Schizophrenia is a common mental disorder which occurs in approximately 1 out of 100 births; however, its pathogenesis still remains elusive. From clinical pharmacological evidence, a deficit of glutaminergic neurotransmission, especially via the NMDA receptor, has been highly suggested. D-serine can activate the NMDA receptor, acting on the glycine site, as an endogenous co-agonist of glutamate. Clinical trials of D-serine with classical neuroleptics can improve part of the symptoms in schizophrenic patients, suggesting a role of D-serine in schizophrenia. Serine racemase, an enzyme enriched in astrocytes, can produce D-serine. To clarify its regulatory mechanism, we have carried out yeast-2-hybrid screening, using the full length of human serine racemase as the bait. We have analyzed an adult human brain library, and picked up 2 positive clones. Both of them represented PICK1. The gene for PICK1 is located on chromosome 22q11-13, which has been suggested as a genetic locus for schizophrenia.

**Transcriptome analysis in two transgenic mouse models for Huntington's Disease.** *S.E. Kotliarova<sup>1</sup>, C. Uchikawa<sup>1</sup>, Y.V. Kotliarov<sup>2</sup>, Y. Kamide<sup>1</sup>, F. Oyama<sup>3</sup>, N. Nukina<sup>1</sup>.* 1) Lab. for CAG repeat diseases, Brain Science Institute, RIKEN, Wako-shi, Saitama, Japan; 2) Research into Artifacts, Center for Engineering, University of Tokyo; 3) Department of Neuropathology, Graduate School of Medicine, University of Tokyo.

Huntington's disease is a hereditary neurodegenerative disorder caused by expansion of the CAG repeat (translated as polyglutamine (pQ) tract) in the exon 1 (ex1) of the huntingtin (htt) gene. We used the construct of human ex1 with expanded pQ, fused with EGFP to create the HD150-1 transgenic mouse model for HD. Although mice expressing 150-180 pQ revealed progressive neurological phenotype, neuronal cell loss was not observed in HD150-1 mice suggesting neuronal dysfunction is responsible for disease phenotype.

To find genes affected by mutant htt, we applied GeneChip technology (Affymetrix, Mu11K) for the analysis of mRNA from brain of HD150-1 mice in asymptomatic animals at 8 weeks and in early symptomatic animals at 12 weeks. In addition, we used R6/2 8week mice to find the commonly affected genes in 2 models. To analyze data we developed the software for Multiple Comparisons Analysis (MCA) using VBA on MSExcel. As a result we found differential expression of about 360 genes (from examined ~11000) in transgenic mice and their control littermates in all animal groups. We annotated 78% of potentially affected genes (the rest 22% were ESTs). Among the known genes 22.7% belong to signal transduction pathways; 13.5% to basic anabolism and catabolism pathways; 12.8% involved in nervous system function; 12.1% in immunity; 11% in RNA synthesis and processing; 8.9% in protein synthesis and modification and 7.8% in cell structure/motility. The majority of differentially expressed genes (57.5%) were down regulated.

We analyzed expression of genes involved in nervous system function in more details by TaqMan-based RT-PCR assay. Such genes as enkephalin and somatostatin are affected in different HD mouse models as well as in other triplet diseases mouse models, suggesting that the common mechanism may underlie neuronal dysfunction in CAG repeat diseases.

**Huntington's disease intermediate allele and new variant CJD.** *P.S. Harper<sup>1</sup>, R. Evans<sup>2</sup>, L. Elliston<sup>1</sup>, J.W. Ironside<sup>2</sup>, A.L. Jones<sup>1</sup>, L. Lazarou<sup>1</sup>.* 1) Wales Medical Genetics Service and Inst Medical Genetics, Univ of Wales Col Medicine, Cardiff, Wales, UK; 2) National CJD Surveillance Unit, Western General Hospital, Edinburgh, UK.

We report a female patient with onset age 28 and death age 30 years from a rapidly progressive neurodegenerative illness, with an initial psychiatric presentation but including involuntary movements, raising a clinical suspicion of Huntington's disease (HD). The patient's mother had also died from a poorly defined dementing illness age 67 years, but there was no family history of HD. Molecular analysis of the daughter showed an expanded HD allele of 36 repeats, but this was not considered an adequate cause for the disorder at this young age.

Neuropathology showed a spongiform encephalopathy with amyloid plaques and undefined deposition of prion protein, the features being characteristic of new variant Creutzfeldt-Jakob disease (nvCJD), associated in the UK with the infective prion agent of bovine spongiform encephalopathy. There were no brain features of HD.

This unusual case raises the possibility that the HD locus might influence nvCJD susceptibility, or that prion exposure might modify expression of an HD intermediate allele. Investigation of a full series of nvCJD and classical CJD with respect to the HD and other CAG repeats is required to determine whether the present case represents more than a chance association.

**Study on the genes responsible for E2F-1-mediated neuronal death in Down syndrome brains.** *K. Motonaga<sup>1</sup>, M. Itoh<sup>1</sup>, H. Maki<sup>2</sup>, H. Ninomiya<sup>2</sup>, K. Ohno<sup>2</sup>, M. Oshimura<sup>3</sup>, S. Takashima<sup>4</sup>, Y. Goto<sup>1</sup>.* 1) Department of Mental Retardation and Birth Defect Research, National Institute of Neuroscience, NCNP, Kodaira, Tokyo, Japan; 2) Department of Neurobiology, Tottori University School of Life Sciences, Yonago, Tottori, Japan; 3) Department of Molecular and Cell Genetics, Tottori University School of Life Sciences, Yonago, Tottori, Japan; 4) National Institute of Neuroscience, NCNP, Kodaira, Tokyo, Japan.

The gene of amyloid precursor protein (APP) is located on human chromosome 21 (hu-chr21), and accumulation in the brain of amyloid b protein (Ab), as a breakdown product of APP, is thought to be a leading factor for early onset of dementia in Down syndrome (DS) adults because of trisomy for hu-chr 21. Recent studies indicate the hypothesis that Ab can be neurotoxic in vitro and in vivo. Our recent study revealed that up-regulation of transcription factor, E2F-1 was found in elderly DS brains exhibiting the neuropathological features of Alzheimer-type dementia (DAT). Enhanced immunoreactivity for E2F-1 was detected in the pyramidal neurons of the cerebral cortex from DS brains with DAT, in accordance with Ab deposition in the neurons. As to the Ab neurotoxicity in vitro, E2F-1 mediates death of Ab treated cortical neurons. As p53 and p73 are known to be the transcriptional targets of E2F-1, we investigated p53 and p73 expression in DS brains. P73 alone was up-regulated in the pyramidal neurons of DS brains with DAT, implying that the activation of E2F-1-p73 pathway is a critical for Ab-triggered neuronal death in DS brains with DAT. To elucidate further, we generated the model neurons for DS: PC12 cells into which a segment of hu-chr 21 was introduced. The model neurons containing a segment with genes of Down syndrome critical regions exhibited E2F-1-mediated neuronal death with apoptosis. By using the neurons, our major goal is to determine gene dosage effect of what gene(s) of hu-chr 21 causes the overproduction of Ab and neurodegeneration in DS brains.

**Genetic analysis of spinocerebellar ataxia type 6 in a very large kindred from a mountainous isolate of**

**Azerbaijan.** *S.N. Illarioshkin<sup>1</sup>, S.A. Klyushnikov<sup>1</sup>, L.V. Novikova<sup>1</sup>, M.G. Adjamatov<sup>1</sup>, P.A. Slominsky<sup>2</sup>, E.D. Markova<sup>1</sup>, S.A. Limborska<sup>2</sup>, I.A. Ivanova-Smolenskaya<sup>1</sup>.* 1) Department of Neurogenetics, Institute of Neurology, Moscow, Russia; 2) Department of Human Molecular Genetics, Institute of Molecular Genetics, Moscow, Russia.

Autosomal dominant ataxias represent a heterogeneous group of disorders associated with 14 known chromosomal loci. One of the most common forms of dominant ataxias, spinocerebellar ataxia type 6 (SCA6), is caused by moderate CAG repeat expansion in the coding region of the *CACNLIA4* gene on chromosome 19p13.1. We examined a very large consanguineous 5-generation family residing in a mountainous isolate of Azerbaijan in which 42 family members suffered from an autosomal dominant ataxic disorder. Direct DNA analysis identified this disorder as SCA6—the first case of SCA6 in the countries of the former Soviet Union. In total, 27 relatives were examined personally and underwent molecular testing (including 20 affected individuals). Clinical findings included cerebellar ataxia, dysarthria, and mild pyramidal spasticity. On MRI (performed in three patients), the signs of isolated cerebellar atrophy were found; brainstem auditory evoked potentials were relatively spared. The ages at disease onset ranged from 26 to 50 years. There was clear evidence for anticipation in this family, with difference in onset ages between generations of 7-10 years. DNA analyses showed that each of the affected persons inherited one mutant *CACNLIA4* allele with 23 copies of CAG repeats. Therefore, this allele was characterized by genetic stability and the lack of change in CAG repeat length upon transmission in a number of meioses.

*Conclusions.* The present family demonstrated that anticipation in SCA6 may not be related to genetic instability of the expanded CAG repeat-containing allele, and confirmed the complexity of molecular mechanisms underlying the phenomenon of anticipation. Taking into consideration the consanguineous nature of the family under study, we suggest that homozygosity at some hypothetical modifying loci may account for some genetic characteristics of the disorder observed in this SCA6 family.

**Analysis of candidate genes for autism on chromosomes 7q, 2q and 16p.** *E. Maestrini, on behalf of IMGSAC.*

<http://www.well.ox.ac.uk/~maestrin/iat.html>.

Autism is a severe neurodevelopmental disorder, likely to arise on the basis of a complex genetic predisposition. The IMGSAC has completed a whole genome screen for autism susceptibility loci on 86 sib-pairs; regions on 12 chromosomes were further investigated in 66 additional sib-pairs. In the total data set of 152 sib-pairs, chromosome 2q gave the highest result with a MLS of 3.74 at D2S2188, followed by chromosome 7q with a MLS of 3.37 at D7S477, and chromosome 16p with a MLS of 2.93 at D16S3102. Candidate gene studies are in progress in order to isolate the susceptibility genes at these three loci. All coding and functionally relevant regions of candidate genes are being systematically screened for sequence variants using DHPLC and sequencing. Screening is being carried out in a sample of 40-50 autistic subjects chosen from IMGSAC families which are contributing to the linkage peaks on 2q, 7q, or 16p, respectively. This strategy selects for cases who are more likely to carry etiological variants at these loci compared to a random patient sample. All DNA variants with putative functional significance identified in each gene are tested in a control sample to investigate their frequency in the normal population. In addition, intragenic SNPs detected through the screening are tested in the complete IMGSAC family data set for association with autism, using the Transmission Disequilibrium Test. At present, analysis has been completed for four adjacent genes localised to a region in 7q32, which contains an imprinted domain: PEG1/MEST, COPG2, CPA1, and CPA5. No evidence for an etiological variant was found at any of these genes. Given previous reports suggesting a parent of origin-specific effect at the 7q locus, we also tested the hypothesis that imprinting mutations in the PEG1/COPG2 domain might play a role in autism. Both DNA methylation studies and replication timing analysis indicated a normal imprinting regulation of the PEG1/COPG2 domain. Our analysis strongly suggests that it is unlikely that these four genes play a major role in autism aetiology. Other genes currently under investigation include: RLN, DLX5/DLX6, WNT2 on chromosome 7q; DLX1 and DLX2, TBR1, CHN1, GAD1 on chromosome 2q; GRIN2A, CBP and TBX6 on chromosome 16p.

**Genetic association between Alzheimer disease and the polymorphic markers on chromosome 10.** *T. Miki<sup>1</sup>, H. Yamagata<sup>1,2</sup>, M. Matsubara-Tsutsui<sup>1</sup>, J. Nakura<sup>1</sup>, T. Nomura<sup>1</sup>, K. Kohara<sup>1</sup>, K. Kamino<sup>3</sup>, I. Kondo<sup>2</sup>.* 1) Dept Geriatric Medicine, Ehime Univ Sch Medicine, Ehime, Japan; 2) Dept Hygiene, Ehime Univ Sch Medicine, Ehime, Japan; 3) Dept Clinical Neuroscience, Osaka Univ Grad Sch Med, Osaka, Japan.

The apolipoprotein E (APOE) gene is the only known genetic risk factor for late onset Alzheimer disease (LOAD). However, 50% of LOAD cases carry no APOE4 alleles, suggesting that there must be additional risk factors. Recently several reports suggest that there may contain one or more genes on chromosome 10 associated with LOAD by genetic linkage studies. To investigate the association of chromosome 10 markers with the risk of AD, we carried out a case-control study using microsatellite markers D10S1423 (10p) and D10S583(10q). We examined DNA samples of 50 sporadic, early onset AD patients, 146 LOAD patients, and 204 controls by PCR based assays. In D10S1423, ten alleles ranging in size from 206 to 242 bp ((GATA)n) were identified. There was no statistically significant difference in genotype or allele frequency distributions between cases and controls for the polymorphisms at D10S1423. In D10S583, fifteen alleles ranging in size from 187 to 221 bp ((CA)n) were identified. The multiallelic test on all the 15 alleles showed a statistically significant difference in allele frequencies between the LOAD patients and control subjects ( $P = 0.018$ ;  $df=14$ ). Especially, the frequency of the 203bp allele was significantly lower in LOAD patients than controls ( $p<0.007$ ). Carriers of the 203bp allele had a 0.23-fold decreased risk of developing LOAD than noncarriers. The odds ratio for the ApoE4 and the noncarriers of the 203bp allele was 3.68. The results showed that the D10S583 marker is associated with sporadic LOAD, independent of ApoE4 status. Taken together, the present study supports the previous reports that the D10S583 marker is in linkage disequilibrium with the putative LOAD locus (AD6) on chromosome 10q. The marker is located in intron of the kinesin-like 1 gene (KNSL1). The order of the nearby genes is cen-IDE-KNSL1-HHEX-qter. Therefore, these genes are the strong candidates for LOAD.

**Exon 11 of the chromosome 22 gene WKL1, previously shown to exhibit a base pair mutation in rare cases of schizophrenia, was found to contain an insertion/deletion polymorphism, affecting the receptor channel amino acid sequence.** *A. McQuillin<sup>1</sup>, G. Kalsi<sup>1</sup>, H. Moorey<sup>1</sup>, G. Lamb<sup>1</sup>, S. Mayet<sup>1</sup>, D. Quested<sup>2</sup>, H. Gurling<sup>1</sup>.* 1) Molecular Psychiatry lab, University College London, Windeyer Inst. 46 Cleveland St. London, England W1T 4JF UK; 2) Ealing Hospital, North West London Mental Health Trust.

A missense mutation in exon 11 of a novel gene encoding a potassium channel on chromosome 22 was found to be associated with six cases of catatonic schizophrenia in a single large pedigree (Meyer et al, 2001, *Molecular Psychiatry*, 6, 302-306). We have screened exon 11 of the WKL1 gene in 200 cases of schizophrenia by direct sequencing, including cases of catatonic schizophrenia, but could not detect the previously reported mis-sense mutation. We did, however, find an insertion/deletion affecting both the 3 prime end of exon 11 and the neighbouring intron. Preliminary analyses showed that the insertion/deletion was found to be in Hardy Weinberg equilibrium in both cases and controls and that it was probably not associated with schizophrenia. The insertion/deletion is composed of repeated sequence from exon 11 and intron 11 and is predicted to affect the protein structure of WKL1. Our finding suggests that variation in the WKL1 gene can exist without being associated with schizophrenia.

**Updated analysis of MTHFR in American Caucasian lumbosacral myelomeningocele (NTD) families.** *E.C. Melvin<sup>1</sup>, D.G. Siegel<sup>1</sup>, S. Slifer<sup>1</sup>, L. Mehlretter<sup>1</sup>, S. Samal<sup>1</sup>, D.S. Enterline<sup>1</sup>, T.M. George<sup>1</sup>, J.S. Nye<sup>2</sup>, M.C. Speer<sup>1</sup> and NTD Collaborative Group.* 1) Center for Human Genetics, Duke Univ Medical Ctr, Durham, NC; 2) Northwestern University Medical Center, Chicago, IL.

Neural tube defects (NTD) are common birth defects with both genetic and environmental causes. Maternal periconceptional folic acid supplementation reduces the recurrence risk for NTDs by up to 70%;, suggesting that genes involved in folate metabolism are feasible candidates. The thermolabile variant of the methylenetetrahydrofolate reductase (MTHFR) gene has been associated with NTDs in some reports, and not associated in other reports. And, reports of heterozygote advantage in NTD cases have been suggested. We updated our original analysis of MTHFR in 65 families (Speer et al, 1997) by evaluating the 677C->T polymorphism in 145 American Caucasian sporadic NTD families in which the proband is affected with lumbosacral myelomeningocele. We found no evidence for 1). allele frequency differences between parents and controls; 2). allele frequency differences between cases and controls; 3). linkage disequilibrium in family triads; 4). maternal-fetal interaction; or 5). heterozygote advantage at MTHFR in these pedigrees (all p values > 0.05). When the 1298A->G polymorphism was considered independently and in tandem with the 677C->T polymorphism, the results are consistent, showing no evidence for involvement of MTHFR in these families. These data confirm our previous report of no association of lumbosacral myelomeningocele with MTHFR, suggesting that this gene does not play a major role in the development of NTDs in these families. Reported associations may be population-specific or mediated by environmental factors not relevant or common in our sample. Alternatively, associations with MTHFR may be dependent on level of lesion.

**Polymorphism Analysis of the human striatum-enriched CalDAG-GEFI gene with Japanese schizophrenia patients.** *H. Kawasaki<sup>1</sup>, H. Mitsuyasu<sup>1</sup>, N. Maeda<sup>1</sup>, T. Tahira<sup>2</sup>, H. Ninomiya<sup>3</sup>, Y. Fukumaki<sup>4</sup>, D.E. Housman<sup>5</sup>, A.M. Graybiel<sup>6</sup>, K. Hayashi<sup>2</sup>, N. Tashiro<sup>1</sup>.* 1) Dept Neuropsychiatry, Kyushu Univ, Fukuoka, Japan; 2) Div Genome Analysis, Res Ctr Genet Info, Med Inst Bioregulation, Kyushu Univ, Fukuoka, Japan; 3) Dazaifu Pref Hosp, Fukuoka, Japan; 4) Div Disease Genes, Res Ctr Genet Info, Med Inst Bioregulation, Kyushu Univ, Fukuoka, Japan; 5) Cent for Cancer Res, MIT, Cambridge, MA; 6) Dept Brain and Cognitive Sci, MIT, Cambridge, MA.

We previously reported the isolation of striatum-enriched novel guanine nucleotide exchange factor (GEF) that has both calcium (EF-hand) and diacylglycerol (DAG) binding domains (CalDAG-GEFI) and the presence of its ortholog, CalDAG-GEFII (identical to RasGRP, Ebinu et al., 1998). These genes are part of the novel second-messenger regulated GEF gene family whose GEF activities are regulated by the binding of second-messenger molecules such as cAMP, calcium and DAG. It is shown that CalDAG-GEFI proteins are localized at the synaptic terminals of GABAergic output neurons in the striatum (Kawasaki et al., 1998). Since the dysregulation of the striatal GABAergic output neurons are implicated in the pathophysiological mechanisms of schizophrenia, CalDAG-GEFI gene can be a good candidate for molecular studies of schizophrenia. All 17 exons of human CalDAG-GEFI were amplified by PCR to isolate single nucleotide polymorphisms (SNPs) using 12 Japanese individuals. Initial screening was by dHPLC, subsequently, the SNPs were evaluated by direct sequencing. As a result, total 5 SNPs including one previously reported were isolated. We have genotyped total 4 SNPs (2 newly isolated (IVS9(-92)A/Del and IVS10(+12)C/T), and 2 registered (IVS9(-44)C/T (rs556356) and IVS10(-43)C/T (rs553618)) in the schizophrenia patients (n=51) and normal controls (n=52) (Japanese population) to evaluate the association between schizophrenia phenotype and these markers. Direct sequencing and single nucleotide extension were employed as genotyping methods. No significant differences in the allele frequencies of the novel SNPs were found. Two other registered SNPs were monomorphic in the Japanese population.

**Polymorphism analysis of the human dopamine receptor (DRD4) gene with Japanese schizophrenia patients.** *H. Mitsuyasu<sup>1</sup>, H. Kawasaki<sup>1</sup>, N. Maeda<sup>1</sup>, A. Tahara<sup>1</sup>, Y. Matsuo<sup>1</sup>, T. Tahira<sup>2</sup>, H. Ninomiya<sup>3</sup>, Y. Fukumaki<sup>4</sup>, K. Hayashi<sup>2</sup>, N. Tashiro<sup>1</sup>. 1) Dept Neuropsychiatry, Kyushu Univ, Fukuoka, Japan; 2) Div Genome Analysis, Res Ctr Genet Info, Med Inst Bioregulation, Kyushu Univ, Fukuoka, Japan; 3) Dazaifu Pref Hosp, Fukuoka, Japan; 4) Div Disease Genes, Res Ctr Genet Info, Med Inst Bioregulation, Kyushu Univ, Fukuoka, Japan.*

The human dopamine D4 receptor (DRD4) gene is considered to be a good candidate for susceptible genetic components of schizophrenia, because an atypical antipsychotic drug, clozapine has a relatively high affinity to DRD4 (Van Tol et al., 1991), and elevation of the density of DRD4 and DRD4 mRNA expression were found in the postmortem brains of schizophrenia patients (Seeman et al., 1993, Stefanis et al., 1998). Many polymorphisms have been reported in the DRD4 gene locus. Previously we reported 9 novel single nucleotide polymorphisms (SNPs) in the upstream region of the DRD4 gene in the Japanese population (Mitsuyasu et al., 1999). We genotyped 5 SNPs in the region with 208 Japanese schizophrenia patients and 210 normal controls. (Mitsuyasu et al., 2001). We collected total 32 polymorphisms from a 4.9-kb region of entire DRD4 gene, which includes 27 SNPs and 5 other polymorphisms (repeat; 3, deletion; 2), based on our experiments, database, and published sources. Most of them were accumulated within approximately 1-kb area where exon 1 and the promoter region are located. Out of them, we genotyped 8 polymorphisms (tandem duplication; 1, known SNPs; 4, novel SNPs; 3) in the upstream region of the DRD4 gene with the Japanese schizophrenia patients (n=69-110) and normal controls (n=63-95) by PCR and direct sequencing method. We analyzed the association between schizophrenia patients and these polymorphisms by chi square test. Allele and genotype frequencies between the Japanese schizophrenia patients and normal controls were not significantly different. Genotyping of other polymorphisms of DRD4 gene is in progress.

**Linkage and association of the glutamate receptor 6 gene with autism.** *S. Jamain*<sup>1</sup>, *C. Betancur*<sup>2</sup>, *H. Quach*<sup>1</sup>, *A. Philippe*<sup>2</sup>, *M. Fellous*<sup>1</sup>, *B. Giros*<sup>2</sup>, *C. Gillberg*<sup>3</sup>, *M. Leboyer*<sup>2</sup>, *T. Bourgeron*<sup>1</sup>. 1) Immunology, Pasteur Institute, Paris, France; 2) INSERM U513, Faculte de Medecine de Creteil, 94000 Creteil, France; 3) Department of Child and Adolescent Psychiatry, Goteborg University, 41119 Goteborg, Sweden.

A genome scan was previously performed and pointed chromosome 6q21 as a candidate region for autism. This region contains the glutamate receptor 6 (GluR6 or GRIK2) gene, a functional candidate for the syndrome. Glutamate is the principal excitatory neurotransmitter in the brain and is directly involved in cognitive functions such as memory and learning. We used two different approaches, the affected sib-pair (ASP) method and the transmission disequilibrium test (TDT), to investigate the linkage and association between GluR6 and autism. The ASP method, conducted on 59 families, showed a significant excess of allele sharing, generating an elevated multipoint maximum LOD score (GENEHUNTER-PLUS NPL= 3.28; P = 0.0005). Using 107 additional families with a single affected child, a significant maternal transmission disequilibrium was observed (TDT linkage P = 0.0004). Furthermore, TDT (with only one affected proband per family) and Haplotype Relative Risk (HRR) analyses showed significant association between GluR6 and autism (TDT association P = 0.008; HRR P = 0.01). In contrast to maternal transmission, paternal transmission of GluR6 alleles was as expected in the absence of linkage, suggesting a maternal effect such as imprinting. Mutation screening was performed in 33 affected individuals, revealing several nucleotide polymorphisms (SNPs), including one amino acid change (M867I) found in 8% of the autistic subjects. This change takes place in a highly conserved domain of the protein and seems to be more maternally transmitted than expected to autistic males (P = 0.007). Taken together, these data suggest that GluR6 is in linkage disequilibrium with autism.

**QTL Association Analysis of the Dopamine D4 and Dopamine Transporter Genes in Adult ADHD. P.**

*Muglia*<sup>1,2</sup>, *U. Jain*<sup>2</sup>, *B. Inkster*<sup>1</sup>, *J.L. Kennedy*<sup>1</sup>. 1) Neurogenetics Section, CAMH, Department of Psychiatry, University of Toronto, Ontario, Canada; 2) Adult ADHD Clinic, CAMH.

Converging lines of evidence support a key role for the dopamine system in Attention Deficit Hyperactivity Disorder (ADHD). The genes for the dopamine D4 receptor and the dopamine transporter (DRD4 and SLC6A3) have been studied in a number of child ADHD samples. The 7-repeat alleles of the dopamine D4 receptor gene have been reported to increase the risk for ADHD in children while the investigation on the SLC6A3 3'UTR VNTR has shown less clear results. We investigated whether DRD4 and SLC6A3 alleles increase the risk for the variant of ADHD that persists in adulthood. We tested for the presence of association considering the Adult ADHD phenotype as a categorical and as a continuous trait as evaluated with the Brown Adult ADD scale. 153 Adult ADHD patients were studied (mean age: 37.69; S.D.+11.86; range: 19 to 69; 101/52 male female). We found evidence of association of the DRD4 7 alleles with Adult ADHD considered as a categorical phenotype (Chi-squared for genotype-wise TDT = 11.587814, 5 df, p = 0.041). No association was detected between either the DRD4 or the SLC6A3 when we performed a linear regression considering the risk alleles as the independent variable and the Total Brown scores, that measure ADHD core symptomatology as the independent variable. However the patients with the 7 repeat alleles have higher but not significant Brown total scores (means 86.02+ 22.10) when compared to patients without the 7 allele (mean = 82.42; t = 0.993; p = 0.32). Our results confirm that, as in child samples from other studies, the DRD4 7 is conferring a small risk in the adult variant of ADHD.

**Analysis of mutations in microtubule-associated protein tau (MAPT) gene in fronto-temporal dementia (FTD) in Japanese population.** *N. Maeda<sup>1</sup>, H. Kawasaki<sup>1</sup>, H. Mitsuyasu<sup>1</sup>, K. Ogomori<sup>1</sup>, M. Takita<sup>2</sup>, A. Tahara<sup>1</sup>, Y. Matsuo<sup>1</sup>, T. Tahira<sup>3</sup>, K. Hayashi<sup>3</sup>, N. Tashiro<sup>1</sup>.* 1) Dept Neuropsychiatry, Kyushu Univ, Fukuoka, Japan; 2) Dept Psychiatry, Imazu Red Cross Hosp, Fukuoka, Japan; 3) Div Genome Analysis, Res Ctr Genet Info, Med Inst Bioregulation, Kyushu Univ, Fukuoka, Japan.

Fronto-temporal dementia (FTD) is the second largest degenerative dementia group after Alzheimer's disease (AD). The symptoms of FTD are characterized by progressive personality and behavioral changes. However, memory and visual spatial orientation are preserved in relatively late stage in contrast to AD. It is shown that a positive familial aggregation can be observed in almost half of the FTD cases. It is also reported that approximately 10-40% of FTD cases with a positive family history are caused by mutations in the microtubule-associated protein tau (MAPT) gene. Exon and intronic mutations of MAPT gene result in several neurodegenerative disorders such as AD, Pick's disease, FTD, corticobasal degeneration and progressive supranuclear palsy. The different tau mutations may result in disturbances in the interactions of the protein tau with microtubules, resulting in hyperphosphorylation of tau protein, assembly into filaments, and subsequent cell death. So far, total 13 mutations which are responsible for FTD have been reported. In this study, we have collected DNA samples from 26 FTD in Japanese population. We have analyzed 13 reported mutations (1 mutation in exon9 (Gly272Val), 4 in exon 10 (Asn279Lys, D280, Pro301Leu and Ser305Asn), 1 in exon 12 (Val337Met), 2 in exon 13/14 (Gly389Arg and Arg406Trp) and 5 stem-loop mutations in intron 10 (+1G/A, +3G/A, +13A/G, +14C/T, +16C/T) of human MAPT gene in Japanese FTD patients (n = 7-14). Direct sequencing method was employed for this analysis. We found no reported mutations in the Japanese FTD samples. These results suggest that MAPT gene may not be involved in the pathophysiological mechanisms of FTD in Japanese population. Further investigation of mutations in the other exons and introns of MAPT gene is in progress.

