14q11.2-q24.3.** *M. Muglia*<sup>1</sup>, *A. Magariello*<sup>1</sup>, *G. Nicoletti*<sup>1</sup>, *A. Patitucci*<sup>1</sup>, *A.L. Gabriele*<sup>1</sup>, *F.L. Conforti*<sup>1</sup>, *R. Mazzei*<sup>1</sup>, *M. Caracciolo*<sup>1</sup>, *G. Casari*<sup>2</sup>, *B. Ardito*<sup>3</sup>, *M. Lastilla*<sup>3</sup>, *L. Mangone*<sup>4</sup>, *A. Gambardella*<sup>1,4</sup>, *A. Quattrone*<sup>1,4</sup>. 1) IMSEB-CNR, Mangone Cosenza, Italy; 2) Stem Cells Research Institute, San Raffaele Hospital, Milano; 3) Department of Neurology, Miulli Hospital, Acquaviva delle Fonti-Bari; 4) Institute of Neurology, School of Medicine Catanzaro.

Hereditary spastic paraplegia (HSP) is a heterogeneous group of disorders of the motor system, characterized clinically by slowly progressive lower extremity spasticity and weakness. Clinically HSP is classified as pure form if neurological impairment is limited to progressive lower extremity spastic weakness and complicated form if additional symptoms such as seizures, dementia, amyotrophy, extrapyramidal disturbance or peripheral neuropathy also occur. Most pure forms are inherited with an autosomal dominant trait, although families with an autosomal recessive or X-linked mode of inheritance have also been described. At least seven loci associated with the pure form have been demonstrated: SPG4 (2p22), SPG13 (2q24-q34), SPG8 (8q23-24), SPG3(14q11-q21), SPG10(12q13), SPG6 (15q11.1) and SPG12 (19q13). In this study, we describe the clinical findings of a multi-generation Italian kindred with SPG13. Eleven affected individuals and twenty-four unaffected subjects participated in the genetic study. Using twelve microsatellite markers linkage to chromosome 14 was detected. Significant LOD scores were obtained with D14S255, D14S978 and D14S747 with the maximum LOD score of 4.58 with D14S255. Haplotypes analysis locates the SPG13 gene between markers D14S266 and D14S281. A gene (LOC 63380), belonging to the ATPase family, is located in this region. The fourteen coding exons of this gene from a patient and a healthy control were sequenced, but no point mutations were observed in these individuals relative to the published wild-type sequence. This finding excludes this gene as causative for SPG3.

**A Novel Autosomal Recessive Pure Hereditary Spastic Paraplegia in a Saudi Family Showing linkage to Chromosome 13q.** *C.A. Hodgkinson, S.A. Bohlega, E.J. Cupler, S.N. Abu-Amero, C.E. Boumah, M. Kambouris, B.F. Meyer, V.A. Bharucha.* Biological & Medical Research, KFSH&RC, RIYADH, SAUDI ARABIA.

Hereditary spastic paraplegia (HSP) is a complex disorder arising from mutations at a larger number of different loci. Transmission of the trait can be either autosomal dominant or recessive, and can also be X-linked. HSP is usually divided by the mode of transmission (dominant or recessive), and also as "pure" and "complex". In pure HSP no other traits are associated with the development of paralysis, whereas in the case of complex HSP other traits such as mental retardation are associated with the disorder. In a consanguineous marriage two unaffected parents produced eight children. Five of the children have shown difficulty in walking since early childhood, and are severely spastic. None of these individuals displays any apparent mental retardation or any visual defects. Spastic changes appear to be limited to the lower extremities. No other affected relatives have been reported. A whole genome scan using the CHLC marker set has linked the locus for the paraplegic trait to chromosome 13q by autozygosity. No HSP locus has been previously linked to chromosome 13, and therefore this family exhibits a novel form of autosomal recessive pure HSP. The interval underlying the HSP trait has been further refined using 17 additional markers to determine the limits of the homozygous region. Based upon these data, and on mapping of marker sequences to the newly available human genome sequence, we conclude that the gene causing this novel HSP lies within a 2.8 Mega-base region.

**Mutation screening of two candidate genes: Human peptide transporter and Human glypican 5 in families affected with bipolar disorder.** *M. Maheshwari<sup>1</sup>, E.S. Gershon<sup>2</sup>, S.L. Christian<sup>2</sup>, R.A. Gibbs<sup>1</sup>*. 1) Dept Molec/Human Gen, Baylor Col Medicine, Houston, TX; 2) Dept of Psychiatry, University of Chicago, Chicago.

Schizophrenia is a complex disorder. Gene mapping studies have identified chromosome 13q32 as one of the regions with evidence of linkage to schizophrenia and bipolar disorder. Human peptide transporter (HPEPT1) and human Glypican 5(GPC5) are two of the candidate genes within approximately 10 cM region of chromosome 13q32 region. In order to find susceptibility genes, we performed mutation screening of these two genes in 7 families (n=20) affected with bipolar disorder. The genomic structures of HPEPT1 and GPC5 were determined by direct comparison of their full-length cDNA with the sequence of human chromosome 13 genomic clones. Intronic oligonucleotide primer pairs flanking the coding fragments were designed for both the genes using program primer 3. Screening of the coding region of the genes for the sequence variants was performed by PCR amplification of each coding fragment. Twenty samples of seven families with bipolar disorder and a control sample were analyzed for twenty coding fragments of HPEPT1 and seven coding fragments of GPC5 gene. PCR reactions were carried out under the standard PCR conditions. Sequencing of each sample was done using the bodipy chemistry on an ABI 3700 DNA sequencer and analysis was done using sequencer program. No mutation or polymorphisms were identified in the GPC5 gene. Two variants were discovered in HPEPT1 gene, one in fragment 16 and the other one in fragment 20. Sequence analysis revealed a T to C substitution in third position of codon encoding alanine at 1403 position (Frag. 16) of mRNA and A to G substitution at position 2242 (Frag. 20) of mRNA. Of these, 6 individuals were homozygote CC, 15 heterozygote TC (Frag. 16) and 3 were heterozygote AG (Frag. 20). In the next step we plan to do genotype association studies of observed polymorphisms in larger samples of bipolar disorder and control population.

**Linkage of bipolar disorder susceptibility loci to chromosomes 22q and 13q in two independent family sets.** *J.R. Kelsoe<sup>1</sup>, S.H. Shaw<sup>1,2</sup>, Z. Mroczkowski-Parker<sup>1,3</sup>, T. Shectman<sup>1,3</sup>, M. Alexander<sup>1,3</sup>, R.A. Remick<sup>4</sup>, A.D. Sadovnick<sup>5</sup>, S. McElroy<sup>6</sup>, P. Keck<sup>6</sup>.* 1) Department of Psychiatry, UCSD, La Jolla, CA; 2) Department of Medicine, UCSD, La Jolla, CA; 3) San Diego VA Healthcare System, La Jolla, CA; 4) Department of Psychiatry, St. Paul's Hospital, Vancouver, Canada; 5) Department of Medical Genetics, University of British Columbia, Vancouver, Canada; 6) Department of Psychiatry, University of Cincinnati, Cincinnati OH.

Bipolar disorder or manic depressive illness is a severe psychiatric disorder with 1% prevalence and strong evidence for genetic factors. We have previously reported a genome scan of bipolar disorder in a set of 20 families from the general North American population. The regions with the strongest evidence of linkage in this study were 22q and 13q. The genome-wide maximum lod score in this sample was 3.8 at D22S278 on 22q13. We now report our linkage analysis of the same markers on 22q and 13q in a new set of 32 families similarly ascertained from the North American population. This second family set includes 194 subjects, 69 of whom have bipolar I or bipolar II disorders and 59 of whom have recurrent major depression. In this second family set on 22q, a maximum lod score of 2.2 was obtained at D22S684 approximately 2 MB from D22S278. Lod scores between 1.5 were also obtained near D22S419 which was a possible secondary peak in the first study. Linkage to 13q32 was also supported in this second family sample with a lod score of 2.29 at D13S154. Analyses of the combined sample of 52 families yielded multiple markers with lod scores between 2 - 2.5 on 22q in each the two regions detected in the previous sample. On 13q, the multipoint maximum lod score peaked approximately 7 cM proximal to D13S154 (lod = 3.40) with a second peak occurring between D13S225 and D13S796 (lod = 2.58). Together, these data in a second family set are consistent with our first study, as well as, other published reports and support the presence of at least one bipolar disorder susceptibility locus on both 22q and 13q. As each of these regions have been implicated in several studies of schizophrenia, they also raise the possibility of common susceptibility loci for these two disorders.

**PARK6 IS A MAJOR LOCUS IN EARLY-ONSET PARKINSONISM.** *E.M. Valente<sup>1,2</sup>, F. Brancati<sup>1,4</sup>, A. Ferraris<sup>1,4</sup>, A.R. Bentivoglio<sup>3</sup>, V. Bonifati<sup>4</sup>, J. Vaughan<sup>2</sup>, A. Pizzuti<sup>1,4</sup>, G. De Michele<sup>5</sup>, V. Caputo<sup>1</sup>, A. Brice<sup>6</sup>, T. Gasser<sup>7</sup>, M. Breteler<sup>8</sup>, B.A. Oostra<sup>8</sup>, B. Dallapiccola<sup>1,4</sup>, N.W. Wood<sup>2</sup> and European Consortium on Genetic Susceptibility in Parkinson Disease.* 1) C.S.S. Mendel Institute, Rome, Italy; 2) Institute of Neurology, London, UK; 3) Istituto di Neurologia, Università Cattolica, Rome, Italy; 4) Università La Sapienza, Rome, Italy; 5) Dipart. di Scienze Neurologiche, Università Federico II, Naples, Italy; 6) INSERM U289, Hôpital de la Salpêtrière, Paris, France; 7) Neurologische Klinik, Ludwig Maximilians Universität, Munich, Germany; 8) Erasmus University, Rotterdam, the Netherlands.

Parkinson's disease (PD) is a common neurodegenerative disorder characterised by tremor, rigidity and bradykinesia. Autosomal recessive juvenile parkinsonism (ARJP) is a clinically and genetically distinct entity, in which common PD features are associated with early onset, good response to levodopa and early levodopa-induced dyskinesias. So far, only 1 ARJP gene (Parkin) has been cloned, and several mutations have been detected in AR families and sporadic cases. However, in at least 50% of ARJP patients, no mutation could be found in the Parkin gene. We have recently mapped a novel recessive locus (PARK6) to chromosome 1p in a large Sicilian family with ARJP. We studied 25 European ARJP families not linked to Parkin. All available family members were genotyped for markers spanning the PARK6 locus. Pairwise and multipoint LOD scores were calculated and haplotypes were constructed. We detected linkage in 8 families from 4 different countries. Reconstruction of shared haplotypes between the affected sibs from each family and determination of the smallest region of homozygosity in a consanguineous family reduced the candidate interval to 9 cM. These findings confirm the linkage of a subset of Parkin-negative ARJP families to the PARK6 locus. No common haplotypes were detected among the linked families, suggesting different independent mutational events. PARK6 appears to be a major locus for ARJP in European patients.

**MAPPING OF AUTOSOMAL RECESSIVE CHRONIC DISTAL SPINAL MUSCULAR ATROPHY TO CHROMOSOME 11q13 IN A LARGE KINDRED.** *L. Viollet<sup>1</sup>, P. Burlet<sup>1</sup>, E. Vial<sup>1</sup>, A. Barois<sup>2</sup>, G. Rebeiz<sup>3</sup>, A.*

*Munnich<sup>1</sup>, S. Lefebvre<sup>1</sup>.* 1) INSERM U-393, Hopital Necker, Paris, France; 2) Fdration de l'Enfant, Hopital Raymond Poincar 92380 Garches, France; 3) Dept Neurology and Neuropathology, American University Hospital, Beirut, Lebanon.

Distal spinal muscular atrophy (distal SMA) represents a heterogeneous group of neuromuscular disorders caused by progressive anterior horn cell degeneration causing progressive motor weakness and muscular atrophy predominantly in the distal part of the limbs. Distal SMAs are also known as spinal-type Charcot Marie Tooth disease (spinal-CMT), distal Hereditary Motor Neuropathy type II or neuronal motor neuropathy form of Peroneal Muscular Atrophy. Various forms have been reported, with autosomal dominant or recessive mode of inheritance. We report here on chronic autosomal recessive distal SMA in a large inbred family, with various ages at onset. Since this condition shared neurological features with spinal muscular atrophy with respiratory distress and diaphragmatic paralysis (SMARD) mapped to chromosome 11q13-q21, we tested the disease for linkage. We mapped the disease locus to chromosome 11q13 in the genetic interval (D11S4076 and D11S1321) which encompasses the SMARD gene ( $Z_{max}$ : 4.59 at recombination  $q = 0$  at locus D11S4136). Thus, despite differences in the age at onset, clinical course and severity, this study supports the view that both chronic distal SMA and SMARD could be allelic disorders. The occurrence of diaphragmatic paralysis in some patients further reinforces this view. The study of candidate genes of the region will hopefully lead to the identification of the disease causing mutation and will determine whether SMARD and chronic distal SMA are indeed accounted for by the same gene. However, given the substantial size of our interval (~18.6-Mb according to the Human Genome Project Working Draft at UCSC database) and the high gene density of the 11q13 region, additional pedigrees are needed to refine this genetic interval.

**Additional, physically-ordered markers increase evidence of linkage between bipolar disorder and chromosome 18q22.** *T.G. Schulze<sup>1</sup>, Y.-S. Chen<sup>1</sup>, J.A. Badner<sup>1</sup>, M.G. McInnis<sup>2</sup>, J.R. DePaulo, Jr.<sup>2</sup>, F.J. McMahon<sup>1</sup>.* 1) Psychiatry, The University of Chicago, Chicago, IL; 2) Psychiatry, Johns Hopkins University, Baltimore, MD.

Prior studies in the Johns Hopkins University / Dana Foundation Bipolar Disorder Pedigrees indicated linkage of bipolar affective disorder (BPAD) to chromosome 18q21-23. Most of the linkage evidence derived from families with affected phenotypes in only the paternal lineage and from marker alleles transmitted on the paternal chromosome. We recently confirmed this finding in an analysis of a dense set of 32 microsatellite markers in the linkage region. We furthermore observed that paternal allele-sharing across 18q21-23 was greater in families with at least 2 siblings who had a particular subtype of BPAD known as bipolar II disorder. Multipoint affected sib-pair analysis of the 81 affected sib-pairs in these families produced a peak paternal lodscore of 4.67, with an approximate 1-lod support interval of 12 male cM. We have now added 6 additional markers to the 6 markers in and near the previous 1-lod support interval. Since recombinational ordering of such a dense set of markers is prone to errors, we instead determined marker order physically, according to the available human genome sequence. The complete set of 12 markers spans a region of 5.5 Mb with a mean inter-marker distance of 1.2 male cM, twice as dense as the previous marker set. Multipoint affected sib-pair linkage analysis revealed an increase in the peak paternal lodscore from 4.67 to 5.42 (empirical  $p < 0.007$ ). Linkage resolution also increased: The approximate 1-lod support interval narrowed from 12 to 9 male cM on chromosome 18q22. Our results support our previous findings and define a relatively small region suitable for further studies aimed at identifying the genetic variation that accounts for these linkage findings. This study also illustrates how sequence information can be used to minimize errors in marker order and thus increase the information value of linkage signals in studies of complex phenotypes.

**X-Linked Bilateral Perisylvian Polymicrogyria maps to Xq.** *L. Villard<sup>1</sup>, K. Nguyen<sup>1</sup>, C. Cardoso<sup>5</sup>, C. Lese<sup>5</sup>, A. Weiss<sup>5</sup>, M. Sifry-Platt<sup>3</sup>, A.W. Grix<sup>3</sup>, J.B. Graham<sup>4</sup>, R.M. Winter<sup>2</sup>, R.J. Leventer<sup>5,6</sup>, W.B. Dobyns<sup>5,7</sup>.* 1) INSERM U491, Faculté de Médecine La Timone, Marseille 13385, France; 2) Department of Clinical and Molecular Genetics, Institute for Child Health, London, UK; 3) Department of Medical Genetics, Kaiser-Permanente Point West Medical Offices, Sacramento, CA; 4) Medical Genetics and Birth Defects, Cedars-Sinai Medical Center, Los Angeles, CA; 5) Dpt of Human Genetics,; 6) Dpt of Neurology,; 7) Dpt of Pediatrics, The University of Chicago, 928 E 58th St, Chicago, IL 60657.

Polymicrogyria (PMG) is a human brain malformation characterized by excessive gyration and an abnormal cortical cytoarchitecture. It is presumed to be a defect of cortical development affecting late neuroblast migration or neuronal organization. Although the brain distribution is variable, the majority of cases are bilateral and involve the cortex surrounding the Sylvian fissures. The most frequent manifestations include epilepsy, speech and feeding difficulties, mental retardation and spasticity. In most cases, the cortical malformation is the only birth defect. Whilst intrauterine cytomegalovirus infection and vascular compromise are likely causes of PMG, evidence has accumulated supporting a genetic etiology. We have focused our analysis on the X-linked form of perisylvian PMG based on literature reports of X-linked inheritance, skewing of sex-ratio toward males in our series of patients, a preponderance of males among multiplex families and two multiplex families with affected males related through carrier females. We have included in the analysis five families with bilateral perisylvian PMG (BPP), two with definite and three with probable X-linked inheritance. We have genotyped 40 X-linked microsatellite markers providing good coverage of the entire X chromosome. Lod scores were computed using 2-point and multipoint linkage analysis softwares. Our results show significant linkage ( $Z > 2$  at  $\theta=0$  in 2-point,  $Z > 3$  in multipoint analysis) of PMG with a small region of the long arm of the X chromosome. A detailed physical and transcriptional map of the critical region is available and candidate gene analysis is currently underway to identify the causative gene defect.

**Investigation of association of SNPs with schizophrenia in a linked region on chromosome 10p.** *S.G. Schwab<sup>1</sup>, P. Sklar<sup>2</sup>, J. Hallmayer<sup>3</sup>, M. Albus<sup>4</sup>, M. Rietschel<sup>1</sup>, B. Lerer<sup>5</sup>, D.B. Wildenauer<sup>1</sup>*. 1) Dept Psychiatry, Univ Bonn, Bonn, NRW, Germany; 2) Whitehead Institute/MIT Center for Genome Research, Cambridge, MA, USA; 3) Stanford University, Palo Alto, Ca, USA; 4) Mental State Hospital, Haar, Germany; 5) Hadassah Medical School, Jerusalem, Israel.

Evidence for a potential susceptibility locus for schizophrenia on chromosome 10p has been obtained by a genome-wide survey of 71 sib-pair families using microsatellite markers. Availability of parents in these families facilitated investigation of all used microsatellite markers for association/linkage disequilibrium in presence of linkage by the transmission disequilibrium test (TDT). Moderate P values were obtained for D10S211. MALDI TOF mass spectroscopy was used to evaluate SNPs available from the SNP Consortium TSC data base in a region of 2-3 Mb for association with the trait. Several SNPs close to a potential candidate gene, the gene for a phosphatidylinositol-4-phosphate-5-kinase (PIP5K2A), produced nominally significant P values. Four novel polymorphisms within the genomic sequence of PIP5K2A have been discovered exhibiting P values  $<.02$ . One of the SNPs (G/A,  $P = .0022$ ) was found to be located in exon 7 causing a substitution of asparagine with serine. In addition, two SNPs located approx. 500kb downstream of the PIPK2A gene yielded P values of .00056, and .017. The positive regions are being further evaluated using all available SNPs and high throughput SNP genotyping using MALDI TOF mass spectroscopy in order to fine-map the area.

**Genetic analysis of the mutilated foot (*mf*) rat: an animal model for human hereditary sensory neuropathy.** *M.M.*

*Reilly*<sup>1</sup>, *M-J. Lee*<sup>1</sup>, *M.G. Sweeney*<sup>1</sup>, *D. Stephenson*<sup>2</sup>, *M. Davis*<sup>1</sup>, *M. Groves*<sup>1</sup>, *H. Houlden*<sup>1</sup>, *N.W. Wood*<sup>1</sup>, *F. Scaravilli*<sup>1</sup>.

1) Institute of Neurology, Queen Square, London, UK; 2) MacLaughlin Institute, USA.

The mutilated foot (*mf*) rat, derived from the Sprague-Dawley (SD) strain, is a spontaneous mutant with an autosomal recessive neuropathy. Clinical manifestations include ataxia, anaesthesia with increased pain threshold, and progressive ulceration leading to the destruction of the feet. The pathological features are a marked reduction in the number of myelinated and unmyelinated nerve fibers in the lumbar dorsal roots, and decreased neuron numbers in the cervical and lumbar dorsal root ganglia. The number of motor axons in the *mf* rat is also decreased; however, muscle power and muscle bulk are not affected. The clinical and pathological manifestations are similar to human hereditary sensory neuropathy types I and II (HSN I and II). The aim of this study is to find the causative gene for the *mf* rat in order to help our understanding of the human hereditary sensory neuropathies.

We have initially utilized a positional cloning approach allied with a backcross strategy, to establish genetic linkage in *mf* rats. Lewis rat strains were backcrossed with *mf* rats. A total of 254 second generation rats were collected, of which 119 had the mutilated foot phenotype. A genome-wide search, using simple repeat microsatellite markers, demonstrated linkage to the distal end of rat chromosome 14. Fine mapping located the *mf* locus to a 1.5 cM region between markers *D14Got73* and *D14Got76*. Mapping studies are currently underway to further refine this interval.

**Screening of candidate genes related to myelination for mutations associated with schizophrenia.** *H.J. WILLIAMS<sup>1</sup>, N.M. WILLIAMS<sup>1</sup>, G. SPURLOCK<sup>1</sup>, N. NORTON<sup>1</sup>, K.L. DAVIS<sup>2</sup>, J.D. BUXBAUM<sup>2</sup>, V. HAROUTUNIAN<sup>2</sup>, R. SAUNDERS<sup>1</sup>, A.G. CARDNO<sup>1</sup>, G. McCARTHY<sup>1</sup>, M.C. ODOANOVAN<sup>1</sup>, M.J. OWEN<sup>1</sup>.* 1) Neuropsychiatric genetics, UWCM, Cardiff; 2) Department of Psychiatry, Mount Sinai School of Medicine, New York.

Hakak and colleagues (PNAS, 98, 8, 2001) recently used DNA microarray analysis to assay the expression levels of over 6000 genes in the postmortem dorsolateral prefrontal cortex of 12 schizophrenics and matched controls. A total of 89 genes that are involved in a range of biological processes, including synaptic plasticity and neuronal development, were reported to show an altered expression profile in schizophrenics. However, their most notable finding was the differential expression of a number of genes related to myelination (MAL, CNP, MAG, transferin gelsolin and ErbB3), suggesting a disruption in oligodendrite function in schizophrenia. We have now screened each of these 6 genes for sequence variants using DHPLC and sequencing. All identified SNPs have been genotyped by primer extension and their allele frequencies estimated in an association sample of 184 DSMIV schizophrenic patients and 184 matched controls by a method of DNA pooling based on the ABI SnaPshot assay. SNPs with a significant difference in allele frequencies were then typed in a second sample of similar size by the same pooling method. Only SNPs that yielded significant results in both samples were subsequently genotyped individually in the same sample to confirm the allelic association. Of the SNPs identified the biggest difference in allele frequency between affecteds and controls yielded a  $\chi^2$  of 5.27 ( $p=0.02$ ), however the results of the association analysis of each SNP will be presented.

**Identification and Characterization of Neuropsychiatric Disease Candidate Genes in a Region of Chromosome 1 Linked to Schizophrenia.** *A. Parker<sup>1</sup>, A. Foti<sup>1</sup>, K. Burke<sup>1</sup>, C. Reeves<sup>1</sup>, G. Barnes<sup>1</sup>, K. Glatt<sup>1</sup>, R. Martin<sup>1</sup>, M. Harmon<sup>1</sup>, K. Rinard<sup>1</sup>, S. Lewitzky<sup>1</sup>, A. Meyer<sup>1</sup>.* 1) Dept. Human Genetics, Millennium Pharmaceuticals Inc., Cambridge, MA; 2) Dept. Mental Health and Alcohol Research, National Public Health Institute, Helsinki, Finland; 3) Dept. Human Genetics, UCLA, Los Angeles, CA; 4) Genetics Institute, Wyeth-Ayerst Research, Cambridge, MA.

Availability of draft human genome sequence and large gene-expression datasets has led to reanalysis of complex trait positional cloning strategies. An accepted approach to narrowing a linkage result has been to type densely spaced markers across the linked region, followed by LD and/or haplotype sharing analyses. This strategy uses anonymous markers, treating all genes in a linked region as potential candidates; while objective, it is also resource intensive, as linkage often implicates >30 MB genomic intervals. An alternative is first to identify and minimally characterize all genes in a linked interval, followed by intensive investigation of only genes consistent with the disease hypothesis at hand.

Genome-wide linkage analysis of 445 Finnish pedigrees ascertained on a sib pair concordant for schizophrenia or schizophrenia spectrum condition revealed linkage to 1q41-q43 (results reported elsewhere). Genomic sequence, cDNA, gene expression, gene prediction, and literature databases were used to annotate the gene content of a 33 cM (35.4 MB) interval, revealing 242 putative genes. Based on these data, we ranked the genes with respect to their possible functional relevance to schizophrenia. Two genes, DISC1 and a novel CAM kinase, were selected as leading candidates for analysis in our pedigree sample. We performed detailed TaqMan expression studies of both genes using microdissected human brain tissues; one showed a specific pattern of expression consistent with the hypothesized neuroanatomy of schizophrenia. SNP genotyping experiments revealed polymorphisms in both genes with nominally significant evidence for association with schizophrenia.

**Associations between 65 polymorphisms in 36 candidate genes and cardiovascular disease-related quantitative phenotypes.** *D.L. Newman<sup>1</sup>, M. Abney<sup>1,2</sup>, M.S. McPeck<sup>1,2</sup>, H. Dytch<sup>1</sup>, M.A. Grow<sup>3</sup>, A.S. Silbergleit<sup>3</sup>, C. Carlson<sup>3</sup>, A.M. Scanu<sup>4</sup>, S. Cheng<sup>3</sup>, C. Ober<sup>1</sup>.* 1) Dept Human Genetics, Univ Chicago, Chicago, IL; 2) Dept Statistics, Univ Chicago, Chicago, IL; 3) Roche Molecular Systems, Inc, Alameda, CA; 4) Dept Medicine, Univ Chicago, Chicago, IL.

To identify genetic risk factors for common diseases, we studied >700 Hutterites who are derived from 64 founders and members of a 1,623-person pedigree. Exposures to environmental risk factors, such as a high fat/salt diet, are uniform in this communal society. We measured systolic (SBP) and diastolic (DBP) blood pressure, and fasting LDL, HDL, Lp(a) and triglycerides (TRI) in Hutterites <sup>3</sup>14 years old and genotyped their DNA for 65 variants in 36 genes by allele-specific hybridization to strip blots (Roche Molecular Systems, Inc). The effect of each allele on the phenotype was assessed by a novel association test developed for studies in large inbred pedigrees; the relatedness among subjects is accounted for by variance components (Abney et al., 2000, *Am J Hum Genet* 66:629). Significance, assessed by a permutation-like test, accounted for the number of tests per allele (locus-specific *P*) and the number of variants examined overall (global *P*). 6 alleles had global  $P < 0.05$  and locus-specific  $P < 0.001$ : *APOE*-E2 was associated with LDL, *CETP* -630C/-628A with HDL, *APOC3* -482C and 3175C each with TRI, *LPA* 93T with Lp(a), and *ACE* allele D with SBP. No markers reached this level of significance for DBP. Thus, independent loci influence these related phenotypes in the Hutterites and these alleles are the same as those present in outbred populations. Further, 3 chromosomal regions housing these genes, 6q (*LPA*), 11q (*APOC*), 19q (*APOE*), were identified in genome-wide screens (GWS) for the corresponding phenotypes with markers that were 2-9 cM from the candidate locus, indicating that these loci may have relatively large effects on the phenotypes. Associations on GWS were not detected for the remaining 3 traits, suggesting that even in a young founder population dense maps may be required to detect linkage disequilibrium with all susceptibility loci for common diseases. Supported by NIH HL56399 and Hoffmann-LaRoche, Inc.

**A genome wide scan for early onset primary hypertension in Scandinavian families.** *O. Melander<sup>1</sup>, K. Bengtsson<sup>1,2</sup>, M. Orho-Melander<sup>1</sup>, F. Fyhrquist<sup>3</sup>, U. Hulthén<sup>1</sup>.* 1) Dept of Endocrinology, Malmö University Hospital, Malmö, Sweden; 2) Dept of Community Medicine, Malmö University Hospital, Malmö, Sweden; 3) Dept of Medicine, Helsinki University Hospital, Helsinki, Finland.

Primary hypertension is a multifactorial disorder and the importance of genetic factors increase with decreasing age at onset of the disease. The aim of the present study was to identify such genetic factors by searching for hypertension susceptibility loci. To address this we performed a genome wide scan in families with clustering of early onset primary hypertension (EOHT). **METHODS:** EOHT was defined as presence of established and pharmacologically treated primary hypertension no later than at age 50 years. Families with at least two members with EOHT were collected from six different health care centres in southern Sweden and Finland. Ninety-one families with 243 affected members were ascertained (mean 2.7; range 2-6 per family). The mean age at onset of EOHT was  $40.0 \pm 7.7$  years, age at time of study  $57.9 \pm 10.1$  years and body mass index  $27.4 \pm 4.4$  kg/m<sup>2</sup>. Another 129 individuals were genotyped to obtain phase information and to estimate allele frequencies. PCR with fluorescence labelled primers was used to genotype 363 microsatellite markers (average density approximately 10 cM). Multipoint non-parametric affected pedigree member linkage analysis was performed using GENEHUNTER v.2.0. **RESULTS:** The analysis revealed eight peaks with non-parametric lod scores (NPL) >2. Best evidence for linkage was found on chromosome 2 at 120.1 cM (NPL=2.27), chromosome 3 at 117.4 cM (NPL=2.30) and chromosome 12 at 118.5 cM (NPL=2.22). Additional NPL scores >2 were seen on chromosome 1 at 102 cM (NPL=2.17), on chromosome 14 at 80.2 cM (NPL=2.05) and at 96.9 cM (NPL=2.04), on chromosome 19 at 93 cM (NPL=2.10) and on chromosome 22 at 27.7 cM (NPL=2.12). **CONCLUSIONS:** A genome wide scan in families with early onset primary hypertension revealed putative susceptibility loci on chromosomes 1, 2, 3, 12, 14, 19 and 22.

**A genome scan of aortic root diameter (ARD) in hypertensive African Americans and Whites in the HyperGEN study.** *A.I. Lynch<sup>1</sup>, D.K. Arnett<sup>1</sup>, L.D. Atwood<sup>2</sup>, R.B. Devereux<sup>3</sup>, D.W. Kitzman<sup>4</sup>, P.N. Hopkins<sup>5</sup>, A. Oberman<sup>6</sup>, D.C. Rao<sup>7</sup>.* 1) University of Minnesota, Minneapolis, MN; 2) Boston University, Boston, MA; 3) Cornell University Medical College, New York, NY; 4) Wake Forest University, Winston-Salem, NC; 5) University of Utah, Salt Lake City, UT; 6) University of Alabama, Birmingham, AL; 7) Washington University School of Medicine, St. Louis, MO.

Variation in the structure of the aortic root is thought to have a genetic basis. For example, Marfan's syndrome, which commonly includes aortic root dilation, involves the fibrillin-1 gene on chromosome 15. It has previously been shown that the inter-individual variation in aortic root diameter (ARD) is highly heritable, particularly in African Americans. In this study, we performed a genome-wide linkage scan for ARD measured by 2-dimensional echocardiography in the Hypertension Genetic Epidemiology (HyperGEN) study, one of the four networks in the NHLBI Family Blood Pressure Program (FBPP). We used data collected on 1129 African American siblings from 504 hypertensive sibships whose mean age was 51 years, and 883 White siblings from 374 hypertensive sibships whose mean age was 60 years. Standardized residual values of ARD were calculated using a linear regression model adjusting for age, age<sup>2</sup>, and field center in the minimally adjusted model, separately in sex and race groups. Height, weight, diastolic, and systolic blood pressure were also included in the fully adjusted model. Multipoint linkage analysis was performed using the GENEHUNTER2 variance components method with 367 anonymous markers spaced an average of 9.2 cM apart. Suggestive evidence for linkage was found on chromosome 5 at 85.25 cM (marker D5S1501) in African Americans, with a maximum LOD score of 2.07 in the minimally adjusted model, which decreased to 1.22 in the fully adjusted model. Suggestive evidence for linkage was also found on chromosome 1 at 156.76 cM (between markers D1S534 and D1S1653) in Whites, with a maximum LOD score of 2.40 in the minimally adjusted model, which decreased to 2.17 in the fully adjusted model. Our findings suggest that genes present on chromosomes 1 and 5 may influence the variation in ARD.

**Genome Wide Scan for Thoracic Aortic Aneurysms / Dissections, a Clinically and Genetically Heterogeneous**

**Disorder.** *S.N. Hasham*<sup>1</sup>, *D. Guo*<sup>1</sup>, *C.J Vaughan*<sup>2</sup>, *S. Shete*<sup>3</sup>, *A. Muilenberg*<sup>4</sup>, *C.T. Basson*<sup>2</sup>, *D.M Milewicz*<sup>1</sup>. 1) Dept. of Internal Medicine, University of Texas Medical School, Houston, TX; 2) Div. of Cardiology, Dept. of Medicine, Weil Medical College of Cornell University, The New York Presbyterian Hospital; 3) Dept of Epidemiology, M.D.Anderson Cancer Centre, Houston, TX; 4) The University of Iowa,Iowa.

Thoracic aortic aneurysms/dissection (TAAs) is the most frequent fatal condition in the spectrum of chest pain syndromes. Aortic aneurysms are completely asymptomatic until a life threatening event like rupture occurs. Cystic medial degeneration, an intrinsic feature of various entities such as hypertension, aging and connective tissue disorders, has been associated with the risk of aneurysms. 20% of TAAs are familial and show an autosomal dominant mode of inheritance with variable penetrance. Our lab identified a major locus at 5q13-14 in half of the known families while Dr Basson has mapped another locus at 11q23-24. Further genetic heterogeneity was seen by the identification of 11 families not linked any known loci. Analysis of clinical phenotype indicates a more diffuse arteriopathy in family associated with 11q compared to the families linked to the 5q. TAAs in the families linked to 5q is often associated with bicuspid aortic valves. A whole genome scan was carried out in four families with similar clinical phenotype. To evaluate the significance of the genome scan, we simulated the complete analysis under the assumption of no linkage and complete linkage. Of the putative loci identified, two loci at 4q and 12q showed a LOD score of suggestive linkage with two or more markers. A 12.5cM and 18cM haplotype is seen to be segregating in these families at 4q and 12q respectively. Fine mapping was carried out at these two loci using more families and markers spaced at 1-3cM. This confirmed the putative loci at 4q, under heterogeneity. Three major families are linked neither to the new suggestive loci nor to one of the two known loci indicating further heterogeneity. . Present study identified putative third locus for TAAs and also addressed the possibility of associating the clinical phenotype with the genetic heterogeneity.

**Genome scan for cardiovascular risk factors in three populations.** *B.T. Heijmans<sup>1</sup>, M. Beekman<sup>2,3</sup>, N. Lakenberg<sup>1</sup>, H.E.D. Suchiman<sup>1</sup>, G.P. Vogler<sup>4</sup>, U. DeFaire<sup>5</sup>, J.B. Whitfield<sup>6</sup>, P. de Knijff<sup>2</sup>, C. Kluff<sup>3</sup>, G.J.B. van Ommen<sup>2</sup>, R.R. Frants<sup>2</sup>, N.L. Pedersen<sup>5</sup>, N.G. Martin<sup>7</sup>, D.I. Boomsma<sup>8</sup>, P.E. Slagboom<sup>1</sup>.* 1) Medical Statistics, Leiden University Medical Centre, The Netherlands; 2) Human Genetics, Leiden University Medical Centre, The Netherlands; 3) TNO Prevention and Health, Leiden, The Netherlands; 4) Center for Developmental and Health Genetics, Pennsylvania State University, USA; 5) Karolinska Institute, Stockholm, Sweden; 6) Royal Prince Alfred Hospital, Sydney, Australia; 7) Queensland Institute for Medical Research, Brisbane, Australia; 8) Psychology, Free University of Amsterdam, The Netherlands.

The genetic basis of cardiovascular disease (CVD) is highly complex. Less complex intermediate phenotypes can be studied instead of clinical endpoints. For CVD, such phenotypes include plasma levels of lipids and apolipoproteins, which are highly heritable. The aim of our study is to map and identify genes with a major effect on these intermediate phenotypes in the general population. We are performing a genome-wide scan in population-based samples of Dutch, Swedish and Australian dizygotic twin pairs. Genehunter was used to obtain IBD status for sibling pairs. Linkage analysis was carried out in Mx using a maximum likelihood variance components approach, which included data from untyped monozygotic twins and adjusted phenotypic data for age and sex. Initial analysis of the Dutch sample indicated suggestive linkage with LDL cholesterol for chromosome 19. When marker density was increased to 6 cM, the maximum LOD-score (MLS) for LDL cholesterol was 3.8 at 65 cM in the Dutch sample (194 DZ pairs). In the Swedish population (44 DZ pairs), the MLS was 1.4 at the same location. No linkage was observed in the Australian sample (242 DZ pairs). Fine-mapping strategies were explored and indicated a 25 cM region in the Dutch sample harboring a candidate gene, which is currently being investigated. Our results provide support for the presence of a locus on chromosome 19 contributing to the variation of LDL cholesterol levels in the Dutch and Swedish population.

**A genome-wide linkage scan for essential hypertension.** *K.T. Kristjansson<sup>1</sup>, A. Kristinsson<sup>2</sup>, A. Manolescu<sup>1</sup>, Th. Hardarson<sup>2</sup>, H. Knudsen<sup>1</sup>, S. Ingason<sup>1</sup>, A. Kong<sup>1</sup>, J. Gulcher<sup>1</sup>, K. Stefansson<sup>1</sup>.* 1) Clinical Collaborations, deCODE Genetics Inc., Reykjavik, Iceland; 2) Department of Medicine, National University Hospital (Landspítalinn), IS-108 Reykjavik, Iceland.

Hypertension defined as arterial blood pressure above 140 mmHg systolic and above 90mmHg diastolic, affects up to 20 % of the adult population and 50% of those more than 60 years of age. It is one of the principal risk factors for stroke, myocardial infarction (MI), peripheral arterial occlusive disease (PAOD), congestive heart failure (CHF), and end-stage renal disease. We performed a genome-wide scan with 930 microsatellite markers using 120 extended Icelandic families with 490 hypertensive patients. The families were identified by cross matching a list of hypertensive patients from the Hypertension Clinic of the University Hospital (Landspítalinn) in Iceland with a genealogy database of the entire Icelandic nation. We analysed the data using the Allegro program and determined statistical significance by applying affecteds-only allele-sharing methods (which does not specify any particular inheritance model) implemented. The Allegro program, a linkage program developed at deCODE Genetics, calculates lod scores based on multipoint calculations. The linkage scan gave an allele-sharing lod score of 4.0 at one specific locus. We designate this locus EH1 and report on the further mapping of this locus.

**Evidence for linkage of low HDL-cholesterol trait on 8q23 and no evidence for linkage to the ABC1 gene in Finnish low HDL families.** A. Soro<sup>1,2</sup>, P. Pajukanta<sup>1</sup>, H.E. Lilja<sup>1,3</sup>, K. Ylitalo<sup>2</sup>, J.S.A. Viikari<sup>4</sup>, M-R. Taskinen<sup>2</sup>, L. Peltonen<sup>1,3</sup>. 1) Dept of Human Genetics, UCLA, Los Angeles, CA, USA; 2) Dept of Medicine, University of Helsinki, Finland; 3) Dept of Human Molecular Genetics, NPHI, Helsinki, Finland; 4) Dept of Medicine, University of Turku, Finland.

The strong relationship between low levels of high-density lipoprotein cholesterol (HDL-C) and coronary heart disease has stimulated genetic research of this complex trait. To elucidate the genetic background of the common form of the familial low HDL-C, we collected 25 extended Finnish families with familial low HDL-C and premature CHD and carried out a genome-wide scan. We found suggestive evidence for linkage (two-point lod score above 2.0) in four chromosomal regions: 2p, 8q23, 16q24.1-24.2 and 20q13.11. The significance of these initial findings for low HDL-C was further addressed by analyzing markers in these regions in an independent study sample of 29 Finnish families with familial combined hyperlipidemia (FCHL), a trait closely overlapping with familial low HDL-C. The pooled data analysis of low HDL and FCHL study samples, using low HDL as a tested trait, provided support for linkage in three of these regions on 8q23, 16q24.1-24.2 and 20q13.11. The highest statistical evidence for linkage was observed on chromosome 8q23 (a two-point lod score of 3.9), gaining support also in the multipoint analysis. Importantly, this locus has earlier been linked to HDL-C in Mexican Americans. Further, the region on chromosome 20q has previously been linked to body adiposity, hyperinsulinemia and type 2 diabetes, suggesting a partially shared genetic background of these traits and HDL-C. In addition, a locus on chromosome 2p showed evidence for linkage only in the FCHL families, this locus being 72 cM telomeric from the 2p locus initially observed only in the low HDL families. The contribution of the ABC1 gene, regulating HDL-C levels, seemed to be excluded as a major causative locus both by linkage analysis of the 25 families, and by sequence analysis of the low HDL probands. In conclusion, our genome-wide scan provided evidence for loci on 8q23, 16q24 and 20q13 affecting the HDL-C levels in Finnish low HDL families.

**A genome-wide scan for circulating levels of fibrinogen in the Framingham Heart Study.** *Q. Yang*<sup>1</sup>, *G.H. Tofler*<sup>2</sup>, *L.A. Cupples*<sup>1</sup>, *M.G. Larson*<sup>3,4</sup>, *D. Levy*<sup>3,4</sup>, *R.B. D'Agostino*<sup>5</sup>, *C.J. O'Donnell*<sup>3,6</sup>. 1) Epidemiology & Biostatistics, Boston Univ Sch Public Hlth, Boston, MA; 2) Royal North Shore Hospital, Sydney, Australia; 3) NHLBI/Framingham Heart Study, Framingham, MA; 4) Preventive Medicine and Epidemiology, Boston Univ Sch Medicine, Boston, MA; 5) Mathematics & Statistics, Boston Univ, Boston, MA; 6) Cardiology Division, Massachusetts General Hospital, Harvard Medical School, Boston, MA.

The circulating level of fibrinogen predicts future coronary heart disease and stroke. Levels of fibrinogen are correlated among family members, suggesting a heritable component to its regulation. Variants of fibrinogen gene subunits (all subunits reside on 4q28) are associated with fibrinogen levels. However, it is unknown what role, if any, is played by genetic variants on other chromosomes in the regulation of fibrinogen in the general population. We sought to confirm that fibrinogen is heritable, and we then examined for evidence of linkage to chromosomal regions in a large population-based cohort. Fibrinogen levels were measured in family members as part of routine examinations for the original and Offspring cohorts of the Framingham Heart Study. We conducted a 10 cM genome-wide scan in 330 extended families (1702 genotyped; 1595 phenotyped [402 parents, 1193 children, 852 Parent-offspring pairs, 823 Sibling pairs]). Variance-component methods were used to estimate heritability and to perform linkage analysis using sex-specific normalized residuals, adjusted for age and for age plus other important covariates. Estimated heritability was 0.30 for the age-adjusted fibrinogen and 0.23 for multivariate-adjusted fibrinogen. The highest multipoint LOD score for fibrinogen was found on chromosome 5 (LOD score 1.32 at 183 cM from the p-terminus). The next highest LOD score was found on chromosome 2 (1.16 at 58 cM). While there is no linkage reaching genome-wide significance, these data suggest that there may be influential genetic regions on chromosomes other than chromosome 4 that contribute to circulating levels of fibrinogen. Further investigation of these regions is warranted to identify fibrinogen-regulating genes.

**Importance of a cluster analysis in the promoter region of TNF $\alpha$  for the genetic risk constellation in patients with coronary artery disease.** *U. Schagdarsurengin<sup>1</sup>, P. Greiser<sup>1</sup>, S. Schulz<sup>1</sup>, D. Rehfeld<sup>2</sup>, T. Süß<sup>2</sup>, A. Kabisch<sup>3</sup>, U. Müller-Werdan<sup>2</sup>, K. Werdan<sup>2</sup>, I. Hansmann<sup>1</sup>, C. Gläser<sup>1</sup>.* 1) Inst Human Genetics, Univ Halle, Halle, Germany; 2) Dep Intern Med, Univ Halle, Halle, Germany; 3) Inst Transf Med/Bloodbank, Univ Halle, Halle, Germany.

TNF $\alpha$  is a monocyte/macrophage derived cytokine with multiple coronary atherosclerosis affecting functions. We investigated the cluster of three polymorphisms (PM) of TNF $\alpha$  of the functionally important promoter region, the G-238A, G-308A and C-863A PM in 306 probands, 146 CAD patients (age at first MI 47.9y, 125 males) and 160 healthy controls (41.8y, 108 males). Considering the progress of coronary atherosclerosis by the age of onset, 39.6% with extremely high coronary risk had already undergone their first MI at juvenile age, before 45y. **Results:** The analysis of the clustered genotypes -863/-308/-238 in the 306 probands resulted in only four frequent clusters, the wildtype cc/gg/gg (0.44), and three types with heterozygous mutation, one on position 863 (ca/gg/gg: 0.21), another 308 (cc/ga/gg: 0.19) and last 238 (cc/gg/ga: 0.05). The CAD and the control subgroup showed comparable results. But considering the age of onset we found distinct differences in the CAD patients: the cluster cc/gg/ga was more frequent in the juvenile high risk group than in the older one (0.10 vs. 0.02, n.s.). A creation of clusters of only two PMs in the juvenile and senior patients resulted in significantly different distribution concerning 863/238 PMs caused by the high frequency of 238 mutation carriers (0.17 vs. 0.02,  $p < 0.02$ ) and likewise tendencies in the cluster 308/-238 (0.10 vs. 0.04, n.s.). The combination 863/-308 did not show significances or tendencies. The separate analysis of each PM demonstrated only a high correlation of the 238 PM to progress of CAD: the mutation carriers (GA+AA) were significantly more frequent in the juvenile high risk patient group (MI before 45y; 0.17 vs. 0.05,  $p < 0.02$ , RR 3.35). **Conclusion:** Cluster analyses should absolutely bear in mind the weight importance of each polymorphic marker in the risk constellation. Our results show the importance of the 238-promoter PM of TNF $\alpha$  as an evident genetic risk marker for CAD.

**Recent progress in identification of the X-linked infantile spinal muscular atrophy (XL-SMA) gene: Refined linkage analysis results in candidate gene investigations.** *H. Basterrecha*<sup>1</sup>, *D. Dressman*<sup>2,3</sup>, *M.E. Ahearn*<sup>1</sup>, *A. Meindl*<sup>4</sup>, *N.T. Bech-Hansen*<sup>5</sup>, *R.D. Clark*<sup>6</sup>, *B. Wirth*<sup>7</sup>, *M. Barmada*<sup>3</sup>, *E. Hoffman*<sup>2</sup>, *L. Baumbach*<sup>1</sup>. 1) Univ. Miami Med Sch, Miami, FL; 2) Children's National Med Ctr, Washington, DC; 3) Univ. Pittsburgh, Pittsburgh, PA; 4) Ludwig Maximilians Univ, Munchen, Germany; 5) Univ Calgary, Alberta, Canada; 6) USC Cancer Ctr, Los Angeles, CA; 7) Univ Bonn, Bonn, Germany.

We have previously reported an X-linked form of infantile lethal motor neuron disease (MIM 30021), which closely resembles Werdnig-Hoffman disease, except for additional features of early onset or congenital contractures and/or fractures, in a single family that mapped to Xp11.3-q11.2. We have identified 12 unrelated families from North America and Central or Western Europe. Of these, eight families have been tested for linkage on the X-chromosome; all of these map to the same region as the first family. One of these is thought to represent a new mutational event. The cumulative LOD score for the families is 7.8148 at a  $q=0.0$  in the Xp11.3-q11.2 region. Further multipoint linkage analysis has narrowed the disease gene interval to a region redefined by DXS8080-DXS7132. These results strongly support the existence of a major disease locus in this region. From the approximately 100 genes in the *XL-SMA* candidate region, potential candidate disease genes have been identified: a) Genes involved in neuronal and muscle development; b) Genes involved in cell-to-cell communication; c) Genes involved in RNA processing/gene expression; d) Genes expressed in fetal muscle or central nervous system. We are developing high-throughput mutation screening methods for candidate gene studies. Our latest results will be presented. In conclusion, we have demonstrated overwhelming evidence that an X-linked form of infantile SMA can be detected in many regions of the world; that families representing new mutations in the yet-to-be identified gene exist; and that a single disease locus resides in the pericentromeric region of the X chromosome. It is our expectation that the *XL-SMA* disease gene will be identified in the next year, allowing for molecular diagnosis of suspected cases.

**Syndromic X-linked mental retardation and hypopituitarism maps to Xq23-25.** *N.D. Leslie<sup>1</sup>, M. Keddache<sup>1</sup>, S. Chernausek<sup>2</sup>, J. Abuzzahab<sup>2</sup>.* 1) Division of Human Genetics, TCHRF 1041, Children's Hosp Research Fndn, Cincinnati, OH; 2) Division of Endocrinology, Children's Hospital Research Fndn, Cincinnati, OH.

A family is described in which mental retardation accompanied by hypopituitarism segregates as an apparent X-linked recessive trait. Six affected males in a 3 generation pedigree exhibit a phenotype with severe-moderate mental retardation associated with expressive language dysfunction and short stature. Additional features include a large forehead with a frontal cowlick, downturned mouth, short philtrum, excessive sweating, constipation, and self-abuse. The proband has growth hormone deficiency and another affected male in a previous generation experienced hypoglycemia, for which he was treated with cortisone injections. Obligate female carriers are not mentally retarded, although many have depression or bipolar affective disorder. Linkage analysis for X-chromosomal markers at 10 Cm density resulted in a maximum lod score of 2.3 with marker DXS 8055 at Xq23-25. Recombination events at flanking markers DXS 1106 and DXS 1001 defined the 20 cM critical region. X-linked panhypopituitarism has been associated with reported in association with mental retardation in families carrying a duplication of Xq26-27. In addition, mental retardation associated with bipolar disorder had been reported in a female with a balanced translocation at Xq24, interrupting the glutamate receptor 3 gene (GRIA3). In both of the previously reported families, the breakpoints mapped telomeric to the distal bound of the critical region defined in this family. Data from this family further support the hypothesis that multiple genes for syndromic mental retardation are clustered in the Xq22-27 region.

**Genetic heterogeneity in schizophrenia II: conditional analyses of affected schizophrenia sibling pairs provides evidence for an interaction between markers on chromosomes 8p and 14q.** *Y.-F. Chiu<sup>1</sup>, J.A. McGrath<sup>2</sup>, M.H. Thornquist<sup>2</sup>, P.S. Wolyniec<sup>2</sup>, G. Nestadt<sup>2</sup>, K. Swartz<sup>2</sup>, V.K. Lasseter<sup>2</sup>, K.-Y. Liang<sup>3</sup>, A.E. Pulver<sup>2</sup>.* 1) Department of Biostatistics, University of North Carolina, Chapel Hill, NC., 27599, USA; 2) Department of Psychiatry and Behavioral Sciences, The Johns Hopkins School of Medicine, Baltimore, MD 21231, USA; 3) Departments of Biostatistics and Epidemiology, The Johns Hopkins School of Hygiene and Public Health, Baltimore, MD 21205, USA.

Information from multiple genome scans and collaborative efforts suggests that schizophrenia is a heterogeneous, complex disorder with polygenic and environmental antecedents (1). In a previous paper we demonstrated that stratification of families on the basis of co-segregating phenotypes (psychotic affective disorders [PAD] and schizophrenia spectrum personality disorders [SSPD]) in first degree relatives of schizophrenic probands increased linkage evidence in the chromosome 8p21 region (D8S1771) among families with co-segregating SSPD (2). We have now applied a method of conditional analysis of sib-pairs affected with schizophrenia, examining shared alleles identical-by-descent (IBD) at multiple loci (3). The method yields enhanced evidence for linkage to the chromosome 8p21 region conditioned upon increased allele sharing at a chromosome 14 region. The method produces a more refined estimate of the putative disease locus on chromosome 8p21, narrowing the region from 18 cM (95% confidence interval) in our previous genome scan (4), to approximately 9.6 cM. We have also shown that the affected siblings sharing 2 alleles IBD at the chromosome 8p21 region and 1 allele IBD at the chromosome 14 region differ significantly in clinical symptoms from non-sharing affected siblings. Thus the analysis of allele sharing at a putative schizophrenia susceptibility loci conditioned on allele sharing at other loci provides another important method for dealing with heterogeneity.

**The Effectiveness of Computational Methods in Haplotype Prediction.** *K.F. Lewis<sup>1</sup>, C.F. Xu<sup>1</sup>, K.L. Cantone<sup>1</sup>, P. Khan<sup>1</sup>, C. Donnelly<sup>1</sup>, N. White<sup>1</sup>, N. Crokker<sup>1</sup>, P.R. Boyd<sup>1</sup>, D.V. Zaykin<sup>2</sup>, I.J. Purvis<sup>1</sup>.* 1) Molecular Genetics, GlaxoSmithKline, Stevenage, Hertfordshire, England; 2) Population Genetics, GlaxoSmithKline, Research Triangle Park, North Carolina, USA.

Haplotype analysis has been used for narrowing down the location of disease susceptibility genes and for investigating many population processes. Conventionally, Haplotype phases are established by laborious processes, such as studies using extended pedigrees or using molecular methods. A cheap alternative strategy is to use computational algorithms to predict haplotype phases from genotype data. In this study, we have empirically evaluated the effectiveness and accuracy of such computational methods in haplotype prediction. We experimentally determined the genotypes and haplotypes of 5 single nucleotide polymorphisms (SNPs) in the N-Acetyltransferase 2 gene (NAT2, 850-bp, n=81) and 5 SNPs on chromosome X (140-kb, n=77). We applied the expectation-maximisation (EM) algorithm and the subtraction algorithm to predict haplotype frequencies and individual haplotype phases. Both algorithms provided effective and accurate estimates for haplotype frequencies and individual haplotype phases for the NAT2 region, where there was near complete linkage disequilibrium (LD) between SNPs. For the chromosome X locus, both computational methods were adequate in estimating overall haplotype frequencies. However, neither method was effective or accurate in predicting individual haplotype phases for this region, where marked LD was not maintained. We found that the EM algorithm provided a better estimate of haplotype frequency than the subtraction method for both genetic regions.

**Clinical Applications: An Interactive Clinical Data Management System For Genetic Studies.** *R.V. Jones, B.L. Chesnut, C.P. Blach, C.W. Howe, C.S. Haynes, E.R. Hauser, M.A. Pericak-Vance.* Center for Human Genetics, Duke University Medical Center, Durham, NC.

Genetic studies in complex traits require the collection and management of large clinical datasets. The ability to integrate these clinical data with laboratory results for genetic analysis is critical for a successful outcome. Thus, we developed Clinical Applications (CA), a modular Windows-based front-end system for the PEDIGENE® database. While ensuring patient confidentiality through security measures, an intuitive user interface enables a researcher to extract clinical data from the database for a desired individual, family, group, site or the entire study for viewing or editing purposes or for generating reports. Reports list demographic, sample, general medical history, or study-specific clinical exam data in a grid-format that can be subsequently sorted, filtered, edited, printed, or saved to files for use in genetic analysis. CA also assists in quality control measures by tracking the changes made to the data and by whom. Users can also readily obtain summarizing clinical information on overall diagnostic impression as well as stratification by clinical subtypes. New features, reports, studies, or clinical exams can be incorporated into the system by adding or modifying the appropriate modules. This flexibility also allows the system to be adapted to work with other databases and applications. Using this approach, genetic analyses can be customized to take advantage of the available phenotypic information. CA has been invaluable in our genetic linkage and association studies and is a prototype system for similar studies of complex traits.

**A graphical model approach to exact calculation of multilocus genetic probabilities on large pedigrees.** *S.C. Heath.* Dept Epidem & Biostat, Mem Sloan-Kettering Cancer Ctr, New York, NY.

Calculation of genetic probabilities underlies both parametric and non-parametric genetic linkage analysis, and limitations of the algorithms to calculate these probabilities restrict the types of problems that can be analyzed. The existing algorithms either restrict analysis to simple pedigrees with few loci (Elston-Stewart), or very small pedigrees with many loci (Lander-Green). Both of these algorithms can be considered as special cases of a more general graphical model approach, developed to calculate the probability of Bayesian networks.

The advantage of the graphical model approach occurs when the observed data constrain the possible genotypes of observed individuals, such that certain genotype combinations have zero probability. This occurs, for example, with codominant markers when it is assumed that there are no marker errors. In this case, the graphical model approach can take full advantage of the constraints imposed by the data, possibly allowing for more complex problems to be analyzed than is possible using either the Elston-Stewart or the Lander-Green algorithms.

In the extreme case when every pedigree member is genotyped, multilocus calculations with >10 loci can be rapidly performed on even very large and complex pedigrees (>2000 individuals, >100 loops). In general, it is almost always possible to perform an exact calculation if everyone is genotyped, no matter how many loci and how large the pedigree (although it is not difficult to construct pathological counter-examples). In the more realistic case where several people have missing genotypes, the graphical model approach can still provide advantages over the existing algorithms, but computational requirements increase rapidly as the informativeness of the data decreases.

The application of the new graphical model approach to a range of different pedigrees (both real and simulated) will be presented, and comparisons of the computational requirements made (where possible) with existing linkage analysis packages. This work was supported by NIH grant GM58757-03.

Program Nr: 1885 from the 2001 ASHG Annual Meeting

**A Framework for the Objective Measurement of Genetic Variation.** *N.J. Markward, M.Z. Peliás, B.J.B. Keats, W.P. Fisher, Jr.* Department of Genetics, L.S.U. Health Sciences Center, New Orleans, LA.

Geneticists have mistaken numbers or numerical formulations of their observations for mathematical, interchangeable units of measurement. This assumption is incorrect and reflects a bias that has pervaded Western philosophy since Galileo: "...that the book of Nature is written in the language of mathematics." In actuality, numerical variables, including counts of nucleotide and amino acid sequences, levels of gene expression, and population allele frequencies, are premathematical in that they do not provide the common exchange currency genomic research requires for generality and inferential stability across laboratories, samples, and scientific constructs. Premathematical numbers must be converted from their context-dependent form to an abstract, mathematical language of measurement. Only then can meaningful inferences be drawn about how molecular variation influences person-specific disease susceptibility and temperament, as well as how individual-level variation contributes to population dynamics and speciation. This project demonstrates how raw genetic information may be converted to a common mathematical, sample-independent measurement scale, as mandated by a simple, eloquent mathematical law. The resulting quantities function as additive units of interchangeable value that may be plugged into any quantitative genetic formula. Implications are drawn for research theory, clinical practice, and public policy formulation.

**Mendel version 4.0: a complete package for the exact genetic analysis of discrete traits in pedigree and population data sets.** *K. Lange<sup>1,2,3</sup>, R. Cantor<sup>1</sup>, S. Horvath<sup>1,4</sup>, M. Perola<sup>1</sup>, C. Sabatti<sup>1,3</sup>, J. Sinsheimer<sup>1,2,4</sup>, E. Sobel<sup>1</sup>.*  
1) Departments of Human Genetics; 2) Biomathematics; 3) Statistics; 4) Biostatistics, University of California, Los Angeles, CA.

The Mendel software program performs likelihood-based statistical analysis to solve a variety of genetic problems. Where appropriate, the analysis will use either the Lander-Green-Kruglyak or Elston-Stewart algorithms, whichever is more efficient for each individual pedigree. This program includes options to:

- 1) order and map a set of markers along a chromosome;
- 2) localize a disease gene on a fixed marker map,  
using either parametric or non-parametric linkage methods;
- 3) test for allelic association by the TDT or the gamete-competition model;
- 4) determine haplotypes;
- 5) identify potential genotyping errors;
- 6) determine kinship coefficients conditional on marker data;
- 7) perform genetic risk calculations;
- 8) test for paternity or other pedigree relationships;
- 9) estimate allele frequencies, with or without using the pedigree structure;
- 10) estimate trait genotype penetrances;
- 11) identify deviations from Hardy-Weinberg and linkage equilibrium; and
- 12) simulate genetic data by gene dropping.

Mendel has been completely rewritten for this new version and now includes flexible input formats. Unix and Windows versions of this program, sample analysis files, and documentation are available.

**Multiplexing of primer extension products for mass spectrometry.** *M. Wjst*<sup>1</sup>, *N. Herbon*<sup>1</sup>, *T. Bettecken*<sup>2</sup>, *T. Immervoll*<sup>1</sup>. 1) Inst fuer Epidemiologie, GSF Forsch Umwelt & Gesundh, Neuherberg Munich, Germany; 2) Inst fuer Humangenetik, GSF Forsch Umwelt & Gesundh, Neuherberg Munich, Germany.

MALDI-TOF (matrix assisted laser desorption ionisation time of flight) mass spectrometry is a fast and precise method for detecting single base variation in DNA sequences (Ross, Nature Biotechnol 1998; 16:1347). In addition it offers the advantage of combining different primer extension reactions in a single tube.

Method: We designed primers for 500 consecutive SNPs on chromosome 6p21 obtained from the SNP consortium (snp.cshl.org) with Primer3 software ([www.genome.wi.mit.edu/genome\\_software/other/primer3.html](http://www.genome.wi.mit.edu/genome_software/other/primer3.html)). Biotinylated primer for the capture PCR were set to a target size of 25 bases, PCR product size to 80 to 140 bases while extension primers should be on average 16 base long. Criteria for multiplexing were (i) annealing T<sub>m</sub> of extension primer within a 50C interval (ii) same ddNTP stopmix solution (iii) least square mass differences of the extension product weights and (iv) at least 50 D differences of extension product weights. The multiplexing program is available at [cooke.gsf.de/wjst/group/develop/snp\\_menu.cfm](http://cooke.gsf.de/wjst/group/develop/snp_menu.cfm)

Results: Automatic assay design was possible for 408 SNPs with most failures due to insufficient sequence information, followed by annealing problems within repeat regions. Due to the large resolution range of the fragments between 4500 and 7500 Dalton multiplexing was straightforward: Bipllexing resulted in 214 assays (52% of original set), triplexing in 152 (37%), quadruplexing in 127 (31%), pentaplexing in 111 (27%), hexaplexing in 99 (25%). Pentaplexing of the first 300 SNPs resulted in a ratio of 28%, 250 SNPs of 27%, 200 SNPs of 34%, 150 SNPs of 33% and 100 SNPs of 37% compared to the original set.

Conclusion: Pentaplexing of at least 250 SNPs is probably the most economic way to combine primer extension products for mass spectrometry.

**A web-based software system for linkage analysis and information management.** *G.Y. Yu, J.X. Liu, D.T. Xie, R.M. Thompson, R. Zayas, R.S. Raike, C.M. Gomez.* Dept Neurology, Univ Minnesota, Minneapolis, MN.

It has become feasible to conduct high-throughput genotyping in a regular laboratory setup due to the availability of standard microsatellite marker sets, and advances in automatic devices for DNA extraction, amplification, and electrophoresis. The challenges remain to be the information management and efficient data analysis, especially for a small laboratory. We developed a web-based software system to address the challenges. This system provides information management services and an intuitive graphic user interface (GUI) for integrated analysis programs. The core of the system is a database-backed application and a GUI that communicate over the internet. Many data analysis programs can be easily integrated. We have currently integrated LINKAGE (FASTLINK) and SLINK. Using this system, we are performing a genome-wide scan for dominantly inherited ataxia genes. It streamlines our data entry and analysis process. The system employed the three-tier client/server architecture. On the front-end, an easy-to-use GUI is presented in a web browser. An authorized user can enter data, validate Mendelian consistency, import or export formatted files, do analysis, and report results through the GUI. On the backend, there is a relational database. It stores marker information, pedigree information, clinical data, disease models, DNA sample data, and genotyping data. Users can make any combination of a pedigree set, a marker set, and a disease model to perform an analysis using any integrated program. The database also stores all the analysis information, including all input files and final results. In the middle, a Java application serves as a four-way bridge between the browser, the database, the genetic analysis programs, and the platform on which the application is running. The system is object-oriented designed and implemented in Java, and is platform- and database- independent. It thus provides flexibility, reusability, scalability and maintainability.

**Mutations in the Diastrophic Dysplasia Gene (DTDST) are not a frequent cause of Idiopathic Talipes Equinovarus (Clubfoot).** *L. Bonafe<sup>1</sup>, S.H. Blanton<sup>2</sup>, A. Scott<sup>3</sup>, A. Ward<sup>4</sup>, S. Broussard<sup>4</sup>, C.A. Wise<sup>5</sup>, A. Superta-Furga<sup>1</sup>, J.T. Hecht<sup>4</sup>.* 1) University Children's Hospital, Zurich Switzerland; 2) Univ of VA, Charlottesville; 3) Shriner's Hospital for Children, Houston, TX; 4) Univ of TX HSC, Houston, TX; 5) Scottish Rite Hospital, Dallas TX.

Idiopathic talipes equinovarus (ITEV) or isolated club foot is a common birth defect whose etiology remains elusive. Many studies suggest a genetic etiology with either a single gene or multifactorial inheritance most often invoked. A recent report suggested homozygosity for the R279W mutation in the sulfate transporter gene (DTDST; SLC26A1) as the etiology of ITEV in two sibships. We have assembled a collection of 203 sporadic parent-child trios, 72 parent-child trios with a positive family history and 48 multiplex families with ITEV. Although the affected individuals in the two reported sibships had additional anomalies, we decided to investigate a possible role for DTDST in isolated clubfoot. Using closely linked flanking markers, D5S1507 and D5S1469, in a subset of our families we tested DTDST as a candidate gene for ITEV. TDT scores gave suggestive results and therefore we sequenced the DTDST gene of ten ITEV probands who had a positive family history and also had the excessively transmitted allele. No alterations in the sequence were identified. Two R279W heterozygous individuals (1%) were found out of the 207 tested probands with ITEV; this is consistent with the frequency of the R279W mutation in a control population. Our findings suggest that the DTDST gene does not play a significant role in the etiology of ITEV.

**Toward the identification of the MKS2 gene causing the Meckel syndrome.** *Y. Sirot<sup>1</sup>, L. Benedetti-Clech<sup>1</sup>, J. Augé<sup>1</sup>, J. Roume<sup>1</sup>, V. Cormier-Daire<sup>1</sup>, M. Le Merrer<sup>1</sup>, G. Gyapay<sup>2</sup>, A. Munnich<sup>1</sup>, M. Vekemans<sup>1</sup>, T. Attié-Bitach<sup>1</sup>.* 1) Dept Genetique INSERM U393, Hopital Necker Enfants Malades, Paris, France; 2) Centre National du Séquençage, Génoscope, Evry, Paris.

Meckel syndrome (MKS) is a rare, lethal, autosomal recessive congenital malformation syndrome characterized by occipital meningoencephalocele, multicystic dysplasia of the kidney, cystic and fibrotic changes of the liver, and polydactyly. So far, two MKS loci have been mapped to chromosomes 17q21-23 and 11q13 in finnish (MKS1) and african-middle eastern families respectively (MKS2). In an attempt to identify the MKS2 gene, we constructed an integrated map across the 0 cM critical region between markers D11S4079 and Ac18610A. This map has allowed us to pursue our gene candidate analysis by RT-PCR sequencing of two patients and to exclude a third gene (PTD015). In addition, we established the structure of a novel gene by construction of a EST contig and its comparison with human genomic sequence. This gene which is conserved in the mouse, *Drosophila* and *C.Elegans* is being tested by RT-PCR sequencing. Finally, the expression patterns of PTD015 and this novel gene are being studied using In Situ Hybridization on human embryos.

**Lack of Confirmation of Linkage to Previously Reported Regions for NSCLP.** *S. Patel*<sup>1</sup>, *J. Mulliken*<sup>2</sup>, *S.H. Blanton*<sup>3</sup>, *J.T. Hecht*<sup>1</sup>. 1) UTHSC, Houston, TX; 2) Boston Children's Hospital, MS; 3) University of Virginia, Charlottesville.

Nonsyndromic cleft lip and palate (NSCLP) is a common craniofacial birth defect occurring in 1/700 livebirths. The etiology of NSCLP is complex with genetic and environmental factors playing a role. Identification of the genetic factors has been a challenge. Genome scans and candidate gene approaches have been used to identify potential NSCLP genes. Prescott et al. (2000), using sib-pair analysis, reported suggestive linkage to 9 chromosomal regions. In our study, we have tested linkage and association to markers in these regions in a collection of 72 multiplex NSCLP families. In addition, we have tested markers tightly linked to the metalloproteinase (MMPI) gene family on chromosome 11 as these genes, especially MMPI13, play an important role in cranial neural crest cell migration and cell-cell adhesion. The data was analyzed using traditional parametric linkage analysis, non-parametric linkage analysis and the TDT, all as implemented by GENEHUNTER. No evidence was found for either linkage alone or linkage and association. These results suggest that these regions do not play a major role in the development of familial NSCLP.

**Genetics of familial keloids.** *A.G. Marneros<sup>1,2</sup>, J.E.C. Norris<sup>3</sup>, B.R. Olsen<sup>1,2</sup>, E. Reichenberger<sup>1,2</sup>*. 1) Department of Cell Biology, Harvard Medical School, Boston, MA; 2) Harvard-Forsyth Department of Oral Biology, Harvard Dental School and Forsyth-Institute, Boston, MA; 3) Department of Plastic Surgery, St. Luke's/Roosevelt Hospital Center, New York City, NY.

Keloids are proliferative fibrous growths that result from an excessive tissue response to skin trauma. Most keloids occur sporadically, but some keloid cases are familial. The genetics of keloid formation have, however, only rarely been documented, and the mode of inheritance is not known. We studied the clinical and genetic characteristics of 14 pedigrees with familial keloids. The ethnicity of these families is mostly African-American (10), but also Caucasian (1), Japanese (2), and African-Caribbean (1). The pedigrees account for 341 family members, of which 98 display keloids. Of the affected family members, 38 are male, and 60 are female. The age of onset varies from early childhood to late adulthood. There is variable expression of keloids within the same families, some affected members having only minor ear lobe keloids, whereas others have very severe keloids affecting large areas of the body. In the described pedigrees, 7 individuals are obligate unaffected carriers, revealing nonpenetrance in about 6.7% of keloid gene carriers. Syndromes associated with keloids, namely Rubinstein-Taybi and Goeminne syndrome, were not found in these families. Additionally, linkage to the gene loci of these syndromes was excluded. A complete genome wide screen using 403 microsatellite markers was performed in the ten largest pedigrees. Preliminary linkage data suggest locus heterogeneity, since distinct loci with significant and suggestive linkage were identified in single families. The pattern of inheritance observed in these families is consistent with an autosomal dominant mode with incomplete clinical penetrance, and variable expressivity. This is the most comprehensive collection of keloid families described to date, and it allows for the first time the elucidation of the clinical genetics of the familial form of this wound healing disorder, and the mapping of keloid gene loci.

**Fine mapping of a diabetes susceptibility gene on chromosome 12 in Caucasian samples.** *M.G. Ehm, M.C. Karnoub, G. Chandra, S.L. Chissoe, S. Haneline, E.H. Lai, Q. Nguyen, D. Yarnall, D.V. Zaykin, M.J. Wagner, D.K. Burns.* GlaxoSmithKline, Res Triangle Pk, NC.