**EXPRESSION OF DISC-1 AND ITS POSSIBLE FUNCTIONS: IMPLICATION FOR THE PATHOGENESIS OF SCHIZOPHRENIA.** *Y. Ozeki<sup>1,2</sup>, K. Fujii<sup>1</sup>, A. Kamiya<sup>1</sup>, H. Otsuki<sup>1</sup>, X. Luo<sup>2</sup>, N. Yamada<sup>1</sup>, R.L. Margolis<sup>2</sup>, M. Okawa<sup>1</sup>, S.H. Snyder<sup>2</sup>, C.A. Ross<sup>2</sup>, A. Sawa<sup>2</sup>.* 1) Psychiatry, Shiga Univ. of Med. Sci, Otsu, Shiga, Japan; 2) Dept. of Neuroscience and Psychiatry, Johns Hopkins Univ. Sch. of Med.

DISC-1 (Disrupted-In-Schizophrenia) is a transcript whose open reading frame is disrupted by a balanced chromosomal translocation in a large Scottish family. The chromosomal translocation is highly associated with major mental illnesses in the family, suggesting that DISC-1 may confer vulnerability to major mental illnesses, especially schizophrenia. In our preliminary in situ hybridization experiments in rat, we found high expression of DISC-1 messenger RNA in olfactory bulb, moderate expression of DISC-1 in hippocampus and cortex, and little in cerebellum. This could be consistent with a function in olfaction, limbic functioning, cognition, and memory, processes thought to be involved in schizophrenia. To evaluate protein expression of DISC-1, we have developed an antibody against DISC-1. Using the antibody, we have confirmed the existence of DISC-1 at protein level, which is enriched in olfactory bulb and hippocampus. To clarify its biological significance, we have initiated yeast-2-hybrid screening. Identification of DISC-1 interactors will help elucidate possible pathways in which DISC is involved, and hence may provide insight into the normal function of DISC-1. We have obtained several possible interactors of DISC-1, most of which belong to actin-associated cytoskeletal components. We hypothesize that DISC-1 and its interactors form a functional multiprotein complex beneath the plasma membrane, perhaps in conjunction with ion channels and receptors.

**WNT2 and Autism.** *T.H. Wassink<sup>1</sup>, J. Piven<sup>2</sup>, V.J. Vieland<sup>1,3</sup>, J. Juang<sup>4</sup>, R.E. Swiderski<sup>5</sup>, J. Pietila<sup>5</sup>, C.C. Searby<sup>5</sup>, T. Braun<sup>5,6</sup>, G. Beck<sup>5</sup>, S.E. Folstein<sup>7</sup>, J.L. Haines<sup>8</sup>, V.C. Sheffield<sup>5</sup>.* 1) Dept Psychiatry, University of Iowa College of Medicine; 2) Neurodevelopmental Disorders Research Center and Department of Psychiatry, University of North Carolina; 3) Department of Biostatistics, University of Iowa College of Public Health; 4) Department of Statistics and Actuarial Science, University of Iowa; 5) Department of Pediatrics and the Howard Hughes Medical Institute, University of Iowa College of Medicine; 6) Interdepartmental Genetics Ph.D. Program, University of Iowa; 7) Department of Psychiatry, Tufts University College of Medicine; 8) Program in Human Genetics, Vanderbilt Medical Center.

The WNT family of genes influence development, including development of the central nervous system. WNT2 is located in the 7q31-33 autism linkage region and is adjacent to an autism chromosomal breakpoint. A mouse knockout of Dvl1, (Dvl genes are essential for WNT functioning) exhibits a behavioral phenotype characterized primarily by diminished social interaction. We, therefore, screened WNT2 as an autism candidate gene. We identified two families containing non-conservative coding sequence variants that segregated with autism in those families. We also identified LD between a WNT2 3'UTR SNP and our sample of autism families. The LD arose almost exclusively from a subgroup of affected sibling pair families defined by the presence of severe language abnormalities, and was also found to be associated with the evidence for linkage to 7q from our previously published genome-wide linkage screen. Furthermore, expression analysis demonstrated WNT2 expression in the human thalamus. To follow up these preliminary findings, we have assessed the functional relevance of the WNT2 sequence variants in cell-based transfection assays. We have identified and genotyped more SNPs in and around WNT2 in order to further characterize the LD. We have also screened a number of genes related to WNT function, such as Frizzled-1 and Frizzled-9, as autism candidate genes. No coding sequence changes unique to autism have yet been found in these genes, though a number of polymorphisms useful for testing for LD have been identified.

**Distribution of Parkin gene mutations in subgroup of Parkinson's disease.** *A. Parsian*<sup>1</sup>, *B. Racette*<sup>2</sup>, *R. Sinha*<sup>1</sup>, *J. Perlmutter*<sup>2</sup>. 1) Birth Defects Center, Univ Louisville Hlth Sci Ctr, Louisville, KY; 2) Department of Neurology, Washington Univ, St. Louis, MO.

Mutations in parkin gene are major cause of autosomal recessive juvenile parkinsonism (AR-JP) but their role in idiopathic Parkinson's disease (PD) is not clear. There are only few reports that suggest a possible association between parkin mutations and early onset atypical PD, but there is no conclusive evidence in support of these findings. In order to evaluate the pathogenesis of parkin gene in subgroups of PD, we screened a sample of PD patients (N= 433) and normal controls (N= 110) with four most common mutations in different exons of the parkin gene. A total of 10 mutations in exon 4 and 2 in exon 7 in form of heterozygote were detected in PD group and none in controls. However, no mutation was observed in exons 6 and 8 in any group. There was no correlation between any mutation and family history or age of onset. We concluded that these mutations are not playing any critical role in the development of PD among our patients.

**The human SCA3 gene: Genomic organization and functional promoter analysis.** *I. Schmitt, B. Evert, H. Khazneh, T. Klockgether, U. Wuellner.* Neurology, University of Bonn, Bonn, Germany.

Spinocerebellar ataxia type 3 (SCA3) is a progressive neurodegenerative disorder caused by pathological expansion of a CAG motif within the translated region of the *SCA3* gene. Although a partial cDNA sequence has been known for about seven years molecular features of the genomic structure of the gene and the transcription start side are still unknown. Furthermore Northern blot studies indicate that 60% of the *SCA3* cDNA sequence (5' and 3' UTR) are missing.

We have analysed the genomic structure and identified the putative promoter region of the *SCA3* gene. 5'-RACE experiments and the comparison with the rat *SCA3* cDNA Sequence extended the known 5'-end of the human cDNA by 44 bp. 3'-RACE analysis lead to a complete *SCA3* cDNA sequence of about 6 kb. The gene consists of at least 11 exons and spans a region of about 47 kb. Analysis of a 1 kb DNA fragment at the 5'-flanking region of this gene revealed the presence of a TATA-less promoter containing GC-rich regions, a CCAAT and multiple potential Sp1 binding sites. Luciferase reporter assays performed in human and non-human cell lines demonstrated a promoter activity of this fragment in the lower range which is in accordance with the low RNA levels detected in previous expression studies. Subsequent 5' deletions of this fragment confined promoter elements to a 600 bp region upstream of the translational start side.

**Further evidence that genes outside of the folate-homocysteine metabolic axis influence neural tube development: the human *T* locus and spina bifida.** A.S. Whitehead, S. Barbaux, M. McDonnell, K. Hoess, L.E. Mitchell. University of Pennsylvania School of Medicine, Philadelphia, PA.

Studies establishing that prenatal folic acid supplementation can prevent up to 70% of all neural tube defects (NTD) have spurred interest in the relationship between genes involved in folate-homocysteine metabolism and NTD risk. However, not all NTD are prevented by folic acid, and animal data suggest that neural tube development is influenced by a variety of genes. The human *T* locus is an attractive candidate gene for NTD, since mutations in the mouse homologue (Brachyury) produce phenotypes similar to human spina bifida. Previous studies from Europe have provided evidence that the TIVS7 polymorphism of human *T* is associated with NTD risk. Specifically, the TIVS7-2 allele was found to be preferentially transmitted from heterozygous parents to their affected offspring. This finding has thus far not been confirmed in the U.S., but the single published study is based on a small sample. As the relative contribution of any gene to the overall risk of spina bifida is likely to vary across populations, it is essential that the role of this variant be determined in a contemporary U.S. sample. Consequently, the transmission disequilibrium test was used to evaluate the TIVS7 polymorphism in data from spina bifida family trios ascertained through two institutions in the Delaware Valley. Consistent with the European studies, the TIVS7-2 allele was transmitted in excess from heterozygous parents to affected offspring (28/46). In addition, these heterozygous parents transmitted the TIVS7-2 allele less frequently than expected to their unaffected offspring (12/32). The difference in the pattern of transmissions to affected and unaffected offspring was significant ( $P=0.04$ ). Relative to TIVS7-1 homozygotes, the risks to heterozygotes and TIVS7-2 homozygotes, were estimated to be increased by 1.4 and 2.5-fold, respectively. Hence, these data provide further evidence that the TIVS7 variant, or a variant with which it is in linkage disequilibrium, is a risk factor for spina bifida and help to refine our understanding of the "genetic architecture" of this condition.

**Association of a variation in the brain-derived neurotrophic factor (BDNF) gene with familial Parkinson's disease.** *R. Sinha*<sup>1</sup>, *B. Racette*<sup>2</sup>, *J.S. Perlmutter*<sup>2</sup>, *A. Parsian*<sup>1</sup>. 1) Birth Defects Center, Univ Louisville Hlth Sci Ctr, Louisville, KY; 2) Department of Neurology, Washington Univ, St. Louis, MO.

Idiopathic Parkinson's disease (PD) is one of the most common neurodegenerative disorders with the frequency of 1% in people over the age of 50 years. Most cases of PD are sporadic and only 20-25% have a positive family history with complex mode of inheritance. Brain-derived neurotrophic factor (BDNF) is one of the growth factors with dopaminergic activity. Intrathecal infusion of BDNF reduces loss of dopamine neurons and ameliorates parkinsonism in the MPTP treated monkey model of PD. In addition, it has been shown that BDNF has therapeutic effects on PD. To determine the role of BDNF gene in the development of familial and sporadic PD, we screened our sample with a variation (C270T) in the 5' non-coding region of the gene. The sample comprised of 170 patients with and 227 without a positive family history for PD and 196 matched controls. Comparison of the allele frequency between familial PD and normal controls was highly significant ( $p= 0.0002$ ) but not between sporadic PD and controls. Both PD groups were categorized based on age of onset (AON) of <30, <50, and >50 years. There was no significant difference between the three AON subtypes of PD in familial and sporadic groups. However, we identified two patients in AON of <30 and one in <50 years group who were homozygous for mutated allele. Our data indicate the possibility of linkage disequilibrium between this variation and a mutation in coding region of BDNF gene. Our results also indicate that BDNF plays a role in the development of familial PD that is consistent with the results of clinical and animal model studies.  $\leq$ .

**Neurological dysfunction in a mouse model of SCA7 is associated with proteolytic cleavage of polyglutamine-expanded ataxin-7.** *B.L. Sopher<sup>1</sup>, Y.H. Fu<sup>2</sup>, R.T. Libby<sup>1</sup>, Y. Kinoshita<sup>3</sup>, D.D. Einum<sup>4</sup>, J. Huang<sup>5</sup>, D.E. Possin<sup>5</sup>, R.S.*

*Morrison<sup>3</sup>, L.J. Ptacek<sup>4,6</sup>, A.R. La Spada<sup>1</sup>.* 1) Dept Lab Medicine, Univ Washington, Seattle, WA; 2) Dept Neurobiol & Anat, Univ Utah, Salt Lake City, UT; 3) Dept Neurosurg, Univ Washington, Seattle, WA; 4) Dept Human Genet, Univ Utah, Salt Lake City, UT; 5) Dept Ophthal, Univ Washington, Seattle, WA; 6) HHMI, Univ Utah, Salt Lake City, UT.

Spinocerebellar ataxia type 7 (SCA7) is an autosomal dominant disorder characterized by gait ataxia and retinal degeneration, and is caused by a CAG repeat expansion. To determine the mechanism of ataxin-7 polyglutamine neurotoxicity, we produced transgenic mice that express ataxin-7 with 24 or 92 glutamines using the murine prion protein promoter. After generating antibodies against human ataxin-7, we probed Western blots from the 92Q mice and identified an 130 kD band, confirming expression of full-length ataxin-7. IHC analysis indicates that ataxin-7 protein in the 92Q mice forms nuclear aggregates in neurons of the cortex and brainstem. Furthermore, the ataxin-7 transgene is expressed in the pontine nucleus, inferior olive, and cerebellar granule cell layer, all regions affected in patients. While breeding the 92Q mice, it soon became apparent that they display a neurological phenotype, presenting as an unsteady gait. The gait ataxia progressed until the mice start falling, become less explorative, and develop a chronic tremor. Such affected mice also show decreased survival. Based on RT-PCR analysis, the expression levels of the ataxin-7 92Q transgene are roughly twice that of endogenous murine ataxin-7. PrP-SCA7-c24Q transgenic mice with comparable expression levels, however, are asymptomatic. An intriguing feature of our SCA7 model is the presence of an N-terminal truncation fragment that migrates at ~ 55 kD on SDS-polyacrylamide gels and may be detected in 92Q mice with the 1C2 antibody. As ataxin-7 92Q aggregates do not immunostain with antibodies raised against the C-terminal region, our data suggest that proteolytic cleavage is occurring prior to ataxin-7 aggregation, and thus may be required for the neurotoxicity.

**Association of HOPA polymorphisms with Major Depression and Phobia.** *R.A. Philibert, K. Kaspers, D. Langbehn, E.P. Troughton, R. Yucuis, H.K. Sandhu, R.J. Cadoret.* Psychiatry Research/MEB, Iowa City, IA.

Thyroid hormone has a prominent role in the development and homeostasis of the Central Nervous System. Consequently, genes participating in thyroid hormone receptor mediated signal transduction are prime candidates for neuropsychiatric illness susceptibility factors. .Previously, we have associated exonic polymorphisms in a Xq13 thyroid receptor co-activator named HOPA with a modest increase in vulnerability to a broad spectrum of neuropsychiatric illness, including depression, psychosis and hypothyroidism. To test and extend these findings, we have now examined the relationship between HOPA polymorphisms and neuropsychiatric illness in a cohort of Iowa adoptees. Consistent with our prior findings, HOPA polymorphisms were associated with an increased risk for major depression as well as phobic conditions. There was suggestive evidence that the increased psychiatric morbidity in these subjects could represent epistasis: e.g., an interaction between the HOPA variant and a genetic diathesis for another psychiatric condition such as biologic parent antisocial behavior. Since thyroid function tests were not available on these subjects, used obesity as a surrogate for hypothyroidism. Interesting, HOPA polymorphism were associated with a marked increased risk for obesity. We conclude that HOPA polymorphisms may be a moderate risk factor for increased susceptibility to a broad spectrum of neuropsychiatric illness and hypothesize that the type of illness manifested might be related to a separate genetic diathesis. Further studies are needed to better define the syndrome associated with HOPA polymorphisms and the molecular mechanisms through which they occur. To this end, a larger adoptee sample would allow an answer to the question of interactions between genetic diatheses for psychopathology and HOPA variant, and also allow testing of gene-environment interactions to control for psychiatric outcomes which better reflect the genotype.

**Candidate gene screening on Japanese autism patients.** *T. Yamagata*<sup>1</sup>, *H. Li*<sup>1</sup>, *M. Mori*<sup>1</sup>, *K. Suwa*<sup>1</sup>, *A. Yasuhara*<sup>2</sup>, *M.Y. Momoi*<sup>1</sup>. 1) Department of Pediatrics, Jichi Medical School, Minamikawachi, Tochigi, Japan; 2) Department of Pediatrics, Kouri Hospital, Kansai Medical University, Neyagawa, Osaka, Japan.

Several candidate genes were analyzed for possible causative mutations among autistic children in Japanese patients using their DNA from lymphoblastoid cells. Patients diagnosed as pervasive developmental disorder or autism according to the criteria of DSM-IV were enrolled in this study after the informed consents by their parents. Up to one hundred autistic patients were enrolled. The genes studied included those of peptide hormones and their G-protein-coupled receptors, such as secretin and gastrin releasing peptide receptor (GRPR), and methylation-related genes, such as MeCP2, MBD1, MBD2 and MBD3. All exons and promoter regions of these genes were amplified by PCR and the mutation was screened by DHPLC, and finally confirmed by direct sequencing. We previously reported the base changes in E-box and GC-box, and two missense mutations in secretin gene screening on autism patients. This time we increased the patients including six patients who responded to secretin treatment. No causative mutation was detected in secretin gene on newly involved patients even in the patients who responded to the treatment with secretin. And also no causative mutation was detected in GRPR. We found two missense mutations and some base changes in introns near the exons in MECP2, but they were considered as polymorphism. There were some base changes in MBD1, MBD2 and MBD3 but we could not confirm their contribution to the disease. The fact that no causative mutations were detected on secretin gene in the patients who responded to secretin treatment suggested the involvement of the secretin receptor or the processes of intracellular signal transduction after secretin binding can be responsible for the development of their autism. The methylation-related genes were highly polymorphic. We need to analyze these genes further to clarify the contribution to autism.

**Identification of a functional variant in the NMDAR1 receptor subunit resulting in altered effects of ethanol.** *J.G.*

*Rudolph*<sup>1</sup>, *R.H. Lipsky*<sup>2</sup>, *R. Peoples*<sup>2</sup>. 1) Applied Genomics and Molecular, Transgenomic Inc., Gaithersburg, MD; 2) NIAAA, National Institutes of Health, Rockville, MD.

The N-methyl-D-aspartate (NMDA) receptors are perhaps the most well understood subtype of excitatory amino acid receptors. These receptors play crucial roles in physiological processes such as synaptogenesis and neuronal plasticity. Dysfunctions of NMDA receptors seem to play a crucial role in the neurobiology of disorders including Parkinson's disease, Alzheimer's disease, epilepsy, and ischemic stroke. NMDA receptor function may also be pivotal to the pathophysiology of addictive behaviors, including alcoholism. We have undertaken a project to discover functional polymorphisms in NMDA receptors. Denaturing high performance liquid chromatography (dHPLC) was used to identify candidate sequence variants in PCR amplified products obtained from a panel of genomic DNAs from 500 unrelated individuals of diverse clinical and ethnic background. DNA sequence variants were confirmed by direct sequencing of PCR products and in some cases, by RFLP analysis. Using this approach, we identified seven gene variants in NR1 and NR2B. One of which resulted in an amino acid change. All of the variants were previously unidentified. The gene variant 8396G>A resulted in a cyctine to tyrosine substitution at position 744. When expressed in human embryonic kidney cells with the native NR2A subunit, this receptor variant demonstrated significant alterations in electrophysiology, in terms of the effects of ethanol upon the receptor. Significant functional changes such as these could result in the predisposition of an individual to alcohol abuse.

**Neurodegeneration and mild gait abnormalities in Huntington's disease knock-in mice.** *V.C. Wheeler<sup>1</sup>, C.-A. Gutekunst<sup>2</sup>, V. Vrbancac<sup>1</sup>, L. Lebel<sup>1</sup>, J.-P. Vonsattel<sup>3</sup>, J.F. Gusella<sup>1</sup>, M.E. MacDonald<sup>1</sup>.* 1) Molecular Neurogenetics Unit, Massachusetts General Hospital, Charlestown, MA; 2) Department of Neurology, Emory University School of Medicine, Atlanta, GA; 3) Division of Neuropathology, College of Physicians and Surgeons of Columbia University, New York, NY.

Huntington's disease (HD) is an autosomal dominant, neurodegenerative disorder. The expansion of a CAG repeat in the HD gene produces an elongated glutamine tract in the huntingtin protein, which, through an unknown mechanism results in the loss of medium spiny neurons in the striatum.

We have generated precise genetic mouse models of HD by inserting expanded CAG repeats into the homologous mouse (*Hdh*) locus. Mice expressing mutant huntingtin containing 92 and 111 glutamine repeats (*HdhQ92* and *HdhQ111*) show a progressive cellular phenotype. This phenotype is glutamine length-dependent, dominantly inherited and selective for medium-spiny striatal neurons, providing strong evidence that the underlying process is important in HD pathogenesis.

We have investigated the role played by wild-type huntingtin by examining the cellular phenotype in hemizygous *HdhQ111/Hdhex4/5* or *HdhQ92/Hdhex4/5* mice expressing one copy of mutant huntingtin but no wild-type huntingtin. No difference was found between hemizygous and heterozygous mice demonstrating that this phenotype is neither slowed nor accelerated by wild-type huntingtin.

At two years of age *HdhQ111* mice show striatal neurodegeneration, increased immunoreactivity to glial fibrillary acidic protein and a subtle gait abnormality. These findings support the idea that the *Hdh* knock-in mice, at younger ages, are equivalent to presymptomatic HD gene carriers, in whom pathogenic processes are underway, but who have yet to display overt clinical symptoms. Therefore, the mice provide a resource to understand the early cellular changes attributable to mutant huntingtin that will eventually lead to cell death, and to test drugs which may act in these early pathways.

**Genetic analysis of Chromosome X in migraine families.** *T. Wieser*<sup>1, 2</sup>, *J. Pascual*<sup>3</sup>, *M. Barmada*<sup>1</sup>, *M. Soso*<sup>1</sup>, *A. Oterino*<sup>3</sup>, *K. Gardner*<sup>1,4</sup>. 1) Neurology, Human Genetics, University of Pittsburgh, Pittsburgh, PA; 2) Neurology, Martin-Luther University of Halle, Germany; 3) Neurology, University Marques de Valdecilla, Spain; 4) Veterans Administration Medical Center, Pittsburgh, PA.

**Objective:** Investigate 66 families with migraine and possible X dominant inheritance for evidence of allele sharing, linkage to Chromosome X. **Background:** Familial clustering of migraine is recognized but the disorder is thought to be genetically complex since it does not consistently follow Mendelian inheritance patterns. We previously recognized a paternal bias for transmission of migraine to daughters by segregation analysis of 60 families. Others have proposed that female predominance for migraine is not entirely attributed to hormonal factors. An X-linked dominant component and locus at Xq24-28 has been suggested for familial migraine. **Methods:** We screened the entire X chromosome in 66 families diagnosed according to IHS criteria. Families with possible male to male transmission were excluded (five). Eighteen markers (ABI PRISM Mapping Set, Panel 28) spanning the entire X chromosome spaced 10cM apart were genotyped using a 3700 ABI PRISM DNA Analyser. Alleles were assigned using the GeneScan Analysis software. Analysis for affected relative allele sharing and linkage was performed using ALLEGRO, VITESSE 1.1 programs and the maximized maximum LOD score (MMLS) method with a variety of allele frequencies, phenocopy rates, penetrances. **Results:** Eighty multi-generational families and 14 sibships were ascertained from Spain (27), Germany (18) and America (35) among 478 total samples. One hundred and fifty-five had migraine without aura, 101 migraine with aura, 32 hemiplegic migraine, and 44 were of uncertain type (IHS 1.7). Linkage analysis of 66 families, all forms of migraine showed combined LOD 1.53, theta 0 at marker DXS8051, Xp22.22 using dominant model, 80% penetrance, 5% phenocopy rate, 20% allele frequency. **Conclusion:** Our results suggest further analysis of this region and Chromosome X is warranted for identification of migraine susceptibility loci. This study was supported by the AHS/Pfizer (KG), AHA(KG), Martin -Luther Univ of Halle, Germany (TW), Foundation Marques de Valdecilla (JP).

**Murine KvDMR1, a putative imprinting control region, exhibits enhancer-blocking activity in a soft agar colony forming assay.** *M.J. Higgins, G.V. Fitzpatrick.* Department of Cancer Genetics, Roswell Park Cancer Inst, Buffalo, NY.

The finding that imprinted genes are often clustered in large imprinted domains implies that the mono-allelic expression of these genes could be regulated by shared cis-acting DNA sequence(s). The best candidates for such regulatory elements are differentially methylated CpG islands characteristic of imprinted genes. The 1 Mb imprinted domain on mouse distal chromosome 7 (human 11p15.5) consists of at least eight imprinted genes. The differentially methylated region (DMR) located between *Igf2* and *H19* has been shown to play a role of an imprinting control region (ICR) as it is important for the proper imprinting of both genes. This ICR functions as a chromatin insulator that, when unmethylated, blocks communication between *Igf2* and its enhancers. Interestingly, the deletion of *Igf2/H19* ICR does not affect imprinting of the genes upstream of *Ins*, suggesting that there must be an additional ICR in the domain. We have shown that targeted deletion of KvDMR1, a differentially methylated CpG island within the *Kcnq1* gene, in mouse resulted in the loss of imprinting of several distal chromosome 7 genes (Fitzpatrick et al, this meeting). To address the possible mechanisms by which KvDMR1 normally suppresses the genes on paternally inherited chromosome, this element was tested for enhancer-blocking activity in a soft agar colony-forming assay using stably integrated constructs. A 3.5 kb DNA sequence containing KvDMR1 was sub-cloned (in different orientations) between the Ed enhancer and the Vd1 promoter fused to the neo gene (both the enhancer and the promoter are from human TCR locus), or upstream of the enhancer. We found that when KvDMR1 was placed between the promoter and the enhancer, the number of neo-resistant colonies was reduced by 95% compared to the control. This effect was dependent on the orientation of KvDMR1 relative to the promoter. Positioning KvDMR1 upstream of the enhancer did not suppress the number of colonies. These results are consistent with KvDMR1 being an insulator rather than a silencer. The possible cause of the orientation-dependent effect of the KvDMR1 insulation is being investigated. Funded by NIH/NCI Grant CA63333.

**Monozygotic twins discordant for Beckwith-Wiedemann syndrome also have different patterns of KvDMR1 methylation and KCNQ10T1 allelic transcription in the chromosome 11p15 imprinted region.** *R. Weksberg<sup>1</sup>, J. Nishikawa<sup>1</sup>, Y. Fei<sup>1</sup>, C. Shuman<sup>1</sup>, T. Stockley<sup>4</sup>, L. Best<sup>5</sup>, D. Chitayat<sup>1</sup>, J. Cameron<sup>1</sup>, M. Li<sup>1</sup>, P. Sadowski<sup>2</sup>, J. Squire<sup>3</sup>.* 1) Hospital for Sick Children & Division of Metabolic & Clinical Genetics and Department of Paediatrics; 2) Molecular & Medical Genetics, University of Toronto; 3) Ontario Cancer Institute & Departments of Laboratory Medicine, Pathobiology, & Medical Biophysics, University of Toronto; 4) Hospital for Sick Children, Departments of Paediatric Laboratory Medicine and Molecular & Medical Genetics, University of Toronto; 5) University of North Dakota.

An intriguing aspect of the Beckwith-Wiedemann syndrome (BWS), a disorder of growth regulation and tumor predisposition, is the apparent excess of female monozygotic (MZ) twins discordant for this syndrome. Less frequently, discordant male MZ twin pairs are reported. BWS is associated with a variety of genetic and epigenetic alterations of imprinted genes on human chromosome 11p15.5. These alterations include paternal uniparental disomy, and imprinting defects at KvDMR1/KCNQ10T1. Mechanisms to explain discordance in BWS MZ twin pairs include postzygotic events leading to skewed X inactivation or epigenetic changes such as, paternal 11p15 UPD in the affected twin only. In our study of KCNQ10T1 transcription and KvDMR1 methylation in monozygotic twins discordant for BWS, we were able to assess lymphoblasts from 10 twin pairs (9 female, 1 male), all of which showed alterations in KvDMR1 methylation and/ or KCNQ10T1 allelic transcription. Given that MZ twin pairs may share their fetal circulation, we also examined fibroblasts available from 5 twin pairs (4 female, 1 male), and showed that in each pair, the affected twin exhibited loss of maternal methylation at KvDMR1 and/or biallelic expression of KCNQ10T1, whereas the unaffected twin maintained normal methylation of KvDMR1 and monoallelic expression of KCNQ10T1. This consistent difference in KvDMR1/KCNQ10T1 status in these twin pairs suggests that there may be a relationship between postzygotic epigenetic alteration in the imprinted 11p15 region and monozygotic twinning. Studies of X inactivation are underway.

**Association of Tetralogy of Fallot with a distinct region of del22q11.2.** A. Frisch<sup>1,4</sup>, E. Birk<sup>2,4</sup>, A.Y. Weintraub<sup>1,4</sup>, Y. Barhum<sup>1,4</sup>, V. Kotlyar<sup>1,4</sup>, H. Schlesinger<sup>1,4</sup>, R. Rockah<sup>1,4</sup>, B.A. Vidne<sup>3,4</sup>, G. Kessler-Icekson<sup>1,4</sup>. 1) Felsenstein Medical Research C, Tel Aviv University, Petah Tikva, Petah-Tikva, Israel; 2) Pediatric Cardiology, Schneider Childrens Medical Center of Israel; 3) Cardiothoracic Surgery, Beilinson Hospital; 4) Rabin Medical Center, Petach-Tikva, Israel.