We undertook a genome-wide screen (389 microsatellite markers) in samples of 835 Caucasian individuals collected as part of the American Diabetes Association's GENNID study. Multipoint nonparametric linkage analyses were performed with diabetes, and diabetes or impaired glucose homeostasis (IH). We have previously reported linkage to diabetes (LOD=1.91) and diabetes or IH (LOD=2.81) near D12S853 (map position 82 cM). While these results were not replicated in samples collected in phase 2 of the GENNID study, evidence for linkage of type 2 diabetes to this region on chromosome 12 has been reported by two other investigators on independent Caucasian family samples. We identified, mapped and genotyped 551 markers at an average density of 20 Kb, in a sample of 153 unrelated cases taken from the above Caucasian families, and 133 unrelated Caucasian population controls. In this work, we will outline the statistical methods used to fine map the putative susceptibility gene in this region.

Single marker tests of association of genotypes for single markers include chi-squared tests and Hardy-Weinberg equilibrium tests (Nielsen, Ehm, Weir 1999). To assess association of haplotypes with disease, we employed a sliding window approach in conjunction with the Zaykin et al (in preparation) haplotype trend test. To investigate whether our marker map is sufficient to extract all of the information in the region, we have investigated the marker allele frequencies and summarized the extent of linkage disequilibrium. Additionally, we are investigating the information content of the haplotypes to summarize how efficiently the marker map is extracting information in the region. We have identified 6 regions for follow-up based on the results of these tests and are typing these markers in an independent Caucasian case and control collection. We are investigating whether any of these SNPs is associated with the evidence for linkage (Horikawa, Oda, Cox et al 2000).

**Linkage studies of *FASL* polymorphisms in type 1 (insulin dependent) diabetes in Danish families.** *R.L. Nolsoe, O.P. Kristiansen, Z.M. Larsen, J. Johannesen, F. Pociot, T. Mandrup-Poulsen.* Steno Diabetes Center, Gentofte, Denmark.

**Background/Aims.** Type 1 (insulin dependent) diabetes mellitus is the result of a T cell dependent selective destruction of the pancreatic beta cells. There is evidence that the apoptosis inducing T cell effector, Fas ligand (FasL) may play a role in the pathogenesis of type 1 diabetes, probably on the level of the T cell. FasL mediated apoptosis is important in maintaining peripheral self-tolerance and in down-regulating an immune response. **Methods.** We therefore evaluated the human FasL gene on chromosome 1q23 as a candidate susceptibility gene for type 1 diabetes and scanned the entire *FASL* (promoter, exons 1-4 and 3'UTR) for polymorphisms using single strand conformational polymorphism analysis and direct sequencing. **Results.** We identified two novel polymorphisms, a g-C843T and a g-A475T, in a negative regulatory region of the promoter. A Danish type 1 diabetes family collection of 1143 individuals comprising 257 families (420 affected and 252 unaffected offspring) was typed for the g-C843T polymorphism and for a *FASL* microsatellite. Haplotypes were established and data were analysed using the extended transmission disequilibrium test, ETDT. We found no significant deviation from random transmission patterns for the haplotypes, ( $P_{etdt}=0.20$ ). **Conclusion.** We found no overall evidence for linkage of the *FASL* polymorphism to type 1 diabetes and conclude that *FASL* does not contribute to the genetic susceptibility to type 1 diabetes.

**Localizing genes involved type 1 and type 2 diabetes in a genetically isolated population.** *C.M. Van Duijn<sup>1</sup>, N. Vaessen<sup>1</sup>, J. Pullen<sup>2</sup>, J.J. Houwing-Duistermaat<sup>1</sup>, P. Snijders<sup>1</sup>, L.A. Sandkuijl<sup>1</sup>, M. Edwards<sup>2</sup>, P. Heutink<sup>1</sup>, B.A. Oostra<sup>1</sup>.* 1) Genetic Epidemiology Unit, Dept Epidemiology & Biostatistics and Clinical Genetics, Erasmus Univ Medical Sch, Rotterdam, Netherlands; 2) Oxagen, UK.

Type 1 (DM1) and type 2 (DM2) diabetes have a substantial genetic component. The HLA-DR/DQ region and the insulin gene are involved in DM1 while in DM2 calpain-10 has been implicated. For both diseases, other genes must be involved. The aim of the present study was to identify new loci involved in diabetes in a genetically isolated population. In the middle of the 18th century, 150 settlers founded the population in Soutwestern part of the Netherlands, which now comprises 20,000 inhabitants. Of the 46 DM1 patients ascertained, 43 could be linked to a common ancestor within 15 generations. The number of HLA-DR3/DR4 carriers in patients was significantly lower compared to that of DM1 patients from the general Dutch population ( $p=0.0001$ ) suggesting other loci may be more important in our isolate. The genome wide screen using 420 markers showed a peak at D6S1014 located in the HLA-region with a p-value of 0.009. Based on this finding we used a p-value of 0.016 (=LOD score 1.0) as a cutoff in the 2 genome screens. Using this criterion, there was evidence for a DM-1 locus reported earlier at chromosome 8q (D81128; $p=0.003$ ) and a new locus on chromosome 17q (D17S2059; $p=0.012$ ). Both loci showed a conserved haplotype in patients ( $p$ -trend=0.0005 for both markers). The 128 DM2 patients who were ascertained could be aggregated into 79 nuclear families linked to each other within 13 generations. There was no evidence for a role of calpain-10 in our isolate. Of the 770 used in the genome screen, 9 yielded a lodscore over 1.0. To replicate the initial findings of the genome screen, an independent study of serum glucose, a risk factor for DM2, in first degree relatives was conducted. For 2 loci, one yielding a LOD score 2.3 in the initial DM2 screen, the relation between the conserved DM2 haplotype and serum glucose was replicated in relatives. Although the genes involved in DM1 and DM2 loci remain to be identified, our initial results suggest that the population is suitable for localization of new diabetes genes.

**Role of resistin sequence variation in type 2 diabetes and insulin resistance.** *H. Wang, W. Chu, C. Hemphill, S.C. Elbein.* Division of Endocrinology, Univ Arkansas for Medical Sciences, Little Rock, AR.

Insulin resistance in fat and muscle characterizes type 2 diabetes (T2DM). Resistin, a novel cysteine-rich signaling molecule, is secreted by adipose cells and is increased in genetic and diet-induced models of obesity and insulin resistance. Insulin sensitivity improves when resistin levels fall. Thus, resistin may explain the connection between insulin resistance and obesity. We hypothesized that sequence variation in or near the resistin gene might account for observed differences in insulin sensitivity and diabetes risk among nondiabetic members of families with multiple T2DM siblings. We used available sequence data to predict the genomic structure and designed primers to screen 800 bp of 5' flanking region and 2.5 kb of intron and coding regions, including the 3' flanking region, using single strand conformation polymorphism analysis (SSCP) under 2 conditions. We tested 44 unrelated diabetic individuals and 20 nondiabetic individuals at extremes of insulin sensitivity from 63 families of Northern European ancestry ascertained for two individuals with T2DM. Variants were confirmed by fluorescent bidirectional sequencing. We identified one 5' flanking SNP, 2 3' flanking SNPs and a trinucleotide repeat, and 5 intronic SNPs, but no coding SNP. We typed the 5' flanking SNP and one intronic SNP in 129 unrelated cases (T2DM) and 118 unrelated nondiabetic controls, and in 122 nondiabetic family members (96 normal, 26 impaired glucose tolerance) who had undergone minimal model determination of insulin sensitivity. Neither variant was associated with T2DM. Neither variant affected insulin sensitivity with or without body mass index (BMI) as a covariate. Likewise, no effect was found on BMI as a trait. The two variants were in significant linkage disequilibrium ( $p < 0.001$ ). Work is in progress to type additional variants that are not in complete linkage disequilibrium. To our knowledge, this is the first analysis of resistin variation in humans. Our data suggest that resistin variants are unlikely to alter diabetes risk or insulin sensitivity in Caucasians, but variation might be important in other ethnic groups or in a more obese population.

**Linkage analysis of chromosome 13 in families selected for specific language impairment.** *C.W. Bartlett<sup>1</sup>, J. Flax<sup>1</sup>, P. Tallal<sup>1</sup>, L.M. Brzustowicz<sup>1,2,3</sup>*. 1) Dept Neurosci/Ctr M&BN, Rutgers Univ, Newark, NJ; 2) Dept Genetics, Rutgers Univ, New Brunswick, NJ; 3) New Jersey Medical School, Newark, NJ.

Specific language impairment (SLI) is a developmental disorder characterized by a failure to learn language normally, in absence of specific environmental and neurological explanations. In the process of a genome scan, five nuclear and extended families (N=58) with at least two affected individuals were genotyped at 10 cM intervals spanning chromosome 13. Three phenotypic classifications with both dominant and recessive models were tested with parametric linkage analysis: 1) Clinical Impairment; 2) Reading Impairment; and 3) Language Impairment. The analysis was completed in three steps. First, pairwise linkage analysis was conducted on all markers with one marker giving a lod score  $> 1.5$  at D13S800 in 13q21. 3-point analysis of the same region gave a lod score  $> 2$ . Next, four additional markers were genotyped in the region at approximately 5 cM intervals. Finally, 4-point analysis of the region gave a lod score of 2.68 ( $\alpha = 1$ ) close to marker D13S800 under a recessive Reading Impairment model. This region corresponds to the same location in previous work in autism where subsetting multiplex families based on language criteria increased the evidence for linkage in this region. These results suggest the most likely location of a putative SLI locus is located near D13S800 and may represent the same locus seen in autism research.

**Further evidence for linkage of autosomal dominant medullary cystic kidney disease (ADMCKD) on chromosome 1q21.** *S. Ala-Mello*<sup>1</sup>, *M. Auranen*<sup>2</sup>, *J.A. Turunen*<sup>2</sup>, *I. Järvelä*<sup>2,3</sup>. 1) Dept Medical Genetics, Univ Helsinki, Helsinki, Finland; 2) Dept of Molecular Medicine, National Public Health Institute, Helsinki, Finland; 3) Helsinki University Central Hospital, HUCH Laboratory Diagnostics, Laboratory of Molecular Medicine, Helsinki, Finland.

**Background.** Autosomal dominant medullary cystic kidney disease (ADMCKD) is characterized by the development of cysts at the corticomedullary border of the kidneys, it resembles nephronophthisis (NPH) with an autosomal recessive mode of inheritance. Genetic linkage has been shown either on chromosome 1q21 (ADMCKD1) or 16p12 (ADMCKD2), and there exist families that are not linked to the aforementioned loci. No disease-causing gene underlying this disorder has been reported.

**Methods.** We searched the Finnish Transplantation Register and hospital records to identify all the ADMCKD families in the Finnish population. Detailed clinical information of the patients was collected. Linkage analysis was used to study whether the Finnish families originating from a homogenous population showed genetic linkage to the ADMCKD1 or ADMCKD2 loci. Also, the coding region of a strong candidate gene, natriuretic peptide receptor A (NPRA) located on the chromosome 1q21 critical region was sequenced.

**Results.** Five of the six families showed linkage to the previously identified region of chromosome 1q21. Family 6 with hyperuricemia as a prominent clinical feature was linked to neither of the ADMCKD loci. Wide inter- and intrafamilial variability in the clinical picture of the patients was detected. The NPRA gene mutation was excluded as a causative gene by sequencing.

**Conclusion.** This study locates the gene for ADMCKD1 close to a marker D1S1595 in a region < 5cM, and further confirms the existence of at least three loci for the medullary cystic kidney disease. Heterogeneity of the symptoms complicates the clinical diagnosis and classification of the patients. Further studies are needed to identify the disease-causing gene.

**Linkage of quantitative endophenotypes in autistic sibpairs.** *M. Alarcón*<sup>1</sup>, *R.M. Cantor*<sup>2</sup>, *AGRE Consortium*<sup>3</sup>, *D.H. Geschwind*<sup>1</sup>. 1) UCLA Department of Neurology, Los Angeles, CA; 2) UCLA Department of Human Genetics, Los Angeles, CA; 3) Cure Autism Now, Los Angeles, CA.

Autism is characterized by repetitive behaviors and deficits in language and social skills. Linkage analyses of the autism diagnosis have been performed but results have not been consistent. Its apparent complex genetic etiology suggests that associated quantitative endophenotypes may be important in identifying linkage. To identify quantitative trait loci (QTL) that influence autism-related traits, we performed a nonparametric multipoint genome scan analysis in 152 families from the Autism Genetic Resource Exchange (AGRE; Geschwind et al., in press). The families were ascertained for the presence of at least two children with autism spectrum disorders based on the Autism Diagnostic Interview (ADI-R; C. Lord et al., 1994). Three quantitative traits from the ADI-R were analyzed: age at first word, age at first phrase and a composite measure of repetitive or stereotyped behavior, which we call ocd. Parents and offspring were genotyped for 335 markers and multipoint sibpair analyses were conducted using Genehunter (L. Kruglyak et al., 1996). The strongest evidence supporting linkage for the ADI-R item 'age at first word' was observed on chromosome 7q ( $Z = 2.98$ ,  $p=0.001$ ). This region is about 25 cM away from the SPCH1 locus (S. E. Fisher et al., 1998) and less than 3 cM away from a previously reported autism susceptibility region (International Molecular Genetic Study of Autism Consortium, 1998). The result for language delay was supported by a subsequent multipoint analysis of additional markers in the chromosome 7q region ( $Z=2.85$ ,  $p=0.002$ ). Moreover, the peak fine mapping result for ocd ( $Z=2.48$ ,  $p=0.007$ ) was in a region overlapping the language QTL. These findings suggest that the putative susceptibility gene on chromosome 7 may be a QTL for the language and repetitive behavior deficits associated with autism.

**Mixture models for linkage and association analysis with covariates.** *B. Devlin<sup>1</sup>, S-A. Bacanu<sup>1</sup>, B.L. Jones<sup>2</sup>, K.M. Roeder<sup>3</sup>*. 1) Dept Psychiatry, Univ Pittsburgh, Pittsburgh, PA; 2) Dept Genetics, Univ Pittsburgh, Pittsburgh, PA; 3) Dept Statistics, Carnegie Mellon University, Pittsburgh, PA.

One of the challenges to determining the genetic etiology of complex diseases is genetic heterogeneity. Covariates, such as attributes or environmental exposures of the subjects, can be used to focus tests on more homogeneous subsets of the data to detect linkage (Schaid et al., 2001, *Am J Hum Genet* 68:1189-1196; Devlin et al., *Genet Epidemiol*, in press) or association. For example, age of onset was a key covariate for the discovery of BCRA1; fasting insulin and body-mass index could be key covariates for determining the genetic risk factors for Type 2 diabetes. For ASP linkage analysis, we formulated the problem as a mixture model in which a disease mutation is segregating in only a fraction of the ASP, with the remaining fraction being unlinked. Covariate information is used to predict membership within two groups, corresponding to the linked and unlinked ASP. Then tests for linkage are conducted using all families, each family being weighted by the probability of membership in the cluster of interest. We are currently extending the mixture model approach to association analysis, especially family-based analysis. Here the covariate information is again used to cluster families into two groups, which correspond to families deriving at least a portion of their liability from alleles at a candidate locus (i.e., linked and associated families) versus those families having the disease for other reasons. Because the structure of the linkage and association models is similar, we expect the theoretical framework to extend naturally. We evaluate the performance of these methods by simulation.

**Genome-wide multipoint linkage analyses of five extended multiplex pedigrees from the Oceanic Nation of Palau.**

*S-A. Bacanu<sup>1</sup>, B. Devlin<sup>1</sup>, K. Roeder<sup>2</sup>, B. Galke<sup>3</sup>, D. Novasad<sup>3</sup>, K. Cuenco<sup>1</sup>, S. Tiobek<sup>4</sup>, C. Otto<sup>4</sup>, W. Byerley<sup>3</sup>.* 1) Dept Psychiatry, WPIC, Pittsburgh Medical Ctr, Pittsburgh, PA; 2) Dept Statistics, Carnegie Mellon University, Pittsburgh, PA; 3) Dept Psychiatry, University of California, Irvine, CA; 4) Belau National Hospital, Korror, Palau.

The Oceanic Nation of Palau has been geographically and culturally isolated over most of its 2000 year history. In our early studies of schizophrenia in Palauans, we selected five large, multigenerational pedigrees for linkage analysis and genotyped markers every 10 cM (CHLC/Weber screening set 6). The number of affected/unaffected individuals genotyped per family ranged from 11/21 to 5/5. We fit a simple dominant and recessive model to these data using multipoint linkage analysis implemented by SIMWALK2. As might be expected, the most informative pedigrees produced the best linkage results. After genotyping additional markers in the region, one such pedigree produced a LOD = 3.4 (5q distal) under the dominant model. Seven of 9 schizophrenics in the pedigree, mostly third and fourth degree relatives, share a 15 cM, 7 marker haplotype. For a different pedigree, another promising signal occurred on distal 3q, LOD = 2.6 for the recessive model. For two other pedigrees, the best LODs were modest, slightly better than 2.0 on 5q and 9p, while the fifth pedigree produced no noteworthy linkage signal. Currently, all available schizophrenics have been ascertained (n=154 of 156) along with key relatives. (n=495). Using this completely ascertained population of schizophrenic families, a genome wide scan has been performed at the Center for Inherited Diseases (CIDR) genotyping facility using microsatellite markers spaced every 10 megabases. Genome wide multipoint results will be presented based on these new data.

**Evidence of genetic heterogeneity in Seckel syndrome.** *L. Faivre<sup>1</sup>, M. Le Merrer<sup>1</sup>, S. Lyonnet<sup>1</sup>, A. Verloes<sup>2</sup>, N. Dagonneau<sup>1</sup>, B.C. Xavier<sup>1</sup>, A. Munnich<sup>1</sup>, V. Cormier-Daire<sup>1</sup>.* 1) Dept Genetics, Hopital Necker Enfants Malade, Paris, France; 2) Medical Genetics Centre, CHU Sart Tilman, Liege, Belgique.

Seckel syndrome is a rare autosomal recessive condition belonging to the group of osteodysplastic primordial dwarfism. This syndrome is characterized by the association of severe pre and postnatal growth retardation, microcephaly with mental retardation and a typical bird-headed facial appearance. This syndrome has been suggested to be clinically heterogeneous. Recently, a locus for Seckel syndrome has been mapped to chromosome 3q22.1-q24 by homozygosity mapping in two consanguineous families originating from the same village in Pakistan. Here, we exclude linkage to chromosome 3q22.1-q24 in five consanguineous families originating from Europe (1), North Africa (3) and Africa (1) using 6 microsatellite markers of the region of interest distant from 5 cM (D3S1309 to D3S1282 from the centromere to the telomere). These results support the view that Seckel syndrome is a genetically heterogeneous condition. Studies of additional families with this condition will help to define whether or not this locus is a major locus for Seckel syndrome, and if genetic heterogeneity is related to phenotypic or ethnical differences. Furthermore, we also exclude linkage to chromosome 3q22.1-q24 in two multiplex consanguineous families presenting type II osteodysplastic primordial dwarfism.

**Localization of the Human SLE Susceptibility Genes Within the HLA Using a Recombinant Ancestral Haplotype Approach.** *R.R. Graham<sup>1</sup>, W.A. Ortmann<sup>1</sup>, P.M. Gaffney<sup>1</sup>, S.A. Selby<sup>1</sup>, P.E. Stuart<sup>2</sup>, J.T. Elder<sup>2</sup>, P.K. Gregersen<sup>3</sup>, T.W. Behrens<sup>1</sup>.* 1) Medicine, University of Minnesota, Minneapolis, MN; 2) Dermatology, University of Michigan, Ann Arbor, MI; 3) Genetics, North Shore University Hospital, Manhasset, NY.

The Human Leukocyte Antigen (HLA) region on Chromosome 6p21.3 is a primary genetic susceptibility locus in many autoimmune diseases, including Systemic Lupus Erythematosus (SLE). Previous studies in SLE have been unable to precisely localize this effect due to the extensive linkage disequilibrium in the HLA, a paucity of informative markers, small sample sizes, and the limitations of case/control approaches. The recent sequencing of the HLA region has allowed us to develop a dense map of highly informative microsatellite markers spanning this 3.6 Mb region. Here, we report the genotyping of 44 markers in the Minnesota SLE family collection, which is comprised of 334, primarily Caucasian, families. Analyses of the collected marker data demonstrates that the HLA region confers susceptibility to SLE as measured by tests for both linkage (LOD>3.5) and association (Pedigree Disequilibrium Test [PDT] global p value =  $3 \times 10^{-8}$  at M6S115). We found that two extended HLA haplotypes, the 8.1 and 7.1 ancestral haplotypes bearing the HLA-DR2/DQ6 and HLA-DR3/DQ2 alleles, respectively, are strongly associated with disease and account for most of the observed effect. The extensive disequilibrium present at the HLA has the potential to make the localization of disease genes a challenge. Indeed, we found that more than half of the 8.1 and 7.1 founder haplotypes in our population span at least 2.2 Mb. A recombinant ancestral haplotype approach was employed to better localize the susceptibility genes present on the 8.1 and 7.1 haplotypes. This approach has narrowed the relevant region of the 8.1 (-DR3) haplotype to an ~1.1 Mb (MICA-M6S230) interval, while the susceptibility region of the 7.1 (-DR2) haplotype was localized to an ~400 kb region in the Class II region (M6S137-M6S232). These data have allowed us to significantly narrow the SLE disease-gene containing intervals within the HLA and should facilitate gene identification.

**A transmission disequilibrium test that allows for genotyping errors in the analysis of single nucleotide**

**polymorphism data.** *D. Gordon*<sup>1</sup>, *S.C. Heath*<sup>2</sup>, *X. Liu*<sup>1</sup>, *J. Ott*<sup>1</sup>. 1) Lab Statistical Genetics, Rockefeller Univ, New York, NY; 2) Lab Mathematical Genetics Memorial Sloan-Kettering Cancer Center, New York, NY.

Our work assesses the effects of genotyping errors on the type I error rate of a particular transmission disequilibrium test (TDTstd) that assumes data are errorless, and introduces a new transmission disequilibrium test (TDTae) that allows for random genotyping errors. We evaluate the type I error rate and power of the TDTae under a variety of simulations, and perform a power comparison between the TDTstd and the TDTae for errorless data. Both the TDTstd and the TDTae statistics are computed as 2 times a log-likelihood difference, and both are asymptotically distributed as chisquare with 1 df. Genotype data for trios are simulated under a null hypothesis, and under an alternative (power) hypothesis. For each simulation, errors are introduced randomly under a specific model via a computer algorithm with different probabilities (called allelic error rates). The TDTstd statistic is computed on all trios that show Mendelian consistency, while the TDTae statistic is computed on all trios. The results indicate that TDTstd shows a significant increase in type I error when applied to data in which inconsistent trios are removed. This type I error increases both with an increase in sample size and an increase in the allelic error rates. TDTae always maintains correct type I error rates for the simulations considered. Furthermore, TDTae shows power of at least 0.958 for several simulations. Finally, the power of TDTstd is at least that of TDTae for simulations with errorless data.

**Genomic Screen for Genes Responsible for Early Onset Open Angle Glaucoma.** *E.A. DelBono<sup>1</sup>, S. Lynch<sup>1</sup>, G. Yanagi<sup>1</sup>, M. Maselli<sup>1</sup>, Y. Bradford<sup>2</sup>, J.L. Haines<sup>2</sup>, J.L. Wiggs<sup>1</sup>.* 1) Ophthalmology, Mass Eye and Ear Infirmary, Boston, MA; 2) Program in Human Genetics, Vanderbilt School of Medicine, Nashville, TN.

One gene responsible for early onset primary open angle glaucoma has been cloned (TIGR/Myocilin). However, previous studies have shown that only 8-20% of families affected by dominant juvenile glaucoma have mutations in this gene. Using a collection of autosomal dominant juvenile glaucoma families without mutations in the TIGR/Myocilin gene, we have performed a genome-wide screen to identify the chromosomal locations of additional genes responsible for this condition. Twenty-five pedigrees consisting of a minimum of three affected individuals in two generations (198 total individuals, 105 affected) were used for this study. Juvenile glaucoma was defined as: age of diagnosis before age 35, IOP greater than 22 in both eyes, glaucomatous optic nerve damage in both eyes, and visual field loss in at least one eye. Individuals with secondary causes of glaucoma, including evidence of anterior segment dysgenesis and pigment dispersion syndrome, were excluded. For the initial genome screen, only affected pedigree members and spouses were included in the analysis. Two hundred thirty eight markers spanning the human genome at approximately 10 cM intervals were analyzed. Two-point lod scores were calculated using an autosomal dominant model. Five regions on chromosomes 3, 5, 9, 12 and 20 demonstrated initially interesting results (two point lod score >1.0). Multipoint analyses of chromosomes 5, 9 and 20 resulted in higher lod scores for markers located in these regions. None of these regions correspond to previously identified glaucoma loci. These initial results identify five chromosomal regions that may contain genes responsible for juvenile open angle glaucoma. Supported by Research to Prevent Blindness and NIH Grant EY09847.

**Selective taste blindness to caffeine and sucrose octa acetate: Novel bimodal taste distributions unrelated to PROP and PTC.** *P.A.S. Breslin, C.D. Tharp, D.R. Reed.* Monell Chemical Senses Ctr, Philadelphia, PA.

As part of larger project to identify individuals who demonstrate a total inability to taste bitterness, we also have observed a frequent inability to detect and rate bitterness from selected compounds, especially sucrose octaacetate (SOA) and caffeine. SOA and caffeine insensitivity appear commonly in the population at large (>30%). Our goal is to identify the genes responsible for SOA and/or caffeine blindness in these subjects by linkage analyses. This SOA/caffeine study has the advantage of examining a human phenotype that parallels the well-characterized mouse SOA insensitivity phenotype. Historically, it has been very rare to find bimodal bitterness frequency histograms for compounds that are not structurally related to phenylthiocarbamide (PTC) and propylthiouracil (PROP). SOA and caffeine are not unimodally distributed, but rather display either a bimodal or trimodal distribution. Previously, Whitney and colleagues looked for bimodality in the human frequency histogram for SOA detection thresholds, but did not find it. He was motivated by the fact that the mouse *Soa* gene influences threshold behavioral sensitivity and he wanted to determine if humans had a similar polymorphism. It is essential to note that Whitney and colleagues were measuring detection thresholds for SOA and not suprathreshold bitterness ratings as we are. It is common for detection thresholds and suprathreshold ratings not to correlate well. It is fortuitous that we have found a non-normal distribution for SOA, since we may now attempt to determine if a similar gene to *Soa* is involved with human ratings of SOA and perhaps also with ratings of caffeine. The pattern of family correlations for SOA is different than for overall bitterness sensitivity, with high parent-offspring and high sibling correlations, suggesting a greater contribution of additive gene effects. The difference in correlations between SOA and caffeine among parent-offspring and sibling groupings suggests that SOA and caffeine are likely following different modes of inheritance, and therefore supports our inference that the SOA and caffeine receptors are not the same gene. Supported by DC2995: PASB & DC04188: DRR.

**A Multiple Threshold Liability Model Suggests Linkage of Alcohol Dependence to Three Loci in the COGA Data Set.** *J. Corbett<sup>1</sup>, N.L. Saccone<sup>1</sup>, L. Bierut<sup>1</sup>, A. Goate<sup>1</sup>, H.J. Edenberg<sup>2,3</sup>, J. Nurnberger<sup>2</sup>, H. Begleiter<sup>4</sup>, T. Reich<sup>1</sup>, J.P. Rice<sup>1</sup>.* 1) Department of Psychiatry, Washington University, St. Louis, MO; 2) Department of Medical and Molecular Genetics, Indiana University, Indianapolis, IN; 3) Department of Biochemistry and Molecular Biology, Indiana University, Indianapolis, IN; 4) Department of Psychiatry, Suny Health Science Center, Brooklyn, NY.

Previous analyses of the Collaborative Study on the Genetics of Alcoholism (COGA) data set using Affected Sib Pair (ASP) methods have yielded suggestive linkage to alcohol dependence on regions of chromosomes 1, 2, and 7. These analyses used one or more diagnoses of alcohol dependence (DSM-III-R + Feigner Definite (COGA), DSM-IV, or ICD-10) as an affectation criterion. Suggestive linkage has also been reported on chromosome 4 for related phenotypes, including "Maximum Number of Drinks in a 24 Hour Period" ("Max Drinks"), "Pure Unaffected," and certain ERP phenotypes. We propose the use of a Multiple Threshold Liability Model to take advantage of the hierarchical nature of the alcohol dependence diagnoses in the COGA dataset. Taking the estimated liability values from this model, we performed a linkage analysis using a variance components method implemented in MX. There were three regions whose lod scores exceeded 1.5. The first such region, on chromosome 1, yielded a lod score equivalent of 2.59 at the marker D1S532. This is in the region of linkage for alcohol dependence previously reported in the COGA dataset. The second such region was found on chromosome 4, where there was a lod score equivalent of 1.73 near the ADH3 locus. While not in a region of previously reported linkage for alcohol dependence, it is at the same marker where a signal was reported for "Max Drinks," as well as very near the possible protective locus found using "Pure Unaffected." The final result was on chromosome 8 at the marker D8S1988 with a lod score equivalent of 2.16. While there have been no previous reports of linkage to alcohol phenotypes in this region, it is homologous to a region on rat chromosome 5 which has been shown to have linkage to an alcohol consumption trait.

**Towards localizing the gene encoding Friedreich Ataxia 2.** *J.K. Brock<sup>1</sup>, J.M. Dooley<sup>1</sup>, D.C. Riddell<sup>2</sup>*. 1) Neurology, IWK Health Center, Halifax, NS, Canada; 2) Pathology, IWK Health Center, Halifax, NS, Canada.

Friedreich Ataxia (FRDA) is an autosomal recessive progressive neurodegenerative disease. Classical FRDA is characterized by onset before 20 years of age, progressive ataxia, dysarthria, loss of deep tendon reflexes, with pyramidal tract dysfunction and sensory axonal neuropathy. Although variable in expression, most clinically described FRDA maps to human chromosome 9q13. Exceptions are a clinically similar phenotype which is associated with selective vitamin E deficiency (AVED) mapping to chromosome 8q13, and a second, clinically indistinguishable phenotype (FRDA2), which has not yet been mapped. We have identified 2 FRDA families in which the ataxic phenotype does not map to 9q13, and in which Vitamin E levels are normal, ruling out AVED. Based on work in yeast, three genes have been identified which interact with frataxin, (produced from the FRDA gene), and could represent reasonable candidates for the second FRDA gene. PCR-based linkage analysis using an intragenic marker and three flanking markers from the human homologue of one of these (the MIPEP gene) have been done. The results are partially informative and indicate that the ataxic phenotype in both of our unusual FRDA families segregates with the MIPEP gene region. Based on the number of family members studied, the odds of obtaining these results due to random segregation would be 1 in 473 (LOD score of 2.68). Although a LOD score of 3 is considered evidence of tight linkage, we still feel that MIPEP is a reasonable candidate and additional markers and family members are being examined to support this interpretation.

**Identification of gene locations from maximum likelihood ASP linkage analysis: What lessons can we learn from peak shape?** *M.P. Bass<sup>1</sup>, E.R. Martin<sup>1</sup>, M. Boehnke<sup>2</sup>, E.R. Hauser<sup>1</sup>*. 1) Ctr Human Genetics, Duke Univ Medical Ctr, Durham, NC; 2) Univ of Michigan, Ann Arbor, MI.

Estimates of disease gene location resulting from ASP linkage analysis are often imprecise, with large standard deviations (Roberts et al.,1999) and variation dependent on both sample features and genetic map characteristics. In previous simulation studies we have shown that two estimates of disease gene location generated from the same model and sample can result in location estimates as much as 20 cM apart, on average (Hauser et al.,1998). Furthermore, the shape of the maximum likelihood curves can be multimodal with large dips between regions showing interesting linkage results, say a lod score above 1 in a complex disorder. Typically follow-up studies of interesting linkage results focus attention on regions with lod scores above a certain threshold level. We used simulation studies to examine how often the disease locus can occur in a dip in the likelihood curve, first for an ideal situation with all parents typed, correctly specified map parameters and no genotyping error. Then we varied the family structure, map and marker specifications and genotyping error rate to gauge the effects on lod score curve shape. In the ideal situation for a variety of critical lod score values, we observed substantial numbers of replicates with the disease locus in the dip and the situation becomes worse as we move from the ideal situation. We discuss characteristics of the peaks when the disease locus is in the dip and examine features of these lod score curves.

**Cleft lip with or without cleft palate in Turkey: assessment of candidate regions.** *M.E. Cooper<sup>1</sup>, L.L. Field<sup>2</sup>, B.S. Maher<sup>1</sup>, R. Tobias<sup>2</sup>, G. Tunçbilek<sup>3</sup>, G. Gürsu<sup>3</sup>, M.L. Marazita<sup>1</sup>.* 1) School of Dental Medicine, Univ. of Pittsburgh, Pittsburgh, PA; 2) Univ. of British Columbia, Vancouver, BC, Canada; 3) Hacettepe Univ., Ankara, Turkey.

Cleft lip with or without cleft palate (CL/P) is a common congenital anomaly, with birth prevalences ranging from 1/500 to 1/1000 depending on the population. A number of genetic loci have shown positive linkage or association results in European Caucasian populations. The purpose of the current study was to assess whether any of those loci have positive results in Turkish Caucasian CL/P families. 14 affected individuals whose parents were consanguineous (all first cousin matings) were identified as part of our on-going studies of oral-facial clefts in Ankara, Turkey. 9 markers from chromosomes 2, 4, 6, 14, 17 and 19 were assessed (TGFA, D4S175, F13A1, D6S291, TGFB3, D17S250, D17S579, D19S49, APOC2) because each have positive linkage and/or association results with CL/P reported. LOD scores were calculated between each of the 9 markers and CL/P, as well as model-free allelic association statistics (TDT). For the LOD score calculations, an autosomal recessive model was assumed for the inheritance of CL/P. All calculations were done in the total dataset, plus in a CL subset (5 families whose probands had cleft lip alone) and a CLP subset (9 families whose probands had cleft lip plus cleft palate). Of the 10 markers, a significantly positive TDT result was obtained with TGFA in the total dataset ( $p=0.03$ ), as well as the CL ( $p=0.05$ ), and CLP ( $p=0.03$ ) subsets. None of the markers showed statistically significant positive LOD scores with CL/P, although TGFA had LOD's of approximately 1.0 in the total dataset and the CLP subset. An association with TGFA in Caucasian families was the first positive association reported for CL/P, although there have since been conflicting studies reported. This is the first study investigating these candidate regions with CL/P in Turkey. Supported by NIH grant DE12472.

**Autosomal recessive Charcot Marie Tooth families linked to the 1q21 locus.** *H. AZZEDINE<sup>1</sup>, G. Durosier<sup>1</sup>, M. Tazir<sup>2</sup>, N. Birouk<sup>3</sup>, A. Bouhouch<sup>3</sup>, M. Salih<sup>4</sup>, T. Hamadouche<sup>5</sup>, D. Mahmoudi<sup>6</sup>, A. Masmoudi<sup>6</sup>, A. Vandenberg<sup>7</sup>, E. Dubourg<sup>8</sup>, D. Grid<sup>9</sup>, A. Brice<sup>1</sup>, E. Leguern<sup>1</sup>.* 1) INSERM U289, Hopital de la Salpetriere Paris France; 2) Service de Neurologie Hopital Mustapha Algiers Algeria; 3) Laboratoire de Neurogenetique Hopital des specialites Rabat Morocco; 4) Department of Pediatrics College of Medecine & KKUH King Saud University Saudi Arabia; 5) Institut Pasteur Algiers Algeria; 6) Service de Neurologie Hopital Mayot Algiers Algeria; 7) Universite Rockefeller Lyon1 Hopital de l'antiquaille Lyon, France; 8) Unite Fonctionnelle de Pathologies Neuromusculaires Hopital de la Salpetriere Paris France; 9) AFM-Genethon, Hopital de la Salpetriere Paris, France.

Charcot-Marie-Tooth (CMT) disease is a pathologically and genetically heterogeneous group of hereditary motor and sensory neuropathies characterised by slowly progressive weakness and atrophy, primarily in peroneal and distal leg muscles. Two major types have been distinguished, in which the neuropathy is either demyelinating or neuronal. Electrophysiological studies on median motor conduction velocity (MNCV) have confirmed the distinction between the demyelinating and axonal forms of the disease. Several loci and various modes of inheritance were described: Autosomal Dominant, X linked and Autosomal Recessive CMT (ARCMT). The first locus for an axonal form of ARCMT2 was identified on chromosome 1q21 in a large consanguineous family from Morocco (Bouhouche et al., 1999). In order to refine the candidate interval, we selected 34 consanguineous families representing 125 subjects, 45 of whom are affected. All these individuals were screened using 9 polymorphic markers (D1S514, S2858, S2715, S2777, S2721, S2624, S506, S2435 and D1S2721) covering 15.4 cM including the 1.7 cM candidate region. Only 3 families from North Africa shows an homozygosity region compatible with linkage of these families to this locus. Indeed, a 4.2 maximal combined lod score was reached with marker D1S2721. The patients present with a phenotype similar to those in the morrocan family. In conclusion, we report 3 new families linked to the 1q21 locus. This form of ARCMT represents 9% of the families in our series.

**Fine-Scale SNP Genotyping for Autism using Single Base Extension and Tag Arrays.** *L. Crawford, S. Smalley, S.F. Nelson.* Dept Human Genetics, UCLA, Los Angeles, CA.

Autism is a complex neurodevelopmental disorder with an incidence perhaps as high as 1 in 500 that causes severe lifelong deficits in social and language skills. There is little understanding of the biological or genetic mechanisms underlying this disorder, although there is persuasive evidence of a genetic component. Several genes (e.g.: HTT, HOXA1, and VIPR2) and chromosomal regions ( e.g.: chr 4p, 7q, 16p) have been implicated due to candidate gene studies and several genome scans. Single Nucleotide Polymorphisms (SNPs) are particularly promising tools for localizing genes for complex disorders because they are so abundant (with 1 per several hundred bases). Tens of thousands of SNPs are in coding regions and may themselves alter gene function. We are using SNP's to 1) densely fine map regions implicated in Autism (chromosomes 7 and 16) , 2 ) more densely cover genes that have been associated with Autism to support or refute these findings and 3) study a broad selection of brain expressed genes containing coding and/or functionally relevant SNPs. Our Autism sample set has been collected at the UCLA NPI and consists of 88 affected individuals (36 from simplex families). We have found that an SBE (Single Based Extension) Tag Array addresses the need for low cost per genotype, flexibility of format and high throughput. In large-scale SNP genotyping, it is also important to reduce the high costs of identifying SNPs that are sufficiently polymorphic from those listed in dbSNP . We have found that many are either not real SNPs or are not sufficiently polymorphic. We will discuss reliable selection criteria for SNPs as well as discuss details of the SBE assay. Our SBE tag array currently allows 16 fold multiplexing for the initial PCR and 40 fold multiplexing during the single-base extension step. We are able to genotype 16 individuals for 400 SNPs at a time for a total of 6,400 genotypes per slide. Since the tags on the array do not change it is easy to utilize the same array for genotyping candidate genes or fine mapping.

Program Nr: 1913 from the 2001 ASHG Annual Meeting

**Weighting schemes in conditional model-free linkage analysis.** *e. della-chiesa, m. martinez.* EMI 00-06, INSERM, Evry, France.

Weighting schemes have recently been proposed for model-free linkage analysis of complex traits. These conditional approaches allow to map two trait loci to two separate genetic markers. Evidence for linkage at a region is assessed by weighting families to their evidence for linkage at a first region [Kong and Cox 1997]. Here, we have used both simulated and real data to investigate the effects of weighting schemes on the outcomes of model-free linkage analysis. The methodological problems we have investigated are (1) test procedures (2) derivations of weights and (3) incorporation of between-family variability in linkage information. In the simulated family data, we derived type I and type II error rates of different weighting schemes by multipoint allele-sharing linkage analyses [Kong and Cox 1997] with the package program Allegro. Weighting schemes in conditional model-free linkage analysis were also evaluated for mapping the putative non-HLA DR Rheumatoid Arthritis susceptibility gene(s) in our European genome scan (ECRAF).

**A novel Locus for autosomal dominant nuclear cataract mapped to chromosome 2p12-2q13 in a Pakistani family.**

*A. Hameed<sup>1</sup>, S. Khaliq<sup>1</sup>, M. Ismail<sup>1</sup>, K. Anwar<sup>1</sup>, S.S. Bhattacharya<sup>2</sup>, S.Q. Mehdi<sup>1</sup>.* 1) Dr. A. Q. Khan Research Laboratories, Biomedical and Genetic Engineering Division, 24-Mauve Area, G-9/1, Islamabad, Pakistan; 2) Department of Molecular Genetics, Institute of Ophthalmology, University College London, Bath Street, London EC1V 9EL, UK.

Congenital cataract is one of the commonest disorder of the eye in infants. Cataract may occur as an isolated anomaly or as part of a multisystem syndrome. Congenital cataracts can occur sporadically but most are familial. Familial cataracts are clinically and genetically heterogeneous and are mainly inherited in an autosomal dominant fashion with a high degree of penetrance. On the basis of whole genome search, here we report the mapping of a novel locus for autosomal dominant congenital nuclear cataract (adNCat) to 2p12 in a Pakistani family. The maximum lod score ( $Z = 4.19, q = 0$ ) was obtained for the marker D2S2333. Distal and proximal crossovers were observed with markers D2S286 and D2S1790 respectively. These crossovers define the critical disease interval to approximately 9cM. A genome database analysis of the target interval is being undertaken to identify candidate genes for the disease.

**Pedigree selection may increase genetic homogeneity in complex phenotypes: an example from lupus with hemolytic anemia.** *J. Kelly<sup>1</sup>, J. Kilpatrick<sup>1</sup>, S.K. Nath<sup>1</sup>, B. Namjou-Khales<sup>1</sup>, G.R. Bruner<sup>1</sup>, R.H. Scofield<sup>1,2,3</sup>, J.B. Harley<sup>1,2,3</sup>.* 1) Oklahoma Medical Research Foundation, Oklahoma City, OK; 2) University of Oklahoma, Oklahoma City, OK; 3) U.S. Dept. of Veterans Affairs Medical Center, Oklahoma City, OK.

Systemic lupus erythematosus (SLE) is a complex autoimmune disorder of unknown etiology. The hematologic abnormalities (hemolytic anemia, leukopenia, lymphopenia and thrombocytopenia) in SLE are classic manifestations of the disease. We evaluated hemolytic anemia as a selection criterion in an effort to identify a more homogenous set of pedigrees multiplex for SLE and, hence, to reveal genetic effects not previously detected. From our collection of 160 pedigrees multiplex for SLE, we analyzed a subset of 35 pedigrees (16 African-American (AA), 17 European-American (EA) and 2 Hispanic) that contained at least one SLE patient who also suffered from hemolytic anemia. Both non-parametric and maximum-likelihood model-based genome-wide linkage analyses were conducted using 328 microsatellite markers (Weber #8). In accordance with the recommendations for significant ( $LOD_{Est}^{33.3}$ ,  $p \leq 0.00002$ ) and suggestive linkage ( $LOD_{Sug}^{31.9}$ ,  $p \leq 0.00017$ ), significant linkage to hemolytic anemia was identified at 11q14 in the AA pedigrees ( $LOD_{max}=5.22$ ), and at 1q24 ( $LOD=4.00$ ) in the EA pedigrees. In addition, eight regions reached or surpassed the criteria for suggestive linkage. These are linkages important in lupus because they were identified in pedigrees multiplex for this phenotype. Their relationship to hemolytic anemia is, at present, unknown. Also, pedigree selection in SLE using this additional criterion appears to identify more genetically homogeneous pedigrees. Indeed, the 11q14 linkage in 16 AA pedigrees is quantitatively much more impressive than any linkage identified to date using large collections of pedigrees with SLE alone as the phenotype. This example demonstrates that analyzing families selected by their clinical manifestations increases the power to detect linkage for this complex disease and shows, again, the extraordinary power that clinical features have to inform disease genetics.

**Linkage Analysis in Dominant Intermediate Charcot-Marie-Tooth Neuropathy (DI-CMT).** *M.L. Kennerson<sup>1,2</sup>, D. Zhu<sup>1</sup>, R.J.M. Gardner<sup>3</sup>, E. Storey<sup>4</sup>, J. Meroroy<sup>5</sup>, G.A. Nicholson<sup>1,2</sup>.* 1) Neurobiology Laboratory, Anzac Research Institute, Concord Hospital, Concord, New South Wales, Australia; 2) Molecular Medicine Laboratory, Concord Hospital, Concord, New South Wales, Australia; 3) Genetic Health Service Victoria, Royal Children's Hospital, Victoria, Australia; 4) Department of Neurosciences, Monash University, Victoria, Australia; 5) Austin and Repatriation Hospital, Victoria, Australia.

Charcot-Marie-Tooth (CMT) neuropathy is one of the most common groups of human hereditary disorders. The CMT syndrome includes many hereditary disorders of peripheral nerve affecting both motor and sensory neurones. Two major clinical types have been defined according to whether they are primarily disorders of Schwann cells with nerve conduction slowing (CMT I) or disorders of distal portions of neurones 'axonal neuropathies' (CMT II). Motor nerve conduction velocities (NCVs) in the most common form of CMT type I (CMT1A) is typically about 20 m/sec and usually less than 40 m/sec. In axonal neuropathies (CMT II) the median NCVs are usually faster. The term 'intermediate conduction velocity' has been used to describe families with NCVs in different affected individuals in both the CMT I and CMT II ranges. For this study we have used the value of 45 m/sec to define the cut off between type I and II. We have identified a family whose NCVs in different affected individuals range from 24-54 m/sec. Segregation of the disease is consistent with autosomal dominant inheritance and we have called this form of CMT, Dominant Intermediate Charcot-Marie-Tooth neuropathy (DI-CMT). To map the gene for DI-CMT thirty-nine members of the family were recruited including 7 affected females and 5 affected males. A genome wide screen using markers located at 10 cM intervals was undertaken. Two point linkage analysis has shown the most likely location for the gene causing DI-CMT to lie in the 19p12-p13.2 region ( $Z_{max}=5.58$  at  $\theta=0.0$ ). Further studies to refine the locus are continuing to facilitate positional cloning strategies and possible positional candidate genes are undergoing mutation screening.

**Novel mutation in the ryanodine receptor associated with Malignant Hyperthermia** . *S. McWilliams*<sup>1</sup>, *T. Nelson*<sup>2</sup>, *R.T. Sudo*<sup>3</sup>, *N. Sambuughin*<sup>1</sup>. 1) Laboratory of Neuromuscular Disorders, Barrow Neurological Institute, Phoenix, AZ; 2) Department of Anesthesiology, Wake Forest University, Winston-Salem, NC; 3) Departamento de Farmacologia Basica e Clinica, ICB, Universidade Federal do Rio de Janeiro, Brazil. .

Malignant Hyperthermia (MH) is an autosomal dominant disorder that predisposes susceptible individuals to a potentially life-threatening crisis when exposed to specific commonly used anesthetic agents. During anesthesia, affected individuals experience a sudden hypermetabolic reaction characterized by increased body temperature, cardiac distress, muscle rigidity, and biochemical imbalances. These effects are thought to be caused by the abnormal regulation of calcium through the calcium release channel, ryanodine receptor (RYR1), in skeletal muscle. Mutations in the RYR1 gene account for over 50% of all known MH associated mutations. Linkage analysis of the RYR1 gene region at chromosome 19q13 was performed in a large Brazilian family with MH and all affected members of this family showed identical haplotypes cosegregating with MH. Subsequent sequencing of RYR1 gene mutational hot spots identified a novel nucleotide substitution C to T at 7063 nucleotide position, causing an amino acid change from Arg to Cys at 2355 in the ryanodine receptor. This amino acid change is cosegregated with MH in the Brazilian family and involves a conserved region among different types of ryanodine receptors. Further population studies will address the incidence of this mutation and its impact on the diagnosis of MH.

**A locus for dominant Hereditary Spastic Ataxia.** *I.A. Meijer<sup>1</sup>, C.K. Hand<sup>1</sup>, K.K. Grewal<sup>2</sup>, M.G. Stefanelli<sup>2</sup>, E.J. Ives<sup>2</sup>, G.A. Rouleau<sup>1</sup>.* 1) Centre for Research in Neuroscience, McGill University, Montreal General Hospital Research Institute, Montreal, H3G-1A4, Canada; 2) Discipline of Medical Genetics and Division of Neurology, Faculty of Medicine, Health Sciences Centre, Memorial University, St. John's, Newfoundland, A1B-3V6, Canada.

Hereditary spastic ataxia is a term used to describe a heterogeneous group of neurodegenerative disorders characterized by progressive lower limb spasticity, ataxia (dysarthria, nystagmus and impaired ocular movements), and occasionally dementia. We collected two large families (family 13 and family 71) from Newfoundland with adult onset autosomal dominant hereditary spastic ataxia presenting with leg spasticity, head jerk, dysarthria, dysphagia and eye movement abnormalities. A genome wide scan was performed on family 71 and the results showed strong evidence for linkage ( $Z_{\max} 3.26$  at  $q = 0.06$ ). Analysis of the second family, family 13, confirmed linkage ( $Z_{\max} 7.2$  at  $q = 0$ ) to this locus. Extensive haplotype analysis using polymorphic markers was performed and a shared haplotype spanning 13.6 cM was established. Key recombinants in each family refine the disease locus to approximately 5.1 cM. Several interesting candidate genes are reported in the critical region and will be considered for mutation screening. This is the first report of a dominant spastic ataxia locus.

**A new Spinocerebellar Ataxia, SCA 15.** *M.A. KNIGHT<sup>1,2</sup>, M. KENNERSON<sup>3,4</sup>, G.A. NICHOLSON<sup>3,4</sup>, R.J.M. GARDNER<sup>1,5</sup>, E. STOREY<sup>5,6</sup>, P.Q. THOMAS<sup>1</sup>, S.M. FORREST<sup>1,2</sup>.* 1) MURDOCH CHILDRENS RESEARCH INSTITUTE, ROYAL CHILDREN'S HOSPITAL, MELBOURNE, VIC; 2) DEPARTMENT OF PAEDIATRICS, UNIVERSITY OF MELBOURNE, MELBOURNE, VIC; 3) DEPARTMENT OF MOLECULAR MEDICINE, CONCORD HOSPITAL, SYDNEY, N. S. W; 4) NEUROBIOLOGY LABORATORY, ANZAC RESEARCH INSTITUTE, CONCORD HOSPITAL, SYDNEY, SYDNEY, N. S. W; 5) GENETIC HEALTH SERVICES VICTORIA, MELBOURNE, VIC; 6) DEPARTMENT OF NEUROSCIENCES, MONASH UNIVERSITY, ALFRED HOSPITAL CAMPUS, MELBOURNE, VIC.

We have studied a large Australian kindred with a dominantly inherited "pure" cerebellar ataxia. A notable observation has been the very slow rate of progression in some family members. The atrophy affects predominantly the superior vermis, but the hemispheres may be involved to a lesser extent. Pedigree information does not permit a firm conclusion as to whether or not anticipation exists. Before performing a whole genome wide scan, gene testing excluded the known spinocerebellar ataxia (SCA) loci for the following SCAs 1, 2, 3, 6, 7 and 8, and molecular linkage analysis excluded SCAs 4, 5, 6, 10, 11, 12, 13, 14 and 16. Thus we hypothesised that this might represent a new SCA clinical phenotype. It was evident that the family had no male-to-male transmission. No linkage was detected using markers on the X chromosome thus necessitating the performance of a full genome scan. Simulation analysis of the pedigree indicated a maximum LOD score of 4.4 with the power to exclude at an average of 5.4-cM either side of any marker. Analysis of the results from the whole genome scan at a 10-cM level suggested two novel areas of linkage, one at 3pter-3p24.2 and the other at the q arm telomere of chromosome 17. Multipoint analysis indicated that the chromosome 17 locus was a false positive. The candidate locus is located on chromosome 3pter-3p24.2 and has been designated as SCA15. The multipoint LOD score maps the disease to a 30-cM interval with a peak LOD score of 3.5. Candidate genes identified using bioinformatics are currently being screened to identify the disease causing mutation.

**Fine Mapping of a second locus involved in susceptibility for systemic lupus erythematosus on chromosome 4p13 in Icelandic pedigrees.** *C.M. Johansson<sup>1</sup>, K. Steinsson<sup>2</sup>, H. Kristjánsdóttir<sup>2</sup>, G. Gröndal<sup>2</sup>, M.E. Alarcón-Riquelme<sup>1</sup>*. 1) Genetics and Pathology, Rudbeck laboratory, Uppsala University, Uppsala, Sweden; 2) Department of Rheumatology, Center for Rheumatology Research, Landspítalinn, University Hospital Reykjavik, Iceland.

We have previously published a genomescan (Lindqvist, et al, *J Autoimmunity*, 14:169,2000) on Icelandic multicase families with systemic lupus erythematosus (SLE). We identified a region on chromosome 4p13 linked to SLE. The Maximum lod score (MLS) using a recessive model was  $Z=3.20$  for marker D4S1627, found in 6 extended pedigrees. The present investigation revealed a MLS of  $Z=3.94$  with the original marker for 10 Icelandic pedigrees. Several other microsatellite markers located close to D4S1627 show lod scores between 1.0 and 3.6 delimiting the region to about 5cM. Haplotype analyses have made it possible to delimit the region even further. Analysis of families from other geographical locations did not reveal evidence for linkage. This suggests either of two possibilities: a) that this locus is important in SLE in Icelandic families and potentially the result of a founder effect, or b) that our linkage is a false positive result. Nevertheless, multipoint analysis increases the lod score, supporting the presence of this locus. This locus is potentially syntenic to a mouse lupus susceptibility locus described in a cross of (MRL/lpr X C57Bl6/lpr) mice called *lmb2*. Further studies will reveal whether this region indeed harbour a SLE susceptibility gene or not.

**Genome Search for QTL Controlling Pulse Pressure: A Practical Application of the Unified Haseman-Elston**

**Algorithm.** *J. Li*<sup>1</sup>, *T. Niu*<sup>1,2</sup>, *X. Xu*<sup>1</sup>, *J. Rogus*<sup>3</sup>, *J. Yang*<sup>4</sup>, *N. Schork*<sup>1,5,6,7</sup>, *Z. Fang*<sup>4</sup>, *X. Xu*<sup>1,4,8</sup>. 1) Prog Population Genetics, Harvard Sch Public Health, Boston, MA; 2) Cardiovascular Division, Department of Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 3) Section on Genetics and Epidemiology, Joslin Diabetes Center, One Joslin Place, Boston, MA; 4) Institute for Biomedicine, Anhui Medical University, Hefei, China; 5) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH; 6) Genset Corporation, La Jolla, CA; 7) Jackson Laboratory, Bar Harbor, ME; 8) Channing Laboratory, Department of Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA.

The Haseman-Elston (H-E) method has played an important role in sibpair linkage analysis. To systematically search for genetic loci that regulate pulse pressure (an independent predictor for cardiocascular diseases from diastolic pressure), we scanned the entire autosomal genome using 647 sibpairs ascertained for extreme blood pressure. We applied the unified H-E algorithm in linkage analysis. Using the computer program XWXW, we detected a suggestive linkage on chromosome 2 near *D2S405-D2S1788* ( $Z=3.19$ ,  $P=0.0007$ ), a region previously linked to SBP. This linkage signal persisted after controlling for the influence of diastolic blood pressure (DBP). Possible positional quantitative trait locus (QTL) candidates include *CALM2* (calmodulin 2) at 2p21.3-p21.1, *NCX1* (Na<sup>+</sup>-Ca<sup>2+</sup> Exchanger 1) at 2p23-p22, and *POMC* (pro-opiomelanocortin) at 2p23.3. Another region on chromosome 22 near *D22S420-Mfd313* also provided suggestive evidence of linkage by the unified H-E procedure ( $Z=3.38$ ;  $P=0.0004$ ). Possible QTL candidates include *ADORA2A* (adenosine A2a receptor) and *COMT* (catechol-O-methyltransferase), both were at 22q11.2. Our results revealed that putative QTLs for PP may be located on chromosomes 2 and 22, and that in practical scenarios, the unified H-E method is efficient for mapping QTLs.

**Paget disease of bone: mapping of two loci at 5q35-tel and 5q31 and genetic heterogeneity.** *J. Morissette<sup>1</sup>, N. Laurin<sup>1</sup>, J.P. Brown<sup>2</sup>, A. Lemainque<sup>3</sup>, A. Duchesne<sup>1</sup>, D. Huot<sup>4</sup>, Y. Lacourcière<sup>5</sup>, G. Drapeau<sup>6</sup>, J. Verreault<sup>7</sup>, V. Raymond<sup>1</sup>.* 1) Molec Endocrinology, CHUL Res Ctr, Quebec, QC, Canada; 2) Rheumatology-Immunology, CHUL Res Ctr; 3) Centre national de génotypage, Evry, France; 4) Thetford Mines, PQ, Canada; 5) CHUL Res Ctr; 6) Victoriaville, Qc, Canada; 7) CUSE, Sherbrooke, PQ, Canada.

Paget disease of bone is characterized by focal increases of the bone remodeling process. It is the 2nd most common metabolic bone disease after osteoporosis. Genetic factors play a major role in the disease and two loci have been mapped for the disorder: PDB1 at 6p and PDB2 at 18q21-q22. The gene(s) causing the disorder still remain to be characterized. To decipher the molecular basis of Paget disease of bone, we performed genetic linkage analysis in 24 large French-Canadian families (479 individuals) in which the disorder was segregating as an autosomal dominant trait. A genome-wide scan with 379 microsatellites was performed on the 3 most informative family nuclei. Regions with LOD score values between 1.0 and 3.0 were assessed by higher-density mapping and haplotype analysis in the extended families. Genetic heterogeneity was investigated using HOMOG. We report strong evidence for linkage at chromosome 5q35-tel in 8 of the kindreds. Significant evidence for heterogeneity was observed at D5S408 ( $c^2 = 3.86$ ;  $p < 0.05$ ). Under heterogeneity, the maximum LOD score value of 8.71 was obtained at D5S2073. The same characteristic haplotype was shown by all pagetic patients in these 8 families, suggesting a founder effect. Recombination event confined the disease region to a 6 cM interval between D5S469 and the telomere. The 16 other families were used to map a 2nd locus at 5q31. Under heterogeneity, a maximum LOD score value of 3.70 was detected at D5S500 with  $q = 0.00$  ( $c^2 = 10.13$ ;  $p < 0.0002$ ). Key recombination events in the 2 families refined the 5q31 disease region to a 11.2 cM interval between D5S642 and D5S1972. Finally, 2 other kindreds were excluded from both the 5q35-qter and 5q31 loci. These observations demonstrate the mapping of 2 novel loci for Paget's disease of bone and provide further evidence for the genetic heterogeneity of this disorder.

Program Nr: 1923 from the 2001 ASHG Annual Meeting

**Tests of Allele Sharing and Allelic Association for Affected Sib Pairs.** *L. Lazzeroni.* Health Research and Policy, Stanford University, Stanford, CA.

Affected sib pair (ASP) data contain information about allele-sharing and allelic association, either of which can point to the presence of a disease-related gene. I will introduce a generalized ASP test that can be tailored to the combination of sharing and association likely to exist in a given setting. The proposed test can substantially increase the power to detect anticipated alternative hypotheses at little or no cost for less likely alternatives. The test is valid under most models of genetic risk, disease etiology and genotype-haplotype frequencies. When the test does detect a disease-related locus, the results offer clues about the possible contributions of the observed and linked loci that can be useful in deciding how to proceed.

**Mapping of autosomal recessive microcephaly in Indian families.** A. Kumar<sup>1</sup>, S. Rao<sup>1</sup>, A.K. Hanumanthajah<sup>1</sup>, S.C. Girimaji<sup>2</sup>. 1) MRDG, Indian Institute of Science, Bangalore, India; 2) Department of Psychiatry, National Institute of Mental Health and Neurosciences, Bangalore, India.

Microcephaly is defined as a condition in which the head circumference of an affected individual is  $>3$  SD below the mean for age. Microcephaly occurs due to a variety of reasons including intrauterine infections, drugs taken during pregnancy, maternal phenylketonuria, cytogenetic abnormalities, single-gene disorders and syndromes of as-yet-undetermined etiology. True or primary microcephaly (MCPH, MIM 251200) appears to be a distinct subtype. It is defined by the absence of associated malformations and of secondary or environmental causes. It is inherited as an autosomal recessive trait. Mental retardation in true microcephaly ranges from mild to severe, but other neurological deficits are absent. True microcephaly shows genetic heterogeneity with five known loci: MCPH1 on chromosome 8p22-pter, MCPH2 on chromosome 19q13.1, MCPH3 on chromosome 9q34, MCPH4 on chromosome 15q and MCPH5 on chromosome 1q31. We have ascertained five consanguineous families with true microcephaly from the state of Karnataka, India. On examination, the head circumferences of the affected individuals were found to be  $>5-7$  SD below the population age-related mean. All the affected individuals had mild to severe mental retardation and none were able to read and write, but could speak and had basic self-care skills. To establish linkage of these five Indian families to known MCPH loci, microsatellite markers were selected from each of the five known MCPH loci and used to genotype the families. The results showed that all but one families were not linked to known MCPH loci as alleles were not homozygous at each polymorphic marker locus examined. The only exception, family IISC-2 showed homozygosity of alleles (identical by descent) at markers D8S1819, D8S277 and D8S1825 in the affected individual, suggesting linkage of this family to MCPH1 locus. We are in the process of determining the extent of homozygous region in this family using additional microsatellite markers. The work is in progress to establish linkage of other four families using a genome-wide linkage screen. (Supported by SDTC grant PC11014).

**A potentially novel form of Batten's disease in Portugal.** *L. Huo*<sup>1</sup>, *C.A. Teixeira*<sup>2,4</sup>, *M.M. Barmada*<sup>3</sup>, *M.G. Ribeiro*<sup>4,5</sup>, *M.C.S. Miranda*<sup>4,5</sup>, *D.A. Stephan*<sup>1</sup>, *R.M.N. Boustany*<sup>2</sup>. 1) Research Center for Genetic Medicine, Children's National Medical Center, Washington, DC; 2) Departments of Pediatrics and Neurobiology, Duke University Medical Center, Durham, NC 27710; 3) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA; 4) Genetic Neurobiology Department, Institute of Cellular and Molecular Biology, University of Porto, Portugal; 5) Enzymology Unit, institute of Medical genetics, Porto.

The neuronal ceroid lipofuscinoses (NCLs), commonly referred to as Batten's disease, are a group of neurodegenerative disorders. Clinically, NCLs are characterized by rapid deterioration of vision, seizures, progressive development of mental retardation, movement disorders and behavioral changes. Incidence of the NCLs is approximately 1 to 5 in 100,000 births in the general population. The NCLs comprise eight forms classified initially by clinical symptoms and age at onset. Mutations in genes causing CLN1, 2, 3, 5 and 8 have been identified. We have identified a cohort of families from Portugal with a clinical presentation similar to CLN6. In addition, founders from Portugal settled Costa Rica, where the CLN6 gene was identified. Thus, we tested the hypothesis that CLN6 causes disease in our Portuguese families by linkage analysis. The CLN6 locus has been mapped to chromosome 15q21-23 to 4 cM between markers D15S125 and D15S1000. We analyzed 7 Portuguese families using 4 polymorphic markers within the critical region on 15. There was no evidence of linkage in any of the families, and no evidence for excess allele sharing between families at this locus (max lod score is -6.16 at D15S983). We also screened for the clinically similar mutations in CLN1,2 and 3 genes, but none were identified. These negative results suggest that we may have uncovered a novel Batten variant.

**Transmission disequilibrium analysis for a schizophrenia susceptibility locus on chromosome 18p. M.K.**

*Kikuchi<sup>1,2</sup>, K.Y. Yamada<sup>1</sup>, T.T. Toyota<sup>1,2</sup>, M.I. Itokawa<sup>1</sup>, M.E. Ebihara<sup>1</sup>, S.O. Ohno<sup>1</sup>, E.H. Hattori<sup>1</sup>, K.Y. Yoshitsugu<sup>1,2</sup>, H.S. Shimizu<sup>3</sup>, T.Y. Yoshikawa<sup>1</sup>.* 1) Molecular Psychiatry, RIKEN, wako, Japan; 2) Department of Neuropsychiatry, Tokyo Medical and Dental University, Tokyo, Japan; 3) Hokushin General Hospital, Nagano, Japan.

The region of chromosome 18 short arm, especially 18p11.2, is reported as one of schizophrenia susceptibility loci. Recently, we have cloned a novel myo-inositol monophosphatase, IMPA2, from 18p11.2, identified several genetic variants, and found a significant association between the gene and schizophrenia in a case control study. In this study, we aimed to systemically narrow down a susceptibility region and confirm an existence of locus conferring a risk to the disease on 18p short arm, by means of family-based association analysis and multi-stage genetic analyses. We analyzed 119 Japanese nuclear families with schizophrenia, using 27 microsatellite markers on the 18p and proximal q-arm spacing at ~5cM, and TDT/S-TDT statistics. This first stage screening revealed the marker D18S53 on 18p11.2, which gave a significant P-value of 0.0124. Then we examined the 18p11.2 region, using additional 10 markers densely spacing at 0.4 Mb in average. In this second stage screening, we detected two markers, D18S40 and D18S852, which showed significant distortion of transmission in schizophrenia offsprings ( $P = 0.0184$  and  $0.0196$ , respectively). For the third stage, we tested the three significant markers (D18S53, D18S40 and D18S852), using the independent case (containing 130 schizophrenics) and control (containing 150 individuals) panel. In this analysis, only D18S852 still remained to have a significant allelic association. These results suggest that a schizophrenia predisposing gene may be located in the 18p11.2 region in Japanese cohorts. We are now further analyzing this region using single nucleotide polymorphisms, and by performing haplotype transmission analysis to obtain a firm evidence of association.

**Linkage analysis in autosomal dominant congenital cataract families.** *V. Kumar<sup>1</sup>, D. Singh<sup>2</sup>, K. Sperling<sup>3</sup>, J.R. Singh<sup>1</sup>.* 1) Ctr Gen Disorders, Human Gen, Guru Nanak Dev Univ, Punjab, India; 2) Dr. Daljit Singh Eye Hospital, Amritsar, Punjab, India; 3) Institute of Human Genetics, Charite, Humboldt-University, Berlin, Germany.

Purpose: To localize and identify the responsible gene(s) for autosomal dominant congenital cataract (ADCC) in 2 Indian families. Methods: Gene mapping studies using 65 highly polymorphic fluorescently labelled microsatellite markers, selected from known candidate gene regions, were carried out in two large informative ADCC families, showing different clinical types. One showed polymorphic type of cataract while the second had opalescent type of congenital cataract. Genotyping was done on ABI-377 sequencer with GENOTYPER 2.0 software. Two-point and multipoint linkage analyses were performed using the MLINK and LINKMAP components of the linkage program package (ver 5.1) respectively. Results: On basis of the obtained 2-point and multipoint lod score values, we have excluded the known candidate gene regions at 1pter-p36.1, 2q33-35, 3q21-22, 12q13, 13q11.12, 14q24-qter, 15q21-22, 16q22.1, 17p13, 17q24, 19q13.4, 21q22.3, and 22q11.2-12.2 in these 2 families. Conclusion: Our results indicate the existence of at least one more gene underlying autosomal dominant congenital cataract. Since already there exists a report of gene localization for polymorphic congenital cataract at 2q33-35, the exclusion of this locus in present polymorphic type of congenital cataract family supports the existence of genotypic heterogeneity for this type of cataract. In order to achieve better understanding of the phenotype-genotype correlations for the observed heterogeneity in congenital cataract, and for the identification of the various factors involved in lens opacification, the molecular characterisation of different phenotypes is essential.

**Correlation between linkage and association tests in families.** *E.R. Martin, M.P. Bass, E.R. Hauser.* Center for Human Genetics, Duke University Medical Center, Durham, NC.

A common strategy for identifying complex disease genes is to conduct linkage analyses first and then follow significant results with family-based tests for association in an attempt to further localize the disease gene. To help interpret the results from linkage and association tests conducted on the same data, it is desirable to know when the tests are correlated. It has been shown analytically that the transmission/disequilibrium test (TDT), as a test of linkage, and the mean haplotype allele-sharing test of linkage are independent under the null hypothesis of no linkage. However, it is unclear what the relationship is between family-based tests that focus on testing for association and allele-sharing linkage tests. To examine this question, we used computer simulations to compare the pedigree disequilibrium test (PDT), a test for association in pedigree data, and Siblink, a nonparametric affected-sib-pair test of linkage. The PDT tests for deviations from the composite null hypothesis of no linkage or no association, while Siblink tests the null hypothesis of no linkage. Thus it was of interest to examine the correlation between these methods for various levels of both linkage and allelic association. Specifically, we considered a disease locus with a marker locus with: 1) no linkage and no association; 2) linkage and no association; 3) no linkage and association; 4) linkage and association. Model parameters were taken to be consistent with observed SNP data around the APOE locus. Preliminary results suggest that, for complex diseases, substantial correlations are likely to be found only when there is both linkage and allelic association between marker and disease loci. However, as expected, the degree of correlation depends highly on the underlying model. These results will have important implications in how we interpret the joint behavior of linkage tests and family-based tests for association in the same data.

**Sampling strategies for linkage mapping of susceptibility genes in complex diseases with late age of onset using affected sibling linkage methods.** *T. Mary-Huard, M. Martinez.* EMI00-06, INSERM, Evry, France.

For complex diseases, affected sibling (AS) linkage analysis is an alternative to the lod score method. For adult onset diseases, parental genotypes are often unknown, and IBD rates are estimated using the available DNA information in families, under the specified marker allele frequencies. It is clear that the loss of parental DNA information can be balanced by genotyping additional unaffected relatives. Most study designs are based on the analysis of nuclear families with the inclusion of the Unaffected Siblings. For realistic sibship sizes the power of this sampling strategy may remain low. The marker information from other types of unaffected relatives, as the offspring (OF) of the AS, can be worth to include. In this work, we have conducted Monte Carlo simulation studies to compute the power of different family structures: (i) Nuclear Families; AS = 2, US = 0 or 2 and P = 0 or 2 genotyped parents; (ii) 3-Generation Pedigrees: NF (AS = 2, US = 0 or 2 and P = 0) and the OF = 2 for each AS. The power of each sampling strategy was compared as a function of: (1) the type of analysis (i.e., single or multipoint ASP analysis), (2) the Marker Heterozygosity and (3) the Map Density (i.e. 2 to 10 markers spanning a 10cM map). One thousand replicates for each sample size (n) of families were simulated and analysed using two Maximum Likelihood Score methods; MLB [Abel et al 1998] and Zlr [Kong and Cox, 1997] statistics as implemented in the MLBGH and Allegro package programs. Our goal is to propose sampling guidelines for our European genome scan of Parkinsons disease. As expected, there is no advantage in using 3-Generation Pedigrees when using pairwise ASP analyses. The relative power of each ASP statistic is dependent on the genetic model, but MLB and the exponential Zlr statistics are shown to be equivalent in these data. Conversely, when using multipoint ASP analyses, the power of GP tends to be greater than that of NF. The power of the 3-GP strategy increases with the map density, especially when MH is not very low (<60%). The relative power of each strategy is also discussed in terms of amount of marker genotyping effort.

**Comparative genome scans of cleft lip with or without cleft palate in Chinese and Turkish families.** *M.L.*

*Marazita<sup>1</sup>, L.L. Field<sup>2</sup>, M.E. Cooper<sup>1</sup>, B.S. Maher<sup>1</sup>, Y. Liu<sup>3</sup>, G. Tunçbilek<sup>4</sup>, G. Gürsu<sup>4</sup>.* 1) School of Dental Medicine, Univ. Pittsburgh, Pittsburgh, PA; 2) Univ. of British Columbia, Vancouver, BC, Canada; 3) Zhabei Eye Hospital, Shanghai, China; 4) Hacettepe Univ., Ankara, Turkey.