Congenital heart defects (CHD) appear in greater frequency among relatives of patients and in individuals with DiGeorge and velo-cardio-facial syndromes (DGS/VCFS). A majority of DGS/VCFS patients and part of the patients with conotruncal heart defects manifest hemizygous deletions within chromosome 22q11.2 (del22q11). We tested the frequency of del22q11 in myocardial tissues of 31 CHD patients, 21 with Tetralogy of Fallot (TOF) and 10 with double chamber right ventricle (DCRV). DNA isolated from tissues removed at corrective surgery was analyzed for homo- or heterozygosity of 9 polymorphic short tandem repeat markers along the 22q11.2 region. DNA from the blood of 45 healthy individuals represented the general population. Homozygosity for 3 consecutive markers was considered an indication for hemizyosity and deletion. Ten out of the 21 TOF patients (48%) showed an indication for deletions of various sizes. No such indication was found for DCRV patients. Heterozygosity for markers D22S1648, D22S941, D22S944 was lower in the TOF group compared with normal controls defining a minimal critical region for the deletion. Our findings support an association between TOF and hemizyosity in 22q11.2, suggesting a distinct region, between markers D22S1638 and COMT, that may harbor TOF susceptibility genes.

**Variations In COL6A1 Coding Region And Congenital Heart Defects In Down Syndrome.** *U.L. Fairbrother, M.J. Baptista, G.E. Davies, D. Trikka, A.M. Kessling.* Medical and Community Genetics, Imperial College, London, Middex, UK.

The pathology of free trisomy 21 cannot ensue simply from overexpression since all individuals with Down Syndrome (DS) do not have a congenital heart defects (CHD). Phenotypic variation is likely to be related to specific alleles, and their protein products, which function well in the diploid but not in the trisomic state. Genetic studies, using RFLP analysis, have implicated the COL6A1-A2 gene cluster at 21q22.3 in CHDs through genotype and haplotype analysis. Notably, in partial trisomy and individuals with DS and a CHD, COL6AI has never been excluded from a causal role. COL6A1 has 36 exons, 30 of which have been screened by single stranded conformational polymorphism (SSCP) analysis in 97 families, including grandparents, parents, individuals with DS with and without CHDs and siblings. Of the individuals with DS, 19 had complete AV canal defect or atrioventricular septal defect (AVSD), 11 had ventricular septal defect (VSD), 5 had atrial septal defect (ASD), 4 had ASD and VSD, 3 had tetralogy of Fallot (ToF), 3 had AVSD and ToF and 4 had other defects. We have shown, for the first time, that there is a higher than expected level of variation in the COL6A1 coding region. In all, 22 variable amplicons have been identified. Mutations have been detected in exons encoding the N-terminal and triple-helical (TH) region, with the most variable region being in exons encoding the C-terminal globular region of collagen VI  $\alpha 1$  chain. We have identified a G to T donor splice site mutation in the triple helical exon 6 which would lead to the addition of 17 amino acids and then premature truncation of the protein product. A parent is heterozygous for this mutation whereas a child, who has received two copies, has AVSD. Alteration and truncation of the TH domain is likely to interfere with helix formation and mutations in the C-ter globular domain will affect chain-chain recognition. We hypothesise that combinations of mutations embedded in particular COL6A1 haplotypes, in trisomic individuals, disturb the supramolecular structure of collagen VI and modulate the predisposition of an individual with DS to a single or several types of CHD.

**Analysis of genetic polymorphisms in the TGFb1, CYP11B2, APOE and AT1R genes in the pathogenesis of acute myocardial infarction at young age and their prognostic role.** S. Carturan<sup>1</sup>, S. Guarrera<sup>1</sup>, A. Gagnor<sup>2</sup>, C. Rolfo<sup>2</sup>, C. Di Gaetano<sup>1</sup>, A. Piazza<sup>1</sup>, GP. Trevi<sup>2</sup>, S. Bergerone<sup>2</sup>, G. Matullo<sup>1</sup>. 1) Dip. Genetica, Biol e Bioch, Università di Torino, Torino, Italy; 2) Divisione di Cardiologia Universitaria, Torino, Italy.

The aim of our study is to evaluate the role both as predisposing and/or prognostic determinants of IMA of polymorphisms in the following genes: Transforming Growth Factor b1 (TGFb1), Aldosterone Synthase (CYP11B2), Apolipoprotein E (Apo E) and Angiotensin I Type 1 Receptor (AT1R). We genotyped a large cohort of subjects with IMA occurred at age <45 years (174 cases, 90.2% males, mean age 39 years) and healthy controls matched by age and sex. Among cases, a subset of 94 patients with follow-up >4 years (mean=7.27±3.31) has been selected to investigate the role of the polymorphisms in the post-IMA decourse: 47 cases had a second or more events (9 re-IMA, 23 PTCA, 20 CABG, 4 deaths). A statistically significant association has been found between IMA at young age and CAD familiarity (p<0.001), smoking (p<0.001), hypercholesterolemia (p=0.026), hypertriglyceridemia (p<0.001) and hypertension (p<0.001). The prevalence of the CC genotype of CYP11B2 gene was 28.7% in the cases vs 17.2% in controls (p=0.040, OR=1.56 95%CI 1.10-2.20); the prevalence of the GG genotype of TGFb1 gene was 28.1% in the cases vs 12.8% in controls (p=0.002, OR=1.94 95%CI 1.33-2.81). In the >4 years follow-up group, a statistically significant increase in the frequency of the Apo E e4 allele has been found among the cases who experienced a second event (e4 carriers vs non-e4 p=0.020, OR=3.59 95%CI 1.40-9.19). A significant increase in the frequency of the C allele of AT1R gene has also been observed in the same group (AC+CC vs AA p=0.017, OR=2.75 95%CI 1.36-5.56). No significant association has been found between CYP11B2 and TGFb1 polymorphisms and a worst prognosis. Our results suggest that the GG genotype of TGFb1 gene and the CC genotype of CYP11B2 gene should be regarded as risk factors for the occurrence of IMA at young age, while the presence of the Apo E e4 allele or AT1R C allele may be associated to a worst prognosis after IMA has occurred.

**Gene Expressions in Apoptosis pathways under Hypothermia conditions can reverse Pathophysiological process of Rabbit Myocardial ischemia.** *S.-H. Chen<sup>1,2</sup>, X.-H. Ning<sup>1,2</sup>, M.A. Portman<sup>1,2</sup>*. 1) Department of Pediatrics, University of Washington, Seattle, WA; 2) Children's Hospital and Regional Medical Center, Seattle, WA.

Functional deterioration of a heart is evident during myocardial ischemia, and can apparently be reversed by hypothermia (<30° C) treatment. The molecular mechanism of this reversal is unknown. We have chosen an isolated heart model to study gene expression under ischemic and hypothermic conditions. Twenty-nine rabbit hearts were divided into a control group (N, n=5), an ischemic group (I, n=12) and a hypothermia group (H, n=12). Functional parameters of the experimental hearts were measured by left ventricular developed pressure (DP), the product of DP and heart rate (PRP), the maximum of the first derivative of DP (dP/dtmax), coronary flow (CF) and oxygen consumption (MVO<sub>2</sub>). Hearts in the hypothermia group showed significant improvement over the ischemic group, after 45 min of re-perfusion. Recovery rates were 37±4 (DP), 32±4 (dP/dtmax), 33±4 (PRP), 57±4 (CF), and 41±4 (MVO<sub>2</sub>) for the I group, and 89±3, 94±4, 88, 92±6, and 92±4 for the H group. Analyses of cDNA Arrays (Clontech Laboratory Inc. and Super Array Inc) identified 14 genes that showed significant changes in expression (greater than 2 to less than 0.5 fold) in the hypothermia group compared to the ischemic or control group. Seven of the 14 genes were related to apoptosis pathways: Tumor suppressor and apoptosis gene (p53), Growth-arrest and DNA damage-inducible transcript 1 (GADD45), caspase 10 (mch4), p21, mad3, bak and bcl-x. Expression of the major apoptosis gene p53 was further investigated by a quantitative RT-PCR method. In the ischemic heart, p53 expression was found to increase 4.7 fold and in the hypothermic heart, p53 expression was about 0.7 fold of the controls. Change in gene expression in the hypothermic group was always accompanied by an excellent functional recovery of the heart. This data indicates that under ischemic condition, hypothermia is protective of myocardial damage by preventing over-expression of key apoptosis genes.

**Genetic susceptibility to preeclampsia: evaluation of eNos , TGFB3, and AGT mutations.** *D.M. Caprau<sup>1</sup>, J.C. Murray<sup>1</sup>, H.L. Mertz<sup>2</sup>, Y. Kim<sup>1</sup>, D.C. Merrill<sup>2</sup>.* 1) Dept of Pediatrics University of Iowa, Iowa City, IA; 2) Wake Forest University, Winston-Salem, NC.

Genetic Susceptibility to Preeclampsia: Evaluation of NOS, TGFB3, and AGT Mutations. D. Caprau, J.C. Murray, H.L. Mertz, Y. Kim, D.C. Merrill Objective: Previous studies have suggested an association of preeclampsia (PRE) with several genes involved in cardiovascular control. The objective of this study was to evaluate the association between PRE and allelic variants of eNOS, TGFB3 and Angiotensinogen (AGT) genes in Caucasian women. Methods: Samples were extracted from whole blood or buccal cells of preeclamptic patients and controls. PRE was diagnosed using standard criteria (new onset hypertension and proteinuria). Controls (CON) consisted of women who had undergone at least two term pregnancies unaffected by PRE. All samples were genotyped for each polymorphism using PCR followed by SSCP analysis. Results: The 27 bp repeat intron four of eNOS was typed in 1,001 samples (680 controls and 321 cases). Heterozygous and homozygous carriers of the eNOS 27 bp repeat mutation were observed with similar frequencies in CON and PRE subjects (homozygous: CON=2.8%; PRE=2.8%; heterozygous: CON=23.4%; PRE=22.4%,  $p=0.94$ ). For TGFB3, the CA repeat at 14q24 was analyzed on 713 samples (299 cases and 414 controls). No significant association between PRE and this loci was observed ( $p=0.28$ ). Five hundred sixty-three samples (272 controls and 291 cases) were genotyped for the A(-6)G mutation of the AGT gene. 5 of 272 (1.8%) of controls versus 13 of 291 (4.5%) of PRE subjects were homozygous for this mutation ( $p=0.0764$ ). Overall 85 of 272 (31.3%) of CON versus 112 of 291 (38.5%) of PRE subjects were carriers of this mutation ( $p=0.072$ ). Conclusion: These data suggest a possible association of a mutation in the AGT gene and susceptibility to PRE. Further sample analysis is underway to confirm these preliminary results.

**Variable Cardiac Phenotypes in Chromosome 4q- Syndrome with dHAND Deletion.** *T. Huang*<sup>1</sup>, *S. Weremowicz*<sup>2</sup>, *G. Cox*<sup>1</sup>, *A.E. Lin*<sup>3</sup>, *W. Golden*<sup>4</sup>, *G.L. Feldman*<sup>5</sup>, *S. Vermeulen*<sup>6</sup>, *U. Moog*<sup>7</sup>, *C. Schrandt-Stumpel*<sup>7</sup>, *C.C. Morton*<sup>2</sup>, *J.G. Seidman*<sup>8</sup>, *C.E. Seidman*<sup>9</sup>. 1) Div of Gen/Harvard Med School, Children's Hospital, Boston, MA; 2) Departments of Pathology and Obstetrics, Gynecology and Reproductive Biology Brigham and Womens Hospital, Boston; 3) Teratology Program, The Brigham and Womens Hospital; 4) Division of Genetics, University of Virginia, Charlottesville; 5) Department of Medical Genetics, Henry Ford Hospital, Detroit, Michigan; 6) Centrum Medische Genetica, UZG-K5, De Pintelaan; 7) Department of Clinical Genetics University of Limburg; 8) Department of Genetics, Howard Hughes Medical Institute, Harvard Medical School; 9) Department of Cardiology, The Brigham and Womens Hospital, Howard Hughes Medical Institute, Boston.

Terminal deletions of chromosome 4q are commonly associated with cardiovascular malformations (CVMs). The dHAND gene, a basic helix-loop-helix transcription factor expressed in the developing heart, has been mapped to 4q33. A targeted deletion mouse showed that dHAND plays an important role in heart development. To examine the association of dHAND haploinsufficiency with the CVMs which occur in some patients with 4q terminal deletions, we performed fluorescence in situ hybridization (FISH) with a dHAND genomic probe on 5 patients. Of the three with a deletion of the dHAND locus, two had a CVM (both valvar pulmonic stenosis). Of the two patients without a deletion of the dHAND gene, one had a small atrial septal defect noted on autopsy. In this small series of terminal 4q deletions, haploinsufficiency of the dHAND seems not to correlate well with a CVM. This may be explained by low penetrance of the d-HAND gene or other factor(s) which contribute to the development of the CVMs.

**Molecular characterization of deletions, mutations and meiotic recombination within the genomic region 22q11 in patients with congenital heart defects.** *J. Rosell<sup>1,3</sup>, L. Torres-Juan<sup>1</sup>, N. Govea<sup>1</sup>, M.A. de la Fuente<sup>2</sup>, F. García-Algas<sup>2</sup>, D. Heine-Suñer<sup>1,3</sup>.* 1) Genetics Department, University Hospital Son Dureta, Palma de Mallorca, Balearic Islands, Spain; 2) Paediatrics Department, University Hospital Son Dureta, Palma de Mallorca, Balearic Islands, Spain; 3) Biology Department, University of the Balearic Islands, Palma de Mallorca, Balearic Islands, Spain.

De novo deletions in the 22q11 genomic region have an estimated prevalence at birth of 1/600-1/4000 according to different authors. Most patients have the same 3 Mb deletion but show a complex and variable phenotype that ranges from a DiGeorge syndrome to isolated congenital heart disease. There are two not completely solved issues in this complex disease: 1) is the absence of genotype-phenotype correlation and 2) what are the molecular mechanisms that result in such a high incidence of de novo deletions. To try and answer such questions in an unbiased manner we have performed FISH analysis on patients with conotruncal heart defects (the most frequent clinical feature found in patients with the 22q11 deletion, 75%). Such analysis detected deletions in 8/55 subjects (14.5%), which is similar to that reported in other studies. We then used 17 polymorphic markers to further characterise these deletions and detect other atypical deletions by loss of heterozygosity. Such analysis determined that most patients carried the typical 3 Mb deletions and that these had originated de novo. We also found that 4 deletions affect the maternal chromosome and 1 the paternal chromosome. Recently, mutations in the *Tbx1* gene which maps to the 22q11 region, have been shown to cause conotruncal heart defects in mice. SSCP analysis of this gene in non-deleted patients has been unsuccessful so far in detecting any mutations. Phenotype-genotype correlation has also been examined in an effort to delineate clinical differences that may distinguish deleted and non-deleted patients. Finally, we have constructed a high resolution genetic map that outlines the recombinational characteristics of the 22q11 region and which may help explain the high rate of deletions observed in this disease.

**Family based investigation of the role of a polymorphism in the paraoxonase (PON) 1 gene in ischaemic heart disease (IHD).** *M.S. Spence<sup>1</sup>, P.G. McGlinchey<sup>1</sup>, C. Patterson<sup>2</sup>, C. Belton<sup>3</sup>, G. Murphy<sup>1</sup>, D. McMaster<sup>3</sup>, D. Fogarty<sup>4</sup>, P.P. McKeown<sup>1, 3</sup>.* 1) Regional Medical Cardiology Centre, Royal Victoria Hospital, Belfast, Northern Ireland, UK; 2) Department of Epidemiology and Public Health, Queen's University, Belfast; 3) Department of Medicine, Queen's University, Belfast; 4) Antrim Area Hospital, Northern Ireland.

**Background:** IHD is a complex phenotype arising from the interaction of genetic and environmental factors. Oxidative modification of low-density lipoprotein (LDL) is currently thought to be central to the pathogenesis of IHD. Paraoxonase (PON1) is an HDL associated enzyme that protects LDL from oxidative modification. A polymorphism at codon 192 of the PON1 gene results in a glutamine (Q) to arginine (R) substitution and is associated with altered paraoxonase activity. Several, but not all case-control studies have implicated this polymorphism with the risk of IHD. Given these conflicting results we have used a family based association test to investigate the presence of linkage disequilibrium between the codon 192 PON1 polymorphism and IHD in a well-defined Irish population.

**Methods:** A total of 157 families were recruited (418 individuals). The presence of linkage disequilibrium between the codon 192 PON1 polymorphism and IHD was investigated using the combined transmission disequilibrium test (TDT) / sib TDT. This test is unaffected by population admixture and was specifically designed for the investigation of complex diseases. Only one discordant sibship or trio was included from each family to ensure the analysis was a valid test of association. We tested for excess transmission of the Q or R allele to affected individuals.

**Results:** 50 of 134 discordant sibships and 20 of 25 trios (proband and both parents) were informative for the analysis. There was no statistically significant excess transmission of either allele to affected individuals, ( $p=0.60$ ).

**Conclusion:** using a recently developed family-based association test we found no evidence that the codon 192 polymorphism in the PON1 gene is associated with IHD, in our study population.

**Evidence that interaction occurs among genes regulating plasma levels of apolipoprotein A2.** *L.J. Raffel<sup>1,2</sup>, L.W. Castellani<sup>2</sup>, L.S-C. Cheng<sup>1,2</sup>, R.C. Davis<sup>2</sup>, M. Quinones<sup>2</sup>, A.H. Xiang<sup>3</sup>, P-Z. Wen<sup>2</sup>, J. Diaz<sup>3</sup>, W.A. Hsueh<sup>2</sup>, T.A. Buchanan<sup>3</sup>, J.I. Rotter<sup>1,2</sup>.* 1) Cedars-Sinai Medical Ctr, Los Angeles, CA; 2) UCLA School of Medicine, Los Angeles, CA; 3) USC Keck School of Medicine, Los Angeles, CA.

Apolipoprotein A2 (ApoA2) is the second most abundant protein present in HDL. While elevated plasma ApoA2 levels are associated with obesity, diabetes and increased plasma free fatty acids, no mechanism for this association is apparent. Transgenic animal studies have shown that elevated ApoA2 increases weight, plasma free fatty acids, leptin, and insulin.

As part of a study of the genetics of hypertension and insulin resistance, a 10 cM genome scan has been completed in 390 members of 77 Hispanic families ascertained via hypertensive probands. We have observed loci on chr. 1, 2, 3, 6 and 7 that show linkage with plasma ApoA2 levels. To further investigate these observations, we performed additional analyses, including oligogenic analysis and 2 locus-joint effects using SOLAR. Oligogenic analysis was done conditioning on the chr. 6 locus (69 cM), which had the largest single locus LOD score (3.61). Evidence for linkage remained significant for loci on chr. 1 (214 cM, LOD 1.42,  $p=0.01$ ), 3 (7 cM, LOD 1.77,  $p<0.005$ ), and 7 (79 cM, LOD 1.5,  $p<0.009$ ). Linkage to chr. 2 was no longer significant. There is also evidence for interaction among these loci in determining ApoA2 levels, with the following joint LOD scores: chr.6-chr.3, 5.38 ( $p=0.000001$ ); chr.6-chr.7, 5.11 ( $p=0.000003$ ); chr.6-chr.1, 5.03 ( $p=0.000003$ ); chr.1-chr.3, 5.08 ( $p=0.000003$ ); chr.1-chr.7, 4.31 ( $p=0.000017$ ); chr.3-chr.7, 4.57 ( $p=0.000009$ ).

These results suggest that ApoA2 levels are regulated by at least 4 loci and that these loci act synergistically. The locus on chr. 1 is in the region of the ApoA2 structural gene, but possible candidate genes for the chr. 3, 6 and 7 loci remain to be identified. Further analyses of these families, including fine mapping in the peak linkage regions, should allow us to better localize the underlying genes and perhaps identify candidates that regulate this important phenotype.

**ACE and AGT polymorphisms in ischaemic stroke and carotid stenosis: association and sibs study. T.V.**

*Tupitsina<sup>1</sup>, O.V. Miloserdova<sup>1</sup>, P.A. Slominsky<sup>1</sup>, Eu.A. Koltsova<sup>2</sup>, V.I. Skvortsova<sup>2</sup>, S.A. Limborska<sup>2</sup>.* 1) Inst. of Molecular Genetics, Moscow, Russia; 2) Russian State Medical Academy, Moscow, Russia.

Family and twins study demonstrated that genetic factors may be involved in stroke. Previously, insertion/deletion (I/D) Alu-polymorphism in the angiotensin-converting enzyme (ACE) gene and M235T polymorphism in the angiotensinogen gene has been suggested as a risk factors for some cardiovascular diseases. There fore, cardiovascular factors are well-known risk factors for ischaemic cerebrovascular disease (ICVD). We have investigated the distribution of alleles of ACE and angiotensinogen genes in group of patients with ischaemic and their sibs. All patients and sibs with ischaemic stroke were investigated for the stenosis of the internal carotid artery (CS). There was a significant difference ( $P < 0.05$ ) in the distribution of ACE alleles, homozygosity for the presumed susceptibility deletion allele being more common in patients with profound (>50%) CS than in healthy control subjects and healthy sibs. There was also a significant difference ( $P < 0.05$ ) in patients with CS in comparison with matched ICVD patients without CS, both in allelic frequencies and in homozygosity for the deletion allele. However, ID allele distribution demonstrated no evidence for statistically significant differences in frequencies of I/D alleles or II/DD/ID genotypes between ICVD patients and healthy control subjects. Our results indicate that the ACE gene polymorphism may be a risk factor for the development of CS - but not for ICVD. M235T angiotensinogen gene polymorphism is not risk factor for ICVD or CS in our patient's group - we don't find any significant differences in allele and genotype distribution between ICVD and CS patients and healthy control subjects.

**Inverse regulation of LDL receptor-related protein (LRP) on transcriptional and translational level in patients with CAD.** *S. Schulz<sup>1</sup>, U. Schagdarsurengin<sup>1</sup>, P. Greiser<sup>1</sup>, G. Birkenmeier<sup>2</sup>, L. Weidhase<sup>3</sup>, A. Nordwig<sup>3</sup>, A. Kabisch<sup>4</sup>, K. Werdan<sup>3</sup>, I. Hansmann<sup>1</sup>, C. Gläser<sup>1</sup>.* 1) Inst Human Genetics, Univ Halle, Halle, Germany; 2) Inst Biochemistry, Univ Leipzig, Leipzig, Germany; 3) Dep Internal Med, Univ Halle, Halle, Germany; 4) Inst Transf Med/Bloodbank, Univ Halle, Halle, Germany.

LRP, is a multifunctional cell receptor which binds and internalizes a variety of important ligands and is therefore considered to be a candidate gene for degenerative diseases like atherosclerosis and Morbus Alzheimer. **Material and Methods:** We investigated the individual LRP-mRNA and protein expression in native monocytes from 36 male patients with angiographically proven severe coronary atherosclerosis (average age: 51.7 years) in contrast to 36 healthy long-standing male blood donors (average age: 47.3 years). The investigations on transcriptional level were carried out by means of a competitive RT-PCR. For specific detection of LRP protein expression we applied a macro array analysis using a commercially available LRP standard protein of human placenta of known concentration as a reference.

**Results:** We measured a significantly 1.82 fold higher LRP-mRNA expression in coronary patients in comparison to healthy controls (223 ag/cell vs. 122.3 ag/cell,  $p < 0.001$ ). However the investigation of LRP-protein expression revealed an inverse pattern: Whereas the expression of the coronary patients amounted to 1.6 pg/cell the controls showed a significant higher protein expression of 6 pg/cell ( $p < 0.001$ ). Obviously a high LRP-mRNA expression was associated with a low protein expression, and vice versa. These results suggest a complex regulatory mechanism of the LRP at transcriptional and translational level. The detected lower protein expression in coronary patients may be due to a severe unbalanced metabolism in atherosclerosis. This could lead to a diminished receptor-mediated endocytotic pathway in coronary patients which may then be compensated by increasing the mRNA expression. These findings supply evidence for the importance of the expression pattern of the receptor in the assessment of atherosclerosis development.

**Association between hypertension, AGT, DCP1, and LPL genes, and environmental factors: results of Nutrition and Health Survey in Taiwan, 1993-1996.** *W.H. Pan<sup>1</sup>, P.J. Shieh<sup>1</sup>, H.Y. Chang<sup>2</sup>, C.S.J. Fann<sup>1</sup>*. 1) Inst of Biomedical Sciences, Academia Sinica, Taipei, Taiwan, Taiwan; 2) National Health Research Institute, Taipei, Taiwan.

Linkage between *angiotensinogen (AGT)*, *angiotensin converting enzyme (DCP1)* and hypertension has been repeatedly studied. Our previous study has also indicated that markers of *lipoprotein lipase (LPL)* and *DCP1* may be linked to young-onset hypertension in Taiwanese. Using the DNA samples collected by the Nutrition and Health Survey in Taiwan (NAHSIT), we carried out an association study on hypertension and *AGT*, *DCP1*, and *LPL* genes. We randomly selected 208 hypertensive subjects (96 subjects aged < 40 and 112 subjects aged 40+) and 248 age, sex, and region matched controls from the NAHSIT database. Genotyping was carried out for *DCP1 D/I* polymorphism, *AGT M235T* and *AGT T174M* polymorphism, and for microsatellite markers of *DCP1 (ATA108a05)* and of *LPL*. Nutrient intakes of the previous 24-hours, anthropometric measurements, and clinical chemistry profiles were also included as environmental factors in the analysis. Hypertensive men and women tend to be more obese, had higher level of serum triglyceride, uric acid, and glucose, and drank more alcohol (in men only) than their normotensive counterparts. No association was found between hypertension and any gene. But presence of M allele of *AGT T174M* and allele 4 (with 157 AAT repeats) of the *ATA108a05* was associated with an odds ratio of 5.65 (1.4-22.9) for hypertension risk. Gene-environmental interaction was found between *AGT M235T* polymorphism and body mass index and between *DCP1 D/I* polymorphism and the ratio of dietary polyunsaturated fatty acid to saturated fatty acids. In addition, a clear dose-response relation was observed between D allele of *DCP1* and serum triglyceride level in men. These data indicate that genes and environmental factors interact in their contributions to the development of hypertension.

**C-260T polymorphism in the promoter region of the CD14 receptor gene is associated with pro-inflammatory response in patients with unstable angina.** *P.F. Pignatti<sup>1</sup>, C. Stranieri<sup>1</sup>, G. Liuzzo<sup>2</sup>, E. Trabetti<sup>1</sup>, C. Alongi<sup>1</sup>, D.J. Angiolillo<sup>2</sup>, M. Santamaria<sup>2</sup>, V. Rizzello<sup>2</sup>, C. Colizzi<sup>2</sup>, F. Ginnetti<sup>2</sup>, A. Buffon<sup>2</sup>, L.M. Biasucci<sup>2</sup>, A. Maseri<sup>2</sup>.* 1) Sect Biol & Genetics, Mother & Child, Biol & Gen, Verona, Italy; 2) Cardiology, Catholic University, Rome, Italy.

The CD14 membrane receptor is an important mediator for monocytes (MO) activation by bacterial lipopolysaccharides (LPS). In this study, we examined whether the C-260 T polymorphism in the CD14 gene influences the activation of circulating MO and the acute phase response in unstable angina (UA). CD14 C-260 T polymorphism, plasma levels of C-reactive protein (CRP), and interleukin-6 (IL-6) production were determined in 87 UA patients (Group 1A, 52 patients with CRP  $\geq$  3 mg/L; Group 1B, 35 patients with CRP  $<$  3 mg/L), in 39 stable angina patients (Group 2), and in 68 healthy subjects (Group 3). LPS-stimulated production of IL-6 by circulating MO was significantly higher in Group 1A (4.4 ng/mL, 2.1-10.6 ng/mL) than in Group 1B (1.9 ng/mL, 0.7-6.8 ng/mL) or in Group 2 (1.4 ng/mL, 0.4-6.3 ng/mL) ( $p < 0.01$ ). The TT genotype was present in 23/52 (44%) Group 1A, in 4/35 (11%) Group 1B, in 7/39 (18%) Group 2 patients, and in 14/68 (20%) Group 3 controls, a significant difference in TT genotype distribution between Group 1A and Groups 1B and 2 ( $p = 0.001$ ) or Group 3 ( $p = 0.02$ ). TT homozygotes showed an increased production of IL-6 by circulating MO in response to LPS-challenge (4.1 ng/mL, 1.6-10.6 ng/mL) than carriers of the other two genotypes (2.5 ng/mL, 0.24-6.3 and 3.1 ng/mL, 0.9-9.6 ng/mL, respectively;  $p < 0.01$ ). TT homozygotes had significantly higher CRP plasma levels (5.9 mg/L, 0.6-43.4 mg/L) than carriers of both the CC (1.7 mg/L, 0.8-29.7 mg/L) and CT (2.7 mg/L, 0.1-29.4 mg/L) genotypes ( $p < 0.05$ ). In conclusion, the C-260T polymorphism in the promoter region of the CD14 receptor gene is associated with UA and is correlated with an enhanced responsiveness of circulating MO after LPS-challenge in UA, suggesting that the inflammatory response in UA may be genetically determined.

**Somatic mutations in sporadic juvenile hemangioma.** *J.W. Walter<sup>1</sup>, P.E. North<sup>2</sup>, A. Mizeracki<sup>2</sup>, M. Waner<sup>2</sup>, J.F. Reinisch<sup>3</sup>, J. Walker<sup>3</sup>, F. Blei<sup>4</sup>, C. Patterson<sup>5</sup>, D.A. Marchuk<sup>1</sup>.* 1) Duke Univ Medical Ctr, Durham NC; 2) Univ Arkansas, Little Rock AR; 3) Childrens Hospital, Los Angeles CA; 4) NYU Medical Ctr, New York NY; 5) Univ North Carolina, Chapel Hill NC.

Juvenile hemangioma is the most common tumor of infancy, and occurs in as many as 10% of all births. These benign vascular lesions enlarge rapidly during the first year of life by hyperplasia of endothelial cells and attendant pericytes, then spontaneously involute over a period of years, accumulating fibrofatty tissue. At least three distinct hypotheses have been proposed to account for hemangioma formation: (1) The proliferative vascular cells are derived from a distinct anatomical location (e.g., placental origin hypothesis). (2) Normal vascular cells are responding to aberrant signal from adjacent tissue (e.g., extrinsic growth factors). (3) The vascular cells from the lesion are intrinsically altered (e.g., somatic mutation).

To test this latter hypothesis, we obtained 15 proliferative hemangiomas that had been surgically resected, and dissected to enrich for the proliferative component of the lesions. 12 of 15 hemangiomas showed evidence of monoclonality, using X-inactivation assays at the HUMARA locus. Control tissue from overlying skin showed no evidence of monoclonality, suggesting an intrinsic defect in the proliferative endothelial cells. Genes involved in angiogenesis were sequenced in these samples. Two lesions were found to harbor mutations in VEGF receptors resulting in amino acid substitutions: P1147S in VEGFR2, and P954S in VEGFR3. Both mutations occur somatically, as neither is found in adjacent normal tissue. Both proline to serine substitutions occur in the kinase regions of these receptors, and preliminary biochemical studies of the VEGFR2 mutation suggest a loss of kinase activity. We propose that multiple independent events can cause hemangiomas, as suggested by the high incidence of these tumors in the population. The identification of somatic mutation of VEGF receptors in a subset of these tumors is an important step toward understanding the molecular etiology of hemangiomas.

**Clonal analysis of endometriotic lesions using laser capture microdissection and PCR-based HUMARA assay. S.**

*Guo<sup>1</sup>, Y. Wu<sup>1</sup>, E. Strawn<sup>2</sup>, A.A. Balla<sup>3</sup>, Z. Basir<sup>3</sup>, O. Kokanovic<sup>1</sup>.* 1) Dept of Pediatrics, Box 26509, Med Col Wisconsin, Milwaukee, WI; 2) Dept. of Obstetrics and Gynecology, Medical College of Wisconsin, Milwaukee, WI; 3) Dept. of Pathology, Medical College of Wisconsin, Milwaukee, WI.

Endometriosis is a common gynecological disorder that generally follows a benign course, yet displays characteristics similar to malignant neoplasia. Several recent clonality studies suggested that the majority of endometriotic lesions are monoclonal in origin. In these studies, the clonality of epithelial cells was evaluated based on a polymorphic trinucleotide CAG repeat marker of the X-linked human androgen receptor gene HUMARA. With this approach, only the inactivated (methylated) HUMARA allele is selectively amplified by PCR following methylation-sensitive enzyme digestion and therefore a methylation pattern can be established. To minimize the chance of contamination that could lead to spurious clonal determination, we used laser capture microdissection (LCM) to accurately sample individual epithelial cells from endometriotic lesions and control samples out of frozen tissues and hence determine their clonality with greater certainty. Three samples of endometriotic lesions and their corresponding controls from three patients were analyzed. All of the control samples showed heterozygous for the CAG repeat polymorphism and hence were polyclonal in origin. The epithelial cells in two endometriotic lesion samples on the other hand showed monoclonal patterns. Our results corroborate previous reports on the clonality of endometriotic lesions. Since the use of LCM allows accurate and precise tissue sampling from small endometriotic lesions, our results brought more certainty that endometriotic lesions are monoclonal in origin and may thus carry a neoplastic potential.

**A female with Fragile-X shows an affected male-like phenotype and skewed inactivation of the functional chromosome.** *D. Heine-Suñer<sup>1,4</sup>, G. Picó<sup>2</sup>, L. Torres-Juan<sup>1</sup>, M. Bernués<sup>1</sup>, J. Iglesias<sup>3</sup>, F. Barceló<sup>1</sup>, J. Rosell<sup>1,4</sup>.* 1) Department of Genetics, University Hospital Son Dureta, Palma de Mallorca, Balearic Islands, Spain; 2) Department of Paediatrics, University Hospital Son Dureta, Palma de Mallorca, Balearic Islands, Spain; 3) Department of Immunology, University Hospital Son Dureta, Palma de Mallorca, Balearic Islands, Spain; 4) Department of Biology, University of the Balearic Islands, Palma de Mallorca, Balearic Islands, Spain.

Fragile X syndrome is the most common form of inherited mental retardation. It is caused by the increase in length of a stretch of CGG triplet repeats within the FMR1 gene. A full mutation (>200 repeats) leads to methylation of the CpG island and silencing of the FMR1 gene. We present here a family with two young sisters (11 and 16 years old) that are compound heterozygotes for the full mutation and a 53 repeat allele (premutation grey zone), one of them showing mental retardation and clinical features of an affected male (speech delay, hyperactivity, large ears, prominent jaw, gaze aversion), while the other is borderline normal (mild delay). Southern blot analysis to detect methylation status showed that the sister with mental retardation had practically all her cells (skin and blood) with the normal FMR1 gene inactivated, while her sister had most of her blood cells with the mutated FMR1 gene inactivated. Furthermore, skewed X-inactivation of the non-functional chromosome was also observed in another affected, mildly retarded female member of the family. Analysis of X-inactivation in the extended family with the Androgen Receptor (AR) inactivation assay confirmed a highly skewed X-inactivation pattern in the two sisters and other members of the family. Molecular analysis by PCR of family members carrying the 53 repeat allele showed that it is inherited in a stable manner and thus, does not behave like a premutation. Further investigations are under way to confirm that the peculiar phenotype observed in one sister is caused by an extremely skewed inactivation of the functional chromosome. ñññ.

**Temperament and Character Profiles of ADHD and Subtypes.** *D.E. Lynn, J.R. McCracken, J.J. McGough, G. Lubke, A. Liu, S. Smalley.* Child and Adolescent Psychiatry, UCLA, 300 Medical Plaza LA, CA.

Objective: Our study was designed to investigate the link between Attention Deficit Hyperactivity Disorder (ADHD) in adults, Novelty Seeking (NS) temperament scores on the Temperament Character Inventory (TCI), and genotype at polymorphisms in the D4 Dopamine Receptor (DRD4) Gene. Method: Data from 171 parents from 96 families were used. This study draws from a larger molecular genetic study of ADHD, in which ascertainment criteria was to have at least two children affected (an Affected Sib Pair, ASP) with ADHD in each family. Of these 171 parents, 56 (33%) parents had a lifetime history of ADHD, of these 25 (12%) continued to meet DSM-IV criteria (i.e. persistent ADHD). 115 (67%) of these showed no history of ADHD. Latent variable modeling and analysis of variables (ANOVA) were used to test whether TCI factors could predict ADHD outcome measures. Results: Using Latent Variable Modeling, we were able to confirm the first order factor of the TCI. We found that NS predicted ADHD Diagnosis ( $R^2 = .28$ ). Using ANOVA, we found elevated NS is associated with a lifetime history of ADHD ( $p < .01$ ). Character measures from the TCI predict subtype of ADHD ( $p < .05$ ). There was no association found between the DRD4 gene and TCI measures in this sample. Conclusions: In this unique sample of parents of multiplex families, NS is a potential risk factor for development of ADHD. Genetic influences underlying temperament may contribute to the etiology of ADHD and character may be a mediator of the variation in outcomes of ADHD.

**Subtelomeric plasticity: the FSHD enigma.** *R.J.L.F. Lemmers<sup>1</sup>, P. de Kievit<sup>1</sup>, M.J.R. van der Wielen<sup>1</sup>, E. Bakker<sup>1</sup>, G.J. van Ommen<sup>1</sup>, G.W. Padberg<sup>2</sup>, R.R. Frants<sup>1</sup>, S.M. van der Maarel<sup>1</sup>.* 1) Human & Clinical Genetics, LUMC Leiden, Leiden, Netherlands; 2) Dept. of Neurology, UMCN Nijmegen, Nijmegen, The Netherlands.

Subtelomeres are dynamic structures as exemplified by the recombinogenic nature of the D4Z4 repeat on chromosome 4qter. Rearrangements of this subtelomeric repeat array are not only confined to chromosome 4, but may also occur between chromosome 4 and a highly homologous repeat on chromosome 10qter. As a result, (partial) D4Z4 repeats are frequently observed on chromosome 10. Likewise, homologous units from chromosome 10 may also be present on chromosome 4.

Partial deletions of the D4Z4 repeat on chromosome 4 cause autosomal dominant facioscapulohumeral muscular dystrophy (FSHD). Partial deletions on chromosome 10 are non-pathogenic. The extensive clinical variability of FSHD, the high *de novo* mutation frequency, and the clinical overlap with other syndromes necessitates a highly specific genetic test. Yet, the dynamic behavior of these subtelomeric repeats compromises FSHD diagnosis. Genetic diagnosis is based on sizing of the D4Z4 repeat array with probe p13E-11, which also recognizes the homologous repeat on chromosome 10. To discriminate between both chromosomes, *BlnI* is used which recognizes chromosome 10 units, but not chromosome 4 units.

To further optimize complete allele assignment of repeat arrays on both chromosomes and to assist the study of subtelomeric plasticity, we introduce the restriction enzyme *XapI*. It displays opposite characteristics of *BlnI* by uniquely digesting 4-type repeat units and leaving 10-type repeat units undigested. Using the combination *EcoRI*, *EcoRI/BlnI* and *XapI* unequivocally allows detailed analysis of the recombinogenic behavior of these subtelomeric domains by complete characterization of each allele, whether homogeneous or hybrid. This is particularly useful in case of co-migrating 4-type and 10-type arrays, for the assignment of hybrid fragments to their original alleles and in case of suspected FSHD with non-standard allele configurations as demonstrated by exclusion of one patient carrying an apparently short hybrid repeat array.

**Paternally inherited deletions of CSH1 in Silver-Russell syndrome.** *T. Eggermann<sup>1</sup>, S. Prager<sup>1</sup>, S. Mergenthaler<sup>1</sup>, K. Eggermann<sup>1</sup>, M.B. Ranke<sup>2</sup>, K. Zerres<sup>1</sup>, H.A. Wollmann<sup>2</sup>.* 1) Inst Human Genetics, Technical Univ Aachen, Aachen, Germany; 2) Childrens Hospital, University of Tuebingen, Germany.

Silver-Russell syndrome (SRS) is a syndrome of severe pre- and postnatal growth retardation and typical dysmorphic features. Rare chromosomal aberrations have been reported in SRS, among these are two balanced translocations involving 17q24-q25. We recently described a patient with a paternally inherited heterozygous deletion of the chorionic somatomammotropin hormone 1 (CSH1) gene. The CSH1 gene is member of the growth hormone (GH) gene cluster in 17q22-24 which consists of two growth hormone genes and three CSH genes. Genomic alterations in the GH cluster are well known, causing different phenotypes depending on the size of the deletion and the genes involved. By screening 62 SRS cases with marker D17S254, we now detected a second patient with a heterozygous deletion in the GH cluster inherited by his father. Quantitative analysis using a PCR-based protocol showed that the patient and his father were hemizygous for CSH1 while the neighboring gene GH2 was not deleted. Screening of 50 unrelated controls did not reveal haploinsufficiency of CSH1. While the central role of GH1 in human growth is well established, the roles of CSH1 and other components of the cluster remain to be investigated. It will be interesting to see, under which circumstances haploinsufficiency of CSH1 causes clinical features. Furthermore, the finding of a second case with CSH1 deletion shows the usefulness of molecular genetic CSH1 testing in SRS patients, which should be added to a routinely performed cytogenetic and uniparental disomy 7 analyses in SRS.

**Absence of prevalent sequence variations in the HSP60 and HSP10 chaperonin genes in 65 cases of Sudden Infant Death Syndrome (SIDS).** *P. Bross<sup>1</sup>, J.J. Hansen<sup>1</sup>, Z. Li<sup>1,2,3</sup>, M. Nyholm<sup>1</sup>, S. Kølvråa<sup>3</sup>, J.B. Lundemose<sup>4</sup>, L. Bolund<sup>3</sup>, H. Yang<sup>2</sup>, N. Gregersen<sup>1</sup>.* 1) Res. Unit for Mol. Med. at Aarhus University Hospital, Århus, Denmark; 2) Chinese Academy of Sciences Inst. for Genome Research, Beijing, China; 3) Inst. of Human Genetics at Aarhus University, Århus, Denmark; 4) Inst. of Forensic Medicine at Aarhus University Hospital, Århus, Denmark.

The Hsp60 chaperonin and the co-chaperonin Hsp10 function together at a strategic point in mitochondrial protein folding. Variations in these chaperonins - that are highly conserved between species - may be expected to have rather dramatic pleiotropic effects by affecting the folding of many mitochondrial proteins. An RFLP study on infants dead in sudden infant death syndrome (SIDS) indicated that a certain RFLP in the Hsp60 gene was overrepresented in this group compared to controls. We have analysed 10 Danish SIDS cases and 10 control individuals by high quality sequencing of both strands in the HSP60 and the HSP10 coding region, the intron sequences proximal to the exon/intron junctions and the bi-directional promoter localised between the genes. In addition, 55 SIDS cases were screened by single run sequencing of the same regions. Altogether, we detected 13 variations in the Hsp60/10 genes. 4 of them are located in the promoter region, 5 in introns and 4 in the Hsp60 coding region. Two of the variations in the coding region alter the amino acid code. One of them (G537A) is present at similar frequency in both the SIDS group and controls. The other amino acid variation (N158S) is only found in one allele of a single SIDS case and is not present in 100 control alleles. None of the 13 sequence variations detected in the HSP60 and HSP10 genes is significantly overrepresented in 65 SIDS infants indicating that mutations in these genes are no prevalent cause of sudden infant death. The variation N158S that is observed in only one SIDS individual may represent a rare disease allele of the HSP60 gene.

**The 11q deletion disorder: A prospective study of 91 cases and identification of a candidate gene for heart defects.** *P.D. Grossfeld<sup>1</sup>, C. Jones<sup>2</sup>, F. Cotter<sup>2</sup>, J. Chen<sup>1</sup>, P. Lozano<sup>1</sup>, L. Zelante<sup>3</sup>, M. Del'Aquilla<sup>1</sup>, F. Parente<sup>1</sup>, K. Chien<sup>1</sup>.* 1) Div of Pediatric Cardiology, Univ University of California, San Diego, San Diego, CA; 2) St. Bartholomew School of Medicine, London, England; 3) Medical Genetics Service, Rotondo, Italy.

Jacobsen Syndrome (JS) is a dysmorphic disorder caused by terminal deletions of 11q. We studied 91 JS cases. These patients commonly have congenital heart disease (CHD), mental retardation (MR) (language and music comprehension deficits), thrombocytopenia, genitourinary defects, short stature, eye problems, craniofacial defects, pyloric stenosis, and chronic constipation. Fifty-four percent of JS children have CHD, most commonly left-sided obstructive lesions and perimembranous ventricular septal defects. Other heart defects seen in JS include conotruncal defects, pulmonary stenosis, double outlet left ventricle, AV canal defect, tricuspid atresia, and transposition of the great arteries. We performed deletion mapping by Fluorescent In Situ Hybridization of 35 JS patients with CHD and identify a minimal region for heart defects in 11q containing ~20 known genes. We also define the molecular breakpoint of a patient with a severe heart defect and demonstrate that the breakpoint interrupts a gene that is within the JS cardiac minimal region. This gene, OBCAM (Opiate-Binding Cell Adhesion Molecule) is a member of the immunoglobulin gene superfamily. We demonstrate that this gene is expressed in a chamber-specific pattern in the heart. We also show that Neurotrimin and Limbic-Associated Membrane Protein (LAMP), two other members of the IgLON subfamily of cell adhesion molecules, are also expressed in a cardiac chamber-specific pattern in the heart. We propose that cell adhesion molecules have a role in cardiac development and that loss of heterozygosity of OBCAM may contribute to the development of congenital heart defects. We have also identified critical minimal regions for the other phenotypes in JS. Minimal regions for pyloric stenosis, genitourinary defects and MR are within the cardiac minimal region, thereby defining a region containing less than 20 genes that may be responsible for each of these defects.

**Microarray analysis of a Smith-Magenis patient.** *C.N. Vlangos<sup>1</sup>, S.H. Elsea<sup>1,2</sup>*. 1) Graduate Program in Genetics, Michigan State University, East Lansing, MI 48824; 2) Departments of Zoology and Pediatrics and Human Development, Michigan State University, East Lansing, MI 48824.

Smith-Magenis syndrome (SMS) is a multiple congenital anomalies/mental retardation disorder and possible contiguous gene deletion syndrome associated with an interstitial deletion of chromosome 17p11.2. The SMS critical interval has been described, and we have recently completed a BAC/PAC contig across the entire SMS critical interval. The critical interval contains 16 known genes and 12 expressed sequence tags. Haploinsufficiency of one, or many, of the genes in the critical interval may act to manifest the distinct SMS phenotype. We report here the expression pattern of lymphoblastoid cell lines derived from an SMS patient and a parental control using Affymetrix GeneChip<sup>TM</sup> analysis. Lymphoblasts were obtained from fresh blood samples collected from a female SMS patient harboring the common deletion and her phenotypically normal mother. Lymphoblasts were transformed using Epstein-Barr virus. RNA was isolated from the transformed cell lines and reverse transcribed into cDNA, which was then transcribed *in vitro* into biotin labeled cRNA. The cRNA was fragmented and hybridized to Affymetrix GeneChips<sup>TM</sup>. After hybridization, the probe arrays were washed and scanned. The variation in gene expression between the patient cell lines and the parental control indicate which genes in the critical interval may be expressed in a haploinsufficient manner. As well, this study will identify genes outside of the SMS critical interval whose expression may be altered by haploinsufficiency of genes within the SMS region. This is the first study reported to examine the affects of haploinsufficiency toward gene expression utilizing microarray analysis.

**Characterization of a (9,15) translocation in a patient with autism.** S.A. Copeland-Yates<sup>1, 2</sup>, B.R. Dupont<sup>1</sup>, C.D. Skinner<sup>1</sup>, R.C. Michaelis<sup>1</sup>. 1) J.C. Self Research Institute, Greenwood Genetic Center, Greenwood, SC; 2) Department of Biochemistry and Genetics, Clemson University, Clemson, SC.

Autism is a developmental disorder characterized by restricted and repetitive behaviors, deficient social interaction skills, and communication impairments. It is thought to be the most heritable of all pervasive developmental disorders, but to date no disease gene has been associated with autism. Chromosomal translocations can be useful in locating causative genes, as the translocation may disrupt a gene or separate a gene from its regulatory region. In our investigations, we have discovered an autistic patient with a *de novo* balanced translocation involving chromosomes 9 and 15. The translocation breakpoints are located in 9q32 and 15q22. Further studies on this patient using fluorescence *in situ* hybridization (FISH) revealed a bacterial artificial chromosome (BAC) that is disrupted by the breakpoint on chromosome 15. Examination of the sequence of this BAC did not reveal any known genes, but several transcripts are present within the region covered by the BAC. Southern blot analyses using cDNAs corresponding to these transcripts have been performed, but no changes in banding patterns have been found. The location of the breakpoint on chromosome 9 has yet to be defined.

**Male infertility in Kuwait: Molecular and Cytogenetic study.** *F.M. Mohammed<sup>1</sup>, S. AL-FADHLI<sup>1</sup>, O. RUSHDI<sup>2</sup>, S.A. AL-AWADI<sup>3</sup>, K.K. NAGUIB<sup>3</sup>.* 1) Molecular Genetics Laboratory, Faculty of Allied Health, KUWAIT, KUWAIT, KUWAIT; 2) Kuwait Medical Genetics Center, Maternity Hospital, KUWAIT; 3) Family Planning Department, Ministry of Health, KUWAIT.

A case control study of 90 male patients with primary infertility presented by azoospermia/severe oligospermia were studied clinically, cytogenetically and molecularly in order to highlight male infertility in Kuwait. Out of these patients 9 patients (10%) had chromosomal aberration, represented by Klinefelter syndrome/variant (77.8%), XYY syndrome (11.1%) and XX male syndrome (11.1%). Screening of the patient group using the multiplex PCR study revealed detection of microdeletion in one case (1.2%). Six PCR products were deleted in four out of five multiplex reactions and were further confirmed using single PCR reaction. On the other hand, screening for microdeletion in Yq11 using RBM1, RBM2, DAZ and SPGY1 genes revealed undetectable deletion in all patients except the patient who showed microdeletion upon multiplex PCR analysis. He showed deletion of the DAZ and SPGY1 gene specific primer sets. No detectable deletion in the control group was found. The low frequency of microdeletion in the present study may be due to small sample size. Y microdeletion screening is important not only to define the aetiology of spermatogenic failure, but also because it gives precise information for a more appropriate clinical management of the infertile male and his future male child.

**Molecular Cloning of a t(18;21)(p11.1;p1.1) Translocation Associated with Psychosis in one Family. J.M.A.**

*Meerabux<sup>1</sup>, Y. Iwayama<sup>1</sup>, S. Detera-Wadleigh<sup>2</sup>, L. DeLisind<sup>3</sup>, T. Yoshikawa<sup>1</sup>.* 1) Molecular Psychiatry, Brain Sci Inst. Riken, Wako, Saitama, Japan; 2) Intramural Program, National Institute of Mental Health, Bethesda, MD; 3) Department of Psychiatry & Behavioral Science, State University of New York at Stony Brook, Stony Brook, NY.

Linkage studies have identified the pericentric region of chromosome 18p as being associated with both bipolar disorder and schizophrenia. We are currently analyzing four cell lines derived from members of a single family. The mother and one son suffered from psychosis whilst two siblings suffered from schizophrenia. Three of the cell lines were cytogenetically identical, carrying a balanced t(18;21)(p11.1;p11.1) translocation as the sole abnormality. The fourth cell line derived from a female schizophrenic with severe symptoms, displayed an unbalanced translocation, having lost the derivative chromosome 21 and gained a normal 21. This resulted in a loss of heterozygosity between 18p11.1-pter. FISH analysis has localized the breakpoint on chromosome 21 to the BAC 2503J9. This clone lies immediately upstream of the published chromosome 21p sequence and contains the TPTE gene, although this gene was not disrupted by the translocation. The breakpoint lies approximately 180 kb telomeric to TPTE. No coding sequences have as yet been detected in the immediate vicinity of the breakpoint on chromosome 21. The breakpoint on chromosome 18 mapped to an unknown distance below IMPA2, a positional and functional candidate gene for psychosis. Although we have yet to identify a gene in this region, the severity of symptoms in the patient with a loss of heterozygosity suggest a role in pathogenesis for a gene on chromosome 18, either at, or proximal to the translocation breakpoint. It is likely that the pericentric and therefore heterochromatic sequences on chromosome 21 exert a regulatory effect in this translocation.

**Implications of chromosome 8p inversions for genetic mapping: neuropsychiatric diseases as an example.** *R.A. Ophoff<sup>1</sup>, S.K. Service<sup>1</sup>, M. Tampilic<sup>1</sup>, M. Eeva<sup>2</sup>, C. Sabatti<sup>2</sup>, A. Palotie<sup>2</sup>, N.B. Freimer<sup>1</sup>*. 1) Center for Neurobehavioral Genetics, Dept of Human Genetics/Psychiatry, UCLA, Los Angeles, CA; 2) Dept of Human Genetics, UCLA, Los Angeles, CA.

It has recently been reported (Giglio et al (2001) *Am J Hum Genet* 68:874-883) that submicroscopic inversions of chromosome 8p of several megabases in length are very common in normal populations. These inversions probably arise from homologous recombination in olfactory receptor gene clusters that flank the inversion, and may have recurred several times in human history. Several independent linkage studies have implicated the region that includes these inversions in susceptibility to neuropsychiatric disorders, including schizophrenia and Tourette syndrome. We recently completed a genome-wide association study of severe bipolar disorder in the isolated population of the Central Valley of Costa Rica, and found the strongest genome-wide evidence for linkage disequilibrium with markers that are contained within or immediately adjacent to these inversions. These common rearrangements could substantially affect statistical analyses of genotyping data from this region and could play a role in disease susceptibility, for example, by altering gene expression in and near the breakpoints.

We have used simulation methods to evaluate the effect of a change of marker order (inversion) on linkage analysis. Additionally, we are defining at the base-pair level, the chromosomal breakpoints, which are heavily loaded with repeat sequences that are present at several other loci in the human genome; this will permit development of simple assays that can be used to identify the frequency of the inversions in affected and unaffected individuals in the studies that have mapped putative neuropsychiatric loci to this region.

**Molecular characterisation of interstitial duplications and triplications involving chromosome 15q11-q13.** *N.S.*

*Thomas<sup>1</sup>, S.E. Roberts<sup>1</sup>, C.E. Browne<sup>1</sup>, N.R. Dennis<sup>2</sup>, P.A. Jacobs<sup>1</sup>.* 1) Wessex Regional Genetics Laboratory, Salisbury District Hospital, Salisbury, UK; 2) Human Genetics, Southampton General Hospital, Southampton, UK.

Chromosome 15 is frequently involved in the formation of structural rearrangements. We report the molecular characterisation of 16 independent interstitial duplications and 3 triplications of the Prader-Willi Angelman critical region (PWACR). Ten duplications were familial, while 5 duplications and all 3 triplications were de novo. The vast majority of PWS and AS deletions include the entire 4 Mb PWACR cassette, and the common deletion breakpoints occur within low copy number repeats flanking the PWACR. All 16 duplications were of an almost uniform size, including two not visible by routine G-banding, and shared the common deletion breakpoints. This implies that some, if not all, duplications and deletions are the reciprocal products of each other. Triplication breakpoints were more variable and extended distally beyond the PWACR, suggesting that structural abnormalities of chromosome 15 involve more than one mechanism. The formation of duplications involved both interchromosomal (n=11) and intrachromosomal (n=5) events. Unlike CMT1A/HNPP rearrangements, duplications and deletions of the PWACR can occur in both male and female meiosis and involve both inter- and intra-chromosomal events. We observed no meiotic instability in the transmission of duplications, although recombination occurred in one family between the normal and duplicated chromosome 15 homologues. The PWACR contains a number of imprinted genes and in all probands except one, the additional copies were maternal in origin. In one family, the duplication was paternal in origin, yet appeared to segregate in a sibship of 3 with an abnormal phenotype, including developmental delay and a behavioural disorder. There was no correlation between rearrangement size, mechanism of origin and clinical severity.

**Deletion of chromosome 2q37.3: report of a case and of candidate genes for autism and osteodystrophy.** *M. Smith, J.R. Escamilla, P. Filipek, M.E. Bocian, C. Modahl, P. Flodman, M.A. Spence.* Dept Pediatrics, Univ California, Irvine, Irvine, CA.

We recently studied a patient who meets criteria for autism disorder and has a deletion of 2q37.3 region on one chromosome. We have defined the extent of the deletion using molecular cytogenetic techniques and 20 non-overlapping BAC clones. We identified new polymorphic markers in the 2q37.3 deletion region. Using these markers we determined that the deletion occurred on the paternally derived chromosome. In the 2q37.3 deletion region we identified four autism candidate genes suggested by the expression of these genes in brain and by neuropathology in autism. Two of the genes that we identified in the 2q37.3 deletion region are abundantly expressed in bone and cartilage. These genes represent candidate genes for the osteodystrophy observed in patients with 2q37.3 deletions. Nine other patients with autism and chromosome 2q37 deletions have been described in the literature. Perhaps certain genetic changes e.g. deletions of specific chromosomal regions, loss of function mutations in critical genes, lead to severe disruption of development and autistic disorder without the presence of additional mutations of autism predisposing genes elsewhere in the genome. A more comprehensive screening of patients with autism is required to determine the frequency of 2q telomeric region deletions. Chromosome 2q telomeric probes for FISH analysis and the polymorphic markers that we identified in the 2q37.3 region serve as screening tools to detect deletions. Also it is possible that in patients without 2q37.3 deletions, examination of polymorphic markers may be informative since specific alleles of these markers may be in linkage disequilibrium with the autism phenotype. In subsequent studies it will be important to search for mutations in candidate genes that map in 2q37.3 in patients with autism who do not have chromosomal abnormalities. Patients with autistic disorder and with chromosomal abnormalities provide an important resource for identification of regions of the genome containing genes important in autism.

**Gene-expression profiles of human small airway epithelial cells treated with low doses of 14- and 16-membered macrolides.** *Y. Yamanaka*<sup>1,3</sup>, *M. Tamari*<sup>2</sup>, *T. Nakahata*<sup>3</sup>, *Y. Nakamura*<sup>1</sup>. 1) Human Genome Center, Inst. of Med. Sci., Univ Tokyo, Tokyo, Japan; 2) SNP Research Center, The Institute of Physical and Chemical Research (RIKEN), Tokyo, Japan; 3) Department of Pediatrics, Kyoto University Graduate School of Medicine, Kyoto, Japan.