Cleft lip with or without cleft palate (CL/P) is a common congenital anomaly, with birth prevalences ranging from 1/500 to 1/1000 depending on the population. Reported birth prevalences are consistently higher in Asian populations than in Caucasians. Therefore, it is of interest to determine whether the CL/P etiological factors in Asian populations differ from those in Caucasians. Families were identified as part of our on-going studies of oral-facial clefts; included in the analyses described here were 36 multiplex families from Shanghai, China and 18 inbred families from Ankara, Turkey. These are the first reported genome-scan studies in either population. Genotyping of Weber Screening Set 9 (387 STRPs with average spacing of ~ 9 cM, range 1-19 cM) was done by the Mammalian Genotyping Service of Marshfield Laboratory. Multipoint LOD scores and multipoint heterogeneity LOD scores (HLODs) were calculated between each marker and CL/P. Calculations were done under a range of assumptions as to the genetic model for CL/P. In addition, the model-free multipoint NPL statistic was calculated. The following regions had positive results (HLOD > 1.0 and/or NPL p-values < 0.05) in the Turkish families: chromosome 1 (168-275 cM), chromosome 3 (26-45 cM), chromosome 4 (33-73 cM), chromosome 6 (34 cM), chromosome 11 (37-85 cM), chromosome 12 (150-166 cM), chromosome 18 (3-41 cM). The following were positive in the Chinese families: chromosome 1 (90-110 cM), chromosome 2 (220-250 cM), chromosome 3 (130-150 cM), chromosome 4 (140-170 cM), chromosome 6 (70-100 cM), chromosome 18 (110 cM), chromosome 21 (30-50 cM). Therefore, a few regions were similar between the two populations, but most of the regions with positive results were unique to either the Chinese or Turkish families. Supported by NIH grants DE09886 and DE12472.

**The Lupus SCOR combined genome scan for systemic lupus erythematosus: common and ethnic-specific susceptibility regions.** *C.D. Langefeld<sup>1</sup>, J. Kelly<sup>2</sup>, K.L. Moser<sup>3</sup>, P.M. Gaffney<sup>3</sup>, R.R. Graham<sup>3</sup>, W.M. Brown<sup>1</sup>, S.S. Rich<sup>1</sup>, J.B. Harley<sup>2</sup>, T.W. Behrens<sup>3</sup>, R.P. Kimberly<sup>4</sup>* for the SCOR in the Genetics of SLE. 1) Wake Forest University School of Medicine, Winston-Salem, NC; 2) Oklahoma Medical Research Foundation, Oklahoma City, OK; 3) University of Minnesota, Minneapolis, MN; 4) University of Alabama, Birmingham, AL.

Systemic lupus erythematosus (SLE) is a chronic autoimmune inflammatory disease characterized by the production of pathogenic autoantibodies. With a sibling risk ratio near 20, SLE has a strong genetic component. Here, the Specialized Center of Research (SCOR) in the Genetics of SLE, whose goal is to map and clone genes predisposing to SLE and related autoimmune phenotypes, reports the results of a combined genome scan of 313 SLE pedigrees. These pedigrees, containing at least two siblings with SLE, originate from collections assembled at the University of Minnesota (MN: 187 pedigrees, 656 individuals genotyped, 399 SLE patients) and the University of Oklahoma (OK: 126 pedigrees, 681 individuals genotyped, 298 SLE patients). The number of pedigrees (SLE patients) by ethnic group were 226 (499) Caucasian (CA), 57 (133) African American (AA) and 30 (66) other. We constructed a combined map of 703 microsatellite markers (MN: 366, OK: 274, Both: 63) using marker order and distances from the Mammalian Genotyping Center in Marshfield, WI. We report the maximum LOD score (nearest marker, combined LOD, AA pedigrees' LOD, CA pedigrees' LOD) computed from multipoint nonparametric linkage regression analysis using the NPL(pairs) statistic. Three chromosomal regions exceed genome-wide significance: chr 6 (D6S2410, LOD=4.9, AA LOD=1.6, CA LOD=2.6); chr 4 (D4S403, LOD=3.7, AA LOD=0.00, CA LOD=4.5); chr 16 (D16S3253/D16S503, LOD=3.5, AA LOD=0.1, CA LOD=3.2). Additional regions of interest include chr 1 (D1S2785, LOD= 2.1, AA LOD=0.0, CA LOD=1.8); chr 7 (D7S507, LOD= 2.5, AA LOD=0.0, CA LOD=2.9); and chr 20 (D20S481/D20S119, LOD=2.0, AA LOD=0.0, CA LOD=2.7). Among AA pedigrees, the strongest evidence for linkage was 15-20 cM qter of D6S2410 (D6S1031, LOD=3.8, AA LOD=2.5, CA LOD=1.4). Our peak on 1q (D1S2785) coincides with that of Shai et al. (1999).

**Association of Tau with Late-Onset Parkinson Disease.** *S.A. Oliveira<sup>1</sup>, E.R. Martin<sup>1</sup>, W.K. Scott<sup>1,3</sup>, M.A. Nance<sup>3</sup>, R.L. Watts<sup>3</sup>, J.P. Hubble<sup>3</sup>, W.C. Koller<sup>3</sup>, R. Pahwa<sup>3</sup>, M.B. Stern<sup>3</sup>, B.C. Hiner<sup>3</sup>, J. Jankovic<sup>3</sup>, C.G. Goetz<sup>3</sup>, G.W. Small<sup>3</sup>, M.A. Hauser<sup>1</sup>, L.T. Middleton<sup>2,3</sup>, A.D. Roses<sup>2,3</sup>, J.L. Haines<sup>3</sup>, B.L. Scott<sup>1,3</sup>, M.A. Pericak-Vance<sup>1,3</sup>, J.M. Vance<sup>1,3</sup>.* 1) Center for Human Genetics, Duke University Medical Center, Durham, NC; 2) GlaxoSmithKline, Research Triangle Park, NC; 3) Duke CHG/GlaxoSmithKline PD Genetics Collaboration.

The microtubule-associated protein tau promotes microtubule assembly and stability, and may be involved in the establishment and maintenance of neuronal polarity. Mutations in the tau gene have been identified in several neurodegenerative diseases such as frontotemporal dementia with parkinsonism linked to chromosome 17 (FTDP-17), progressive supranuclear palsy (PSP), and pallido-ponto-nigral degeneration (PPND). In a complete genomic screen, we found evidence of linkage in idiopathic Parkinson disease (PD) families to a region on chromosome 17q21 encompassing the tau gene. To investigate whether the tau gene is also involved in the most common form of PD, we tested five single nucleotide polymorphisms (SNPs) within the tau gene for association with PD using family-based tests of association. The SNPs were analyzed individually and in haplotypes. We found evidence of significant association ( $p < 0.05$ ) for three of the five SNPs tested. Furthermore, stronger association was obtained with haplotype analysis, with a positive association with one haplotype ( $p = 0.009$ ) and a negative association with a second haplotype ( $p = 0.007$ ). This study implicates tau as a susceptibility gene for idiopathic PD.

**Chromosome 12 mapping of late-onset Alzheimer disease among Caribbean Hispanics.** *J.H. Lee<sup>1</sup>, R. Mayeux<sup>1,2</sup>, S.N. Romas<sup>1,2</sup>, D. Mayo<sup>3</sup>, V. Santana<sup>1</sup>, J. Williamson<sup>1</sup>, A. Ciappa<sup>2</sup>, H.Z. Rondon<sup>1</sup>, P. Estevez<sup>1</sup>, R. Lantigua<sup>1,2</sup>, M. Medrano<sup>4</sup>, M. Torres<sup>5</sup>, Y. Stern<sup>1,2</sup>, B. Tycko<sup>2</sup>, J.A. Knowles<sup>3</sup>.* 1) Sergievsky Ctr Columbia Univ, NY, NY; 2) Taub Inst Columbia Univ, NY, NY; 3) Columbia Genome Ctr, Columbia Univ, NY, NY; 4) Univ Tecnol de Santiago, DR; 5) Plaza de la Salud Hospit, DR.

Support for linkage to chromosome 12p for late-onset, familial Alzheimers disease (AD) has been inconsistent. We studied 79 families from a study of familial AD among Caribbean Hispanics. We studied 35 markers on chromosome 12, concentrating on regions where previous studies showed evidence for linkage. Two-point linkage analysis based on the affected sibpair model gave the strongest support for D12S1623 (LOD=3.15) and D12S1042 (LOD=1.43). Support for A2M was weak (LOD=0.75). In late onset families (onset>65 yrs), the LOD score for D12S1623 was 1.63, while that for D12S1042 was 1.43. There were too few early onset families. In APOE-e4 negative families (affecteds without 4), the LOD score for D12S1623 was reduced (0.81), while that for D12S1042 was elevated (1.73). The LOD scores for D12S1057 and D12S398 exceeded 1. In APOE-e4 positive families (affecteds with 4), none of the LOD scores reached 1.

Multipoint affected relative pair analysis showed peaks flanking the same markers, D12S1623 (NPL=1.52; p=0.028) and D12S1057 (NPL=1.57; p=0.027). In late-onset families, the NPL score for D12S1623 was 2.01 (0.006), while that for D12S1057 was 1.63 (p=0.021). In APOE-e4 negative families, the region flanking D12S1623 remain elevated (NPL=1.74; p=0.013), but the support for the region D12S1042 decreased (NPL=1.1; p=0.077). In APOE-e4 positive families, there was no evidence of linkage for the region flanking D12S1623, but the NPL score for the D12S1042 region did not change (NPL=1.34; p=0.053).

This study of Caribbean Hispanics with late-onset familial AD provides modest support for linkage to 12p. Further, the evidence of linkage was strongest for D12S1623 in the absence APOE-4, suggesting that this locus may act independently of APOE.

**A familial chordoma locus maps to chromosome 7q33.** X. Yang<sup>1</sup>, M.J. Kelley<sup>2</sup>, J.F. Korczak<sup>3</sup>, E. Sheridan<sup>4</sup>, A.M. Goldstein<sup>1</sup>, D.M. Parry<sup>1</sup>. 1) DCEG, NCI, Bethesda, MD; 2) Department of Medicine, Duke Univ., Durham, NC; 3) Epidemiology Section, Karmanos Cancer Institute and Department of Internal Medicine, Wayne State University School of Medicine, Detroit, MI; 4) St. James University Hospital, Leeds, UK.

Chordoma, a rare tumor originating from notochordal remnants, represents 1-4% of all primary bone tumors. Five families with two or more relatives with chordoma have been described worldwide, suggesting the existence of an inherited predisposition. We genotyped 22 family members for 365 STR markers spaced about 10 cM apart and performed a genome-wide analysis for linkage in one reported family with 10 individuals with chordoma. Two-point linkage analysis using the MLINK program from the LINKAGE package was performed under the assumption of autosomal dominant inheritance of a rare disease allele. Possible linkage to chromosomes 4, 7, 17, or 19 was suggested based on two-point lod scores greater than 1.0 in the affecteds-only analysis. Additional STR markers at approximately 2 cM intervals were genotyped in each of these four regions. Chromosome 7q gave the greatest evidence for linkage, with a maximum two-point lod score of 2.21 at  $q=0$  in the affecteds-only analysis. Further analysis of chromosome 7q markers with additional members of this family (total of 11 affected individuals) and two unrelated families with two or three affected individuals, under the assumption of locus homogeneity, showed two-point lod scores greater than 3 at six markers in the affecteds-only analysis ( $Z_{\max}[q=0]=4.05$  at marker D7S500). Multipoint analysis based on only affected individuals gave a maximum lod score of 4.78 using GENEHUNTER with an approximate 2-lod support interval from marker D7S512 to marker D7S684. Haplotype analysis of the three families showed a minimal disease gene region from D7S512 to D7S684, a distance of 11.1 cM and approximately 7.1 MB. These results map a familial chordoma locus to 7q33. Further analysis of this region to identify this gene is ongoing.

**The Silver syndrome variant of hereditary spastic paraplegia maps to 11q12-q14, with evidence for genetic heterogeneity within this subtype.** *H. Patel*<sup>1</sup>, *P.E. Hart*<sup>2</sup>, *T.T. Warner*<sup>2</sup>, *R.S. Houlston*<sup>3</sup>, *M.A. Patton*<sup>1</sup>, *S. Jeffery*<sup>1</sup>, *A.H. Crosby*<sup>1</sup>. 1) Dept Medical Genetics, St George's Hospital Medical School, London, UK; 2) Department of Clinical Neurosciences, Royal Free Hospital School of Medicine, London, UK; 3) Section of Cancer Genetics, Institute of Cancer Research, Surrey, UK.

The hereditary spastic paraplegias (HSPs) are a complex group of neurodegenerative disorders characterised by lower limb spasticity and weakness. Silver syndrome (SS) is a particularly disabling dominantly inherited form of HSP complicated by amyotrophy of the hand muscles. Having excluded the multiple known HSP loci, a genomewide screen for linkage was undertaken in one large multigenerational SS family which revealed evidence for linkage of the SS locus, which we have designated SPG17, to chromosome 11q12-q14. Haplotype construction and analysis of recombination events permitted the minimal interval defining the SPG17 locus to be refined to ~13cM, flanked by markers D11S1765 and D11S4136. A second SS family was not linked to the SPG17 locus demonstrating further genetic heterogeneity in HSP, even within this clinically distinct subgroup. The ciliary neurotrophic factor (CNTF) gene, which comprises just two exons, also resides within this region of the genome. Unfortunately, sequence analysis failed to reveal any disease-specific mutations, excluding this gene from a role in the pathogenesis.

**Strategies for Linkage Analysis of Extended Pedigrees.** *K.A. Rinard<sup>1</sup>, M. Harmon<sup>1</sup>, G. Chan<sup>1</sup>, A. Foti<sup>1</sup>, S. Maruti<sup>1</sup>, A. Parker<sup>1</sup>, R. Martin<sup>1</sup>, J. Meyer<sup>1</sup>, C. Richard<sup>2</sup>, J. Lonquist<sup>3</sup>, T. Partonen<sup>3</sup>, T. Varilo<sup>3</sup>, T. Paunio<sup>3</sup>, J. Ekelund<sup>3</sup>, L. Peltonen<sup>3,4</sup>.* 1) Human Genetics, Millennium Pharmaceuticals, Cambridge, MA; 2) Genetics Institute, Wyeth-Ayerst Research, Cambridge, MA; 3) National Public Health Institute, Helsinki, Finland; 4) Human Genetics, UCLA School of Medicine, Los Angeles, CA.

Large extended pedigrees present unique challenges for linkage analysis. As part of a study of schizophrenia in Finland, we have analyzed an extended pedigree composed of 122 nuclear families. This pedigree extends horizontally and includes many wings connected through clusters of individuals for whom DNA is unavailable. For analysis, we used nonparametric statistics combined with Markov Chain Monte-Carlo methods as implemented in SIMWALK. However, two of these nonparametric statistics we believe to be the most powerful for these data are not usable. The NPLall statistic is computationally infeasible if there are more than 20 affecteds in a pedigree, and statistic B (dominant effect) becomes conservative with such complex pedigree structure. To overcome these issues, we devised a method of breaking the pedigree into smaller pieces to facilitate analysis, by preserving overlapping founder trees when possible and by separating sub-pedigrees connected through untyped individuals. This was done blind to any knowledge of allele sharing. The 122 family pedigree was split into 22 smaller pedigrees containing 437 subjects, 241 with DNA and 91 affecteds. Analysis of these sub-pedigrees produced strong evidence for linkage at chromosome 1q32, with  $p=0.00001$  (NPLall) in the largest sub-pedigree, and weaker evidence in the remaining sub-pedigrees. In comparison, analyses using a large pedigree structure more similar to the actual structure weakens evidence for linkage, with  $p=0.001$  (statistic B). The difference between these two results likely is caused by limitations in the nonparametric statistics, in addition to possible locus heterogeneity. These results highlight the need for improved techniques for linkage analysis.

**A potential locus for Adult-Onset Primary Open Angle Glaucoma (POAG) maps to 2p14-2p16. S.**

*Suriyapperuma*<sup>1</sup>, *A. Child*<sup>2</sup>, *T. Desai*<sup>1</sup>, *G. Brice*<sup>2</sup>, *R.P. Crick*<sup>3</sup>, *M. Sarfarazi*<sup>1</sup>. 1) Molecular Ophthalmic Genetics, University of Connecticut Health Center, Farmington, CT; 2) Department of Cardiological Sciences, St. Georges Hospital Medical School, London, UK; 3) International Glaucoma Association, London, UK.

We used 322 affected subjects from 91 families and scanned the entire of genome in search of a new locus for Adult-Onset POAG. Initially, 13 different loci were detected, but additional genotyping did not establish a firm linkage to most of these locations. However, one locus on 2p14-p16 consistently showed linkage in one large British family with 9 affected subjects. This family consists of a total of 113 members, of whom 77 are alive. The phenotype of affected subjects includes low to moderate intraocular pressure, onset after 40 and glaucomatous visual field loss. Forty-nine members representing 3 different generations were sampled and subsequently genotyped for 22 DNA markers. Haplotypes were constructed for 49 affected and normal subjects, ranging from 33-87 years of age. All the 6 living affected individuals (67-83 years of age) share a haplotype from D2S123 to D2S329, a region of approximately 27 cM. However, 3 other subjects with ocular hypertension (OH) have recombined within this region thus limiting this new locus to 8 cM, between D2S123 and D2S2165. Eleven normal subjects with a mean age of 48 years are also gene carriers for at least part of this region. Two-point linkage analysis using only affected, OH and elderly members of this family provided LOD score values ranging from 2.25 to 3.0. Six other British and 1 Jamaican family also share at least smaller portions of this region. When all families were analyzed together, the highest LOD score of 8.84 was obtained for D2S2320. Our results provide preliminary evidence for a new POAG locus on 2p14-2p16 region. Screening of several candidate genes from this region failed to identify any disease-causing mutations.

**Preliminary meta-analysis for BMI in NHLBI FBPP study.** X. Wu<sup>1</sup>, R. Cooper<sup>1</sup>, X. Zhu<sup>1</sup>, A. Weder<sup>2</sup>, I. Borecki<sup>3</sup>, M. Bray<sup>4</sup>, C. Hanis<sup>4</sup>, B. Lewis<sup>5</sup>, N. Risch<sup>6</sup>, P. Savage<sup>7</sup>. 1) Department of Preventive Medicine and Epidemiology, Loyola University Medical Center, Maywood, IL; 2) Division of Hypertension and Hyperlipidemia, University of Michigan, Ann Arbor, MI; 3) Division of Biostatistics, Washington University School of Medicine, St. Louis, MO; 4) Institute for Molecular Medicine and Human Genetics Center, University of Texas Houston Health Science Center, Houston, TX; 5) Department of Epidemiology, University of Alabama, Birmingham, AL; 6) Department of Genetics, Stanford University, Stanford, CA; 7) National Heart, Lung and Blood Institute, Bethesda, MD.

A meta-analysis of genome scans for obesity, characterized as body mass index (BMI), was undertaken using the results from the 8 individual studies conducted separately in the NHLBI Family Blood Pressure Program (FBPP). Data were available on a 6245 individuals from 4 ethnic groups (white, black, Mexican American and Asian); genotyping was on-going for another 5,000 participants. The sample represents by far the largest single collection of genome-wide data scan that has been analyzed for obesity, and provides a test of the reproducibility of linkage analysis for a complex phenotype. Genome-wide linkage analyses were first performed separately in each of the 4 ethnic groups in the four networks using the variance component method. No single region achieved genome-wide significance, nor were results of suggestive significance found in more than one sample. A modified Fishers omnibus procedure was then used to combine the p value across the genome from each scan. The most significant result was found at 30.81 cM on chromosome 7 (LOD = 3.26) from the meta-analysis; the largest LOD score among single studies at this location was 1.88. Other meta-analysis methods based on IBD sharing are being used in on-going analyses. Although admittedly preliminary, these findings suggest that loci/regions with a large and consistent effect on obesity across populations are unlikely to be found with current linkage methods. Under some circumstances, meta-analysis may improve the power detecting linkage in the combined analysis, however, more refined analytic techniques may need to be developed.

**Linkage of congenital fibrosis of the extraocular muscles to chromosome 12 in an Indian family.** *C.P. Venkatesh<sup>1</sup>, V.S. Pillai<sup>1</sup>, A. Raghunath<sup>1</sup>, V.S. Prakash<sup>1</sup>, R. Vathsala<sup>1</sup>, M.A. Pericak-Vance<sup>2</sup>, A. Kumar<sup>3</sup>.* 1) Retinal Ophthalmology, Minto Eye Hospital, Bangalore, Karnataka, India; 2) Center for Human Genetics, Duke University Medical Center, Durham, USA; 3) MRDG, Indian Institute of Science, Bangalore, India.

Congenital fibrosis of the extraocular muscles (CFEOM) is a syndrome of congenital ophthalmoplegia and bilateral ptosis. Classical CFEOM is characterized by congenital nonprogressive bilateral ptosis and external ophthalmoplegia with eyes fixed in a strabismic position. Affected individuals typically must tilt their heads back to compensate for the ptosis and fixed downward position of the globes. CFEOM is genetically heterogeneous disorder. In some families, CFEOM can be inherited as an autosomal recessive trait with a locus mapped on chromosome 11q13 (CFEOM2). CFEOM can also be inherited as an autosomal dominant trait with loci mapped on chromosome 12cen (CFEOM1) in eight families and chromosome 16q24 (CFEOM3) in a single family. We have ascertained a four-generation CFEOM family from the state of Karnataka, India in which the disorder is segregating as an autosomal dominant trait. All the affected individuals of this family have bilateral congenital ptosis and external ophthalmoplegia. The maximum expected lod score in this family (4 allele locus; HET=0.75; 10,000 replicates) is 2.02. To assess linkage in this family to the CFEOM1 (MIM 135700) and CFEOM3 (MIM 604361) loci, microsatellite markers from both within and flanking the candidate regions were genotyped. Linkage to CFEOM3 locus was excluded ( $Z < -2.00$ ), whereas analysis of chromosome 12 markers (pter-D12S61-D12S1631-D12S87-D12S345-D12S59-cen-D12S1048-D12S1668-D12S1090-D12S85-qter) was positive. The maximum two-point lod score was 1.8 at  $\theta = 0$  with marker D12S345. The peak multipoint lod score was 2.36 between D12S87 and D12S345. Markers D12S61, D12S1631, D12S87, D12S345, D12S59, D12S1048 and D12S1668 cosegregated with the disease locus in all affecteds. Recombination in three affecteds between D12S1668 and D12S1090 placed the candidate region centromeric to D12S1090. These data supported linkage to CFEOM1 in this family.

**Chromosome 17 linked dementia in the absence of tau mutations.** *R. Rademakers<sup>1</sup>, M. Cruts<sup>1</sup>, B. Dermaut<sup>1</sup>, G. Roks<sup>2</sup>, M. Van den Broeck<sup>1</sup>, C.M. Van Duijn<sup>1,2</sup>, C. Van Broeckhoven<sup>1</sup>.* 1) Department of Molecular Genetics, Flanders Interuniversity Institute for Biotechnology (VIB), University of Antwerp (UIA), Antwerpen, Belgium; 2) Department of Epidemiology and Biostatistics, Erasmus Medical Center, Rotterdam, The Netherlands.

We studied a four-generation pedigree with autosomal dominant inherited atypical dementia, containing 13 affected individuals with a mean age at onset of  $63 \pm 7$  years (range: 55 to 78 years). Clinical diagnoses included Alzheimer Dementia (AD), Frontotemporal Dementia (FTD) and Parkinson Dementia (PD). In this family, mutations in the amyloid precursor protein (APP), the presenilins (PSEN) and the microtubule binding domains of the microtubule associated protein tau (MAPT) were previously excluded. To identify the disease-causing gene in this family, a genome-wide search was performed with 400 microsatellite markers defining a 10 cM resolution human index map. Using two-point linkage analysis, we were able to detect conclusive linkage to chromosome 17q21 with a LOD score of 3.18 with marker D17S1868, well above the maximum false positive LOD score of 1.71 obtained in simulation studies. When additional markers were used to refine the candidate region, meiotic recombination events located the disease gene in a 6.4 cM interval between markers D17S946 and D17S958 with a maximum multi-point LOD-score of 5.06 at marker D17S951. Since the MAPT gene, known to cause neurodegeneration in FTD-families, is located within this candidate region, we sequenced all 15 coding or partially coding exons of MAPT for mutations. Also exon -1 and 1 kb sequence of the 5'UTR containing the core- and proximal promoter, as well as intron 13 and at least 60 bp of intronic sequence flanking exon 10 were analyzed. More than 20 sequence variations in non-coding regions, as well as 12 coding sequence variations were identified. However, no sequence variation segregating with the disease haplotype were found. Our findings suggest that either another gene mapping to chromosome 17q21, or a novel mutation in as yet unanalyzed regions of the MAPT gene could be responsible for the atypical dementia segregating in this family.

**Exclusion of genetic linkage to known loci in a large French Canadian family with Lewy body parkinsonism. K.A.**

*Scoggan<sup>1</sup>, D.A. Grimes<sup>1,4</sup>, J.D. Grimes<sup>4</sup>, L. Racacho<sup>1</sup>, F. Han<sup>1</sup>, B.A. Schwarz<sup>4</sup>, J. Woulfe<sup>3</sup>, D.E. Bulman<sup>1,2</sup>.* 1) Molecular Medicine Program, Ottawa Health Research Institute; 2) Division of Neurology, The Ottawa Hospital; 3) Department of Pathology and Laboratory Medicine, The Ottawa Hospital; 4) Parkinson's Disease and Movement Disorders Clinic, Ottawa, Ontario, Canada.

Parkinson's disease (PD) is the second most common progressive neurological disorder affecting greater than 3% of the population over age 65 and 10-30 % of cases are familial. The identification of disease causing mutations in families with PD has contributed to the understanding of this complex disorder. We have identified a large French Canadian kindred that segregates Lewy body positive PD as an autosomal dominant trait. This family spans five generations and consists of more than 90 individuals, in which 65 have now been examined. Individuals were genotyped and two point linkage analysis was performed to assess linkage to known PD genes or loci. The  $\alpha$ -synuclein (4q21.3-23), Parkin (6q25.2-27), ubiquitin carboxy-terminal hydrolase L1 (4p16), 4p14-16.3, and 2p13 loci were excluded in this kindred using closely linked markers. The clinical and pathological features of this family are consistent with the diagnosis of Lewy body positive Parkinson's disease. Data from this study further demonstrate genetic heterogeneity for familial parkinsonism and indicate that there is at least one other genetic determinant for Lewy body parkinsonism.

**Evidence of further genetic heterogeneity for both autosomal dominant and autosomal recessive limb-girdle muscular dystrophy.** *A.L. Starling, M. Vainzof, R. Pavanello, M. Canovas, A. Cerqueira, M.R. Passos-Bueno, M. Zatz.* Center for the study of the human genome, IBUSP, University of Sao Paulo, Sao Paulo, Brazil.

Fifteen genes responsible for limb-girdle muscular dystrophy have been identified to date including six autosomal dominant (LGMD1A-F) and nine autosomal recessive (LGMD2A-I). We have ascertained three Brazilian families that were excluded by linkage analysis (and protein studies when possible) for these 15 LGMD causing genes. The first family with nine affected members (7 males and 2 females) in 3 generations displays AD inheritance. Two of the affected patients were submitted to muscle biopsy and electromyography which showed a myopathic pattern in both exams. In all affected members the onset occurred after age 30, with proximal weakness in the upper and lower limbs and a variable presence of calf hypertrophy. Serum creatine kinase (CK) was increased 2 - 9 fold. The second family also with AD inheritance has four affected members (3 males and 1 female) in 2 generations. All of them have a history of cardiac problems, weakness of proximal limbs and a CK increase 3 - 6 fold. The age at onset ranged from 25 to 30 years old. The last family, with four affected males has an atypical inheritance. The affected patients have weakness of proximal limbs (predominantly in the lower limbs in three patients but in the upper limbs in the last one), calf hypertrophy and the age at onset ranged from 10 to 15 years old. The CK was grossly elevated (50-80 fold). Electromyography showed a myopathic pattern and the biopsy showed a normal pattern for dystrophin, calpain, dysferlin, the four sarcoglycans and telethonin. We are currently performing a genome-wide scan to identify the disease loci in these three families. Supported by FAPESP-CEPID, PRONEX and CNPq.

**Complete Genomic Screen in Idiopathic Parkinson Disease.** *W.K. Scott<sup>1,3</sup>, J.M. Stajich<sup>1,3</sup>, B.L. Scott<sup>1,3</sup>, M.A. Nance<sup>3</sup>, R.L. Watts<sup>3</sup>, J.P. Hubble<sup>3</sup>, J.L. Haines<sup>3</sup>, W.C. Koller<sup>3</sup>, R. Pahwa<sup>3</sup>, M.B. Stern<sup>3</sup>, B.C. Hiner<sup>3</sup>, J. Jankovic<sup>3</sup>, F.H. Allen<sup>3</sup>, C.G. Goetz<sup>3</sup>, G.W. Small<sup>3</sup>, F. Mastaglia<sup>3</sup>, L.T. Middleton<sup>2,3</sup>, A.D. Roses<sup>2,3</sup>, J.M. Vance<sup>1,3</sup>, M.A. Pericak-Vance<sup>1,3</sup>.* 1) Duke University Medical Center, Durham, NC; 2) GlaxoSmithKline, Research Triangle Park, NC; 3) Duke CHG/GlaxoSmithKline PD Genetics Collaboration.

The relative contribution of genes versus environment in idiopathic Parkinson disease (PD) is controversial. While genetic studies have identified two genes in which mutations cause rare single gene variants of PD and relative risk studies have suggested a genetic component, recent twin studies have suggested that little genetic contribution exists in the common late-onset forms of PD. To identify genes associated with idiopathic PD, we performed a complete genomic screen (N=344 markers, average spacing 10cM) in 174 multiplex (2 or more sampled affected individuals) idiopathic PD families [containing 870 sampled members (378 affected), 185 sampled affected sibling pairs and 70 other sampled affected relative pairs]. Mean age at onset was  $59.9 \pm 12.6$  years. Diagnosis of PD was based on the presence of two of the following signs: tremor at rest, bradykinesia, and rigidity, as well as the absence of atypical features and other causes of parkinsonism. A clinical adjudication board reviewed all cases for accuracy and consistency across sites. Two-point parametric (MLOD) and multipoint non-parametric (LOD\*) linkage analysis detected significant evidence for linkage (MLOD or LOD\* > 2) to five distinct chromosomal regions: chromosome 6q in the parkin gene in families with at least one individual with PD onset < 40 years; chromosomes 17q, 8p, and 5q in late-onset families, and chromosome 9q in families with evidence of levodopa non-responsive patients. The result on chromosome 17q is in the vicinity of the tau gene. Tau haplotypes are associated with idiopathic PD in our sample (Oliveira et al, this meeting). These data indicate that contrary to previous reports, multiple genetic factors are indeed important contributors to the development of idiopathic late-onset PD.

**Investigation of association of polymorphisms in TNFR1 and TNFR2 in Alzheimers disease patients.** *R. Perry*<sup>1</sup>, *J. Collins*<sup>2</sup>, *L. Harrell*<sup>1</sup>, *D. Blacker*<sup>3</sup>, *R. Tanzi*<sup>3</sup>, *M. McInnis*<sup>4</sup>, *S. Bassett*<sup>4</sup>, *R. Go*<sup>1</sup>. 1) Univ Alabama at Birmingham, Birmingham, AL; 2) Greenwood Genetic Center, Greenwood, SC; 3) Massachusetts General Hospital, Boston, MA; 4) Johns Hopkins University, Baltimore, MD.

Using non-parametric analyses in 266 sib-pair families from the NIMH sibling dataset, we previously reported results of a collaborative genome wide scan where polymorphic markers located at 1p36 and 6p21 were associated with Alzheimers disease (AD) (Collins et al, 2000; Go et al, 1998; Collins et al, 1998). We recently reported a haplotype containing alleles of the 238 and 308 promoter polymorphisms of the tumor necrosis factor (TNF) gene and the microsatellite TNFa, located ~16.5 kb upstream of TNF, was associated with AD in subset of the above families (Collins et al, 2000). From a subset of 320 families with an age of onset over seventy years (total NIMH sibling dataset = 481), we found suggestion of linkage at two regions on chromosome 1, including the same 1p terminal region. The tumor necrosis factor receptor 2 (TNFR2) gene, one of two main receptors for TNF, is located at 1p36.22. We used family-based association testing to look at the T@G polymorphism at position 196 in exon 6 of TNFR2 that leads to a M@R substitution. However, we did not find any significant association between TNFR2 and AD in 150 families with at least two affected and one unaffected siblings (SIBASSOC, p=0.71, S-TDT, p=0.28, SDT, p=0.63). The other receptor TNF binds to, TNFR1, is located at 12 p terminal, a region where other genome wide scans have indicated as suggestively linked to AD (Kehoe et al, 1999; Rogaeva et al, 1998). We genotyped an A@G silent change in codon 12 of exon 1 of TNFR1 and two polymorphisms located in introns 5 and 7 in the same set of families. The codon 12 silent change was significantly associated to AD (FBAT, p=0.02). Preliminary analyses on the other two polymorphisms do not appear to show any significant association with AD. There appears to be significant linkage disequilibrium between the exon 1 polymorphism and the intron 5 polymorphism, but not the intron 7 nucleotide change. Results of further haplotype analyses will be presented at the meeting.

**A score test for detecting quantitative trait loci using sibships of arbitrary sizes.** *K. Wang*<sup>1</sup>, *J. Huang*<sup>2,1</sup>. 1) Dept Biostatistics, Univ Iowa, Iowa City, IA; 2) Dept Statistics and Acturial Science, Univ Iowa, Iowa City, IA.

The Haseman-Elston method is widely used for mapping quantitative trait loci using independent sib-pair data. However, this method does not use all the information in the data because it only considers the sib-pair trait value difference (Wright, 1997). In addition, its generalization to non-independent sib-pairs is not straightforward. Here we introduce a score test statistic derived from a normal likelihood based on multiplex sibship data conditional on IBD sharing probabilities. This score test is asymptotically equivalent to the corresponding likelihood ratio test, but it is easier to implement since it does not require maximization of the likelihood function. Because the proposed test uses all the trait values, not just the pair-wise differences, it makes more efficient use of the data. The proposed test is also naturally applicable to sibships of arbitrary sizes. The performance of the proposed score test are evaluated via simulations. The results indicate that the proposed test is more powerful than the Haseman-Elston method under variety of situations.

**Mapping of Spondylothoracic Dysplasia ( Jarcho-Levin syndrome) to chromosome 2q32.1 in Puerto Rican**

**population.** *A. Santiago-Cornier*<sup>1,3,5</sup>, *N. Ramirez*<sup>4</sup>, *V. Franceschini*<sup>1,3</sup>, *J. Acevedo*<sup>2</sup>, *H. Roman*<sup>1,3</sup>, *E. Rosado*<sup>1</sup>, *L. Garcia*<sup>6</sup>, *J. Torres*<sup>3</sup>. 1) Genetic Division, Ponce School of Medicine, Ponce, PR; 2) Dept. of Nursing, Univ. of Puerto Rico at Arecibo, Arecibo, PR; 3) Dept. of Biochemistry, Ponce School of Medicine, Ponce, P.R; 4) Dept. of Orthopedics, Mayaguez Medical Center, Mayaguez, P.R; 5) Dept. of Pediatrics, Ponce School of Medicine, Ponce, PR; 6) Dept. of Neonatology, University of Puerto Rico School of Medicine, Rio Piedras, PR.

Spondylothoracic dysplasia also know as Jarcho-Levin syndrome (JLS MIM#277300) is an autosomal recessive disorder with high prevalence in Puerto Rican population. JLS main features includes multiple spinal anomalies, fusion of the ribs at the costo-vertebral joint, bilaterally symmetrical fanning out of the chest, umbilical and inguinal hernias and severe restrictive respiratory function. In this investigation we describe the localization of the first Jarcho-Levin syndrome locus and provide evidence that the spondylothoracic dysplasia maps to chromosome 2 in 18 Puerto Rican families. We collected blood samples from 78 individuals, 26 of whom were affected. We performed a genomewide linkage analysis in these families. Haplotype analysis and recombination events localized the disease gene to a 12cM region between markers D2S1384 and D2S1363 with a maximum LOD score of 5.7 and 3.7 respectively for all the informative (11) families. Previous research on a similar disease, spondylocostal dysplasia ,proved to have mutations on Delta homologue, DLL3 gene. These findings provide evidence that both diseases are due to mutations in different genes. Mutation analysis of candidate genes within the region is currently undergoing .Genotype-Phenotype correlations of affected and heterozygous family members will make possible to examine gene dosage in JLS. Evaluation of additional JLS patients will allow us to evaluate a possible founder effect and its extension in Puerto Rican population and to use the narrowest region of shared haplotypes to search for the disease gene.

**The gene for Familial Hypobetalipoproteinemia is linked to a 2.0 cM interval on 3p21.1-22.** *B. Yuan<sup>1</sup>, R.J. Neuman<sup>2</sup>, D.S. Gerhard<sup>3</sup>, P. Yue<sup>1</sup>, K.Y. Liu<sup>2</sup>, S.H. Duan<sup>1</sup>, M. Averna<sup>1</sup>, G. Schonfeld<sup>1</sup>.* 1) Lipid Research, Internal Medicine, Washington Univ, St. Louis, MO; 2) Dept Psychiatry, Washington Univ, St. Louis, MO; 3) Dept Genetics, Washington Univ, St. Louis, MO.

We previously reported linkage of the familial hypobetalipoproteinemia (FHBL) trait to ca.10 cM region on 3p21.1-22 in one kindred with FHBL. We identified and genotyped 21 additional FHBL kindreds (131 individuals and 58 affecteds) to reduce the candidate region and make the identification of the gene feasible. Individuals with abnormally low apoB levels were considered affected, and parametric and nonparametric analyses demonstrated that at least 3 families were potentially linked to the same region as reported previously. Markov chain Monte Carlo linkage analysis of the quantitative apoB level further confirmed linkage to this region. Three recombination events allow us to reduce the candidate region from ca. 10 cM to 2.0 cM, between the markers D3S2407 and D3S1767. To identify the candidate gene, we constructed a 2.2-Mb sequence-ready contig map completely covering the critical region defined by recombination events by assembly of the 56 BAC/PAC clones published in NCBI database. In this region are approximately 200 genes or expressed sequence tags (ESTs). To find the disease gene, we are screening for variations and mutations in the candidate genes using Southern blotting for detection of large-scale genomic rearrangements and direct sequencing to find nucleotide substitutions, microdeletions or insertions.

**Power comparison of phase-known versus phase-unknown haplotype analyses for case-control designs.** *L.E. Green, E.M. Lange, C.D. Langefeld.* Public Health Sciences, Wake Forest University, Winston-Salem, NC.

It is widely known that the relative power of haplotype analyses under a case-control design is greater when haplotype phase is known rather than when phase is probabilistically inferred. We have conducted a simulation study, using likelihood ratio tests, to investigate how many additional cases and controls must be sampled when inferring phase using the EM algorithm in order to have equivalent power to that of 500 cases and 500 controls for which phase is known. We simulated data for a case-control design using a slight modification of the algorithm outlined by Devlin and Risch (1995). We assumed a single biallelic disease-predisposing locus and either 2, 3 or 4 equally spaced biallelic markers (allele frequencies of 0.4 and 0.6). We randomly sampled cases and controls from a simulated population of 95,000 individuals based on a founding population of 500 unrelated individuals and 20 generations of random mating. We varied the recombination fraction ( $q=0.01$  and  $0.001$ ) and the genetic model (dominant, recessive;  $I_s=1.5, 2.0$  and  $3.0$ ) for a total of 12 sets of simulations containing 10,000 replications each. Under each of the conditions, the phase known analysis was more powerful than the phase-unknown analysis for equal sample sizes. For 2, 3, and 4 marker simulations, average increases in sample size of 19%, 42% and 68%, were needed respectively, when inferring phase in order to achieve equivalent power to that of the phase-known analysis. Overall, decreasing  $q$  from 0.01 to 0.001 increased the number of cases and controls needed for the phase-unknown analysis to have equivalent power to that of the phase-known. For example in the 3 marker simulations, decreasing  $q$  required an additional 57 cases and controls for equivalent power. Varying the genetic model (i.e.,  $I_s$ , dominant and recessive models) did not appear to qualitatively alter the above conclusions. These results suggest that, conditional on the specific costs, it may be more effective to recruit additional cases and controls and infer phase than to determine exact phase via recruiting additional family members or through laboratory techniques.

**Genetic heterogeneity in hemifacial microsomia: evidence for three loci at 14q32, 2q35 and 11q12-q13. D.**

*Kelberman<sup>1</sup>, J. Tyson<sup>1</sup>, D.C. Chandler<sup>2</sup>, A. McInerney<sup>3</sup>, J. Slee<sup>4</sup>, M. Calvert<sup>5</sup>, J. Goldblatt<sup>4</sup>, E.A. Haan<sup>6</sup>, N.G. Laing<sup>2</sup>, S. Malcolm<sup>1</sup>, S.L. Singer<sup>7</sup>, R.M. Winter<sup>1</sup>, M. Bitner-Glindzicz<sup>1</sup>.* 1) Clin and Mol Gen Unit, Institute of Child Health, London, UK; 2) Australian Neuromuscular Research Institute, Needlands, Western Australia; 3) NHGRI, NIH, Bethesda, MD; 4) Genetic Services, King Edward Memorial Hospital, Western Australia; 5) Maxillofacial and Dental department, Great Ormond Street Hospital for Children NHS Trust, London, UK; 6) Adelaide Childrens' Hospital, South Australia; 7) Dept of Maxillofacial Surgery, Princess Margaret Hospital, Western Australia.

Hemifacial microsomia (HFM) is a common birth defect involving first and second branchial arch derivatives. The phenotype is extremely variable, in addition to craniofacial anomalies there may be cardiac, vertebral and central nervous system defects. The majority of cases are sporadic, but there is substantial evidence for genetic involvement in this condition including rare familial cases that exhibit either autosomal dominant or recessive inheritance. A genome wide search for linkage in three families with features of HFM (two dominant, one recessive) was performed to identify the disease loci. Linkage was identified, in one family, to a region of approximately 10.7cM on chromosome 14q32, with a maximum multipoint lod score of 3.00 between microsatellite markers D14S987 and D14S65. This locus harbours the Goosecoid gene, an excellent candidate for HFM based on mouse expression and phenotype data. Coding region mutations and gross rearrangements of the gene were excluded. No exonic variation was observed in 120 sporadic cases of HFM. Evidence for genetic heterogeneity is provided by the second family in which linkage was excluded from this region. Linkage analysis in this family was suggestive of a disease locus on chromosome 11q12-q13. A locus at 2q35 has been found in a recessive family with HFM associated with external auditory canal atresia, deafness, acro-osteolysis and Mullerian anomalies. This region harbours two members of the WNT protein family.

**Modelling admixture and extracting information about linkage that is generated by admixture from marker genotypes.** *C.J. Hoggart<sup>1</sup>, P.M. Mckeigue<sup>1</sup>, D. Clayton<sup>2</sup>.* 1) London School of Hygiene and Tropical Medicine, London, UK; 2) Department of Medical Genetics, Cambridge University, UK.

Where there has been admixture between two or more ethnic groups that vary in disease risk for genetic reasons, it is possible to map the genes underlying this ethnic variation in a manner analogous to linkage analysis of an experimental cross. This approach relies on selection of markers that have large frequency differentials between the parental populations. We report preliminary results with a statistical analysis program which models admixture using a Bayesian approach, giving the posterior distribution of individual admixture and ancestry at each locus by Markov chain Monte Carlo simulation. The program can deal with any number of parental populations and any number of linked marker loci. Information about the ancestry of one or both parents can be included where available. We describe several applications of this program to data on admixed African-American and Caribbean populations. In case-control and cross-sectional studies, we have modelled the relationship of individual admixture to risk of diseases such as hypertension and systemic lupus erythematosus. In case-only or cross-sectional studies, we can test each marker locus for linkage with genes that underlie these ethnic differences in disease risk. We can also test whether the ancestry-specific allele frequencies (probabilities of each allelic state given the ancestry of the allele) have been mis-specified. Where necessary we can re-estimate these frequencies for each admixed population under study. This makes it possible to apply admixture mapping even where allele frequencies in one or both parental populations are unknown.

**Use of microcell mediated mouse chromosome transfer for gene localization.** *A.N. Mankad<sup>1</sup>, M.P. Cosma<sup>2</sup>, B.A. Cox<sup>1</sup>, C. Reifsteck<sup>1</sup>, S. Olson<sup>1</sup>, M. Grompe<sup>1</sup>.* 1) Molecular and Medical Genetics, Oregon Health & Science Univ., Portland, OR; 2) Telethon Institute of Genetics and Medicine (TIGEM), Napoli, Italy.

Microcell mediated chromosome transfer, a recognized technique for introduction of a single chromosome into recipient cells, combined with an assay for complementation of a cellular genetic defect, can be used to localize a gene to a particular chromosome. The standard microcell donors contain single, specific human chromosomes in a mouse background. Human chromosome transfer using these donors unambiguously identifies the complementing chromosome; however, as many as 22 MMCT fusions may be required. In addition, sub-localization of the gene relies on polymorphic differences between donor and recipient chromosomes, which may be difficult to find in the region of interest. One way to circumvent these difficulties is to transfer mouse chromosomes rather than human ones, and assay for complementation of the genetic defect by a mouse gene. The donor cells for this modified MMCT are mouse A9 fibroblasts that have been infected with retrovirus carrying a neomycin resistance cassette, which integrates randomly, marking approximately one chromosome per cell. Since a different neo-marked mouse chromosome is transferred from each donor cell, each fusion potentially covers the entire genome, not just a single chromosome. Additionally, pervasive species differences make it easy to assay for successful mouse chromosome transfer, as well as sub-localize or map the mouse gene, via mouse chromosome FISH, mouse microsatellite PCR, or B2 repeat PCR. The latter amplifies DNA between ubiquitous rodent-specific repeat sequences with a single primer, and the product appears as a smear with a distinct series of bands for every possible subset of chromosomes. Six microcell fusions applying the modified protocol generated 54 hybrid clones from one recipient cell line; of these, about 30 were independent clones, only one was a whole cell hybrid, and one was a confirmed mono-chromosomal hybrid. These results validate the use of this microcell mediated mouse chromosome transfer technique for rapid generation of independent hybrids and scanning of the genome for localization of a gene of interest.

**Association Studies for Quantitative Traits in Structured Populations.** *K.M. Roeder<sup>1</sup>, S-A. Bacanu<sup>2</sup>, B. Devlin<sup>2</sup>.* 1) Dept Statistics, Carnegie Mellon Univ, Pittsburgh, PA; 2) Dept Psychiatry, Univ Pittsburgh, Pittsburgh, PA.

Association between disease and genetic polymorphisms often contributes critical information in our search for the genetic components of common diseases. During 1999, Devlin and Roeder (*Biometrics* 55:997-1004) introduced genomic control, a statistical method that overcomes a drawback to the use population-based samples for tests of association, namely spurious associations induced by population structure. In essence, genomic control (GC) uses markers throughout the genome to adjust for any inflation in test statistics due to substructure. To date genomic control (GC) has been developed for binary traits and bi- or multiallelic markers. Tests of association using GC have been limited to single genes. In this report, we generalize GC to quantitative traits (QT) and multilocus models. Using statistical analysis and simulations, we show that GC controls spurious associations in reasonable settings of population substructure for QT models, including gene-gene interaction. Through simulations we explore GC power for both random and selected samples, assuming the QT locus tested is causal and its specific heritability is 2.5 - 5%. We find that GC, combined with either random or selected samples, has good power in this setting, and that more complex models induce smaller GC corrections. The latter suggests greater power can be achieved by specifying more complex genetic models, but this observation only follows when such models are largely correct and specified a priori.

**Outlier Detection and False Discovery Rates for Whole-genome Association Studies.** *J-Y. Tzeng<sup>1</sup>, B. Devlin<sup>2</sup>, K.M. Roeder<sup>1</sup>, L. Wasserman<sup>1</sup>.* 1) Dept Statistics, Carnegie Mellon University, Pittsburgh, PA; 2) Dept Psychiatry, Univ Pittsburgh, Pittsburgh, PA.

Benjamini and Hochberg (J. R. Stat. Soc. Ser. B, 1995, 57:289-300) introduced an approach to multiple hypothesis testing that controls the false discovery rate (FDR), defined as the fraction of false rejections among those hypotheses rejected. The procedure is very appealing because it controls a quantity that is often of greater scientific relevance than the overall type I error rate. When applied to a genome scan it chooses a near optimal threshold value that balances costs of both false non-discoveries and false discoveries. We define a statistic, called the matching statistic, for locating regions of the genome that exhibit excess similarity among cases when compared to controls. Such regions are reasonable candidates for harboring disease genes. We find the asymptotic distribution of the statistic while accounting for correlations among sampled individuals. We use the FDR method for multiple hypothesis testing to find regions of excess sharing. The p-values for each region involve estimated nuisance parameters. We show that the FDR method based on p-values and with estimated nuisance parameters asymptotically preserves the FDR property.

**Fine mapping on chromosome 20 shows evidence of linkage for BMI and fat mass in type 2 diabetes affected sib-pairs from West Africa.** C. Rotimi<sup>1</sup>, R. Kittles<sup>1</sup>, D. Parish-Gause<sup>1</sup>, G. Chen<sup>1</sup>, G. Vosgianian<sup>1</sup>, P. Furbert-Harris<sup>1</sup>, A. Amoah<sup>2</sup>, J. Acheampong<sup>3</sup>, J. Oli<sup>4</sup>, B. Osotimehin<sup>5</sup>, T. Johnson<sup>6</sup>, G. Dunston<sup>1</sup>, F. Collins<sup>7</sup> and AADM Study Investigative Group. 1) National Human Genome Center, Howard University, Washington, DC; 2) University of Ghana; 3) University of Science and Technology, Ghana; 4) University of Nigeria Teaching Hospital; 5) University College Hospital, Nigeria; 6) University of Lagos, Lagos, Nigeria; 7) National Human Genome Research Institute, Bethesda, MD.

Several candidate genes for type 2 diabetes and associated risk factors have been mapped to chromosome 20 (chr20). We performed fine mapping of two regions spanning 66 cM at 20p11.2-20p13 and 20q12.3-20q13.1. These regions were mapped using 13 highly polymorphic microsatellite markers in a newly identified cohort of 360 affected sibling pairs (ASP) with type 2 diabetes, located in two countries in West Africa. Equal numbers of patients were enrolled from three sites in Nigeria (Enugu, Ibadan and Lagos) and two sites from Ghana (Accra and Kumasi). Populations of the west coast of Africa, from Senegal to Angola, were major contributors of Africans to the Americas and other parts of the world during the Middle Passage. By studying West Africans we hope to shed light into reasons for the apparent increased susceptibility of African Americans to diabetes, obesity and associated complications. Using affected sib-pair analysis as described in GENEHUNTER and S.A.G.E (sibpal2), we obtained suggestive evidence of linkage between BMI, fat mass and a 17cM region (31.2-48.5) on chr20. The strongest evidence occurred at the position corresponding to marker D20S471 (location 20p11.22) with a maximum logarithm of odds score (MLS) of 2.3 for BMI and 2.5 for Fat mass. The single-point analysis p-value was 0.0294 for BMI and 0.0279 for fat mass. Our findings suggest that one or more genes affecting obesity may be located in 20p11.22 region of chr20. Since this chromosomal region includes several plausible candidate genes for obesity, we suggest that more detailed analyses are needed to elucidate the putative gene(s) for obesity and related phenotypes in this and other populations.

**The low activity H1 haplotype of *PDGFRA* P1 promoter may predispose to spina bifida in individuals of Mexican descent.** K.-S. Au<sup>1</sup>, K.A. Volcik<sup>1</sup>, S. Featherston<sup>1</sup>, H. Northrup<sup>1,2</sup>. 1) Dept Pediatrics, Univ Texas Medical Sch, Houston, TX; 2) Shriners Hospital for Children, Houston, TX.

Abnormal platelet-derived growth factor alpha-receptor (*Pdgfra*) expression has been suspected to cause spina bifida (SB) in various mouse models. *PDGFRA* binds to both homodimers and heterodimers of PDGF-A and PDGF-B whereas PDGF b-receptor binds only to PDGF-B. It was postulated that either premature- or delayed- differentiation of neural glia and cartilage precursor cells could result in abnormal closure of neural tube. Various isoforms of human *PDGFRA* were identified and two separate promoters (P1 and P2) control their expression. Promoter P1 is located 5' to exon 1 and P2 is located in intron 12 of *PDGFRA*. Retinoic acid treatment stimulates *PDGFRA* transcription from P1 and promotes differentiation of Tera-2 cells, while expression from P2 promotes proliferation of the Tera-2 cells. Eight SNPs in the P1 region were identified and found to contribute to 5 different haplotypes (Joosten et al., 2001). Two major haplotypes, H1 and H2a, were detected in about 90% of those studied. The H1 haplotype consists of nucleotide changes that interrupt the SP-1 and GCF binding sites. Promoters with the H1 haplotype have only 1/6 the activity of those with the H2a haplotype. Presence of the H1/H2a haplotype was suggested to increase the risk for NTDs. We examined the *PDGFRA* promoter in a group of 85 sporadic SB patients of Mexican descent and found over-representation (49.4%) of the H1/H2a haplotype. Interestingly, 20% of our patients were homozygous for the H1/H1 haplotype. Together, homozygous and heterozygous H1 haplotypes constituted 69.4% of our SB population. Our finding is consistent with the double mutant patch/undulated mouse model suggesting that low activity of the *PDGFRA* predisposes to spina bifida. Low expression of the P1-derived mRNAs controlled by H1 haplotype in SB patients may promote expression of *PDGFRA* isoforms from P2 by default and delay differentiation of neural glia and cartilage precursor cells for proper closure of neural tube. A larger sample (450 SB patients and 700 unaffected parents) is currently undergoing testing. (Joosten et al., Nat.Genet.27:215-7,2001).

**A high-throughput SNP typing system for genome-wide association studies.** *Y. Ohnishi<sup>1</sup>, T. Tanaka<sup>1</sup>, K. Ozaki<sup>1</sup>, R. Yamada<sup>1</sup>, A. Sekine<sup>1</sup>, H. Suzuki<sup>2</sup>, Y. Nakamura<sup>1,2</sup>.* 1) SNP Research Center, RIKEN, Tokyo, Japan; 2) Laboratory of Molecular Medicine, Human Genome Center, Institute of Medical Science, University of Tokyo, Tokyo, Japan.

One of the most difficult issues to be solved for the whole-genome association study using SNPs is reduction of the amount of genomic DNA for genotyping. To genotype an individual blood sample for hundreds or thousands of SNPs by any of the presently-available technologies requires too large quantity of genomic DNA to be practical. To overcome this problem, we combined the Invader assay system with multiplex PCR carried out in the presence of antibody to Taq polymerase as well as a novel 384-well card system that can reduce a reaction volume very small. We amplified 100 genomic DNA fragments, each containing one SNP, in a single tube, and analyzed each SNP by the Invader assay. This procedure correctly genotyped 98 of the 100 SNP loci examined, in PCR-amplified samples from 10 individuals; the genotypes were confirmed by direct sequencing. The reproducibility and universality of the method were confirmed using two additional sets of 100 SNPs in 100 genomic fragments. Since we used 40 nanogram of genomic DNA as a template for multiplex PCR, the amount needed to assay one SNP was only 0.4 nanogram; therefore more than 200,000 SNPs theoretically could be genotyped at once when 100 microgram of genomic DNA is available. Our results strongly indicate the feasibility of undertaking genome-wide association studies using blood samples of only 5-10 milliliter. We have constructed a high-throughput genotyping facility using these technologies, which allows us to perform as many as 384,000 typings in one day.

**Haplotype analysis of the IL-1b gene and positive correlation with extracellular IL-1 beta protein levels.** *S.K. Hall<sup>1</sup>, D.G Perregaux<sup>3</sup>, C.A Gabel<sup>3</sup>, L.K. Durham<sup>2</sup>, A.B. Seymour<sup>1</sup>*. 1) Pharmacogenomics, Pfizer, Groton, CT; 2) Biostatistics and Reporting, Pfizer, Groton, CT; 3) Inflammation, Pfizer, Groton, CT.

The cytokine Interleukin (IL)-1 is a primary mediator in the pathogenesis of inflammatory diseases such as rheumatoid arthritis (RA), asthma and inflammatory bowel disease (IBD). Genetic variation within the IL-1 gene cluster has been associated with increased risk to develop these diseases. Previous studies have associated a C3953 T variant in exon 5 of IL-1b with increased LPS-stimulated IL-1b protein secretion as well as linking two promoter variants to an increased risk of H. pylori induced hypochloridia and gastric cancer. We have investigated these polymorphisms as a haplotype within the IL-1b gene to test for a genetic contribution to interpatient variance observed with a blood-borne, two-step cytokine production assay that measures extracellular IL-1b levels generated in response to LPS and the combination of LPS/ATP; the nucleotide triphosphate enhances posttranslational processing. LPS-stimulated blood samples from 31 healthy donors were assessed for extracellular IL-1b. Genotypes were determined at three polymorphic loci throughout the IL-1b gene: C-511T, T-31C, and C3953T in each of the 31 subjects to test for association with secreted IL-1b protein levels. We observed very strong linkage disequilibrium between the -511 and -31 polymorphisms ( $p < .000000000005$ ), in particular between the T allele at -511 and the C at -31. Individuals homozygous for the haplotype comprised of T-511, C-31 and C3953 (T-C-C) had a significantly higher mean level of LPS-induced IL-1b secretion compared to individuals with zero or one copy of this haplotype (3.5 ng/ml vs 1.7 ng/ml,  $p = .036$ ). These data provide suggestive evidence that genetic variation within regulatory elements of the IL-1b gene may be associated with altered posttranslational processing efficiency.

**Determination of single nucleotide polymorphisms using a high throughput mass spectrometry based system. B. Darnhofer, M. Denissenko, L. Leppin, K. Smylie, C. Rodi. Molecular Biology, SEQUENOM, Inc., San Diego, CA.**

Detailed mapping of single nucleotide polymorphisms (SNPs) in the human genome is believed to greatly assist in determining the origins of complex diseases and understanding the causes of adverse drug reactions. Validating the diagnostic candidate SNPs can be a challenging task because the frequency of the contributing polymorphisms is often very low. Furthermore, the genetic basis of many diseases is often composed of not one, but multiple gene variants. To facilitate the scoring of SNPs, the rapid high-throughput MassARRAY system has been developed, which provides a fully automated and accurate solution to these challenges. This system is complemented by a single-tube assay method in which the genotyping primer is annealed to the amplified target in a region immediately adjacent to the polymorphic site. The primer is then enzymatically extended a few bases through the polymorphic site and terminated. The resulting diagnostic product is then robotically dispensed onto a chip and the genotype automatically determined using the mass obtained with MALDI-TOF (Matrix Assisted Laser Desorption Ionization - Time Of Flight) mass spectrometry. This method is fully compatible with 96 as well as 384 microtitre plate formats and further increases in throughput can be realized through the use of multiplexing. Multiplexed analysis data for 192 SNP-containing sequences are presented.

**Randomly assembled arrays for SNP genotyping.** *M. Chee<sup>1</sup>, J.-B. Fan<sup>1</sup>, M. Wenz<sup>2</sup>, E. Wickham<sup>1</sup>, K. Hayashibara<sup>2</sup>, J. Chen<sup>1</sup>, T. Paner<sup>2</sup>, D. Doucet<sup>1</sup>, L. Zhou<sup>1</sup>, B. Kermani<sup>1</sup>, R. Shen<sup>1</sup>, M. Hansen<sup>1</sup>, F. Steemers<sup>1</sup>, C. Zhao<sup>1</sup>, S. Barnard<sup>1</sup>, D. Che<sup>1</sup>, K. Gunderson<sup>1</sup>, D. Barker<sup>1</sup>, J. Efcavitch<sup>2</sup>, A. Oliphant<sup>1</sup>.* 1) Illumina, Inc., San Diego, CA; 2) Applied Biosystems, Foster City, CA.

Randomly ordered, self-assembled arrays of beads provide a novel and versatile technology platform for intrinsically parallel analysis of complex biological samples. Arrays of beads are randomly assembled onto patterned optical fiber bundles (1). Individual beads have diameters of ~ 3 microns, and ~ 50,000 beads are assembled into a single array. Each bead contains oligonucleotide probes which hybridize with high specificity to complementary sequences in a complex nucleic acid mixture. The identity of each bead, unknown at the time of array assembly, is determined by a hybridization-based decoding procedure.

We have developed a highly multiplexed method for SNP genotyping by combining an oligonucleotide ligation-based assay with read-out on random arrays of universal capture probes (2). In addition, by formatting the miniaturized arrays into a matrix that matches a 96-well microtiter plate, many samples can be processed simultaneously and efficiently in an automated fashion. This combination of technologies provides a system for genetic analysis with the capacity and versatility to match the needs of analysis on a genomic scale. Fundamental aspects of the technology will be reviewed, and the application of these arrays to large-scale SNP genotyping will be discussed.

**Novel multiplex PCR device used for CA-repeat and SNP genotyping.** *E.S. Mansfield<sup>1</sup>, J. Wu<sup>1</sup>, B. Chen<sup>1</sup>, A. Nguyen<sup>1</sup>, D. Dutta<sup>1</sup>, M. Pho<sup>1</sup>, G. Bogdan<sup>1</sup>, D. Albagli<sup>1</sup>, M.T. Cronin<sup>1</sup>, P. Fortina<sup>2</sup>, R. Anderson<sup>1</sup>.* 1) ACLARA BioScience, 1288 Pear Ave. Mountain View, CA 94043; 2) The Children's Hospital of Philadelphia, 310C Abramson Building, 34th and Civic Center Blvd. Philadelphia, PA 19104.

Mapping of Mendelian and complex genetic disorders has been facilitated by availability of dense genetic maps of common sequence polymorphisms. CA-repeat genotyping has successfully confirmed linkage of a susceptibility locus (IBD1) on chromosome 16 for Crohn's disease, a common complex genetic disorder (AJHG 68: 1165-1171, 2001) and led to the identification of the gene by directing both genetic and physical mapping projects (Nature 411: 599-606, 2001). Generally simple sequence repeat markers such as CA-repeats are analyzed as pooled products from multiple single-plex PCR reactions to prevent primer interaction, allelic dropout or appearance of excessive peak suttering that complicate analysis or may lead to typing errors. This process is inefficient since it adds both sample processing steps and causes substantial reagent waste. We describe the use of a novel LabCard device under development at ACLARA to co-amplify a set of 10 CA-repeat markers linked to the IBD1 gene region. More consistent representation of allelic products and better signal-to-noise were observed when the multiplex PCR was carried out in the prototype LabCard device than conventional multiplex tube reactions. Further, the device enables 960 PCR reactions to be simultaneously carried out in industry standard 96-well thermal cyclers. Representative analytical data from the MegaBACE and ABI 3100 capillary array systems will be presented. We have also used prototype devices for multiplex target amplification in primer extension-based SNP genotyping assays.

**SNP-TRAP, a simplified method for detecting SNPs.** *A. Orpana*<sup>1</sup>, *P. Pajukanta*<sup>2</sup>, *A. Palotie*<sup>3</sup>, *L. Peltonen*<sup>2</sup>. 1) Clinical Chem. and Med. Genet., Univ. of Helsinki, Helsinki, Finland; 2) Dept. of Human Genetics and; 3) Dept. of Pathology, UCLA, Los Angeles, Ca.

The production of sufficient amounts of SNP data for genetic analyses of large study samples requires high specificity, sensitivity and accuracy from the analytical method applied. A number of SNP analysis techniques including both solid phase (e.g. arrays) technologies and homogenous assays, as well as electrophoresis-based techniques, have been introduced to accommodate genotyping needs for increasing numbers of SNPs available. In addition to relative complexity of current methods, the high assay and instrumentation costs have become increasingly important concerns. Labelling or modification of oligonucleotide primers with anchoring groups, together with mandatory purification steps, increases the cost, becoming a challenge for high volume genotyping. We have developed a robust and easily applicable assay without the need to purchase kits or expensive special equipment. The SNP-TRAP-method uses standard primers, basic DNA polymerase and a commercial fluorescence dye. The SNP is detected by cyclic extension of a primer in the presence of one of the biotinylated deoxyribonucleotides, trapping of the biotin-dNTP-labelled primer onto streptavidin plates and quantitating the bound oligonucleotide using a single stranded DNA specific fluorescent dye. We employed the SNP-TRAP in the fine mapping of 33 intragenic SNPs in chromosome 1q21, linked to familial combined hyperlipidemia. The SNPs were selected using public and commercial databases, and the primers were designed with the help of several primer design programs available in the web. The majority of the SNPs (75%) resided in the 5 and 3 regions of the genes, often containing analytically challenging DNA structures e.g. long GC stretches and repeats. The unequivocal genotype calling was successful for 70% of SNPs: out of 47 SNPs, 33 were successfully genotyped on the first round. All SNPs were confirmed by an independent method. For SNP-TRP genotyping we developed an allele calling algorithm facilitating easy data production. The reliability and ease of SNP-TRAP provides a new tool for low- to mid-scale SNP screening.

**Phenotype stratification of linkage analysis in primary open-angle glaucoma (POAG): Evidence for age of onset heterogeneity.** *R.R. Allingham<sup>1</sup>, J.L. Wiggs<sup>2</sup>, K.R. LaRocque<sup>1</sup>, M.A. Hauser<sup>1</sup>, F.L. Graham<sup>1</sup>, B. Broome<sup>1</sup>, E.A. del Bono<sup>2</sup>, R. Bailey<sup>3</sup>, J.L. Haines<sup>3</sup>, M.A. Pericak-Vance<sup>1</sup>.* 1) Duke Univ Medical Ctr, Durham, NC; 2) Massachusetts Eye and Ear Infirmary, Boston, MA; 3) Vanderbilt University, Nashville, TN.

We employed phenotype stratification to further examine previously identified chromosomal regions of interest in POAG. Families (n = 86) with at least 2 affected members were analyzed. POAG was defined as: age of onset (AOO) (based on age of first diagnosis (AOD)) > 35yrs and 2 of the following criteria: IOP > 21 mmHg both eyes, glaucomatous optic neuropathy both eyes, and visual field (VF) loss. Families were stratified using the following criteria based on the clinical features of one affected individual: AOD < 45 yr; IOP > 29 both eyes; severe VF loss or glaucoma-related blindness both eyes; or history of glaucoma surgery. Combinations of these risk factors were also analyzed. Linkage analysis of phenotypically stratified family sets was performed on regions on chromosomes 1,4,14,15,17, and 19, identified in a genome-wide scan (Wiggs et al, 2000). Linkage analysis was performed using model-dependent (MLOD) and model-independent (MLS) methods. Stratification of POAG families by IOP, VF loss, history of glaucoma surgery, or combinations of these criteria did not affect the previous linkage results. However, stratification by AOO alone gave increased evidence for linkage to the chromosome 15 candidate region increasing linkage results in 4 adjacent markers (GABRB3, D15S822, D15S217, D15S165) with MLOD and/or MLS scores > 1.5. Maximal MLS and MLOD scores were 2.43 (at D15S217) and 2.32 (at D15S822), respectively. These data provide evidence for genetic heterogeneity based on AOD in families with POAG. Monte Carlo simulation methods will be used to confirm the significance of these findings. Similar findings have been described in other late-onset disorders such as Alzheimer disease and breast cancer. These data suggest that AOO is a potentially useful stratification variable in identifying genes in POAG. Support: The Glaucoma Research Foundation, Barkhouser Glaucoma Research Fund, and NIH Grant EY10886.

**Trp64Arg mutation in the 3-adrenergic receptor gene can predict difficulty in improving body fat distribution, glycemic control and insulin resistance in response to hypocaloric diets in overweight male patients with cardiovascular disease.** *H. Ryu<sup>2</sup>, E.Y. Cho<sup>1</sup>, J.H. Kwon<sup>1</sup>, E.K. Im<sup>1</sup>, Y.S. Jang<sup>1</sup>, O.Y. Kim<sup>2</sup>, J.H. Lee<sup>1,2</sup>, H.Y. Park<sup>1</sup>.* 1) Cardiovascular Genome Center, Seoul, South Korea; 2) Dept of Food and Nutrition.

The purpose of this study was to determine whether Trp64Arg mutation in the 3-adrenergic receptor gene affects the ability of overweight cardiovascular disease (CVD) men to improve body fat distribution, glycemic control and insulin resistance in response to hypocaloric diets. Twenty seven overweight heterozygous CVD men with the genetic variant were compared with 55 homozygous overweight CVD men with the normal allele. There were no significant differences in baseline characteristics such as age, BMI, serum concentrations of lipids, glucose and insulin between the 2 groups. Both groups followed the hypocaloric diet calculated from the total caloric requirement minus 300 kilocalories for 16 weeks. Body weight decreased by 4% ( $P < 0.001$ ) in the normal allele group and 3% ( $P < 0.001$ ) in the Trp64Arg variant group. CVD males with the normal allele showed a decrease in the serum concentrations of triglyceride (-20%), total cholesterol (-7%), LDL cholesterol (-7%) and apolipoprotein B (-8%) and 4-11% decrease in total and visceral fat area at L1 and L4 levels after the weight loss. A weight loss in CVD men without the mutation decreased fasting levels of insulin (-24%), the area under the curve (AUC) for glucose (-11%) and insulin (-23%) and increased the AUC for C-peptide (+35%) during oral glucose tolerance test. CVD men with the Trp64Arg variant showed no significant changes in serum lipids, glucose and insulin levels and visceral fat area, even though calorie intake, physical activity levels and baseline characteristics were similar in both groups. These present results show that the Trp64Arg variant of the 3-adrenergic receptor gene may predict difficulty in improving serum lipid profiles, glycemic control, insulin resistance and visceral fat accumulation in response to hypocaloric diets in overweight patients with CVD.

***CD18, A Positional Candidate Influencing Eosinophilia in the Hutterites. J.M. PINTO<sup>1</sup>, M. ABNEY<sup>1,2</sup>, M.S. MCPEEK<sup>1,2</sup>, D.H. SCHNEIDER<sup>1</sup>, D.K. NOLAN<sup>1</sup>, R. PARRY<sup>4</sup>, A.I. SPERLING<sup>3</sup>, C. OBER<sup>1</sup>.*** 1) THE DEPARTMENTS OF HUMAN GENETICS; 2) STATISTICS; 3) MEDICINE, THE UNIV. OF CHICAGO, CHICAGO, IL 60637; 4) THE DEPARTMENT OF MEDICINE, THE UNIV. OF SOUTH DAKOTA, SIOUX FALLS, SD 57105.

Eosinophilia is a phenotype associated with asthma and atopy. A genome-wide screen for loci influencing the quantitative trait eosinophilia was conducted in the Hutterites, a founder population of European ancestry. This population has several advantages for mapping studies, including extensive linkage disequilibrium (LD), fewer susceptibility alleles, and a communal lifestyle ensuring similar environment. Peripheral blood eosinophils were measured in 580 subjects who are derived from 64 founders and are members of a 1,623-person pedigree. A genome-wide screen identified a linkage to D21S1446 ( $P=0.00018$ ) by homozygosity-by-descent (HBD) mapping, a novel method for mapping QTLs in large inbred pedigrees. In this approach, the relatedness among subjects is accounted for by variance components (Abney et al., 2000, *Am J Hum Genet* 66:629). The b2 integrin chain (*CD18*) locus is 3.91 cM from D21S1446. This gene encodes the b subunit of several leukocyte cell adhesion molecules, including LFA-1. *CD18* has been implicated in antigen induced eosinophil recruitment and Th2 cell homing in animal models of atopic disease and also in eosinophil degranulation *in vitro*. It is thus a promising candidate for allergic disease. Using public database searches and DHPLC we identified three variants in *CD18* in the Hutterites: 3'UTR (C/T), intron 8 (C/T), and exon 11 (A/G). All individuals were genotyped for these variants. Using the HBD method, homozygosity for the 3'UTR C allele was significantly associated with lower eosinophil levels ( $P=0.0027$ ). Neither the other variants nor haplotypes showed an association with this phenotype. These results suggest a direct role for the 3'UTR variant or a variant in LD with the 3'UTR C allele in influencing eosinophil levels in humans. Supported by NIH grants 5-T32-DC00058 and HL-56399.