Although long-term treatment with low doses of 14-membered macrolides is widely applied in management of patients with chronic inflammatory diseases, e.g. diffuse panbronchiolitis, chronic bronchitis, or chronic lung damage in newborns, the physiological mechanisms underlying the action of macrolides in these conditions are unclear. To clarify the pathological basis of these diseases and also to aid in design of novel drugs to treat them, we chose to investigate the molecular target(s) of macrolides. Our experiments involved long-term culture of human small airway epithelial cells (hSAEC) in media containing 14-membered macrolides erythromycin (EM) or clarithromycin (CAM), or a 16-membered macrolide, josamycin (JM), which lacks clinical anti-inflammatory effects. We then analyzed gene-expression profiles in the treated cells using a cDNA microarray consisting of 18,432 genes. We identified nine genes whose expression was significantly altered during 22 days of culture with EM, and seven that were altered by CAM in that time. Four of those genes revealed similar behavior in cells treated with either of the 14-membered macrolides, but not JM. The products of these four genes may be candidates for mediating the ability of 14-membered macrolides to suppress chronic inflammation.

**Association studies of 22 single nucleotide polymorphisms (SNPs) in complement C3, C5, C3aR and C5aR genes for bronchial asthma.** *K. Hasegawa<sup>1</sup>, M. Tamari<sup>1</sup>, X-Q. Mao<sup>2</sup>, T. Enomoto<sup>3</sup>, Y. Dake<sup>3</sup>, S. Doi<sup>4</sup>, H. Fujiwara<sup>4</sup>, A. Miyatake<sup>5</sup>, K. Fujita<sup>5</sup>, Y. Nakamura<sup>6</sup>, T. Shirakawa<sup>1,2</sup>.* 1) Lab. for Functional Analysis, RIKEN SNP Research Center, Tokyo, Japan; 2) Department of Health Promotion & Human Behavior, Kyoto University Graduate School of Public Health, Kyoto, Japan; 3) Department of Otolaryngology, Japanese Red Cross Society Wakayama Medical Center, Wakayama, Japan; 4) Osaka Prefectural Habikino Hospital, Osaka, Japan; 5) Miyatake Asthma Clinic, Osaka, Japan; 6) Laboratory of Molecular Medicine, Human Genome Center, Institute of Medical Science, The University of Tokyo, Tokyo, Japan.

Bronchial asthma (BA), one of the most common of all chronic inflammatory diseases in human populations, is considered to be due to the interaction between environmental and genetic factors. The complement system plays an immunoregulatory role in the interface of innate and acquired immunities. Recent studies provided evidence on the link of C5 and C3a to murine airway hyperresponsiveness, a partial model of human asthma. We searched C3, C5, C3aR and C5aR genes for single nucleotide polymorphisms (SNPs) in the genomic DNAs from BA patients. We have identified 22 SNPs among these genes, and conducted genetic association study in both Japanese (n=384) and British (n=300) populations. A G1896A (Thr612Thr) variant in the C3 gene showed weakly significant association ( $\chi^2=4.29$ ,  $p=0.038$ , Odds ratio=1.56, 95%CI:1.02-2.40) with higher total serum IgE levels (>500IU/ml) in the Japanese childhood BA. Further studies to clarify functional and genetic mechanisms of these genes on the development of asthma may provide a new insight into bronchial asthma.

**Amino-acid substitutions in the IKAP gene product significantly increase risk for bronchial asthma in children.**

*M. Tamari*<sup>1,2</sup>, *S. Takeoka*<sup>2</sup>, *M. Unoki*<sup>2</sup>, *Y. Onouchi*<sup>2</sup>, *S. Doi*<sup>3</sup>, *H. Fujiwara*<sup>3</sup>, *A. Miyatake*<sup>4</sup>, *K. Fujita*<sup>4</sup>, *K. Hasegawa*<sup>1</sup>, *T. Shirakawa*<sup>1,5</sup>, *Y. Nakamura*<sup>2</sup>. 1) Lab. for Functional Analysis, RIKEN SNP Research Center, Tokyo, Japan; 2) Laboratory of Molecular Medicine, Human Genome Center, Institute of Medical Science, The University of Tokyo, Tokyo, Japan; 3) Osaka Prefectural Habikino Hospital, Osaka, Japan; 4) Miyatake Asthma Clinic, Osaka, Japan; 5) Department of Health Promotion & Human Behavior, Kyoto UNiversity Graduate School of Public Health, Kyoto, Japan.

The complex etiology of bronchial asthma (BA), one of the most common inflammatory diseases throughout the world, involves a combination of various genetic and environmental factors. In the course of a project to screen the entire human genome for single nucleotide polymorphisms (SNPs) that might represent useful markers for large-scale association analyses of common diseases and pharmacogenetic traits, we identified six SNPs within the gene encoding I $\kappa$ B-associated protein (IKAP), a regulator of the NF- $\kappa$ B signal pathway. Most of these SNPs were in linkage disequilibrium with each other. We observed a strong allelic association between BA in childhood and two of the SNP sites, T3214A (Cys1072Ser) and C3473T (Pro1158Leu);  $P=0.000004$  for T3214A and  $P=0.0009$  for C3473T. T3214A was also associated with BA in adult patients ( $P=0.000002$ ) but C3473T was not ( $P=0.056$ ). To confirm the above results, we compared estimated frequencies of haplotypes of the six SNPs between BA patients and controls. We found a strong association between BA in childhood and a specific haplotype, TGAAAT, that involved two amino-acid substitutions (819T, 2295G, 2446A, 2490A, 3214A, and 3473T;  $P=0.00004$ , odds ratio=2.94, 95%CI=2.48-3.4). On the other hand haplotype TACGTC, which differed from the TGAAAT haplotype in the last five nucleotides, was inversely correlated with the BA phenotype ( $P=0.002$ , odds ratio=9.83, 95%CI=8.35-11.31). These results indicated that specific variants of the IKAP gene, or a variant in linkage disequilibrium with the TGAAAT haplotype, might be associated with mechanisms responsible for early-onset BA.

**Maternal genetic effects as risk factors for common birth defects: maternal MTRR genotype and spina bifida.**  
*L.E. Mitchell, K. Hoess, S. Barbaux, A.S. Whitehead.* University of Pennsylvania School of Medicine, Philadelphia, PA.

It is generally recognized that the maternal genotype may have an effect on the phenotype of offspring that is in addition to the effect of maternally transmitted alleles. This effect is genetic with respect to the mother but acts as an environmental effect on the offspring. Recent case-control studies of the relationship between genes for folate/cobalamin metabolizing enzymes (MTHFR, MTRR) and spina bifida risk have highlighted the importance of considering both maternal and fetal genotypes as potential risk factors. However, using the case-control approach it is not possible to clearly differentiate between such effects. The two-step transmission disequilibrium test (2sTDT) provides a novel approach for differentiating between maternal and fetal genotypic effects. To assess fetal genotypic effects, transmissions from heterozygous parents to affected offspring are evaluated. To assess maternal genetic effects, the phenotype of interest becomes "having an affected child" and transmissions from heterozygous maternal grandparents of affected individuals, to the mothers of these individuals are evaluated. The 2sTDT was used to evaluate the relationship between variation at the MTRR locus and spina bifida, as part of an ongoing study of genetic and environmental risk factors for this condition. This study was specifically designed to evaluate both maternal and fetal genotypic effects and, hence, includes DNA samples from affected individuals, parents, and maternal grandparents. The MTRR A66G polymorphism, which is a functional variant, was significantly related to having a child with spina bifida. Specifically, heterozygous maternal grandparents of affected individuals transmitted the G allele to the *mothers of offspring with spina bifida* more frequently than expected (12/15,  $P=0.02$ ). In contrast, there was no evidence of excess transmission of the G allele from heterozygous parents to offspring with spina bifida (39/76,  $P=0.82$ ). These results further highlight the importance of assessing both maternal and fetal genotypic effects, and provide the first direct evidence that maternal genetic effects play an important role in the etiology of spina bifida.

**MSX1 Variant is Associated with Cleft Lip/Palate in a South American Population.** *A.R. Vieira<sup>1,2</sup>, I.M. Orioli<sup>2</sup>, E.E. Castilla<sup>3</sup>, M.E. Cooper<sup>4</sup>, M.L. Marazita<sup>4</sup>, J.C. Murray<sup>1</sup>.* 1) Dept Pediatrics, Univ Iowa, Iowa City, IA; 2) ECLAMC at UFRJ, Rio de Janeiro, Brazil; 3) ECLAMC at Fiocruz, Rio de Janeiro, Brazil, and CONICET, Buenos Ires, Argentina; 4) Division of Oral Biology and Dept Human Genetics, Univ Pittsburgh, Pittsburgh, PA.

ECLAMC (Estudio Colaborativo Latino Americano de Malformaciones Congenitas or Latin American Collaborative Study of Congenital Malformations) is a program which has investigated the causes of congenital malformations and their frequencies in Latin American hospitals since 1967. Beginning in January 1998, ECLAMC has collected biological samples from children with nonsyndromic oral-facial clefts and their mothers for molecular analysis. Nonsyndromic oral-facial clefts are common congenital malformations known to occur in approximately 1/1,000 live births in ECLAMC hospitals. The present study used the transmission disequilibrium test (TDT)-based analysis to detect non-Mendelian transmission of one DNA sequence variant in MSX1 to 217 South American children from their respective mothers. The anonymous markers D7S1797 and two others derived from a published sequence for chromosome 1 (HS272L16 Accession # AL023754) were also evaluated and there was no evidence of genome-wide transmission distortion. The results show strong association between nonsyndromic cleft lip with/without cleft palate and MSX1 ( $p=0.002$ ) but not for cleft palate only and MSX1 ( $p=0.33$ ). When cleft lip only cases were analyzed separately, the association with MSX1 was not as strong ( $p=0.025$ ). Also, there was no association between cleft lip with cleft palate and MSX1 ( $p=0.111$ ). When cleft lip with cleft palate and cleft palate only cases were analyzed together, we did not find association with MSX1, although the values were borderline ( $p=0.06$ ). This result supports previous linkage and linkage disequilibrium findings with MSX1 in humans and mice and suggests that MSX1 mutations make a substantial contribution to clefts in South American populations.

**A TDT and candidate gene analysis shows TGFB3 involved in non-syndromic clefting in an Asian population.**  
*E.A. Park, Y. Watanabe, S. Daack-Hirsch, S. O'Brien, R. Schultz, A. Viera, M. Shi, J.C. Murray.* Dept Pediatric, Univ Iowa, Iowa City, IA.

Cleft lip and palate is a common congenital structural anomaly with complex etiology involving both genetic and environmental factors. Candidate gene analysis has already suggested the involvement of both MSX1 and TGFB3 in Caucasian populations, and in the case of MSX1, specific etiologic mutations have been identified. TGFB3 is a member of the TGFB family that acts hormonally to control the proliferation and differentiation of multiple cell types. Transgenic knockout mice, in vitro expression and the previous association studies support the involvement of TGFB3 in palatogenesis. To extend the candidate gene approach, we have developed a panel of 500 nuclear triads (father, mother, affected child) with high quality DNA samples drawn from a Philippines non-syndromic cleft lip and palate population. We use 150 of these triads in an initial analysis of common SNP or tandem repeat variants at candidate gene loci and then look for evidence of transmission distortion using the TDT test. These 150 triads have to date been analyzed for the genes GCP2, MTHFR, JAGGED2, MSX1, PAX9, TGFA, and TGFB3. In the case of TGFB3, significant transmission distortion was observed ( $p=0.02$ ) in the initial screening panel of 150 triads. Confirmation of this is now being extended to 350 additional triads. The overall search is also being extended to additional genes whose expression pattern or location suggest a role in clefting. Sequence analysis of TGFB3 exons has identified a new mutation in the promotor region of some NS CL/P families whose analysis is now being extended to these cases, as well. The confirmation of association of TGFB3 with clefting in an Asian population further supports its role in the etiology of non-syndromic clefting and emphasizes the need to carry out additional high-throughput sequence analysis of the coding and regulatory regions of this gene for etiologic mutations.

**Coriell Autism Research Resource: multiplex families and their Hoxa1 polymorphism status.** *R.T. Johnson<sup>1</sup>, L.H. Toji<sup>1</sup>, A. Mars<sup>2</sup>, C.M. Beiswanger<sup>1</sup>, J.C. Leonard<sup>1</sup>, P.K. Bender<sup>1</sup>, J.C. Beck<sup>1</sup>.* 1) Coriell Cell Repositories, Coriell Inst Medical Research, Camden, NJ; 2) Department of Pediatrics, Robert Wood Johnson Medical School, New Brunswick, NJ.

A genetic resource of DNA samples to support the study of autism in families where more than one child is affected or where one child is affected and one demonstrates another significant and related developmental disorder has been built at the Coriell Institute for Medical Research in collaboration with the the University of Medicine and Dentistry Robert Wood Johnson Medical School. An open bank of anonymously collected materials documented by a detailed clinical diagnosis forms the basis of this database of information about the disease. Three criteria were used to assess the autistic phenotype: the ADI (Autism Diagnostic Interview), the ADOS (Autism Diagnostic Observational Schedule-Generic), and the DSM IV Diagnostic Criteria for 299.00 Autistic Disorder. All clinical interviews were conducted face-to-face. For each donor subject tested, a representative Autistic Diagnostic Criteria Score Sheet used to collect data is provided. Currently, there are 28 multiplex families in the Resource including 28 probands and 119 first, second or third degree relatives. 60 individuals have been examined clinically, as described. 44 of these individuals have a diagnosis of autistic disorder by two or more criteria; 37 of these satisfy all three criteria. There are 24 affected sib or first-cousin pairs with a diagnosis of autistic disorder by two or more criteria; 12 of these pairs meet all three criteria. With growing interest in the possible association between HOX genes and autism we have ascertained the frequency of one common polymorphism in exon 1 of Hoxa1 (a single base substitution, A218G), in affected and unaffected families. Our data are in agreement with Ingram et al (*Teratology* 62: 393-405, 2000), and show a similar proportion of subjects in the autistic families with the polymorphic variant. Further information about this resource, including information on ordering, can be found at <http://locus.umdj.edu/autism> or by contact with the Coriell Cell Repositories.

**Mutations in MSX1 are associated with Non-Syndromic Orofacial Clefting.** P. Jezewski<sup>1,4</sup>, A. Vieira<sup>1,2</sup>, R. Schultz<sup>1</sup>, J. Machida<sup>3</sup>, Y. Suzuki<sup>3</sup>, B. Ludwig<sup>1</sup>, S. Daack-Hirsch<sup>1</sup>, S. O'Brien<sup>1</sup>, C. Nishimura<sup>1</sup>, M. Johnson<sup>1</sup>, J.C. Murray<sup>1</sup>. 1) Genetics, Univ Iowa, Iowa City, IA; 2) ECLAMC at UFRJ, Brazil; 3) Aichi-Gakuin Univ, School of Dentistry, Japan; 4) Periodontics, College of Dentistry, Univ Iowa.

Nonsyndromic orofacial clefting is a complex, multifactorial, common birth defect affecting from 1/700 to 1/2500 births. Autosomal dominant, syndromic hypodontia with orofacial clefting is caused by a nonsense mutation in exon 1 of MSX1 while AD selective tooth agenesis is found with an MSX1 change at R196P. Diagnostic resequencing of MSX1 exons and an intronic homology region (IHR) was accomplished in over 1000 cases and controls from Asia, Europe, North and South America, to search for potential mutations in NSOFC. This survey revealed 28 sequence variants, with 13 in the coding regions of the gene. These variants were evaluated as potential etiologic mutations in NSOFC. From the eight amino acid substitutions found, 5 were non-conservative changes. An amino acid sequence homology-based program, SIFT, was used to classify amino acid substitutions as tolerated or deleterious. An R151S substitution was considered intolerant when compared to MSX1 orthologs back to zebrafish. A dizygotic twin with bilateral clefting had G116E while the other twin did not and had unilateral clefting. G116E and V114G were rated intolerant by SIFT when compared to orthologs back to *Xenopus*. E78V, found in several probands from unrelated Filipino families was conserved among mammals. One control individual had a nonconservative amino acid change, G16D, but it was not conserved even in mice. Case and control frequencies were assessed in those variants present at >1% of the population (12/28). Two different point mutations were found in the intronic homology region (IHR) in two Iowa probands but not in any other samples. Cumulatively, these findings point to such variants being etiologic for nonsyndromic orofacial clefting. These results may explain 1-2% of cases of NSOFC and can dramatically change recurrence risks in families from the empiric 3-5% to as high as 50%. Further family, population and functional studies are in progress.

**The HCR susceptibility allele for psoriasis at PSORS1 locus shows altered secondary structure and a possible role in keratinocyte proliferation.** *K. Asumalahti*<sup>1</sup>, *O. Elomaa*<sup>1</sup>, *S. Suomela*<sup>3</sup>, *T. Laitinen*<sup>1</sup>, *R. Ikonen-Vatjus*<sup>5</sup>, *C. Jansen*<sup>4</sup>, *J. Karvonen*<sup>5</sup>, *S-L. Karvonen*<sup>5</sup>, *T. Reunala*<sup>6</sup>, *E. Snellman*<sup>7</sup>, *T. Uurasmaa*<sup>4</sup>, *U. Saarialho-Kere*<sup>3</sup>, *J. Kere*<sup>2</sup>. 1) Dept. of Medical Genetics; 2) Finnish Genome Center, Univ. of Helsinki; 3) Dept. of Dermatology, Helsinki; 4) Turku; 5) Oulu and; 6) Tampere Univ. and; 7) Pajjat-Hame Central Hospitals, Finland.

Psoriasis is a common chronic skin disease characterized by hyperproliferation and loss of differentiation of keratinocytes. We have previously shown that HCR gene at PSORS1 is highly polymorphic and associates strongly with psoriasis. We expanded our family material to become representative of most of Finland. In TDT analysis of 91 Finnish trios we found that four SNPs of the HCR gene form a coding susceptibility allele, HCR\*WWCC, which associates with psoriasis stronger than HLA-Cw\*6 or CDSN\*5. We also verified two new exons in the HCR gene, adding 135 bp 5' of the gene and 26 amino acids to the beginning of the protein. These exons did not contain new polymorphic sites in psoriasis patients. The HCR protein does not have significant homology with previously studied or known proteins. Secondary structure predictions suggest that it contains several segments of coiled-coil structures and contains a Leucine zipper motif. When we compared the structure predictions for the different allelic forms, the psoriasis associated susceptibility allele was predicted to have an altered secondary structure. By immunohistochemical analysis of skin biopsies the HCR protein was seen both in the nuclei and cytoplasm of keratinocytes. In normal and patients' non-lesional skin, staining was detected in basal keratinocytes. However, the staining pattern was different in psoriatic skin where the strongest staining was seen in non-proliferating cells and weak staining in proliferating cells, identified by the expression of the Ki67 proliferation marker. Our results contribute both genetic and functional evidence on the involvement of HCR in psoriasis susceptibility. The HCR gene may have a role in keratinocyte proliferation or differentiation. The altered secondary structure of the susceptibility allele may affect the antigenic properties of the protein.

**Down-regulation of decorin in fibroblasts of patients with classical Ehlers-Danlos syndrome.** *W. Just<sup>1</sup>, I. Hausser<sup>2</sup>, C. Grond-Ginsbach<sup>3</sup>, T. Trautmann<sup>1</sup>, S. Walter<sup>1</sup>.* 1) Dept Human Genetics, Univ Ulm, Ulm, Germany; 2) Dept Dermatology, Univ Heidelberg, Heidelberg, Germany; 3) Dept Neurology, Univ Heidelberg, Heidelberg, Germany.

Ehlers-Danlos syndrome (EDS) is characterized by loose-jointedness and fragile, bruisable skin. EDS I (MIM 130000) is the severe form of classic EDS, and EDS II (MIM 130010) is the milder one. There is evidence that EDS types I and II are allelic, and that mutations in *COL5A1* and *COL5A2* cause the syndrome in about 40%; of the reported investigated cases. In single families, mutations in collagen 1 and the tenascin gene have been detected. Another molecule of the extracellular matrix is decorin. Decorin (*DCN*) is a small leucine-rich proteoglycan (SLRP). *Dcn* null mice show an increased fragility of skin and altered shape and interfibrillar distance of collagen fibrils. Therefore, *DCN* might be a candidate gene for idiopathic fragile skin disorders. We present data about studies in the *DCN* gene of unrelated patients with EDS types I and II, diagnosed according to clinical symptoms and ultrastructural collagen fibril aberrations, who had not been checked for mutations in the *COL5A1/2* genes. We have sequenced all exons with their splice junctions of *DCN* on genomic DNA of 16 EDS I/II individuals. Not a single mutation nor a polymorphism was found. In addition we measured transcript levels in skin fibroblasts of these patients. There is a significant decrease in transcript levels to an average of about 60%; in comparison to healthy controls. Data was obtained from 42 measurements of Northern blots with total or poly-(A)<sup>+</sup>RNA. We suggest that a factor upstream of decorin contributes to the down-regulation of decorin on the mRNA level. In the meanwhile, at least in one of our EDS patients a *COL5A2* mutation was detected. The diminished amounts of processed decorin proteoglycan molecules may be a consequence of other disease-causing mutations and co-influence the precise assembly of collagen fibers, leading to fragile skin and other connective tissue disorders.

**Characterization of a psoriasis locus, PSORS5, on chromosome 3q21.** *L. Samuelsson<sup>1</sup>, D. Hewett<sup>2</sup>, T. Martinsson<sup>1</sup>, J. Riley<sup>2</sup>, I. Purvis<sup>2</sup>, A. Ineroth<sup>3</sup>, J. Wahlstrom<sup>1</sup>.* 1) Clinical Genetics, Sahlgrenska Univ Hosp-East, Gothenburg, Gothenburg, Sweden; 2) UK Discovery Genetics, Glaxo Smith Kline Research & Development, Stevenage, U.K; 3) Dermatology, Sahlgrenska Univ Hosp, Gothenburg, Sweden.

Psoriasis is a chronic inflammatory disease of the skin with both genetic and environmental risk factors. In a genome-wide screen a candidate region on chromosome 3q21 was identified in a Swedish nuclear family set of 134 affected sib-pairs. Linkage was mainly found in families originating from south-west Sweden and the disease locus is likely to be caused by a founder mutation. Likewise, families affected with joint involvement show stronger linkage to the region compared to families without joint involvement. This psoriasis susceptibility locus has been denoted PSORS5. In order to fine-map the PSORS5 locus an SNP map spanning 900-1200 kb was created. 644 individuals from 195 families affected by psoriasis and originating from south-west Sweden were genotyped for a total of 26 SNP markers. The transmission/disequilibrium test (TDT) was used to assess linkage disequilibrium between marker and disease. Five of the 26 SNPs showed significant association ( $p > 0.05$ ). All five markers are located within a 160 kb region. When analysed as a haplotype, alleles of the five markers associated with psoriasis to a p-value of  $< 10^{-7}$ . The 160 kb region was analysed by the Genscan exon-prediction software and a number of putative open-reading frames were identified. Homology searches revealed one previously unidentified gene located in the region. All confirmed and predicted coding sequences have been direct sequenced in 24 psoriatic individuals and 24 healthy control subjects in order to identify potential disease-involved polymorphisms. If there were a significant deviation in allele frequencies between cases and controls, the total family set was genotyped for the polymorphism and results were analysed by the transmission disequilibrium test.

**Insertion/Deletion Polymorphism of the Angiotensin I-Converting Enzyme Gene is Associated with Type 2**

**Diabetes.** *Y. Feng*<sup>1,2</sup>, *T. Niu*<sup>3</sup>, *X. Xu*<sup>3</sup>, *C. Chen*<sup>3</sup>, *Q. Li*<sup>1</sup>, *R. Qian*<sup>4</sup>, *X. Xu*<sup>2,3,5</sup>. 1) Division of Endocrinology, the Third Affiliated Hospital of Beijing University, Beijing, China; 2) Center for Ecogenetics and Reproductive Health, Beijing University, Beijing, China; 3) Prog Population Genetics, Harvard Sch Public Health, Boston, MA; 4) Division of Endocrinology, the First Affiliated Hospital of Beijing University, Beijing, China; 5) The Channing Laboratory, Department of Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA 02115.

Type 2 diabetes is a complex disorder resulting from the interaction of several genes and environmental factors. To date, major susceptibility genes have not been found for this devastating disease. Angiotensin I-converting enzyme (ACE) is a key enzyme in renin-angiotensin system. Some previous studies suggested that ACE gene insertion/deletion (I/D) polymorphism in intron 16 was associated with vascular complications in type 2 diabetic patients. In an attempt to examine the role of ACE gene I/D polymorphism in type 2 diabetes, we conducted an association study among 132 case-control pairs recruited from northern China. The genotype frequencies for II, ID and DD were 39.8%, 39.8% and 20.3%, respectively in the case group, and 44.8%, 44.8% and 10.4%, respectively in the control group. Comparing DD vs. II/ID genotypes, the DD frequency was found significantly higher in the case group than that in the control group ( $\chi^2=4.77$ ,  $p=0.03$ ). With adjustment of age and gender, the DD genotype was observed to be significantly associated with an increased risk of type 2 diabetes [odds ratio (OR)=2.23, 95% CI: 1.09-4.56]. In conclusion, our data showed that the DD genotype confers increased susceptibility to type 2 diabetes in a population of Chinese ethnicity.

**Gene expression profiling in skeletal muscle of subjects with different glycaemic tolerance.** *C.M. Lindgren<sup>1</sup>, J. Lehar<sup>2</sup>, J. Hirschhorn<sup>2</sup>, A. Vaag<sup>3</sup>, P. Poulssen<sup>3</sup>, K.F. Eriksson<sup>1</sup>, M. Gaassenbeek<sup>2</sup>, C. Ladd<sup>2</sup>, P. Tamayo<sup>2</sup>, M.J. Daly<sup>2</sup>, M. Ridderstråle<sup>1</sup>, H. Beck-Nielsen<sup>3</sup>, E.S. Lander<sup>2</sup>, D. Altshuler<sup>2</sup>, L.C. Groop<sup>1</sup>.* 1) Department of Endocrinology, Institution of Medicine, Lund University, Malmö, Sweden; 2) Whitehead Institute, Center for Genome Research, Massachusetts Institute of Technology, MA, USA; 3) Department of Endocrinology and Internal Medicine, Odense University Hospital.

Type 2 diabetes mellitus is a metabolic disorder caused by impaired insulin action in target tissues (like muscle) and pancreatic beta-cell dysfunction. We hypothesized that variation in the transcriptional process may be associated with differences glucose tolerance and studied variation in gene transcripts in skeletal muscle biopsies between 28 men with normal (age 66±9) and 26 men with abnormal (age 65±9) glucose tolerance, obtained after a euglycemic hyperinsulinemic clamp (Group A). In addition, the acute effect of insulin was evaluated in biopsies taken before and after a euglycemic clamp from 7 monozygotic twin pairs (4 women/10 men) (Group B). Labeled cRNA was analyzed on microarrays including over 6800 genes. Results of group A were analyzed using k-NN statistics and group B by a pair-wise comparison of samples taken before and after insulin infusion. Significance was assessed using permutations although the number of permutations in group B is limited due to the smaller numbers of samples. In the muscle biopsies, we found 209 genes differentially expressed when comparing hyperglycemic men with normoglycemic men (group A),  $p < 0.05$ . In the twins we observed 89 genes which were influenced by insulin (group B),  $p < 0.05$ . In summary, the expression profile in skeletal muscle differs significantly between individuals with different glucose tolerance, which may reflect transcriptional events important in the development and maintenance of abnormal glucose tolerance. The study was, however, not designed to allow conclusions on whether these represent primary changes or develop secondarily to hyperglycemia. A larger group of monozygotic twins may shed light the clues of physiological mechanisms elicited in muscle by insulin stimuli obtained in this study.

**Methylation pattern of a CpG island of ZAC gene in transient and permanent neonatal diabetes mellitus. Y.**

*Makita*<sup>1,2</sup>, *T. Ishii*<sup>2</sup>, *Y. Ito*<sup>2</sup>, *K. Fujieda*<sup>2</sup>, *A. Hata*<sup>1</sup>. 1) Public Health, Asahikawa Medical College, Asahikawa, Hokkaido, Japan; 2) Pediatrics, Asahikawa Medical College, Asahikawa, Hokkaido, Japan.

Depending on their clinical courses, whether a recovery from diabetic condition occurs or not during neonatal period, neonatal diabetes mellitus can be classified into neonatal and permanent types (TNDM and PNDM). In TNDM, paternal duplicated alleles or methylation defect in a maternal allele in a ZAC gene region, a maternally imprinting gene, are responsible for the etiology. However, in a pure form of PNDM, which has no other symptoms except hyperglycemia, molecular defects have not been elucidated so far. In the present study, we analyzed methylation pattern in a CpG island of ZAC gene both in TNDM and PNDM patients. The CpG island extends from a nucleotide number 52460 to 53407 of AL109755 (accession no.). We arbitrary divided the CpG island into two, from 52481 to 52910 and from 52951 to 53260, and named the regions B and A. Then sequencing analysis after bisulfide treatment was performed. In TNDM patients, demethylation pattern of both two regions was observed. However, in four Japanese PNDM patients, the demethylation pattern was observed only in a region A. This methylation pattern could be a molecular defect causing PNDM and might explain the difference of clinical phenotype between TNDM and PNDM.

**SCA8 repeat contractions in the male germline occur before meiosis.** *M.L. Moseley<sup>1</sup>, L. Rasmussen<sup>1</sup>, J. Pryor<sup>2</sup>, K. Roberts<sup>2</sup>, J.W. Day<sup>1</sup>, L.P.W. Ranum<sup>1</sup>.* 1) Institute of Human Genetics, Univ MN, Mpls, MN; 2) Dept Urologic Surgery, Univ MN, Mpls, MN.

Spinocerebellar ataxia type 8 (SCA8) is caused by an untranslated CTG expansion. SCA8 is distinct from other SCAs in that disease penetrance is markedly reduced. Although either parent can transmit the CTG expansion, there is a maternal penetrance bias for transmitting the disease. This bias is consistent with the observation that maternal transmission most frequently results in the expansion of the CTG repeat tract, whereas paternal transmissions almost always result in shorter less penetrant repeat tracts. We evaluated SCA8 instability in sperm samples from individuals with expansions ranging in size from 80 to 800 repeats in blood, and found that the SCA8 repeat tract in sperm underwent contractions in which nearly all of the resulting expanded alleles have repeat lengths of <100 CTGs. The repeat contractions in sperm likely play a role in the reduced penetrance associated with paternal transmissions.

To investigate the origin of these homogeneous and often dramatic contractions in the male germline, we have examined the expansion length in cells at different stages of spermatogenesis. Germ cells from testis tissue of an SCA8 subject were sorted into 2N (spermatogonia), 4N (spermatocytes), and 1N (spermatids) by fluorescence flow cytometry. We found that a 300 repeat allele in blood contracted to a tight window of ~100 repeats in the 2N spermatogonial fraction, a stage of spermatogenesis prior to meiosis. Why the SCA8 expansion contracts during male germ cell mitosis, but is stable in all somatic tissues studied to date remains unclear. One hypothesis is that there may be a growth advantage for spermatogonial stem cells with smaller repeat tracts. If this finding is confirmed in testis samples from other men and other families, it will aid in genetic counseling about the risks of disease transmission in families with an established pathogenic range.

**Genome-wide linkage analysis to presbycusis in the NHLBI Framingham Heart Study.** *A.L. DeStefano<sup>1</sup>, G.A. Gates<sup>2</sup>, N. Heard-Costa<sup>1</sup>, R.H. Myers<sup>1</sup>, C.T. Baldwin<sup>1</sup>.* 1) Boston Univ Sch Medicine, Boston, MA; 2) Virginia Merrill Bloedel Hearing Research Center, Univ Washington, Seattle, WA.

Hearing impairment in the adult population (presbycusis) is estimated to affect 45.9 % of individuals over age 48. Although environmental exposures play a role in age related hearing impairment, studies in both human populations and animal models indicate that there is a genetic component to presbycusis. For this study, standard pure-tone audiograms were obtained on subjects using environments and methods meeting ANSI standards. Pure tone thresholds averaged (PTA) across distinct frequencies (low, medium and high) were used to provide quantitative measures of hearing loss. These measures were also used to define clinical subtypes of which sensory presbycusis, typified by predominately high frequency loss, is the most common. In contrast, strial presbycusis has a relatively flat loss across the low-frequency spectrum with variable degrees of high-frequency loss. While strial presbycusis is less common than sensory presbycusis, it is more heritable ( $h^2 = 0.31 - 0.48$ ). In this study, we conducted a genome wide scan to examine linkage to low and medium PTA in 328 extended pedigrees in the NHLBI's Framingham Heart Study, a community-based longitudinal study in which participants were selected randomly from the population of Framingham, MA. Regression analysis was used to adjust medium and low PTAs for age, age<sup>2</sup> and age<sup>3</sup> and standardized residuals were created. Normalized residuals based on rank were also created and used for analysis. Two-point and multipoint quantitative trait linkage analyses were conducted using the SOLAR package. Six chromosomal locations yielded suggestive evidence of linkage and were located on chromosomes 10, 11, 14 and 18. Several of the regions identified in this study overlap with genes known to cause congenital deafness. Thus, the linkage results suggest that the same genes that cause Mendelian-early onset hearing loss may contribute to age-related hearing loss.

**The Crohn's disease susceptibility gene identified by positional cloning is not associated with rheumatoid arthritis.** *F. Cornelis*<sup>1</sup>, *F. Merlin*<sup>2</sup>, *C. Pierlot*<sup>1</sup>, *S. Moindrault-Cailleau*<sup>1</sup>, *J.P. Hugot*<sup>2</sup>, *S. Lesage*<sup>2</sup> for ECRAF. 1) Laboratoire Europeen de Recherche pour la Polyarthrite Rhumatoide, Universite Paris VII, Evry, France; 2) Fondation Jean Dausset - CEPH, Paris, France.

Crohn's disease and rheumatoid arthritis (RA) are chronic inflammatory diseases of the bowel and joints, respectively. NOD2 was shown to be implicated in Crohn's disease by positional cloning, an insertion deletion polymorphism being the most strongly associated. ECRAF genome scan provided linkage of  $p=0.16$  at that location (D16S411). The aim was to investigate this polymorphism in sporadic and familial RA. Genotyping of the polymorphism was performed on ABI377 for 56 families with 1 RA patient and both parents, as well as in 42 unrelated RA patients from affected sib-pair families. Out of the 56 simplex families, all parents were homozygous for the allele that is not associated with Crohn's disease, but 10 parents who were heterozygotes. From those, the Crohn's allele was transmitted 6 times to the RA offspring. All RA patients from multiplex families were homozygous for the other allele. In conclusion, no evidence was found for a role of that polymorphism in RA susceptibility.

**Fine mapping of the chromosome 16q11-14 susceptibility locus in human SLE sib-pair families.** *P.M. Gaffney<sup>1</sup>, W.A. Ortmann<sup>1</sup>, R.R. Graham<sup>1</sup>, C.D. Langefeld<sup>2</sup>, S.S. Rich<sup>2</sup>, T.W. Behrens<sup>1</sup>*. 1) Department of Medicine, University of Minnesota, Minneapolis, MN; 2) Department of Public Health, Wake Forest University, Winston-Salem, NC.

Systemic Lupus Erythematosus (SLE) is a complex autoimmune disease of unknown etiology, with a strong genetic contribution. We have recently reported the results of genome-wide marker screens in SLE sib-pair families, which have identified a region in the centromeric region of the long arm of chromosome 16 that shows strong evidence for linkage in our family collection (LOD 4.86, D16S415). In order to narrow the region for gene identification we have initiated a fine mapping effort in the 16q11-14 region in 193 SLE sib-pair families. Analysis of the first 17 markers on the fine map indicate the best evidence for linkage is found close to marker D16s757 (LOD=2.6), with a 1.5 LOD support interval of approximately 5 cM. Further mapping with both microsatellites and single nucleotide polymorphisms is underway, with a goal of identifying regions exhibiting linkage disequilibrium in our SLE population. The recent identification of the NOD2 gene as the relevant susceptibility gene in this region for Crohns disease, an autoimmune disorder of the gut, has prompted us to examine this gene as a candidate for SLE. Progress in the fine mapping and candidate gene analysis will be presented.

**No support for linkage of chromosome 17<sub>q21-24</sub> to Essential Hypertension in the MRC British Genetics of Hypertension (MRC BRIGHT) Study.** *J. Knight<sup>1</sup>, P. Munroe<sup>1</sup>, W. Lee<sup>2</sup>, N. Brain<sup>2</sup>, J. Pembroke<sup>1</sup>, S. O'Shea<sup>1</sup>, M. Brown<sup>3</sup>, N. Samani<sup>4</sup>, N. Benjamin<sup>1</sup>, M. Farrall<sup>5</sup>, D. Clayton<sup>3</sup>, P. Ratcliffe<sup>5</sup>, J. Webster<sup>6</sup>, M. Lathrop<sup>7</sup>, A. Dominiczak<sup>2</sup>, J. Connell<sup>2</sup>, M. Caulfield<sup>1</sup>.* 1) Barts and the London, UK; 2) Universities of Glasgow; 3) Cambridge; 4) Leicester; 5) Oxford; 6) Aberdeen, UK; 7) CNG, France.

The MRC BRIGHT study is funded to recruit 1500 hypertensive families based upon affected sibling pairs with pre-diagnosis blood pressures in the upper 5% of the blood pressure distribution (145/95mmHg) and onset prior to 60 years of age. Recruitment is now complete and 1700 families have been extensively phenotyped. Recent studies have demonstrated linkage of chromosome 17<sub>q21-24</sub> with human essential hypertension. The BRIGHT resource is ideal for candidate gene/region studies therefore, we assessed whether markers on chromosome 17 previously linked to hypertension are a cause of high blood pressure in this population.

Nine microsatellite markers were selected for analysis in 859 families. All of the markers were amplified using PCR and then genotyped using Applied Biosystems 377 protocols and software. The genotypes were second checked manually and also using a bespoke Microsoft Access data checking tool.

No evidence of linkage was found between the markers studied and essential hypertension in the entire cohort. Maximum likelihood (ML) LOD scores in MAPMAKER/SIBS ranged from 0 to 0.04, in GENEHUNTER the N.P.L. values ranged between -1.6 and 0.19. This data enables us to exclude a gene with a relative risk to a sibling of 1.25 from being present in this chromosomal region. We also analysed increased severity of hypertension as a sub-phenotype. Two groups were selected based on multiple pre-treatment recordings a) 123 families with diastolic readings of 100mmHg or greater and b) 185 families with systolic readings of 160mmHg or greater. Resultant ML LOD scores and N.P.L. values were all 0 or below. Our results suggest if there is a gene(s) on chromosome 17<sub>q21-24</sub> it exerts only a small influence on blood pressure in this population, however it maybe present in other sub-groups of this resource.

**Genetic study of generalized and partial epilepsy - linkage on chromosome 12.** *M.Z. Labuda<sup>1</sup>, S. Bourgoin<sup>1</sup>, A. Gambardella<sup>2</sup>, A. Siren<sup>3</sup>, U. Aguglia<sup>2</sup>, A. Quattrone<sup>2</sup>, E. Andermann<sup>4</sup>, K. Simola<sup>3</sup>, M. Koivikko<sup>3</sup>, M. Pandolfo<sup>1</sup>.* 1) Ctr de Recherche, CHUM, Montreal, Quebec, Canada; 2) Institute of Neurology, School of Medicine, Catanzaro, Italy; 3) Department of Pediatrics, Tampere University Hospital, Finland; 4) Montreal Neurological Institute, Montreal, Quebec, Canada.

We studied seven families with dominantly inherited idiopathic epilepsy. Four families with temporal lobe epilepsy (TLE) had been previously tested for known partial epilepsy loci on chromosomes 20q, 15q, 10q, 8q, 19q 22. Three families with febrile convulsions as the main phenotype were tested for relevant loci on chromosome 2q, 19p, 19q and 11. In all cases, no evidence of linkage was found. Families were then subjected to a genome-wide scan. While three families were previously reported to map on chromosome 5 (ASHG 2000, abstract ), the other two families showed suggestive linkage to chromosome 12. One of these families (5 affected individuals) segregates a TLE phenotype and is from a small community in the Southern Italian region of Calabria, the other one is from Finland and segregates a phenotype that includes febrile convulsion and absence epilepsy (5 affected individuals). We have tested three more small TLE families from the same community in Calabria for linkage to chromosome 12 and found that two are consistent. The cumulative lod score for chromosome 12 markers is 3.6 at  $\theta = 0.0$ . Moreover, another Finnish family previously mapped to chromosome 5 was also consistent with linkage to chromosome 12 with maximum lod score of  $Z=0.72$  at  $\theta=0.1$ ). In addition, and rather surprisingly considering their diverse geographic origin, affected individuals in four families share the same haplotype in a 0.4 Mb interval. However, the frequency of this haplotype on normal chromosomes in the studied populations is 23%. We suggest the possibility of a new epilepsy locus on chromosome 12. In addition, the apparent cosegregation of epilepsy with markers from chromosomes 5 and 12 in a large Finnish family suggests the possibility of digenic contribution to the phenotype.

**Investigation of Chromosome 22 Genes in Rheumatoid Arthritis.** *E. Petit-Teixeira, J. Osorio, G. Bana, S. Moindrault-Cailleau, P. Dieude, C. Pierlot, C. Sardou, S. Lasbleiz, S. Faure, O. Alibert, T. Bardin, B. Prum, F. Cornelis for ECRAF.* Laboratoire de Recherche Europeen pour la Polyarthrite Rhumatoide, Universite Paris VII, Evry, France.

**Background:** Rheumatoid Arthritis (RA) is a multifactorial disease. The chromosome 22 sequence provides a tool to search for RA candidate genes, with the help of RA genome scans performed in Europe (ECRAF), JAPAN and USA (NARAC).

**Objective:** To investigate chromosome 22 genes for RA, using their (putative) function and linkage data.

**Method:** Systematic examination of chromosome 22 genes (known, related and predicted genes), searching for RA candidates based on gene function. Localization of genome scan markers (22/ECRAF, 4/NARAC, 6/JAPAN) within the chromosome 22 sequence along with all genes. Plotting of linkage results according to marker sequence position, defining suggested loci by markers with linkage  $p < 0.05$  and their flanking markers.

**Results:** Out of the 545 genes examined, 18 (3 per cent) were selected as RA candidates, the major candidates being IL17R, MIF and IL2RB. For them, linkage evidence was  $p=0.06$ , 0.5 and 0.5, respectively, as provided by ECRAF closest marker (less than 3cM away), JAPAN and NARAC scan being not contributing (no evidence of linkage with the closest markers). There was one suggested RA locus from linkage data (D22S1160 with  $p = 0.001$ , flanked by D22S274 and D22S1170/ ECRAF), with no gene selected as candidate.

**Conclusion:** The combination of chromosome 22 sequence, with functional information on genes, and linkage data, provided 18 RA candidate genes, with IL17R as number one. Sequence and fine genome scan information, ECRAF genome scan being performed on 1109 markers in total, contributes in prioritizing candidate gene studies in RA. Refinement of linkage data, taking into account the clinical and heterogeneity of the disease, is warranted to take full advantage of the linkage data. The GenHotel program is available to test RA candidates (<http://www.polyarthrite.net>).

**Genomic Screen for POAG susceptibility genes: Follow-up studies and candidate gene evaluation.** *J.L. Wiggs<sup>1</sup>, R.R. Allingham<sup>2</sup>, L.R. Bailey<sup>3</sup>, J. Auguste<sup>1</sup>, E.A. DelBono<sup>1</sup>, B. Broome<sup>2</sup>, F. Lennon Graham<sup>4</sup>, M. Hauser<sup>4</sup>, M.A. Pericak-Vance<sup>4</sup>, J.L. Haines<sup>3</sup>.* 1) Dept Ophthalmology, Mass Eye & Ear Infirmary, Boston, MA; 2) Dept Ophthalmology, Duke University School of Medicine, Durham NC; 3) Program in Human Genetics, Vanderbilt University School of Medicine, Nashville, TN; 4) Center for Human Genetics, Duke University School of Medicine, Durham NC.

We have previously completed an initial genome screen to identify the chromosomal locations of POAG susceptibility genes. This initial study identified 16 chromosomal regions that demonstrated interesting results (lod score >1.0) and/or p-value < 0.05). Additional evidence for POAG loci on chromosomes 2, 4, 14, 15, 17, and 19 was obtained in a second dataset. The purpose of the present study is to further refine these chromosomal regions using additional markers, and including unaffected family members for IBD information, as well as a third group of affected sibling pairs. For this study POAG was defined as age of diagnosis greater than 35, intraocular pressure greater than 22 mm Hg in both eyes, glaucomatous optic nerve damage in both eyes, and visual field loss in at least one eye. Markers that previously demonstrated interesting results as well as near-by markers located 2.5 cM from the original positive markers were analyzed using GENEHUNTER+. Unaffected pedigree members were included in the analysis as unknowns to help identify the parental alleles. The results for the combined dataset continue to show evidence for linkage to all regions, with increased scores for chromosome 15 (from 1.0 to 2.12 for marker D15S165). The remaining regions were basically unchanged. Thus, while chromosomes 2, 4, 14, 17, and 19 remain interesting, the results of this study provide further evidence of a POAG susceptibility gene on chromosome 15. Evaluation of candidate genes within these regions are ongoing. Supported by NIH grant EY10886.

**Genome-Wide Deletion Screen in CHARGE Association.** *S.R. Lalani<sup>1</sup>, C. Bacino<sup>1</sup>, D.W. Stockton<sup>1,4</sup>, L. Molinari<sup>1</sup>, N.L. Glass<sup>2,3</sup>, S.D. Fernbach<sup>1</sup>, J. Towbin<sup>1,3</sup>, W. Craigen<sup>1</sup>, J.W. Belmont<sup>1,3</sup>.* 1) Department of Molecular and Human Genetics; 2) Department of Anesthesia; 3) Department of Pediatrics; 4) Department of Medicine, Baylor College of Medicine, Houston, TX 77030.

CHARGE Association is a common complex of congenital anomalies including ocular coloboma, heart malformation, choanal atresia, retarded growth and development, genitourinary defects, cranial nerve anomalies, and ear abnormalities. Although most evidence points to genetic causation, the etiology of CHARGE is completely unknown. Among possible genetic mechanisms, de novo dominant mutation of an unknown gene with extraordinary pleiotropy or, alternatively, submicroscopic contiguous gene deletion are the most likely. To address the possibility of a deletion as the explanation for at least some cases of CHARGE, we have undertaken genotyping in case/parent trios to detect potential loss of heterozygosity. Extensive phenotypic information has also been collected on each of the 55 affected cases. We have designed a multilevel screening methodology in which an increasingly dense set of markers are used to detect non-mendelian inheritance. For our primary screen, we employed low-density short tandem repeat (STR) markers of 10 cM average distance from ABI Linkage Mapping Set. About 400 markers were used to genotype 10 core trios. Preliminary analysis of the data has shown non-mendelian inheritance pattern in 5 out of 400 markers. Two of these markers, D20S178 and D19S420 have been restudied with fluorescent in situ hybridization (FISH). These experiments showed that the locus was intact on both homologues and preferential allele amplification was the most likely explanation. We are analyzing the other markers using the same methodology. Secondary screening is being initiated with the ABI LMS-HD5 marker set that increases the marker density to an average spacing of 5 cM. We have studied 110 of these 411 markers, with no evidence of loss of heterozygosity. Subsequent screenings at increasing density will be undertaken using additional STRs and single nucleotide polymorphisms (SNPs) to survey markers spaced at 0.1 - 1 Mb intervals.

**Variation At The Nod-2 Locus In Familial And Sporadic Cases Of Crohns Disease In The Ashkenazi Jewish Population.** Z. Zhou, X. Lin, P. Akolkar, B. Gulwani-Akolkar, S. Katz, J. Silver. Department of Medicine, North Shore University Hospital-New York University School of Medicine, Manhasset, NY.

Purpose: Crohns disease (CD), a chronic inflammatory bowel disease, is known to be associated with genetic predisposition. A susceptibility locus, IBD1, has been mapped to the chromosome 16q11-12 region containing the NOD-2 gene. Recent reports indicate that allelic variants in the NOD-2 gene, a member of the CED4/APAF1 superfamily of apoptosis regulators, are associated with CD susceptibility and that homozygosity at this locus for any of three recently defined sequence variants confers a greatly increased risk of CD. These sequence changes include two missense mutations, R675W and G881R, and a frameshift insertion, 980insC. The aim of this study was to determine the frequency of these NOD-2 variants in familial and sporadic CD patients in the Ashkenazi population. Methods: Allele and genotype frequencies of these three variants were determined in 438 CD patients of Jewish descent; 153 patients had a family history of CD and 285 were "sporadic" cases. Variants were detected by PCR using allele-specific primers labeled with fluorescent dye. Results: Although the frequency of the R675W mutation was comparable in familial and sporadic cases (0.053 vs 0.050), the frequency of the G881R and the 980insC mutations was significantly higher in the familial cases than in the sporadic cases (0.137 vs 0.058,  $p=0.000079$ , and 0.091 vs 0.050,  $p=0.020$ ). As a result, the number of CD patients that were homozygous or compound heterozygotes for the NOD-2 mutants was significantly higher in the familial cases than in the sporadic cases (12.4% vs 4.91%,  $p=0.0028$ ). Conclusions: The NOD-2 mutations play a significantly greater role in causing disease in the familial cases than in the sporadic cases. Furthermore, this difference is due to significantly greater frequency of the G881R and 980insC, but not R675W, mutations in the familial cases.

**Approach to defining expression ratio of the SNRPN/B/B' members of the Sm family of spliceosomal proteins.**

*P.A. Smith, V.N. Evdokimova, R.J. Herrera.* Biological Sciences, Florida International University, Miami, FL.

Human small nuclear ribonucleoprotein-associated peptides N, B, and B' (SNRPN or SmN, SNRPB/B' or SmB/B') belong to the Sm family of proteins initially identified by their reactivity with autoimmune sera from patients with systemic lupus erythematosus. Sm proteins bind to small nuclear RNAs U1, U2, U4, and U5, and are thus part of the spliceosome, but the functions of the individual polypeptides have yet to be completely determined. The SmN locus is imprinted and has been implicated in Prader-Willie syndrome (PWS), a neurogenetic disorder caused by the loss of gene(s) from paternal 15q11-q13. Expression studies at the mRNA and protein levels for humans and a mouse model of PWS have suggested a tissue-specific pattern for SmN and its murine homolog. Furthermore, a compensatory feedback loop has been proposed to regulate levels of SmB/B' and SmN. However, a clear picture of expression patterns of all three human proteins at the RNA level has yet to be achieved. The possible tissue-specific expression patterns of SmN and its murine homolog have lead to suggestions that they play a role in tissue-specific alternative splicing, possibly involving recognition of cryptic splice sites. The goal of this study is to determine at the mRNA level the expression ratio of the SmB, SmB', and SmN proteins in different tissues. Total RNA was extracted from frozen human tissue samples by the single-step guanidinium acid-phenol method. After RT-nested PCRs, PCR products were then separated in an 8% polyacrylamide gel and visualized by silver staining. Initial results have indicated that SmB is ubiquitous, as expected. The SmB' system is currently being optimized. For SmN, the expected size product was detectable in all tissues examined, with multiple bands present in some tissues.

**Linkage and association analysis of chromosome 3 in autistic disorder.** *M.A. Pericak-Vance<sup>1</sup>, Y. Shao<sup>1</sup>, K. Raiford<sup>1</sup>, C.M. Wolpert<sup>1</sup>, H.H. Wright<sup>2</sup>, R.K. Abramson<sup>2</sup>, G.R. DeLong<sup>1</sup>, M.L. Cuccaro<sup>2</sup>, J.R. Gilbert<sup>1</sup>.* 1) DukeCtr Human Genetics, Duke Univ Medical Ctr, Durham, NC; 2) W.S. Hall Psychiatric Institute, University of South Carolina, Columbia, SC.

Genomic screen analysis of 99 multiplex Autistic Disorder (AutD) revealed evidence for linkage on chromosome 3 with D3S3680 (36.1 cM) resulting in a peak two point MLS=2.02. Subsequently we genotyped an additional 90 multiplex AutD families from the Autism Genetic Resource Exchange (AGRE) for markers in this region. With the new data the two point MLS score for D3S3680 increased to 3.16. Several other markers in the region also gave support for linkage in the expanded dataset including D3S4545 (26.3 cM), D3S3589 (32.3 cM) and D3S1259 (36.7 cM) with MLS=2.32,1.95 and 1.16, respectively. The peak multipoint MLS was at D3S1259 (MLS=2.66). The oxytocin receptor gene (OXTR) is located on chromosome 3p25-p26 near our peak region. Animal models have shown that OXTR is expressed in brain as well as uterus and mammary gland and has an effect on neural development. OXTR has also been shown to induce stereotypic behaviors in mice. To evaluate the OXTR as a potential AutD candidate gene we genotyped several SNPs in OXTR and tested for association using 2 different family-based association methods, the pedigree disequilibrium test (PDT) and TRANSMIT (TMT) in the combined AutD dataset. We found no evidence for association with either method in any of the OXTR SNPs. These data suggest that the OXTR gene is not a major contributor to risk in AutD, however, the region on chromosome 3 potentially harbors an AutD susceptibility gene.

**Autism DNA methylation profiling using CpG microarrays.** *C.H. Wang<sup>1,2,4</sup>, Y. Liu<sup>2</sup>, P.S. Yan<sup>3</sup>, T. Huang<sup>3</sup>, J.H. Miles<sup>4</sup>, R.E. Hillman<sup>4</sup>.* 1) Dept of Psychiatry and Neurology, Univ Missouri, Columbia, MO; 2) Dept of Biochemistry, Univ Missouri, Columbia, MO; 3) Dept of Pathology and Anatomical Sciences, Univ Missouri, Columbia, MO; 4) Dept of Child Health, Univ Missouri, Columbia, MO.

Autism is a complex neurodevelopmental disorder with a multigenic etiology. The wide spectrum of autism phenotypes may be the result of aberrant expression of many susceptibility genes. DNA methylation is a recognized regulatory mechanism of gene expression. Abnormal genomic methylation may underlie the pathogenesis of autism. In order to study the epigenetic influence of DNA methylation on autism, we applied a differential methylation hybridization (DMH) method to isolate the CpG islands that are abnormally methylated in autism. CpG microarrays were constructed from a CGI library enriched for CpG islands. Individual CGI clones were selected against repetitive sequences and amplified by colony PCR. A total of 768 CGI clones, each containing at least one methylation sensitive BstUI site, were manually dotted, in duplicate, onto a nylon membrane. Forty DNA samples were selected, 20 each from autism and control groups. Total genomic DNA was digested with MseI, subtracted from repetitive sequences, then digested with BstUI. The methylated fragments (undigested by BstUI) were PCR amplified, radiolabeled, and hybridized to the CpG microarray membranes. Each membrane was used only once. The radiodensities of each hybridized CGI clone were captured by a phosphoimager and analyzed by an ImageQuant software. We have identified at least three interesting clones. One clone is hypomethylated in the autism genome and emits a mean density of 1.1053 among autism samples, as opposed to 2.4375 among the controls. Two other clones are hypermethylated in the autism genome. One emits a mean density of 8.8947 in autism and 6.3125 in control samples. The other emits a mean density of 5.8947 in autism and 4.5000 in control samples. These data suggest that aberrant DNA methylation may be observed in the CpG islands within the autism genome. We are currently isolating these CGI clones in order to relate their sequences to functional genes.

**Candidate gene analysis of cleft lip/palate with hypodontia outside the cleft.** *R.L. Slayton<sup>1</sup>, L. Williams<sup>1</sup>, J.C. Murray<sup>1</sup>, J.J. Wheeler<sup>1</sup>, A.C. Lidral<sup>2</sup>, C. Nishimura<sup>1</sup>.* 1) The University of Iowa, Iowa City, IA; 2) The Ohio State University, Columbus, OH.

The etiology of orofacial clefting is complex and involves both genetic and environmental factors. Dental anomalies associated with cleft lip and/or palate (CL/P) include variations in number, size and position of developing teeth. Evidence for a similar genetic etiology for both orofacial clefting and hypodontia comes from a variety of sources, including knock-out mouse models and single gene disorders where both clefting and hypodontia are observed. The purpose of this pilot study was to determine if the candidate genes previously studied in subjects with CL/P are associated with hypodontia outside the region of the cleft. Subjects were ascertained as a population-based case-control study within the University of Iowa Craniofacial Anomalies Research Center (CARC). A subset of the CARC subjects were selected based on the availability of both dental records and genotyping information. One hundred twenty subjects met both criteria. A dental chart review was performed to verify the type of orofacial clefting and to identify the type and location of dental anomalies present (including missing teeth, supernumerary teeth and microdontia). Polymorphic markers in candidate genes were screened using PCR/SSCP. Candidate genes included MSX1, TGFB3, TGFA and PAX9. Chi-square analysis was used to evaluate the frequency of alleles for cases and controls for each SNP and the CLUMP program was used to analyze di-nucleotide repeat polymorphisms. The overall prevalence of hypodontia in this sample was 46.7% with 28.3% of subjects having missing teeth outside of the cleft. Dental anomalies were more frequently associated with CL/P than with CPO ( $p < 0.01$ ). In addition, hypodontia outside the cleft region was more likely to occur in subjects with CLP than in CL or CPO ( $p < 0.01$ ). Analysis of candidate genes found no significant association between the subjects with hypodontia outside the cleft region when compared to either non-cleft controls or controls with clefting but no hypodontia outside the cleft region.