**Mapping the gene for Noonan syndrome (NSI) to a 200-kb region on chromosome 12q24.2.** O. Bartsch<sup>1</sup>, A. Frensel<sup>1</sup>, D. Novotna<sup>2</sup>, E. Kocarek<sup>2</sup>, V. Krutilkova<sup>2</sup>, M. Havlovicova<sup>2</sup>, P. Goetz<sup>2</sup>, G. te Kronnie<sup>3</sup>, E. Pantchechnikova<sup>4</sup>, L. Musante<sup>4</sup>, H.H. Ropers<sup>4</sup>, V. Kalscheuer<sup>4</sup>. 1) Institut für Klinische Genetik, Technische Universität Dresden, Germany; 2) Inst. of Biology and Medical Genetics, 2nd Medical Faculty, Charles University, Prague, Czech Republic; 3) Dept. of Pediatrics, Lab of Oncology, University of Padova, Italy; 4) Max-Planck-Institute for Molecular Genetics, Berlin, Germany.

Noonan syndrome (NS) is a well known autosomal dominant disorder. Jamieson et al. (Nature Genetics 1994;8:357-60) mapped a gene for Noonan syndrome to chromosome 12q between D12S84 and D12S366, and demonstrated non-linkage in one family (genetic heterogeneity). Legius et al. (EJHG 1998;6:32-7) narrowed down the interval to a 5-cM region on chromosome 12q24 between markers D12S84 and D12S1341. We report a boy with NS and a cytogenetically balanced translocation of t(2;12)(q37;q24). The clinical diagnosis of NS is definite, but interestingly the 9-yr-old boy displays a partial phenotype without heart defect and without developmental delay. He demonstrates a suggestive face with ptosis (right eyelid only), low-set rotated ears, short neck, and marked webbing of the neck. Additional signs include hirsutism, broad thorax, mild pectus excavatum, small penis, cubiti valgi, height below 3rd centile (-3.5 SD), hearing loss, and retardation of bone age. His intelligence is above-normal with excellent performance in school. We established a lymphoid cell line and computed regional maps with NCBI Entrez Map View. Using FISH mapping and a panel of BAC and YAC clones, we identified BAC clones spanning the breakpoints on chromosomes 2q37 and 12q24, respectively; the breakpoint on 12q24 resides within the 5-cM region between D12S84 and D12S1341. There was no evidence for a chromosomal microdeletion. Our results place the gene for Noonan syndrome (NSI) on chromosome 12q24.2 into or near the breakpoint-spanning BAC clone measuring 187 kb in length. Additional FISH mapping studies followed by positional cloning are in progress.

**Fine Mapping of Autosomal Recessive Progressive Cataract.** *G.D. Billingsley<sup>1</sup>, A.D. Paterson<sup>3</sup>, F.L. Munier<sup>4,5</sup>, A. Balmer<sup>5</sup>, D.F. Schorderet<sup>4</sup>, E. Héon<sup>1,2,3</sup>.* 1) Vision Science Research Program; 2) University of Toronto, Department of Ophthalmology; 3) The Hospital for Sick Children Research Institute; Toronto, Ontario, Canada;; 4) Unit of Oculogenetics and Division of Medical Genetics, CHUV; 5) Hôpital Ophthalmique Jules Gonin, Lausanne, Switzerland.

Cataracts constitute the leading cause of blindness worldwide and the mechanisms of lens opacification remain unclear. The genetics of this condition are complex with 18 loci for autosomal dominant cataract and 2 for autosomal recessive cataract identified to date. Disease causing mutations have been identified in 12 genes. Using a large 3 generation family, we recently mapped a third locus for autosomal recessive cataract to a 14 cM disease interval at 9q13-q22. This unique autosomal recessive cataract is characterized by primarily cortical pulverulent (dust-like) opacities with progressive nuclear and posterior subcapsular involvement and early nuclear sclerosis (browning of the nucleus). Cataract surgery was usually required by the age of 40 years to restore visual function. Further genotype and haplotype analysis has narrowed the disease interval to a 10 cM region defined by D9S1843 and D9S1680 and a potential area of homozygosity that would narrow the interval to 4 cM. This is the second autosomal recessive locus identified but the only one associated with a non-congenital progressive cataract. Also, this new locus does not correspond to a known candidate locus in mice or human. Analysis of the eighteen genes identified in the 10 cM interval suggests that the ARPC gene will be novel. The molecular characterization of this phenotype may shed light on the complex cascade of events modulating lens differentiation and lens opacification in the more common age-related cataracts.

**Narrowing the CLN6 region on chromosome 15.** *H. Gao*<sup>1</sup>, *J. Espinola*<sup>1</sup>, *T. Lerner*<sup>1</sup>, *R-M. Boustany*<sup>2</sup>, *M.E. MacDonald*<sup>1</sup>. 1) Molecular Neurogenetics Unit, Massachusetts General Hospital, Charlestown MA; 2) Pediatric Neurology, Duke University Medical Center, Durham, NC.

Neuronal ceroid lipofuscinoses (NCLs) are an inherited group of fatal neurodegenerative disorders characterized by loss of vision and seizures and the accumulation of an autofluorescent lipopigment in neurons and other cells. The NCLs comprise eight forms classified initially by clinical symptoms and age at onset but now recognized as being due to mutations in distinct genes (CLN1- CLN8). CLN6, the gene for a variant late infantile NCL (vLINCL), has been mapped to chromosome 15q21-23 by homozygosity mapping (Hum Mol Genet 6:591-595, 1997; Neurogenetics 1:217-222, 1998). The genetic region has been progressively narrowed using recombination analyses and homozygosity mapping from 12 cM to 10 cM, between D15S1020 and AFM142VC1 (Mol Genet Metab 66:332-336, 1999), and then to 4 cM between D15S125 and D15S1000 (Mol Genet Metab 66:329-331, 1999). Using multiallele markers, developed from dinucleotide repeat sequences from across the minimal genetic region, we have identified a major haplotype, shared by affected chromosomes from 10 vLINCL families. The coding regions of six candidate genes have been scanned for mutation by single-strand conformational polymorphism (SSCP) analysis. Furthermore, by generating new polymorphic markers from dinucleotide repeats in the genomic DNA sequence we have identified a shared sub-region of the major haplotype that narrows the minimal CLN6 region to less than 1cM. Thus, our results suggest that many vLINCL families may share the same CLN6 defect and, by refining the candidate region significantly focus efforts to identify the CLN6 defect.

**Variations in the CAPN10 gene associate with non-insulin dependent diabetes in Icelanders.** V. Emilsson<sup>1</sup>, S. Halldorsson<sup>1</sup>, G. Thorleifsson<sup>1</sup>, R. Benediktsson<sup>2</sup>, G. Sigurdsson<sup>2</sup>, A. Kong<sup>1</sup>, K. Stefansson<sup>1</sup>, J. Gulcher<sup>1</sup>, V. Gudnason<sup>2</sup>, I. Reynisdottir<sup>1</sup>. 1) deCode Genetics Inc., Lynghals 1, 110-Reykjavik, Iceland; 2) The Icelandic Heart Association, Lagmuli 9, 108-Reykjavik, Iceland.

Approximately 4% of the adult population is affected by non-insulin dependent diabetes (NIDDM), which is characterized by insulin resistance coupled with pancreatic b-cell dysfunction and accompanying chronic hyperglycaemia. The disease is commonly associated with obesity, hypertension and dyslipidemia. Recently, an intronic variation (UCSNP43, G/A) in the calpain 10 gene (CAPN10 maps within the NIDDM1 locus at 2q), encoding a cysteine protease, was found to be significantly associated with NIDDM susceptibility among Mexican Americans. Moreover, the at-risk genotype (G/G) has been associated with decreased rates of insulin-stimulated glucose disposal as well as reduced CAPN10 mRNA expression in skeletal muscle. We have analysed association of variations in CAPN10 with high fasting plasma glucose (FG<sup>37</sup>mM) in Icelandic subjects. The study groups consist of 285 NIDDM patients (FG<sup>37</sup> mM; age (yr)=71±11; BMI=27±4) and a random sample of 267 unrelated and undiagnosed subjects. Frequencies of five intronic variations in the CAPN10, including the causal variation UCSNP43, were genotyped by the fluorescence polarization method or gel electrophoresis. A major allele frequency of the different variations in the random sample was between 64 and 90%. The association with the variation in UCSNP43 is statistically significant (two-sided p-value=0.027), whilst the association with a 32 bp repeat variation (UCSNP19) and an A/G variation (UCSNP62) was marginally significant (p=0.056 and p=0.055, respectively). Frequencies of the associated at-risk allele UCSNP43, in both study groups, were similar to that found among Mexican Americans. Moreover, the at-risk allele conferred an estimated population-attributable risk that accounts for 26% of NIDDM cases in the study population. Carriers of one or both at-risk alleles had an increased risk, compared to non-carriers, or 11 and 61%, respectively. Thus, by independent observations, our study confirms that variations in CAPN10 influence susceptibility to NIDDM.

**Searching for diabetic nephropathy susceptibility genes in the Finnish population using linkage and association studies.** *B. He<sup>1</sup>, A-M. Österholm<sup>1</sup>, J. Pitkäniemi<sup>2</sup>, L. Liu<sup>1</sup>, T. Berg<sup>1</sup>, J. Tuomilehto<sup>2</sup>, K. Tryggvason<sup>1</sup>.* 1) Division of Matrix Biology, MBB, Karolinska Institute, Stockholm, Sweden; 2) The Finnish National Public Health Institute, Helsinki, Finland.

Microvascular changes (microangiopathy) are one of the main complications of diabetes and they are considered to be the primary cause of kidney and eye damages that affect diabetic patients. Diabetic nephropathy (DN) is characterized by thickening of the glomerular basement membrane, and clinically it is manifested by persistent proteinuria and end stage renal disease. DN affects 35% of patients with insulin-dependent diabetes mellitus (IDDM). Family studies have provided evidence for genetic determinants of nephropathy. So far, candidate gene studies have not been successful and no genes have been reported to be directly associated with DN. A locus linked to DN on chromosome 3q has been reported in an American Caucasian population. This finding was confirmed by our ongoing genome wide scan. In follow-up linkage studies, we genotyped 15 markers spanning 64 cM on chr3q in 50 Finnish DSPs. A MLS of 3.0 was obtained by multipoint linkage analysis. Subsequently, 1-lod-unit support interval of 9 cM was determined. A physical map (about 9.7 Mb) of the critical region was constructed based on the Celera database. In total, the database revealed approximately 140 genes, both identified and predicted. Twenty-four multi-allelic markers in this region were localized, and used for further population-based association studies. In a dataset of 184 Finnish cases and 83 controls, two adjacent markers showed statistically significant association ( $p=4.6 \times 10^{-7}$  and 0.01). We identified and localized 5 new repeats within these two adjacent markers by sequence searching. Two of them also showed significant association. Therefore, the critical region most likely bearing the gene might be 300 Kb in length. By DNA analysis, a known gene and several other predicted genes were found in the region. The known gene is a very promising candidate, since expression was detectable in kidney. An intronic SNP of the known gene gave a strong association ( $p=0.0003$ , OR=2.0). Association studies in a Danish population are ongoing.

**Analysis of chromosome 1 for SLE susceptibility loci in a new set of 69 multicas families.** *B. Johanneson<sup>1</sup>, G. Lima<sup>2</sup>, M. Alarcon-Riquelme<sup>1</sup>, Collaboration on the genetics of SLE<sup>1</sup>, BIOMED II collaboration on the genetics of SLE and Sjogrens Syndrome<sup>1</sup>.* 1) Dept. of Genetics and Pathology, Uppsala University, 751 85 Uppsala, Sweden; 2) Dept. of Immunology/Rheumatol., Inst. Nacl. Cien. Med. Nutr., 1400 Mexico DF, Mexico.

**AIM** SLE is a complex and heterogeneous disease with a genetic component. Combinations of susceptibility genes are likely to exist in different populations. Several susceptibility loci have been identified in different genomescans, with varying results. Our aim was to confirm susceptibility regions on chr 1, using a new set of 69 multicas families (422 individuals ) from defined populations, and determine if ethnical differences lie behind the variable results.

**RESULTS** A total of 5 regions with markers showing suggestive linkage ( $LOD > 2,2$ ) were detected using parametric two-point linkage analysis on 41 microsatellites for chr. 1. All regions have been reported previously. Two show contributions from all populations (1q23-24 and 1q25-31). 1p36 and 1p21-22 were contributed mainly from South European and American families (mainly from Mexico and Colombia). The 1q41-44 region has contributions from mainly European and Chinese families. The study shows that by using clear defined populations, it is possible to determine the genetic effect contributed by each population to each susceptibility region.

**Association studies involving multiple variant alleles of the low affinity Fcγ Receptors.** *V. Magnusson<sup>1</sup>, J. Odeberg<sup>2</sup>, M.E. Alarcón-Riquelme<sup>1</sup>*. 1) Dept. of Genetics and Pathology, Rudbeck laboratory, Uppsala University, Sweden; 2) Dept. of Biochemistry and Biotechnology, Royal Institute of Technology, Sweden.

The aim with our study is to determine the distribution of FcγRs alleles in ethnically diverse populations and investigate their influence on susceptibility for developing autoimmune disorders, such as rheumatoid arthritis (RA) and systemic lupus erythematosus (SLE). RA and SLE are complex systemic disorders whose expression is influenced by multiple genes and environmental factors. Identification of genetic risk factors underlying specific disease manifestations, for example lupus nephritis would be of great importance in order to dissect the genetic component in these diseases. We have focused on the low-affinity receptors for IgG because of their importance in the immune response and regulation. Variant genotypes of these receptors have been reported to differ between disease and control populations. Several single nucleotide polymorphisms (SNPs) at the FcγRIIA, FcγRIIA and FcγRIIB loci were analysed, including SNPs of functional or clinical importance as well as new SNPs identified by in silico search and sequencing. The study populations consist of 300 Mexican and Swedish RA patients, 300 Mexican and Swedish SLE patients, and 400 ethnically matched controls, for each group. Genotyping was done by allele-specific PCR, restriction enzyme digestion or pyrosequencing. P-values and odds ratios (OD) with 95% confidence interval were estimated using the SAS procedure FREQ. We have found an association in the Swedish as well as in the Mexican population between the R-allele at the FcγRIIA-131 locus and SLE, ( $p=0.01$  and  $p=0.001$ , respectively) in female patients. This association was not found in the patients with RA.

**Family based association tests for censored data with pedigrees.** *O. Mokliatchouk.* Mathematics & Computer Science, Drexel University, Philadelphia, PA.

Family based association tests are currently developed for categorical, quantitative and censored traits with nuclear families and for categorical and quantitative traits with pedigrees. Although these methods can be applied to data on traits with variable age at onset and pedigrees, they are not efficient, since they do not incorporate all available information. The proposed tests are extensions of a family based association test to data on traits with variable age at onset and pedigrees. Proportional hazards regression models are used to motivate the methods. Conditioning on the minimal sufficient statistics for association in the absence of linkage is used to avoid confounding due to factors other than linkage. The tests involve estimating survival function of the censored trait given the observed marker genotypes and unobserved trait genotypes. A theory for such estimation is developed. Results of simulations that explore the performance of these procedures are described. The procedures are illustrated through an analysis of data on APOE genotype, a mutation of alpha-2 macroglobulin gene (A2M) and Alzheimers disease.

**Candidate genes for late-onset Alzheimers disease on chromosome 12.** *E. Luedeking-Zimmer*<sup>1</sup>, *S.T. DeKosky*<sup>1,2</sup>, *M.I. Kamboh*<sup>1,2</sup>. 1) Human Genetics, University of Pittsburgh, Pittsburgh, PA; 2) Psychiatry, University of Pittsburgh, Pittsburgh, PA.

Alzheimers disease (AD) is a genetically heterogeneous neurodegenerative disorder. To date, apolipoprotein E (apoE) is the only universally accepted susceptibility gene for late-onset AD. ApoE accounts for less than 50% of the risk of late-onset AD, indicating the likelihood of other unknown susceptibility loci. Recently, linkage studies have provided strong evidence for a late-onset locus located on chromosome 12 among non-APOE\*4 carriers. A broad 50 cM pericentromeric region between markers D12S358 (12p13) and D12S1632 (12q13) is the predicted region of a putative gene(s). In this study, we have examined 9 polymorphisms in 5 candidate genes located in this region in a large case-control cohort (597 cases and 530 controls). The examined candidate genes include, -2 macroglobulin (A2M), complement component 1R (C1R), and oxidized-LDL receptor (OLR1) in the 12p13 region, and LDL receptor-related protein (LRP1), and transcription factor LBP-1c/CP2/LSF in the 12q13 region. No association was observed with the 2, 3, and 1 polymorphisms examined in the A2M, LRP1, and C1R genes, respectively. A modest association was observed with a 3 UTR polymorphism in the transcription factor LBP gene with and odds ratio (OR) of 0.65 (95% CI 0.45-0.96;  $p=0.03$ ). All exons and intron-exon boundaries of the OLR1 gene were screened for mutation detection by D-HPLC and DNA sequencing and we identified 3 novel polymorphisms in intron 4, intron 5 and in the 3UTR. All three polymorphisms were in linkage disequilibrium and showed a significant association with AD among non-APOE\*4 carriers, with the strongest effect observed for the 3 UTR polymorphism (OR=0.55, 95% CI 0.36-0.83;  $p=0.005$ ). Our data suggest the existence of two putative genes for AD on chromosome 12p and 12q regions.

**A Genome-Wide Scan of QTLs for Obesity-Related Phenotypes Using Sibling Pairs.** *T. Niu*<sup>1,2</sup>, *Z. Fang*<sup>3</sup>, *L. Duprat*<sup>4</sup>, *X. Xu*<sup>1</sup>, *D. Chen*<sup>5</sup>, *J. Jin*<sup>2</sup>, *S. Lewitzky*<sup>4</sup>, *J. Meyer*<sup>4</sup>, *X. Xu*<sup>1,2,6</sup>. 1) Prog Population Genetics, Harvard Sch Public Health, Boston, MA; 2) Institute of Biomedicine, Anhui Medical University, Hefei, Anhui, China; 3) Anqing Public Health Bureau, Anqing, Anhui, China; 4) Genetics Division, Millennium Pharmaceuticals, Inc., Cambridge, MA; 5) Anhui Meizhong Institute for Biomedicine and Environmental Health, Anqing, Anhui, China; 6) Channing Laboratory, Department of Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA.

To identify quantitative trait loci (QTLs) that contribute to obesity, we performed a genome-wide scan of obesity-related phenotypes using data collected from a total of 154 nuclear families (407 siblings) in Anqing, China, resulting in 416 concordant or discordant sibpairs for body mass index (BMI) (i.e., the siblings are either at the lowest or the highest decile of the age- and gender-specific BMI distributions in a general population of the same community). A total of 502 microsatellite markers were genotyped in 22 autosomes. Using the XWXW computer program that implements the unified Haseman-Elston algorithm, we detected several moderate linkage signals for covariate-adjusted BMI on chromosomes 6p ( $Z = 2.84$ ,  $p=0.002$ ), 7q ( $Z=2.82$ ,  $p=0.002$ ), and 17q ( $Z=2.72$ ,  $p=0.003$ ). With respect to covariate-adjusted waist circumference, a peak was observed on chromosome 2p ( $Z=2.82$ ,  $p=0.002$ ). Regarding covariate-adjusted waist-to-hip ratio, a suggestive signal was found on chromosome 14q ( $Z=2.61$ ,  $p<0.005$ ). Follow-up studies using denser markers are needed to pursue those linkage signals located near known biological candidate genes for obesity, and those that overlap with positive linkages reported previously.

***IGF2R as a candidate gene for autoimmune diabetes.*** *J.A. McCann, Y. Xu, L. Marchand, C. Polychronakos.*  
Endocrine Genetics, McGill University Health Center, Montreal, Quebec, Canada.

Genetic susceptibility to Type I diabetes is a polygenic trait. The HLA locus on 6p21 (IDDM1) and the insulin locus on 11p15.5 (IDDM2) together account for a little more than half the genetic effect. The remaining genetic susceptibility is determined by several other loci with smaller effects, some of which have been localized by sib-pair linkage analysis. Among these is IDDM8 on 6q26. Identification of the gene involved in IDDM8 requires systematic scanning of the region encompassed. We selected IGF2R, encoding the IGF-II receptor, because of the importance of the IGF system in both beta cell regeneration and functioning of the immune system. Using eight polymorphisms found throughout the IGF2R, we studied a group of diabetic children from the Montreal area, including those of French Canadian background, a homogenous population in which the small number of ancestral chromosomes maximizes the probability of finding linkage disequilibrium between markers and disease. Deviation of allele transmission from heterozygous parents to diabetic children from the expected 50% was examined. Since IGF2R is imprinted in the mouse, and under some circumstances in the human, we examined paternal and maternal transmissions separately. Of the polymorphisms studied, only one in exon 16 showed a transmission disequilibrium between mothers and fathers to their diabetic children. This effect was most strongly seen in the French Canadian population. Of the 23 heterozygous French Canadian mothers, 17 transmitted the G allele and only 6 transmitted the A allele ( $p=0.017$ ). In fathers, the corresponding numbers are 10 and 10 (NS). When non-French Canadian populations were examined, the same results were found in families of Italian descent but not in an internationally mixed sample set. Our data suggest that IGF2R, or a near-by imprinted gene in linkage disequilibrium with our marker, may be the gene involved in IDDM8. If it is IGF2R itself, it must be universally imprinted in some tissue and/or developmental stage crucial to autoimmune diabetes.

**Candidate gene polymorphisms and type 2 diabetes among Samoans: significant associations at HNF-1b and GCK loci.** *D.T. Smelser<sup>1</sup>, X. He<sup>1</sup>, S.T. McGarvey<sup>2</sup>, D.E. Weeks<sup>3</sup>, R. Indugula<sup>1</sup>, R. Deka<sup>1</sup>.* 1) Environmental Health, University of Cincinnati, Cincinnati, OH; 2) International Health Institute, Brown University, Providence, RI; 3) Human Genetics, University of Pittsburgh, Pittsburgh, PA.

The contemporary adult Samoan population of Polynesia has a very high prevalence of type 2 diabetes, ranging from 3 and 5% among men and women, respectively, in the independent country of Samoa to 25 and 15% among men and women, respectively, in American Samoa. We have tested for association between type 2 diabetes and eight candidate gene polymorphisms (PC1, PPAR $\gamma$ 2, FABP2, HNF-1b, GCK, NPY, ADR $\beta$ 3, UCP3) in a sample of 96 controls without type 2 diabetes and 180 affected individuals. The controls were derived from both polities, which showed no allele frequency differences; the affected individuals were drawn from American Samoa. Genotype frequencies were found to be in conformity with Hardy-Weinberg (H-W) expectations excepting the affected samples at the FABP2 locus. We performed a chi-square based association test and Fisher's Exact Test using genotype frequencies, which showed significant difference between cases and controls at two loci, HNF-1b ( $p = 0.027$ ) and GCK ( $p = 0.009$ , two-tailed). Both of these genes are implicated in the pathway of glucose metabolism (Bach et al. 1991. *Nucleic Acids Res* 19:3553; Matschinsky 1990. 39:647). Interestingly, the affected samples at the FABP2 locus show significant deviation from H-W proportions, whereas the controls are at the expected equilibrium. This is indicative that the FABP2 locus may be associated with type 2 diabetes among the Samoans. We are testing other candidate loci as well as looking at other polymorphisms within each locus. Supported by NIH grants AG09375, HL52611, DK55406, and DK59642.

**Statistical Analysis of Direct Identity-by-descent Mapping.** *B. Yakir*<sup>1</sup>, *D. Siegmund*<sup>2</sup>. 1) Dept Statistics, Hebrew Univ, Jerusalem, Israel; 2) Dept. of Statistics, Stanford Univ, Stanford, CA.

Genomic mismatch scanning (Nelson et al., 1993) allows one to determine directly, without genotyping, the regions inherited identical-by-descent (IBD) by pairs of relatives, including pairs of distant relatives of unknown relationship. Application of this technique to ostensibly unrelated, but putatively distantly related, pairs of affecteds has been suggested by Cheung et al. (1998) as a method for fine genetic mapping by identification of regions shared IBD by a larger number of affected pairs than would be expected by chance. Several different methods for statistical analysis of such data were discussed by Grant et al. (1999) under restrictive assumptions about the form of the data. In this paper we (i) model the alternating genomic regions of IBD and non-IBD of a relative pair as a continuous time two state Markov chain having intensities determined by the relationship (which in general is unknown), (ii) derive the score statistic to test for linkage, (iii) describe a method to approximate chromosome wide or genome wide p-values, and (iv) obtain confidence regions for map location. To avoid problems associated with lack of knowledge of the relationship of the affected pairs and hence the intensities in (i), we develop our p-value approximation and confidence regions by conditioning on an appropriate sufficient statistic for each pair, namely the IBD status at an initial position on a chromosome, the proportion of the chromosome shared IBD, and the number of transitions between regions of sharing and non-sharing. This allows us in effect to estimate important parameters of the average relationship in our sample from the observed pattern of IBD sharing without directly estimating the relationships themselves.

**Linkage disequilibrium (LD) domain mapping identifies PSORS1 candidate regions for psoriasis susceptibility.**

*C.D. Veal<sup>1</sup>, E.K. Heath<sup>1</sup>, M.H. Allen<sup>2</sup>, M. Ameen<sup>2</sup>, M. Munro<sup>1</sup>, D. Tillman<sup>4</sup>, D. Burden<sup>4</sup>, S. Powis<sup>3</sup>, J.N.W.N. Barker<sup>2</sup>, R.C. Trembath<sup>1</sup>.* 1) Department of Genetics, University of Leicester, Leicester, United Kingdom; 2) St John's Institute of Dermatology, King's College, London, United Kingdom; 3) Royal Free Hospital, London, United Kingdom; 4) Department of Dermatology, University of Glasgow, Scotland, United Kingdom.

Psoriasis is a complex inflammatory skin disease affecting on average 2% of all populations, it is characterised by keratinocyte hyperproliferation, immune cell infiltration and angiogenesis. Previous genome wide scans have identified a number of putative susceptibility loci, with linkage to a region at the boundary of the MHC class III/I at 6p21 representing the major and consistent finding. LD mapping has refined this to an approximately 300kb region around HLA-C. To further characterise this region we have sequenced a total of 64kb between and including HLA-C and the CDSN in 8 psoriatics to identify SNPs that may be of biological relevance to psoriasis. SNPs that were identified with a minor allele frequency greater than 0.2 within the coding region of the characterised genes OTF3, SC1, HCR and CDSN were then genotyped in a UK cohort of caucasian affected offspring trios (n=175) and family based tests of association were performed. Strong allelic association was seen for SNPs within OTF3 ( $p=4.3 \times 10^{-6}$ ) HCR ( $p=8.7 \times 10^{-7}$ ) and CDSN ( $p=4.9 \times 10^{-6}$ ). Specifically association arises through SNPs leading to non-conservative amino acid substitutions with exception of OTF3 in which the associated SNP is silent. Analysis of LD between SNPs in the unrelated parents showed strong LD between OTF3 and HCR ( $D'=0.997$ ) explaining the association with the silent SNP in OTF3, however both these genes show a lack of LD with CDSN SNP 1243 ( $D'=0.015$ ) in this cohort indicating that association at CDSN is independent of HCR/OTF3. Association of these non-conservative changes at the protein level identify both HCR and CDSN as potential functional candidates. A further 100 SNPs have been identified in this region enabling definition of the extent of linkage disequilibrium in this region and elucidate the relationship between these genes and polymorphisms to psoriasis.

**LINKAGE AND ASSOCIATION OF A FUNCTIONAL SINGLE NUCLEOTIDE POLYMORPHISM (SNP) IN THE FcgRIIA GENE WITH SLE.** *J.C. Edberg<sup>1</sup>, C.D. Langefeld<sup>2</sup>, K.L. Moser<sup>3</sup>, J. Kelly<sup>4</sup>, J.M. Kaufman<sup>4,5</sup>, S.S. Rich<sup>2</sup>, J.B. Harley<sup>4,5</sup>, R.P. Kimberly<sup>1</sup>, the SCOR in Genetics in SLE<sup>1,2,3,4,5</sup>.* 1) Univ of Alabama at Birmingham, AL; 2) Wake Forest University, Winston-Salem, NC; 3) Univ Minnesota, Minneapolis, MN; 4) Oklahoma Med Res Foundation, Oklahoma City, OK; 5) Univ Oklahoma Health Sci Ctr & US Dept Veterans Affairs, Oklahoma City, OK.

Genome scans of multiplex SLE families have identified multiple loci linked to SLE. Two candidate genes in the 1q23 region, FcgRIIA and FcgRIIA, contain SNPs in the coding region that alter the binding of IgG. Case-control studies provide evidence of an assoc between these SNPs and SLE. To test for family-based assoc, we genotyped and analyzed 126 multiplex families with SLE (61% Cauc, 32% Afr-Amer); genotyping was done independently at 2 sites. Multipoint non-parametric linkage analysis of these SNPs provides evidence for linkage at both loci (FcgRIIA:NPL score=2.54  $p < 0.006$ ; FcgRIIA: NPL score=2.62,  $p < 0.005$ ). Analysis of family-based assoc using the TDT and the PDT revealed strong assoc at the FcgRIIA locus with little or no evidence of assoc at the FcgRIIA locus. These two SNPs are in significant linkage disequilibrium ( $p < 0.0009$ ). There was no evidence of an assoc with an extended haplotype ( $p = 0.06$ ). Based on these results, the association between these SNPs and SLE is primarily due to the FcgRIIA SNP where the risk allele was transmitted 61 times and not transmitted 28 times (TDT-based O.R.=2.17,  $p = 0.005$ ). This study implicates FcgRIIA in susceptibility to SLE.

	Caucasians	(n=77)	Afr-Amer	(n=40)	All	(n=126)
	TDT	PDT	TDT	PDT	TDT	PDT
FcgRIIA	p=0.388	p=0.097	p=0.074	p=0.437	p=0.134	p=0.089
FcgRIIA	p=0.012	p=0.044	p=0.016	p=0.020	p=0.0005	p=0.002

**Evaluation of expression and genetic variations of Th1-type cytokines in peripheral blood mononuclear cells from asthmatic patients in Iceland.** *I.F. Birkisson<sup>1</sup>, U.S. Bjornsdottir<sup>1</sup>, E. Halapi<sup>2</sup>, D.L. Shkolny<sup>2</sup>, T. Arnason<sup>2</sup>, D. Gislason<sup>1</sup>, T. Gislason<sup>1</sup>, H. Hakonarson<sup>1,2</sup>.* 1) Medical Department, University of Iceland, Reykjavik, Iceland; 2) deCODE Genetics Inc., Reykjavik, Iceland.

Recent evidence support the concept that deficiency in the Th1 cytokine pathway is associated with increased susceptibility to allergic airways disease such as asthma. This study examined whether i) single nucleotide polymorphisms (SNPs) exist in the promoter region of the two subunits forming the IL-12 gene in asthmatic patients, ii) mRNA and protein expressions of STAT4, IL-12, IFN-g, and their receptors are altered in asthma, and; 3) genetic linkage to the IL12 gene is present in asthmatic families in Iceland. The promoter region of the IL12 gene was sequenced in 94 asthmatic patients and 94 non-asthmatic controls. Linkage was examined in 140 families that included over 400 asthmatic patients and 400 of their unaffected relatives. We sequenced 3.5 kb of genomic DNA and examined for induced changes in mRNA and protein expressions of isolated PBM cells in 15 asthmatic patients and 15 non-asthmatic controls, using kinetic PCR, ELISA and flow cytometry. The patients phenotypes were determined by 3 Allergists in accordance with the ATS criteria. Age ranged from 18-64 years. Spirometry, IgE levels, methacholine challenge test and skin test was performed in all patients. The results demonstrate, no evidence of alteration of the Th1 pathway in our asthmatic patients. No polymorphism was detected in the two promoter regions of the IL-12 gene and no linkage was detected to microsatellite markers in close association of the two IL-12 genes, on chromosomes 3 and 5 respectively, in the asthmatic patients. Moreover, we found no differences, in neither mRNA or protein expressions in the IL-12 pathway, between patients and controls, using the experimental techniques described above. Taken together, we found no evidence of altered Th1 type cytokine expression or action in our asthmatic patients, and we uncovered no genetic differences or linkage to the IL-12 gene. We conclude that this study fails to support the concept that decrease in Th1 type cytokine response is a primary event in asthma.

**Comparison of Haseman-Elston Methods for Assessing Parent-of-Origin Effects in Linkage Analysis.** *R.L.*

*Hanson, S. Kobes, R.S. Lindsay, W.C. Knowler. DAES, NIDDK, Phoenix, AZ.*

We recently developed a method to assess parent-of-origin effects in linkage analysis of quantitative traits in sibships. This method can use variance components (VC) or Haseman-Elston (HE) methods, but the VC method is more powerful than the classic HE. As recently proposed modifications of the HE method enhance its power for nonimprinted loci, we analyzed simulated data to assess the properties of these modified methods for assessment of parent-of-origin effects.

Data were simulated for a variety of models for 956 siblings in 263 nuclear families who had participated in a linkage study. The HE linkage method involves regression analysis of a function (F) of the trait values in the sibling pair against the proportion of marker alleles shared identical by descent, partitioned into maternally- and paternally-derived components. In the classic HE, F is the squared trait difference (HE-SD). We evaluated proposed modifications in which F is the trait product corrected for the grand mean (HE-PGM), the product corrected for the family-specific mean (HE-PFM) or a weighted combination of the squared difference and squared sum (HE-COM).

Power of the HE-PFM and HE-COM methods was comparable to the VC method, while HE-SD and HE-PGM were somewhat less powerful. For example, in 500 replicates of a maternally-expressed locus (heritability=30%), LOD > 3 with the maternal chromosome was observed in 84% of VC, 72% of HE-SD, 75% of HE-PGM, 86% of HE-PFM and 84% of HE-COM analyses, and none of the methods had LOD > 3 to the paternal chromosome in any replicate. However, in data generated for a nonimprinted locus, type I error rates for a test of equal parental effects were inflated for all HE methods: a nominally significant result ( $p < 0.05$ ) was observed for 10% of HE-SD, 11% of HE-PGM, 14% of HE-PFM and 12% of HE-COM analyses, compared with 4% of VC analyses.

These analyses suggest that these modifications of the HE method do not appear to be superior to the VC method for assessing parent-of-origin effects.

**Nonparametric disequilibrium mapping of functional sites using haplotypes of multiple tightly linked single-nucleotide polymorphism (SNP) markers.** *R. Cheng<sup>1</sup>, J.Z. Ma<sup>2</sup>, F.A. Wright<sup>3</sup>, S. Lin<sup>4</sup>, X. Gao<sup>3</sup>, D. Wang<sup>3</sup>, R.C. Elston<sup>5</sup>, M.D. Li<sup>1</sup>.* 1) Department of Pharmacology; 2) Department of Preventive Medicine, University of Tennessee, Memphis, TN; 3) Division of Human Cancer Genetics; 4) Department of Statistics, Ohio State University, Columbus, OH; 5) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH.

When a gene has been implicated in causing disease, it is desirable to exhaustively survey allelic variation within it for any association to disease. As the genotyping speed and efficiency of single nucleotide polymorphisms (SNPs) increase, such studies will fuel increasingly comprehensive tests of the hypothesis that common variants contribute significantly to the risk of common diseases. Using the SNP map, it becomes possible to evaluate the extent to which common haplotypes contribute to the risk of disease. In this study we propose a procedure for mapping functional sites or regions within the sequence data of candidate genes using multiple SNPs. Based on a case-parent trio family design, we use expectation maximization (EM) algorithm-derived haplotype frequency estimates of multiple tightly linked SNPs from both unambiguous and ambiguous families to construct a contingency statistic *S* for linkage disequilibrium analysis. In our procedure, window searching for functional sites or regions can cover any number of loci without limitation except for that of computer storage. Within a window, all possible widths of haplotypes are utilized to find the maximum statistic *S* for each site (or locus). Furthermore, this method can be applied to regional or genome-wide scanning in order to study linkage disequilibrium using SNPs. The proposed procedure was applied to scan simulated sequence data and we found that the functional sites for candidate genes could be successfully identified.

**Lack of association between Common ATM polymorphisms and breast cancer risk.** *F. Durocher*<sup>1,2</sup>, *L. Williams*<sup>2</sup>, *S. McBride*<sup>2</sup>, *J. Hall*<sup>3</sup>, *S. Angele*<sup>3</sup>, *B. Ponder*<sup>2</sup>, *A. Dunning*<sup>2</sup>, *D. Easton*<sup>1</sup>. 1) CRC Genetic Epidemiology Unit, and; 2) Department of Oncology, University of Cambridge, Strangeways Research Laboratory, Worts Causeway, Cambridge, UK, CB1 8RN; 3) International Agency for Research on Cancer, 150 Cours Albert Thomas, 69008, Lyon, France.

Ataxia-telangiectasia (AT) is a recessive syndrome characterized by cerebellar degeneration, immunological defects and cancer predisposition. Most cases of the disease are the result of mutations in the ATM gene. Epidemiological studies have shown an increased risk of breast cancer in obligate heterozygotes in AT families. In the present study, we investigated the potential association of sporadic breast cancers with three common ATM polymorphisms: P1054R in exon 23, D1853N in exon 37 and IVS\_48 in intron 48.

Genotypes in these three polymorphisms were determined in a series of up to 2592 sporadic breast cancer cases and 1964 controls subjects, from the East Anglian region, UK, by a fluorescent method. The associations between specific genotypes and the risk of developing breast cancer were performed by logistic regression analysis to calculate odds ratio (OR) and floating confidence intervals (FCI).

No significant association with breast cancer was found with any of the three polymorphisms analysed individually; (ORs: 1.25, 95% CI 0.82-1.75; 0.98 95% CI 0.85-1.13 and 0.97 95% CI 0.85-1.12) for heterozygotes of the P1054R, D1853N, and IVS\_48 polymorphisms, respectively. Furthermore, no particular haplotype or combinations of genotypes appeared to be associated with a significantly increased risk. However, the D1853N polymorphism exhibited significant departure from Hardy-Weinberg equilibrium for both the breast cancer cases and the controls ( $p=0.0015$  for cases and controls combined), suggestive of a selective advantage in heterozygotes.

**Complex and Unstable Haplotypes of the *CDKN1A* Gene.** *L. Geller*<sup>1</sup>, *G.P. Larson*<sup>1</sup>, *C. Ouyang*<sup>1</sup>, *S. Flanagan*<sup>2</sup>, *T.G. Krontiris*<sup>1</sup>. 1) Division of Molecular Medicine, Beckman Research-City of Hope, Duarte, CA; 2) Division of Neuroscience, Beckman Research-City of Hope, Duarte, CA.

As a major downstream target of TP53, CDKN1A (p21, *CIP1*, *WAF1*) inhibits the G1-to-S cell cycle checkpoint and serves as a potent negative regulator of the mammalian cell cycle. In a recent analysis of breast cancer risk, we identified four rare, potentially pathogenic SNPs within the promoter, coding, and 3' untranslated regions of *CDKN1A*. In addition to risk-associated sequence variants, other SNPs were quite prevalent within the promoter and flanking regions. Through sequencing of cloned PCR fragments, we identified 20 complex haplotypes from breast cancer patients and unaffected controls. The four potentially cancer-associated SNPs were present on 3 different haplotypes. Approximately 80 SNPs, insertions, deletions, and microsatellites were present within the 28 kb region characterized. We observed at least ten independent crossovers and many gene conversion events in the region within and surrounding *CDKN1A*. Linkage disequilibrium extended over the entire 28 kb region, and included two microsatellites. These results--the complex haplotype architecture at this locus, as well as the distribution of rare, cancer-associated variants over multiple haplotypes--have important implications for genome-wide association tests based on linkage disequilibrium of SNPs.

**Linkage and linkage disequilibrium fine-scale mapping of 16 cM region on chromosome 4p16-15.2 in pedigrees multiplex for human systemic lupus erythematosus.** *C.L. Gray-McGuire<sup>1,2</sup>, J. Kelly<sup>1</sup>, H. Tiwari<sup>2</sup>, J.B. Harley<sup>1</sup>*. 1) Oklahoma Medical Research Foundation, Oklahoma City, OK; 2) Case Western Reserve University, Cleveland, OH.

Systemic lupus erythematosus (SLE) is a complex autoimmune disorder involving at least hormonal, environmental, and genetic factors. To date, six genome scans of linkage to SLE have been conducted and more than fifteen regions of interest identified. However, only three of these regions have both attained a level of significance equivalent to a lod score of 3.3 and been confirmed in an independent study, one of which is 4p16-15.2. This linkage effect was first identified in a collection of 77 European American pedigrees multiplex for SLE and then confirmed in an independent collection of 148 European American affected sibling pairs. Subsequent to this confirmation, genotypes were collected for eleven microsatellite markers spanning a 16 cM region (average of 1.1 cM spacing) on 4q16-15.2. Haplotypes were scanned for double recombinations and the genotypes of potentially erroneous individuals were reexamined and either verified or removed. Fine scale multipoint model-free linkage analysis of 270 European American sibling pairs (affected and unaffected) and 101 European American affected relative pairs resulted in a p-value less than 0.01 and lod score greater than 4, respectively. Linkage disequilibrium analysis also indicates an effect in this region with significant results over a 3.1 cM region on 4p16. These results not only confirm linkage in this region, but suggest that the original effect identified to 4p16-15.2 can be isolated to 4p16, the p-terminal end of chromosome 4.

**Using Run Test to Assess Global Significance of Association between a Disease Gene and Multiple SNPs.** C.S.J. Fann<sup>1</sup>, I.B. Lien<sup>2</sup>, W.C. Chou<sup>2</sup>, C.J. Chang<sup>3</sup>. 1) Epidemiology & Public Health, Inst Biomed Sci, Acad Sinica, Taipei, Taiwan; 2) Department of Mathematics, National Chang Hua University of Education, Taiwan; 3) Department of Medical Research, National Taiwan University Hospital, Taiwan.

Association tests (family based or not) between a putative disease gene and a large number of single nucleotide polymorphism (SNP) have gained tremendous popularity recently. With many SNPs, if one examines association using one marker/haplotype after another along the genetic map, will produce large number of testing results and inflate type I error. Using Bonferroni's procedure to adjust problems arisen from multiple comparisons is too conservative since tests at nearby marker loci may be dependent. In the presence of linkage disequilibrium, positive results of association should appear correlatively between a disease gene and flanking SNPs. In this study, we propose to use "longest run" statistics in "run test" to assess the global association between multiple SNPs and a putative disease gene. If p-value obtained from an association test is smaller than a preset threshold (e.g.  $p < 0.05$ ) then assign an index of 1, otherwise assign 0. In general, three situations are observed: a) many 0 and a few 1, b) 1 and 0 appear randomly, c) many 1 and a few 0. Data from a string of such indices are tested for randomness first to exclude situation b. If non-randomness is found and with more index of 1 (situation c) then the probability observing a longest run of index of 1 is used to assess global association. In reality, the indices in the disease gene susceptible region, although likely to be ones, may contain a small number of zeros due to the chosen threshold. The conventional run test based on perfect longest run may be too conservative. Therefore, a new class of run, which refers as *k-zero* run with fixed length of  $n$ , denoted by  $L_{k,n}$  is developed. Furthermore, let  $\max L_{k,n}$  denotes the longest *k-zero* run for the whole sequence then a segment of a chromosome is considered susceptible if  $\max L_{k,n} > C$ , where  $C$  satisfies  $P(\max L_{k,n} > C | H_0) < \alpha$  and  $H_0$  is the null hypothesis of randomness. Both the exact distribution and asymptotic properties of this test is investigated.

Program Nr: 1987

**A regression-based haplotype TDT for quantitative traits in pedigree data.** *V. George*<sup>1</sup>, *C. Chen*<sup>2</sup>, *H. Tiwari*<sup>2</sup>. 1) Dept of Biostatistics, Medical College of Wisconsin, Milwaukee, WI; 2) Case Western Reserve University, Cleveland, OH.

Recently, the transmission/disequilibrium tests (TDT) using single marker have been generalized in various ways to allow for haplotypes made of several tightly linked markers. Analysis of linkage using transmission of haplotype is more informative than that using single marker, and therefore should provide better statistical power. In this presentation, we propose a haplotype-based TDT for quantitative traits using a multiple regression approach. The proposed method allows the trait to be correlated, and also it allows adjustment for relevant covariates in the model. We investigate the statistical power and validity of the method by simulating haplotypes at various distances from the quantitative trait locus.

**SNP Density Requirements in Mapping Genes for Complex Diseases.** *Y-S. Chen, N. Akula, T.G. Schulze, S. Potluri, F.J. McMahon.* Dept Psychiatry, Univ Chicago, Chicago, IL.

The required marker density to detect association with disease has been the subject of considerable debate. Since the extent of linkage disequilibrium (LD) in outbred samples has been estimated by different studies to range from about 3 kb to greater than 100kb, the number of SNPs needed to screen a 10 MB target region may vary from 50 to 1700. To decide the appropriate SNP density for further study of a bipolar disorder linkage region on chromosome 18q21-23, we estimated LD between SNP markers on the first finished long-range sequenced in the region: AC006203. Public databases yielded 70 SNPs; 7 additional SNPs were discovered in-house by resequencing 8-20 unrelated Europeans. These 77 SNPs were then screened in a panel of 20 unrelated European CEPH founders using single-base extension methods. 37% (26 of 70) of the public SNPs and 100% (7 of 7) of the in-house SNPs yielded at least one heterozygote. The 33 polymorphic SNPs all mapped back uniquely to the original clone at a mean density of about one SNP per 5.6 kb (range 239 -11,082 bp). We selected the 33 SNPs with at least one detectable heterozygote for genotyping in an additional set of 50 unrelated European CEPH founders. Overall, genotype data was 99.6% complete. Minor allele frequencies averaged 0.25 (range 0.01- 0.50). Haplotype frequencies, p-values, and LD parameters for all possible pairwise comparisons were estimated with EH+ (Zhao et al 2000). LD decayed over physical distance in a reasonably predictable manner, falling from 1.0 to 0.5 over about 62 kb. These data agree closely with those of Reich et al. 2001, which suggests that the 18q region is not atypical. Statistically-significant LD ( $p < 0.05$ ) was detectable between 80% of marker pairs 2 kb apart and 60% of marker pairs at 5 kb. Based on these data, a SNP map of approximately 10 kb density should be adequate to screen this region for trait-marker associations. These data may actually underestimate the extent of LD in this region since they are based on phase-unknown genotypes from unrelated individuals. Determination of background LD is an important preliminary step in planning association studies of linked regions.

**Comparison of two micro-array based methods and Pyrosequencing for SNP genotyping.** *D.C. Chen<sup>1</sup>, J. Saarela<sup>1</sup>, I. Nuotio<sup>1</sup>, A. Jokiahho<sup>1</sup>, L. Peltonen<sup>1</sup>, A. Palotie<sup>2</sup>.* 1) Dept. Human Genetics and; 2) Pathology, UCLA, Los Angeles, CA.

Over one million sequence verified single nucleotide polymorphisms (SNPs) are currently deposited in the public databases. The challenge has now shifted from SNP identification to high-through SNP genotyping. Accordingly, efficient, flexible, and low cost SNP genotyping is a necessity for dense marker mapping as well as candidate gene association studies in complex diseases. We compared the performance of three SNP genotyping techniques based on primer extension: Affymetrix Genflex™ Tag array, an RNA polymerase extension based array and Pyrosequencing. A robust solid-phase single nucleotide extension reaction technique based on tritium detection was used as a reference method (Syvanen et al, Genomics, 1990). Fifteen SNPs, confirmed by sequencing, were selected on chromosome 17q. Using all four techniques including the reference method, 15 SNPs were studied in 96 related individuals. Without extensive optimization, we were able to genotype 10 out of 15 SNPs using the Genflex Tag array, 11 out of 15 SNPs using the RNA polymerase extension array, 11 out of 15 SNPs using Pyrosequencing and 12 out of 15 SNPs using the reference method. High GC content of the template and high tendency for sequencing primer to form dimer/hairpin loops are contributing factors to nonworking SNPs. The concordance rate of individual genotypes to the reference method varied among SNPs and ranged from 72% to 92 % for the Genflex™ Tag array, 83% to 97% for the RNA polymerase extension array and 87% to 99% for Pyrosequencing. The performance of different methods in the accuracy of genotyping was relatively similar. However, Pyrosequencing provided the highest proportion of successful SNP analyses and the highest precision for individual allele calls. It is likely that the single stranded template used both in the reference method and in Pyrosequencing is the major contributing factor for the better performance.

**LD across the *CYP2D6* region: implication for whole genome association scans in pharmacogenetic studies.** *L.K.*

*Hosking<sup>1</sup>, P. Boyd<sup>1</sup>, M. Nissum<sup>3</sup>, K. Cantone<sup>1</sup>, C.-F. Xu<sup>1</sup>, I. Purvis<sup>1</sup>, R. Khakhar<sup>1</sup>, S. Varsani<sup>1</sup>, R. Cutts<sup>1</sup>, U. Lieberwirth<sup>3</sup>, K. Hagen-Mann<sup>3</sup>, D. Preuss<sup>3</sup>, Y. Brunner<sup>3</sup>, M. Ehm<sup>2</sup>, J. Riley<sup>1</sup>.* 1) Discovery Genetics Europe, GlaxoSmithKline, Gunnels Wood Road, Stevenage, Hertfordshire, SG1 2NY UK; 2) GlaxoSmithkline, Genetics Research, 5 Moore Drive, P.O. Box 13398, Research Triangle Park, NC 27709, USA; 3) MWG Biotech AG, Anzinger Strasse 7, 85560 Ebersberg, Germany.

The clinical response of an individual to a medicine is dependent upon both genetic and environmental factors. *CYP2D6*, which metabolises approximately 30% of marketed medicines, has multiple genetic variants giving rise to different *CYP2D6* metabolising phenotypes. Association between the *CYP2D6* recessive poor metaboliser (PM) phenotype and genetic variation flanking the gene has been investigated. 33 single nucleotide polymorphisms (SNPs) with an average spacing of 26kb, were identified from an 870kb region on human chromosome 22 encompassing *CYP2D6*. Linkage disequilibrium and strong association (p values ranging from  $1.85 \times 10^{-3}$  to  $1.80 \times 10^{-33}$ ) were observed over 430kb between SNPs spanning *CYP2D6* and the PM phenotype. These findings support the strategy for the potential application of genome wide association scans in pharmacogenetic studies.

**Testing linkage disequilibrium in the presence of tight linkage and locus heterogeneity.** *J. Huang*<sup>1,2</sup>, *D. Wang*<sup>2</sup>, *Y. Jiang*<sup>4</sup>, *V.J. Vieland*<sup>1,3</sup>. 1) Statistics & Actuarial Sci, Univ Iowa, Iowa City, IA; 2) Dept of Biostatistics Div of Statistical Genetics, Univ of Iowa, Iowa City, IA; 3) Dept of Psychiatry, Univ of Iowa, Iowa City, IA; 4) Dept of Preventive Medicine and Epidemiology, Loyola Univ Medical Center.

Once a candidate gene has been discovered, it may be of interest to identify polymorphisms within the gene that display linkage disequilibrium (LD). This situation differs from one in which the interest is in detecting linkage via LD, since here the interest is in detecting LD under the assumption that there is tight linkage. We have developed a likelihood-based approach to assessing LD which conditions on tight linkage (recombination fraction (RF)=0). In addition, this approach makes use of all affected and unaffected individuals in the data (nuclear families); and it also allows explicitly for locus heterogeneity. The proposed likelihood has two parameters: an LD coefficient and a locus heterogeneity parameter. The latter parameter is the proportion of families in which the RF is 0, and the remaining proportion represents the families in which the RF is 0.5. A likelihood ratio test for LD in the presence of tight linkage and locus heterogeneity can be based on this likelihood. We have conducted simulation studies using recessive, dominant, additive and multiplicative models with various combination of disease and marker allele frequencies. The results show that the proposed test in general has better power than the TDT and a test proposed by Martin et al. (1997).

**Mutation screening and association study of *ATP10C* in Autism.** S. Kim<sup>1</sup>, L.B.K. Herzing<sup>2</sup>, J. Veenstra-VanderWeele<sup>1</sup>, C. Lord<sup>3</sup>, R. Courchesne<sup>4</sup>, B.L. Leventhal<sup>1,3,6</sup>, D.H. Ledbetter<sup>2</sup>, E. Courchesne<sup>4,5</sup>, E.H. Autism is a complex genetic disorder. 15q11-q13 is of particular interest, because of previous reports of individuals with autism with predominantly maternal duplication or triplication of 15q11-q13. Linkage disequilibrium (LD) between polymorphisms in this region and autism has been also reported by several groups. Recently, a novel maternally expressed gene, *ATP10C*, was characterized and mapped to chromosome 15q11-q13 region, 200kb distal to *UBE3A*. It encodes a putative aminophospholipid translocase. Because of its physical location and maternal expression pattern in brain, *ATP10C* was considered to be a candidate gene for chromosome 15-associated autism. In an effort to find the genes responsible for autism in this chromosomal region, the coding and splicing regions of *ATP10C* were screened for sequence variants. Several polymorphic markers including five nonsynonymous SNPs were identified. To further investigate transmission disequilibrium between *ATP10C* and autism, a family-based association study was performed for 14 markers in 117 autism trios. Significant transmission disequilibrium was not found, suggesting *ATP10C* is unlikely to contribute to susceptibility to autism. However, the physiological role of the nonsynonymous SNPs and the functional implications of the SNPs identified from the 5' flanking region and the intron 2 splicing region may be evaluated in further studies.

**Tight association between diplotype configuration at NAT2 gene and adverse effects of sulfasalazine in patients with rheumatoid arthritis.** *Y. Kitamura*<sup>1</sup>, *E. Tanaka*<sup>2</sup>, *M. Saito*<sup>1</sup>, *N. Kamatani*<sup>1,2</sup>. 1) Division of Statistical Genetics, Institute of Rheumatology, Tokyo Women's Medical University, Tokyo, Japan; 2) Institute of Rheumatology, Tokyo Women's Medical University, Tokyo, Japan.

**Purpose:** Part of the variations in adverse reactions to a drug can be explained by polymorphisms at the gene coding for drug-metabolizing enzyme. Arylamine-N-acetyltransferase 2 (NAT2) catabolizes sulfasalazine (SASP), a drug used for treatment of rheumatoid arthritis (RA). 7 SNPs have been identified in human NAT2 gene. Based on EM-algorithm, we estimated the *diplotype configuration* (i.e. a combination of 2 haplotypes) at NAT2 gene for Japanese subjects with RA treated with SASP and compared the *diplotype configurations* with outcomes of the patients.

**Materials and Methods:** Peripheral blood was withdrawn from 144 patients with RA who had been treated with SASP after informed consent was obtained. DNA was extracted and genotypes at 7 loci were determined by digestion with restriction enzymes. We have developed EM-algorithm-based LDSUPPORT software, which estimates posterior distribution over *diplotype configurations* for each subjects from genotypic data (Kitamura et al., 2001 manuscript submitted for publication).

**Results:** 6 haplotypes (wild-type; WT and 5 variants) were extracted for Japanese population. Estimated frequency for WT was 72.2%, while those for variant haplotypes were 19.1% (*GTTCAAG*:M2), 7.6% (*GTTGAA*:M3), 0.4% (*GCCCAAG*, *GTTGAG*) and 0.3% (*GCCTGGG*:M1). 16 patients were with adverse reactions to SASP. The patients with adverse effects had higher proportion of M2 (34.4%) and those without adverse effects had 17.2% ( $p < 0.05$ ). The patients without WT haplotype had higher incidence of adverse reactions than those with WT haplotype (62.5% vs 8.1%,  $p < 0.001$ ). In addition, the patients without WT haplotype had higher incidence of severe adverse reactions than those with WT haplotype (25.0% vs 1.5%,  $p < 0.005$ ).

**Conclusions:** Patients without WT haplotype had higher incidence of adverse reactions to SASP. Genotyping and subsequent estimation of *diplotype configuration* at NAT2 gene is useful to predicting the occurrence of adverse reactions to SASP.

**Determination of linkage disequilibrium patterns and mutation rate by high density SNP genotyping.** *D. Keen<sup>1</sup>, A. Ferrie<sup>2</sup>, J. Zielenski<sup>3</sup>, L.C. Tsui<sup>3</sup>, R. Parad<sup>4</sup>, R. Chung<sup>5</sup>, A. Menon<sup>6</sup>, M. Ramos-Arroyo<sup>7</sup>, F. Baas<sup>8</sup>, J. Kushner<sup>9</sup>, D. Housman<sup>1</sup>.* 1) MIT, Cambridge, MA; 2) Variagenics Inc, Cambridge, MA; 3) Hosp for Sick Children, Toronto, Canada; 4) Children's Hosp, Boston, MA; 5) Mass Gen Hosp, Boston, MA; 6) Univ of Cincinnati, OH; 7) Hosp Virgen del Camino, Pamplona, Spain; 8) Neurol Acad Med Ctr, Amsterdam, Netherlands; 9) Univ of Utah, Salt Lake City, UT.

In order to model the relationship between SNP haplotypes and functionally significant DNA sequence variation in humans we have investigated patterns of SNP distribution in CFTR (chromosome 7) and HFE (chromosome 6). We initially carried out a detailed sequence comparison over 5 kb surrounding the DF508 mutation of CFTR in 32 ethnically diverse individuals and 30 DF508 homozygotes. A number of SNP haplotypes are apparent in normal individuals, but there is no sequence variation among DF508 chromosomes. These data indicate that the DF508 mutation occurred on a specific haplotype and no recombination nor mutation has occurred within this 5 kb region since the original DF508 mutation arose. We extended the haplotype analysis to other CFTR mutations. Of particular interest, G542X, the second most frequent CFTR mutation in Caucasians, occurs on exactly the same haplotype background as DF508. Both DF508 and G542X have been estimated to originate 10-50,000 years ago based on microsatellite analysis. We carried out a detailed sequence comparison (65 kb) between the DF508 and G542X chromosomes. Both sequences were identical for more than 50 kb of this region with one exception, suggesting a mutation rate on the order of one base pair per  $10^8$  bases replicated per generation. The origins of framework haplotypes in the 65 kb region have been assessed by genotyping all SNPs in a number of ethnically divergent populations. The 65 kb sequenced region is divided by a recombinational hot spot identified through analysis of SNP haplotypes in normal individuals. A parallel analysis has been carried out in the HFE region of chromosome 6. Results of these studies have significant implications for the design and implementation of SNP based population association studies.

**Association Analysis of Autistic Disorder and SNPs in the chromosome 15 GABA<sub>A</sub> receptor subunit genes. M.M.**

*Menold<sup>1</sup>, Y. Shao<sup>1</sup>, E.R. Martin<sup>1</sup>, C.M. Wolpert<sup>1</sup>, K.L. Raiford<sup>1</sup>, H.L. Abel<sup>1</sup>, S.A. Ravan<sup>2</sup>, R.K. Abramson<sup>2</sup>, H.H. Gilbert<sup>1</sup>.* 1) Center for Human Genetics, Duke University Medical Center, Durham, NC; 2) W.S. Hall Psychiatric Institute, University of South Carolina, Columbia, SC; 3) Division of Neurology, Pediatrics, Duke University Medical Center, Durham, NC; 4) Helsinki University Central Hospital, Helsinki, Finland.

Autistic disorder (AutD) is a complex neurodevelopmental disorder with onset in early childhood (less than 36 months of age). It is characterized by abnormalities in social interactions and communication, as well as stereotypic and repetitive behaviors. Twin and family studies have shown evidence for a genetic component, but no clear mode of inheritance has been identified. Data from several genomic screens, as well as that from cytogenetic studies have indicated that a disease locus for AutD is located on the proximal portion of chromosome 15q. Contained within this region are genes for three of the subunits of the gamma-aminobutyric acid type A (GABA<sub>A</sub>) receptor. The neurotransmitter GABA mediates synaptic inhibition in the adult brain through its interaction with the GABA<sub>A</sub> receptors. These receptors are usually pentameric structures comprised of several different homologous subunits. The functional properties of a particular receptor are dependent upon the subunit composition. Two studies have shown evidence in support of linkage and association of AutD to the gene for one of these subunits: GABRB3. In order to further define the association between the chromosome 15q GABA<sub>A</sub> receptor subunit genes and AutD, we analyzed 16 single nucleotide polymorphisms (SNPs) located within GABRB3, GABRA5 and GABRG3, in 226 AutD families. The pedigree disequilibrium test (PDT) was used to test for linkage disequilibrium (LD). PDT results showed evidence for significant LD with two adjacent SNPs in the GABRG3 gene: exon5\_539T/C, P=0.02 and intron5\_687T/C, P=0.03. All other results were not significant (P>0.05). These data suggest that the GABRG3 gene contributes to genetic susceptibility in AutD and may represent the chromosome 15 AutD risk gene.

**Maximum likelihood estimator of two-biallelic markers haplotype frequencies, and its application in an LD exact test.** *S. Lissarrague, L. Essioux.* Statistical Genomics Dept, Genset Corp, Evry, France.

With the increased number of available markers and the decreasing costs of genotyping, large scale association studies are now feasible. One of the cornerstone parameter for performing such strategy is the linkage disequilibrium between neighboring markers, that requires estimation of two markers haplotypes frequencies (Reich et al. 2001). In association studies, haplotype analyses have become more and more popular because they can be more powerful than single markers associations (Fallin et al. 2001). Up to now, Estimation of haplotype frequencies are performed using iterative algorithms in order to find the most probable haplotypes frequencies given the genotypes data, such as the E-M algorithm (Excoffier and Slatkin, 1995). Those heuristics methods can be computationally intensive, and sometimes can lead to false solution due to local minimum of the likelihood function. Herein, we present An analytical maximum likelihood estimator of haplotypes frequencies in a set of unrelated individuals in the special case of two bi-allelic markers. The estimator is equivalent to the solution obtained by the E-M algorithm but is far less computationally intensive and always gives the true estimator. We then applied this estimator to construct an optimized exact likelihood ratio test for Linkage equilibrium which is more precise and less computer intensive than the traditional Monte-Carlo approach.

Significant linkage disequilibrium (LD) around disease alleles would enable the use of nearby genetic markers to detect association to disease. Thus, measuring LD near disease alleles and within genes is relevant for the prospects of mapping disease genes.

We identified 17 informative single nucleotide polymorphisms (SNPs) in 19 kb surrounding a known disease allele, *PPARG* Pro12Ala (associated with type 2 diabetes). Typing these SNPs in >300 Caucasian trios revealed strong LD: there are only 4 major haplotypes in this region, 3 with the ancestral proline allele and 1 bearing the alanine allele. Additional markers showed LD at distances of over 80 kb. Remarkably, 7 of the 17 SNPs were nearly perfect proxies for Pro12Ala, demonstrating that the resolution limit of genetic mapping at this locus has been reached in this Caucasian population. We next studied LD in 33 additional genes, chosen for relevance to cardiovascular traits. For all 804 publicly available SNPs within the 33 genes or in the 5 kb on either flank, we attempted assay design and genotyping in 92 individuals from 12 CEPH families. Consistent with results from random genomic regions (Bolk et al. abstract), LD varied from gene to gene, but strong LD was seen over entire genes. For such genes, all common haplotypes could be marked by typing only a few SNPs. These results suggest that LD-based association may well be a useful approach to mapping common disease alleles. However, prior explicit determination of LD structure may be required to maximize the efficiency of such an approach.

Program Nr: 1998 from the 2001 ASHG Annual Meeting

**Study of linkage disequilibrium between human dopamine D1 receptor (DRD1) gene and bipolar disorder.** X. Ni, J.M. Trakalo, E. Mundo, F. Macciardi, L. Lee, J.L. Kennedy. Neurogenetics Section, Ctr Addiction & Mental Health, Toronto, Ontario, Canada.

Abstract: Based on the dopamine hypothesis, the dopamine D1 receptor (DRD1) gene is considered to be a good candidate gene for bipolar (BP) disorder. In the present study, we analysed three polymorphisms of the DRD1 gene, -800T/C, -48A/G and 1403T/C in 286 BP disorder trios. Both the extended transmission disequilibrium test (ETDT) and haplotype TDT were performed on the genotype data to test the presence of linkage disequilibrium between DRD1 gene and bipolar disorder. With the same test we also calculated the maternal transmission or paternal transmission for each allele. Though no association was found for each individual polymorphism, there was a significant association between DRD1 gene and BP disorder for haplotype TDT analysis ( $X^2=21.307$ ,  $df=7$ ,  $p=0.0028$ ). These results may indicate that the DRD1 gene plays a role in the etiology of bipolar disorder. Keywords: bipolar disorder, genetics, linkage, transmission disequilibrium test, haplotype transmission disequilibrium test, dopamine D1 receptor gene.

**Type 2 diabetes and calpain-10 gene polymorphisms in Samoans.** *H-J. Tsai<sup>1</sup>, G. Sun<sup>2</sup>, D.E. Weeks<sup>1</sup>, S.T. McGarvey<sup>3</sup>, R. Kaushal<sup>2</sup>, M. Wolujewicz<sup>2</sup>, R. Deka<sup>2</sup>.* 1) Human Genetics, University of Pittsburgh, Pittsburgh, PA; 2) Environmental Health, University of Cincinnati, Cincinnati, OH; 3) International Health Institute, Brown University, Providence, RI.

Although genome wide scans have identified several potential chromosomal susceptibility regions in several human populations, finding a causative gene for type 2 diabetes has remained an enigma. Horikawa et al. (Nat Genet. 2000. 26:163-175) reported a novel gene, calpain-10 (*CAPN10*), located in a previously identified region on chromosome 2q37.3, as a putative type 2 diabetes susceptibility gene. Three single nucleotide polymorphisms (UCSNP43, UCSNP19, UCSNP63) were shown to be involved in increased risk to the disease among Mexican Americans. We have tested the association of these three polymorphisms with type 2 diabetes among the Samoans of Polynesia, who have a very high prevalence of the disease. In the US territory of American Samoa, prevalence is 25% and 15% in men and women, respectively, compared to 3% and 5% in men and women, respectively, from the independent country of Samoa. In our study sample consisting of 96 controls and 295 affected sib pairs in 174 families recruited in American Samoa, we failed to detect any association between cases and controls in allele frequencies, haplotype frequencies or haplotype combinations of SNP43, 19 and 63. Also, there was no evidence of linkage in our data in the region of chromosome 2 containing these SNPs. Three plausible scenarios could explain these observations: the underlying biological mechanism is too complex and needs further research; *CAPN10* is a susceptibility gene in some particular ethnic groups; our study lacks power to detect the effects of *CAPN10* polymorphisms. With regard to power, however, our number of families (174) is comparable to the number (170) in the original Horikawa et al. study. Supported by NIH grants AG09375, HL52611, DK55406 and DK59642.

**Linkage Disequilibrium Mapping of a Putative Type 2 Diabetes Locus (1q21-q23) using Pooled DNA.** *J.K. Wolford, S. Kobes, R.L. Hanson, C. Bogardus, M. Prochazka.* NIDDK/PECRB, NIH, Phoenix, AZ.

We have previously reported linkage of type 2 diabetes mellitus to Chromosome 1q21-q23 in Pima Indians and are presently fine-mapping this putative diabetes susceptibility locus by linkage disequilibrium using densely spaced single nucleotide polymorphisms (SNPs) to complement analyses of known positional candidate genes in this region. From public databases and through our own work we have identified over 3500 SNPs spanning a ~20 cM region of the linkage interval. We are currently screening these markers for differences in allelic frequency in 2 pools consisting of 150 diabetic and 150 non-diabetic Pimas (none are first degree relatives). Using the MassArray technology of Sequenom, Inc, we have to date assayed 1029 potential SNPs in these pools, including 90 SNPs which we identified by sequencing or denaturing high performance liquid chromatography and 939 obtained from dbSNP (<http://www.ncbi.nlm.nih.gov/SNP>). Of these, 522 SNPs (50.7%) were informative (allelic frequency >10%), 151 SNPs (14.7%) were non-informative (allelic frequency ≤10%), and 356 (34.6%) SNPs were non-polymorphic in our samples. Further analysis of the raw spectra for each assay indicated 339 SNPs (32.9 %) with either a high baseline or multiple peaks and consequently, we are repeating these assays. Average density is 1 informative SNP per 41.3 (±5.4) kb and the largest gap is 1.4 Mb; gaps greater than 50 kb (N=28) are being filled with additional SNPs. Preliminary analyses have identified 7 SNPs (4 of which are clustered within a 1 Mb region) with significantly different ( $P < 10^{-3}$ ) allele frequencies in the diabetic vs. non-diabetic pools and we are presently genotyping these in individual samples.

**Analysis of extent of linkage disequilibrium using more than a thousand of SNPs throughout the genome in Japanese population.** *T. Tsunoda*<sup>1</sup>, *R. Yamada*<sup>1</sup>, *M. Yamaguchi*<sup>1</sup>, *H. Kawakami*<sup>2</sup>, *Y. Ohnishi*<sup>1</sup>, *A. Sekine*<sup>1</sup>, *T. Tanaka*<sup>1</sup>, *Y. Nakamura*<sup>1,2</sup>. 1) SNP Research Center, RIKEN, Tokyo, Japan; 2) Institute of Medical Science, University of Tokyo, Tokyo, Japan.

Recent progress in whole-genome discovery and high throughput genotyping technology of single nucleotide polymorphisms (SNPs) has brought much possibility to detect association between SNP markers and common complex genetic traits with linkage disequilibrium (LD) mapping strategy. The sensitivity to locate regions in association and the efficiency to pinpoint genuine locus in the associated regions of LD mapping method largely depend on the extent of LD. The extent of LD is expected to vary among ethnic groups and regions in the genome. We evaluated for the first time the extent of LD throughout the genome excluding sex chromosomes with 1,227 SNPs genotype data from more than 752 of Japanese. The SNPs genotyped located on exons, surrounding introns and 5 flanking region of known or predicted-in-silico genes throughout the genome. More than 752 Japanese individuals were genotyped for each SNP. From all the SNPs assayed, only the SNPs with their minor allele frequency more than 0.2 were included for analysis of LD to exclude pseudo-LD. Every SNP was mapped on a complete contig from NCBI. LD index,  $D$ , between every pair of two SNPs on the same contig was calculated using EM-algorithm. The result of the large-scale analysis showed that the average  $D$  in a Japanese population dropped below 0.5 at 40kb, which was between Utah population (60kb) and Nigerian population (<5kb), and the fraction of  $D > 0.5$  was 25% at 90-110kb. Our result suggested that the use of Japanese population will enable more efficient pinpointing of genuine loci than the case using the Utah population.

**Multilocus measures for linkage disequilibrium.** *J.P. Rice, N.L. Saccone, P.-Y. Kwok.* Washington University School of Medicine, St. Louis, MO.

The utility of genetic linkage maps has been in part due to the existence of a metric (map distance), which allows the map locations of markers to determine all possible recombination fractions between markers, and allows the placement of new markers or disease genes. In contrast, a marker may lie between two markers in strong disequilibrium, and yet be in equilibrium with both. Mechanisms such as drift, mutation and population admixture may lead to patterns inconsistent with linkage disequilibrium (LD) that is solely due to recombination. The available set of Single Nucleotide Polymorphisms (SNPs) has grown at a rapid pace, although most analyses have been descriptive and based on pair-wise comparisons.

We develop a set of conditional LD measures for a set of markers (X,Y,Z) where the usual D and D-prime statistics are computed between X and Z conditional on the genotype at the intervening marker Y. We note the changes between generations in the  $2 \times 2 \times 2$  table of frequencies if LD is due to recombination, and present simple examples in which the conditional measures can be computed algebraically. In this setting the conditional measures are small even after one generation of random mating.

We examine 6 SNPs on the X chromosome within a 500 kb region on Xq28. Three SNPs (Xq3449-1, Xq3274-1, and Xq1452-1) showed D-primes of 0.66 and 0.36 between consecutive pairs, with conditional values of 0.06. If these three were used as a "map" in this region, the other 3 SNPs showed significant LD with at least one of them. Two of the extra SNPs had D-prime values of 1 and -1 with one of the SNPs in the map. The map thus captures the LD information in this region.

From the limited data available so far, it is clear that some sets of SNPs show irregular patterns for these conditional measures. However, given the number of SNPs available in any region, it is likely that a subset can be chosen with moderate LD between each pair and minimal conditional LD. It remains to be seen whether such a map would be optimal for the detection of disease genes through LD mapping.

**Strong linkage disequilibrium among the CYP2C subtypes in Japanese population.** *M. Saito*<sup>1</sup>, *Y. Kitamura*<sup>1</sup>, *T. Kubota*<sup>2</sup>, *T. Iga*<sup>2</sup>, *N. Kamatani*<sup>1</sup>. 1) Institute of Rheumatology, Tokyo Women's Medical University, Tokyo, Japan; 2) Department of Pharmacy, University of Tokyo Hospital, Tokyo, Japan.

**Purpose:** Proteins that constitute cytochrome P450 (CYP) are important for oxidative degradation of various foreign compounds. They are coded for by a family of CYP-related genes among which CYP2C subfamily plays an important role. The 3 genes, CYP2C18, CYP2C19, and CYP2C9 all of which belong to the CYP2C subfamily have been mapped to the same region of chromosome 10. We examined the linkage disequilibrium (LD) in this region to investigate the nature of this gene family.

**Materials and Methods:** The genotypic data of polymorphism at 4 sites in CYP2C18 and CYP2C19 have been published by Kubota *et al.* (Kubota *et al.*, 1998, *Biochemical Pharmacology*, **55**, 2039-2042). These and additional data for a SNP of CYP2C9 were used for the estimation of haplotype frequencies and the calculation of posterior probability of diplotype configuration for each of the subjects using LDSUPPORT, an expectation-maximization (EM)-based maximum likelihood estimation software.

**Results:** Although the 3 genes are scattered over at least 100 kb region (0.25 cM), there was a strong LD between SNPs in the 3 genes. Between the SNPs of CYP2C18 and CYP2C19, the LD was virtually complete. The estimated frequency for wild type, T (T<sub>478</sub>->C in CYP2C18) - T (T<sub>204</sub>->A in CYP2C18) - G (G<sub>636</sub>->A in CYP2C19) - G (G<sub>681</sub>->A in CYP2C19) - A (A<sub>1075</sub>->C in CYP2C9), was 53% (34% in the assumption of no LD), and those for other major variant haplotypes were 31% (CTGAA, 7.4% in no LD) and 13% (TAAGA, 0.8% in no LD).

**Conclusions:** The genotypic data in the genomic region containing 3 genes belonging to a subfamily of CYP2C showed an evidence of strong LD. The function of CYP2C which includes the protection of the organism from unpredictable attacks of foreign compounds is somewhat similar to that of HLA (human leukocyte antigen) in which a strong LD is reported. The strong LD among the genes of CYP2C may have been maintained during the evolution of a defense mechanism.

**A Pakistani family with autosomal recessive non-syndromic hearing loss linked to the DFNB7/11 locus. R.**

*Abbasi<sup>1</sup>, S.A. Shami<sup>1</sup>, R. Qamar<sup>2</sup>, Q. Ayub<sup>2</sup>, S. Khaliq<sup>2</sup>.* 1) Department of Biological Sciences, Quaid-i-Azam University, Islamabad, Pakistan; 2) Biomedical and Genetic Engineering Division, Dr. A. Q. Khan Research Laboratories, Islamabad, Pakistan.

Autosomal recessive non-syndromic hearing loss is the most common form of severe inherited childhood deafness. We studied nineteen members of a large consanguineous Pakistani family affected with autosomal recessive, non-syndromic, prelingual profound hearing loss. Previously reported loci for autosomal recessive non-syndromic hearing loss were excluded, with the exception of marker D9S301 on chromosome 9q21.11. All the affected individuals were homozygous for this marker and provided a strong evidence of linkage with the disease phenotype with a maximum LOD score of 5.70. The combined DFNB7/DFNB11 locus has been previously mapped to chromosome 9q13-q21 in separate families of Indian and Israeli origin. This locus span an interval of approximately 1cM bounded by the markers D9S1806 and D9S769. Two genes expressed in the cochlea (ZNF216 and TMEM2) that map to this region have already been excluded for disease association. There are several putative genes spanning this region in the database that could be associated with the disease phenotype.

**Quantitative trait loci underlying variation in blood cell concentrations.** *D.M. Evans<sup>1</sup>, G. Zhu<sup>1</sup>, I.H. Frazer<sup>2</sup>, N.G. Martin<sup>1</sup>.* 1) Genetic Epidemiology, Queensland Institute of Medical Research, Brisbane, Queensland, Australia; 2) Centre for Immunology and Cancer Research, University of Queensland, Princess Alexandra Hospital, Brisbane, Australia.

Blood cell concentrations remain stable across time in healthy individuals, yet vary widely between different individuals. We and others have demonstrated that part of this large interindividual variation is the result of genetic factors. The aim of the present study was to identify quantitative trait loci responsible for this variation. Complete blood cell counts (i.e. hemoglobin, red cell count, mean cell volume, platelet, neutrophil, eosinophil, basophil, monocyte and lymphocyte counts) and lymphocyte subsets analyses (CD4+ T cell, CD8+ T cell, B cell and natural killer cell counts) were performed in 232 pairs of dizygotic twins at twelve, fourteen and sixteen years of age. A genome scan consisting of 400 highly polymorphic markers was performed on each twin's DNA. Identity by descent probabilities for each twin pair were calculated using Genehunter 2.0 and this information was incorporated into a variety of structural equation models for variance components linkage analysis.

Univariate linkage analyses identified promising regions of genetic linkage for eosinophil count, platelet count and CD4-CD8 ratio. These linkages were present at similar chromosomal regions at age twelve, fourteen and sixteen in the case of platelets and eosinophils, and at twelve and fourteen years only in the case of CD4-CD8 ratio. Analyzing each cell count longitudinally using multivariate structural equation models increased the power to detect linkage at some of these markers. The genomic region of interest for platelets mapped closely to a gene which has been implicated in platelet formation, albeit in a minor role. The regions of interest for eosinophils and CD4-CD8 ratio, however, did not contain any obvious candidate genes. We are currently genotyping an additional 200 dizygotic pairs in an attempt to increase the evidence for linkage at these loci.

**Evidence of an Epistatic Interaction in a Genetic Linkage Study of Autism.** *M.F. Dowd, R. Mankoski, S. Santangelo, S. Folstein.* CLSA, New England Medical Center, Boston, MA.

Epistatic interactions were investigated in the followup data from 86 families in the Collaborative Linkage Study of Autism. Followup data were available for selected regions on chromosomes 1, 2, 4, 6, 7, 8, 11, 13, 14, 15, 16, 19, and X. Although it is known that genes involved in epistatic interactions can be detected by using single-locus linkage methods, we are more interested here in where the interactions are taking place, i.e., which specific pairs of loci are involved. We first considered correlations between family NPL scores from various locations along the genome and produced a short list of candidate locus-pairs, which we then analyzed using the program GENEHUNTER-TWOLOCUS. A wide range of epistatic as well as heterogeneity models were considered. We found significant evidence of an epistatic interaction between loci that are located at D1S1653 and D13S217, where parametric two-trait-locus analysis yields a MOD-score greater than 6. One of the most interesting aspects of this result is that the signal near D1S1653 under one-trait-locus analysis was not particularly strong and the one near D13S217 was marginal. This appears to re-confirm the finding by Schork et al., (1993) that parametric two-trait-locus analysis can reach higher power to detect linkage than its single-trait-locus counterpart.

**Localization of Migraine Susceptibility Genes to Chromosomes 1q, 19p and Xq.** *L.R. Griffiths<sup>1</sup>, R.A. Lea<sup>1</sup>, R.P. Curtain<sup>1</sup>, S. Quinlan<sup>1</sup>, J. Chappell<sup>1</sup>, J.C. MacMillan<sup>2</sup>.* 1) Genomics Research Centre, Griffith University Gold Coast; 2) Queensland Clinical Genetics Service, Royal Childrens Hospital, Brisbane, Queensland, Australia.

Studies in our laboratory have been directed towards identifying genes involved in the complex neurological disorder, migraine. These studies have localized migraine gene components on chromosomes 19p13(1), Xq24-28(2) and more recently on 1q(3). These studies have utilized large multigenerational migraine pedigrees of sufficient power for significant independent results, with one family (MF1) showing both cosegregation and significant allele sharing (NPL=6.64, P=0.0026) for markers located across a 12.6cM region of 19p13, and two families (MF7 and MF14) showing significant excess allele sharing to Xq markers with a max LOD score of 2.388 (P=0.0005). More recently we have identified two additional families showing significant excess allele sharing to the same Xq24-28 region. Also of interest, recent studies have indicated that MF14, one of the families showing allele sharing on Xq, also shows significant allele sharing (P=0.001) to 1q markers, indicating that the disorder in a single large affected pedigree may involve more than one and possibly interacting gene components. Results from 82 independent migraine pedigrees also show significant allele sharing (P=0.013) and allele transmission distortion (P=0.021) to this region of 1q. Overall, these 1q studies resulted in a max LOD score of 3.11 (P=0.00007) obtained for the D1S249 marker located within the 1q31 genomic region. Hence our results indicate that migraine is a complex polygenic disorder, involving multiple and possibly interacting gene loci.

**A Complete Set of Constraints and Parameterisation of Two-Locus Affected Sib-Pair IBD Probabilities. O.**

*Bengtsson*<sup>1,2</sup>, *T.P. Speed*<sup>3,4</sup>, *S. Dudoit*<sup>5</sup>. 1) Dept Biostatistics, AstraZeneca R&D Mölndal, Sweden; 2) Dept Math Stat, Chalmers Univ of Technology, Göteborg, Sweden; 3) Walter and Eliza Hall Institute of Medical Research, Melbourne, Australia; 4) Dept Statistics, Univ of California, Berkeley; 5) Div of Biostat, School of Public Health, Univ of California, Berkeley.

To increase power in the analysis of affected sib-pair (ASP) data, estimation of the identity by descent (IBD) probabilities is often constrained to the possible triangle (Holmans 1993). We extend previously derived constraints (Cordell et al. 1995) on the nine joint IBD probabilities at two unlinked loci to a set of nine linearly independent inequalities which constitute the natural two-locus analogue of the triangle.

The constraints follow from similar constraints on the sixteen sex-specific IBD probabilities (allowing parental imprinting), that are satisfied under two types of general models. Under one model, including no population genetic assumptions, restrictions on the penetrances are needed. These restrictions are, however, satisfied by e.g. the multiplicative, additive and heterogeneity multi-locus penetrance models. The other model includes Hardy-Weinberg equilibrium (HWE), random mating (RM) and linkage equilibrium (LE), but no penetrance assumptions.

Two-locus ASP IBD probabilities satisfying the constraints can be conveniently expressed in terms of a set of parameters that are unconstrained, except for being positive and summing to one. Under HWE, RM and LE the parameters may be interpreted in terms of genetic variance components, population prevalence and sibling recurrence risk (cf. Cordell et al. 2000). Unconstrained parameters are advantageous in estimation and derivation of statistical tests. Furthermore the parameterisation readily extends to more than two loci and is promising as a means for better understanding the relationship between gene interaction (defined by multi-locus penetrances) and joint IBD proportions.

**Linkage analysis of a family with Late Onset Atrophic Macular Degeneration and exclusion of candidate loci.** *R. Ayyagari<sup>1</sup>, L.E. Kakuk<sup>1</sup>, S. Atkins<sup>1</sup>, P.A. Sieving<sup>1,2</sup>*. 1) Department of Ophthalmology and Visual Sciences, University of Michigan, Ann Arbor, MI; 2) National Eye Institute, NIH, Bethesda, MD.

We identified a large pedigree with autosomal dominant late onset atrophic macular degeneration. Affected individuals initially showed perifoveal RPE atrophy that evolved to central areolar chorioretinal atrophy with age. Ganzfeld ERG showed normal rod and cone function despite marked reduced visual acuities of 20/30 to 20/400. Visual symptoms became apparent around age 40, with strong penetrance. Linkage analysis excluded the known macular degeneration loci, including Stargardt's macular degeneration, Sorsby's fundus dystrophy, Best's macular degeneration, Stargardt-like macular degeneration (STGD3), STGD4, North Carolina macular degeneration, progressive bifocal chorioretinal atrophy, Doyn's Honey Comb Dystrophy, Cone Rod Dystrophy 3 (CORD3), CORD7, RDS/Peripherin. We have also completed scanning 25% of the genome for linkage using 10-cM marker panel with out identifying a region with positive LOD scores. We are in the process of genome wide scanning to map the disease locus in this family. The phenotype observed in this family overlaps with other forms of atrophic macular degenerations including age-related macular degeneration (AMD). Based on our current results it is likely that the disease locus in this family is associated with a novel gene that has not previously been shown to be involved in macular degeneration.

**A new form of Autosomal Dominant late onset Spinal Muscular Atrophy.** *A.L.F. Bernardino<sup>1</sup>, A. Richieri-Costa<sup>2</sup>, M.R. Passos-Bueno<sup>1</sup>, A.M.P. Cerqueira<sup>1</sup>, M. Zatz<sup>1</sup>.* 1) Centro de Estudos do Genoma Humano, Univ de São Paulo, São Paulo, São Paulo, Brazil; 2) Centro de Reabilitação em Anomalias Craniofaciais, Univ de São Paulo, São Paulo, Brasil.

A large family with at least 40 affected members by an Autosomal Dominant (AD) late onset Spinal Muscular Atrophy was reported by Finkel et al.; (1962) and Richieri-Costa et al.; (1981). The manifestations are slow loss of muscle strength and progressive proximal atrophy (which starts in the lower limbs and progresses to the upper limbs) hipoactive or absent tendinous reflexes and generalized fasciculation. Through linkage analysis we have excluded the 6 genes responsible for AD Limb-Girdle Muscular Dystrophies, 2 genes responsible for AD Spinal Muscular Atrophy and 5 genes responsible for AD Charcot-Marie-Tooth Neuropathy. In an attempt to identify the disease-causing gene we are currently performing a genome wide scan using microsatellite markers at an average distance of 10cM. So far, fourteen chromosomes were screened and excluded (1, 3, 5, 7, 9, 13, 14, 15, 16, 17, 19, 20, 21 and 22) and we are continuing the analysis for the other chromosomes. Supported by: FAPESP-CEPID, PRONEX, CNPq.

**A first locus for non syndromic autosomal recessive optic atrophy (OAR1).** *F. BARBET<sup>1</sup>, S. GERBER<sup>1</sup>, J.-M. ROZET<sup>1</sup>, I. PERRAULT<sup>1</sup>, D. DUCROQ<sup>1</sup>, S. HANEIN<sup>1</sup>, J.-L. DUFIER<sup>2</sup>, A. MUNNICH<sup>1</sup>, J. KAPLAN<sup>1</sup>.* 1) Laboratoire de Recherches sur les Handicaps Genetiques de l'Enfant, INSERM U393, Hopital des Enfants Malades, Paris Cedex 15, FRANCE; 2) Service d'Ophtalmologie, Hopital Necker, Paris, FRANCE.

In contrast with dominant optic atrophies, in which the optic atrophy is usually an isolated event, autosomal recessive optic atrophies (ROA) are frequently multisystem diseases. Yet, we ascertained 7 unrelated multiplex families in which the optic atrophy is not associated with any other symptom. The goal of this study was to localize one or more genes responsible for this very uncommon visual disorder. Putative linkage with the dominant optic atrophy gene (OPA1) on chromosome 3q28 was first excluded in all seven families. Subsequently, a wide genome search for homozygosity was undertaken in 2/7 multiplex and consanguineous families affected with non syndromic OAR. The 382 pairs of fluorescent oligonucleotides of the Genescan Linkage Mapping Set, Version II (Perkin Elmer Cetus) have been studied under conditions recommended by the manufacturer. Amplified fragments were electrophoresed and analyzed on an automatic sequencer (ABI 377). The polymorphic markers have an average spacing of 10 cM throughout the genome. Linkage analyses were performed using M-LINK and LINKMAP of the 5.1 version of the Linkage program. We found evidence for homozygosity in one of the two families studied here. In this family originating from France, four affected children and one healthy child were born from second cousin parents. All 4 affected patients were found to be homozygote for polymorphic markers which were informative in their parents. Pairwise lod-score values calculated in this family gave a maximum lod-score of 3.51 at  $Q = 0$  with the most informative marker. This locus has been excluded by linkage analyses in the six other families. In conclusion, we report here the first mapping of isolated autosomal recessive optic atrophy in 1/7 multiplex families. These data strongly suggest the genetic heterogeneity of this rare condition.

**Affected Sib Pair Tests in Inbred Populations.** *W. Liu, B.S. Weir.* Bioinformatics Program, North Carolina State University, Raleigh, NC.

Affected-sib-pair (ASP) methods study the possible genetic linkage between a putative disease susceptibility locus and marker loci by demonstration within families of nonrandom segregation of parental alleles in affected children. Some ASP tests study the proportions of identical by descent (IBD) marker alleles, others study the identical by state (IBS) marker alleles. Both IBD and IBS tests generally assume that parents are unrelated and not inbred. If there is relatedness and inbreeding, even if only because of evolutionary history, the expected proportions of both IBD and IBS marker alleles are increased. If the usual ASP methods are applied in an inbred population, therefore, high false positive rates may be obtained. We have modified two identity by state test statistics (t-test and chi-square test) of Lange to allow inbreeding in the population. In both tests, the expected parental mating type frequencies were modified. We evaluated the power and false positive rates of both tests under three disease model using simulated data and compared them with those obtained from the usual tests. When the population inbreeding coefficient is large, both the false positive rates and power are reduced when the modified test statistic were applied, although power remained high under a recessive disease model. Our modified IBS tests could provide a good screen when the disease is known to be recessive.

**Fine-mapping of the mouse *ApoB regulator gene 1 (Abrig1)* locus, which regulates plasma apoB levels, to a 2-cM segment of chromosome 6.** L.S. Huang, T.L. Lee, M. McQuade, N. Luo, P.W. Lau, C. Ko, S.C. Chua, Jr. Dept Medicine, Columbia Univ, New York, NY.

Elevated plasma apolipoprotein B (apoB) is a strong predictor of atherosclerosis and coronary heart disease. We have previously shown that *ApoB regulator genes (Abrgs)* are associated with plasma apoB levels in congenic human apoB transgenic (HuBTg) mouse strains. The gene products likely regulate the levels of apoB via hepatic apoB secretion rates. Using F2 and N2 crosses between C57BL/6 (B6-high apoB) and 129/Sv (129-low apoB) strains, we mapped *Abrig1* and *Abrig2* to mouse chromosomes 6 and 4, respectively. Interval-specific congenic strains for *Abrig1* were generated by selecting animals heterozygous for the two markers which define the interval: D6Mit55 and D6Mit199. Incipient congenics (N3-N7) preserved the phenotype of *Abrig1*: Plasma human apoB levels in B6 HuBTg mice containing one copy of 129 allele of *Abrig1* were always lower (30%) than those in B6 HuBTg mice. Both known and new markers spanning the critical interval were used to genotype N4 mice (n=843). The genetic distances among critical markers are as follows: D6Mit55 (49.7 cM) -D6Mit44 (51.5 cM) -D6CU39 (53.5 cM) -D6CU14 (54.0 cM) -D6Mit344 (55.7 cM) -D6Mit368 (56.4 cM) -D6Mit199 (68.0 cM). Reference distances derived from the MGI Database are underlined. Results from N4 recombinants showed that *Abrig1* is within a 2-cM segment flanked by the D6Mit44 and D6CU39 markers. Genetic analysis of F2 and N2 mice (n=88 total) derived from another cross (B6xC3H) also confirmed the presence (LOD=6.2 at D6Mit150, 51.0 cM) of *Abrig* variants between the B6 and C3H strains. Identification of mouse *Abrig* genes may prove useful for finding human orthologues that regulate plasma apoB levels.

**A quantitative trait locus (QTL) on chromosome 5 is associated with plasma apoB responsiveness to fish oil in human apoB transgenic mouse strains.** *C. Ko, S. Kim, W.M. Wu, V. Thassanapaff, S.C. Chua, Jr., L.S. Huang.* Dept Medicine, Columbia University, New York, NY.

An elevation of plasma apoB level is associated with a high risk of atherosclerosis and coronary heart disease. Utilizing a human apoB transgenic (HuBTg) mouse model, we have shown that the responsiveness of plasma apoB levels to fish oil (FO) feeding is genetically regulated. Upon 2 weeks of FO feeding, the C57BL/6 (B6) strain showed a low response in the apoB level, while the FVBxB6 F1 mice showed a high response. To identify genetic factors regulating this responsiveness, F1 HuBTg mice were backcrossed to B6 wild-type mice to generate N2 offspring. Male N2 HuBTg mice (n=150) were fed a chow diet until 8 weeks of age and switched to FO for 2 weeks. Animals were bled before (baseline) and 2 weeks after FO feeding. Plasma human apoB levels were assessed at both time points. Male N2 mice were subjected to a total genome scan using microsatellite markers. Linkages between plasma apoB levels and genotypes were assessed using Map Manager QT program. Analysis of the results derived from 53 markers revealed a significant linkage (LOD score =3.1) between marker D5Mit43 (83.0 cM, chromosome 5) and plasma apoB levels after 2 weeks of FO feeding. Homozygotes for the B6 allele (BB) had significantly lower plasma apoB levels than heterozygotes (FB) ( $85\pm 13$  vs.  $95\pm 16$  mg/dl,  $p=0.0002$ ). No significant differences were found in the baseline plasma apoB levels between both groups of animals (BB vs. FB:  $81\pm 10$  vs.  $82\pm 10$  mg/dl). These results showed that homozygotes had a low response (DapoB= $3\pm 14$  mg/dl), whereas heterozygotes had a high response (DapoB= $13\pm 16$  mg/dl) to FO. In summary, we have identified a QTL on chromosome 5 which regulates the responsiveness of plasma apoB levels at a specific time interval following fish oil feeding. Further studies of this QTL may shed light on the mechanisms regulating plasma apoB responsiveness to fish oil.

**A genome wide scan reveals a putative novel locus for primary ciliary dyskinesia (PCD) in the Faeroe Island population.** *D. Jeganathan<sup>1</sup>, M. Meeks<sup>1</sup>, C. Gehrig<sup>2</sup>, A.J. Walne<sup>1</sup>, M.G. Dunn<sup>1</sup>, H. Bisgaard<sup>3</sup>, J.L. Blouin<sup>2</sup>, R.M. Gardiner<sup>1</sup>, E.M.K. Chung<sup>1</sup>, H.M. Mitchison<sup>1</sup>.* 1) Department of Paediatrics and Child Health, RFUCMS, University College London, UK; 2) Division of Medical Genetics, Geneva University Cantonal Hospital and School of Medicine, CMU, Geneva, Switzerland; 3) Department of Paediatrics, CUH, Copenhagen, Denmark.

PCD is an autosomal recessive disorder (incidence of 1:20,000 live births) characterised by respiratory tract infections, sinusitis, bronchiectasis and subfertility. The clinical phenotype results from dysmotility of the cilia which is associated with a variety of different structural abnormalities. About 50% of patients exhibit laterality defects (Kartagener syndrome). To identify a gene locus for PCD, we studied 4 nuclear families (7 affecteds and 14 unaffecteds) from the isolated Faeroe Island population. The Faeroe Islands have a small population of 45,000, established relatively recently (approximately 1100 years ago). Patients have an outer dynein arm ciliary defect and none display situs inversus. A genome wide scan identified a region consistent with linkage on chromosome 16. High density haplotype analysis refined the region of linkage to a 23cM interval on chromosome 16p12 between D16S3041 and D16S409. Linkage analysis at this interval using GENEHUNTER gave a maximum multipoint lodscore of 2.7 between D16S412 and D16S3093. Assuming a single ancestral mutation accounts for all patients in this isolated population, the identification of linkage disequilibrium by additional marker typing should further refine the critical interval. The narrowed region between D16S412 and D16S3093 spans a distance of about 5.5Mb, approximately of which 50% is available as finished genomic sequence. We are constructing a transcript map for the isolation of positional candidate genes. An axonemal dynein heavy chain, DNAH3, maps to marker D16S417 within our narrowed region (Maiti et al., *Eur J Hum Genet* 8:923, 2000). This presents an excellent candidate gene for PCD in our patients. The identification of intragenic variants within DNAH3 has extended the linkage analysis. Currently further characterisation and mutation screening of this gene is underway.

Program Nr: 2016 from the 2001 ASHG Annual Meeting

**The Ising Model in Physics and Statistical Genetics.** *J. Majewski<sup>1</sup>, H. Li<sup>2</sup>, J. Ott<sup>1</sup>*. 1) Laboratory of Statistical Genetics, Rockefeller Univ, New York, NY; 2) Department of Biochemistry and Biophysics, University of California, San Francisco.

Interdisciplinary communication is becoming a crucial component of the present scientific environment. Theoretical models developed in diverse disciplines may often be successfully employed in solving seemingly unrelated problems that can however be reduced to similar mathematical formulation. The Ising model has been proposed in statistical physics as a simplified model for analyzing magnetic interactions and structure of ferromagnetic substances. Here, we present an application of the one-dimensional, linear Ising model to affected sib pair (ASP) analysis in genetics. By analyzing simulated genetic data, we show that the simplified Ising model with only nearest neighbor interactions between genetic markers has statistical properties comparable to much more complex genetic analysis algorithms, such as those implemented in the Allegro and Mapmaker-Sibs programs. We also adapt the model to include epistatic interactions and demonstrate its usefulness in detecting modifier loci with weak individual genetic contributions. A reanalysis of type-I diabetes data detects several susceptibility loci not previously found with other analysis methods.

**Linkage analysis of a dichotomous trait incorporating an associated quantitative trait: combining the likelihoods of IBD sharing and variance component methods.** *Y. Jiang*<sup>1</sup>, *J. Huang*<sup>2,3</sup>. 1) Preventive Medicine and Epidemiology, Loyola University Medical Center, Maywood, IL; 2) Department of Statistics and Actuarial Science, University of Iowa, Iowa City, IA; 3) Department of Biostatistics Division of Statistical Genetics, University of Iowa, Iowa City, IA.

Many complex disorders, such as asthma, autism, diabetes, and schizophrenia, are studied as dichotomous traits, but are also associated with certain quantitative biological markers or physiological risk factors. Incorporation of the correlational information between the dichotomous and the associated quantitative trait can increase the power to detect genes that predispose a disease trait. We proposed a likelihood based linkage analysis method that jointly consider the dichotomous and the quantitative trait for sib pair data. This likelihood is based on the conditional probability of the quantitative trait and all the marker data given the affection status, to account for the fact that the families collected for linkage analysis are usually ascertained based on affection status. We write this conditional probability as the combination of a likelihood based on IBD sharing scores given the dichotomous trait status and a variance component likelihood for the quantitative trait. A likelihood ratio (LR) test for linkage can be based on this likelihood. We conducted simulation studies to evaluate the properties of the proposed LR test, and found that it in general has higher power to detect linkage than the test based on IBD sharing but not incorporating the correlated quantitative trait.

**Evidence for Genetic Heterogeneity in Brachydactyly Type A1.** *E. McCready*<sup>1,2</sup>, *C.M. Armour*<sup>1,3</sup>, *A.G.W. Hunter*<sup>3</sup>, *D.E. Bulman*<sup>1,2</sup>. 1) Department of Microbiology and Immunology, University of Ottawa; 2) Ottawa Health Research Institute; 3) Eastern Ontario Regional Genetics Program, Children's Hospital of Eastern Ontario, Ottawa, Ontario, Canada.

Brachydactyly Type A1 (BDA1) is a rare, congenital disorder that affects normal bone development, resulting in shortened digits. The phenotype of affected individuals can range from a severe form, in which the middle phalanges are absent or fused to the terminal phalanges, to a mild form, in which shortness of the middle phalange is more pronounced in digits 2 and 5 than the remaining digits. Recent genetic linkage studies have mapped the disease locus to chromosome 2q35-36 in two unrelated Chinese kindreds. Previous evidence of a balanced translocation between chromosome 5q and 17q in a young girl with BDA1 and Klippel-Feil anomaly further suggests that there may be a second BDA1 locus on either chromosome 5 or 17. To examine the location of genes that cause BDA1 we initiated a genome-wide scan in a four-generation, Canadian family with mild disease. Affected individuals in the family were characterized by shortened middle and distal phalanges, proximal first phalanx and fifth metacarpal. Affected individuals also tended to be of short stature. Polymorphic markers from across the genome, with particular emphasis on markers from chromosomes 5 and 17, were examined in 34 family members including 20 affected individuals. Using two-point linkage analysis, a maximum LOD score of 6.91 was observed at marker D5S477 (recombination fraction = 0.00), thus supporting linkage of BDA1 to this region. Haplotype analysis further defined an 11cM critical interval on chromosome 5p13.3-13.2. Preliminary scans of candidate genes from the region, including cadherin-6 and NPR3, have excluded mutations in the coding regions of these genes as the cause of the disease. This region represents a novel locus for BDA1 and provides evidence for genetic heterogeneity in this disease.

**Haplotype Data Mining for Optimization of Rheumatoid Arthritis Fine Genome Scan.** *J. Osorio y Fortea, S. Cailleau Moindrault, E. Petit, G. Bana, C. Pierlot, V. Arbelaz, P. Dieude, T. Bardin, B. Prum, F. Cornelis.*

GenHotel/Laboratoire de Recherche Europeen pour la Polyarthrite Rhumatoide, Genopole 91057, Evry, France/ECRAF (European Consortium on Rheumatoid Arthritis Families).

**Background.** Rheumatoid arthritis (RA) is a multifactorial disease. To search for RA loci, a genome scan was performed in 88 RA sib-pair families with 1109 microsatellite markers, providing an average spacing of 3,5 cM. All families were not informative for every marker, leading to a lack of genetic information. The density of the scan together with the informativity of the markers provided an opportunity to rescue the missing information through haplotyping.

**Objective.** Use of haplotype data mining to optimize linkage analysis.

**Method.** Haplotyping of the 88 families was performed for the first 756 markers with Genehunter2 program. The genotype from 2 flanking informative markers was used to complete the missing data for non-informative markers when those markers were spaced by less than 10 cM, assuming that the probability of double crossing over was negligible (<1%). A new linkage analysis was then performed with Sibpairna4 program from the package Analyze. Suggested RA loci were defined by markers with linkage  $p < 0.05$ .

**Results.** Haplotyping led to an average of 20% increase of informative events (parents informative for the transmission of identical by descent alleles to affected sib-pair). Linkage analysis of the 756 markers, which had suggested 53 susceptibility loci, showed after haplotyping 65 new loci. Apparent double recombinants were detected, pinpointing probable genotyping errors.

**Conclusion.** Haplotype data mining of fine genome scan data contributes to linkage analysis optimization. In addition to the identification of new loci and error-detection, haplotyping helps classifying families according to IBD at a candidate locus, to search for interaction between susceptibility loci.

**Linkage of familial membranoproliferative glomerulonephritis, type III to chromosome 1q31-32.** *J.J. Neary<sup>1</sup>, F. Zhang<sup>2</sup>, B. Zhao<sup>2</sup>, M. Booze<sup>2</sup>, S. West<sup>2</sup>, P.J. Conlon<sup>1</sup>, J.M. Vance<sup>2</sup>, M.A. Pericak-Vance<sup>2</sup>, W.K. Scott<sup>2</sup>, M.P. Winn<sup>2</sup>.* 1) Department of Nephrology, Beaumont Hospital, Dublin 9, Ireland; 2) Department of Medicine, Duke University Medical Center, Durham, NC.

Membranoproliferative glomerulonephritis type III is a chronic, progressive renal disease. The diagnosis is based on renal pathology, specifically immunofluorescence and ultrastructural appearance. The renal disease is characterized by mesangial cell proliferation as well as subendothelial and subepithelial deposits. The clinical features of MPGN are usually chronic in nature and include the nephrotic syndrome (high grade proteinuria, hypoalbuminemia, edema, hyperlipidemia, lipiduria, and hypercoagulability and frequently hypertension) and hematuria. Renal dysfunction occurs in ~50% of patients. Progression to end-stage renal disease (ESRD) is variable, but some patients stabilize and even improve. Here we present an Irish family in which there are nine affected members over three generations and the condition is inherited in an apparent autosomal dominant fashion. This is the only reported family with an inherited form of MPGN, type III. A stringent classification system was adopted to increase the power of the analysis. Affected subjects were defined as those with renal biopsy confirmation or who had end-stage renal disease or persistent and significant proteinuria or haematuria. A genome-wide scan was performed in the Duke Center for Human Genetics using a panel of 405 polymorphic microsatellite markers that define a 10cM resolution index map. Four separate markers on chromosome 1q31-32 generated strong evidence (two-point lod scores > 2) for linkage; one marker generated a peak LOD score of 3.24 at Q=0.00. Further fine-mapping studies are currently underway. This is the first time that MPGN, type III has been mapped to a locus and several plausible candidate genes are located in the region.

**Jouberts Syndrome: extension of genetic linkage to chromosome 9q34.3.** *L.C. Keeler<sup>1,2</sup>, E.P. Leeflang<sup>1</sup>, L. Sztriha<sup>3</sup>, L. Al-Gazali<sup>3</sup>, M. Nour-E-Kamal<sup>3</sup>, P.M. Frossard<sup>4</sup>, R. Bayoumi<sup>5</sup>, K. Saar<sup>6</sup>, F. Rueschendorf<sup>6</sup>, M. Reis<sup>6,7</sup>, B. Ben-Zeev<sup>8</sup>, J.G. Gleeson<sup>1,2</sup>.* 1) Neurosciences Graduate Program, U. Calif., San Diego, La Jolla, CA; 2) Neurosciences, U. Calif., San Diego, La Jolla, CA; 3) Paediatrics, United Emirates U., Al Ain, United Arab Emirates; 4) Pathology, United Emirates U., Al Ain, United Arab Emirates; 5) Biochemistry, United Emirates U., Al Ain, United Arab Emirates; 6) Medicine, Sultan Qaboos U., Al-Khod, Muscat, Sultanate of Oman; 7) Mikrosatellitenzentrum, Max-Delbrück-Centrum; 8) Institute of Human Genetics, Charité, Humboldt University, Berlin; 8) Sheba Meed. Ctr., Ramat-Gan, Israel.

Jouberts syndrome is a rare autosomal recessive disorder characterized by complete absence or significant hypoplasia of the cerebellar vermis. Common clinical features include episodic tachypnea and apnea in the neonatal period, abnormal eye movements, hypotonia, and developmental delay. Pathological examination suggests possible defects in hindbrain patterning, neuronal migration, and axon guidance. Jouberts is phenotypically heterogeneous; clinical features vary even between identical twins, suggesting partial penetrance for some phenotypes. Recently, homozygosity mapping revealed linkage to a 13-cM region of chromosome 9q34.3 in 2 consanguineous Omani pedigrees with a peak two-point LOD score of 3.7 at  $\theta = 0$  (Saar et al., 1999). We have ascertained two additional multiplex pedigrees, one consanguineous and one non-consanguineous, that suggest linkage to this interval. We are currently performing candidate gene analysis of 17 known genes and several ESTs in this region from all four 9q34.3 linked pedigrees. One Palestinian and one Iranian family, with distinct clinical phenotypes, did not show linkage to this region, suggesting genetic heterogeneity. We have obtained DNA samples from a large Pakistani pedigree that also does not link to this region. We are currently performing whole genome mapping in this family.

**A new locus for autosomal dominant high myopia maps to chromosome 17q21-23.** *T. Young*<sup>1,2</sup>, *P. Paluru*<sup>1</sup>, *E. Heon*<sup>3</sup>, *K. Bebhuck*<sup>2</sup>, *C. Armstrong*<sup>2</sup>, *S. Ronan*<sup>2</sup>, *A. Holleschau*<sup>2</sup>, *J. Petersen*<sup>2</sup>, *A. Alvear*<sup>2</sup>, *S. Wildenberg*<sup>2</sup>, *R. King*<sup>2</sup>. 1) Children's Hospital of PA, Philadelphia, PA; 2) University of Minnesota, Minneapolis MN; 3) Hospital for Sick Children, Toronto Canada.

**Purpose:** To map the gene(s) associated with autosomal dominant high myopia. **Methods:** A multi-generation French-Canadian family with autosomal dominant (AD) severe myopia was ascertained. Myopic individuals had no clinical evidence of syndromic disease, anterior segment abnormalities, or glaucoma. The family contained 87 individuals and DNA was available for 31 (10 affected). The average age of diagnosis of myopia was 8.9 years (range 2-11). The average spherical equivalent refractive error for affected adults was -13.925 diopters (range -5.50 to -50.00). The most severely affected individual had axial length measurements of 35.85 and 35.64mm OD and OS, respectively. Two-point linkage analysis using the FASTLINK program was run at 90% penetrance, using a myopia gene frequency of 0.0133. Linkage was excluded for microsatellite markers specific to two previously identified AD high myopia loci on chromosomes 18p11.31 and 12q22-q23. Syndromic myopia linkage was excluded using intragenic or flanking markers for Stickler syndromes type 1, type 2 and type 2B, Marfan syndrome, Ehlers Danlos syndrome type 4, and juvenile glaucoma prior to a full genome screen. **Results:** A two-point LOD score of 2.53 was obtained with microsatellite marker D17S949. A LOD score of 4.05 for marker D17S1290 was obtained after fine-point mapping using 35 additional flanking markers. Haplotyping defined an interval of 11 cM at chromosome 17q21-23. **Conclusion:** A third locus for autosomal dominant high myopia has been confirmed. Gene identification for this common complex disorder should provide insight into its pathophysiology. Supported by Research to Prevent Blindness, Inc, and the National Eye Institute, NIH.

**Linkage Disequilibrium Mapping of a Psoriasis Susceptibility Locus at 3q21.** *C.G. See<sup>1</sup>, D.R. Hewett<sup>1</sup>, J. Polding<sup>1</sup>, K. Cantone<sup>1</sup>, D. Smart<sup>1</sup>, J.H. Riley<sup>1</sup>, L. Samuelsson<sup>2</sup>, F. Enlund<sup>2</sup>, T. Martinsson<sup>2</sup>, J. Wahlstrom<sup>2</sup>, G. Swanbeck<sup>3</sup>, I.J. Purvis<sup>1</sup>.* 1) Molecular Genetics, GlaxoSmithKline, Stevenage, Hertfordshire, England; 2) Department of Clinical Genetics, Gothenberg University Hospital/East, S-416.85 Gothenberg, Sweden; 3) Department of Dermatology, Gothenberg University, Sahlgrenska University Hospital, S-413 Gothenberg, Sweden.

A genome wide linkage analysis has identified a psoriasis susceptibility locus at 3q21 in patients from southwestern Sweden. Preliminary linkage disequilibrium mapping with CA repeats narrowed the size of the candidate region to an estimated 1 Mb, an interval bounded by a single YAC. A set of 20 novel single nucleotide polymorphisms (SNPs) were identified from this region. The SNPs were ordered by mapping to a series of recombinant YACs with nested deletions. Genotyping of 188 families for these novel SNPs was performed by a combination of PCR-RFLP and Taqman technologies. Linkage disequilibrium mapping using TDT analysis showed 3 markers with significant disease association (p value < 0.05). The 150kb spanning these 3 SNPs has been sequenced. Additional markers and candidate transcripts are currently being isolated.

**Linkage and interaction of loci on 1q23 and *IBD1* may contribute to susceptibility to systemic lupus**

**erythematosus (SLE).** *B.P. Tsao*<sup>1</sup>, *J.M. Grossman*<sup>1</sup>, *S.K. Kim*<sup>1</sup>, *D.J. Wallace*<sup>2</sup>, *C-J. Chen*<sup>3</sup>, *C.S. Lau*<sup>4</sup>, *E.M. Human Genetics, UCLA, Los Angeles, CA.

SLE is an autoimmune disease caused by deposition of self-reactive autoantibodies and immune complexes resulting in inflammation and tissue injury. Six genome scans of different SLE multiplex family cohorts support multiple putative susceptibility loci. Seeking replication in an independent sample, we examined candidate loci (1q23, 14q21-23, 16p12-q13 [*IBD1*; inflammatory bowel disease 1], and 20p12) using a cohort of 109 multiethnic nuclear families containing 135 SLE-affected sibpairs. Model-free, multipoint linkage analyses (SIBPAL2, S.A.G.E. 4.0) showed evidence for linkage at 1q23 (peak at D1S484, mean allele sharing [MAS] of .57,  $p = .0008$  by variance component regression analysis of the combined data from the 135 affected sibpairs, 205 SLE discordant sibpairs, and 72 unaffected sibpairs) and at *IBD1* (peak at D16S3136, MAS = .59,  $p = .02$ ). Linkage evidence at 20p12 was weak (MAS = .52 to .55,  $p = .04$  to .07). Linkage to 14q21-23 was excluded ( $I_s = 1.8$ ) by a multipoint linkage analysis. Because *IBD1* has been mapped in genome scans of several autoimmune diseases, we postulated that it might harbor an autoimmune-modifier gene. Thus, we examined the potential interaction between *IBD1* and 1q23, and between *IBD1* and 20p12. The distribution of haplotype sharing at 1q23 increases as the degree of haplotype sharing at *IBD1* also increases ( $p = .0055$  by the Jonckheere-Terpstra exact test). No evidence of an interaction was observed between *IBD1* and 20p12. Analysis of pedigrees conditioned on those showing linkage to *IBD1* increases allele sharing at 1q23 (MAS = .66). Exploiting interaction between linked region may facilitate gene mapping efforts.

**Genome Scans for Apolipoproteins A-I and B in the NHLBI Family Heart Study (FHS).** *K.A. Weis<sup>1</sup>, D.K. Arnett<sup>1</sup>, M.Y. Tsai<sup>2</sup>, H. Coon<sup>3</sup>, G. Heiss<sup>4</sup>, L.D. Atwood<sup>5</sup>, Y. Hong<sup>6</sup>.* 1) University of Minnesota, Minneapolis, MN; 2) Fairview-University Medical Center, Minneapolis, MN; 3) University of Utah, Salt Lake City, UT; 4) University of North Carolina, Chapel Hill, NC; 5) Boston University School of Medicine, Boston, MA; 6) Washington University, St. Louis, MO.

Low plasma levels of apolipoprotein A-I, the major protein component of HDL, and elevated plasma levels of apolipoprotein B, the major protein constituent of LDL, are associated with increased risk of coronary heart disease. Several studies have shown that plasma apo A-I and B levels are influenced by genetic factors. Recent genome-wide scans have shown linkage to previously uncharacterized genomic regions, indicating additional loci influencing apolipoprotein levels. We conducted genome-wide scans for apo A-I and apo B using two subgroups from the NHLBI Family Heart Study (FHS): 1) sibships with at least one sibling at increased risk for CHD (937 white individuals in 355 families genotyped by the University of Utah for 243 markers) and 2) 401 families selected as the largest pedigrees in FHS with the greatest familial variation in CHD risk (1048 white individuals in 305 families genotyped by the Mammalian Genotyping Service (MGS) for 402 markers). A genome-wide scan was also performed on a non-redundant combination of these two subgroups (1321 white individuals in 473 families with 645 anonymous markers). Multipoint variance components linkage analysis was conducted using GENEHUNTER2. Apo A-I and B were adjusted for field center in a sex-specific linear regression model, and standardized residuals were calculated. These residual phenotypes were further adjusted in GENEHUNTER2 with the direct addition of standardized age, age<sup>2</sup>, and body mass index. For apo A-I, a maximum LODscore of 1.88 was obtained with the combined marker set on chromosome 12 at 83.2 cM, near marker D12S1052. For apo B, a maximum LODscore of 1.53 was obtained with the MGS marker set on chromosome 10 at 93.9 cM (LODscore decreased to 1.44 in the combined analysis), near marker D10S1432. In conclusion, our study did not find any chromosomal regions significantly linked to apolipoproteins A-I or B in the FHS population.

**Genome scan on fifty-six multiplex bipolar pedigrees collected by the NIMH Genetics Initiative (Bipolar Disorder).**

*V.L. Willour<sup>1</sup>, P.P. Zandi<sup>1,2</sup>, D.F. MacKinnon<sup>1</sup>, S.G. Simpson<sup>1</sup>, J.B. Potash<sup>1</sup>, E.S. Gershon<sup>3</sup>, J.I. Nurnberger<sup>4</sup>, T. Reich<sup>5</sup>, J.R. DePaulo, Jr.<sup>1</sup>, M.G. McInnis<sup>1,6</sup>.* 1) Department of Psychiatry, Johns Hopkins University, Baltimore, MD; 2) Department of Mental Hygiene, Johns Hopkins University, Baltimore, MD; 3) Department of Psychiatry, University of Chicago, Chicago, IL; 4) Department of Biochemistry and Molecular Biology, Indiana University, Indianapolis, IN; 5) Department of Psychiatry, Washington University, St. Louis, MO; 6) Department of Epidemiology, Johns Hopkins University, Baltimore, MD.

The NIMH Genetics Initiative (Bipolar Disorder) has ascertained 153 multiplex bipolar pedigrees that have been genotyped in two waves. The results of the wave one analyses have been reported (Nurnberger et al., 1997). We are now reporting the wave two genome scan results for the twelve chromosomes that Johns Hopkins has genotyped: chromosomes 2, 4, 7, 9, 11, 13, 14, 18, 19, 20, 21, and X. The microsatellite marker maps range from 5.8 cM (chromosome X) to 10.3 cM (chromosome 7). Three affection status models (ASM I-III) were used in the linkage analyses. Multipoint nonparametric analyses using GENEHUNTER v 2.0 and XGENEHUNTER v 1.3 produced three candidate regions. A broad peak that spans 4q32-4q35 is visible under all affection status models; it reaches its maximum NPL of 2.7 ( $p=0.005$ ) under ASMI. The broad peak at 20p12 reaches an NPL of 2.63 ( $p=0.006$ ) under ASMI. The 11p15 peak reaches an NPL 2.42 ( $p=0.006$ ) under ASMI. All three of these regions have been previously implicated in bipolar disorder. Continued high-density genetic mapping in these regions is warranted.

**Genetic founder effect at the hereditary neuralgic amyotrophy (HNA) locus on chromosome 17q25.** *G.D.J. Watts, K.C. O'Briant, P.F. Chance.* Pediatrics, University of Washington, Seattle, WA.

Hereditary neuralgic amyotrophy (HNA) is an autosomal dominant disorder that is associated with episodic, recurrent brachial plexus neuropathy. To date no families other than those from Caucasian decent have been reported. Recent studies mapped the HNA locus to chromosome 17q25. To further refine the HNA locus we carried out genetic linkage studies in four pedigrees with a high density set of DNA markers from chromosome 17q25. All pedigrees demonstrated linkage to chromosome 17q25 and an analysis of recombinant events placed the HNA locus within an approximate 1Mb interval flanked by markers D17S722 and D17S802. In order to test the power of linkage disequilibrium mapping we compared genotypes of 12 markers from probands of 7 pedigrees of European extraction, that show linkage to chromosome 17q25. This identified a founder effect in 6 of the 7 pedigrees with a minimal shared haplotype that further refines the HNA locus to an approximate 500Kb interval. These findings suggest that for the pedigrees from the United States at least one mutation in the HNA gene was introduced from European roots.

**Evidence of linkage for keratoconus to chromosome 16 based on a genome-wide linkage analysis.** *H. Tynnismaa*<sup>1,2</sup>, *P. Sistonen*<sup>3</sup>, *S. Tuupanen*<sup>1,2</sup>, *T. Tervo*<sup>4</sup>, *A. Dammert*<sup>5</sup>, *T. Latvala*<sup>5</sup>, *T. Alitalo*<sup>1,2</sup>. 1) Dept Obstetrics and Gynecology, Helsinki University Central Hospital, Finland; 2) Dept Medical Genetics, University of Helsinki, Finland; 3) Finnish Red Cross, Blood Transfusion Service, Helsinki, Finland; 4) Dept of Ophthalmology, Helsinki University Central Hospital, Finland; 5) Dept of Ophthalmology, University of Oulu, Finland.

Keratoconus (MIM148300) is a noninflammatory corneal thinning and irregular steepening disorder with an incidence of 1:2000. In western populations the disease is the leading single indication for corneal transplantation surgery. Most of the cases are sporadic. It has been suggested that 6-10% of the keratoconus cases follow autosomal dominant inheritance with incomplete penetrance or variable expression. The pathogenesis of the disorder is unclear. Due to scarcity of large family material, no genome-wide linkage scans to localize the gene/genes have been published. Here we present the first results of genome-wide linkage analysis, which was performed using DNA samples of 20 keratoconus families from Northern Finland. The diagnosis of the patients was based on computer-assisted videokeratoscopy. Linkage analysis was performed using the GENEHUNTER program, assuming autosomal dominant inheritance and a gene penetrance of 0.5. The initial screen was performed using a panel of 369 markers with an average spacing of 10cM. This resulted in four promising regions on chromosomes 2,10,15 and 16, with LOD scores >1.5. Additional flanking markers were genotyped and increased multipoint LOD scores were obtained only for the markers on chromosome 16. Strong evidence for linkage was observed on chromosome 16 with a maximum multipoint LOD score of 4.10 and non-parametric linkage (NPL) scores of 3.27 ( $p=0.00006$ ) for the same locus. We are currently fine-mapping the candidate region on chromosome 16 as a first step to isolate the keratoconus gene. Even though it is not yet known whether the gene on chromosome 16 will be defective in keratoconus patients world widely, identifying the keratoconus gene in Finnish families will improve the understanding of the pathogenesis of this complex trait.

**Studies on Charcot-Marie-Tooth disease with vocal fold paralysis (CMT2C) reveal further evidence for genetic heterogeneity.** *I. Puls<sup>1</sup>, K. Bidus<sup>2</sup>, D. Drayna<sup>5</sup>, M.K. Floeter<sup>4</sup>, E. Mann<sup>2</sup>, J.P. Taylor<sup>1</sup>, K.R. Wagner<sup>3</sup>, K.H. Fischbeck<sup>1</sup>, C. Ludlow<sup>2</sup>.* 1) Neurogenetics Branch (NINDS), NIH, Bethesda, MD; 2) Laryngeal and Speech Section (NINDS), NIH, Bethesda, MD; 3) Johns Hopkins University, Neurology Department, Baltimore, MD; 4) Electromyography Section (NINDS), NIH, Bethesda, MD; 5) Section on Transcription Factors, Sensory Receptors and Channels (NIDCD), NIH, Bethesda, MD.

CMT2C is a motor-sensory polyneuropathy with autosomal dominant inheritance and vocal fold paralysis that is caused by axonal degeneration of peripheral nerves. Two families with this particular phenotype have been linked to chromosomes 2q14 and 6q16. We collected 4 different families from the United States with no evidence of a common ancestor. The patients showed signs of distal weakness and atrophy with mild sensory loss and uni- or bilateral vocal fold paralysis. The onset of symptoms and disease progression were variable both within and between the families examined. Nerve conduction studies gave evidence for axonal polyneuropathy. Linkage to known loci for CMT2C was tested, using standard protocols and published polymorphic markers. The analysis suggested linkage to chromosome 2q14 for one family. Linkage to chromosome 2 and 6 could be excluded for the other three. Our results indicate that there is genetic heterogeneity for CMT with vocal fold paralysis, with at least a third locus existing in addition to the two previously described. Extension of our pedigrees and a genome wide screen is in progress.

**Linkage Analysis of Nonsyndromic Cleft Lip and Palate in 30 Filipino Families with Multiple Affected**

**Individuals.** *R. Schultz*<sup>1</sup>, *S. O'Brien*<sup>1</sup>, *S. Daack-Hirsch*<sup>1</sup>, *M. Cooper*<sup>2</sup>, *M. Marazita*<sup>2</sup>, *J. Murray*<sup>1</sup>. 1) Dept Pediatrics, University of Iowa, Iowa City, IA; 2) Cleft Palate Center, University of Pittsburgh, Pittsburgh PA.

Cleft lip and palate (CL/P) is a congenital anomaly present in on average 1/1000 live births. About 30% of cases are syndromic, with various causes such as Mendelian disorders, chromosomal anomalies, or teratogen exposure. The remaining 70% are nonsyndromic (NS), in which the affected individual has no other abnormalities. Several loci were selected for study to determine whether they demonstrated linkage to NS CL/P. Loci were chosen based on previous suggestive findings and include 1p36, 4p16.2 (MSX1), 2p13.2 (TGFA), 14q24.3 (TGFB3), 4q31, 6p23, and 19q13. Microsatellite repeat or other highly polymorphic markers in these regions were selected. 30 Filipino families comprising 292 individuals of whom 114 are affected were used for the linkage study. An additional 63 families comprising 149 affected individuals are available for replication of any significant or suggestive results obtained from the initial 30 families. The MSX1-CA repeat and the microsatellite repeat marker D6S1029 have been genotyped for all 30 families. Parametric linkage analysis was carried out by the LINKAGE program with the FASTLINK update, and nonparametric analysis was carried out by GENEHUNTERnpl. The Family Based Association Test 1.2 program was used to perform the TDT analysis. The MSX1 repeat gave a maximum LOD score of 1.20 at theta=0.2, a SIMIBD p-value of 0.2, and a multiple allele p-value for the TDT of 0.34. D6S1029 had a maximum LOD score of 0.31 at theta=0.3, a SIMIBD p-value of 0.06, and a multiple allele p-value for the TDT of 0.76. The LOD score of 1.26 for the MSX1-CA repeat and the SIMIBD p-value of 0.06 for D6S1029 are suggestive of linkage, although not significant. Genotyping is being extended to other markers in these regions and to the additional 63 families for validation. Since the mouse knockout of *Msx1* has cleft palate and MSX1 mutations have been found in rare cases of apparent NS CL/P, this locus is very plausible for linkage.

**LINKAGE MAPPING TO CHROMOSOME 3q24 AND EVIDENCE FOR A FOUNDER EFFECT FOR HERMANSKY-PUDLAK SYNDROME IN CENTRAL PUERTO RICO.** *J.R. Toro, W.A. Gahl, S. Bale.* National Institutes of Health, NIH, Bethesda, MD.

Hermansky-Pudlak Syndrome (HPS) is an autosomal recessive disorder characterized by oculocutaneous albinism, a bleeding diathesis due to platelet storage pool deficiency, and lysosomal accumulation of ceroid lipofuscin. HPS occurs with a high frequency in northwest Puerto Rico (PR), where 1 in 21 individuals is a carrier. HPS patients from northwest PR are homozygous for a 16-bp duplication in exon 15 of the HPS1 gene; this mutation is associated with significant risk of pulmonary fibrosis. The objective of this study is to determine the phenotype and genotype of HPS patients from central PR and map the gene for a new subtype of HPS. All patients lacked platelet dense bodies on electron microscopy, confirming the diagnosis of HPS. All patients also lacked the 16-bp duplication in HPS1. All patients had ancestry from central PR and exhibited only mild visual defects and mild pigment dilution of hair, eyes and skin. These findings differed significantly from HPS individuals with the 16-bp duplication in HPS1. Using homozygosity mapping on pooled DNA from 6 families from central PR, we mapped the putative new HPS susceptibility gene to chromosome 3q24. This region on chromosome 3q24 was analyzed using 21 polymorphic markers. Contiguous homozygous markers defined an ancestral haplotype in all affected individuals. Recombination allowed us to tentatively narrow the critical region to a 1.6 cM interval on chromosome 3q24. The ancestral haplotype encompassed at least 11 cM and we estimated that the recombination with the ancestral chromosome has occurred in approximately 44% of cases. Using the Luria & Delbruck method, we estimated that the mutation occurred in central Puerto Rico approximately in 1880-1890. History books, church records and genealogical studies revealed that common ancestors of three of our families emigrated from the town of Ciales to the towns of Aibonito and Barranquitas because of harsh economic conditions in Ciales approximately. It is possible that genetic isolation of the mountainous terrain of this area contributed the development of this second founder mutation causing HPS in central Puerto Rico.

**Loci on Chromosomes 7 and 2 Interact to Increase Linkage Evidence in Autistic Disorder.** *Y. Shao<sup>1</sup>, W.K. Scott<sup>1</sup>, K.L. Raiford<sup>1</sup>, C.M. Wolpert<sup>1</sup>, A. Ashley-Kock<sup>1</sup>, M.L. Cuccaro<sup>2</sup>, J.R. Gilbert<sup>1</sup>, M.A. Pericak-Vance<sup>1</sup>.* 1) Ctr Human Genetics, Duke Univ Medical Ctr, Durham, NC; 2) W.S. Hall Psychiatric Institute, University of South Carolina, Columbia, SC.

Our genomic screen analysis of 99 autistic disorder (AutD) families revealed suggestive evidence for linkage to chromosome 2q at D2S116 (198 cM; MLS=1.12). In addition analysis of linkage disequilibrium for D2S116 showed an allele-specific p-value < 0.01. Recently, Buxbaum et al. (2001) also reported linkage to the same 2q region (Heterogeneity LOD score (HLOD) = 1.96) in an independent genome screen. Their evidence for linkage increased (HLOD=2.99) when they restricted their analysis to the subset of AutD patients with delayed onset (>36 months) of phrase speech (PSD). We similarly classified our AutD sibships, identifying 37 AutD families with PSD. Analysis of our PSD subset increased support for to 2q linkage (MLS =2.82,HLOD=2.05. The evidence for heterogeneity decreased in the PSD subset (the proportion of linked families (a) increased from 0.25 to 0.90). We observed similar linkage enhancement in the PSD subset at another candidate region on Chr7. Our MLS score increased from 1.17 to 2.00 and the HLOD from 0.67 to 1.46. The evidence for heterogeneity also decreased (a increased from 0.30 to 0.90). We also observed evidence for statistical interaction between these 2 unlinked regions in the overall dataset. The non-parametric lod score (LOD\*) from GENEHUNTER+ for chr7=1.09 in baseline analysis but increased to 2.97 when families were weighted by their evidence for linkage at d2s116. The conservative c-square test with df =1 yielded a p-value <0.005 to show the significance of the interaction with the increased weighted lod. Significant interaction between unlinked regions as well as phenotypic homogeneity provides additional evidence that loci from these two regions contribute to AutD risk and suggests that this is a powerful approach to identify susceptibility genes for AutD.

**Haplotype analysis in patients with velopharyngeal insufficiency (VPI) minimizes one VPI locus in 2.8Mb region of 22q11.** *L.P. Tsai<sup>1</sup>, K.S. Tsou<sup>2</sup>, Y.R. Shi<sup>3</sup>, J.Y. Wu<sup>3</sup>, F.J. Tsai<sup>3</sup>*. 1) Dept Pediatrics, Taipei Mun Womens/Child Hosp, Taipei; 2) Dept Pediatric Psychiatry, Taipei Mun Womens/Child Hosp, Taipei; 3) Dept Medical Research, China Medical College Hospital, Taichung, Taiwan.

Velocardiofacial syndrome (VCFS) and DiGeorge syndrome (DGS) exhibit a wide spectrum of anomalies, including cleft palate, congenital heart defects of the conotruncal type, facial dysmorphism, cellular immunity disorder and learning disabilities. Most patients were hemizygous in the region 22q11, and share a 3-Mb deletion flanked by D22S427 and D22S306/308. Most of the remaining cases had a smaller, 1.5-Mb deletion. However, there was no correlation between the phenotype and the presence or size of the deletion so far. To define the specific deletion that is responsible for certain phenotype, instead of study on complex VCFS/DCS patients, we used the eleven consecutive simple tandem repeat polymorphic markers mapped to 22q11 to genotype patients of isolated phenotype. Haplotype analysis was performed with patients and their parents. In this way, we found that five patients of velopharyngeal insufficiency (VPI) free from congenital heart defects had a similar 2.8-Mb deletion flanked by D22S1623 and D22S303, which is distal to the most common 3-Mb deletion region of VCFS/DGS with a 1.7-Mb overlap. Most patients with conotruncal heart defect had deletion more proximal to this 2.8-Mb region. Our data suggest that one gene or a set of genes within this 2.8Mb region is essential for velopharyngeal function. Haploinsufficiency of these genes cause symptoms of VPI clinically. Compared with the previous reports, it seems that molecular analysis on isolated phenotype patients related to VCFS is a better approach to get phenotype/genotype correlation. We recommend that haplotype analysis is needed for patients with VPI to further narrow down the region and look for the candidate gene(s) for VPI.

**Genetic Analysis of Kindler Syndrome.** *D.H. Siegel<sup>1</sup>, H. Penagos<sup>2</sup>, C.B. Wiebe<sup>3</sup>, H.S. Feiler<sup>4</sup>, K.C. Wilhelmsen<sup>4</sup>, E.H. Epstein<sup>1</sup>.* 1) Dermatology, UCSF, San Francisco, CA; 2) Dermatology, Chiriqui Regional Hospital, Social Security Bureau of Panama, David, Panama; 3) Oral Biological and Medical Sciences, Faculty of Dentistry, University of British Columbia, Vancouver, BC, Canada; 4) Ernest Gallo Clinic and Research Center, Department of Neurology, UCSF, Emeryville, CA.

Kindler syndrome is a rare autosomal recessive disorder with changes resembling both epidermolysis bullosa and congenital poikiloderma. Twenty-six patients with Kindler syndrome from the Ngobe tribe of Bocas del Toro, Panama were examined, and blood samples were collected. Abnormalities included congenital acral blisters, photosensitivity, poikiloderma, cigarette paper-like wrinkling of the dorsal hands and feet, periodontal disease, phimosis in males, and webbing of the digits. Several regions of decreased allelic heterogeneity were identified in an 811 marker genome-wide scan on pooled DNA samples. A subsequent genome-wide scan of DNA from 16 individual patients and 8 related unaffected controls confirmed one of these, with a maximum LOD score of 2.48. Individual genotyping defined a 300-Kb area of homozygosity in the Panamanian patients. Genotyping of DNA from additional patients from Japan, the Middle East, the United States and Canada confirmed this region of homozygosity containing four annotated genes. Mutational analysis is currently underway.

**The power of using classification and regression tree to reduce heterogeneity in the affected sibpair analysis.** *J.L. Chen<sup>1</sup>, C.J. Chang<sup>2</sup>, C.S.J. Fann<sup>1</sup>*. 1) Inst Biomed sci, Acad Sinica, Taipei, Taiwan; 2) Department of Medical Research, National Taiwan University Hospital, Taipei, Taiwan.

The power to detect linkage is always reduced if data consists of a mixture of heterogeneous sibpairs. To circumvent such problems, we proposed a method that uses cluster analysis, classification and regression tree with meaningful covariates to identify more homogeneous subgroups to detect genetic linkage for qualitative and quantitative traits previously. In this study, we examined the power of this method by considering a few factors, the extent of locus heterogeneity (percentage of unlinked family), sample size of sibpair and underlying assumption of related covariates using Monte Carlo simulation approach. Family data consist of sibpairs and ten covariates were generated according to some known distributions. Among these covariates, only four (three continuous and one binary) were related to assumed traits. An interaction between two covariates (one binary, one continuous) was also assumed. The algorithm implemented with classification and regression tree was able to pick up 4 related covariates about 70% of the time and it was about 90% to pick up 3 related covariates in 1000 replicates. The simulation results indicated the power was generally acceptable (>80%) regardless of any factor when sample size was large ( $n=500$ ). However, with small sample ( $n=100$ ), power dropped from 81% to 42% if ratio of covariate means increased from 0.5 to 0.8. Power was 74% and 52% when the percentage of unlinked family was 30% and 70% respectively. The presence of interaction reduced the power even further. According to our simulations, power was low in small sample if the percentage of unlinked family is more than 30% and ratio of covariate means is bigger than 0.65. In conclusion, this method performs well when sample size is large; however, caution should be taken with smaller sample size.

**Regressive Threshold Model for Sib Pair Analysis of Complex Diseases with Variable Age of Onset.** *L. Briollais.*  
Department of Epidemiology and Biostatistics, Samuel Lunenfeld Research Institute, Mount Sinai Hospital, and  
Department of Public Health, University of Toronto, Toronto, Canada, M5G 1X5.

Most chronic human diseases exhibit variability in their age of onset and have a complex mode of inheritance. Model-free linkage analysis methods have become popular in gene mapping of complex diseases (CDs) but few of them can account for censored observations. We propose here a new regressive-based approach for sib-pair analysis of CDs with variable age of onset that allows for a residual familial correlation, measured risk factors and gene by environment interaction. The rationale is to assume that the disease is determined through an underlying continuous variable, e.g. the liability, normally distributed in the general population and correlated among family members. Affected individuals at age-of-onset  $k$  have a liability that lies between two time-dependent thresholds  $[T_k, T_{k+1}]$ , the thresholds demark the quantiles of the standard normal cdf. The first moment of the liability distribution is expressed as a function of measured risk factors and genotype risks at the marker locus. Conditionally to the proportion of alleles shared ibd, the covariance between sibs' liabilities is a sum of two products: the variance accounted for by the trait locus by the estimated proportion of allele shared ibd, and the variance resulting from a polygenic effect and/or shared environment by a residual sib-sib correlation. The likelihood is expressed using the truncated normal distribution theory and parameter estimation is performed by maximum likelihood methods. The null hypothesis of no linkage is tested by comparing the variance of the trait locus to 0. Our first simulation studies under different genetic models showed that the method was associated with acceptable levels of Type I error and a gain in power was obtained when a residual familial correlation was accounted for and in some cases in presence of gene by environment interaction. This approach can be easily extended to multivariate phenotypic traits, large families and multiple loci and thus provides a new opportunity for gene mapping of complex diseases.

**Construction of a Confidence Set of Markers for the Location of a Disease Gene Using Affected-Sib-Pair Data.** *S. Lin.* Dept of Statistics, Ohio State Univ, Columbus, OH.

We have previously proposed a confidence-set approach to find tightly linked genomic regions in parametric linkage analysis. Two fundamental advantages of this approach are (1) its ability to localize disease genes to small chromosomal regions at the stage of an initial genome-scan study and (2) the avoidance of the need of multiplicity adjustment for the number of markers tested. Here we extend the confidence-set approach to non-parametric linkage analysis of affected-sib-pair (ASP) data based on their identity-by-descend (IBD) information. Non-parametric methods are usually more suited for mapping complex traits since their underlying genetic models are often unclear. The confidence-set approach is based on testing a non-traditional formulation of hypotheses, with the null (tight linkage) and alternative (loose or no linkage) hypotheses being the "reverse" of the traditional formulation of null (no linkage) and alternative (linkage) hypotheses. From the corresponding theory between hypothesis testing and confidence set, construction of a confidence set of markers amounts to collecting the markers that are not rejected when testing the non-traditional formulation of hypotheses. Two well-known statistics in non-parametric linkage analysis are based upon for constructing confidence sets, the Two-IBD test (proportion of ASPs sharing two alleles IBD), and the Mean test (average number of alleles shared IBD in the APSs). In order to construct confidence sets using these two tests, we need to specify the marker IBD distribution, which is shown to be completely determined by either the disease incidence data or the variance components of a trait, without specifying a penetrance model. Our results show that the two main advantages of the confidence-set approach are retained when the method is generalized to non-parametric analysis. Furthermore, we study accuracy of confidence sets in terms of choice of tests, underlying disease incidence data, and amount of data available. From the results, we conclude, among other things, that the Mean test outperforms the two-IBD test in most situations, but the reverse is true for traits with small additive variance.

**Power of the ordered subset method for detection and localization of genes in linkage analysis of complex traits.**

*E.R. Hauser<sup>1</sup>, M.P. Bass<sup>1</sup>, E.R. Martin<sup>1</sup>, R.M. Watanabe<sup>2</sup>, W.L. Duren<sup>3</sup>, M. Boehnke<sup>3</sup>.* 1) Center for Human Genetics, Duke University Medical Center, Durham, NC; 2) Department of Preventive Medicine, USC Keck School of Medicine, Los Angeles, CA; 3) Department of Biostatistics, University of Michigan, Ann Arbor, MI.

We have proposed the ordered subset method for identification and localization of genes for complex traits in genetically heterogeneous samples (Hauser et al. 1998; Ghosh et al. 2000). Leal and Ott (2000) have shown that stratification of such samples into genetically homogeneous subsets can provide increased evidence for linkage, depending on the strength of the genetic effect in the linked stratum and the size of the strata. However, in practice it may be difficult to identify strata prior to the linkage analysis. The ordered subset method does not require specification of individual strata prior to analyses but rather, uses trait-related covariates, such as mean age of onset, to rank families. The families are added to the analysis in rank order one by one and the maximum lod score is calculated as each family is added. The set of families providing the maximum subset lod score is identified as well as the maximum likelihood estimates of location and genetic effect for this subset. We test the null hypothesis that ordering families by the covariate does not improve the maximum subset lod score by calculating an empirical p-value. This p-value is estimated from the distribution of maximum subset lod scores obtained by randomly permuting the order of the families and recalculating the maximum subset lod score. We examine the power of this approach in detecting linkage in a simulation study using a variety of genetic heterogeneity models and relationships to a generic trait-related covariate. One appealing feature of this method is that the estimate of the location of the disease gene is recalculated in the subset. We examine improvements in disease gene localization using this ordered subsets method.

**A score test for detecting linkage to quantitative traits.** *H. Putter*<sup>1</sup>, *L.A. Sandkuijl*<sup>1,2</sup>, *J.C. van Houwelingen*<sup>1</sup>. 1) Dept of Medical Statistics, Leiden University Medical Center, Leiden, The Netherlands; 2) Dept of Human and Clinical Genetics, Leiden University Medical Center, Leiden, The Netherlands.

The two most popular methods to detect linkage of a quantitative trait to a marker are the Haseman-Elston (HE) regression method and the variance components likelihood ratio test. In the literature these methods are frequently compared and the relative advantages and disadvantages of each method are well known. In this paper, we derive a score test for the variance component attributable to a specific quantitative trait locus in a variance components model and show that for sib-pairs it is mathematically equivalent to a recently proposed version of the HE method that optimally combines the sum squared and the difference squared of the centered phenotype values of the sibs. Since score tests and likelihood ratio tests are equivalent for large sample sizes, the variance components likelihood ratio test is also asymptotically equivalent to this optimal HE test. This fact gives a theoretical explanation of the empirical observation from simulation studies reporting similar power of the variance components likelihood ratio test and the optimal HE method. Perhaps more importantly for practical purposes, the score test can also be extended in a natural way to support the simultaneous analysis of more than two subjects and multivariate phenotypes.

**Non-positive semidefinite identity-by-descent matrices for highly heritable traits lead to singularities in the extended pedigree variance components model.** *J.S.C. Ronald<sup>1</sup>, N. Ertekin-Taner<sup>2</sup>, S.G. Younkin<sup>1</sup>, L.H. Younkin<sup>1</sup>, M. Hutton<sup>1</sup>, S.G. Younkin<sup>1</sup>.* 1) Neuroscience, Mayo Clinic, Jacksonville, FL; 2) Genetic Epidemiology, Mayo Clinic, Rochester, MN.

Quantitative traits have been used to map disease loci for thrombosis, obesity, and diabetes. We have successfully applied a similar approach to late-onset Alzheimers disease by performing linkage analysis on plasma amyloid b protein (Ab42) levels in extended pedigrees using the SOLAR variance components method. This method uses maximum likelihood to model the phenotype covariance matrix by decomposing it into locus specific, residual genetic, and environmental components. An essential requisite for accurate calculation of lod scores is that the fitted phenotype covariance matrix be non-singular. Provided that the locus specific identity-by-descent (ibd) matrix is positive semidefinite (psd), any nontrivial linear combination of the ibd, kinship, and identity matrices, each weighted by its appropriate variance component, will result in a positive definite matrix. While the true ibd matrix is always psd, an estimated ibd matrix may have negative eigenvalues. A non-psd ibd matrix ensures that there will be combinations of variance components in the interior of the parameter space that result in a singular phenotype covariance matrix. In this situation, likelihood maximization algorithms may produce arbitrarily high or low lod scores that are artifact of singularities. We have observed that the regression based method of Fulker et al. for estimating multipoint ibd (mibd) coefficients as implemented in SOLAR results in non-psd mibd matrices. In our experience, the smallest eigenvalue of typical mibd matrices is only slightly negative (on the order of  $-10^{-1}$ ), and therefore singularities only occur in models where the trait heritability is substantial ( $>85\%$ ). For a trait with heritability exceeding 85%, as occurs for plasma Ab42 in certain sets of families, several options are available. These include restricted searches of the parameter space and transformation of the mibd matrices, either of which ensures that the phenotype covariance matrix stays positive definite.