**The *hairless* gene in androgenetic alopecia: Results of a systematic mutation screening and a family-based association approach.** A.M. Hillmer<sup>1</sup>, R. Kruse<sup>2</sup>, F. Macciardi<sup>3</sup>, U. Heyn<sup>1</sup>, R.C. Betz<sup>1</sup>, T. Ruzicka<sup>2</sup>, P. Propping<sup>1</sup>, M.M. Noethen<sup>1,4</sup>, S. Cichon<sup>1,4</sup>. 1) Institute of Human Genetics, University of Bonn, Bonn, Germany; 2) Department of Dermatology, University of Duesseldorf, Duesseldorf, Germany; 3) Unit of Biostatistics and Genetic Epidemiology, University of Toronto, Toronto, Canada; 4) Department of Medical Genetics, University of Antwerp, Antwerp, Belgium.

Genetic disposition and androgen dependence are important characteristics of the common patterned loss of scalp hair known as androgenetic alopecia (AGA). The genetic factors contributing to AGA are currently unknown. Recently, the human *hairless* gene (*HR*) has been cloned and mutations have been reported in families with autosomal recessive universal congenital alopecia and papular atrichia. The main feature of these disorders is persistent complete absence of hair at or shortly after birth. This suggests that *HR* is essential and specific for the development of hair. Therefore, *HR* can be considered a candidate for involvement in AGA. To test this hypothesis, we systematically screened the *HR* gene for genetic variability by means of single strand conformation analysis in 46 unrelated men with AGA. We detected 15 single nucleotide substitutions including eight missense mutations (205C®T, 1010G®A, 1190G®A, 1577T®C, 1727C®T, 1772A®G, 1859G®A, 3064A®G), four silent mutations (1305T®C, 2370T®C, 3234C®G, 3339C®A), and three mutations in exon-flanking intronic sequences (2611-68C®T, 2611-52T®C, 3379-29G®T). To test for an involvement of the *HR* gene in the development of AGA, seven common variants were genotyped in 61 families, yielding a total sample of 93 parent-offspring trios. The results were analyzed with the transmission/disequilibrium test (TDT). A significant association was found between AGA and variants 3379-29G/T (p=0.024) and 2611-68C/T (p=0.047), respectively. This result suggests an involvement of the *HR* gene in the development of AGA. Definite conclusions, however, require replication of the finding in independent samples.

**Alleles of the putative taste receptor gene TAS1R3 may influence the pleasantness of sucrose and aspartame in human subjects.** *D.R. Reed<sup>1</sup>, X. Li<sup>1</sup>, Z. Chen<sup>1</sup>, A.A. Bachmanov<sup>1</sup>, G.K. Beauchamp<sup>1</sup>, M.G. Tordoff<sup>1</sup>, M. Max<sup>2</sup>, R. Margolskee<sup>2</sup>, L.M. Bartoshuk<sup>3</sup>, V. Duffy<sup>3,4</sup>.* 1) Monell Chemical Senses Center, Philadelphia, PA; 2) Mount Sinai School of Medicine, New York, NY; 3) Yale University, New Haven, CT; 4) University of Connecticut, Storrs, CT.

The *Tas1r3* gene is a candidate for the saccharin preference locus (*Sac*), a locus that is allelic in mice, and that influences the intake and preference for substances humans report as sweet. For instance, mice with the *Sac<sup>d</sup>* allele drink equal amounts of water and 1.6 mM saccharin when offered both choices, whereas those with the *Sac<sup>b</sup>* allele drink 90% of their fluid as saccharin. A missense mutation (I60T) in the mouse is currently the most likely mutation to account for the phenotypic differences. The human ortholog of *Tas1r3* exists on chromosome 1p36. To determine whether allelic variants of this gene exist in humans, and are associated with differences in human behavior toward sucrose and aspartame, the TAS1R3 genes of 30 unrelated human subjects were sequenced. Three sequence variants that resulted in a predicted protein change were found. Twenty-three additional subjects were genotyped and phenotyped. In following up on these polymorphisms, six heterozygotes and forty-seven "wt" homozygotes subjects were compared for their ratings of intensity and pleasantness. Heterozygous subjects reported that 5% ( $p=0.13$ ), 10% ( $p=0.021$ ), and 20% ( $p=0.0011$ ) sucrose was more pleasant than subjects with the homozygous genotype. Subjects with the heterozygous genotype also rated aspartame as more pleasant than those with the homozygous genotype ( $p=0.05$ ). Intensity ratings did not differ between genotypes. The mutation present in the heterozygotes is predicted to act as "gain of function" mutation to alter receptor activity. Further work is needed to determine whether this effect of genotype is specific to sweet taste and extrapolates to other human populations.

**A genome-wide association study of psoriasis vulgaris using polymorphic microsatellite markers and microarray**

**technology.** *G. Tamiya<sup>1</sup>, A. Oka<sup>1</sup>, K. Okamoto<sup>1,2</sup>, T. Endo<sup>3</sup>, S. Makino<sup>1</sup>, H. Hayashi<sup>1</sup>, M. Iizuka<sup>4</sup>, E. Tokubo<sup>1</sup>, R. Sato<sup>1,2</sup>, A. Takaki<sup>1</sup>, Y. Sakurai<sup>1</sup>, M. Ota<sup>5</sup>, Y. Nagatsuka<sup>1</sup>, T. Imanishi<sup>3</sup>, T. Gojobori<sup>3</sup>, A. Ozawa<sup>4</sup>, H. Inoko<sup>1</sup>.* 1) Dept Molecular Lifescience II, Sch Medicine, Tokai Univ, Isehara, Japan; 2) Chugai Pharmaceutical Co., Ltd, Gotemba, Japan; 3) National Institute of Genetics, Mishima, Japan; 4) Dept Dermatology, Sch Medicine, Tokai Univ, Isehara, Japan; 5) Shinshu Univ, Sch Medicine, Matsumoto, Japan.

The aim of this study is to exclusively identify genes related to psoriasis vulgaris by genome-wide association analysis using polymorphic microsatellite markers. Our previous data suggested that microsatellite markers showed a linkage disequilibrium with disease-related alleles spanning from 100 to 200 kilobases (kb). For the purpose of the genome-wide association studies, we identified and designed primers for microsatellite sequences from the human genome draft sequence, resulting in the assignment of 30,000 polymorphic microsatellite markers which are separated by 100 kb intervals. From this genotype study we have specifically identified the polymorphic markers which we plan to submit to the public genomic repository. These identified polymorphic markers within the Japanese population include previously published markers such as the Genethon markers as well as our newly identified markers. We have applied the polymorphic markers to conduct a genome-wide association study of psoriasis vulgaris-susceptibility genes. We report here our findings to date of different susceptibility locations within the genome including confirmation of our previous findings that identified a psoriasis-susceptibility locus near the HLA-C gene within the MHC region of chromosome 6. In addition, we report our preliminary findings on the comparison of gene expression in human affected and normal skin using the expression microarray system. We propose that the information gathered from these highly upregulated/downregulated and normally expressed genes in diseased skin using the DNA microarray technology will complement our genome-wide association studies. We believe this combined approach will accelerate identification of disease-related genes.

**Progress toward characterization and gene analysis of distal translocation breakpoint at 7q31.2 in Autistic disorder.** *P.-T. Xu, P. McCoy, M.M. Menold, J.M. Vance, J.R. Gilbert, M.A. Pericak-Vance.* Department of Medicine, Duke Univ Medical Ctr, Durham, NC.

Autistic disorder (AutD) is a severe neurodevelopmental disorder characterized by impairments in reciprocal social interaction and communication, and restricted and stereotyped patterns of interests and activities, with an onset before three years of age. Multiple genome screens has indicated an AutD susceptibility locus on chromosome 7q. We have identified an AutD family in which three sibs inherited from their mother a paracentric inversion in the chromosome 7 (Ch 7) candidate region [inv(7)(q22-q31.2)]. To further identify the location of distal breakpoint at Ch 7q31 region, we utilized available Ch 7 genomic sequence of Ch 7 BACs and/or PACs to refine mapping and sequencing data in the inversion region and overlap a region of 2,500,000 base pair of genomic sequence. Based on the genomic sequence we have developed 9 probes for pulse field gel analyses (PFGE). Patient and control genomic DNAs from inversion family and other AutD families were analyzed using multiple rare-cut restriction enzymes. Preliminary results demonstrate that the distal breakpoint may localize in a PFGE map and gap area estimated about 100 kb (approximately 109,000,000 ~110,000,000). The patterns and status of gene expression and transcription in inversion patients are presented.

**Identification of candidate genes for Parkinson's Disease (PD) by profiling gene expression in the substantia nigra.**

Stajich<sup>1</sup>, E.R. Hauser<sup>1</sup>, E.R. Martin<sup>1</sup>, J.M. Vance<sup>1,2</sup>.* 1) Section of Medical Genetics; 2) Division of Neurology, Department of Medicine; 3) Department of Pathology, Duke University Medical Center, Durham, NC.

Parkinson's Disease (PD) is a heritable neurological disorder characterized by pathological degeneration of the substantia nigra, most notably loss of dopaminergic neurons. We hypothesize that this degeneration is the result of an altered pattern of gene expression in this tissue. Genes whose expression in the substantia nigra are significantly up- or down regulated in affected individuals therefore constitute good candidate susceptibility genes for this disorder. Additional candidate genes will be identified as those genes that are expressed in the normal substantia nigra at higher levels than in other regions of normal human brain. Candidate genes will then be analyzed by family based association studies using nearby single nucleotide polymorphisms (SNPs). We are prioritizing analysis of candidate genes that display association and also map to regions linked to PD in our recent genome scan. Serial Analysis of Gene Expression (SAGE) and Affymetrix microarray analysis are being used to profile gene expression in substantia nigra tissue collected from PD patients and age-matched controls. SAGE is a powerful technique that allows quantitative determination of all transcripts present in a given tissue by cloning and sequencing large numbers of unique 13-base pair tags associated with each gene. We present here a detailed profile of genes expressed in the normal control substantia nigra, as compared with other regions of the brain. The 10 most abundantly expressed genes in the control substantia nigra are KIAA0493, gelsolin, osteonectin, sperm associated antigen 7, cystatin C, KIAA1378, leucine rich repeat (in FLII) interacting protein 1, KIAA0729, carboxypeptidase M, and chondroitin 4-O-sulfotransferase 2.

**Multiplex analysis of 65 polymorphisms in coronary artery disease patients.** *C. Stranieri<sup>1</sup>, E. Trabetti<sup>1</sup>, G. Malerba<sup>1</sup>, M. Grow<sup>2</sup>, A. Silbergleit<sup>2</sup>, C. Carlson<sup>2</sup>, D. Girelli<sup>3</sup>, O. Olivieri<sup>3</sup>, R. Corrocher<sup>3</sup>, P.F. Pignatti<sup>1</sup>, H. Erlich<sup>2</sup>, S. Cheng<sup>2</sup>.* 1) Sect Biol & Genetics, Mother-Child, Biol & Genetics, Verona, Italy; 2) Dpt.of Hum. Genetics, Roche Molecular System, Inc., Alameda, CA, USA; 3) Dpt. of Exp. and Clin. Med., Chair of Internal Medicine, Verona, Italy.

Several genes may contribute to the susceptibility to cardiovascular disease, together with environmental factors. The goal of the present study was to test a prototype multiplex PCR- and immobilized probe-based assay to genotype up to 65 variable sites in 36 candidate genes, and possibly correlate genotypes to the risk of coronary atherosclerosis. The polymorphisms are located in genes involved in lipid (apo(a), ApoAIV, ApoB, ApoCIII, ApoE, b3AR, CETP, LDLR, LIPH, LPL, PON1, PON2, PPAR $\gamma$ ) or homocysteine metabolism (CBS, MTHFR), coagulation (FII, FV, FVII, FBG, PAI-1 GpIa, GpIIIa), leukocyte adhesion (ELAM, ICAM), blood pressure regulation (ACE, ATIIR, AGT, STMY1, a adducin, ANP, ADRb2, ENaCa, GNB3), and inflammation (NOS3, TNFa, TNFb). Two groups of subjects from the same population presenting for cardiovascular surgery were selected: 756 with angiographically documented coronary artery disease (CAD+), and 320 with angiographically documented normal coronary arteries (CAD-, controls). Allele and genotype frequencies were estimated in each group. Significant differences were observed in genotype distribution between patients and controls for two ApoCIII gene promoter polymorphisms -455T/C and -641C/A (P=0.002), and the ADRB2 gene Gln27Glu polymorphism (P=0.03). The two ApoCIII gene polymorphisms were in linkage disequilibrium (D'=0.98). The -455C/C (-641A/A) homozygotes were 1.9 times more frequent in cases relative to controls (OR 2.11, 1.38-3.25, P=0.0003). ApoCIII -455 T/C (-641C/A) genotyping, in conjunction with the determination of other genetic and environmental risk factors, may help in estimating CAD susceptibility in at risk individuals.

**Insulin degrading enzyme is not associated with late-onset Alzheimer's disease.** R. Abraham<sup>1</sup>, M. Hamshere<sup>1</sup>, A. Myers<sup>2</sup>, J. Kwon<sup>2</sup>, G. Spurlock<sup>1</sup>, H. Thomas<sup>1</sup>, D. Turic<sup>1</sup>, H. Marshall<sup>2</sup>, F. Wavrant De-Vrieze<sup>3</sup>, D. Compton<sup>3</sup>, B. Hoogendoorn<sup>1</sup>, D. Liolitsa<sup>4</sup>, S. Lovestone<sup>4</sup>, J. Hardy<sup>3</sup>, A. Goate<sup>2</sup>, M. O'Donovan<sup>1</sup>, J. Williams<sup>1</sup>, M.J. Owen<sup>1</sup>, L. Jones<sup>1</sup>. 1) Department of Psychological Medicine, University of Wales College of Medicine, Cardiff, UK; 2) Department of Psychiatry, Washington University School of Medicine, 660 S Euclid, St Louis, MO63110, USA; 3) Laboratory for Neurogenetics, Department of Neuroscience, Mayo Clinic Jacksonville, FL32224, USA; 4) Institute of Psychiatry, De Crespigny Park, Denmark Hill, London SE5 8AF, UK.

Insulin degrading enzyme (IDE; insulysin; EC 3.4.24.56) is a 110kDa neutral metallopeptidase which can degrade a number of peptides including b-amyloid. It is located on chromosome 10 close to a region of linkage for late-onset Alzheimer's disease (AD) and thus is a functional and positional candidate for this disorder. We analysed all the coding exons, untranslated regions and 1000bp of 5' flanking sequence of *IDE* using DHPLC and sequencing to detect sequence variants. We detected eight single nucleotide polymorphisms (SNPs), three in the 5' flanking sequence and five in the coding sequence, of which three were found at <5% frequency. None changed the amino acid sequence. We tested the five SNPs with allele frequencies of >5% in two case-control samples, 133 caucasian late-onset AD cases and 135 controls collected in the UK and 95 caucasian late-onset AD cases and 117 controls collected in the USA. No association of any SNP with late-onset AD was detected. Two of the SNPs were analysed in 86 late-onset AD cases and 94 controls, caucasians, and again no association with late-onset AD was found. Analysis of marker D10S583, which maps 36kb upstream of *IDE* and was previously reported to be associated with AD failed to show association in the UK sample. Substantial LD was detected between the SNPs across the *IDE* gene. We conclude that *IDE* does not make a substantial contribution to late-onset AD, and cannot therefore account for the linkage between late-onset AD and 10q.

**COMT Val158Met and cognitive executive function.** *D. Goldman*<sup>1</sup>, *A. Malhotra*<sup>3</sup>, *M. Egan*<sup>2</sup>, *B. Kolachana*<sup>2</sup>, *D. Warden*<sup>4</sup>, *R.H. Lipsky*<sup>1</sup>, *A.M. Salazar*<sup>4</sup>, *K. Xu*<sup>1</sup>, *T. Goldberg*<sup>2</sup>, *D. Weinberger*<sup>2</sup>. 1) Laboratory of Neurogenetics, NIAAA, Rockville, MD; 2) Clinical Brain Disorders Branch, NIMH; 3) Hillside Hospital, Long Island, NY; 4) Walter Reed Army Hospital, Washington, DC.

Impaired prefrontal cognitive function is a hallmark of schizophrenia, behavioral disinhibition syndrome following head injury, and various psychiatric diseases involving impaired impulse control, for example alcoholism. Augmentation of dopamine in frontal cortex improves performance on tasks that access function of this brain region and simultaneously increases metabolic efficiency, probably through an action on dopamine D1 receptors [P. Goldman-Rakic. An abundant functional polymorphism [candidate allele] of the D1 receptor is not known. However, Val158Met, a common [rare allele=0.42] polymorphism, exerts a four-fold effect on activity of catechol-O-methyl transferase [COMT], which catabolizes dopamine and other catecholamines. We hypothesized that Val158, associated with more rapid dopamine metabolism, would lead to poorer frontal cognitive performance, reduced cortical efficiency, and increased risk of schizophrenia. WCST perseverative errors were predicted by Val158Met genotype in three datasets: Jackson Foundation Head Injury [N=188], Hillside Hospital controls[N=73] and NIMH [N=449]; the NIMH dataset included 175 schizophrenia patients, 219 unaffected siblings and 55 controls. Linkage to schizophrenia was evaluated by the transmission disequilibrium test [TDT]. Also, in part of the NIMH sample, brain metabolic activity was measured by BOLD-MRI during a working memory task. Significant association between Val158 and WCST perseverative errors was seen in all three datasets, despite differences in baseline WCST performance in the several clinical groups. Significant case/control and TDT associations between Val158 and schizophrenia were detected. Finally, Val158 genotypes were associated with cortical inefficiency in the dorsolateral frontal cortex and anterior cingulate regions. These results, obtained in several datasets with extended psychiatric phenotypes, suggest a role for Val158Met in executive cognition, frontal cortical metabolism, and schizophrenia vulnerability.

**Are CFTR gene mutations involved in a subgroup of sarcoidosis patients?** *C. Bombieri<sup>1</sup>, F. Belpinati<sup>1</sup>, M. Zorzetto<sup>2</sup>, I. Ferrarotti<sup>2</sup>, M. Luisetti<sup>2</sup>, P.F. Pignatti<sup>1</sup>*. 1) Section of Biology & Genetics, DMIBG, University of Verona, Verona, Italy; 2) Lab. of Biochemistry & Genetics, Inst. Respiratory Diseases, IRCCS S.Matteo, Univ. of Pavia, Pavia, Italy.

Sarcoidosis is a multifactorial, multisystem immune-mediated granulomatous disorder for which ethnic variation in incidence, and familial clustering, suggest the presence of a genetic component. In a previous investigation (34 patients) we had evidence of an excess of CFTR gene mutations in sarcoidosis patients. A trend towards increased chest X-ray progression was observed in patients with CFTR gene mutations compared with patients without mutations (*Eur. J. Hum. Genet.* 2000; 8:717). In order to increase sample numerosity, 19 new patients with sarcoidosis were enrolled in this study. A DGGE analysis was performed on all exons and intronic flanking regions of the CFTR gene. At the writing of this abstract the analysis is completed for all the gene except one exon. We found one CFTR gene mutation in 3/19 patients (R31C, D513G, G576A-R668C). This is not statistically different from controls. Combining these results with the previous findings, a total of 16/53 (30%) sarcoidosis patients have at least one CFTR mutations, an increase which is not statistically different from controls (10/50) taken from the general population (*Hum. Genet.* 2000; 106:172). The presence of CFTR gene mutations will be correlated with disease progression and with mutations in other genes possibly involved in the disease susceptibility.

**Complex multigenic inheritance influences the development of severe CF liver disease.** *K.J. Friedman<sup>1</sup>, P.R. Durie<sup>2</sup>, L.M. Silverman<sup>1</sup>, M.R. Knowles<sup>1</sup> and the Cystic Fibrosis Liver Disease Consortium.* 1) Depts Pathology & Lab Medicine, and Medicine, Univ North Carolina, Chapel Hill, NC; 2) Dept Pediatrics, Univ Toronto, Ontario, Canada.

Severe liver disease afflicts 2-7% of patients with CF. The risk for CF liver disease (CFLD) is likely influenced by genetic factors. Previously we reported an increased frequency of protease inhibitor (PI) gene mutations, Z & S, among CFLD patients with portal hypertension & cirrhosis. This relationship does not exclude mutations or sequence variants at other loci from contributing to severe CFLD. The mannose binding lectin (MBL2) gene is an adverse modifier of CF lung disease and has been explored in regard to CFLD. We have genotyped 53 CFLD patients for promoter variant -221 X/Y and structural mutations B, C, & D, each associated with reduced MBL2 serum levels. None of these variants is significantly elevated among CFLD patients as a group compared to normal controls. However, CFLD patients (n=42) without PI mutations are more likely to carry two structural MBL2 variants than controls (p=.057, OR 3.7, 95%CI 1.02-13.1), suggesting that mutations in the PI and MBL2 genes are independent risk factors for CFLD. The TGF $\beta$  gene was also evaluated in CFLD patients, as this cytokine mediates the hepatic fibrogenesis initiated by cholangiocytes compromised by CFTR mutations. A high-expression variant of the TGF $\beta$  promoter (T @ -509) might exacerbate the fibrogenic stimuli inherent to CFLD. Although there is no increased frequency of genotypes bearing TGF $\beta$  -509 T among CFLD patients as a whole, 10 of 11 (91%) CFLD patients who also carry a Z or S allele in the PI gene carry one or two -509 T alleles, vs. 55% among normals (p=.026, OR 8.3, 95%CI 1.1-65.6). Furthermore, 3 of these 11 patients (27%) are TT homozygotes compared to 7.5% among normals (p=.05, OR 4.7, 95%CI 1.2-18.7). We also note that 13 CF DF508 homozygous controls without liver disease who also carried a Z or S allele were less likely to carry one or two TGF $\beta$  -509 T alleles than the 11 CFLD patients above (p=.03, OR 11.7, 95%CI 1.14-119.6). Taken together, high expression of TGF $\beta$  may potentiate the adverse impact of PI gene mutations on CFLD.

**Crohn's disease: analysis of the IBD1 frameshift mutation versus linkage evidence.** *J.A. Cavanaugh<sup>1</sup>, K.E. Adams<sup>1</sup>, E.J. Quak<sup>1</sup>, N.R. Beck<sup>1</sup>, P. Pavli<sup>1</sup>, S.R. Wilson<sup>2</sup>, N.J. O'Callaghan<sup>3</sup>, W. Uylaki<sup>4</sup>, J. Eaden<sup>4</sup>, I. Roberts-Thomson<sup>4</sup>, D.F. Callen<sup>3</sup>.* 1) Gastroenterology Unit, Canberra Hosp, Canberra, Australia; 2) Centre for Mathematics and its Applications, Australian National University, Canberra, Australia; 3) Department of Cytogenetics and Molecular Genetics, Women's & Children's Hospital, Adelaide, Australia; 4) Department of Gastroenterology, Queen Elizabeth Hospital, Woodville, Australia.

The inflammatory bowel diseases, consisting of Crohn's disease and ulcerative colitis are amongst the most common complex diseases, with an estimated combined prevalence of 200 per 100,000. Genome scans of patient groups from around the world have implicated more than 5 separate genetic localisations, with one, the IBD1 locus on chromosome 16, having been confirmed in a large international collaborative effort with a combined multipoint LOD score of 5.79. The IBD1 gene has recently been characterised, with the 3020insC frameshift being implicated as the major causal mutation in European and American populations. This mutation occurs at approximately twice the frequency in affected individuals as that in normal individuals. Linkage evidence has offered variable support for the localisation in those populations, with the MLS varying from 3.4 to 2.5. In the Australian population however, an MLS of 6.3 has been reported, suggesting that this disease gene and its mutations may be of greater importance for the expression of the phenotype in Australian patients. Using over 200 Australian multiplex IBD families, more than 100 sporadic cases, and over 100 normal individuals, we show that the IBD1 frameshift mutation is extremely common in Australian CD. The allele frequency in familial CD probands is 0.14, but only 2% of probands are homozygous for the frameshift. The allele frequency is significantly lower in the sporadic form of the disease (0.026) which is nevertheless X 3.7 that observed in the normal population. This is in contrast to the allele frequencies reported in European and American populations. We relate these data to the linkage evidence, and also to disease type and age of onset data.

**Association of a conserved promoter haplotype in the 5-lipoxygenase gene with reduced levels of peripheral eosinophils in Chinese patients with asthma.** *G. Barnes, E. Nolin, S. Lewitzky, J. Shanahan, A. Aelony, J. Roach, J. Meyer.* Millennium Pharmaceuticals Inc, Cambridge, MA.

The product of the 5-lipoxygenase (5LO) gene is involved in the first two steps of the metabolism of arachidonic acid into leukotrienes. The involvement of 5LO in the etiology of asthma is demonstrated by the fact that inhibitors of 5LO are useful in the treatment of asthma. We have scanned the entire 5LO gene for nucleotide variants including the exonic regions, intronic sequences flanking each exon, 5 and 3 UTRs, and the upstream regulatory region. This scan revealed a 6 marker haplotype in the promoter region of 5LO that is conserved at a relatively equal frequency across three distinct ethnic backgrounds (approximately 0.18 in Caucasian, Asian Chinese, and African American individuals). The haplotype consists of four nucleotide substitutions, one insertion/deletion variant, and one previously described polymorphic SP1 binding motif. Five of the variants (the four SNPs and the insertion/deletion) were estimated to be in complete linkage disequilibrium across all three ethnic groups studied. A non-wildtype allele of 4 SP1 repeats (4 allele) resides on the haplotype in Caucasians and Asian Chinese individuals. In the case of African Americans who carry the haplotype, a non-wildtype allele appears to reside on the haplotype but not necessarily the 4 allele. Analysis of this haplotype in a large family collection of Chinese patients with asthma reveals that this haplotype is associated with reduced levels of peripheral eosinophils.

**Putative role for the calpain 10 gene in free fatty acid metabolism.** *M. Orho-Melander, M. Klannemark, M. Svensson, C.M. Lindgren, L. Groop.* Department of Endocrinology, Lund University, Malmö, Sweden.

Intronic variation in the gene coding for the cysteine protease calpain 10 (CAPN10) on chromosome 2q (NIDDM1) has been associated with type 2 diabetes, but information on molecular and physiological mechanisms explaining these associations are limited. Here we addressed this question by studying the role of variants in CAPN10 for phenotypes associated with the metabolic syndrome (MSDR) and FFA metabolism using both a case-control and family-based association study design. Of the genotyped SNPs -43, -44, -19 and -63, the SNP -43 (allele1; 75.5 vs. 69.4%;  $p=0.011$ ) and -63 (allele 2; 11.3 vs. 7.1%;  $p=0.010$ ) as well as haplotypes SNP-43/19/63 (121/121 or 121/112; 17.5 vs. 9.5%;  $p=0.0026$ ) and SNP-43/44 (11/11; 31.6 vs. 20.9%;  $p=0.0017$ ) were associated with type 2 diabetes in 394 type 2 diabetes patients and 297 nondiabetic controls from Finland. 10% of the control subjects and 66% of patients with type 2 diabetes were classified as having MSDR. Allele frequencies of SNP-43 and -63 were similar between type 2 diabetes patients (with or without MSDR) and controls with MSDR (75.5 vs 75.0% and 11.3% vs. 13.8%), while there was a significant difference compared to controls without MSDR (75.5 vs. 68.7%,  $p=0.0056$  and 11.3 vs. 6.4%,  $p=0.0021$ ). Among the control individuals, the SNP-43 genotype 22 was associated with lower fasting insulin ( $6.8\pm 3.4$  vs  $8.5\pm 4.9$  mU/l,  $p=0.021$ ), lower HOMA insulin resistance index ( $1.6\pm 0.8$  vs  $2.1\pm 1.3$ ,  $p=0.0076$ ) and lower fasting free fatty acids, FFA ( $522\pm 186$  vs  $689\pm 233$  mmol/l,  $p=0.0040$ ). The 22 genotype was also associated with lower FFA in the whole study group ( $558\pm 189$  vs  $779\pm 290$  mmol/l,  $p=0.00020$ ), particularly among males ( $473\pm 154$  vs  $697\pm 277$  mmol/l,  $p=0.0010$ ). None of the four SNPs showed distorted transmission of alleles to patients with type 2 diabetes in TDT including 108 trios. However, sex, age and BMI adjusted quantitative TDT revealed association between the SNP-44 and fasting serum insulin ( $p=0.049$ ). In conclusion, the CAPN10 gene is associated with type 2 diabetes, features of insulin resistance and FFA levels. Our results suggest a role for CAPN10 in fatty acid metabolism.

**Novel Myocilin Mutations in West African Individuals with Primary Open Angle Glaucoma.** *K.R. LaRocque<sup>1</sup>, R.R. Allingham<sup>1</sup>, M.A. Hauser<sup>1,2</sup>, L.W. Herndon<sup>1</sup>, B.W. Broomer<sup>1</sup>, M.A. Pericak-Vance<sup>1,2</sup>, P. Challa<sup>1</sup>.* 1) Department of Ophthalmology; 2) Department of Medicine, Section of Medical Genetics, Duke University Medical Center, Durham, NC.