**A multivariate approach for detecting linkage with sib-pair observations.** *X. XU, L. Tian, X. Xu, L.J. Wei.* Program for Population Genetics, and Department of Biostatistics, Harvard School of Public Health, Boston, MA.

Under the circumstance that a single QTL contributes to multiple distinct phenotypic traits, a multivariate linkage test that analyzes multiple traits simultaneously would provide substantial power improvement over individual single-trait tests. We have previously described a simple test procedure extending the unified Haseman-Elston method to allow linkage test with multivariate traits (Xu et al, *Genet. Epidemiol.* 2001, in press). The test is based on linear combination of estimators of the H-E regression coefficient for each individual trait, and works optimally when the narrow-sense heritabilities of the QTLs for all traits are approximately equal. It is common that the true values of the narrow-sense heritabilities vary among traits and are unknown prior to analysis, reducing the efficiency of the multi-trait test. Here, we propose a modification to our previous multi-trait test by adding an empirically determined weight to estimators in the linear combination according to a function of the standardized estimators for the trait, with larger weights going to the traits with larger standardized estimators. We expect the modified method to perform better than the original multi-trait test under condition of unequal narrow-sense QTL heritabilities among different traits. The statistical basis of the modified methods will be discussed, and its type-I error and power will be compared with the original test using both simulated data and real observations. This statistical procedure can be generalized to other multivariate test such as association analysis.

**Suggestive linkage on chromosomes 1 and 15 for a protective alcohol-related phenotype.** *D.M. Dick<sup>1</sup>, J.I. Nurnberger, Jr.<sup>1</sup>, H.J. Edenberg<sup>1</sup>, A. Goate<sup>2</sup>, R. Crowe<sup>3</sup>, J. Rice<sup>2</sup>, V. Hesselbrock<sup>4</sup>, T. Foroud<sup>1</sup>.* 1) Indiana University, Indianapolis, IN 46202-5251; 2) Washington University, St. Louis, MO 63110; 3) University of Iowa, Iowa City, IA 52242-1000; 4) University of Connecticut, Farmington, CT 06030-2103.

Efforts to identify genes involved in alcohol use/abuse have been complicated by uncertainty regarding how best to define phenotypes for genetic analyses. Using data from the Collaborative Study on the Genetics of Alcoholism (COGA), we have been developing quantitative phenotypes characterizing patterns of alcohol use. COGA is a multi-site family-based study that has systematically ascertained alcoholic probands from treatment facilities. A total of 1,227 proband families and 234 control families were recruited in the initial stage of the study. Subjects completed a multi-diagnostic interview and personality questionnaire. A principal component analysis was performed on variables measuring aspects of alcohol use, antisociality, anxiety and guilt about one's drinking, and personality. Three components emerged: the first was characterized by drinking, drinking problems, and high novelty-seeking. The other two were protective: factor two was characterized by high harm avoidance and a later age of onset of drinking, and the third factor was characterized by high reward dependence. A genome screen was completed in 987 individuals from an initial sample of 105 families having at least three first-degree relatives diagnosed as alcohol dependent; a follow-up genomic screen was conducted on 1295 individuals from another 157 multiplex families. The three factors from the principal component analysis were used in a series of quantitative trait sibling pair linkage analyses. Chromosome 1 yielded consistent evidence of linkage to the protective factor two across the initial, replication, and combined samples, with a maximum lod score of 3.3 in the combined sample near the marker D1S518. Chromosome 15 also produced consistent evidence of linkage across the samples, with a maximum lod score of 2.0 between the markers D15S143 and GATA153 in the combined sample; this region is also linked to EEG findings in the COGA sample.

**Assessment of significance for quantitative traits via a permutation-type test.** *M. Abney<sup>1</sup>, C. Ober<sup>1</sup>, M.S.*

*McPeck<sup>1,2</sup>.* 1) Dept Human Genetics, Univ Chicago, Chicago, IL; 2) Dept of Statistics, Univ Chicago, Chicago, IL.

Assessing significance, in particular, genome-wide significance, has proven to be a difficult problem in linkage mapping. One common solution has been to use a proposed "universal" cut-off value for the lod score. This solution, however, cannot provide a true p-value for any one particular study, as every study differs in design and in population considered. One might prefer to take these into account when assessing genome-wide significance. We propose a novel permutation-type method to assess genome-wide and locus-specific significance for tests for detection of linkage or linkage disequilibrium with quantitative traits. The method is applicable under a linear model for the phenotype, with covariates and/or correlated errors allowed. The method can be applied to studies composed of independent sampling units (e.g., independent sib-pairs) or large families with an arbitrarily complex (but known) correlation structure. The difficulty with permutation tests in the latter case arises from the lack of exchangeability. In the case of multivariate normality, we overcome this problem by finding a linear transformation of the phenotypic residuals (i.e., after accounting for age, sex and other covariates) such that the transformed residuals are uncorrelated. Permutations are then done on these uncorrelated residuals before untransforming them and obtaining simulated data sets. This method has the advantage of being an exact permutation test when the phenotype is distributed according to a multivariate normal distribution, and it can be robust to deviations from this assumption. We compare the method with other means of assessing significance and explore its robustness, which depends on the choice of linear transformation. For obtaining genome-wide p-values, our proposed method is applicable when positions of markers are independent of the observed linkage signal, under the null hypothesis (e.g., genome screen data), while there is no such restriction for locus-specific p-values. This work was supported by NIH grants DK55889, HG01645 and the NSF GIG postdoctoral fellowship.

**Genome-wide scan in Finnish families provides evidence for a locus for bipolar disorder on 4q28.3.** *J. Ekholm*<sup>1,3</sup>, *T. Kieseppä*<sup>2</sup>, *T. Partonen*<sup>2</sup>, *T. Paunio*<sup>1</sup>, *M. Perola*<sup>1,3</sup>, *J. Lönnqvist*<sup>2</sup>, *L. Peltonen*<sup>1,3</sup>. 1) Department of Molecular Medicine; National Public Health Institute, Helsinki, Finland; 2) Mental Health and Alcohol Research; National Public Health Institute, Helsinki, Finland; 3) Department of Human Genetics; University of California Los Angeles, Los Angeles, California, USA.

We have carried out a genome wide scan in a Finnish bipolar disorder family set. A total of 41 families were screened with 384 microsatellite markers covering the genome with a 9.3cM resolution. All the families contained at least two siblings with bipolar disorder type I or schizoaffective disorder, manic type defined by DSM-IV. We identified one distinct locus on 4q28.3 providing significant evidence of linkage in two-point analysis. Furthermore, a locus on 12q23.2 gave a two-point LOD score  $> 3.0$  and three loci with a LOD score  $> 2.0$  were observed with markers on 1q31.1, 16p11.1 and on Xq25, a locus already earlier identified in one extended Finnish pedigree (Pekkarinen et al. 1995). For a total of thirteen loci; 1q43, 2pq, 3p12.2, 3q13.31, 3q26.31, 5p12, 7p14, 8p22, 8q24.3, 9p21, 11pq, 14q21 and 14pq the two-point LOD scores exceeded 1.0.

Interestingly, regions on 1q31 ( $Z_{\max} = 2.3$ ; D1S1660), 4q28.3 ( $Z_{\max} = 3.3$ ; D4S1629), 5p13.3 ( $Z_{\max} = 1.6$ ; D5S1470), 12q23.2 ( $Z_{\max} = 3.0$  PAH), 16p11.1 ( $Z_{\max} = 2.9$ ; D16S769) have provided evidence for linkage also in previous studies from other populations (Detera-Wadleigh et al. 1999, Adams et al. 1998, Alda et al. 1998, Morissette et al. 1999, Craddock et al. 1994, Ewald et al. 1998, Dawson et al. 1995, Barden et al. 1998). We are currently finemapping these regions to obtain conclusive evidence for their involvement in the genetic background of bipolar disorder in Finland.

**Mapping of Susceptibility Loci for Vitiligo to Chromosomes 1p and 7.** A. Alkhateeb<sup>1</sup>, G.L. Stetler<sup>1</sup>, W. Old<sup>1</sup>, J. Talbert<sup>1</sup>, C. Miller<sup>1</sup>, P. Pengelly<sup>2</sup>, D.C. Bennett<sup>2</sup>, R.A. Spritz<sup>1</sup>. 1) Univ Colorado Heath Sci Ctr, Denver, CO; 2) Dept Anatomy & Cell Biol, St George's Hosp Med Sch, London, UK.

Vitiligo is a common, acquired, non-contagious disorder characterized by progressive, patchy depigmentation of the skin, overlying hair, oral mucosa, and occasionally the eyes, due to non-inflammatory loss of pigment-forming melanocytes from the affected areas, most likely on an autoimmune basis. Vitiligo is the most common disorder of pigmentation, with a frequency of ~1-3% in different populations. Familial clustering of cases is frequent, in non-Mendelian patterns indicative of a complex trait; ~20% of probands have at least one affected first-degree relative. We have carried out a genome-wide screen for linkage in four large Caucasian multiplex vitiligo kindreds, comprised of up to 14 affected unilineal individuals, selected to provide the greatest chance of detecting linkage. Genome-wide parametric linkage analysis gave indications of linkage at several positions, principally on chromosomes 1p and 7, with apparent locus heterogeneity among families. Non-parametric linkage analysis showed strong evidence of linkage to loci on chromosomes 1p and 7 in a subset of these families. Support for chromosome 1p linkage came principally from one family (14 affected, NPL=24.2,  $P=0.001$ ) and for chromosome 7 linkage from another family (9 affected, NPL=14.1,  $P=0.0003$ ). We then carried out a second non-parametric linkage study limited to chromosome 1 in six medium-sized Caucasian multiplex vitiligo kindreds. This analysis confirmed linkage to the same region of chromosome 1p in some of these families (overall NPL 8.92,  $P=0.0005$ ; HLOD 3.54,  $a=0.36$ ). Our results thus provide strong support for a locus on chromosome 1p, and likely another on chromosome 7, that confers susceptibility to vitiligo in a subset of multiplex families.

**Linkage Disequilibrium Mapping via Coalescent Modelling.** *D.J. Balding*<sup>1,2</sup>, *J.C. Whittaker*<sup>1,2</sup>, *A.P. Morris*<sup>2,3</sup>. 1) Dept Epidemiology/Public Hlth, Imperial Col Sch Medicine, London, England; 2) Dept Applied Statistics, University of Reading, England; 3) Wellcome Trust Centre for Human Genetics, Oxford, England.

Fine-scale linkage disequilibrium (LD) mapping using high-density SNP maps is widely recognised as having the potential to play a major role in identifying genes involved in complex traits. However, methods which analyse markers one at a time are inefficient, and so there is currently considerable interest in developing multipoint methods to fully exploit the information in linked SNP haplotypes. The success of a multipoint method depends on its ability to incorporate the effects of the genealogical history of the case chromosomes in the vicinity of a disease-predisposing mutation, including the effects of recombination, marker mutation, and demography (such as population growth). Most existing multipoint methods assume a star-shaped genealogy, which is an implausible scenario for the genealogical history. This can result in misleading inferences about the location of the disease mutation.

We have developed a Bayesian, Markov chain Monte Carlo method which explicitly models the underlying genealogical tree in the vicinity of a disease locus. Advantageous features of our method include allowing for uncertainty about both the true genealogy and the ancestral SNP haplotypes, allowing for phenocopies and more than one founding disease mutation event (at the same locus), and allowing for population growth. Simulation results suggest a substantial improvement over alternative multipoint LD mapping methods. Output from the method includes the approximate distributions of the location of the disease locus, of the age of the mutation, of the founding SNP haplotype, and of the allocation of case chromosomes into those bearing the most common disease-predisposing mutation, those bearing other mutations at the same locus, and phenocopies.

**Factor analytic methods in QTL mapping.** *L.E. Bauman<sup>1</sup>, J.S. Sinsheimer<sup>1,2</sup>, L. Almasy<sup>3</sup>, J. Blangero<sup>3</sup>, K. Lange<sup>1,2</sup>.*

1) Department of Biomathematics, UCLA School of Medicine, Los Angeles, CA; 2) Department of Human Genetics, UCLA, Los Angeles, CA; 3) Department of Genetics, Southwest Foundation for Biomedical Research, San Antonio, TX.

Variance component models decompose trait variances and covariances within and between pedigree members according to their sources: polygenic background, QTLs, shared environment and random environment. One can model the covariance matrix of a multivariate trait as a linear combination of Kronecker product matrices. Each Kronecker product combines a constant matrix such as a kinship matrix with an unknown matrix of parameters capturing the relationships between the various traits. Maximum likelihood estimation of these parameter matrices must obey complicated nonlinear constraints imposed by positive definiteness. It is possible to pose EM algorithms that finesse these constraints, but they tend to converge slowly. Alternatively, one can reparameterize each covariance matrix by its Cholesky decomposition. This leads to faster optimization algorithms. The Cholesky decomposition perspective also suggests factor analytic decompositions for investigating pleiotropy. Classical factor analysis seeks to explain the covariation between several traits by approximating the trait vector by a linear transformation of a small number of uncorrelated factors. Factor analysis has the potential for data reduction and for uncovering the coordinated control of multiple traits in QTL mapping. In the case of a pleiotropic QTL one would predict that the number of factors would be less than the number of traits. Such insight is more important than the exact nature of the factors. We have adapted our variance component program, FISHER, to perform maximum likelihood estimation using Cholesky and factor analytic decompositions. FISHER has performed well on preliminary application to a variety of data sets, both real and simulated, containing small and large pedigrees, highly correlated traits and QTLs showing pleiotropy. Time permitting, one or more applications will be discussed.

**Variance components linkage analysis of plasma amyloid b protein in typical late-onset Alzheimer's disease (LOAD) pedigrees.** *N. Ertekin-Taner<sup>1,2</sup>, J. Ronald<sup>1</sup>, N. Graff-Radford<sup>3</sup>, L.H. Younkin<sup>1</sup>, J. Adamson<sup>1</sup>, E. Atkinson<sup>4</sup>, M. deAndrade<sup>4</sup>, M. Baker<sup>1</sup>, M. Hutton<sup>1</sup>, S.G. Younkin<sup>1</sup>.* 1) Neuroscience, Mayo Clinic, Jacksonville, FL; 2) Neuroscience, Mayo Clinic, Rochester, MN; 3) Neurology, Mayo Clinic, Jacksonville, FL; 4) Biostatistics, Mayo Clinic, Rochester, MN.

We previously showed that plasma Ab40 and Ab42 are significantly elevated in members of LOAD families compared to controls ( $p < 0.05$ ). To determine the magnitude of the genetic component affecting plasma Ab levels, heritabilities of plasma Ab42 and Ab40 were estimated in 16 extended LOAD pedigrees using variance components method. Heritability estimates of 62% and 49% were found for plasma Ab42 and Ab40, respectively. Bivariate analysis of these two quantitative phenotypes revealed a substantial genetic correlation between plasma Ab42 and Ab40 levels. Inclusion of the ApoEε4 dosage as a covariate did not have a significant effect on the heritabilities of these traits. These results suggest that genetic factors other than ApoE account for a substantial percentage of the phenotypic variance in both plasma Ab42 and Ab40 levels. Kehoe et. al. identified 5 chromosomal loci with multipoint lod scores  $> 3.0$  in the first stage of a genome-wide scan for LOAD in affected sib-pairs. We genotyped these candidate loci, in our independent collection of extended LOAD pedigrees, and performed linkage analysis, using plasma Ab levels as the surrogate phenotype. Evidence for linkage was detected to a locus on chromosome 10 at approximately 80 cM. Remarkably, significant linkage to the same region was obtained independently in the second stage of the LOAD sib-pair genome-wide scan that originally provided the candidate regions for our study. These results provide strong evidence for the existence of a novel LOAD locus on chromosome 10 that increases the risk for LOAD by increasing Ab levels. Our study also demonstrates that using plasma Ab as a surrogate quantitative phenotype may be a powerful approach to discover genetic loci for LOAD. Several candidate genes that reside in the linkage region are being screened for polymorphisms. Studies are underway to test the effects of these polymorphisms on plasma Ab levels and association with LOAD.

**QTLs on chromosomes 11 and 13 contributing to HDL-C levels and its subfractions in extended FCHL pedigrees.** *F. Gagnon, G.P. Jarvik, A.G. Motulsky, S.S. Deeb, J.D. Brunzell, E.M. Wijsman.* University of Washington, Seattle, WA.

A genome screen for HDL-C levels is in progress in 4 large (N=258) familial combined hyperlipidemia (FCHL) families, ascertained through hypertriglyceridemic probands. HDL-C is correlated with the lipid levels that define FCHL. Using joint linkage and segregation analysis based on Bayesian Markov chain Monte Carlo methods, we estimate that 3-4 genes are involved. Our preliminary results, focussing on chromosomes (ch) for which linkage to FCHL or HDL-C has been reported, provide evidence for HDL-C linkage to ch 11q and 13q. Several candidate genes, including the ApoAI-CIII-AIV complex, are in the critical region on 11q. From a joint multipoint analysis with all markers on ch 11 and 13, the posterior:prior probability of linkage (in a 2 cM interval and with a Poisson prior of 4 for the number of quantitative trait loci (QTLs)) is ~5 and ~8 for ch 11 and 13, respectively. Use of APOCIII as a major-gene covariate reduced evidence for linkage to 11q, supporting its role as an HDL-C locus. There is evidence for linkage to 11q and 13q for the HDL-C subfraction HDL3, whereas no or little evidence for linkage is observed for square root HDL2. We are following up on additional signals. These results confirm a previous report of linkage of HDL-C to 13q. Previous reports of linkage of FCHL to this ch 11 region have been published by others but results remain controversial and inconclusive. Ascertainment of families among studies varies with respect to procedures that could affect the HDL-C distribution, and thus could explain the controversial results obtained for linkage of FCHL to the 11q23 region.

**Finer linkage mapping of two regions harbouring suggestive susceptibility loci for osteoarthritis.** *K. Chapman<sup>1</sup>, Z. Mustafa<sup>1</sup>, B. Dowling<sup>1</sup>, B. Sykes<sup>1</sup>, A. Carr<sup>2</sup>, J. Loughlin<sup>1</sup>.* 1) IMM, University of Oxford, Oxford, UK; 2) Nuffield Orthopaedic Centre, Oxford, UK.

Osteoarthritis (OA) is a common late onset disease characterised by a degeneration of the articular cartilage in synovial joints. We have previously reported linkage to a number of chromosomes, principally chromosomes 2q, 4q, 6q, 11q and 16; using an affected sib pair approach. These regions were identified using marker panels of relatively low densities. The resulting linkages were thus very broad and required a finer linkage mapping approach before embarking on linkage disequilibrium/association analysis. To further assist with the finer linkage mapping, we expanded our family collection to 576 families comprising 1572 affected individuals who have undergone hip and/or knee joint replacement surgery due to severe OA.

We here report the refined linkage analysis of two of our regions, those on chromosomes 6q and 11q. In our original analysis of 6q, a broad linkage region was observed with over 50 cM of the chromosome having an MLS of 2.0 or greater. We have now refined this linkage to an interval of 25 cM, centred on markers located approximately 80 cM from the 6p-telomere, with a LOD = 3.0. The finer mapping of chromosome 11q has resulted in us narrowing the linkage peak to an interval of 15cM, centred on markers located approximately 77 cM from the 11p-telomere. This region, with a LOD = 2.0, is located 13 cM proximal to the original, crude 11q linkage. All multipoint linkage analysis was conducted utilising ALLEGRO v1.1. Both linkages are more pronounced in a subset of 150 families in which all the affected individuals are females with hip OA. Such gender and site-specific differences in the degree of OA susceptibility have been reported in epidemiological studies, and may assist in the choosing of appropriate, stratified cohorts for linkage disequilibrium/association analysis. (Supported by The Wellcome Trust and the Arthritis Research Campaign).

**A Locus for Elevated ApoB Levels in Familial Combined Hyperlipidemia.** *H. Allayee<sup>1, 2</sup>, K.L. Krass<sup>1, 2</sup>, P. Pajukanta<sup>1</sup>, R.M. Cantor-Chiu<sup>1</sup>, L. Peltonen<sup>1</sup>, J.I. Rotter<sup>1, 2</sup>, T.W.A. de Bruin<sup>3</sup>, A.J. Lysis<sup>1, 2</sup>.* 1) Dept. of Human Genetics, UCLA, Los Angeles, CA; 2) Dept. of Medicine, UCLA, Los Angeles, CA; 3) Dept. of Medicine, Maastricht University, Maastricht, the Netherlands.

Familial combined hyperlipidemia (FCHL) is a common genetic lipid disorder with a marked risk for premature coronary artery disease. Even though considerable effort has been put towards identifying FCHL susceptibility genes, the disease remains relatively uncharacterized at the genetic level. Various candidate gene studies in several populations and two genome scans in Dutch and Finnish families have been reported for the FCHL phenotype. While the latter studies each identified several loci, there were no obvious regions of overlap in the two genome scans. We speculated that this might be due to phenotypes not defined consistently across studies and to the application of different analytic methods. In order to permit an effective comparison between the two scans, we re-analyzed the genotype data in the Dutch FCHL families by employing the same methods that were used in the parametric linkage analyses of the Finnish families. In a parametric two-point genome scan of the Dutch families, significant evidence for linkage (Max LOD = 3.8 at  $\theta = 0$ ) of elevated apoB levels was observed at a locus on chromosome 1p (peak marker D1S1665). Additional markers in the region were genotyped and the most significant linkage result was obtained with a multipoint analysis of D1S1665 and D1S481 (Max LOD = 4.7). This locus is distinct from the previous FCHL locus identified on chromosome 1q in the Finnish families, although the 1q locus also yields some evidence for linkage in this Dutch sample (LOD = 1.8). Statistically significant evidence for linkage of elevated apoB levels to this new locus on 1p was not observed in the Finnish families, suggesting that FCHL in these two populations is a complex disorder that may be complicated by underlying genetic heterogeneity. The identification of this novel locus influencing apoB levels in this Dutch population may help to unravel the genetic complexity of FCHL.

**Genome scan for celiac disease in a Finnish founder family.** *N.J. Ali-Varpula<sup>1</sup>, P.M. Holopainen<sup>1</sup>, V. Ollikainen<sup>2</sup>, K. Mustalahti<sup>3</sup>, M. Maki<sup>3</sup>, J.A. Partanen<sup>1</sup>.* 1) Department of Tissue Typing, Finnish Red Cross Blood Transfusion Service, Helsinki, Finland; 2) University of Helsinki, Finnish Genome Center, Helsinki, Finland; 3) Tampere University Hospital and Medical School, University of Tampere, Tampere, Finland.

Celiac disease (CD) is a multifactorial autoimmune-like disorder of the small intestine triggered by dietary gluten. The only established genetic risk factors are certain HLA DQ alleles on 6p21.3. Previous genome wide screenings for non-HLA susceptibility genes have suggested several loci with somewhat controversial results, pointing to linkage heterogeneity between populations. Genetic heterogeneity within the study sample can be diminished by concentrating on isolated founder populations. The population of Finland is known to feature strong founder effect. We performed a genome scan in an isolated Finnish subpopulation from the Northern part of Finland: 'Koilliskaira' founder families affected with CD. The families were genealogically confirmed to share an ancestor in 16th century. Genetic linkage between nine families with 23 CD patients and 399 markers was studied, using both multipoint parametric and non-parametric linkage analyses (NPL). A novel susceptibility locus with a significant maximum LOD score of 3.7 was found on chromosome 15q using a highly penetrant dominant model of inheritance. LOD score >2 was found on chromosome 8p, and LOD scores >1 on 2p, 4p, 5q, 12q, 15q and Xq. NPL scores >2 (nominal  $p < 0.01$ ) were obtained for 4p, 8p and 15q. By simulation approach, genome-wise significance for the NPL scores was not, however, reached in this small set of families. Surprisingly, no linkage with the known CD risk locus on chromosome 6p was found, although all patients carried the high risk allele HLA DQ2. The presence of genuine susceptibility factors on chromosomes 4p and 15q is further supported by our evidence from genome scan with an independent set of 60 unrelated Finnish CD families, in which linkage to these non-HLA regions was found. This points to relative homogeneity within this founder family, and its usefulness in genetic studies despite of small number of nuclear families.

**Chromosome 2q Linkage in Idiopathic Talipes Equinovarus (Clubfoot).** *S.H. Blanton<sup>1</sup>, S. Broussard<sup>4</sup>, C.A. Wise<sup>3</sup>, A. Scott<sup>2</sup>, J.T. Hecht<sup>4</sup>.* 1) Univ Virginia Health Sys, Charlottesville, VA; 2) Shriner's Hospital for Children, Houston, TX; 3) Scottish Rite Hospital, Dallas TX; 4) University of TX HSC, Houston.

Idiopathic talipes equinovarus (ITEV) is a common birth defect occurring in 1/1000 livebirths. Males are affected twice as frequently as females and either one or both feet can be involved. Treatment consists of serial casting and surgical correction and the final result is often sub-optimal. While the natural history of ITEV has been well characterized, little is known about the causal factors contributing to this common birth defect. Numerous studies have suggested that genetic factors contribute to the etiology. We have assembled a collection of Hispanic and non-Hispanic White probands in 275 parent-child trios (203 sporadic, 72 with a family history) and 48 extended multiplex families with ITEV. The region 2q31-q33 has been involved in a translocation in an ITEV patient and contains a number of candidate genes, including COL3A1, COL5A1, and ADAM23. DNA markers spanning this region were typed and the results analyzed using the TDT function of GENEHUNTER. For two of the markers, GATA149B10 alone (data shown below) and as a haplotype with D2S2979, a significant result was obtained in the sporadics and is strongest in the White non-hispanic sporadic trios.

Marker	Population	p-value	Permutation Test#
GATA149B10	All Sporadics	0.019	65
	White Sporadics	0.005	19

#indicates how many times out of 1000 would get the same p-value or better by chance.

These results clearly suggest that a gene in this region may play a role in the development of ITEV among sporadic non-Hispanic Whites. There are a number of candidate genes in this region in addition to the three mentioned above and we are evaluating each of them.

**Context-dependent linkage analysis of plasma cholesterol reveals its complex multifactorial etiology.** *K.L.E. Klos<sup>1</sup>, S.L.R. Kardia<sup>1</sup>, J.E. Hixson<sup>2</sup>, S.T. Turner<sup>3</sup>, E. Boerwinkle<sup>2</sup>, C.F. Sing<sup>1</sup>.* 1) Univ Michigan, Ann Arbor, MI; 2) Univ Texas Health Science Center, Houston, TX; 3) Mayo Clinic, Rochester, MN.

Interindividual variation in a quantitative trait that influences the risk of developing a common disease, such as coronary artery disease (CAD), is expected to be influenced by gene-gene and gene-environment interactions. Plasma total cholesterol (TC) is known to be correlated with CAD risk factors that are influenced by genetic and environmental variations. We carried out variance components-based linkage analysis to identify regions of the genome influencing variation in TC within subsets of pedigrees which differed in genetic and environmental context as indexed by BMI, triglycerides (TG) and HDL-cholesterol (HDL-C). Each trait was used to subdivide pedigrees into high and low subsets. Within these subsets a second trait was used to further subdivide pedigrees. Thirty-eight markers were selected approximately every 100cM to represent variation in the genetic background among subsets of pedigrees. For all methods of subdivision, 9.2% of background markers differed significantly ( $p < 0.01$ ) in % heterozygous individuals among subsets. Because subsets may differ in the information content of markers at some genomic locations, we examined specific markers near LOD peaks  $> 2.00$  for % heterozygous individuals among subsets, eliminating one peak on chromosome 20 from further consideration. Within particular subsets evidence remained of linkage with genes influencing TC in 6 regions involving chromosomes 3, 4, 11, 13 and 17. For example, a LOD score of 2.77 in pedigrees with high TG suggests the presence of a gene(s) influencing TC on chromosome 11. A LOD score of 3.21 was observed on chromosome 13 in the subset of pedigrees defined by low BMI and high HDL-C. Two regions of chromosome 17 may contain genes which influence TC under different contexts. We obtained LOD scores of 2.45 on the long arm in pedigrees with high HDL-C, and of 2.26 on the short arm in pedigrees with both high HDL-C and high TG. Our findings further document the importance of context in modeling the relationship between genetic and quantitative phenotypic variation. Supported by NHLBI grant HL39107.

**Linkage between cholesterol 7  $\alpha$ -hydroxylase (CYP7) gene and low-density lipoprotein cholesterol (LDL-C) in increased CHD risk Caucasian families - the NHLBI Family Heart Study.** *J.P. Lin<sup>1</sup>, P. Sholinsky<sup>1</sup>, H.H. Coon<sup>2</sup>, S.C. Hunt<sup>3</sup>, R.H. Myers<sup>4</sup>, D.K. Arnett<sup>5</sup>, Y. Hong<sup>6</sup>.* 1) Division of Epidemiology and Clinical Applications, National Heart, Lung, and Blood Institute, NIH, Bethesda, MD; 2) Department of Psychiatry, University of Utah, Salt Lake City, UT; 3) Department of Internal Medicine, University of Utah, Salt Lake City, UT; 4) Section of Preventive Medicine, Boston University School of Medicine, Boston, MA; 5) Division of Epidemiology, University of Minnesota, Minneapolis, MN; 6) Division of Biostatistics, Washington University School of Medicine, St. Louis, MO.

Genetic factors account for approximately 50% of the individual variation in plasma LDL-C concentrations in the general population. Several candidate genes have been proposed but their relative contributions to the variance in LDL-C are not clear. In a recent study of a randomly sampled population, the allelic variation in the CYP7 gene explained 15% of the phenotypical variation in plasma LDL-C concentrations. In this report we present linkage results between LDL-C and CYP7, as well as apolipoprotein E (APOE) and low-density lipoprotein receptor (LDLR), three pivotal genes in LDL metabolism. Our study population included more than 200 Caucasian nuclear families with increased coronary heart disease (CHD) risk from the NHLBI Family Heart Study. Individuals on medication for high cholesterol, or with Familial Combined Hyperlipidemia, or triglycerides > 300mg/dl were excluded. Haseman-Elston sibling pair (S.A.G.E. 4.0-7) and variance-component (SOLAR) linkage methods were used. The results showed significant linkage between plasma LDL-C concentrations and CYP7 ( $p=0.007$  for Haseman-Elston;  $p=0.017$  for variance-component). The allelic variation in CYP7 accounts for approximately 30% of the phenotypical variation in plasma LDL-C concentrations. When the analyses were repeated on the APOE and LDLR loci, no evidence of linkage was detected. These findings suggest that polymorphism in CYP7 contributes importantly to the variation in plasma LDL-C concentrations in a population at increased risk of CHD.

**A permutation procedure for the haplotype method for identification of disease-predisposing variants.** *H. Li.*  
Rowe Prog Human Gen/Sch Med, Univ California, Davis, Davis, CA.

Once a genetic region involved in a complex disease has been localized through linkage or association studies, we need methods to help us identify the actual disease predisposing genetic variant(s) in the region. A large number of singlenucleotide polymorphic (SNP) sites may exist in this region. It is important to identify genetic variants directly involved in disease from those in linkage disequilibrium, and thus associated with, the disease predisposing variant(s). A question of great interest is to test whether a SNP or a combination of SNPs that influence the trait under investigation has been identified. For many complex HLA-associated diseases, patterns of amino acid site variability raise the possibility that HLA-variation association with a disease may not be due to a given allele but rather one or more variable amino acid sites occurring on several alleles. Here the question is whether an amino acid variant or a combination of amino acid variants involved in disease is identified. To address this question, this paper proposes a permutation procedure for the haplotype method to test whether all the sites involved in the disease have been identified using the haplotypic data of patients and controls. The method is based on the theoretical result of Valdes and Thomson, that, for each haplotype combination containing all the amino acid sites involved in the disease process, the relative frequencies of amino acids variants at sites not involved in disease, but in linkage disequilibrium with the disease-predisposing sites, are expected to be the same in patients and controls. This procedure takes into account the non-independence of the sites sampled and is robust to mode of inheritance and penetrance of the disease, and can definitely specify when all the disease predisposing sites have not been identified. Application to both simulated data and real data sets on type 1 diabetes and alcoholism indicates that the proposed procedure works well in testing the important null hypothesis of whether all the predisposing sites are identified.

**Genome-wide scan for type 2 diabetes mellitus in Japanese.** *N. Iwasaki<sup>1</sup>, X. Wang<sup>2</sup>, P. Schwalz<sup>2</sup>, M. Honda<sup>3</sup>, M. Saito<sup>4</sup>, N. Kamatani<sup>4</sup>, N.J. Cox<sup>2</sup>, G.I. Bell<sup>2</sup>, Y. Iwamoto<sup>1</sup>.* 1) Diabetes Center, Tokyo Women's Medical Univ., Shinjuku-ku, Tokyo, Japan; 2) Howard Hughes Medical Institute, The University of Chicago, Chicago, IL; 3) Shiseikai Daini Hospital, Tokyo, Japan; 4) Institute of Rheumatology, Tokyo Women's Medical Univ., Shinjuku-ku, Tokyo, Japan.

**Background and Aims:** Genetic factors contribute to the development of type 2 diabetes mellitus. We have carried out a genome-wide screen for type 2 diabetes genes in the Japanese population, as a first step in the identification of diabetes-susceptibility genes in this population. **Materials and Methods:** The study population consisted of 256 affected sib pairs (379 diabetic subjects from 164 families) recruited from among the patients attending the Diabetes Clinic of Tokyo Women's Medical University and associated hospitals. The clinical features of the study population are: age-at-diagnosis, 45.3±10.9 years (mean±SD); HbA1c, 7.7±1.74 % and BMI, 23.0±3.0 kg/m<sup>2</sup>. DNA was prepared from blood and genotyped using a panel of 414 markers from chromosomes 1-22. We tested each marker for linkage with type 2 diabetes using both two-point (programs SIBPAIR and SPLINK) and multipoint (GENEHUNTER-PLUS) methods of analysis. **Results:** We found 9 regions that showed nominal multipoint evidence of linkage with type 2 diabetes (i.e. MLS > 0.59, P<0.05). These regions were on chromosomes 1p(25cM), 2q (152-167 cM), 4q (92 cM), 5q (114cM), 6p (33 cM), 8p (4cM), 9p (0-28 cM), 17p (34cM) and 21 (39-52 cM). One region of chromosome 9 (3-21 cM) showed suggestive evidence for linkage with MLS = 3.5 when families are weighted according to the number of (pairwise) independent affected sib pairs. **Conclusions:** Our genome-wide screen has revealed possible locations of genes that may contribute to the development of type 2 diabetes in the Japanese population. These results provide a focus for further genetic studies of type 2 diabetes in Japanese and the identification of genes that increase the risk of type 2 diabetes in this population.

**Detection of genetic heterogeneity among families with multiple affected relatives.** *L. Mirea, L. Briollais, S.B. Bull.* Public Health Sciences, University of Toronto and SLRI, Mount Sinai Hospital, Toronto, ON.

Linkage analyses based on allele-sharing in sets of affected relatives are less powerful when heterogeneity exists among the allele-sharing distributions of sampled families. The presence of genetic heterogeneity may be indicated by variability in symptoms, prevalence, and/or age of onset for the disease. To test for heterogeneity, we propose using family-level binary covariates and family-specific non-parametric linkage scores (NPL). In one approach we extend the linkage likelihood of Kong and Cox (1997, *Am J Hum Genet* 61:1179-1188) to include a family indicator covariate and formulate a likelihood ratio test (LRT) and efficient score test (ESS). Alternatively, asymptotic (T) and permutation methods (Tperm) are applied to assess differences in mean NPL scores between two covariate-defined family subgroups. We investigated these approaches using simulated marker genotypes (10 equally frequent alleles) for samples of 150 families with affected sibling or cousin pairs generated under dominant and recessive inheritance models. Family subgroups were defined by a binary covariate at levels 50%, 60% and 80%. Homogeneous samples included only linked families ( $q=0$ ), whereas covariate values precisely identified linked ( $q=0$ ) and unlinked ( $q=0.5$ ) families within heterogeneous samples. The type I error rate of ESS was grossly inflated while those of LRT and T were for the most part conservative. Additional simulations showed that in the absence of heterogeneity when linkage was either absent or very strong, the empirical distributions of LRT, ESS and T did not follow that specified by standard asymptotic theory. In all scenarios examined, Tperm was found to have a nominal 5% type I error and power in excess of 90% which was comparable to that calculated for LRT, ESS and T using adjusted critical values. The power of all methods decreased more rapidly for the recessive model as the difference between subgroup sizes increased. We recommend the use of Tperm but caution that power will decrease when the covariate selected to stratify families is subject to misclassification.

**Characterisation of a Major Locus for Developmental Dyslexia on 18p11.2.** *I.L. MacPhie<sup>1</sup>, S.E. Fisher<sup>1</sup>, C. Francks<sup>1</sup>, A.J. Marlow<sup>1</sup>, L.R. Cardon<sup>1</sup>, J.B. Talcott<sup>2</sup>, A.J. Richardson<sup>2</sup>, J.F. Stein<sup>2</sup>, A.P. Monaco<sup>1</sup>.* 1) The Wellcome Trust Centre for Human Genetics, University of Oxford, UK; 2) Department of Physiology, University of Oxford, UK.

Developmental dyslexia is a difficulty in learning to read that can not be explained by deficits in intelligence, motivation, educational opportunity, or sensory acuity. It is one of the most frequently diagnosed learning disabilities, estimated to affect between 5 and 10% of school-aged children, and represents a major educational, social and mental health problem. Previous work has clearly shown dyslexia to be a significantly heritable trait, but the genetic etiology remains largely unknown. We recently reported the first complete QTL-based genome-wide scans for dyslexia in two large, independent samples from the UK and the US (Fisher et al, submitted). A highly significant novel QTL influencing multiple reading-related processes was detected yielding top multipoint p values < 0.0003 in both samples. Moreover, this linkage was replicated in a third sample of families from the UK. Using the public sequence databases we have constructed a transcript map of the region between D18S452 and D18S478. The relative scarcity of genes around 18p11 allowed us to identify a small number of candidates between these markers for further analysis. Probands were screened for gene-specific polymorphisms using D-HPLC and the observed variants were then followed up by direct sequencing and tested for association using QTDT. Refinement of the 18p11.2 QTL is an important step towards identifying susceptibility genes for this complex trait and elucidating the molecular mechanisms behind reading disability.

**Liability loci for multifactorial cleft lip and palate map to the same chromosomal locations as liability loci for multifactorial neural tube closure defects in mice.** *D.M. Juriloff, M.J. Harris, T.M. Gunn, M.K. Wu, D.G. Mah, S.L. Dewell.* Dept Medical Genetics, Univ British Columbia, Vancouver, BC, Canada.

The A/WySnJ mouse strain has about 20% cleft lip with or without cleft palate, CL(P), of genetically multifactorial cause. After a cross to C57BL/6J, we used CL(P) embryos from 1,485 BC1 segregants in a genome screen to map the major liability loci, *clf1* and *Clf2*, to Chr 11 near *D11Mit10* and to Chr 13 near *D13Mit13*. Another strain, SELH/Bc, has 10-30% exencephaly, a cranial neural tube closure defect (NTD), of genetically multifactorial cause. After a cross to the normal LM/Bc strain, we used the extremes of 102 testcrossed F2 males in a genome screen to map the major liability loci. The chromosomal regions identified were confirmed in 31 exencephalic F2 segregants and were further confirmed in 24 exencephalic embryos from 758 F2 segregants from a cross of SELH/Bc with the JAX "curly tail" strain. The confirmed exencephaly liability loci mapped to Chr 13 near *D13Mit13* and to Chr 11 near *D11Mit10*, the same regions as the previously mapped CL(P) liability loci. The homologous human linkage groups are located on 17q21 and 5q or 9q. For CL(P), *clf1* is recessive, *Clf2* is semidominant, and the loci interact epistatically. For exencephaly, the risk alleles are semidominant and additive across loci. Each defect is strain specific.

The unexpected convergence of the map locations of the major liability loci for CL(P) and exencephaly from two mouse strains suggests that different alleles at the same loci may be involved in both traits. Our data therefore suggest that human multifactorial NTD and multifactorial CL(P) may share genetic factors in their etiologies.

**TCRG - a positional and functional candidate for asthma: linkage and association analysis among the Finns.** *T. Laitinen*<sup>1</sup>, *A. Polvi*<sup>1</sup>, *P. Sevon*<sup>2</sup>, *J. Vendelin*<sup>1</sup>, *P. Kauppi*<sup>3</sup>, *T. Petäys*<sup>4,5</sup>, *T. Haahtela*<sup>4,5</sup>, *L.A. Laitinen*<sup>3</sup>, *J. Kere*<sup>2</sup>. 1) Dept Medical Genetics; 2) Finnish Genome Center; 3) Dept Pulmonary Medicine; 4) Dept Allergological Diseases, Univ Helsinki; 5) Dept Epidemiology and Health Promotion, National Public Health Institute, Helsinki, Finland.

Recent genome-wide scans have suggested several regions potentially linked to asthma and atopy related traits. One of the loci of interest is located on 7p15-p14. Among Finnish asthma families, this locus was the only locus that exceeded the threshold for genome-wide significance. The finding was further confirmed in two independent data sets, French-Canadians and North-Karelian Finns. As a potentially interesting candidate, the T cell receptor gamma genes (TCRG) has been mapped into this region. TCRG spans ~100kb containing several genes known to be highly polymorphic and rearrange during gamma/delta T cell maturation. Gamma/delta T cells are believed to form the first line of defense on epithelial surfaces and be involved in the development of immune disorders. We screened altogether 11 dinucleotide repeats to find new informative and stable markers in the TCRG locus, and three showed to be polymorphic. Linkage analysis of the TCR markers and one flanking marker (D7S2497) was performed among the Finnish genome scan pedigrees (N=86). The result showed that TCRG is located within the linkage region, but the observed linkage (NPL 3.11, P=0.001) did not exceed the previously found linkages (NPL 3.9, P=0.0001) for the markers upstream to TCRG. Haplotype analysis was done using all the chromosomes retrieved from multiplex and a new set of nuclear families (N=83, a total of 468 chromosomes). Haplotype associations were detected, but they all remain weak (chi-square<6.9). To study if the overall haplotype distribution in TCRG differs from expected among the disease associated compared to control chromosomes, we used Haplotype Pattern Mining. Again, no statistically significant bias in haplotype distribution was found. Our initial results on the TCRG locus suggest that even though TCRG is located in the linkage region, it may not be the genetic regulator of asthma related traits among the Finnish patients.

**Modulation of severity in multiple sclerosis by polymorphisms in and around APOE.** *J.L. Haines<sup>1</sup>, S. Schmidt<sup>2</sup>, L.F. Barcellos<sup>3</sup>, K. deSombre<sup>2</sup>, R.R. Lincoln<sup>3</sup>, P. Bucher<sup>3</sup>, E.R. Martin<sup>2</sup>, E. Lai<sup>4</sup>, A.M. Saunders<sup>2</sup>, J.M. Vance<sup>2</sup>, J.R. Oksenberg<sup>3</sup>, S.L. Hauser<sup>3</sup>, M.A. Pericak-Vance<sup>2</sup> and Multiple Sclerosis Genetics Group.* 1) Program in Human Genetics, Vanderbilt Univ Medical Ctr, Nashville, TN; 2) Center for Human Genetics, Duke Univ Med Ctr, Durham, NC; 3) Dep't Neurology, Univ Cal San Francisco, San Francisco, CA; 4) Glaxo/SmithKline, Resarch Triangle Park, NC.

Multiple sclerosis (MS) is a chronic inflammatory disorder of the central nervous system with a complex etiology. While the contribution of the Major Histocompatibility Complex (MHC) to genetic susceptibility for MS has been established, identifying other risk genes has been problematic. Numerous studies have pointed toward the region on chromosome 19q13 surrounding the APOE gene as likely to harbor an MS susceptibility gene. In addition to gene discovery for MS risk genes in this region, several clinical reports have suggested that the APOE-4 allele may be associated with more severe disease and significantly faster progression of disability in MS. To examine the role of APOE, we genotyped APOE and seven other single-nucleotide polymorphisms (SNPs) located in a surrounding 920 kb region in a data set of 398 families, of which 148 are multiplex (2+ affected family members) and 250 are simplex. Most of these SNPs are within 16 kb of APOE and spaced 2-5 kb apart. Using family-based association analysis, we found statistically significant evidence that APOE itself or a gene in strong linkage disequilibrium with APOE increases susceptibility to MS in the data set of simplex families ( $p=0.002$  for a three-marker haplotype including the APOE-4 allele) but not multiplex families. Analysis of clinical variables indicated that APOE-4 carriers are more likely to have severe disease ( $p=0.03$ ), whereas APOE-2 carriers are more likely to exhibit mild disease ( $p=0.02$ ). This was true in both the multiplex and simplex families. These results suggest that APOE and/or nearby genes may modulate both risk and severity of MS.

**Total genome-scan and dense mapping in search for susceptibility genes in the type I allergy phenotypes: Atopic dermatitis, allergic rhinitis and allergic asthma.** A. Haagerup<sup>1</sup>, A.D. Borglum<sup>1</sup>, H.G. Binderup<sup>1</sup>, T.A. Kruse<sup>2</sup>. 1) Institute of Human Genetics, Aarhus University, Aarhus, Aarhus C, Denmark; 2) Clinical Institute, University of Odense, Odense, Denmark.

Through the ITA-project (Inheritance of Type I Allergy) we sampled 100 nuclear families (N=424) selected by affected sibpairs. Half the families (panel A) qualified for a comprehensive total genome-scan using a set of 446 highly informative microsatellite markers by holding sibpairs with both clinical disease and documented atopy, i.e. RAST > 1+. The other half of the families (panel B) contained clinical affected sibpairs with only one or no RAST positive sibling. The data from the genome-scan was analysed by non-parametric multipoint linkage analysis using MAPMAKER/SIBS and revealed evidence of both major and minor loci for most phenotypes. Best LOD scores were 2.79, 3.26, 2.66, 2.13, and 2.61 for atopic dermatitis (AD), allergic rhinitis (AR), allergic asthma (AA), atopy (RAST > 1+), and elevated total IgE (s-IgE > 100 kU/i), respectively. For a second scan candidate regions on chromosome 3, 4, 5, 6, 9, 12, 18, and X were selected for dense mapping. We used 97 microsatellite markers and analysed all 100 families. LOD scores were computed in both panel A and in the total sample (panel A+B) for the five phenotypes. Evidence for linkage in several candidate regions rose whereas other regions could be discharged. Now candidate genes in the appointed regions are being further investigated.

**Large-scale candidate gene screening and association analysis in schizophrenia.** *N. Norton<sup>1</sup>, N.M. Williams<sup>1</sup>, H.J. Williams<sup>1</sup>, G. Spurlock<sup>1</sup>, N.J. Bray<sup>1</sup>, S. Jones<sup>1</sup>, G.S. McCarthy<sup>1</sup>, G. Jones<sup>1</sup>, S. Zammit<sup>1</sup>, A. Cardno<sup>1</sup>, R. Owen<sup>1</sup>, K.L. Davis<sup>1</sup>, J.D. Buxbaum<sup>2</sup>, V. Haroutunian<sup>2</sup>, M.J. Owen<sup>1</sup>, M.C. O'Donovan<sup>1</sup>.* 1) Neuropsychiatric Genetics, UWCM, Cardiff, S. Glamorgan, UK; 2) Department of Psychiatry, Mount Sinai School of Medicine, New York.

We have screened over 50 candidate genes for schizophrenia for sequence variation using DHPLC. To date, we have identified more than 100 SNPs. In contrast to most sequence variants available in public databases, we have confirmed every reported SNP by a secondary assay, and estimated allele frequencies in DNA pools by either DHPLC analysis or SNaPshot. DNA pooling with SNaPshot allowed allele frequencies to be estimated in up to seven SNPs in multiplex. When compared with individual genotyping, the mean error in estimating the absolute allele frequencies is 0.035 (SD=0.013, maximum = 0.037). More importantly, the mean error for estimating differences between cases and controls (assuming 100% accuracy for individual genotyping) was 0.006 (SD=0.008, maximum = 0.023). Our approach to candidate gene analysis is now to: 1) estimate allele frequencies in case-control pools of schizophrenic and control subjects using SNaPshot; 2) undertake individual genotyping where estimated p value is <0.1; 3) extend analysis to family based association samples. In this presentation, we summarize the results of such analyses of 57 candidates for schizophrenia.<

**Chromosome 19 and atopic asthma in Italian families.** *G. Malerba<sup>1</sup>, M.C. Lauciello<sup>1</sup>, R. Galavotti<sup>1</sup>, E. Trabetti<sup>1</sup>, A.L. Boner<sup>2</sup>, P.F. Pignatti<sup>1</sup>.* 1) Mother-Child & Biol, Genetics, Univ Verona, Verona, Italy; 2) Mother-Child & Biol, Paediatrics, Univ Verona, Verona, Italy.

DNA markers on chromosome 19 have been described to be linked to atopic asthma or related phenotypes in several populations. We have recently reported suggestive linkage of 19q31 DNA markers to atopy or skin prick test positivity (SPT) in a sample of Italian families and we suggested a potential linkage to chromosome 19p with atopy, SPT or total serum elevated IgE (IgE)(Venanzi et al., Clin Exp Allergy 2001 in press). Candidate gene analysis in the 19q region provided no evidence for linkage or transmission disequilibrium for marker IL11. The families have been genotyped with 9 additional DNA microsatellite markers spanning the 19p chromosomal region from D19S591 to D19S884 markers (about 18 cM). Five binary traits were investigated: asthma, SPT, IgE, bronchial hyperresponsiveness to methacholine and atopy. Non parametric pairwise linkage analysis and transmission disequilibrium test (TDT) were performed. Linkage was observed with D19S536 (IgE:p=0.007, asthma:p=0.024), D19S216 (IgE:p=0.04), D19S567 (asthma:p=0.021) and D19S884 (IgE:p=0.037). A significant TDT was observed for D19S120 (IgE:p=0.018), D19S567 (atopy:p=0.037, SPT:p=0.002), FcepsilonR2 (atopy:p=0.037) and D19S534 (IgE:p= 0.004) markers. These results suggest that a gene related to atopic phenotypes maps on chromosome 19p.

**Association of the DBH TaqI A polymorphism with Attention Deficit Hyperactivity Disorder in the Milwaukee Longitudinal Study of ADHD.** *B.A. Navia<sup>1,2</sup>, K.M. Smith<sup>2</sup>, L. Bauer<sup>3</sup>, M. Fischer<sup>3</sup>, M.J. Daly<sup>4</sup>, E. Lander<sup>4</sup>, R. Barkley<sup>5</sup>.* 1) Neurology, NEMC/Tufts Univ. Sch. of Medicine, Boston, MA; 2) Genetics Prg., Sackler School, Tufts Univ., Boston, MA; 3) Neuropsych. Sect., Med. College of Wisconsin, Milwaukee, WI; 4) Whitehead Institute, MIT, Cambridge, MA; 5) Dept. of Psychiatry, UMass Medical Center, Worcester, MA.

Attention Deficit Hyperactivity Disorder (ADHD) is a highly heritable and common disorder that partly reflects alterations in dopamine function. Genetic studies have shown that genes involved in dopamine signaling and metabolism, the 7 repeat allele of the D4 dopamine receptor (DRD4) exon 3 VNTR, the 480 bp allele of the Dopamine Transporter (DAT1) VNTR, and the Dopamine b Hydroxylase (DBH) TaqI A2 allele polymorphism contribute to ADHD susceptibility. We have initiated genetic studies of candidate genes for ADHD in a unique cohort of 158 ADHD and 81 control participants from the Milwaukee Longitudinal Study (MLS) of ADHD. Participants were diagnosed during early childhood, and have been evaluated every 5 years for the past 20 years. Evaluations have included neuropsychological, psychiatric, educational, and social functioning assessments. Eighty-eight Caucasian subjects and 40 age and ethnicity-matched controls from the MLS were genotyped for the DRD4 exon 3 VNTR, DAT1 3' UTR VNTR, DBH TaqI A polymorphism, and the DBH GT repeat polymorphism which has been previously associated with serum DBH activity levels. Results indicate a significant association between the DBH TaqI A1 allele and ADHD ( $p < .01$ ) with a greater number of individuals with the A1, A1 genotype in the ADHD group ( $p < .005$ ). Also, a trend towards an increased frequency of the DBH GT repeat A4 allele in the ADHD group ( $p < .25$ ) was observed. These data support the hypothesis that particular alleles of the DBH gene may confer susceptibility to ADHD. Further studies will aim to genotype other candidate alleles in these individuals and in the full MLS cohort. These data will allow the potential to study the functional phenotypic consequences of candidate alleles on different developmental outcomes of ADHD.

**Chromosome 12 and Late-Onset Alzheimer Disease (AD) is Modified by Apolipoprotein E (APOE) Genotype.**

*K.K. Nicodemus<sup>1</sup>, D. Hedges<sup>1</sup>, A.M. Saunders<sup>1</sup>, P.M. Conneally<sup>2</sup>, G.W. Small<sup>3</sup>, J.R. Gilbert<sup>1</sup>, J.L. Haines<sup>4</sup>, M.A. Pericak-Vance<sup>1</sup>, W.K. Scott<sup>1</sup>.* 1) Duke Univ Med Ctr, Durham, NC; 2) Indiana Univ, Indianapolis IN; 3) Univ of Cal at Los Angeles; 4) Vanderbilt Univ Med Ctr, Nashville TN.

There are several reports of association or linkage between chromosome (chr) 12 markers and AD but there is no consensus for any specific candidate gene. Since the APOE-4 allele is a strong risk factor for AD, we examined whether association between markers on chr 12 and AD is modulated by APOE genotype. We assessed both linkage and association in 251 Caucasian families with discordant sibships and mean age of onset of AD per family > 60 years. The markers spanned a region from 26 to 80 cM. Data were analyzed using two family-based tests of linkage disequilibrium: the pedigree disequilibrium test using (PDT), and TRANSMIT (TMT). We report results of 2-point single-allele tests with 1 df. In the overall dataset, results were significant for the 234-bp allele of d12s1090 (56 cM; p=0.002 TMT; p=0.01 PDT), and for the 175-bp allele of d12s1713 (61 cM; TMT p=0.001; PDT ns). The 234 bp allele at D12S1090 was also associated with AD (p=0.003 TMT; 0.01 PDT) in families where all affected individuals had at least one APOE-4 allele (n=94). However, several novel associations were detected in families where at least one affected individual had an APOE 3/3 genotype (n=67): 218-bp allele of d12s1632 (71.6 cM; p=0.001TMT; p=0.03 PDT), the 186-bp allele of d12s2200 (79.9 cM; p=0.02 TMT; PDT ns) and the 210-bp allele of d12s2200 (p=0.01 TMT; PDT ns). We further examined these APOE-4 independent results in families where all affected members carried the APOE 3/3 or 3/2 genotypes (n=37). Association was found with the 218-bp allele of d12s1632 (p=0.03 TMT; PDT ns); with the 202-bp allele of D12S2200 (p=0.003 TMT; p=0.03 PDT); and with the 175-bp allele of d12s1713 (p=0.0006 TMT; p=0.01 PDT). These data indicate that association between markers on chr 12 and AD is dependent on APOE genotype, and that more than one AD susceptibility gene may exist on chr 12.

**Juvenile myoclonic epilepsy in chromosome 6p11: Recombinations and haplotype sharing reduce the candidate region to 500 kb.** *R. Morita*<sup>1,2</sup>, *D.S. Bai*<sup>2</sup>, *M.E. Alonso*<sup>3</sup>, *T. Suzuki*<sup>1</sup>, *Y. Sugimoto*<sup>1</sup>, *K. Amano*<sup>1</sup>, *M.T. Medina*<sup>2,5</sup>, *J.N. Bailey*<sup>2,6</sup>, *A. Rasmussen*<sup>3</sup>, *J. Ramos-Peek*<sup>3</sup>, *S. Cordova*<sup>3</sup>, *F. Rubio-Donnadieu*<sup>3</sup>, *J. Inazawa*<sup>4</sup>, *A. Jara-Prada*<sup>3</sup>, *A. Ochoa*<sup>3</sup>, *K. Yamakawa*<sup>1</sup>, *A.V. Delgado-Escueta*<sup>2</sup>. 1) Lab Neurogen, Brain Sci Inst, Inst Physical & Chemical Res, Saitama, Japan; 2) Epilepsy Genetics/Genomics Lab, CEP, UCLA and VA GLAHS, West Los Angeles, CA; 3) National Institute of Neurology & Neurosurgery, Mexico City, Mexico; 4) Dept Mol Cytogenetics, Div of Genetics, Med Res Inst, Tokyo Med & Dental Univ, Tokyo, Japan; 5) Autonomous Univ, Tegucigalpa, Honduras; 6) Neuropsychiatric Inst, UCLA, Los Angeles, CA.

Juvenile myoclonic epilepsy, which accounts for 12-30 percent of all epilepsies, starts at 13-15 years of age. Grand mal seizures appear two years later. In 1988, we reported a major susceptibility loci for JME (EJM1) may lie outside the HLA area in chromosome 6p21.3. In 1995-1996, a large family from Belize provided independent proof for linkage to 6p12-11 about 25 cM centromeric to HLA. To reduce the size of the candidate region for EJM1, we constructed a PAC and BAC based physical map composed of 95 clones to order microsatellite markers accurately, and generated six new microsatellites from clone sequences in the EJM1 candidate region. We studied a second large family from Appalachian mountains (USA) that provided independent proof of linkage (LOD>3) to 6p12-11. Informative recombinations and haplotypes in these two large families reduced the size of EJM1 to 500kb flanked by 125gt1 and 408CA1. Linkage analyses, haplotypes and recombinations in 21 other medium-sized JME families (243 individuals; 77 affected) from Mexico and California provided supporting evidence for the EJM1 locus. Pooled LOD scores were significant, e.g., 4.73 for D6S1662 on two point linkage analyses. No evidence of linkage was observed for markers in HLA region. Haplotype analyses identified 14 families whose affected members shared a one megabase 6p11 region flanked by AFMA053WF1 and D6S1960 while recombinations identified the same 6p11 area where 125gt1, D6S427 and 408CA1 reside. Large scale sequencing of this 550kb area is in progress.

**Genetic mapping using haplotype and model-free linkage analysis supports previous evidence for a locus predisposing to severe bipolar disorder at 5q31-q33.** *K.S. Hong<sup>1,6</sup>, A. McInnes<sup>2</sup>, S. Service<sup>1</sup>, T. Song<sup>2</sup>, J. Lucas<sup>2</sup>, S. Silva<sup>3</sup>, E. Fournier<sup>3</sup>, P. León<sup>3</sup>, J. Molina<sup>4</sup>, V.I. Reus<sup>2</sup>, L. Sandkuijl<sup>5</sup>, N.B. Freimer<sup>1</sup>.* 1) Department of Neuropsychiatry, University of California Los Angeles, Los Angeles, CA; 2) Department of Psychiatry, University of California San Francisco, San Francisco, CA; 3) Cell and Molecular Biology Research Center and Escuela de Medicina, Universidad de Costa Rica, San Jose, Costa Rica; 4) Center for Regional Investigations in Mesoamerica, Antigua, Guatemala; 5) Department of Human Genetics, Leiden University, The Netherlands; 6) Department of Psychiatry, Sungkyunkwan University School of Medicine, Seoul, Korea.

In earlier work (Garner et al., 2001) we screened the genome of two separately ascertained but genetically connected Costa Rican pedigrees segregating for severe bipolar disorder (BPI). In that analysis, we had combined the two pedigrees as a single huge kindred and used recently developed algorithms permitting non-parametric linkage analysis of large, complex pedigrees with inbreeding loops (implemented in the package SimWalk2) and obtained strong evidence for linkage to BPI with five microsatellite markers in 5q31-33. In the present study, we genotyped 14 new microsatellite markers in this region on chromosome 5 and applied the same model-free linkage analysis. Significantly high degree of identity-by-descent allele sharing among affected relatives was observed in all the markers spanning approximately 15cM ( $p < 0.01$ ). We also constructed haplotypes with these markers for 74 individuals in the pedigree. Twelve of 19 BPI affected individuals in the larger branch of the pedigree shared a single haplotype over this region, with several more affected individuals sharing at least some parts of this haplotype. These results support the suggestion for a locus at 5q31-q33, that together with a previously reported locus at 18q22-q23, provides the major genetic risk for BPI in these pedigrees.

**First results of a genome-wide scan in Dutch Caucasian sibpairs with type 2 diabetes mellitus.** *J.H.O. van Tilburg<sup>1</sup>, E. Strengman<sup>1</sup>, P.L. Pearson<sup>1</sup>, L.A. Sandkuijl<sup>1</sup>, T.W. van Haefen<sup>2</sup>, C. Wijmenga<sup>1</sup>.* 1) Department of Medical Genetics, University Medical Center, Utrecht, the Netherlands; 2) Department of Internal Medicine, University Medical Center, Utrecht, the Netherlands.

Type 2 diabetes mellitus is increasingly common in adults in most populations in the western world. In the past two decades, twin and family studies have provided strong evidence for a genetic component in diabetes. It is now well established that diabetes mellitus is a multifactorial disease, in which many genes interact not only with each other but also with environmental factors. Factors such as age, physical activity, diet, and obesity play a major role in the disease aetiology.

We are currently performing a genome-wide scan in Dutch Caucasian sibpairs with type 2 diabetes mellitus (DM2), with the aim of identifying susceptibility loci in the Dutch population. Patients were recruited through the Diabetes Service in Breda, and diagnosed according to WHO criteria. So far, our study cohort consists of 586 probands, including 336 sibpairs with a mean sibship size of 3.1 .

We use a screening set of approximately 300 highly polymorphic markers, giving an average spacing of 15 cM. This set will provide a power of  $\pm 90\%$  to detect loci of even modest effect ( $l_s = 1.5$  to  $1.7$ ). The screening set is designed in such a way that multiplex PCR can be performed. The PCR products are pooled into different running sets, before electrophoresis on an ABI 3700, and are analysed using GeneScan version 3.1 software. Alleles sizes of the individual markers are determined by use of GenoTyper version 2.1 software.

To assess for linkage, we applied multi-point non-parametric linkage analysis using the MAPMAKER/SIBS software 2.0 . So far we identified 3 positive peaks on 3 different chromosomes. These peaks are currently further investigated with additional markers.

**Genome-wide scan in Attention Deficit Hyperactivity Disorder (ADHD).** *S.L. Smalley<sup>1</sup>, S.E. Fisher<sup>2</sup>, C. Francks<sup>2</sup>, A.J. Marlow<sup>2</sup>, I.L. MacPhie<sup>2</sup>, J.T. McCracken<sup>1</sup>, J.J. McGough<sup>1</sup>, L. Crawford<sup>1</sup>, T. Kim<sup>1</sup>, A. Liu<sup>1</sup>, S.F. Nelson<sup>1</sup>, A.P. Monaco<sup>2</sup>.* 1) UCLA Center for Neurobehavioral Genetics, Los Angeles, CA; 2) Wellcome Trust Centre for Human Genetics, Oxford, UK.

Attention deficit hyperactivity disorder (ADHD) is a common neurobehavioral condition affecting 5-10% of children and adolescents and 3% or more of adults. It is a condition characterized by symptoms of inattention and/or hyperactive-impulsive behaviors that result in impairment and have their onset in childhood. Genetic influences are predominant based on twin and family studies of ADHD, with estimates of heritability ranging from 60-80%. In an ongoing molecular genetic study of ADHD, we conducted a genome scan in 106 families including 128 Affected Sibling Pairs (ASPs). ADHD status was determined using a best estimate procedure with definite diagnosis following DSM-IV criteria and a probable diagnosis if a case fell one symptom short but met the impairment criteria. Sibs and their parents were genotyped with > 400 highly polymorphic markers spaced at 10cM intervals throughout the entire genome. Results from the scan revealed multipoint MLS values over 1 on chromosomes 10, 11, 12, 16, and 17 for ADHD (definite and probable). Restricting the analyses to those with only a Definite ADHD diagnosis led to MLS > 1 on chromosomes 4, 9, 10, 11, and 12. Additional genotyping in regions with MLS > 1 is in progress in an extended sample of ASPs. This is the first genome-wide scan to have been completed for this important neurobehavioural trait.

**A genome scan for quantitative trait loci influencing age of disease onset and central obesity in a UK population with Type 2 Diabetes.** *S. Wiltshire<sup>1,2</sup>, M. McCarthy<sup>1,2</sup> for the Warren 2 Consortium.* 1) Wellcome Trust Centre for Human Genetics, Oxford, UK; 2) Imperial College Genetics and Genomics Research Institute, London, UK.

Type 2 diabetes and central obesity contribute significantly to global mortality and morbidity. To investigate the genetic basis of central obesity in subjects with type 2 diabetes (T2D), together with factors affecting the progression of T2D, we have examined several quantitative traits from 573 sibships with T2D, from the Diabetes (UK) Warren 2 repository, for linkage to 418 autosomal microsatellite markers. Age of disease onset, body mass index (BMI), waist hip ratio (WHR), and waist and hip circumference measurements, adjusted for age and sex where appropriate, were analysed with Haseman-Elston (HE) and variance components (VC) methods, implemented in GENEHUNTER V2.0. Loci influencing age of onset were identified on 5p15 (HE-LOD=1.37; VC-LOD=1.17), 12p12 (HE-LOD = 1.92; VC-LOD=2.08, additive heritability = 32%), and 12q24 (HE-LOD=0.68; VC-LOD=1.87, additive heritability = 35%). The 12p locus coincides with linkage to T2D observed in US Europids with early onset T2D; that on 12q coincides with linkage to T2D in Finnish subjects from Botnia. There was evidence for linkage to BMI, waist and hip circumferences on chromosome 3q13 (HE-LOD scores of 1.34, 2.75 and 2.27); VC analysis yielded less significant evidence (LOD scores of 1.03, 1.86 and 1.81; additive heritabilities of 24%, 33% and 34%). This region is ~90cM centromeric to the linkages to BMI, waist and hip circumferences observed in the TOPS study and ~90cM from the linkage to BMI observed in the FUSION study. There was evidence for linkage to BMI, WHR, waist and hip circumferences on 12q21-24 (LOD score range: 0.59 (HE, waist) to 1.45 (VC, hip)), and to WHR, waist and hip circumferences on 19p13 (LOD score range: 0.86 (HE, hip) to 1.89 (VC, waist)). In summary, our study suggests the presence of one, perhaps two, loci on chromosome 12 modifying age of onset of T2D, a third locus on 3q influencing central obesity, and some evidence for loci on 12q and 19p influencing central obesity also.

Program Nr: 2073 from the 2001 ASHG Annual Meeting

**Weighting Pedigrees of Varying Sizes in Nonparametric Linkage Analysis.** *H. Sengul, D.E. Weeks, E. Feingolds.*  
Dept Human Gen, Crabtree Hall, Univ Pittsburgh, Pittsburgh, PA.

Over the last 10 years, allele-sharing statistics for "nonparametric" linkage analysis have become an important tool in mapping complex traits. Recent interest in applying these methods to larger and larger pedigrees has made it critical to understand how best to weight contributions from pedigrees of different sizes and configurations when combining them in a single study. For any given trait model and set of pedigrees, one can derive optimal weights, but such an exercise is of limited utility since one expects to have little knowledge of the trait model when studying a complex trait. We approach the problem by finding optimal weights for many trait models and pedigree structures and looking for weighting schemes whose power is robust over large classes of models. We then compare the power of our weighting schemes to that of the weighting schemes implemented in current software, including equal weighting of all families, weighting based on the number of affecteds, and weighting based on the square root of the number of affecteds.

**Test of association and estimation of heritability attributable to SNP effects for quantitative traits with ROMP.**

*A.F. Wilson<sup>1</sup>, M.-H. Roy-Gagnon<sup>1</sup>, C.M. Justice<sup>1</sup>, G.J. Papanicolaou<sup>1</sup>, A.J.M. Sorant<sup>1</sup>, A. Kingman<sup>2</sup>, E.W. Pugh<sup>3</sup>.* 1) Genometrics Section, NHGRI, NIH Baltimore, MD; 2) NIDCR, NIH, Bethesda MD; 3) CIDR, JHU SOM, Baltimore, MD.

With the availability of thousands of single-nucleotide polymorphisms (SNPs) in the human genome, testing for associations between functional SNPs and quantitative traits is becoming increasingly popular. Large scale implementation of these methods will require analytic methods that are computationally fast and that minimize the amount of genotyping. An extension of quantitative genetic theory based on the traditional linear regression of offspring on mid-parent method and the inclusion of a candidate locus effect as a covariate in the regression is presented. This method, ROMP, can be used to estimate the heritability of a quantitative trait, test whether the heritability of the trait is greater than 0, test for an effect of a SNP locus on that trait, and estimate the heritability attributable to that locus. The method uses linear regression and is most appropriately applied to parent-offspring trios or nuclear families, like the TDT. ROMP requires phenotyping data on both parents and offspring, but genotyping data only on the offspring. Unlike model-dependent methods, ROMP does not require the estimation of allele frequencies or genotype-specific means and variances or the computation of the proportion of alleles shared i.b.d. or i.b.s.

Computer simulation was used to determine the type I error rate and power of the method, and to determine the accuracy of estimates of the heritability of the trait and the heritability attributable to the candidate locus.

The ROMP method accurately estimated the heritability of the trait and the heritability attributable to a specific candidate locus. For the models considered, the type I error rate and power of ROMP were comparable to that of other methods. In addition, ROMP appears to be fairly robust with respect to the effects of population stratification. ROMP is computationally fast, does not require specialized software and can be implemented in standard statistical packages such as SAS.

**Genome screen to identify loci contributing to susceptibility for Parkinson Disease.** *N.D. Pankratz<sup>1</sup>, W.C. Nichols<sup>2</sup>, S.K. Uniacke<sup>2</sup>, A. Rudolph<sup>3</sup>, C. Halter<sup>1</sup>, E. Siemers<sup>4</sup>, J.P. Hubble<sup>5</sup>, P.M. Conneally<sup>1</sup>, T. Foroud<sup>1</sup> and Parkinson Study Group.* 1) Indiana University School of Medicine; 2) Children's Hospital Research Foundation; 3) University of Rochester; 4) Eli Lilly and Company; 5) Ohio State University.

Several genes have been identified which contribute to rare, early onset or autosomal dominant forms of Parkinson disease (PD). To identify susceptibility genes contributing to the more common, late onset form of PD, families consisting of at least one pair of living siblings diagnosed with PD were recruited through 58 Parkinson Study Group (PSG) sites distributed throughout North America. A Diagnostic Checklist was completed by the neurologist with inclusion criteria consisting of clinical features highly associated with autopsy-confirmed PD and exclusion criteria highly associated with other non-PD pathological diagnoses. Responses on the Diagnostic Checklist were then used to classify study subjects as having verified PD (230 subjects) or nonverified PD (78 subjects). A genome screen was completed using 382 markers. A total of 148 families having 2 or more affected siblings (162 affected sibpairs) were analyzed. Two models of affection status were considered. Model I included all individuals as affected, regardless of their final diagnostic classification, while Model II included only those individuals with a more stringent diagnosis of verified PD. We report the results of nonparametric linkage analyses of the sibpairs using MAPMAKER/SIBS, Aspex, and Allegro. The strongest finding across all methods was a lod score of 2.55 obtained on chromosome 13 with Model II. Other findings that were consistent across analysis methods include 6 regions with lod scores above 1.5: chromosomes 2 (lod=1.7, Model I), 4 (lod=1.8, Model I), 6 (lod=2.1, Model II), 11 (lod=1.6, Model II), 12 (lod=1.9, Model II), and X (lod=2.0, Model I). The regions on chromosomes 6 and 2 were previously implicated in genome-wide studies of PD and studies of the parkin gene (chromosome 6) are currently ongoing in the families demonstrating linkage to this locus. These results provide further evidence of the presence and location of genes that are involved in genetic susceptibility to PD.

**Refining the critical regions of 17q and 5p containing predisposing loci for multiple sclerosis using SNP-array and LD and haplotype sharing analysis.** *J.S. Saarela<sup>1,2</sup>, H.M. Frostad Riise Stensland<sup>1</sup>, D.C. Chen<sup>1</sup>, S. Finnilä<sup>1</sup>, A. Jokiaho<sup>1</sup>, A. Palotie<sup>3</sup>, L. Peltonen<sup>1,2</sup>.* 1) Department of Human Genetics, UCLA, School of Medicine, Los Angeles, CA; 2) Department of Molecular Medicine, National Public Health Institute, Helsinki, Finland; 3) Department of Pathology, UCLA, School of Medicine, Los Angeles, CA.

Multiple Sclerosis (MS) is one of the most common neurological diseases of young adults. The incidence (2-4/100000) and prevalence (50-100/100000) rates are highest in populations of Northern-European origin. We have used a study sample of 26 multiplex MS-families originating from Finland and established linkage to chromosomes 5p, 6p, 17q and 18q, all loci also identified in other populations. By using a population sub isolate and combined power of linkage and linkage disequilibrium (LD) as well as monitoring for shared haplotypes, the methods frequently used for the fine mapping of monogenic diseases, we have been able to restrict the critical regions for MS loci on chromosomes 17 and 5 from linked 23 and 20 cM intervals to 3 and 9 cM, respectively. The so far better-defined DNA-region on chromosome 17q contains a total of 144 predicted or confirmed genes, the corresponding number for chromosome 5p being over 170. We have selected SNPs in coding and regulatory regions of the predicted transcripts of the critical DNA regions and constructed an SNP-microarray, based on allele-specific primer extension. Out of 80 SNPs analysed so far, the majority show evidence for linkage, but thus far only one SNP mapping between the best multi-allelic markers on chromosome 17 reveals evidence for association in the Haplotype Relative Risk-test ( $p=0.001$ ). The SNP array is currently used to monitor for regional SNPs in a larger, population-wide study sample comprising of single affected MS-families.

**Genome scan linkage analysis of severe, early-onset COPD.** *E.K. Silverman<sup>1</sup>, J.D. Mosley<sup>1</sup>, M. Barth<sup>1</sup>, J. Senter<sup>1</sup>, A. Brown<sup>1</sup>, D.J. Kwiatkowski<sup>1</sup>, H.A. Chapman<sup>4</sup>, J.M. Drazen<sup>1</sup>, F.E. Speizer<sup>1</sup>, D.C. Rao<sup>2</sup>, M.A. Province<sup>2</sup>, E.J. Campbell<sup>3</sup>, S.T. Weiss<sup>1</sup>.* 1) Brigham & Women's Hospital, Boston, MA; 2) Washington University, St. Louis, MO; 3) University of Utah, Salt Lake City, UT; 4) University of California, San Francisco, CA.

Severe alpha 1-antitrypsin (AAT) deficiency is the only proven genetic risk factor for chronic obstructive pulmonary disease (COPD). To study novel genetic determinants of COPD, we enrolled 72 pedigrees ascertained through severe, early-onset COPD probands (FEV1 < 40% predicted, age < 53 years, without severe AAT deficiency). A 10 cM genome screen with short tandem repeat (STR) markers was performed by the NHLBI Mammalian Genotyping Service; 571 individuals were included in multipoint linkage analysis using ALLEGRO. Phenotypes analyzed included moderate airflow obstruction (FEV1 < 60% predicted, FEV1/FVC < 90% predicted), mild airflow obstruction (FEV1 < 80% predicted, FEV1/FVC < 90% predicted), and chronic bronchitis. Multipoint linkage analysis revealed the strongest evidence for linkage to the following locations: moderate airflow obstruction to chromosomes 12 (p=0.003) and 19 (p=0.004), mild airflow obstruction to chromosomes 8 (p=0.006) and 19 (p=0.01), and chronic bronchitis to chromosomes 19 (p=0.009) and 22 (p=0.006). Restricting linkage analysis to cigarette smokers provided increased evidence for linkage in several genomic regions, potentially related to gene-by-smoking interactions. Seven additional STR markers were genotyped on chromosome 12p; maximal evidence for linkage in all subjects was found to moderate airflow obstruction at 36 cM (p=0.0007) and to mild airflow obstruction at 38 cM (p=0.004). In sum, we have found multiple interesting regions with potential linkage to COPD-related phenotypes, with suggestive evidence for linkage of airflow obstruction to chromosome 12p. Further analysis of these chromosomal regions may lead to the identification of new genetic determinants of COPD. (Supported by NIH HL61575).

**Limits of resolution for genetic mapping of complex traits.** *G.J. te Meerman, I.M. Nolte.* Dept Medical Genetics, Univ Groningen, Groningen, Netherlands.

Success in finding mutant genes contributing to complex genetic disease has been minimal so far. This applies to finding approximate locations for contributing genes, by linkage and/or association analysis, as well as to the identification of responsible mutant genes, once association has been found. It seems likely that genotyping will become so cheap, that systematic whole genome screens, using thousands of individuals and tens of thousands of polymorphic markers, 1-3 per identified gene, will become practical in the near future. This will lead to the detection of genes involved in complex genetic disease, although the costs are several orders of magnitude higher than those required to identify rare and highly penetrant mutant genes by linkage analysis. The next question will then be: will we be able to pinpoint the genes and the mutations responsible for disease? The results until now do not give great reason for optimism: the association between markers and disease in the HLA area is strong, but responsible variants have not been identified e.g. in Multiple Sclerosis and Psoriasis. Frequent alleles that are functionally intact and have weak marginal effects cannot yet be identified from the genetic sequence alone. This underlines the necessity of knowing the limits of resolution of genetic mapping. We will show that on theoretical grounds the limit of resolution of statistical and logical gene mapping methods based on haplotype analysis (Beckmann et al, McPeck et al) may be suffice to identify causal polymorphisms, or to reduce the set of candidate causal variants to a few. Phase information is essential for this purpose and SNP based strategies present serious difficulties in this respect. We will demonstrate the asymptotic fine mapping behavior of haplotype sharing methods with some simulation examples. Beckmann L, Fisher C, Deck K-G, Nolte IM, Te Meerman G, Chang-Claude J. Exploring haplotypes sharing methods in general and isolated populations to detect gene(s) of a complex genetic trait. GAW-12 issue Genet Epidemiol 2001, in press McPeck MS, Strahs A. Assessment of linkage disequilibrium by the decay of haplotype sharing, with application to fine-scale genetic mapping. Am J Hum Genet. 1999 Sep;65(3):858-75.

**Evaluation of hybrid MCMC samplers for estimation of genes shared identical by descent and haplotyping.** *M. Szydlowski, S.C. Heath.* Dept of Epidemiology and Biostatistics, Mem Sloan Kettering Can Ctr, New York, NY.

Analysis of extended pedigrees and complex trait models is often beyond the power of exact algorithms. Monte Carlo techniques and the Gibbs sampler in particular have proven useful in many cases. In the presence of tightly linked loci, complex pedigree structure and large groups of full/halfsibs, however, simple samplers often suffer mixing problems ruining any inference. We evaluate the power of various hybrid samplers to tackle multilocus and close linkage problems on human pedigrees. Specifically, the ability of hybrid samplers to estimate the number of genes shared identical by descent (i.b.d.) and the probability distributions of haplotypes is evaluated. We used different pedigrees with both pure hierarchical and complex structures. The complex pedigree is from an isolated Micronesian Island population, consists of 253 individuals and contains several loops and large groups of fullsibs. A number of tightly linked codominant markers were simulated and analyzed with various hybrid samplers. The basic one was the whole locus sampler (L), which generates joint pedigree genotype configurations within a locus and ensures theoretical irreducibility of sampling chain. In addition to L updates we used three multilocus samplers: the whole meiosis sampler (M), which samples a joint segregation indicator pattern for all loci simultaneously and two simple Metropolis steps for sampling multilocus descent graphs in nuclear and three generation families in turn. In conclusion we demonstrate the great ability of hybrid samplers to perform efficient genetic analysis. The hybrid samplers present much better mixing properties when compared to simple samplers allowing for efficient estimates of i.b.d. sharing and haplotypes frequencies. Results on the application of different sampling schemes are presented and the generalization of the hybrid samplers for good performance across various pedigree structures is discussed. Some recommendations on the use of hybrid samplers are given. This work was supported by NIH Grant GM58757-01.

**An analysis of the influence of candidate genes on the refractive error of female DZ twins.** *Q. Prescott<sup>1</sup>, C.J. Hammond<sup>2</sup>, T. Andrew<sup>2</sup>, A.M. Dearlove<sup>3</sup>, T.D. Spector<sup>2</sup>, S.S. Bhattacharya<sup>1</sup>, A.R. Webster<sup>1</sup>.* 1) Dept of Molecular Genetics, Institute of Ophthalmology, London; 2) Twin Research and Genetic Epidemiology Unit, St Thomas Hospital, London; 3) HGMP Resource Centre, Hinxton, Cambridge, UK.

The development of refractive error in humans is due to an aberration of the process of emmetropization, in which the eyes' refractive components develop interdependently to form an accurately focused image on the retina of a distant object of regard. The susceptibility to such aberration is likely due to both environmental and genetic effects. We present a study to determine the contribution of candidate genes in refractive error development in an all-female cohort of dizygotic (DZ) twin pairs (age range 49-79 years, mean 62.4 years) from the St Thomas twin study, recruited independently of ophthalmic status or history. The spherical equivalent and astigmatic cylinder was measured on all subjects (mean +0.8D, range -7.5D to +10.8D). So far alleles of intra- and juxta- genic polymorphisms in two candidate genes have been scored: fibrillin1 and collagen 11a1, mutations in which cause Marfan and Stickler syndrome respectively. Both these disorders are consistently associated with moderate to high myopia in affected individuals. Using refractive error as a quantitative trait, this resource allows the assessment of the influence of these and other candidate genes in the determination of refractive status by the analysis of both allele-sharing and association of refractive status with specific alleles and haplotypes.

**Genetic Susceptibility to Juvenile Rheumatoid Arthritis.** *J.A. Runstadler<sup>1</sup>, K. Laiho<sup>2</sup>, J. Tuomilehto<sup>2</sup>, M.F. Seldin<sup>1</sup>.*  
1) University of California, Davis, Davis, CA; 2) National Public Health Institute, Helsinki, Finland.

This study was undertaken to further define the genetic susceptibility to Juvenile Rheumatoid Arthritis (JRA) using Finnish JRA probands, family and population controls. HLA allele associations have often been weak in JRA studies and dependent on the population being examined. Linkage may therefore be implied where none exists, due to population stratification. In addition, the involvement of other genes within the HLA region has not been ruled out. The current study of JRA utilizes a population (Finnish) with the potential advantage of genetic isolation. In this population, problems due to population stratification and locus heterogeneity are reduced, allowing for greater power. This study also utilized the transmission disequilibrium test (TDT) in addition to a case/control design to examine JRA and JRA subtypes. We have examined 21 microsatellites and 2 insertion/deletion markers spanning an 18 cM region of chromosome 6 encompassing the entire MHC. Each marker was genotyped for a set of 301 Finnish JRA nuclear families and 500 Finnish control individuals. Analysis by association and TDT methods each demonstrated strong evidence for a susceptibility locus near the DQCAR microsatellite ( $p < 0.000001$  for both methods) which is flanked by DQB1 and DRB1. Analysis of closely linked microsatellite markers to DRB1 suggest that DRB1\*0801 and DRB1\*1101 rather than DQA1 or other HLA alleles may be responsible for conferring susceptibility to disease while DRB1\*0401 is protective. These findings are consistent with the most compelling results of previous reports on HLA associations. Subdividing the data by Pauciarticular and Polyarticular RF- subtypes of JRA did not alter the strong association at the DQCAR locus ( $p < 0.000001$ ). Modeling for gene action using TDT data shows the strongest evidence exists for an additive or dominant gene effect at this locus. In Pauciarticular patients, the strong association does not extend proximal to markers MID-104 and MID-108 as it does in Polyarticular patients ( $p < 0.00001$ ). In addition, two other loci within the 18 cM region we examined show association ( $p < 0.05$ ) but are highly dependent on the subclass of JRA examined.

**Identification and genetic analysis of polymorphic loci in the human Nurr1 transcription factor gene NR4A2.**

*K.M. Smith<sup>1</sup>, R. Mankoski<sup>1</sup>, L. Bauer<sup>2</sup>, M. Fischer<sup>2</sup>, R. Barkley<sup>3</sup>, B.A. Navia<sup>1,4</sup>.* 1) Genetics Prog/Sackler Sch., Tufts Univ., Boston, MA; 2) Neuropsych. Sec., Medical College of Wisconsin, Milwaukee, WI; 3) Dept. of Psychiatry, UMass Worcester Med. Cent., Worcester, MA; 4) Neurology, NEMC/Tufts Univ. School of Medicine, Boston, MA.

NR4A2, or Nurr1, is an orphan nuclear receptor implicated in the development of dopaminergic cells of the ventral midbrain. Mice lacking Nurr1 fail to develop dopaminergic cells of the ventral tegmental area (VTA) and the substantia nigra (SN). The dopaminergic cells of the VTA provide innervation to the prefrontal cortex, a signaling system believed to be of major importance to the pathogenesis of neuropsychiatric disorders such as Schizophrenia and ADHD, suggesting that Nurr1, or one of its targets is a potential candidate gene for these disorders. Identification of mutations or polymorphisms in genes that control the development and/or function of the dopaminergic signaling pathways, such as Nurr1 is an important primary step in candidate gene studies for these disorders. We have identified several polymorphic loci in the Nurr1 gene via database searches of the high throughput sequencing database as well as an SSCP screen of Nurr1 coding regions. Database analysis revealed a CA microsatellite repeat polymorphism in the 3' UTR of this gene which was confirmed by PCR. Two alleles were identified, differing by one repeat length. These alleles were tested for an association with ADHD in both a case control study of individuals from the Milwaukee Longitudinal Study of ADHD, and in 35 sib pairs with ADHD and their parents. A trend ( $.25 > p > .1$ ) towards increased transmission of the shorter allele (allele 1) was observed in families with ADHD via TDT analysis. SSCP screening in 90 individuals revealed a rare polymorphism in intron 5 present in one individual, and a more common polymorphism -263 DC in the promoter region with a frequency of approximately .30. Ongoing studies will examine the association of this promoter polymorphism to ADHD as well as determine its effects on the transcriptional regulation of Nurr1.

**Evidence of linkage for speech impairment with chromosome 7 markers.** *J.H. Schick<sup>1</sup>, A.M. Kundtz<sup>1</sup>, H.G. Taylor<sup>2</sup>, L.D. Shriberg<sup>3</sup>, L.A. Freebairn<sup>2</sup>, B.A. Lewis<sup>2</sup>, S.K. Iyengar<sup>1</sup>*. 1) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH; 2) Department of Pediatrics, Rainbow Babies and Childrens Hospital, Case Western Reserve University, Cleveland, OH; 3) Waisman Center on Mental Retardation and Human Development, University of Wisconsin-Madison, Madison, WI.

Speech and language are important human characteristics. The etiology of speech and language impairment is largely unknown, but family and twin studies have indicated a significant genetic component. An autosomal dominant locus (SPCH1) for a severe speech and language disorder was localized to a 5.6 cM region of chromosome 7q31 between D7S2459 and D7S643 (Lai et al., 2000) in a large three-generation pedigree characterized with dyspraxia of speech. We tested the hypothesis that a candidate locus on 7q31 also segregated with a broader phenotype of speech and/or language disorders in nuclear families. We analyzed 7 markers (D7S1789, D7S527, D7S1812, D7S821, D7S2425, D7S692, & D7S486) spanning a 21.26 cM region on 7q31 in a sample ascertained through pre-school probands. Eighty-nine families (N=427) consisting of 196 sib pairs were genotyped. SIBPAL2 (S.A.G.E., Beta 7) was used for single- and multi-point linkage analysis for two binary traits: speech impairment and speech or language disorders. For each binary trait, the linkage analysis was adjusted for: age and socio-economic status. Our preliminary multipoint analyses suggest that a putative gene for the speech only phenotype is located near a 0.55 cM region containing markers D7S527 ( $p=0.0009$ ), D7S1812 ( $p=0.0007$ ) and D7S821 ( $p=0.0062$ ) and flanked by markers D7S1789 ( $p=0.1456$ ) and D7S2425 ( $p=0.0997$ ) located 4.96 cM and 8.60 cM away, respectively. No locus for the broader phenotype of speech and/or language disorders appears to segregate in these families. This study is the first to provide support for the earlier hypothesis that a putative gene for speech disorders localizes to 7q31. Haplotype-based analyses are being conducted and are an initial step in the isolation of the first gene for speech disorders. This research is supported by NIH grants NIDCD-00528 and NIDCD-04005-01.

**Quasi-linkage: a confounding factor in linkage analysis of complex diseases.** *S. Sivagnanasundaram*<sup>1</sup>, *K.W. Broman*<sup>2</sup>, *A. Paterson*<sup>3</sup>, *A. Petronis*<sup>1</sup>. 1) Neurogenetics Section, Centre for Addiction and Mental health, Toronto, CA; 2) Dept of Biostatistics, The Johns Hopkins University, Baltimore, MD; 3) Dept of Genetics and Genomic Biology, The Hospital for Sick Children, Toronto, CA.

According to Mendel's second law, unlinked genomic loci segregate independently during meiosis, and this directly applies to non-homologous chromosomes. An exception to this rule is the phenomenon of quasi-linkage (QL) that describes the non-random segregation of non-homologous chromosomes. Molecular mechanisms of QL are not clear, and so far QL has been explained by the 'affinity hypothesis', that is the tendency of non-homologous chromosomes, through the mutual attraction of their centromeres, to migrate together. QL was initially observed in mice and plants but has not been investigated in humans. We were interested in determining if QL served as a significant confounding factor, that is quasi-linked loci falsely exhibiting co-segregation with disease, in genome scans for complex diseases. We investigated individual markers showing linkage to schizophrenia, asthma, multiple sclerosis, inflammatory bowel disease and type 1 diabetes. 'Disease linked' markers were tested for QL in a pairwise linkage analysis against all other markers exhibiting evidence for linkage in each specific disease. Marshfield genotyping dataset of eight CEPH families was used for this purpose. A wide range of QL maximal lod scores were observed. The highest lod score of 2.28 (theta F= 0.4; theta M= 0.32) was generated for two markers on chromosomes 15p13-q12 and 9q32-q34 which initially demonstrated evidence for linkage to schizophrenia (Kaufmann et al. 1998). A large number of QL lod scores varied between 1 and 2, and although did not reach the level of statistically significant linkage, are within the range of the overwhelming majority of "lukewarm" loci of complex diseases. The above data suggest that QL may be an important confounding factor in the genetics of complex traits, and if so should be taken into account when oligogenic and polygenic traits are investigated. Genome-wide QL maps of reference families would aid in accounting for such confounding effect.

**GenoMapper; mapping system of mouse full length cDNA onto genomic sequences.** *K. Sakai<sup>1</sup>, H. Kiyosawa<sup>1,2</sup>, S. Kondo<sup>1</sup>, I. Yamanaka<sup>1</sup>, T. Saito<sup>1</sup>, Y. Hayashizaki<sup>1,2,3</sup>.* 1) Genome Exploration Res Grp, RIKEN, Genomic Sci Ctr, Yokohama, Japan; 2) Division of Genomic Science, Yokohama City University, Yokohama, Japan; 3) Department of Medicine, Tsukuba University, Tsukuba, Japan.

We developed mapping viewer system to facilitate identifying the candidate genes for positional candidate cloning. In order to construct mouse gene encyclopedia, we have been producing tens of cDNA libraries, isolating cDNA clones, sequencing, and mapping them onto the human genome draft sequences. Our group has also been studying biological profiles of the cDNAs, such as expression analysis by DNA microarray technique and protein-protein interaction (PPI) analysis by mammalian two hybrid assay. The mapping method based on blast was described in our previous paper (Kondo et al.). We mapped mouse cDNAs, along with human RefSeq and the representative sequences of UniGene clusters, onto the human genome draft sequences assembled at University of California, Santa Cruz. The exon predictor programs (GenScan and FgenesH) were also used to identify the possible coding region. Our cDNAs were classified according to their novelty; 1) there are also known genes in the same position on the chromosomes, 2) there are also ESTs, 3) there are only predicted exons by the computer programs, and 4) there are no other genes at all. The description page for each cDNA contains its chromosomal position with links to other data such as alignment to genome sequences, expression, PPI, ORF analysis, FANTOM annotation page (The RIKEN Genome Exploration Research Group Phase II Team and FANTOM Consortium) and also to the external database such as OMIM and Locus Link. Position search is provided to define the cDNAs mapped to the region of interest. All the data gathered and linked to GenoMapper are utilized to narrow down the candidate genes for the phenotypes of interest. The strength of GenoMapper is that it contains novel genes only we have and biological data to reduce the numbers of candidate genes. Overview of GenoMapper system will be presented. Kondo et al. *Mamm. Genome*, in press. The RIKEN Genome Exploration Research Group Phase II Team and FANTOM Consortium, *Nature* 409, 685-690. 2000.

**Homozygosity mapping of three idiopathic mental retardation loci : toward identification of the first autosomal recessive isolated mental retardation gene.** *L. Colleaux<sup>1</sup>, F. Molinari<sup>1</sup>, M. Rio<sup>1</sup>, A. Rothchild<sup>2</sup>, A. Migharbane<sup>3</sup>, A. Munnich<sup>1</sup>.* 1) INSERM U393, Hosp Necker-Enfants Malades, Paris, France; 2) Hadassah Medical school, Jerusalem, Israel; 3) Universite Saint Joseph, Faculte de Medecine, Beyrouth, Liban.

Mental retardation (MR) is the most common developmental disability, affecting largely 2% of the general population. The causes of MR are diverse, but an autosomal recessive mode of inheritance may account for a significant proportion of mentally retarded individuals. The extreme genetic heterogeneity of idiopathic MR and the unavailability of large family pedigrees of nonsyndromic autosomal recessive MR has limited the use of genetic linkage to identify the disease causing genes. While a large number of X-linked mental retardation genes have been found, none of the numerous genes involved in autosomal recessive MR have been hitherto identified. Here we report on the homozygosity mapping of the disease gene in three unrelated inbred families. Genome-wide homozygosity mapping was performed using microsatellite markers at an average distance of 10cM. For each family, the results provided evidence of homozygosity for a single region on chromosomes 11p15.5, 2q13 and 4q24 respectively. Our results emphasize the difficulty encountered in some families to reduce the homozygosity region to a small workable region. However, in one of our family, fine genetic mapping and study of unaffected members of the family allowed us to map the disease causing gene to a small region of about 1.5 Mb.

**GENOME-WIDE SEARCH FOR TYPE2 DIABETES SUSCEPTIBILITY GENES IN JAPANESE AFFECTED SIBPAIRS.** *P. Froguel*<sup>1,3</sup>, *Y. Mori*<sup>1</sup>, *S. Otabe*<sup>1</sup>, *C. Dina*<sup>1</sup>, *K. Yasuda*<sup>2</sup>, *C. Lecoeur*<sup>1</sup>, *K. Hara*<sup>2</sup>, *K. Tobe*<sup>2</sup>, *P. Boutin*<sup>1</sup>, *T. Kadowaki*<sup>2</sup>. 1) Institute of Biology - CNRS UPR-ESA 8090, Lille Cedex, France; 2) Department of Metabolic Diseases, University of Tokyo, Tokyo, Japan; 3) Barts and the London Genome Centre, London, UK.

**Background and Aims :** The genetic background which predisposes to type2 diabetes in the Japanese population is largely unknown. To search for major susceptibility loci, we conducted a 10-cM genome scan for type 2 diabetes traits. **Materials and Methods :** A total of 359 individuals of Japanese origin were ascertained in Japan from 159 families, including 229 affected sibpairs. In 202 males, mean age at diagnosis was 45.9±9.7 yrs and maximal BMI was 26.4±3.0 kg.m<sup>-2</sup>. In 157 females, mean age at diagnosis was 48.3±11.1 yrs and maximal BMI was 27.4±3.8 kg.m<sup>-2</sup>. Fluorescent microsatellite marker set (ABI Linkage Mapping Set version2, MD10) was used for the primary 10cM scan. Additional 33 markers were typed for 13 candidate genes, mainly transcription factors. Non-parametric multipoint linkage analyses were performed by MLBGH1.0, MAPMAKER/SIB2.0 and GENEHUNTERPLUS. **Results:** Non-parametric multipoint linkage analyses performed in the whole population showed 7 potentially linked regions, on 1p36-p32, 3q26-q27, 6p23, 7p22-p21, 11p14-p13 (near Pax6), 15q13-q15 and 20q12-q13 (near HNF4 alpha). Subset analyses according to maximal body-mass index and to early age at diagnosis showed suggestive evidence of linkage with type 2 diabetes on 7p22-p21 (a maximum lod=4.46 in 85 families that were increasingly-ordered-ranked by maximal BMI), 15q13-q15 (MLS = 3.62) and 20q12-q13 (MLS = 2.56). **Conclusions :** These results confirm previous indication for linkage found on chromosome 3q, 15q and 20q and identifies new potential locus on 7p that may confer genetic risk for type 2 diabetes in the Japanese population.

**Single nucleotide polymorphism genotyping in DNA pools.** *E.L. Meaburn, R. Plomin, L. Schalkwyk.* Social, Genetic & Developmental Psychiatry Research Centre, Institute of Psychiatry, Kings College London, De Crespigny Park, London SE5 8AF, UK.

The advent of publicly available single nucleotide polymorphism (SNP) databases has made it increasingly feasible to construct dense marker maps of SNPs for use in allelic association studies of complex diseases. However, a persistent problem is the vast amount of genotyping that is required for such studies, especially for the large samples needed to detect associations of small effect size. DNA pooling facilitates genotyping of large samples because DNA is pooled from all individuals within each phenotypic group. Each pool, rather than each individual is genotyped and the relative allele frequencies of each group are compared. However, DNA pooling has only been used with fluorescent tags on short-sequence repeat markers that detect length polymorphisms, whereas it would be advantageous to use SNPs in DNA pooling research. For this reason we evaluated three SNP genotyping methodologies for their accuracy, robustness, and efficiency for DNA pooling using ten publicly available SNPs in coding regions. We used 1) competitive allele specific fluorescent probes in the Taqman (5' nuclease) assay, 2) Kinetic PCR using allele specific primers and SYBR green (Genome research 2000 10;258-266) and 3) the SNaPshot ddNTP Primer extension reaction kit. We conclude that all three SNP genotyping methods can be extended to DNA pooling. All three methods discriminate over a wide range of allele frequencies and yield accurate pooling results as confirmed by individual genotyping. However, as the polymerase chain reaction is a critical step in all the reactions, we conclude that methods employing real time quantification are more robust than methods that employ endpoint analyses.

Program Nr: 2089 from the 2001 ASHG Annual Meeting

**Analysis of short tandem repeats D3S1358, TH01, TPOX and CSF1P0 with an infrared fluorescent automated DNA sequencer (LI-COR 4200) using an alternative PCR strategy.** *U. Ricci, I. Sani, M.L. Giovannucci Uzielli.* Genetics and Molecular Medicine University of Florence Department of Paediatrics, Azienda Ospedaliera A.Meyer (Italy).

Recently we demonstrated the possibility to analyze a battery of thirteen STRs loci TPOX, D3S1358, FGA, CSF1PO, D5S818, D7S820, D8S1179, TH01, vWA, D13S317, D16S359, D18S51, D21S11 and the X-Y homologous genes amelogenin system by using an infrared-based fluorescent automated DNA sequencer (Electrophoresis 2000;21:3564-3570). We used these systems for paternity testing, UPD-studies and also linkage analyses. No doubt that the analyzed loci are of particular interest for the forensic community, because they represent the core of the Combined DNA Index System (CODIS), used from FBI. Here we introduced a new PCR strategy we used to analyze the multiplex system D3S1358, TH01, TPOX and CSF1PO (called MU2). The previously reported primers for TH01 were substituted with the primers suggested from Edwards et al. (1991). The amplification products were generated using Forward and Reverse unlabelled primers with a little portion of labelled Forward primer, covalently linked at the 5' end to an IR-fluorescent dye (IRDye800). The test resulted no expensive, robust, efficient and extremely sensible. In fact we were able to detect less of 10 pg of genomic degraded DNA. Here we report our results in analyze of bloodstains, archival formalin-fixed paraffin-embedded tissue and six months old histologic sections. Moreover, our test was compared with a capillary fluorescent automated sequencer and the results were in complete agreement, confirming the comparability of the IR-technology with the UV-technology.

**Loci mapping to chromosomes 3 and 9 affect left ventricular dilatation and survival in a transgenic mouse model of dilated cardiomyopathy and heart failure.** *K.M. Carlson<sup>1</sup>, M. Suzuki<sup>2</sup>, N. Golson<sup>2</sup>, H.A. Rockman<sup>2</sup>, D.A. Marchuk<sup>2</sup>.* 1) Genetics, Duke University, Durham, NC; 2) Cardiology, Duke University, Durham, NC.

Cardiac specific over-expression of calsequestrin (CSQ), a sarcoplasmic reticulum  $\text{Ca}^{2+}$  binding protein, in transgenic mice results in cardiac hypertrophy followed by the development of dilated cardiomyopathy (DCM) and premature death. Genetic background plays an important role in the manifestation of DCM in this model. In a DBA/2J (DBA) background, over-expression of CSQ results in depressed cardiac function by 14 weeks of age and premature death by 20 weeks of age. In contrast, the F1 progeny from a DBA-CSQ cross to C57BL/6 (B6) exhibit greater ventricular dilatation and depressed cardiac function by 4 weeks of age and death by 8 weeks of age. In order to map modifier genes acting in this model, we backcrossed DBA/B6 F1-CSQ animals to the parental DBA strain and performed a genome wide screen of 64 N2 animals. We performed quantitative trait loci (QTL) mapping to identify QTLs linked to two phenotypic measures: (1) left ventricular end diastolic diameter (LVEDD) and (2) survival. Using single locus association tests, a single locus on chromosome 3 was significantly linked to survival with a LRS of 24.1 ( $p < .001$ ). Furthermore, the same interval on chromosome 3 was significantly linked to LVEDD with a LRS of 24.3 ( $p < .001$ ). These QTLs were confirmed by performing simple interval mapping using additional progeny and markers. The maximum LRS reached was  $\text{LRS} = 26.5$  ( $p < .001$ ) and  $\text{LRS} = 32.1$  ( $p < .001$ ) for survival and LVEDD respectively. Because survival and ventricular dilatation are correlated in this model, these two loci probably represent the same locus. Using composite interval mapping to mask the effect of the chromosome 3 locus, an additional QTL linked to survival was mapped on chromosome 9 with a LRS of 14.0 ( $p < .05$ ). Our data indicate that multiple genetic modifiers including a strong locus on chromosome 3 and a weaker locus on chromosome 9 are working together to influence cardiac function and survival in the CSQ model of DCM. The identification of these modifiers will enable us to study their role in modifying the outcome of DCM in human patients.

**X-linked myopathy with excessive autophagy (XMEA): clinical spectrum, refined mapping and mutation screening.** *S.A. Alic<sup>1</sup>, R. Aiyar<sup>1</sup>, V. Juel<sup>2</sup>, J. Mandell<sup>2</sup>, M. Villanova<sup>3</sup>, M. Fardeau<sup>4</sup>, S.W. Scherer<sup>1</sup>, M. Auranen<sup>5</sup>, H. Kalimo<sup>6</sup>, B.A. Minassian<sup>1</sup>.* 1) Genetics, Hospital for Sick Children, Toronto, Ontario, Canada; 2) U. Virginia; 3) Inst. Orthopedics Rizzoli, Bologna, Italy; 4) INSERM U533, Paris, France; 5) Nat. Pub. Health Inst., Helsinki, Finland; 6) U. Turku, Finland.

Among the inherited vacuolated myopathies two are X-linked (but not allelic) and both are characterized by lysosomal pathology. One, Danon disease, is associated with cardiomyopathy and mental retardation in addition to skeletal myopathy, and the other, XMEA, is not. In both conditions, vacuoles contain cellular debris. The defective protein in Danon disease has recently been identified as LAMP2, a lysosome associated membrane protein. LAMP2 appears necessary for the maturation of vacuoles into phagosomes following fusion with lysosomes (Nature 2000;406,902-910). The XMEA gene is unknown. We and others recently mapped this gene to the last 7Mb of the long arm of the X chromosome distal to DXS1193. In this communication we describe new XMEA families and show that the disease can present either in infancy/early childhood or in late teenage/early adulthood and that both forms link to the same locus and are therefore likely allelic. We also present identification of a founder haplotype in French families which suggests a narrowing of the gene locus by 2Mb to telomeric to DXS8103. Finally, we report the first American XMEA family and identify a recombination event in this family which confirms the centromeric boundary at DXS8103. Screening of functional candidate genes from the remaining 5Mb for mutations is now underway with 7 genes sequenced to date.

**A Novel Distal Myopathy with Rimmed Vacuoles in a Large Saudi Kindred is Linked to Chromosome 12.** V.A. Bharucha, E.J. Cupler, S.A. Bohlega, C.E. Boumah, S.N. Abu-Amero, M. Kambouris, B.F. Meyer, C.A. Hodgkinson. Biological & Medical Research, KFSH&RC, RIYADH, SAUDI ARABIA.

DMRV is an autosomal recessive myopathy that preferentially involves the anterior compartment lower extremity muscles. Histopathological features reveal rimmed vacuoles with filamentous cytoplasmic and nuclear inclusions (Nonaka, 1981). Hereditary inclusion body myositis (HIBM) and DMRV share some clinical and histological features. These 2 disorders map to overlapping regions of chromosome 9 suggesting that they may be allelic (Ikeuchi, et al. 1997). Their analysis revealed that the DMRV gene is located within a 23.3cM interval defined by D9S319 and D9S276 on chromosome 9. We have analyzed a large inbred kindred from Saudi Arabia in which 12 individuals are affected with distal myopathy, wherein rimmed vacuoles are observed in muscle biopsy. The disorder appears to be transmitted as an autosomal recessive trait. Affected and unaffected individuals were genotyped using markers surrounding and within the region of chromosome 9 previously reported to link to DMRV and HIBM. No linkage was found to this region of chromosome 9. Using markers D2S21, D2S13, D2S291 and D2S21 linkage to the dysferlin gene was also excluded. These data, therefore indicate that this disorder represents a novel clinical and genetic entity. A whole genome scan of affected and unaffected individuals revealed linkage to chromosome 12q with a multi-point LOD score of 3.3 based on an autosomal recessive pattern of inheritance. Additional family members are being analyzed to further refine the interval. These analyses exclude both disorders previously described with clinical similarities to this distal myopathy.

**Allele-specific amplification utilizing novel fluorescent primers for the detection of single nucleotide polymorphisms.** *M. Darfler, A. Gallego, I. Nazarenko, J. Solus.* Molecular Biology R&D, Invitrogen, Rockville, MD.

We have developed assays for detection of single nucleotide differences utilizing homogeneous phase fluorescence detection methods. These assays are based on the use of primers labeled with a single fluorescent dye which do not require a specific quenching moiety. These fluorescent primers exhibit a large increase in intensity when incorporated into double stranded DNA. This property provides a means for real-time or endpoint detection of nucleic acids in a closed tube format that requires no additional steps subsequent to the PCR.

Demonstrated are the use of these fluorescent primers in allele specific amplification (ASA) reactions for both real-time detection during PCR or detection after PCR. Enhancement of the allele discrimination is shown with improvements in the design of the allele specific primer and a unique DNA polymerase which helps to increase the specificity of the allele specific PCR amplification. The combination of these improvements along with a flexible homogenous phase detection system provides a simple and reliable technique for genotyping SNP targets.

The allele specific amplification reaction has also been adapted to a universal allele detection design, where the 5'-end of the ASA primer contains a tail sequence which is identical to the 3' portion of a labeled universal detection primer. This detection scheme eliminates the expense of designing sequence specific detection primers for each specific target in the reaction, since it allows the utilization of the same detection primer for multiple targets. The detection primer design is compatible with alternative fluorescent labels providing the capability of biallelic genotyping reactions. We demonstrate duplex reactions using two universal allele detection primers labeled with FAM and JOE dyes for real-time detection or with FAM and TAMRA dyes for endpoint analysis. Multiple platforms are shown for the analysis of the ASA reactions: real-time detection instruments, fluorescence plate readers and automated fluorescence sequencers for higher throughput of multiple SNPs by separation of several targets of different sizes in a multiplex PCR.

**Mutation screening of the SynGAP gene in patients with dyslexia.** *K.E. Deffenbacher<sup>1</sup>, D.M. Hoover<sup>1</sup>, J.B. Kenyon<sup>1</sup>, R.K. Olson<sup>2</sup>, J.C. DeFries<sup>2</sup>, S.D. Smith<sup>1</sup>*. 1) Dept Molec Genetics, Univ Nebraska Med Ctr, Omaha, NE; 2) Inst Behav Genetics, Univ Colorado, Boulder, CO.

A quantitative trait locus for dyslexia has been localized to a 10cM region on 6p21.3. A 9.5 Mb contig spanning this region has been assembled and was examined for possible candidate genes. SynGAP, a synaptic RasGAP, mapped to this region and was selected as a candidate. SynGAP is highly enriched at excitatory synapses and is associated with NMDA receptors within the postsynaptic density. NMDA receptors play a pivotal role in synaptic plasticity which is, in part, transcription dependent and underlies processes such as long term potentiation, learning and memory. NMDA signaling to the nucleus can occur through activation of the Ras/MAPK pathway which, in turn, is negatively regulated by the GTPase stimulating activity of SynGAP. Based on this putative role in modulating synaptic plasticity SynGAP was selected as a candidate gene for dyslexia. SynGAP is an 1135 amino acid protein that was previously cloned and characterized. Exons 1 to 16 had been predicted and annotated on clone AL050332. Blast search of the 3' end of this clone identified an overlapping clone (AL161903) on which the remaining 3 exons (17-19) were characterized by manual exon prediction. Intronic primers were designed flanking the 19 exons for analysis of the coding regions and splice sites. Mutation screening was performed by direct sequencing using a subset of 47 dyslexic children. Subjects in this subset were selected for a discriminant score and/or nonword recognition phenotype of  $\pm 2$  standard deviations since these phenotypes show strong linkage on 6p21.3. Novel polymorphisms were detected and will be sequenced in 96 control samples for comparison.

**Inherited point mutations in the TPMT gene: CDCE/hifi PCR scan of 37,000 alleles.** X. Li-Sucholeiki, B. Glassner, T. Thompson, A. Tomita-Mitchell, B. Karger, W. Thilly. Peoples Genetics, Woburn, MA.

We have developed a scanning technology employing constant denaturant capillary electrophoresis (CDCE) coupled with high-fidelity (hifi) PCR for point mutations occurring at frequencies as low as  $5 \times 10^{-5}$ . This technology permits the discovery of inherited point mutations in large pooled human samples. As an example, we studied the thiopurine S-methyltransferase (TPMT) gene in 18,707 juveniles. TPMT catalyzes the S-methylation of thiopurine drugs used in cancer treatment. Genetic polymorphism in TPMT has been associated with individual variations in thiopurine toxicity and efficacy. We scanned the coding regions and splice sites, and identified and determined the frequencies of a set of point mutations with frequencies ranging from 14% to 0.01% in this population. The set of mutations observed included a series of novel mutations in addition to those previously reported. Some of the novel mutations may be of clinical importance for thiopurine therapy. This study demonstrates the power of CDCE/hifi PCR as a tool for the comprehensive discovery of mutations in large populations.

**Detection of Sequence Variations in CYP2D6 in Human Diversity Panel DNAs by a New Method for Genetic Variation Screening.** *E.P. Dawson<sup>1</sup>, C.D. Cooper<sup>1</sup>, J.Q. Steward<sup>1</sup>, J.A. Phillips,III<sup>2</sup>*. 1) BioVentures,Inc, Murfreesboro, TN; 2) Vanderbilt University School of Medicine, Nashville, TN.

Genetic variations have been described for a number of drug-metabolizing enzymes, in particular the cytochrome p450s. Some of these variations contribute to the differences in the efficacy or toxicity of many pharmaceutical medications that are observed between individuals. CYP2D6 is an hepatic cytochrome p450 which is involved in the detoxification or activation of a number of important pharmaceuticals and is also thought to play a role in the activation of certain xenobiotics to carcinogens. CYP2D6 has over 70 reported allelic variants. We determined the extent of CYP2D6 sequence variation in defined human diversity panels to establish the frequencies of the reported variants, as well as any unreported variants which might alter the function of CYP2D6. To do this, we utilized genetic variation screening (GVS) to interrogate all 9 exons of CYP2D6 in genomic DNA's of the diversity panels for nucleotide variations. DNA's from over 200 individuals representing 400 alleles were analyzed and variations found by GVS were confirmed by Sanger sequencing. We found several of the previously described CYP2D6 variants and identified multiple variants not previously described in DNAs from the diversity panels. Surprisingly, the frequencies of some variants were different than expected from previous reports in the literature. Our results indicate that: 1) CYP2D6 variation occurs more commonly than expected in defined human diversity panels and 2) the extent and character of this variation can be determined by GVS.

**In Search of Functional Polymorphisms in the *MDR1* Multidrug Transporter in the Asian Population.** *K. Tang*<sup>1</sup>, *S.L. Kao*<sup>1</sup>, *I. Cheong*<sup>1</sup>, *H.C. Liew*<sup>1</sup>, *S.M. Ngoi*<sup>1</sup>, *C.G.L. Lee*<sup>1,2</sup>. 1) Department of Biochemistry, National University of Singapore, Singapore; 2) Department of Medicine, Johns Hopkins University School of Medicine, Baltimore, USA.

Success in long-term cancer chemotherapy is limited by the acquired resistance of cancer cells to diverse structurally-different anti-cancer drugs. One of the major contributors to this acquired resistance is the overexpression of the multidrug resistance (*MDR1*) gene. The *MDR1* gene encodes a 170 kDa P-glycoprotein and belongs to the ATP-binding cassette (ABC) family of transporters. It actively effluxes diverse, structurally unrelated compounds and drugs including several non-cancer drugs. The tissue distribution of the *MDR1* transporter at the interface of important organs (e.g. blood-brain barrier) suggests that this transporter plays an important role in determining the bioavailability of drugs as well as concentration of drugs in sensitive organs like the brain and the fetus. Various studies have suggested that the substrate binding sites within *MDR1* lie in the transmembrane regions 5, 6, 11 and 12. Mutations within the substrate binding regions and elsewhere were found to change substrate specificity of the *MDR1* transporter. Recently, several polymorphisms in the *MDR1* gene in the Caucasian population have been identified. As there are differences in drug response amongst different ethnic groups, we would like to examine the frequency of reported *MDR1* polymorphisms as well as identify novel polymorphisms in our population, which comprises Chinese, Malays, Indians and Eurasians, mainly of Asian origin. Using allele-specific restriction enzyme site analysis, we did not find the reported polymorphism at position 61 of exon 2 (A@G) in 100 individuals studied. However, we identified a putative novel polymorphism in the promoter region of the *MDR1* gene and are in the process of confirming and testing its functionality in a robust reporter assay that we developed. We are also screening for other novel polymorphisms within the *MDR1* gene prevalent in our population and correlating these polymorphisms with *MDR1* gene expression and drug transport using a cell-based drug transport assay.

**A Comparison of EM and Gibbs sampling methodologies in estimating population haplotype frequencies and individual haplotypes in a phase-unknown situation.** *A.B. Seymour<sup>1</sup>, D.M. Meyer<sup>2</sup>, G.R. Warnes<sup>2</sup>, D.P. Dean<sup>3</sup>, S.M. Webb<sup>1</sup>.* 1) Pharmacogenomics, Pfizer, Groton, CT; 2) Biostatistical Reporting, Pfizer, Groton, CT; 3) Discovery Informatics, Pfizer, Groton, CT.

Pharmacogenomic investigation into the role candidate genes play in determining response to certain therapies and to disease susceptibility has been greatly facilitated with the discovery and mapping of novel single nucleotide polymorphisms as a by-product of the human genome sequence completion. Understanding the segregation of SNPs across a candidate gene as a haplotype can increase the information content within each gene and provide an increased likelihood of identifying a locus that contributes to phenotypic variation. Quantitating these haplotypes within a population of unrelated individuals is necessary for testing pharmacogenomic hypotheses. Current high-throughput genotyping technologies do not confer haplotypes, thus methodologies are needed to estimate population haplotype frequencies and individual haplotypes derived from the observed SNP genotype. The two most popular likelihood-based algorithms are the expectation-maximization (EM) algorithm assuming a multinomial probability model and Hardy-Weinberg proportions, and Clark's parsimony method. A novel Markov chain-Monte Carlo algorithm based approach using Gibbs sampling was recently described as providing a more accurate estimate of individual haplotypes. We have developed a Gibbs sampling methodology for the multinomial Hardy-Weinberg model to enable a more accurate calculation of confidence intervals and probabilities around each estimated haplotype. We describe here a comparison of the EM algorithm and our Gibbs sampling method via computer simulations, and on two actual studies. The first study examines 8 single nucleotide polymorphisms spanning 26 kb of the angiotensin converting enzyme genotyped in a population of 250 subjects. In addition, we also compare the efficiency of each approach in a population of 150 subjects, against a two-polymorphism molecularly defined haplotype within the P2X7R gene.

**Fine mapping of region 1p32 that contains the third major locus for autosomal dominant hypercholesterolemia.**

*M. Abi-Fadel*<sup>1</sup>, *L. Villegier*<sup>1</sup>, *S. Rochaud*<sup>1</sup>, *A. Robin*<sup>1</sup>, *J-P. Rabes*<sup>1,2</sup>, *M. Devillers*<sup>1</sup>, *M. Martinez*<sup>3</sup>, *C. Junien*<sup>1,2</sup>, *C. Boileau*<sup>1,2</sup>, *M. Varret*<sup>1</sup>. 1) INSERM U383, Hopital Necker-Enfants Malades, Paris, France; 2) Laboratoire central de biochimie et de genetique moleculaire, CHU Ambroise Pare, Boulogne, France; 3) INSERM U358, Hopital Saint-Louis, Paris, France.

Autosomal Dominant Hypercholesterolemia (ADH), one of the most frequent hereditary disorders, is characterized by an isolated elevation of LDL particles that leads to premature mortality from cardiovascular complications. It is generally assumed that mutations in LDLR and APOB genes account for ADH, however we have shown that ADH is genetically more heterogeneous. We identified 23 ADH families in which we excluded linkage to LDLR and APOB thus demonstrating the implication of a new locus we named FH3. Genetic linkage was obtained in 6 pedigrees localizing FH3 in a 8 cM interval at 1p32-p34.1. This linkage result has been confirmed by S. Hunt et al. in a Utah pedigree. Taken together, the haplotype data define a 1 cM interval for FH3. By radiation hybrid mapping, 6 candidate genes (FABP3, SCP2, APOER2, PAFAH2, AMPK and EPS15) were located outside this interval demonstrating no identity with FH3. Through an e-mapping approach, we built a BAC contig that spans » 3 Mb and contains 2 small non-overlapping areas. The analysis of the human sequence draft reveals more than 30 genes (cloned and predicted). We are currently identifying the expression pattern of these genes and sequencing them in the FH3 families. Current heterogeneity tests estimate that 19% of 23 non-LDLR/non-APOB ADH families are linked to FH3, indicating the implication of a fourth locus called FH4 that we now have also mapped. Finally, we have also detected the possible involvement of a fifth major gene (FH5).

**A physical and transcript map of a region encoding autosomal recessive syndromal and non-syndromal sensorineural hearing loss on human chromosome 11q25.** *E.A.R. Telford, K. Mahmoud, R.F. Mueller.* Molecular Medicine Unit, University of Leeds, Leeds, Yorkshire, United kingdom.

We have previously described the use of autozygosity mapping in a large consanguineous family to identify a gene locus on human chromosome 11q25 causing histiocytosis with associated features of sensorineural deafness and joint contractures. The form of histiocytosis exhibited by this family does not fit readily into any of the recognised classes of the disease and appears to represent a novel form of familial histiocytosis demonstrating autosomal recessive inheritance. We have mapped the minimal critical region of homozygosity in this family to a 1cM interval encompassed by the markers D11S1309 and D11S968. The existence of a novel non-syndromal autosomal recessive deafness locus (DFNB20) in this region was subsequently demonstrated by linkage analyses of 35 consanguineous families segregating non-syndromal sensorineural hearing loss with microsatellite markers from chromosome 11q25. An approximately 3cM region of homozygosity was observed in four affected individuals from a single family spanning the interval D11S1320-qter.

We are currently continuing this research using a positional candidate gene approach to identify and characterise the responsible gene(s) at this locus. We present a detailed physical and transcript map of the 11q25 region that includes ten known genes. Transcripts expressed in cochlear and/or myeloid tissues will be considered as suitable candidates for mutation screening.

We also report the identification of six new polymorphic markers between D11S1320 and D11S968 which enable us to further define the location of the histiocytosis syndrome and facilitates further fine mapping in this region.

**A major marker for normal tension glaucoma: Association with polymorphisms in the *OPAI* gene.** T. Aung<sup>1,2,3</sup>, L. Ocaka<sup>1</sup>, N.D. Ebenezer<sup>1</sup>, A.G. Morris<sup>1</sup>, P.J. Francis<sup>1</sup>, D.L. Thiselton<sup>1</sup>, C. Alexander<sup>1</sup>, M. Votruba<sup>1,2</sup>, G. Brice<sup>4</sup>, A.H. Child<sup>4</sup>, R.A. Hitchings<sup>2</sup>, O.J. Lehmann<sup>1,2</sup>, S.S. Bhattacharya<sup>1</sup>. 1) Molecular Genetics, Institute of Ophthalmology, University College London, United Kingdom; 2) Moorfields Eye Hospital, London, UK; 3) Singapore National Eye Centre, Singapore; 4) St George's Hospital Medical School, London, UK.

**Background.** Normal tension glaucoma (NTG) is a major form of glaucoma, associated with intraocular pressures that are within the statistically normal range of the population. *OPAI*, the gene responsible for autosomal dominant optic atrophy represents an excellent candidate gene for NTG as the clinical phenotypes are similar, and *OPAI* is expressed in the retina and optic nerve. **Methods.** Eighty-three well-characterized NTG patients were screened for mutations in *OPAI* by heteroduplex analysis and bi-directional sequencing. Exons found to be altered in NTG subjects were examined for variations in 100 population controls. A second cohort of 80 NTG patients and 86 population controls was subsequently screened to determine whether the initial findings could be replicated. **Results.** A total of 163 NTG subjects and 186 controls were included in the study. Thirty-two NTG subjects (19.6%) were found to carry two single nucleotide polymorphisms (SNPs) on intervening sequence (IVS) 8 compared to only 7 (3.7%) control subjects ( $\chi^2 = 22.04$ ,  $p = 8 \times 10^{-6}$ , after correcting for testing four genotypes) indicating that the association of this genotype is very strongly associated with the occurrence of disease. **Conclusions.** Polymorphisms in the *OPAI* gene are associated with NTG. Such changes are present in a fifth of NTG cases, which equates to 4-10% of open angle glaucoma.

**Evaluation of serotonin transporter gene (SLC6A4) polymorphisms in mood disorders with comorbid gastrointestinal abnormalities using temperature modulated heteroduplex chromatography.** *A.R. Belous<sup>1</sup>, L. Brown<sup>2</sup>, R.C. Shelton<sup>2</sup>, H. Metrz<sup>3</sup>, R.D. Blakely<sup>1</sup>.* 1) Dept Pharmacology, 412 PRB, Vanderbilt Univ Medical Ctr, Nashville, TN; 2) Dept of Psychiatry, Vanderbilt University, Nashville, TN 37232-8626; 3) Dept of Medicine, Division of Gastroenterology, Vanderbilt University, Nashville, TN 37232-5340.

A major hypothesis regarding the etiology and pathogenesis of mood disorders is that they involve abnormalities of the serotonin (5-HT) system. The serotonin transporter (SERT, SLC6A4) is an important candidate gene for complex disorders linked to altered 5-HT signaling. We are exploiting a candidate gene approach, searching for single nucleotide polymorphisms (SNPs) in SLC6A4 in mood disorders. Our hypothesis is that the same gene and SNPs may be involved in pathogenesis both of primary mood disorders and comorbid disorders involving peripheral physiological responses linked to 5-HT. Major depressive disorder (MDD) often is comorbid with gastrointestinal (GI) disturbances such as Irritable Bowel Syndrome (IBS). The GI tract is rich in 5-HT and SERT proteins that are highly expressed in both epithelial cells and myenteric neurons. Thus, mutations in SERT could support psychiatric disorders with comorbid IBS-like disorders. In our initial study, DNA samples from unrelated individuals with MDD with IBS-like abnormalities and subjects with IBS are being analyzed for SLC6A4 exon and splice junction mutations. PCR amplicons of each SERT exon are analyzed for SNPs using Denaturing High Performance Liquid Chromatography on the WAVE-TM DNA Fragment Analysis System (Transgenomic Inc.), followed by direct DNA sequencing. WAVE analysis of SLC6A4 amplicons has revealed several heterozygous SNPs in exon 1b in patients with either IBS or MDD with IBS-like GI abnormalities. Whether these SNPs or ones in other exons support MDD/IBS will require analysis of additional subjects, careful evaluation of allele frequencies in unaffected populations and functional validation using both SERT-specific antibodies and/or heterologous expression of mutant cDNAs (This work is supported by a NARSAD Young Invest. Award to A.B; DA07390 and MH58293 to R.B; MH01741 to R.S.).

**Polymorphism analysis in the COLIA1 gene of patients with thalassemia major and intermedia.** *E.Y. Fenerci<sup>1</sup>, O. Arisal<sup>2</sup>, N. Sayhan<sup>3</sup>, S. Hacıhanefioglu<sup>1</sup>, S. Erkmén<sup>2</sup>, A. Deviren<sup>4</sup>.* 1) Department of Medical Genetics, Cerrahpasa Medical School, Istanbul University, Istanbul, Turkey; 2) Thalassemia Center, Nicosia Dr.Burhan Nalbantoglu State Hospital, Nicosia, Cyprus; 3) Molecular Oncology and Hematopathology Research and Application Center, Istanbul University, Istanbul, Turkey; 4) Genetics and Teratology Research and Application Center, Istanbul University, Istanbul, Turkey.

Beta thalassemia major is an inherited blood disorder, mainly affecting people originating from Mediterranean region. The disease results in a life-threatening anemia and requires regular blood transfusion and iron-chelating therapy throughout life from early childhood. There is a high incidence of osteopenia and osteoporosis in patients with thalassemia major. Genetic factors play an important role in determining bone density, which is a major determinant of osteoporotic fractures. The inheritance of bone mass is under polygenic control. Type I collagen, which is encoded by COLIA1 and COLIA2 genes, is the major protein in the bone. A polymorphism G®T in the regulatory region of COLIA1 gene at a recognition site for transcription factor Sp1 has recently been strongly associated with reduced bone mass and osteoporotic fractures. The G®T polymorphism is screened in 42 beta thalassemia major and 10 beta thalassemia intermedia patients. After COLIA1 gene was amplified by polymerase chain reaction and digested with BalI restriction enzyme, the products were subjected to a 12% polyacrylamide gel electrophoresis. 64.3% of the beta thalassemia major patients were heterozygous for G/T (Ss) polymorphism and 35.7% were homozygous for G/G(SS). 60% of the beta thalassemia intermedia patients were heterozygous (Ss) and 40% were homozygous (SS). The number of heterozygotes in the beta thalassemia major group compared to the control group was significantly more (F=13.165, p=0.001). The number of heterozygotes in thalassemia intermedia group compared to the control group was also significantly more (F=5.158, p=0.029). Patients who are G/T heterozygotes (Ss) at the polymorphic Sp1 site have a lower bone mineral density than G/G homozygotes (SS) (p=0.01).

**Genotyping diallelic insertion/deletion polymorphisms.** *N.R. Ghebraniou<sup>1</sup>, J. Che<sup>1</sup>, D. David<sup>1</sup>, T. Rusch<sup>1</sup>, J. Chudyk<sup>1</sup>, K. Fieweger<sup>1</sup>, B. Dickinson<sup>1</sup>, Y. Fan<sup>1</sup>, C. Zhao<sup>1</sup>, A. Yu<sup>1</sup>, G. Marth<sup>2</sup>, M. Doktycz<sup>3</sup>, J.L. Weber<sup>1</sup>.* 1) Ctr Medical Genetics, Marshfield Medical Res Fndn, Marshfield, WI; 2) National Center for Biotechnology Information, NLM, NIH, Bethesda, MD; 3) Life Sciences Division, Oak Ridge National Laboratory, Oak Ridge, TN.

Over 2000 human diallelic insertion/deletion polymorphisms have been confirmed and characterized to date at Marshfield using overlapping genomic and cDNA sequences. Overlapping BAC sequences have been the richest source of markers. A searchable database of the indels is available from the Marshfield website ([research.marshfieldclinic.org/genetics](http://research.marshfieldclinic.org/genetics)). For analysis of the indels, we have developed an efficient, homogenous, closed-tube system involving allele-specific PCR and molecular beacons. Molecular beacons are synthetic oligos with a stem/loop structure containing both fluorescent dye and quencher molecules. When the stem is closed, fluorescence is quenched. When the stem is opened, the dye and quencher molecules are physically separated, and fluorescence is dramatically increased. The beacons used in our indel assay have dye-specific universal tails of about 18 bases at the 3' ends that allow them to be incorporated into PCR products. Using two different molecular beacons labeled with Fam and Joe dyes, we can simultaneously detect both alleles in the same reaction. Currently, we carry out the assay in 384 well microtiter plates using reaction volumes as low as 2 ml. In the near future, microtiter plates will be replaced by microtape. Microtape is a continuous, wide plastic strip embossed with periodic 384 well patterns. The price of microtape is about 12% the cost of plates. Microtape also contains index holes along each side, which permit sprocket-driven translation of the tape through pipetting and scanning instruments. Our engineering team has developed several versions of fluorescence scanners for both plates and tape. The latest version will scan a 384 well pattern on the tape in about 10 min. Images from the scanners are processed using software also developed at Marshfield. Through use of the tape and through reduction in reaction volumes, we expect to steadily drop diallelic polymorphism genotyping costs.

**Identification of coding single nucleotide polymorphisms (cSNPs) in genes expressed in tumoral cells using the HCGP-ORESTES database.** *M.C.R. Costa<sup>1</sup>, W.A. Silva Jr<sup>1,2</sup>, A.J. Holanda<sup>1,4</sup>, I. Tojal<sup>1</sup>, E. Dias-Neto<sup>3</sup>, P.E.M. Guimaraes<sup>3</sup>, E.P.B. Ojopi<sup>3</sup>, S.J. Souza<sup>3</sup>, A.J.G. Simpson<sup>3</sup>, M.A. Zago<sup>1,4</sup>.* 1) Molecular Biology and Bioinformatics Laboratory - Center for Cell-Based Therapy, Blood Center of Ribeirao Preto; 2) Federal University of Para - Santarem Branch; 3) Ludwig Institute for Cancer Research (LICR) - Sao Paulo Branch; 4) Medical School of Ribeirao Preto - University of Sao Paulo, Brazil.

Single Nucleotide Polymorphisms (SNPs), the most common type of variation in the human genome, correspond to positions where two alternative bases occur with appreciable frequency in the human population (>1%). Although most of these variations have no clinical or biological significance, an increasing number of single base mutations is being identified as responsible for the molecular basis of genetic disease and cancer or as risk factors for acquired diseases. In this study, we developed an approach to identify cSNPs in genes expressed in tumors using the HCGP-ORESTES database (Human Cancer Genome Project - LICR-FAPESP - Brazil). To this end, it was established a pipeline using the programs Phred, cross\_match and PolyBayes, an algorithm that detects SNPs eliminating paralogs and variations resulting from sequencing errors. Using the PolyBayes output, a user-friendly report with the detailed information about each candidate cSNP was generated, including the flanking region of the variation. In order to include cSNPs already reported, we also performed BLAST searches in the dbSNP. Using this approach, a set of 167,195 ORESTES corresponding to 7,950 human genes was analysed. Only the cSNPs that were detected in two or more different libraries and those present in the dbSNP were computed in the final statistics. A total of 554 candidate cSNPs were identified, being 345 non-synonymous (210 transitions, 135 transversions), and 209 synonymous (163 transitions, 46 transversions). From these, 48 showed to be already deposited in dbSNP. Thus, an approach to identify SNP was developed and performed in silico, a local database was created and experimental validation is in course in our laboratories.

**Association of *NOS1* gene polymorphisms with atopy and eosinophil count in 107 French EGEA families.** *F.M. Demenais<sup>1</sup>, M. Boussaha<sup>1</sup>, M.H. Dizier<sup>2</sup>*. 1) INSERM EMI 00-06, Evry; 2) INSERM U535, Kremlin-Bicêtre, France.

The *NOS1* gene is mapped to 12q24, a region found linked to asthma-related phenotypes by several genome screens. Our screen, conducted in 107 French EGEA families with at least two asthmatic sibs, showed suggestive evidence for linkage of eosinophil count in the vicinity of *NOS1* ( $p = 0.0007$ ). Our goal was to investigate the role of *NOS1* in asthma-related phenotypes in our family sample.

Three multi-allelic polymorphisms within exon 29, intron 2 and promoter region of *NOS1* were genotyped in 212 parents and 279 offspring of the 107 EGEA families. Linkage and association of these variants with asthma phenotypes were investigated using 2 approaches: (1) Transmission Disequilibrium Test (TDT) for binary traits (asthma, MultiRAST Phadiatop, Skin Prick Test (SPT) positivity to at least one of 11 allergens, SPT to Timothy Grass Pollen and SPT to *Dermatophagoides pteronyssinus*, Der p) and (2) combined segregation-linkage analysis based on regressive models for quantitative traits (Immunoglobulin E levels, eosinophil count, slope of dose-response curve to methacholine). TDT-based analyses indicate an excess of transmission of 187 bp allele in intron 2 from parents to offspring affected with either one of three atopy-related phenotypes (SPT, MultiRAST, SPT to Der p), the  $p$ -value being 0.01 for each trait ( $pc = 0.05$  after correction for multiple testing). Preliminary analyses of quantitative traits, using the Man-Whitney test, lead to a significant association of allele 18 of a CA repeat polymorphism in exon 29 with eosinophils, especially in non-asthmatics ( $p = 0.001$ ;  $pc = 0.004$ ). Combined segregation-linkage analysis incorporating linkage disequilibrium confirms this result by showing evidence for an effect of allele 18 of exon 29 on eosinophil count, when considering only non-asthmatic subjects ( $p = 0.01$ ). This variant accounts for 4% of eosinophils variation. This result agrees with the decreased risk of asthma associated with the same allele reported by a recent case-control study.

Supported by INSERM-MSD and IDS.

**Association studies of CTLA-4, CD28 and ICOS gene polymorphisms with type 1 diabetes in the Japanese population.** *K. Ihara<sup>1</sup>, S. Ahmed<sup>1</sup>, F. Nakao<sup>1</sup>, N. Kinukawa<sup>2</sup>, R. Kuromaru<sup>1</sup>, N. Matsuura<sup>3</sup>, I. Iwata<sup>4</sup>, S. Nagafuchi<sup>4</sup>, H. Kohno<sup>5</sup>, K. Miyako<sup>5</sup>, T. Hara<sup>1</sup>.* 1) Dept Ped, Grad Sch Med Sci, Kyushu Univ, Fukuoka, Japan; 2) Dept Med Inform, Grad Sch Med Sci, Kyushu Univ, Fukuoka, Japan; 3) Dept Ped, Kitasato Univ Sch Med, Sagamihara, Japan; 4) Dep Med Biosys Sci, Grad Sch Med Sci, Kyushu Univ, Fukuoka, Japan; 5) Dep Endocrinol Metab, Fukuoka Child Hosp, Fukuoka, Japan.

Co-stimulatory molecules of CD28, Cytotoxic T-lymphocyte associated antigen-4 (CTLA-4), and newly identified Inducible costimulator (ICOS), are expressed on cell surfaces providing regulatory signals for T-cell activation. These genes are candidate susceptibility genes for type 1 diabetes because they are colocalized on chromosome 2q33 including IDDM 12 locus. After determination of the genomic structure and screening for polymorphisms of ICOS gene, we performed association studies between newly identified polymorphisms of ICOS gene or the known ones of CD28 and CTLA-4 genes, and type 1 diabetes. The 49A/G dimorphism in the exon 1 and the (AT)<sub>n</sub> in the 3' untranslated region of CTLA-4 gene were significantly associated with type 1 diabetes. The evaluation of CTLA-4 49A - 3' (AT)<sub>n</sub> 86 bp haplotype frequency in the patients and controls confirmed the results from the analysis of each polymorphic site. Dimorphism in the intron 3 of CD28 gene was associated with type 1 diabetes only in the early onset group. In contrast, there was no association of the microsatellite polymorphisms in the ICOS gene or dimorphisms in the promotor region of CTLA-4. In conclusion, CTLA-4 gene appears to confer risks for the development of type 1 diabetes among three genes encoding costimulatory molecules.

**Frequency of the vCJD-associated M/M 129 PRNP genotype in the Quebec population.** *D. Jung*<sup>1, 2</sup>, *M. Drouin*<sup>1</sup>, *R. Lemieux*<sup>1</sup>. 1) Dept Research & Development, Hema-Quebec, Sainte-Foy, Quebec, Canada; 2) Laval University, Quebec, Quebec, Canada.

The occurrence of new variant-Creutzfeldt Jakob disease (vCJD) in the UK, has raised concerns that asymptomatic blood donor could contaminate the blood supply. To reduce the theoretical risk of transmission of the vCJD prion agent by blood transfusion, the north american blood agencies have introduced a blood donor selection criteria based on length of UK or France residency. The maximal residency period was selected after consideration of regional differences in the travel frequency to UK or France among blood donors (1 or 6 months) and of maximal tolerable impact on blood collection (<5%). The extensive testing done so far on tissues of vCJD patients in the UK has revealed that a genetic factor appears to predispose individuals to develop vCJD. The PRNP gene encoding the normal prion protein has several polymorphisms including the methionine(M) or valine (V) at codon 129. Published data indicate that all vCJD patients tested are M/M homozygous at codon 129 of their PRNP gene while the M/M genotype frequency is only 38% in the European population (V/V 11%, M/V 51%). As a first step in the evaluation of the possible usefulness of PRNP genotyping in donor exclusion, we have set-up a simple laboratory assay for PRNP genotyping at codon 129. The entire coding sequence of the PRNP gene was amplified by PCR and cut with the NspI endonuclease which is only able to digest the amplicon generated from the M129 PRNP gene. Separation of the NspI digested PCR products by gel electrophoresis allows an easy identification of the codon 129 genotype. Sequencing of the amplicons from homozygous and heterozygote individuals has confirmed the M/M, V/V and M/V genotypes. Results obtained with 341 volunteers indicate that the frequency of the M/M genotype (39.5%) appears similar to the one in Europe (38%) V/V and M/V genotypes frequency are respectively 12.5 and 48%. The routine PRNP genotyping of blood donors could permit to strenghten the exclusion criteria currently used.

**Difference in linkage disequilibrium in 300 kb region around smoothelin gene (chromosome 22) among 3 ethnically different populations.** *H. Morisaki*<sup>1</sup>, *Y. Kitamura*<sup>2</sup>, *N. Kamatani*<sup>2</sup>, *T. Morisaki*<sup>1,3</sup>. 1) Dept Bioscience, Natl Cardiovasc Ctr Res Inst, Suita, Osaka, JAPAN; 2) Inst Rheumatol, Tokyo Women's Med Univ, Tokyo, JAPAN; 3) Dept Mol Pathophysiol, Osaka Univ Grad Sch Pharm Sci, Suita, Osaka, JAPAN.

Single nucleotide polymorphisms (SNPs) and short tandem repeat polymorphisms (STRPs) are thought to be powerful tools for the genome-wide linkage disequilibrium (LD) analysis to map traits. However, the success of the analysis depends on the strength and extent of LD between the disease allele and the markers. Although the extent of LD in general population is of interest, little attention has been paid to the differences among ethnically different populations. In this study, 76 SNPs and 2 STRPs around human smoothelin gene scattered over 300 kb region were analyzed in 32 subjects each from Japanese, European American and African American populations. SNPs shared by these three populations were generally present at higher frequencies than unshared SNPs, and LDs between shared SNPs revealed more prominent decay of LD as a function of distance compared to those between SNPs at least one of which is unshared. Japanese exhibited the shortest span of LD in this region, while European Americans showed the longest strength and extent of LD between SNPs differed between the populations, suggesting that SNPs and STRPs for LD analysis should be selected for each population. Analysis of STRPs in the context of the haplotypes constructed by SNPs suggested that STRP polymorphisms are generally younger than SNPs. Whether STRPs are useful for LD analysis for finding disease-related mutations probably depends on when the disease-related mutations occurred.

**Strategies for polymorphism discovery in a disease specific population.** A. Loukola<sup>1</sup>, M. Chadha<sup>1</sup>, B. Nguyen<sup>1</sup>, S.G. Penn<sup>1</sup>, D.R. Rank<sup>1</sup>, D.K. Hanzel<sup>1</sup>, G. Casey<sup>2</sup>, J.S. Witte<sup>3</sup>. 1) Aeomica Inc., Sunnyvale, CA; 2) Department of Cancer Biology, Cleveland Clinic Foundation, Cleveland, OH; 3) Case Western Reserve University, Cleveland, OH.

Single nucleotide polymorphisms (SNPs), are expected to be helpful in identifying human disease genes. Finding SNPs, however, is just the beginning. They have to be confirmed as true variations and their frequencies in different populations need to be determined. Current estimates are that SNPs occur every 300-800 bases along the chromosomes. This density should provide detailed coverage of the genome and allow researchers to locate regions of interest more precisely, by narrowing in on phenotypic loci. In addition, SNPs, or perhaps combinations of them, may also affect gene function and activity. There are a number of strategies for identifying disease important SNPs, and we have examined these strategies. We studied two Cytochrome P450 genes, CYP17 and CYP3A4. We sequenced PCR products covering these two genes in two populations, using a MegaBACE 1000 high-throughput DNA sequencer. One population was 110 individuals from a prostate cancer sibship study (CaP), and the second population was 24 individuals from the Coriell Diversity Set (CDS). In addition we looked for previously discovered SNPs in the public databases. Following SNP discovery, we went on to genotype all the SNPs in both populations, using a single base extension assay (SNUPe). These experiments were carried out to confirm the true frequencies of the SNPs in the different populations. To date we have found a total of 14 novel SNPs in CYP17, and 23 novel SNPs in CYP3A4. In this paper we give a full analysis of the intersection of the SNP frequency found by the different strategies and discuss the merits of using public SNP databases. We conclude that while a large number of SNPs can be discovered using a generic population (CDS), a disease specific population provides unique SNPs. Whether disease specific SNPs turn out to be crucial in disease mapping or have an effect on the phenotype remains to be seen. Our ongoing study aims at finding association between SNPs and an aggressive form of prostate cancer.

**Genetic variation in the matrix metalloproteinase 9 gene, MMP9, in Type 2 diabetes patients with renal disease.**

*S. Hirakawa*<sup>1</sup>, *B.I. Freedman*<sup>2</sup>, *D.W. Bowden*<sup>1,2</sup>. 1) Depts. of Biochemistry; 2) Internal Medicine, Wake Forest Univ. School of Medicine.

Matrix metalloproteinase 9 (MMP9) in 20q12-q13.1 is secreted by glomerular mesangial cells and increased in renal diseases such as membranous nephropathy and renal fibrosis suggesting an association with renal disease. Linkage and association studies in Caucasians with Type 2 diabetes (T2DM) associated nephropathy suggest that at least one T2DM gene is located in 20q12-13.1 (Bowden et al., *Diabetes*, 46:882-886, 1997). We scanned 2.2kb of the promoter and all 13 exons (3.3 kb) of MMP9 for sequence variation in Caucasian and African American (AA) T2DM patients with renal disease. SSCP and denaturing high performance liquid chromatography were used to scan for polymorphisms. Differences were confirmed by direct DNA sequencing. A total of 9 variable sites: 4 in the promoter, 4 in the coding region (A20V exon 1; R279Q exon 6; P574R exon 10; G607G exon 11) and one in the 3' untranslated region were found in Caucasians. 14 variable sites: 8 promoter, 5 coding region (A20V, G15G exon 1; R279Q exon 6; P574R exon 10; G607G exon 11) and one in 3' were found in AAs. Three coding region polymorphisms were observed in both populations. The most common variants in Caucasians were the promoter C-1919T (0.68, 0.32), R279Q (0.30, 0.70), G607G (0.36, 0.64) in coding region and C+6T (0.40, 0.60) in 3' and those in AAs were C-2012T (0.68, 0.32), C-1919T (0.72, 0.28) in promoter, R279Q (0.33, 0.67), G607G (0.59, 0.41) in coding region and C+6T (0.79, 0.21) in 3'. The frequencies of these alleles were compared between patient (T2DM nephropathy) and control populations using the Chi-square test. No significant differences were observed between cases and controls, but 4 differences were observed between Caucasians and AAs: C-2012T (seen one AA patient), P574R ( $p < 0.01$ ), G607G ( $P < 0.01$ ) and C+6T ( $P < 0.01$ ). We have compared our results with those of a similar study in Caucasians (Zhang et al., *Hum Genet* 105, 418-423, 1999). Results were similar in the two studies except we did not see the T-1702A seen by Zhang et al. and they did not find P574R. They also did not observe the C-2012T variant.

**Brain Derived Neurotrophic Factor (BDNF) Is Associated With Childhood Onset Depression.** *N. King*<sup>1</sup>, *C. Barr*<sup>2</sup>, *S. Shaikh*<sup>1</sup>, *B. Devlin*<sup>3</sup>, *K. Wigg*<sup>2</sup>, *M. Kovacs*<sup>3</sup>, *J.L. Kennedy*<sup>1</sup>. 1) Neurogenetics Section, Ctr Addiction & Mental Health, Toronto, ON., Canada; 2) University Health Network, Ontario, Canada; 3) University of Pittsburgh, Pittsburgh, U.S.A.

Childhood onset depression (COD) is associated with significant morbidity, and has been repeatedly shown to have high familial loading. Family studies have found that between 40% and 70% of first-degree relatives of depressed children have a history of major depressive disorder and bipolar illness, compared to a significantly lower rate in relatives of healthy juvenile controls. An interesting candidate locus for COD is brain-derived neurotrophic factor (BDNF), a neurotrophin abundant in the neocortex, amygdala and hippocampus, responsible for neuronal proliferation, differentiation and survival. In animal studies, injection of BDNF provides evidence of an antidepressant effect. We hypothesize that variants at the BDNF locus causing decreased gene expression are associated with a vulnerability to depression. The human BDNF gene maps to 11p13-15. In a sample of 77 COD patients, diagnosed using the DSM-IV, and healthy volunteers matched for ethnicity and sex, we genotyped a dinucleotide repeat polymorphism located 1040 bp upstream of the transcription site, and a G®A (valine®methionine) variation in position 758 of the coding sequence. The dinucleotide repeat showed a significant association with COD with p-value = 0.000035,  $c^2 = 25.759$ , df = 4. Allele 4 (168 bp) conferred a relative risk of 8.0 for child depression (95% C.I. 2.388-33.114), with odds ratio of 9.29 (95% C.I. 2.584-39.700). Results for the G®A polymorphism are  $c^2 = 0.749$ , df = 1, and p = 0.387. Thus far, our results suggest that the BDNF gene may play a role in the etiology of COD. Additional studies are warranted in larger samples, and using alternative strategies such as genomic controls and TDT.

**Determination of human  $\beta_2$ -adrenergic receptor haplotypes by denaturation selective amplification and subtractive genotyping.** *J. Wang<sup>1</sup>, L.M. Humma<sup>2</sup>, E.B. Mougey<sup>1</sup>, C.J. David<sup>1</sup>, J.A. Johnson<sup>2</sup>, J.J. Lima<sup>1</sup>, J.E.*

*Sylvester<sup>1,3</sup>.* 1) Center for Clinical Pediatric Pharmacology, Cell and Molecular Medicine, Nemours Children's Clinic, Jacksonville, FL; 2) Department of Pharmacy Practice, University of Florida College of Pharmacy, Gainesville, FL; 3) Mayo Medical School, Rochester, MN.

The  $\beta_2$  adrenergic receptor ( $\beta_2$ -AR) gene contains single nucleotide polymorphisms (SNPs) at nucleotides -47 (5' Leading Cistron-Cys/Arg-19), 46(Gly/Arg16) and 79(Gln/Glu27) that have been implicated in numerous diseases and/or their modification. Recently, Ulbrecht et al. reported that the Gly16/Gln27/Thr164 haplotype, *but not genotype*, protected women against bronchial hyper-responsiveness. Conventional methods for obtaining haplotype information (i.e. cloning and sequencing or using polymorphism specific primers for amplification) are laborious and time consuming. Thus we sought to develop an alternative method for obtaining haplotype information at positions -47, 46, and 79 of the  $\beta_2$ -AR gene. Inspection of the  $\beta_2$ -AR gene sequence revealed that a region surrounding codon -19 was extremely GC rich and thus melting temperature calculations suggested that this region would determine the denaturation temperature required for successful amplification of the entire gene. In addition the C/G base pair of the Arg-19 allele was found to increase the local melting temperature over the T/A base pair of the Cys-19 allele by 3.6 degrees and establish a new local maximum denaturation temperature. We confirmed this difference in denaturation temperature and found that Cys-19 alleles were selectively amplified at a denaturation temperature of 94°C while the Arg-19 allele required a minimum denaturation temperature of 95°C. Using a combination of this Denaturation Selective Amplification (DSA) and conventional RFLP analysis we were able to successfully haplotype a total of 107 patients and predict that this method will be useful for > 99% of the population at these three SPNs. In addition our observation of DSA suggests caution when analyzing genotyping data and provides a possible explanation for allele dropout during amplification.

**A high speed and large-scale single nucleotide polymorphism (SNP) typing system.** *a. sekine*<sup>1</sup>, *h. suzuki*<sup>2</sup>, *k. hirotani*<sup>2</sup>, *k. jinno*<sup>3</sup>, *t. kitamoto*<sup>1</sup>, *t. sakamoto*<sup>1</sup>, *t. utagawa*<sup>3</sup>, *t. matsumura*<sup>3</sup>, *y. ohnishi*<sup>4</sup>, *t. tanaka*<sup>4</sup>, *y. nakamura*<sup>1,2</sup>. 1) Lab. for Genotyping SNP Res. Cent. RIKEN, Tokyo, JAPAN; 2) Lab. of Mol. Med. Human Genome Cent. Ins. of Med. Sci., Tokyo Univ. ,Tokyo, JAPAN; 3) Jap. Biol. Informatics Consortium, Tokyo, JAPAN; 4) Lab. for Cardiovascular diseases RIKEN, Tokyo, JAPAN.

Single nucleotide polymorphisms (SNPs) are single-base variations that occur at a frequency of approximately one per every 300-1000 bp throughout genome. SNPs are useful genetic tools to uncover the loci containing genes associated with or susceptible to diseases. Since each of common diseases is considered to have associations with 10-20 genetic loci, it is inevitable to screen SNPs throughout the genome in a large number of individuals for identification of susceptible genes as many as possible. To develop a high-speed and large-scale SNP typing system, we recently established a novel technology by a combination of multiplex PCR and the Invader SNP analysis method. The process for genotyping is as follows; (1) multiplex PCR amplification of 96 genomic fragments containing SNPs in one tube, (2) dividing the PCR products for 384 individuals into 96 384-well cards, (3) spotting a reaction mixture corresponding to each SNP to each of the cards using an ink-jet spotter, (4) complete sealing of the card by ultrasonic welding, (5) incubation of the sealed cards at 65°C, and (5) judging genotypes by detection of two fluorescent colors. The multiplex PCR amplification and the sealed card that we developed significantly reduced the amount of genomic DNA necessary for genotyping to 0.1-0.2 ng/SNP as well as the cost for genotyping. The system we set up on the basis of these technologies can achieve about 100 millions SNPs per year, making the genome-wide SNPs screening realistic.

Program Nr: 2115 from the 2001 ASHG Annual Meeting

**Multiplex genotyping of polymorphisms using Pyrosequencing™.** *A. Schiller, J. Dunker, S. Eriksson, A. Alderborn.*  
Pyrosequencing AB, Uppsala, Sweden.

Pyrosequencing™, or real-time sequencing, is a fast and accurate method for SNP analysis. Pyrosequencing AB (Sweden) manufactures the PSQ96™ System, in which 96 different SNPs are analyzed in parallel in approximately 10 min. A dedicated SNP scoring software automatically delivers genotype and a quality assessment for each sample.

In this study, the applicability of pyrosequencing for multiplex genotyping was investigated.

SNPs from the Renin-Angiotensinogen-Aldosterone System (RAAS) were analyzed using pooled simplex PCR products followed by multiplex genotyping. To further enhance cost efficiency in SNP analysis, multiplex PCR followed by multiplex genotyping by pyrosequencing was tested using the Factor V Leiden, Prothrombin G20210A and the PAI1 4G/5G polymorphisms. A third approach was to design several sequencing primers for one PCR fragment containing a number of different polymorphisms, illustrated by allele identification in CYP2D6. All three strategies (pooled simplex PCR/multiplex pyrosequencing, one single PCR fragment/several sequencing primers and multiplex PCR/multiplex pyrosequencing) resulted in highly reproducible and accurate scores, which were in complete accordance with those obtained when genotyping each polymorphism independently. Design of sequencing primers in combination with a reaction specific dispensation order enabled separate typing of the polymorphic positions whilst keeping the genotyping quality identical to that of simplex genotyping. In addition, this approach allowed unequal amplification efficiency to occur without negatively affecting the genotyping results. The sequences surrounding the SNPs and deletion polymorphisms confirmed the correct positioning of the primers on their respective gene sequences. Thus, pyrosequencing enables reliable and robust analysis of several polymorphisms in a single pyrosequencing reaction.

**Interspecies comparisons of the ATM gene.** *T.L. Wayne, Y.R. Thorstenson, P.J. Oefner.* Stanford Genome Technology Center, Stanford University, Palo Alto, CA.

ATM is the gene mutated in the recessive autosomal disease ataxia-telangiectasia. It is also implicated in several types of cancer, making it a putative tumor suppressor gene. To determine the level of selection operating on ATM, we have analyzed the sequence diversity of six species: human (93 individuals), chimpanzee (6 individuals), gorilla (3 individuals), orangutan (3 individuals), New World monkey (1 individual), and Old World monkey (1 individual). PCR was performed using primers designed to the human sequence and all samples were sequenced using a dye terminator reaction. The McDonald-Kreitman test was used to determine the significance of the sequence divergence between species. Specifically, the number of replacement and synonymous mutations found within species (polymorphism) was compared to that found between species (divergence). The neutral evolution model predicts that the ratio of replacement to synonymous differences is the same in divergent sites as it is in polymorphic sites. If this assumption fails, then it is likely that the gene in question is under selective pressure. Whereas most comparisons across species revealed no difference, four revealed significant deviation from the neutral expectation: human compared to gorilla and orangutan, and orangutan compared to gorilla and monkey. Within most species, the synonymous polymorphisms were more numerous than the replacement polymorphisms. Likewise, the Hudson, Kreitman, Aguade (HKA) test was applied to compare the levels of polymorphism and divergence at different loci. In this case, the neutral evolution model predicts that the relationship of polymorphism to divergence is the same for different genes, whereas selection can lead to an uncoupling of polymorphism and divergence. We compared the first 71% of the ATM gene with the last 29%, which contains the conserved kinase, Rad3-like, and Tel1p-like domains. The comparison revealed that the carboxy terminus of the human ATM gene was significantly constrained relative to orangutan, Old World monkey and mouse, but not to chimpanzee or gorilla. Our findings from both tests indicate that ATM is under significant selective pressure.

**Age-related maculopathy (ARM): An expanded genome-wide scan with evidence of susceptibility loci within the 1q31 and 17q25 regions.** *M.B. Gorin<sup>1,2</sup>, D.E. Weeks<sup>1</sup>, Y.P. Conley<sup>1,3</sup>, H.-J. Tsai<sup>1</sup>, T.S. Mah<sup>2</sup>, P.J. Rosenfeld<sup>4</sup>, T.O. Paul<sup>5</sup>, A.W. Eller<sup>2</sup>, L.S. Morse<sup>6</sup>, J.P. Dailey<sup>7</sup>, R.E. Ferrell<sup>1</sup>.* 1) Dept. of Human Genetics, Univ. of Pittsburgh GSPH, Pittsburgh, PA; 2) Dept. of Ophthalmology, Univ. of Pittsburgh SOM, Pittsburgh, PA; 3) Dept. of Health Promotion & Development, Univ. of Pittsburgh SON, Pittsburgh, PA; 4) Dept. of Ophthalmology, Univ. of Miami, Bascom Palmer Eye Inst., Miami, FL; 5) Smith-Kettlewell Eye Research Institute, San Francisco, CA; 6) Dept. of Ophthalmology, University of California Davis, Davis, CA; 7) Dept. of Ophthalmology, Case Western Reserve, Cleveland, OH.

We seek to identify genetic loci that contribute to ARM susceptibility by employing a family -based cohort study for linkage analysis. ARM families consisting of at least two affected siblings were ascertained using eye care records and fundus photographs. Additional family members were used to increase the power to detect linkage. Microsatellite genotyping was conducted by the NHLBI Mammalian Genotyping Service and the NIH Center for Inherited Disease Research. Linkage analyses were conducted with parametric (autosomal dominant) (heterogeneity lod score HLOD) and nonparametric methods ( $S_{all}$  statistic) using three diagnostic models. False positive rates were determined from simulations using actual pedigrees and genotyping data. With our combined set of 391 ARM families, four regions, 1q31, 9p13, 10q26, and 17q25, showed multipoint HLODs or  $S_{all}$ 's 2.0 (under at least one model). Under our most stringent model, the 1q31 HLOD was 2.46 between D1S1660 and D1S1647. Under Model C, the 17q25 HLOD at D17S928 was 3.16. The 1q31 region independently confirms the ARMD1 locus reported by Klein et al. Simulations indicate that the 1q31 and 17q25 loci are unlikely to be false positives. An additional 126 individuals (from prior or new families) were genotyped with the same markers around our four peak signals. Fifteen new markers for regions 1q31 and 17q25 have been genotyped on our entire set of 920 individuals to achieve an average of 2-3 cM spacing. The additional genotyping data should aid in our refinement of the candidate regions.

**Autosomal dominant Stargardt disease: clinical features and linkage analysis in a large Greek pedigree. G.**

*Kitsos<sup>1</sup>, K. Zhang<sup>2</sup>, Z. Yang<sup>2</sup>, E. Economou-Petersen<sup>3</sup>, M. Grigoriadou<sup>4</sup>, A. Pampanos<sup>4</sup>, D.J. Zack<sup>5</sup>, K. Psilas<sup>1</sup>, M.B. Petersen<sup>4</sup>.* 1) Dept Ophthalmol, Univ Ioannina, Greece; 2) Cole Eye Inst, Cleveland Clinic Foundation, Cleveland, OH; 3) Drakopoulion Blood Bank Center, Athens, Greece; 4) Dept Genet, Inst Child Health, Athens, Greece; 5) Wilmer Eye Inst, Johns Hopkins Univ, Baltimore, MD.

Stargardt disease (STGD) is the most common hereditary macular dystrophy and is characterized by decreased central vision during the first decades of life, atrophy of the macula and underlying retinal-pigment epithelium, and presence of yellow spots distributed in the posterior pole of the retina (fundus flavimaculatus). In most instances STGD is inherited as an autosomal recessive trait, and linkage analysis assigned the STGD1 locus to chromosome 1p, due to mutations in the ABCR gene. Several families have been described in which features of STGD are transmitted in an autosomal dominant manner, and dominant loci have been mapped to chromosomes 6q (STGD3, ELOVL4 gene) and 4p (STGD4). We describe a large five-generation pedigree with STGD from Epirus, Greece, comprising 234 individuals (23 affected). Affected individuals of both sexes were found in each generation, consistent with autosomal dominant transmission. Clinical examination revealed visual acuity ranging from 1/50 to 8/10, with age at onset from 7-18 years. Fundoscopic examination showed loss of macular reflex, beaten bronze appearance of the foveal region, and white-yellow spots (flecks) of varying degree. A red-green dyschromatopsia was characteristic. The fluorescein angiography demonstrated areas of dark choroid, window defects, and typical flavimaculatus flecks. The disease was symmetric in the two eyes and progressive with age. Linkage analysis with short tandem repeat (STR) markers excluded linkage to the RDS, STGD3 and STGD4 loci, and a genomewide search is being performed. This family therefore probably represents a new dominant STGD locus.

**Identification of novel exons and analysis of autism-associated sequence variations within the chromosome**

**15q11-q13 region.** *S. Ichikawa*<sup>1</sup>, *Y. Liu*<sup>1</sup>, *J.H. Miles*<sup>2</sup>, *R.E. Hillman*<sup>1,2</sup>, *C.H. Wang*<sup>1,2,3</sup>. 1) Department of Biochemistry; 2) Department of Child Health; 3) Departments of Psychiatry and Neurology, University of Missouri-Columbia, Columbia, MO.

Autism is a neurodevelopmental disorder with core symptoms including impaired social and language development and repetitive, stereotypic behaviors. Previous observations of autism-specific chromosomal abnormalities and suggestive linkage studies indicate that the chromosome 15q11-q13 region may contain an autism susceptibility gene. Recently, we observed an abnormally high rate of meiotic recombination occurring in a small interval between markers D15S986 and D15S1234 in individuals with autism. We also reported the identification of a novel transcript in this region, which is in linkage disequilibrium with autism. To further identify autism candidate genes in this region, we performed exon-trapping experiments using a genomic PAC clone that contains the marker D15S1234. We identified seven independent exons (size 86-120 bp) from this genomic fragment. All seven exons consist of open reading frames and are flanked by conserved splice site sequences. All of the exons have been mapped to the genomic region by comparing to the PAC clone sequence. BLASTN searches detected no homologous sequences in the databases, suggesting that these exons are parts of novel transcripts. Initial mutation analysis using single-strand conformation polymorphism (SSCP) assay in a large group of autism and control samples (N>100) revealed several sequence variations. A total of eight polymorphisms were identified within three exons. One small exon (90 bp) and its flanking 30-bp sequences contain seven polymorphisms, indicating that this region is genetically highly variable. Analysis of allele frequencies detected no significant difference between autism and non-autism controls. Further studies are being conducted using these polymorphic alleles to perform haplotype analysis. We are also obtaining the parental genotypes for a transmission disequilibrium test (TDT). Northern blot analysis will be used to determine the size of these transcripts and their tissue-specific expressions.

**Comparisons of the human and murine pathways in maternally-transmitted deafness.** *Y. Bykhovskaya*<sup>1</sup>, *K.R. Johnson*<sup>2</sup>, *H. Yang*<sup>1</sup>, *K. Taylor*<sup>1</sup>, *R.Y.M. Tun*<sup>1</sup>, *N. Fischel-Ghodsian*<sup>1</sup>. 1) Cedars-Sinai Medical Center, UCLA School of Medicine, Los Angeles, CA; 2) The Jackson Laboratory, Bar Harbor, ME.

The interaction between the mitochondrial and nuclear genomes has been implicated in the development of maternally-transmitted non-syndromic hearing loss in men and mice. A modifier locus on chromosome 8p influences the severity of hearing loss in families with the A1555G mutation in the mitochondrial 12S rRNA gene, and a single adenine insertion in the mitochondrial tRNA-Arg gene influences the severity of hearing loss in mice homozygous for the abnormal allele at the Ahl (age-related hearing loss) locus. We tried to establish whether the mouse region syntenic to the human chr.8 modifier locus influences hearing loss in the A/J-Cast/Ei backcross model, and whether the human region syntenic to the mouse chr.10 Ahl locus influences hearing loss in the human patients with the A1555G mutation. The human modifier gene corresponds to regions on mouse chromosomes 8 and 14. Genetic analysis of the (A/JxCAST)xA/J backcross mice for mouse chromosome markers D8Mit58, D8Mit191, and D14Mit203 was performed. No evidence of a nuclear effect on hearing was found in either of the two regions. The syntenic region of the mouse Ahl locus on human chr.10 was evaluated in 28 Arab-Israeli, Spanish/Italian and Finnish families with maternally inherited non-syndromic deafness. Multipoint nonparametric linkage analysis in all families combined and in 19 chromosome 8 linked families showed no indication of linkage, while the Lod score in the 9 chromosome 8 unlinked families resulted in positive but non-significant value of 1.0. We also tested three polymorphic markers within the human deafness gene in this region, cadherin 23, in all families combined, and in chromosome 8 linked and unlinked subsets by TDT. Single marker analysis as well as haplotype analysis showed no evidence for linkage disequilibrium. These data therefore do not provide any evidence that the homologues of the mouse and human nuclear regions are involved in the maternally transmitted hearing impairment of the other species. This work was supported by NIH/NIDCD grant no. RO1DC01402 and RO1DC04092 (NFG) and contract DC62108 (KRJ).

**Prevalence of mtDNA mutations in childhood deafness in the Greek population.** *M. Grigoriadou<sup>1</sup>, A. Pampanos<sup>1</sup>, T. Iliades<sup>2</sup>, N. Voyatzis<sup>2</sup>, N. Eleftheriades<sup>2</sup>, V. Iliadou<sup>2</sup>, J. Economides<sup>3</sup>, P. Leotsakos<sup>3</sup>, P. Neou<sup>4</sup>, M. Tsakanikos<sup>4</sup>, L. Katsichti<sup>4</sup>, E. Papadopoulou<sup>5</sup>, E. Kleomitis<sup>1</sup>, J. Gyftodimou<sup>1</sup>, A. Skevas<sup>6</sup>, M.B. Petersen<sup>1</sup>.* 1) Genetics Dept, Inst Child Hlth, Athens, Greece; 2) Aristotle Univ Thessaloniki, Greece; 3) "Aghia Sophia" Children's Hosp, Athens, Greece; 4) "P & A Kyriakou" Children's Hosp, Athens, Greece; 5) Univ Gen Hosp Crete, Heraklion, Greece; 6) Univ Ioannina, Greece.

Genetic factors constitute the major etiology of childhood hearing impairment. The majority of cases are non-syndromic and sensorineural and can be caused by defects in genes located both in the nuclear and mitochondrial genomes. Mitochondrial DNA (mtDNA) mutations such as A1555G, A7445G and 7472insC have been reported in several unrelated families, but a more precise estimate of the prevalence of these mutations as causes of non-syndromic, sensorineural childhood hearing impairment has not been well established. In a collaboration with the major referral centers for childhood deafness in Greece, we therefore screened 261 unrelated patients with congenital/childhood onset sensorineural hearing loss for the known mtDNA mutations A1555G in the 12S rRNA gene and A7445G and 7472insC in the tRNA Ser(UCN) gene. DNA from whole blood was analyzed for the mtDNA mutations using PCR-RFLP analysis. The homoplasmic A1555G mutation was detected in two cases, one sporadic case and one family with affected members in both paternal and maternal lineages. We conclude that routine screening for mtDNA mutations in congenital/childhood onset deafness is warranted, even when maternal inheritance has not been clearly established, the identification of an mtDNA mutation being vital for genetic counseling.

**PREVALENCE OF MITOCHONDRIAL MUTATIONS IN FAMILIAL SENSORINEURAL HEARING**

**IMPAIRMENT : IMPORTANCE OF A1555G AND T7511C.** *D. Feldmann<sup>1</sup>, S. Marlin<sup>2</sup>, E. Chapiro<sup>1</sup>, F. Denoyelle<sup>2</sup>, D. Sternberg<sup>3</sup>, D. Weil<sup>4</sup>, C. Petit<sup>4</sup>, E.N. Garabedian<sup>2</sup>, R. Couderc<sup>1</sup>.* 1) Dept of biochemistry and molecular biology, Hosp A.Trousseau, APHP, Paris France; 2) ORL Dept., Hosp A. Trousseau, APHP, Paris France; 3) Dept of biochemistry, Hosp Sapetriere, APHP, Paris France; 4) Unit de Gntique des Dfcits Sensoriels, CNRS URA 1968, Institut Pasteur, Paris.

The mtDNA A1555G mutation has been recognized as a main cause of sensorineural deafness in Spain families with maternally transmitted deafness. As, the A1555G mutation was also found to predispose individuals to aminoglycoside-induced hearing loss, its identification is crucial to prevent amonoglycoside-induced hearing loss. . The T7511C mutation has been previously described in only one large African American familiy with deafness. We studied 41 families and 31 sporadic cases with non-syndromic sensorineural hearing loss. In all the families, the transmission of the deafness was compatible with a maternally transmission. ARNr 12S, ARNt leucine and ARNt serine were screened by denaturing gradient gel electrophoresis and sequencing. The A1555G mutation was observed in a large family (19 affected patients) with maternally inherited deafness. The mutation was homoplasmic in all the patients screened. The affected subjects presented a congenital bilateral and sensorineural hearing loss. The deafness was severe to profound and age-stable. No other mutation was observed in the ARN 12S. In the ARNt serine, the T7511C mutation was observed in two large french families with maternally transmitted deafness. The mutation was homoplasmic or heteroplasmic. The age at onset of deafness was variable. The bilateral and sensorineural hearing loss was stable or progessive. In the ARNt leu and in the ND1gene many different variations were observed : the polymorphisms A3348G, T3396C, T3308C , T3290C and the variants G3316A, T3394C. In conclusion, A1555G and T7511C were observed in 2.6 and 4.8% of the families with maternally transmitted sensorineural deafness. This result shows that T7511C could be a frequent cause of non-syndromic sensorineural deafness and must be screened in families with maternally transmitted sensorineural deafness.

**Identification and characterization of cochlear expressed genes in the DFNB17 interval.** *J.H. Greinwald<sup>1</sup>, V. Pilipenko<sup>1</sup>, Y. Guo<sup>1</sup>, D.I. Choo<sup>1</sup>, A. Ramesh<sup>2</sup>, A.B. Giersch<sup>3</sup>, C.C. Morton<sup>3</sup>, W.C. Nichols<sup>4</sup>, R.J. Smith<sup>5</sup>.* 1) Center for Hearing and Deafness Research, Dept. of Otolaryngology, Children's Hospital Cincinnati, Cincinnati, OH; 2) Dept. of Genetics, University of Madras, Madras, India; 3) Dept. of Pathology, Brigham and Women's Hospital, Boston, MA; 4) Div. of Human Genetics, Children's Hospital Cincinnati, Cincinnati, OH; 5) Molecular Otolaryngology Research Laboratories, Dept. of Otolaryngology, University of Iowa, Iowa City, IA.

The DFNB17 locus for autosomal recessive non-syndromic hearing loss has been mapped to an approximately 3-4 cM interval on human chromosome 7q31. We have determined the cDNA sequence and genomic structure for two novel genes that map to the DFNB17 interval. The first gene, termed HMG-like gene, is composed of 12 exons and contains a putative HMG-like DNA binding domain, which presumably acts as a transcription factor. Analysis of a cochlear cDNA library revealed alternative splicing compared to other tissues. This gene is highly conserved at the DNA and protein level between mouse and human with expression noted in analysis of a mouse inner ear library. The second gene, termed nexin-like gene, contains 9 exons and has homology to the nexin family of serine proteases. The nexin-like gene is similarly expressed in human cochlear and mouse inner ear libraries, respectively. No alternative splicing was noted. *In situ* hybridization studies of the nexin-like gene revealed a unique radial pattern of semicircular canal expression in embryonic day 18 mice. Both genes are also ubiquitously expressed in many different human body tissues. To determine if mutations in either of these genes might be the cause of hearing loss at the DFNB17 locus, we screened the coding and splice-sites regions of the DFNB17 family by direct sequencing. No disease-causing mutations were found. Studies of the untranslated and promoter regions of these genes as well as two actin-related genes in the DFNB17 interval are underway.

To be presented by Karina Lezirovitz instead of R. C. Mingroni-Netto.

**Mitochondrial mutation A1555G (12SrRNA) and connexin 26 35delG mutation are frequent causes of deafness in Brazil.** *R.C. Mingroni-Netto<sup>1</sup>, R.S. Abreu-Silva<sup>1</sup>, M.C.C. Braga<sup>1</sup>, K. Lezirovitz<sup>1</sup>, V.A. Della-Rosa<sup>2</sup>, S. Pirana<sup>3</sup>, M. Spinelli<sup>4</sup>, P.A. Otto<sup>1</sup>.* 1) Department of Biology, Universidade de São Paulo, São Paulo, Brazil; 2) Department of Cell Biology and Genetics, Universidade Estadual de Maringá, Paraná, Brazil; 3) Department of Otorrinolaringology, Faculdade de Medicina, Universidade de São Paulo, São Paulo, Brazil; 4) Pontifícia Universidade Católica de São Paulo.

After detecting the mitochondrial mutation A1555G in a large Brazilian family with nine affected individuals presenting late-onset sensorineural deafness, we studied another sample of 90 individuals, ascertained through 73 index cases with deafness that attended our genetic counseling unit. All patients were tested for the presence of the mitochondrial mutation A1555G and the 35delG mutation in the Connexin 26 gene, regardless of their family history, aminoglycosides treatment, age at onset of deafness or other possible causes of deafness. 27% of the sample consisted of familial cases, the rest of patients being isolated cases. The mitochondrial mutation A1555G was detected in three index cases (4% of the total sample), two familial and one isolated case of deafness. In both the familial cases, the propositi were born to first-cousins. This mutation accounted for 2% of isolated and 10% of familial cases. The 35delG mutation in the Connexin 26 gene was detected in ten index cases (11%), seven being homozygotes and three heterozygotes for this mutation. 35delG mutation was present in 45% of familial cases and in 2% of isolated cases. Therefore, mitochondrial A1555G and Connexin 26 35delG mutations are frequent causes of hearing loss in Brazil, and together they account for 15% of all cases. The simple PCR screening for these two mutations is clearly beneficial for the diagnosis and genetic counseling of deaf patients.

Program Nr: 2125 from the 2001 ASHG Annual Meeting

**A novel mutation in Stat5b impaired DNA-binding affinity in NOD.** *A. Davoodi-Semiromi, M. Laloraya, P.G. Kumar, J-X. She.* Department of Pathology, Immunology and Laboratory Medicine, Center for Mammalian Genetics and Diabetes Center of Excellence, College of Medicine, University of Florida, Gainesville, FL 32610.

Type 1 diabetes (T1D) is a multifactorial autoimmune disease in which susceptibility is determined by genetic and environmental factors. We identified and characterized a novel mutation (C1462A) in the DNA binding domain of Stat5b in the NOD mice using mutation and functional assays. Since the T1D is tightly associated to cytokine-signaling pathways, we sequenced the Stat3, Stat5a and Stat5b genes, mapped to Idd4 interval, and identified a unique mutation that results in a L327M substitution in Stat5b of NOD. This residue is conserved in all identified mammalian STAT proteins and our data from electrophoretic mobility shift assays indicate that the mutation in NOD causes reduced DNA-binding affinity compared to wild-type animals. Our immunoblotting data also indicate that the expression levels of the perforin, Pim-1, c-Myc and IL2R-b genes are down regulated in NOD after GM-CSF stimulation in splenocytes. Identification and characterization of this defect in the Jak-Stat5b pathway provides important new insights into the immunopathogenesis of T1D. *Stat5aStat5bStat3Idd4perforinPim-1c-MycIL2R-b.*

**Identification of the first cardiac ion channel mutation in a patient with drug-induced arrhythmia provides direct evidence of genetic susceptibility to an acquired disorder.** *L. Baumbach, H. Basterrechea, E. Estrella, R. Myerburg, G. Wolff, N. Bishopric.* Pediatrics, Univ. of Miami School of Med., Miami, FL.

Long-QT syndrome (LQTS) is a disorder characterized by an abnormality in cardiac repolarization, causing syncope, seizures, and sudden death. It can be inherited or acquired as an adverse effect of drug therapy. Genes encoding cardiac ion channels have been linked to congenital LQTS, however, good genotype: phenotype correlations do not exist. Although it is not known whether acquired LQTS has a similar genetic basis, a genetic relationship between congenital and acquired forms is suspected. We are developing high-throughput rapid mutation screening methods for the three genes most frequently involved in LQTS: KVLQT1, HERG and SCN5A. Previous work has demonstrated numerous private mutations dispersed throughout these loci, making mutation detection laborious and inefficient. One of our current methodologies employs exon-specific PCR, followed by multiplex SSCP and DNA sequencing. Using this protocol, we can initially analyze all KVLQT1 exons in two SSCP gels. Similar approaches have been adapted to HERG and SCN5A. We have begun investigating genotype-phenotype correlations in congenital and acquired LQTS. Currently, 11 probands and their families are under investigation. SSCP variants in KVLQT1 have been found in two out of two patients with normal baseline QT intervals, but histories of arrhythmias exacerbated by exposures to pharmacological agents. Patient 1, has a family history of cardiac sudden death and syncope, is heterozygous for a KVLQT1 missense mutation (G189R) located in the intracellular loop between the S2 and S3 transmembrane segments. This mutation has been previously reported in three families with LQTS. We are awaiting DNA sequencing results on patient 2. **Our findings provide the first evidence for a genetic basis for pharmacologically-induced arrhythmias.** The development of high throughput mutation screening methodologies will permit genetic screening of larger patient populations, with the ultimate goal of generating a clinically available diagnostic test.

**Identification of genes from a schizophrenia susceptibility locus on 6p24 using bioinformatics and Genome mapping.** *Y. Jiang, K.S. Kendler, X. Chen, R.S. Straub, B.P. Riley.* Dept Psychiatry, Virginia Inst Psych/Behav Gen, Richmond, VA.

Schizophrenia is a psychotic disorder, characterized by a constellation of symptoms including hallucinations and delusions (psychotic symptoms) and symptoms such as severely inappropriate emotional responses, disordered thinking and concentration, erratic behavior, as well as social and occupational deterioration. The location 6p24 has previously been found to be linked with schizophrenia. Genes and genome structure present at this location have not been investigated in details. To facilitate the identification of the disease gene, a 1Mb genomic region including the positive marker D6S940 and D6S470 in previous linkage study was covered by two BAC clone contig NT\_023416 and NT\_023418 with a 50kb gap in between, which was constructed computationally using draft genomic sequence data and existing mapping data for the region. Nine BAC clones have led to the identification and relative ordering of 4 candidate genes in the region, including 1 novel transcripts, one putative gene and tandemly repeated sequences almost identical to the human retrotransposon L1. It constitutes a resource for polymorphic marker discovery and association studies to validate or reject candidate genes. Two candidate genes appear to be particularly promising based upon their proximity to the marker D6S940 and D6S470 and their likely functional roles. One putative gene predicted by Grail and Genescan involved in Apoptosis and the other gene, Matrln-3, encoding an acidic internal matrix protein with perturbation of human retrotransposon L1, a human endogenous retrovirus element in its 3' untranslated region, which is recently found important on the underlying molecular mechanism of schizophrenia.

**Prevalence of HLA-DRB1 alleles in Kuwaiti Arab children with juvenile rheumatoid arthritis.** *M.Z. Haider<sup>1</sup>, K. Alsaeid<sup>1</sup>, E.M. Ayoub<sup>2</sup>*. 1) Dept Pediatrics, Fac Medicine, Kuwait Univ, Safat, Kuwait; 2) Dept Pediatrics, Univ Florida, Gainesville, FL, USA.

The prevalence of human leukocyte antigen (HLA) DR alleles has been determined in 69 Kuwaiti Arab children with juvenile rheumatoid arthritis (JRA) and compared to that in 212 ethnically matched normal healthy controls using a PCR-sequence specific primers (PCR-SSP) method. A considerably high incidence of DR3 was detected in JRA patients compared to the controls ( $P < 0.0001$ ,  $RR = 2.235$ ). The high incidence of HLA-DR3 in JRA patients was accounted for mainly by an excess of DRB1\*0307 ( $P < 0.05$ ,  $RR = 3.072$ ) and DRB1\*0308 ( $P < 0.009$ ,  $RR = 2.663$ ) compared to the controls. Moreover, DR3 was more prevalent when patients with ANA positive JRA were analyzed separately, 73% compared to 58% in the whole JRA patients group. The frequency of DR1 was also higher in the JRA group compared to controls ( $P = 0.019$ ,  $RR = 3.585$ ). Although the incidence of some alleles was higher in the control group (DR13 and DR7), none reached a statistically significant level. All the patients with iridocyclitis had either a DR1 or DR3 allele except for one child. The frequency of DRB1\*03 was found to be much higher in polyarticular subtype of Kuwaiti JRA cases compared to the oligoarticular subgroup and the controls. Also, a nonsignificant increase in the frequency of DRB1\*04, \*11 and \*15 alleles was detected in the polyarticular subtype of the Kuwaiti JRA cases compared to the controls.

**Linkage study of reading disabilities and attention-deficit hyperactivity disorder in the chromosome 6p region.**

*C.L. Barr<sup>1,2</sup>, K. Wigg<sup>1</sup>, Y. Feng<sup>1</sup>, C. Hayes<sup>1</sup>, O. Azeke<sup>1</sup>, A. Ickowicz<sup>2</sup>, R. Schachar<sup>2</sup>, R. Tannock<sup>2</sup>, W. Roberts<sup>2</sup>, M. Malone<sup>2</sup>, J.L. Kennedy<sup>3</sup>, B. Anderson<sup>2</sup>, M. Lovett<sup>2</sup>, A. Young<sup>2</sup>, T. Humphries<sup>2</sup>.* 1) Psychiatry, Toronto Hosp Western Div, Toronto, ON, Canada; 2) The Hospital for Sick Children, Toronto, ON, Canada; 3) The Centre for Addiction and Mental Health, Clarke Division, Toronto, ON, Canada.

It has been well documented that individuals with reading disabilities (RD) often have symptoms of attention-deficit hyperactivity disorder (ADHD). The basis for this overlap is not clear but twin studies have concluded that common genetic influences may predispose children to both conditions. We have begun to investigate the genetic overlap by genotyping markers in the region of 6p that has been reported to be linked to both the RD and ADHD phenotypes. We used two samples of small nuclear families for our studies, one ascertained through a proband with RD and the other through a proband with ADHD. We have investigated a number of markers across this region, some located in candidate genes. These include two genes in the region with the strongest support for linkage to RD, the genes for myelin oligodendrocyte glycoprotein (MOG) and the gamma aminobutyric acid (GABA) beta receptor 1 (GABAB-R1). MOG is a minor component of myelin and has been suggested to be involved in the completion and maintenance of the myelin sheath. Three possible functions for the protein have been suggested: a cellular adhesive molecule, a regulator of oligodendrocyte stability, and a mediator of interaction between myelin and the immune system. The GABAB-R1 gene is an interesting candidate gene for RD and ADHD based on the proposed role of this gene in cognition as well as the role of the GABAB receptors in modulating the release of a number of neurotransmitters including dopamine and norepinephrine, both postulated to be involved in ADHD. Thus far we have not found any evidence for linkage with these markers to either the RD or ADHD phenotypes in either sample.

**Towards identification of a susceptibility gene for bipolar affective disorder: genomic characterisation of**

**chromosome 4q35.** *I.P. Blair<sup>1</sup>, L.J. Adams<sup>1</sup>, R.F. Badenhop<sup>1</sup>, M.J. Moses<sup>1</sup>, A. Scimone<sup>1</sup>, J. Morris<sup>2</sup>, L. Ma<sup>2</sup>, C. Austin<sup>2</sup>, J.A. Donald<sup>3</sup>, P.B. Mitchell<sup>4</sup>, P.R. Schofield<sup>1</sup>.* 1) Neurobiology, Garvan Institute, Sydney, NSW, Australia; 2) Merck Laboratories, West Point, PA; 3) Dept of Biological Sciences, Macquarie University, Sydney, NSW, Australia; 4) School of Psychiatry, University of New South Wales and Prince of Wales Hospital, Sydney, NSW, Australia.

Bipolar affective disorder (BP) is characterised by aberrant mood swings resulting in alternating periods of mania and depression with reversion to otherwise normal behaviour between episodes. The etiology of BP remains unknown. Twin, family and adoption studies reveal the high heritability of BP. We recently identified a susceptibility locus for BP on chromosome 4q35 using linkage analysis in one large pedigree and suggestive linkage to 4q35 in 23 other pedigrees. Our large collection of BP pedigrees has provided us with a unique resource with which to refine the chromosome 4q35 candidate interval to a size that is amenable to positional cloning. We have used the resources of the HGP and Celera to identify overlapping sequenced BAC clones and sequence contigs that represent the region implicated in linkage analysis. A combination of bioinformatic tools and laboratory techniques have been applied to annotate this data and establish a comprehensive transcript map that spans 5 Mb and encompasses the 4q35 susceptibility locus. This map includes 10 known and 12 novel transcripts, which provide a collection of genes for investigation for association with BP. Bioinformatics, along with expression analysis, is being undertaken to give insights into the function of many of these novel genes. Transcripts that show expression and potential function in the brain are being prioritised for investigation as potential BP susceptibility genes. To date, 7 genes have been screened for SNPs in cases and controls from 7 pedigrees which support 4q35 linkage. Numerous intragenic SNPs have been identified and phase known SNP haplotypes are being examined for association with BP in a much larger case-control cohort. This strategy is being applied to all candidate genes from the region.

**Transcriptional dysregulation in Huntington's disease.** *J. Duce*<sup>1</sup>, *C. Hartog*<sup>1</sup>, *L. Elliston*<sup>1</sup>, *G. Bates*<sup>2</sup>, *L. Jones*<sup>1</sup>. 1) Institute of Medical Genetics, Univ of Wales Col Medicine, Cardiff, UK; 2) Division of Medical and Molecular Genetics, GKT School of Medicine, 8th Floor Guy's Tower, Guy's Hospital, London SE1 9RT, UK.

Huntington's disease (HD) is an autosomal dominant neurodegeneration associated with an expanded polyglutamine tract close to the N-terminus of the protein huntingtin. The mechanism by which long glutamine tracts cause HD remains unclear, and examination of huntingtin interactions may provide clues to the pathogenic mechanism. Various transcriptional regulatory proteins interact with huntingtin and we have examined the interactions between huntingtin, the nuclear receptor co-repressor (N-CoR) and the silencing mediator of retinoic acid and thyroid receptor (SMRT), related proteins which repress transcription through thyroid hormone and retinoic acid receptors as well as a number of other sequence-specific DNA binding proteins. Yeast two-hybrid experiments reveal that the N-CoR-huntingtin interaction is stronger than the SMRT-huntingtin interaction, but in both cases interaction is mediated through the homologous C-terminal repression domains. An artificial GAL4-mediated transcriptional reporter system shows that N-terminal huntingtin can recruit repressive activity, and immunohistochemistry in HD brains reveals a marked relocalisation of both N-CoR and SMRT in both early and late stages of disease. Both proteins are recruited infrequently into intranuclear inclusions, but demonstrate a more general relocalisation within neurones, particularly in cortical layers V and VI, and also give consistently stronger immunoreactive signals in HD than control brain. To further examine the effect huntingtin may be having on global gene expression we have examined the levels of gene expression in R6/2 mice, transgenic for exon 1 of the huntingtin protein with around 150 glutamines, using the Affymetrix U74A Genechip. Dysregulated gene expression mediated through the interactions described above may contribute to the alterations in gene expression seen in HD brain and thus contribute to the pathogenesis of HD.

**Chromosome 15 cryptic rearrangements in pervasive developmental disorders.** *F. Gurrieri, L. Russo, T. Giordano, E. De Vincenzi, G. Neri.* *Genetica Medica, Univ Cattolica, Rome, Italy.*

Pervasive developmental disorders (PDDs) represent an heterogeneous group of behavioural deficits, including autism and atypical autism, characterized by impaired communication and social interaction, restricted interests and stereotyped behaviours. PDDs affect around 1:2.500 individuals within the first three years of life with a sex ratio M:F = 4:1. A strong genetic basis has been recognized and several genomic studies, as well as cytogenetic observations, have identified at least 12 candidate loci for genes predisposing to PDD. The 15q11-q13 genomic region is most interesting because linkage/association studies have repeatedly shown positive lodscores in multiplex PDD families. In addition, cytogenetic rearrangements, such as inv-dup15 or cryptic interstitial duplications, have been non-randomly associated with atypical autism. In order to define the prevalence of cryptic 15q11-q13 duplications in PDD, we have genotyped 100 patients with their normal parents by using a set of microsatellite markers mapped in this critical region. The patients were selected through a collaboration with various child neuropsychiatry centers. The molecular screening of 100 PDD families allowed the identification of a patient carrying a molecular duplication of the critical interval including markers from D15S817 to D15S113, which was clearly pathogenic [Gurrieri et al.: *Neurology* 52:1694-97, 1999]. In addition, a maternally derived duplication at a single locus, D15S817, was identified in another two unrelated PDD patients. The presence of such duplication was confirmed with different sets of nested primers. We could not identify any D15S817 duplication in 200 control chromosomes. Although the pathogenicity of these rearrangements needs to be confirmed by further studies, our results show that a cryptic 15q11-q13 duplication is responsible for PDD in 1-3% of patients with this diagnosis. This percentage is relatively high, considering the marked genetic heterogeneity of PDD. Supported by grants from MURST and Sigma-tau.

**DIBD1, a novel gene homologous to *Saccaromyces cerevisiae* ALG9, is disrupted in a family with bipolar affective disorder by a translocation breakpoint at 11q23.** *B.E. Baysal*<sup>1,3</sup>, *J.E. Willett-Brozick*<sup>1</sup>, *J.A. Badner*<sup>2</sup>, *R.E. Ferrell*<sup>3</sup>, *V.A. Nimgaonkar*<sup>1</sup>, *S. Detera-Wadleigh*<sup>4</sup>. 1) Dept. Psychiatry Univ. Pittsburgh Med Ctr; 2) Dept. Psychiatry Univ. Chicago; 3) Dept Hum Genet Univ. Pittsburgh; 4) NIMH Intramural Research Program, NIH.

Bipolar affective disorder (BPAD) is a complex neuropsychiatric disorder characterized by extreme mood swings. We previously described a pedigree in which five individuals with BPAD and one individual with recurrent major depression were carriers of a reciprocal chromosomal translocation t(9;11)(p24;q23). Gene content analyses of breakpoint junctions revealed disruption of a novel gene (DIBD1) at 11q23, a region that has also been implicated in the etiology of schizophrenia and Tourette syndrome. DIBD1 is predicted to encode a 611 amino acid long transmembranous protein, homologous to the *Saccaromyces cerevisiae* ALG9, and is composed of 15 exons spanning approximately 85 kb. ALG9 encodes a mannosyltransferase involved in the protein N-glycosylation pathway, the inborn errors of which cause congenital disorders of glycosylation in human. DIBD1 is ubiquitously expressed in a variety of tissues, including all tested subregions of the brain. Sequence analysis revealed three intra-genic SNPs. The valine residue in the non-synonymous SNP V289I is conserved in 10 other multicellular eukaryotic species, whereas its frequency is approximately 65% in human. We performed linkage and transmission disequilibrium test (TDT) analyses by genotyping 950 individuals including 316 affecteds from two bipolar pedigree series using four tightly linked STRPs and V289I. Nominally significant results were obtained in the subset of 22 multiplex pedigrees under a broad phenotypic definition. Linkage analysis with an intronic STRP gave a lod score of 1.18, ( $p=0.0098$ ) and the TDT using a two-marker-haplotype was significant at  $p=0.04$ . Thus, DIBD1 is a novel gene disrupted in a family with BPAD and the identification of marginally significant linkage/TDT results and the presence of a common non-synonymous SNP at an evolutionarily conserved amino acid position may suggest a role for it in disease pathogenesis in the general BPAD patient population.

**Association of the calcium-sensing receptor gene in Alzheimer's disease susceptibility.** *Y.P. Conley<sup>1,2</sup>, D.N. Finegold<sup>2</sup>, R.E. Ferrell<sup>2</sup>*. 1) Health Promotion & Development, Univ Pittsburgh, Pittsburgh, PA; 2) Human Genetics, Univ Pittsburgh, Pittsburgh, PA.

The calcium-sensing receptor (CASR) is primarily involved with systemic calcium ion homeostasis, although its systemic function does not explain why it is expressed in brain tissue. We have confirmed APP and ApoE as alternative ligands for the CASR, which demonstrates that the CASR could have a function other than mineral ion homeostasis in the brain. Given the association of APP and ApoE with Alzheimer's disease we conducted an age-matched case control study using a polymorphic dinucleotide marker found in intron 4 of the CASR. 284 Alzheimer's disease patients and 97 age-matched non-demented control samples were genotyped for the intragenic marker. We find that the frequency of several alleles differ significantly between AD patients and controls and when the data is dichotomized based on allele frequencies,  $\leq 228$ bp and  $>228$ bp the AD patients have significantly shorter repeat lengths (34%) compared to the controls (19%) with an OR of 2.1 ( $p < 0.005$ ). When the data is dichotomized based on presence of an allele  $\geq 230$  bp in a genotype, 82% of the AD patients had genotypes containing an allele  $\geq 230$  bp compared with 96% of the controls with an OR of 5.1 ( $p < 0.005$ ). Activation of the CASR ultimately results in an increase in intracellular calcium ions, providing a mechanism by which APP and ApoE increase intracellular calcium ion concentration and suggests a mechanism by which they exert their neurotoxic effects. Whether this length polymorphism is functional, or is a marker for functional variation elsewhere in the CASR gene influencing variation in AD susceptibility, this case/control study confirms association of the CASR gene in AD status and strengthens our hypothesis that it plays a role in the Alzheimer's disease process.

**The Genetic Architecture of Exploratory and Fear like behavior in mice: A comparison of two complementary strategies for fine mapping QTLs.** *H. Gershenfeld<sup>1</sup>, Y. Lou<sup>1</sup>, M. Anyango<sup>2</sup>, N. Mohibullah<sup>1</sup>, A. Osoti<sup>2</sup>, R. King<sup>2</sup>, F. Iraqi<sup>2</sup>.* 1) Dept Psychiatry, UTSW, Dallas, TX; 2) ILRI, Nairobi, Kenya.

**BACKGROUND:** Prior work with F2 and N2 crosses have defined loci on chr 1, 10, and 19 that influence open field (OF) and Light-Dark (LD) behaviors by quantitative trait loci (QTL) mapping in mice. **AIMS:** To compare two methods of localizing these QTL and to define candidate regions for human studies. **METHODS:** Interval Specific Congenic Strains (ISCS) for the distal region of chr 10 containing the Exq QTL were bred and studied. As a second strategy, F12 Advanced Intercross Line (AIL) mice (N=1130), originally derived from crossing two markedly differing, parental strains A and C57BL/6 mice were sequentially phenotyped, genotyped, and QTL mapped. **RESULTS:** The ICSC data suggest that the Exq locus is either composed of two linked loci on distal chr. 10 or the possibility of a telomeric location beyond the available markers. From the F12 AIL data, the Exq locus mapped robustly with high statistical significance and explained 4% of the total phenotypic variance for LD behavior. Surprisingly, the large regions containing OF loci on chr. 1 and 19 were localized to several regions with weakly suggestive LOD scores, each explaining about 1% of the variance. **CONCLUSIONS:** These results suggest that gene interactions between linked loci may explain some of the non-replications and difficulties of genome mapping in psychiatric illness. Three findings may be generalizable to complex trait mapping, namely that 1) behavior results from inheriting "many small things" (i.e., modest effect loci explaining 1-5% of the variance), 2) the congenic data suggest gene interactions exist where only combinations of loci have detectable effects, and 3) the genetic architecture underlying complex traits becomes the critical determinant of fine mapping success, highlighting the difference of loci acting in isolation in congenic strains versus the F12 AIL where the Exq loci work in the context of other B6 loci in the genetic background. Support: NIH Grant RO1 MH58882 (HG) , The Southwestern Medical Foundation (HG).

***Noggin* is not a major gene for neural tube defects or Chiari type 1 malformation.** K. Bauer<sup>1</sup>, E.C. Melvin<sup>1</sup>, L. Mehlretter<sup>1</sup>, C. Drake<sup>1</sup>, T.M. George<sup>1</sup>, D. Enterline<sup>1</sup>, M. Hauser<sup>1</sup>, T.H. Milhorat<sup>3</sup>, J.S. Nye<sup>2</sup> and NTD Collaborative Group. 1) Center for Human Genetics, Duke University Medical Center, Durham, NC; 2) Northwestern University Medical Center, Chicago, IL; 3) State University of New York, Brooklyn, NY.

*Noggin* encodes a bone morphogenetic protein (BMP) antagonist expressed in the developing neural tube, condensing cartilage, and chondrocytes. *Noggin* knockout mice show various defects affecting the somites, limbs and neural tube. We investigated *Noggin* using denaturing high performance liquid chromatography (DHPLC) as a candidate gene for neural tube defects (NTDs) and Chiari type 1 malformation. The screen included 202 cases with NTD (142 simplex cases and 60 multiplex cases; 143 lumbosacral myelomeningocele {MM}, 12 lumbosacral/thoracic MM, 23 thoracic MM 12 lipomyelomeningoceles, and 22 miscellaneous NTDs) and 33 individuals diagnosed with non-syndromic Chiari type 1 malformation. The region screened included the 699bp of coding region, 365bp of the 5 prime untranslated region (UTR) and 17 bp of the 3 prime UTR. The DNA from cases was grouped into 42 pools and screened utilizing denaturing high performance liquid chromatography (DHPLC). Any pool showing a variant was separated into its individual constituents and further studied. One heterozygous variant was identified in a male patient with a lumbosacral myelomeningocele. The individual and his available family members were sequenced. The patient's father and a female sibling also carried the variant allele, but neither is affected with open NTD; the patient's mother and another sibling do not have the variant allele. The C->G sequence variant occurred at position 1064, yielding an amino acid residue change from proline to histidine. The variant found in the NTD patient is a new variant. This sequence variation may be unrelated to the patient's NTD since the variant is also present in unaffected relatives, but further investigation is underway to exclude compound heterozygosity in the affected patient. Based on these results, *Noggin* is unlikely to be a major gene predisposing to NTDs or Chiari type 1 malformation.

**Estrogen Receptor gene polymorphism in Italian patients with multiple sclerosis.** *R. Cittadella<sup>1</sup>, I. Manna<sup>1</sup>, V. Andreoli<sup>1</sup>, A. La Russa<sup>1</sup>, G. La Porta<sup>1</sup>, L. Cresibene<sup>1</sup>, L. Bastone<sup>1</sup>, R. Nisticò<sup>2</sup>, L. Mangone<sup>2</sup>, N. Romeo<sup>1</sup>, M. Caracciolo<sup>1</sup>, P.A. Serra<sup>1</sup>, A. Quattrone<sup>1,2</sup>.* 1) IMSEB-National Research Council, Cosenza, Italy; 2) Institute of Neurology, University Magna Graecia, Catanzaro, Italy.

Development of multiple sclerosis (MS), an autoimmune disease, is believed to involve genetic as well as environmental factors. The estrogen receptor 1 gene (ESR1) is an interesting candidate to uncover the genetic background of MS, because the expression of ESR1 has been identified in cells of the immune system and, thus genetic variability of ESR1 may play a role in the development of MS. Estrogen has been reported to have immunosuppressive functions, and most of its effects are mediated via receptors whose function and expression may be modified by DNA polymorphisms. In the present study we investigated the possible role of ESR1 in the pathogenesis of MS by studying intronic polymorphisms of the ESR1 gene. In its first intron two polymorphisms have been shown: T to C approximately 400 bp upstream from exon-2 and A to G approximately 350 bp. These polymorphisms were determined by restriction fragment length polymorphism (RFLP) using PvuII and XbaI respectively after polymerase chain reaction (PCR). One-hundred and thirty-two unrelated Italian patients with clinically definite MS (81 females and 51 males) and 129 unrelated healthy controls (66 females and 63 males), with a similar age range, were selected for this study; all the case patients and the controls were from the same geographical area (Calabria region, Southern Italy). The distribution of the genotypes was very similar to that previously reported in the Caucasian population, but there was no significant difference in allele or genotype frequencies between patients and controls. In conclusion, our findings suggest that the ESR1 gene does not contribute to the development of MS.

**Dopamine D4 receptor (DRD4) and intensity of reaction trait during infancy.** A. De Luca<sup>1,2</sup>, M. Rizzardi<sup>3</sup>, A. Buccino<sup>1,2</sup>, I. Torrente<sup>1,2</sup>, M. Mangino<sup>1,2</sup>, G.P. Salvioli<sup>4</sup>, R. Alessandrini<sup>4</sup>, B. Dallapiccola<sup>1,5</sup>, G. Novelli<sup>2</sup>. 1) Ist. CSS-Mendel, Rome, Italy; 2) Dip. di Biopatologia e Diagnostica per Immagini, Univ. di Roma "Tor Vergata", Rome, Italy; 3) Fac. di Scienze della Formazione, Univ. di Urbino, Urbino, Italy; 4) Ist. di Ped. Preventiva e Neonatologia, Bologna, Italy; 5) Dip. di Medicina Sperimentale e Patologia, Univ. di Roma "La Sapienza", Rome, Italy.

Temperament dimensions are developmental phenomena affected by genetic and environmental factors. During development, some behaviours can either appear or disappear, while others remain continuous and, during the course of development, become more differentiated. We had previously examined the relationship between the common dopamine D4 receptor (DRD4) exon III repeat polymorphism and infants behaviour in Italian neonates at 1 and 5 months of life (De Luca et al. *Neurogenetics* 2001;3:79-82). We found a significant correlation between adaptability and DRD4 long alleles of exon III repeat. In order to extend preliminary results, we longitudinally followed the same group of infants up to 3 years, using the Toddler Temperament Scale (Fullard W., McDevitt S.C. and Carey W.B. 1979). We detected a significant association between intensity of reaction and DRD4 genotypes (4/7 and 4/4). Infants with 4/7 genotype had significantly lower scores on intensity of reaction than infants with 4/4 genotypes [t-value=2.9; df 63; p<0.01]. Infants with 4/7 genotype had significantly lower scores [mean=3.5±0.83, N=18] on intensity of reaction than infants with 4/4 genotypes [mean=4.1±0.79, N=47]. Similar results were obtained either when genotypes were classified by the presence or the absence of the 7-repeat allele, or by the long (>6 repeats) versus the short (<5 repeats) DRD4 alleles. These results confirm and extend the genetic influence of DRD4 gene in human temperament during development.

**Developing of full-length cDNA for novel genes expressed in brain from chromosome 18q21 to create a gene panel for variation/mutation screen in bipolar disorder.** *H. Chen*<sup>1</sup>, *C.A. Ross*<sup>1, 2</sup>, *N. Wang*<sup>1</sup>, *Y. Huo*<sup>1</sup>, *P. Sklar*<sup>3</sup>, *D.F. MacKinnon*<sup>1</sup>, *J. Potash*<sup>1</sup>, *S.G. Simpson*<sup>1</sup>, *J. A bipolar disorder susceptibility locus has been linked to a region on human chromosome 18q21 (Stine et al, 1995; McMahon et al, 1997). To search for candidate genes potentially involved in the disorder, exon trapping was performed on cosmids isolated from 18q21, and resulted in the identification of 145 unique exons, of which 22 are identical to known genes and ESTs, 24 to ESTs only, and 101 have no homology to known genes. A strategy was developed for the generation of a panel of full-length cDNAs corresponding to the identified exons for variation/mutation studies of novel genes expressed in brain in bipolar disorder. This strategy consists of using a modified GLGI method (Generation of Longer 3' cDNA from SAGE tags for Gene Identification) to generate 3' cDNA, and 5' RACE method to generate 5' cDNA, and of combining 3' and 5' cDNAs into full-length cDNA corresponding to each gene expressed in brain. Northern blot analysis will be carried out to examine the expression patterns and the sizes of mRNA species of each gene in the panel. Among 28 trapped exons tested that have no homology to known genes and ESTs, 8 showed the amplification of 0.5-1.6 kb of 3' cDNAs. The full-length cDNAs for two novel genes, a NEDD4-like ubiquitin-protein ligase (termed NEDD4L) and a novel zinc finger gene, have been generated through combining their 3' and 5' cDNA sequences. The remaining 93 trapped exons (excluding the 22 exons identical to known genes) are currently being tested according to the above procedures. The establishment of full-length cDNA panel for genes in 18q21 expressed in brain will be prioritized for variation/mutation screen in bipolar subjects.

**Possible association of NTDs with a poly-histidine tract polymorphism in the ZIC2 gene.** *L.Y. Brown<sup>1</sup>, S.E.*

*Hodge<sup>2</sup>, W.G. Johnson<sup>3</sup>, S.G. Guy<sup>4</sup>, J.S. Nye<sup>4</sup>, S.A. Brown<sup>1</sup>.* 1) Dept. Neural tube defects (NTDs) and brain malformations represent a common finding in chromosome 13q deletion patients. These defects may be due, in part, to hemizyosity for ZIC2, which is located in the 13q32 critical deletion region. Heterozygous mutation in ZIC2 result in holoprosencephaly (HPE) in humans, and diminished expression of Zic2 results in HPE as well as lumbo-sacral NTDs in mice. Taken together, these observations led us to hypothesize that ZIC2 mutations may be a cause of isolated NTD. To test this, we screened 192 NTD patients for mutations in ZIC2. We did not find ZIC2 mutations in these patients; however, we did find evidence of an association between a histidine tract polymorphism in ZIC2 and NTDs.

The ZIC2 gene normally contains a tract of 9 histidines coded for by a triplet repeat. Occasionally this repeat is expanded to code for 10 histidines (10H). While only 0.5% of normal controls carry the (10H) variant of the ZIC2 gene, 6% of NTD patients were found to be heterozygous for the 10H allele ( $c^2 = 9.03$ , significant at the .005 level). When we considered only Hispanic NTD patients and controls, 25% of NTD patients were found to be heterozygous (9H/10H) compared to only 1% of controls ( $c^2 = 17$ ). We attempted to confirm this result with a transmission disequilibrium test (TDT), but our sample was too small to reach definitive conclusions. If this association is confirmed in a larger sample, then subtle alterations in ZIC2 activity may confer a risk of NTD.

**Amyloid b-secretase gene (BACE) is neither mutated nor associated with early-onset Alzheimers disease.** *M. Cruts<sup>1</sup>, B. Dermaut<sup>1</sup>, R. Rademakers<sup>1</sup>, G. Roks<sup>2</sup>, M. Van den Broeck<sup>1</sup>, G. Munteanu<sup>1</sup>, C.M. van Duijn<sup>1,2</sup>, C. Van Broeckhoven<sup>1</sup>.* 1) Flanders Interuniversity Institute for Biotechnology (VIB), University of Antwerp (U.I.A.), Department of Biochemistry, Antwerpen, Belgium; 2) Department of Epidemiology and Biostatistics, Erasmus Medical Centre, Rotterdam, The Netherlands.

The major hallmark of Alzheimers disease (AD) pathology is b-amyloid (Ab) deposition in the brain. Three protease activities named a-, b- and g-secretase are crucial in the proteolytic cleavage of the amyloid precursor protein (APP) to generate Ab. Recently, the b-secretase was identified and named beta-site APP-cleaving enzyme (BACE). Since all known familial early-onset AD (EOAD) related mutations in APP and presenilin (PSEN) increase Ab production by affecting one of the secretase activities, we hypothesized that genetic variations within BACE might be similarly involved in the etiology of EOAD. We performed genetic linkage analyses in families of 9 autosomal dominant probands that had no mutation in APP or PSEN using markers D11S1327, D11S939, D11S1336 located near BACE. No family showed conclusive linkage and in 3 families linkage with BACE was excluded. cDNA and genomic mutation analysis revealed no mutations except for a frequent silent c.786C>G polymorphism (V262) and a c.840+5G>T variation at the fifth nucleotide of intron 5 that was observed in only 1 patient. Next, the V262 polymorphism was analyzed in a sample of 101 presenile AD patients and 185 control subjects. Allele and genotype distributions were not significantly different in cases and controls. Also, no differences were found when the sample was stratified for positive family history or the presence of an APOE4 allele. Together these results show that BACE is not genetically involved in the etiology of EOAD.

**Association study between CAG trinucleotide repeats in the PCQAP gene (PC2 glutamine/Q-rich-associated protein) of the DiGeorge chromosomal region and schizophrenia.** *E. Conti*<sup>1,2</sup>, *A. Reports showing anticipation in families with schizophrenia suggested that a trinucleotide repeat expansion mechanism may be involved in the pathogenesis of the disease. Furthermore, studies of genome-wide trinucleotide repeats using the repeat expansion detection technique suggested possible association of CAG/CTG repeat tracts with schizophrenia. Increased incidence of schizophrenia or schizoaffective disorders has been reported in patients affected by DiGeorge/Velo-Cardio-Facial syndrome (DGS/VCFS). We evaluated the potential role of a CAG polymorphic stretch in the coding region of the novel PCQAP gene mapping within the DiGeorge chromosomal region in schizophrenia susceptibility. We studied the distribution of the CAG repeat alleles in 102 schizophrenic patients and in 100 healthy controls. No unusual expanded CAG trinucleotide repeat was detected in the schizophrenic compared to control subjects. However, an analysis of the difference of allele sizes revealed a significantly greater number of patients with schizophrenia having longer allele sizes (> 17 repeats) when compared to normal controls [O.R.=2.12; 1.15<OR<3.94; CI 95%;  $\chi^2=6.72$ ;  $P<0.01$ ]. This finding may be of functional significance as the PCQAP protein is a component of a multiprotein complex involved in transcription regulation. Large difference in allele sizes could alter the complex stoichiometry resulting in perturbation of gene expression during embryonic development.

**The role for NMDA receptors in the pathogenesis of schizophrenia: no evidence that the NMDAR2B gene is associated with susceptibility to schizophrenia.** *R. Gulli<sup>1</sup>, R. Pioli<sup>2</sup>, A. De Luca<sup>3,4</sup>, S. Begni<sup>2</sup>, A. Pasini<sup>4</sup>, G. Spalletta<sup>4</sup>, E. Bellone<sup>1</sup>, A. Pizzuti<sup>3,5</sup>, G. Novelli<sup>4</sup>, B. Dallapiccola<sup>3,5</sup>, F. Ajmar<sup>1</sup>, M. Gennarelli<sup>2</sup>, P. Mandich<sup>1</sup>, E. Di Maria<sup>1</sup>.* 1) University of Genova, Italy; 2) IRCCS Fatebenefratelli, Brescia, Italy; 3) C.S.S., Mendel Institute Rome, Italy; 4) Tor Vergata University of Rome, Italy; 5) La Sapienza University of Rome, Italy.

The N-methyl-D-aspartate receptors (NMDARs) hypofunction as a mechanism leading to the development of schizophrenia was raised by the evidences that administration of non-competitive NMDAR antagonists trigger psychotic symptoms in schizophrenic patients, and induce psychotic-like behaviours in normal subjects. Animal models further supported this hypothesis. Functional NMDARs comprises the NR1 subunit and one of four NR2 subunits. The NR2B gene, named GRIN2B, is expressed in human brains in the hippocampus, basal ganglia and cerebral cortex. The hypothesis that variations within the genetic background of the NMDAR2B are associated with susceptibility to schizophrenia was investigated through a case-control study. A panel of nine polymorphisms (allele frequencies > 1%) was identified through "in silico" analysis and direct sequencing of a sample series. Allele and genotype frequencies were estimated for five informative polymorphisms on a series of 160 unrelated patients with schizophrenia, assessed according with DSM-IV criteria, and compared with normal subjects. A preliminary analysis on a subset of patients has showed a difference in allele frequencies of one SNP between patients and controls. Conversely, the case-control study on the whole series failed to reveal any significant difference in allele and genotype frequencies. The analysis on extended haplotypes confirmed this finding. This study did not provide any evidence that the NMDAR2B genetic background plays a major role in the development of schizophrenia. However, since no functional variant (i.e. coding SNPs) was detected in the coding sequence, the gene is supposed to be highly conserved. A possible role for the GRIN2B gene in schizophrenia could be eventually sustained by functional variations related with its expression. (Partially granted by Min.Sanita' to EDM).

**Screening of candidate genes for schizophrenia susceptibility in chromosome 8p12-p21.** *E.A. Donarum<sup>1</sup>, K.M. Brown<sup>1</sup>, J.M. Devaney<sup>1</sup>, G. Stevenson<sup>1</sup>, D.A. Stephan<sup>1</sup>, A.E. Pulver<sup>2</sup>.* 1) Research Center for Genetic Medicine, Childrens National Medical Center, Washington, D.C; 2) Johns Hopkins University School of Medicine, Epidemiology-Genetics Program in Psychiatry, Baltimore, MD.

Evidence from several schizophrenia linkage studies, including two genome scans (Blouin et al., 1998; Gurling et al., 2001), implicate chromosomal region 8p21 in schizophrenia susceptibility. From our sample of 54 multiplex schizophrenia pedigrees exhibiting suggestive linkage evidence in the region, we have selected probands from 1.) families exhibiting allele sharing amongst affected family members for markers in the 8p12-p21 region (over 20 cM), and 2.) genome scan families with schizophrenia spectrum disorders diagnosed in relatives ( see Pulver et al., 2000, for stratification analyses of chromosome 8 based on diagnoses in first degree relatives). Genes were chosen as candidates based upon their physical location and their function or expression patterns relevant to schizophrenia hypotheses. The positional candidates included adrenergic, cholinergic, and nictotinic receptors, among others. Mutation detection techniques including from SSCP, dHPLC, and PTT were used to analyse of DNA from 11 probands for candidate genes including: ADRA1A, ADRA1C, NEFL, NEF3, GABRR2, GABRR1, LPL, PNOC, CLU, ADRB3-1,ADRB3-2, GFRA2-1 GFRA2-2, SLC18A1, CHRN3, STC1, and CHRNA2. Aberrant SSCP bands/ (heteroduplexes) were then sequenced. No meaningful amino acid changes were found, excluding these candidates for schizophrenia liability in these carefully selected probands.

**Variance in age of onset of Huntington's disease that is independent of CAG repeat length remains highly heritable.** *J.M. Andresen<sup>1</sup>, L.R. Cardon<sup>2</sup>, S.S. Cherny<sup>2</sup>, J.F. Gusella<sup>3</sup>, M.E. MacDonald<sup>3</sup>, D.E. Housman<sup>1</sup>, N.S. Wexler<sup>4</sup>.* 1) MIT, Cambridge, MA; 2) University of Oxford, United Kingdom; 3) Massachusetts General Hospital, Boston, MA; 4) Columbia University, New York, NY.

Huntington's disease (HD) is a fatal, autosomal dominant neurological illness which causes involuntary movements, severe emotional disturbance, and cognitive decline. The mutation responsible for HD is the expansion of an unstable CAG repeat embedded in the translated open reading frame of exon 1 of the huntingtin gene, which causes expression of an expanded polyglutamine repeat in the huntingtin protein. Huntingtin alleles with 40 or more CAG repeats are 100% penetrant within a normal human lifespan, though age of onset and clinical presentation of the disease vary dramatically among individuals. The length of the triplet CAG repeat is a major determinant of age of onset for HD, with age of onset varying inversely with the number of CAG repeats in the gene. In a large Venezuelan HD kindred we have characterized, repeat length is responsible for 72% of the variance in age of onset. The variance in age of onset after repeat length is factored out, however, remains highly heritable. A residualized age-of-onset quantitative trait score was created which removed that portion of age of onset that could be explained by CAG repeat length. Using maximum-likelihood variance components to estimate between and within sib-pair variances on this new phenotype, the sibling intraclass correlation on residualized age-of-onset was calculated for 172 sibling relationships of 337 individuals who had between 40 and 50 repeats. The correlation was estimated at 0.39 ( $p < 0.0001$ ), which corresponds to a heritability of 78%, assuming shared environmental influences are negligible. This analysis justifies a genome-wide scan for linkage in the Venezuelan HD Kindred to identify quantitative trait loci contributing to the determination of age of onset in this population. The eventual identification of polymorphisms that modify age of onset for HD should give new insight into the pathological processes that underlie HD and could materially assist the development of strategies for clinical intervention.