We have investigated the role of myocilin mutations in a West African primary open angle glaucoma (POAG) population to determine if there is a correlation between the observed phenotype and mutations in myocilin. POAG patients with mutations in myocilin have been shown to have an earlier age of onset as well as a more severe clinical presentation, mirroring the phenotype found in POAG patients in West Africa. POAG patients and controls were recruited at the Emmanuel Eye Clinic in Accra, Ghana. Ascertainment criteria for POAG were age of diagnosis >25 yo and two out of three of the following criteria: 1) applanation IOP  $\geq 22$  in each eye, 2) glaucomatous optic neuropathy OU including cup-to-disc ratio  $\geq 0.7$ , optic disc asymmetry  $\geq 0.2$ , or notching or focal thinning of the optic disc rim, 3) visual field loss measured by modified tangent screen or Humphrey field testing consistent with glaucoma in at least one eye. Age matched unaffected controls were obtained in patients with an IOP <22 mmHg and normal appearing optic nerves. Ninety unrelated affecteds with POAG and 76 control patients were recruited. PCR amplification was performed on each of the three myocilin exons, followed by denaturing high performance liquid chromatography to detect allelic differences. Samples demonstrating a polymorphism were sequenced on both strands. Four individuals with severe POAG were found to have novel missense mutations in exon 3. Two exhibit an Asp380Asn mutation and two an Arg342Lys mutation. These changes were not detected in 152 ethnically matched control chromosomes. Fourteen affected individuals and 8 controls exhibit a translationally silent polymorphism in codon 325 (Thr325Thr). Four percent of the study patients were found to have novel disease-associated mutations in myocilin, which is consistent with the percentage found in other populations. Therefore, mutations in myocilin appear to play a limited role in the pathogenesis of POAG in this region of West Africa.

**An MAOA\_VNTR and Childhood Behavior Disorders.** *D.C. Rowe<sup>1</sup>, S. Black<sup>1</sup>, M. Gilson<sup>1</sup>, H. Brown<sup>2</sup>, A. Abramowitz,<sup>3</sup> S. Sherman<sup>4</sup>, I.D. Waldman<sup>5</sup>.* 1) Div Family Studies/Human Dev, Univ Arizona, Tucson, AZ; 2) Graduate Program in Genetics, University of Arizona, Tucson; 3) Department of Psychiatry, Emory University, Atlanta, GA; 4) Department of Genetics and Molecular Medicine, Emory University; 5) Department of Psychology, Emory University.

The MAOA\_VNTR is a 30 bp repeat polymorphism in the MAOA gene promoter region. The polymorphism is functional, with greater gene expression associated with the A3 allele than with the A1 allele (two rare alleles were grouped with the common ones by their gene expression levels). The protein product of this gene degrades neurotransmitters, preferentially serotonin and norepinephrine. In one prior study, the A3 allele has been associated with a higher level of self-reported aggression in a community sample. We examined the association between the A3 allele and attention deficit disorder (ADHD), hyperactive impulsive disorder (HID), and attention deficit disorder (ADD), diagnosed from symptoms in parental questionnaire reports on their children. The subjects were 156 male children, mean age 9.8 years ( $s = 2.9$  years), divided between clinic referred children and their siblings and control (non-referred) children and their siblings. The allele frequencies were  $A3 = .57$ ,  $A1 = .43$ . Chi square tests comparing the diagnosed boys against boys in the control group yielded no significant differences ( $P > .30$ ). Within-family tests were used to compare the frequency of transmission of the A3 allele vs. that of the A1 allele using informative, heterozygous mothers (fathers being irrelevant because MAOA resides on the X chromosome). These within-family tests were also negative. Thus, this polymorphism in MAOA is probably not affecting the risk of these childhood psychiatric disorders.

**An atypical case of Angelman Syndrome caused by an imprinting defect.** *F.E. Tahmaz, M.A. Kalichman, G.E. Hoganson, F. Quan.* Dept Pediatrics, Div Genetics, Univ of Illinois at Chicago, Chicago, IL.

Angelman Syndrome (AS) is characterized by severe mental retardation, absent speech, seizures, ataxia, inappropriate laughter, and microcephaly. AS is caused by the loss of maternally expressed genes from the imprinted chromosome 15q11-q13 region. A small number of AS patients with an atypical phenotype that includes features of Prader-Willi Syndrome (PWS) (obesity, hypotonia, mild mental retardation) have recently been reported (Gillissen-Kaesbach et al, 1999). In these patients, the maternally-derived SNRPN allele was absent or reduced. We present here an additional case in which a child with a methylation pattern at the SNRPN gene consistent with AS had an atypical phenotype for AS. The patient was a 3 year-old male with severe mental retardation, absent speech, microcephaly (head circumference at 2nd centile), height >95th centile, and obesity (weight 52 lbs, > 95th centile). High resolution chromosomes and Fragile X Syndrome testing were normal, as were a urine organic and amino acid screen. The patient was not dysmorphic and did not have the typical phenotypic characteristics of AS or PWS. However, since the patient's weight had almost doubled over the period of a year, a methylation study for PWS was performed. Methylation-specific PCR of the SNRPN gene revealed that the patient had not inherited a maternally imprinted SNRPN allele, a result that was consistent with AS. The absence of a maternally imprinted SNRPN allele was confirmed by Southern analysis using an XbaI-NotI double digest and a probe specific for the 5'-end of the SNRPN gene. No maternal band was observed. FISH analysis using a probe for the SNRPN gene showed that the patient was negative for a 15q11-q13 deletion. Microsatellite analysis using the markers D15S541, D15S113, GABRB3, and D15S115 was consistent with biparental inheritance of chromosome 15, indicating that the abnormal methylation pattern in this patient was the result of an imprinting defect. The atypical phenotype of our patient may be the result of cellular mosaicism for the imprinting defect or alternatively, a partial imprinting defect.

**A Low Density Lipoprotein Receptor Related Protein-Associated Protein 1 Del/Ins Polymorphism and Phenotypic Variability in Alzheimer Disease.** *D.L. Schutte<sup>1</sup>, M. Maas<sup>1</sup>, K.C. Buckwalter<sup>1</sup>, J.C. Murray<sup>2,3</sup>, B.C. Schutte<sup>2,3</sup>.* 1) Col of Nursing, Univ Iowa, Iowa City, IA; 2) Dept of Pediatrics, Univ Iowa, Iowa City, IA; 3) Genetics PhD Program, Univ Iowa, Iowa City, IA.

Alzheimer's disease (AD) is a neurodegenerative disorder, characterized by dementia. AD exhibits individual variability in age at onset, rate of progression, and specific cognitive, functional, and behavioral features. Genetic variants are potential modulators of phenotypic variability. The purpose of this study was to explore the relationship between variations within six candidate susceptibility loci, including the Low-Density Lipoprotein Receptor Related Protein-Associated Protein (LRPAP1) gene (4p16.3), and repeated measures of cognition, function, and behavior in persons with AD, using outcome data collected in two caregiver intervention studies. Thirty-seven subjects diagnosed with probable or possible AD, who participated in either the Family Involvement in Care Study (PI: Maas) or the Progressively Lowered Stress Threshold Study (PI: Buckwalter), were recruited. Subjects exhibited a mean age at onset of 68.7 years (S.D.=9.08); 92% of the sample were Caucasian. The results of the LRPAP1 analyses are reported here. All subjects were genotyped for a 37bp del/ins polymorphism in intron 5 of the LRPAP1 gene. No differences in allele or genotype frequencies by gender or by age at onset were identified. No statistically significant genotype effects upon cognition or behavior were identified. However, trends were noted in measures of memory and language. The LRPAP1 ins-positive subjects exhibited poorer memory scores (average score difference=8%,  $p=.103$ ) and poorer language scores (average score difference=28%,  $p=.158$ ). LRPAP1 ins-positive subjects were significantly more functionally impaired than subjects without the LRPAP1 insertion allele ( $F_{1,7}=7.36$ ,  $p=.030$ ). These results suggest genetic variations at the LRPAP1 locus modulate AD phenotype beyond risk for disease. Potential genotype-phenotype relationships were identified that require analyses with a larger sample representing the full AD phenotype trajectory.

**Renin-angiotensin system (RAS) DNA polymorphisms and TGF $\beta$ 1-mediated fibrogenic pathway gene expression studies in primary IgA nephropathy (Berger's disease).** A. Turco<sup>1</sup>, C. Patuzzo<sup>1</sup>, M. Brugnara<sup>1</sup>, C. Marcantoni<sup>2</sup>, B. Brezzi<sup>2</sup>, A. Lupo<sup>2</sup>, G. Gambaro<sup>3</sup>, F. Anglani<sup>3</sup>, D. Del Prete<sup>3</sup>, G. Ligabue<sup>4</sup>, L. Furci<sup>4</sup>, R. Magistroni<sup>4</sup>, A. Albertazzi<sup>4</sup>, G. Maschio<sup>2</sup>. 1) Department of Mother & Child, Section of Genetics, University of Verona School of Medicine, Verona, Italy; 2) Division of Medical Nephrology, University of Verona, Italy; 3) Dept of Medical & Surgical Science, Nephrology Division, Univ of Padova, Padua, Italy; 4) Dept of Internal Medicine, Nephrology Division, Univ of Modena, Italy.

Primary IgA nephropathy (IgAN) is the most common human nephropathy and a leading cause of end stage renal disease (ESRD). DNA RAS polymorphisms (RASPs) have been implicated as genetic susceptibility factors in IgAN development and progression towards ESRD. 90 Italian biopsy-proven IgAN patients are being recruited and genotyped for the following gene RASPs: I/D angiotensin converting enzyme (ACE); A1166C, angiotensin II receptor(AT1); and M174T, angiotensinogen (AGT). 100 healthy blood donors were used as normal controls. Comparative RT/PCR was also used in microdissected kidney biopsies to assess glomerular and interstitial mRNA levels of the RAS and the fibrogenic pathway (TGF $\beta$ 1, collagen III and IV, a smooth muscle actin). ACE and AT1 genotype frequencies did not differ significantly between IgAN and control populations. Unexpectedly, glomerular ACE mRNA levels were significantly higher in pts with the ACE-II genotype. No AGT-MM genotypes and a significant higher prevalence of AGT-TM genotypes (T174M) were detected in IgAN pts. Higher M235T TT and lower MM genotype distributions were also observed in the IgAN population. These preliminary results differed significantly from the expected genotype frequencies, given the remarkable under representation of the T174M-MM genotype in IgAN pts. In our pt population the AGT-T allele seems to confer susceptibility to IgAN development. We also assessed whether the AGT T174M polymorphism influenced the relationships between glomerular AGT and fibrogenic pathway gene expression. We found that the MT genotype strongly influenced this correlation. Overall, our preliminary data point to a possible involvement of the AGT T allele in IgAN.

**Transforming growth factor beta-1 (TGF- $\beta$ 1) SNPs are associated with progressive renal insufficiency.** *M. Salah*<sup>1</sup>, *A.M. El Nahas*<sup>2</sup>, *A.I.F. Blakemore*<sup>3</sup>. 1) Biomedical Research Centre, Sheffield Hallam University, Sheffield, UK; 2) Sheffield Kidney Institute, Northern General Hospital, Sheffield, UK; 3) Department of Medical and Community Genetics, Kennedy-Galton Centre, Imperial College of Science, Technology and Medicine, London, UK.

TGF-1 plays an important role in the pathogenesis of glomerulosclerosis and tubulointerstitial fibrosis. Cytokine and growth factor SNPs are receiving increasing interest in association studies with disease entities, including nephropathies. In many cases, genetic associations with cytokine genes affect the clinical course of diseases, rather than simply being susceptibility factors. In this study, we tested TGFB1 gene polymorphisms as possible markers for the progression of chronic renal failure (CRF). We screened 142 Caucasian patients with CRF for TGFB1 SNPs: LEU10PRO, ARG25PRO, C76T and T-509C. 100 ethnically-matched control subjects were also genotyped. We found no significant differences between patient and control groups in allele frequencies or carriage rates, indicating that the markers tested did not affect susceptibility to CRF. We observed a significant association between genotype at codon 25 (odds ratio 5.8, 95%CI 1.7-19.4,  $p < 0.001$ ) and at -509 (odds ratio 2.85, 95%CI 1.2-6.6,  $p < 0.005$ ) with the rate of progression of CRF (slope of 1/creatinine) in patients with primary nephropathies (PKD excluded). Also, an association was found between ARG25PRO and the severity of proteinuria ( $p = 0.046$ ). Alleles at codon 25 and -509 exhibit strong linkage disequilibrium. In immunohistochemistry studies of biopsies from patients with CRF, TGFB1 SNPS were associated with differences in local TGF-1 protein levels and with degree of inflammatory infiltrate. TGFB1 markers may, therefore, be useful as prognostic indicators for the progression of CRF.

**Increased prevalence of thrombophilia and hypofibrinolysis abnormalities in patients with Chronic Fatigue**

**Syndrome: Identification of probable predisposition factors.** *H.H. Harrison<sup>1,2</sup>, D.E. Berg<sup>1</sup>, L.H. Berg<sup>1</sup>, J. Brewer<sup>3</sup>.*

1) HEMEX Laboratories, Phoenix, AZ; 2) Dept. Pathology, Univ Arizona School of Medicine; 3) Plaza Internal Medicine, Kansas City, MO.

Recent data have shown low level activation of coagulation in patients with active Chronic Fatigue Syndrome and/or Fibromyalgia (CFS/FM) [Ref: Blood Coag Fibrinol 10:435-438]. To investigate a predisposing association with genetic abnormalities in thrombophilia and/or hypofibrinolysis we analyzed antithrombin (AT), protein C (PC), protein S (PS), activated protein C resistance (APCR), prothrombin (F2), lipoprotein (a) (Lp(a)), and plasminogen activator inhibitor-1 (PAI-1) in 45 patients with clinically-defined CFS/FM, no known thrombosis or interfering systemic disease, and no anticoagulation. Samples were analyzed with functional, antigen or DNA assays and classified as positive or negative against normal reference values. The cohort was also stratified by the ISAC panel of sensitive indicators of low level activation that included fibrinogen (FIB), prothrombin fragment 1+2 (F1+2), thrombin-antithrombin complexes (TAT), soluble fibrin monomer (SFM), and platelet surface P-selectin (CD62P); with positivity defined as 2 or more assays exceeding ref limits. 33 of 45 patients (73%) were ISAC-pos. Significant differences between the total CFS/FM cohort and general population values were observed for F2 levels ( $P < .001$ ), LP(a) levels ( $P < .005$ ), and PAI-1 levels ( $P < .001$ ); with abnormality frequencies for F2 (0.422), Lp(a) (0.333), and PAI-1 (0.267). PAI-1 was the only marker that was different ( $P < .01$ ) in the ISAC-pos group (0.294) versus the ISAC-neg group (0.150). These results show increased prevalence of abnormalities in inherited thrombophilia and/or hypofibrinolysis factors that yield probable genetic predisposition in patients who develop CFS/FM following acute or chronic infections that damage vascular endothelium. Abnormality rates are similar to patients with thrombotic histories and suggest a potential need for monitoring CFS/FM patients for clinical thrombosis. These results are also consistent with family histories related to CFS/FM and suggest assays useful for future family studies.

**Microarray analysis of a cell culture model of familial Parkinson's Disease, linked to  $\alpha$ -synuclein.** *M.J. Baptista, M.R. Cookson, C. O'Farrell, L. Vink, M. Farrer.* Neurogenetics, Mayo Clinic, Jacksonville, FL., USA.

Parkinsons Disease (PD) is an age related neurodegenerative condition that involves damage to the nigrostriatal dopamine system. The etiology of PD is unclear, but a small number of families show Mendelian inheritance. Point mutations in the gene encoding  $\alpha$ -synuclein, a synaptic protein, have been shown to be associated with autosomal dominant PD. Several studies have identified other regions of linkage in familial PD cases for which the genes in question have not yet been identified. The aim of the current study was to use a cell culture model of synuclein over-expression to identify additional genes relevant to PD.

We have used the oligo-based U95A GeneChip (Affymetrix, Santa Clara, CA) to globally compare the expression levels of 12,500 non-redundant cDNAs and ESTs in stable clonal neuroblastoma cell lines over-expressing either wild type  $\alpha$ -synuclein or one of the disease-associated mutations (A53T). Forty-five genes were identified that gave both (1) a change of at least 2-fold compared to control cell lines and (2) a strong positive probe hybridization. The microarray data was confirmed by quantitative RT-PCR using SYBR green as a reporter. Six of the genes identified encoded transcription factors, having a 5.7 net fold increase in expression in cells over-expressing A53T synuclein as compared to those over-expressing wild type  $\alpha$ -synuclein. Other pathways of interest may include apoptosis, as we have seen a 2-fold down-regulation of the mRNA for caspase-3, a pro-cell death protease. Likewise, we have noted a reduction in expression of the nicotinic acetylcholine receptor alpha 5 subunit, which is known to modulate dopamine release. Some mRNA species were up-regulated in cells expressing mutant synuclein and unchanged in cells over-expressing wild type synuclein, such as the iron responsive binding protein aconitase. It is expected that identification of additional gene families regulated by over-expression of synuclein will form a pathway leading to PD, the identification of which is an important objective in PD research.

**Two new mutations in the CD45 gene in multiple sclerosis patients.** *M. Gomez Lira*<sup>1</sup>, *D. Bonamini*<sup>1</sup>, *A. Salviati*<sup>2</sup>, *PF. Pignatti*<sup>1</sup>. 1) Dept Mother-Child Biol Genetic, Sect Biol-Genetics, Verona, Italy; 2) Dept of Neurological Scienze, Verona, Italy.

Multiple sclerosis (MS) is a chronic disabling disease of the central nervous system characterized by T cell mediated destruction of the myelin. MS is held to be a complex autoimmune disease with a strong genetic component. Inflammation and demyelination are involved in the pathology, indicating that genes influencing the immune system can be implicated in the ethiology of MS. Recently an association between a variant CD45 isoform expression and multiple sclerosis has been observed in case-control studies, (Nature Genetics 2000, Vol 26; 495-99). CD45 is a cell surface protein-tyrosine phosphatase, which is believed to be a critical regulator of lymphocyte activation. It is a high molecular weight glycoprotein with multiple isoforms as a result of alternative splicing. CD45 negatively regulates JAK-STAT signaling in response to multiple cytokines, and genetic inactivation of CD45 in cells enhanced cytokine-triggered proliferation, differentiation and antiviral activities. The expression of a variant isoform of CD45 observed in MS patients is due to a point mutation in exon 4 (C/G at nucleotide 77), which prohibits out splicing of exon 4, leading to strong expression of high molecular weight CD45 isoforms. Other mutations on the CD45 gene could have a similar effect upon protein or protein expression and could be associated to MS susceptibility. In this study we screened 57 MS patients and 62 sex matched control individuals for the C77G in the CD45 gene. The mutation was present in heterozygosity in three MS patients and in one control individual. The difference between MS patients and control individuals is not significant. Other mutations in exon 4, 5, and 6, of the CD45 gene were investigated by screening amplified fragments including exons and exon/intron boundaries by heteroduplex analysis and direct sequence. We have identified two new CD45 gene mutations. A C/T transition at position 77 in exon 4, present in one MS patient, and a G/C transversion at position 69 in exon 5, present in two MS patients. These mutations were not present in 62 control individuals.

**Identifying and characterizing the diabetogenic gene, *iddm4*, in the BioBreeding Diabetes-Resistant rat (BB-DR).**

*C.A. DeScipio*<sup>1</sup>, *S. Novak*<sup>1</sup>, *M. Brace*<sup>1</sup>, *J. Leif*<sup>2</sup>, *K. Lake*<sup>2</sup>, *J. Mordes*<sup>2</sup>, *D. Greiner*<sup>2</sup>, *E.P. Blankenhorn*<sup>1</sup>. 1) Microbiology & Immunology Department, MCP Hahnemann University, Philadelphia, PA; 2) University of Massachusetts Medical School, Worcester, MA.

Type 1 diabetes mellitus (T1DM) is a multifactorial autoimmune disease in both humans and BioBreeding (BB) rats. Diabetes prone (DP) BB rats, but not diabetes resistant (DR) BB rats, develop T1DM spontaneously. T1DM can be induced in 95% of DR-BB rats. Genetic factors implicated in the control of T1DM include both major histocompatibility complex (MHC)-linked and non-MHC-linked genes. At least two non-MHC loci are linked to the expression of T1DM in the BB rat. *Iddm4* is one susceptibility locus. Spontaneous disease requires homozygosity for the mutation causing lymphopenia (*lyp/iddm1*). We have previously mapped *iddm4* to rat chromosome four. *Iddm4* controls insulinitis and diabetes in both DR and DP-BB rats and is likely to be responsible for the generation of autoreactivity. The current goal is to identify the *iddm4* gene and characterize its mechanism of action. Toward this end, we are constructing an *iddm4* speed congenic rat strain. At each generation of breeding we identify new genetic recombinants and determine the ability of the congenic rats to develop T1DM or to transfer it to immunodeficient histocompatible recipients. The *iddm4* interval currently spans 3cM. To identify the *iddm4* gene, we are evaluating genes and expressed sequence tags (ESTs) that map to the *iddm4* interval. We expect that the *iddm4* allele be shared by both BB substrains and not by WF. We are screening these genes and ESTs in BB, WF, and congenic rats for single nucleotide polymorphisms (SNPs) by conformation sensitive gel electrophoresis (CSGE) and for expression differences by slot blot array and real-time PCR. To date, 62 ESTs have been screened by CSGE and 30 have been evaluated by slot blot array. We identified five polymorphic ESTs; these ESTs serve as markers to fine map the interval. None of the 30 ESTs evaluated by slot blot array was found to exhibit a significant change in expression. Expression of candidate genes and ESTs in the 3cM *iddm4* interval is currently being evaluated by real-time PCR.

**Functional analysis of polymorphisms in the promoter region of glutamate receptors and transporter genes.** C.A. Guy, K. Smith, B. Hoogendoorn, S. Coleman, P.R. Buckland, M.C. O'Donovan. Psychological Medicine, UWCM, Cardiff, Wales.

We have searched the promoter regions of glutamate receptors and transporters for common polymorphisms and analysed these for functional effect on gene transcription in a reporter gene assay. As well as being associated functionally with a number of physiological processes, glutamatergic neurotransmission has also been associated with certain pathophysiological processes, including schizophrenia. We have screened the first 500 bp of the promoter region of 25 glutamate ionotropic receptor subunits, 8 metabotropic receptors and 6 transporters for common polymorphisms using denaturing high performance liquid chromatography. A total of 16 promoters were found to contain polymorphisms which were confirmed and characterised by sequencing. Each allele pair was cloned into a modified pGL3 luciferase reporter gene vector, characterised by DHPLC and sequencing, and used to transfect each of three human cell lines (HEK293t, TE671 and JEG-3) along with pCMV-SPAP as an internal control. The relative promoter activity of allele pairs was measured. Several polymorphisms caused significant changes to promoter activity.

**No missense mutation of *WKL1* in a subgroup of probands with schizophrenia.** *J.M. Devaney<sup>1</sup>, E.A. Donarum<sup>1</sup>, K.M. Brown<sup>1</sup>, J. Meyer<sup>2</sup>, K-P. Lesch<sup>2</sup>, D.A. Stephan<sup>1</sup>, A.E. Pulver<sup>3</sup>.* 1) Research Center for Genetic Medicine, Children's National Medical Center, Washington, D.C; 2) Department of Psychiatry and Psychotherapy, University of Würzburg, Germany; 3) Johns Hopkins University School of Medicine, Epidemiology-Genetics Program in Psychiatry, Baltimore, Maryland.

Recently, a Leu309Met mutation in *WKL1*, a gene mapped to chromosome 22q13.33, was reported to co-segregate with periodic catatonia, a clinical sub-type of schizophrenia, in 7 members of an extended pedigree<sup>1</sup>. *WKL1* encodes a putative non-selective cation channel expressed exclusively in the brain, particularly in the amygdala, nucleus caudatus, thalamus, and hippocampus<sup>1</sup>. We screened *WKL1* for etiologic mutations in 28 probands from the United States who were given a consensus diagnosis of schizophrenia and met at least one of these criteria: 1) were from multiplex schizophrenia families where at least two schizophrenic subjects were reported to display catatonic behavior at sometime during the course of their illness, or 2) were from multiplex schizophrenia families where, in a genome scan for schizophrenia susceptibility loci, evidence for excess allele sharing among affected family members for markers in the 22q13 region was seen. In addition, 15 subjects from the 12 original German pedigrees in the Meyer et al. report were similarly screened for causative mutations. This German cohort exhibited the catatonia phenotype but had ambiguous linkage to 22q13 and included the mutation-positive proband as a positive control. The 43 probands were screened for base changes in *WKL1*: 15 SNPs in the non-coding regions of the gene, three SNPs in the 3'UTR, four synonymous coding SNPs and two non-synonymous (amino acid changing) SNPs were identified. We were able to rapidly confirm the Leu309Met nucleotide change in the positive control. No missense mutations were detected in any of the other 42 probands studied. These data exclude the role of *WKL1* in the subjects studied and can be interpreted as providing further evidence of the genetic heterogeneity of schizophrenia.

**A two-stage association study between inflammatory bowel disease and polymorphisms spanning GNAI2.** *B.M. Dechairo*<sup>1,2</sup>, *N. Lench*<sup>1</sup>, *D. van Heel*<sup>3</sup>, *M. Edwards*<sup>1</sup>, *P. Scambler*<sup>2</sup>, *D.P. Jewell*<sup>3</sup>, *A.H. Carey*<sup>1</sup>. 1) Oxagen Ltd, Abingdon, England; 2) Molecular Medicine Unit, Institute of Child Health, University College of London, London, England; 3) Gastroenterology Unit, Nuffield Department of Medicine, Radcliffe Infirmary, Oxford, England.

Inflammatory Bowel Disease (IBD) includes ulcerative colitis (UC) and Crohns disease (CD), two chronic inflammatory diseases of the intestine. Aetiology is unknown but may involve a complex interaction between genetic susceptibility and environmental factors. Recently, several IBD susceptibility loci have been identified by linkage studies. Of these loci, one on chromosome 3p has been detected in two genome scans and a subsequent, region-specific, linkage study. To further analyse this region, we examined an IBD candidate gene within the region, guanine nucleotide-binding protein alpha i2 (GNAI2), for association in a population of 333 IBD European simplex families. In the first stage of the association study, four single nucleotide polymorphisms (SNPs) identified by denaturing high-performance liquid chromatography (dHPLC), were genotyped across a sub-group of 185 families. The SNPs were spaced every 6 kb spanning the genomic region of GNAI2. In the second stage of the association study, only the two flanking SNPs were genotyped in the remaining families due to almost complete marker-marker linkage disequilibrium (LD) between three of the SNPs. Association analysis was performed using the TDT functions implemented in GENEHUNTER 2.0. Positive association was seen with the three SNPs ( $p = 0.004$ ,  $0.02$ , and  $0.007$ ) in LD and with a haplotype of alleles from all four SNPs ( $0.007$ ) in 58 CD families used in the first stage. However, no association was seen in the 156 CD families analysed after the second stage. No association was seen in either stage of the study for both IBD and UC. With no discernable difference in the collection criteria and ethnicity of the CD families used for both stages of the study, the analysis of the combined dataset may be a better reflection of the IBD association to GNAI2. Thus, GNAI2 does not appear to be an IBD susceptibility gene.

**Ethnic specific differences in Nod2 associations to Crohn's disease.** *D.K. Bonen<sup>1</sup>, Y. Ogura<sup>2</sup>, R.H. Duerr<sup>3</sup>, S.R. Brant<sup>4</sup>, G. Nuñez<sup>2</sup>, J.H. Cho<sup>1</sup>.* 1) Medicine, University of Chicago, Chicago, IL; 2) Pathology, University of Michigan, Ann Arbor, MI; 3) Medicine, University of Pittsburgh, Pittsburgh, PA; 4) Medicine, Johns Hopkins University School of Medicine, Baltimore, MD.

Crohn's disease (CD) is a common complex disorder affecting young adults and is associated with higher disease prevalence in Ashkenazi Jews than in non-Ashkenazi Caucasians. We have established that three coding region polymorphisms (Leu1007fsinC, Gly908Arg, Arg702Trp) in Nod2 are highly associated with CD in an American cohort (Nature 411:603, 2001). The Arg702Trp variant is associated with the highest population attributable risk among non-Ashkenazi Caucasians. Functional proof of causation has been established for the frameshift mutation, which shows a marked hyporesponsiveness (NF- $\kappa$ B activity) to bacterial LPS. However, the functional variation associated with Gly908Arg and Arg702Trp is much less dramatic, and their direct role in disease pathogenesis is not established. We report data on novel SNPs and STRs in and near Nod2 that are common to the CD associated variants. Very distinct patterns of inheritance are observed, with Arg702Trp, Gly908Arg, and Leu1007fsinsC occurring on a similar haplotypic background. While Leu1007fsinsC has comparable allele frequencies in non-Ashkenazim and Ashkenazim, Gly908Arg is significantly more frequent among Ashkenazim (10.2%) compared to non-Ashkenazim (4.3%). Furthermore, Gly908Arg demonstrates preferential transmission in both subsets. Given the functional significance of amino acid polymorphisms in the LRR and the consistency of ethnic associations observed for the Gly908Arg variant, its direct role in CD pathogenesis is likely. Arg702Trp has a significantly lower allele frequency among Ashkenazim (2.2%) compared to non-Ashkenazim (10.8%), with an inverse transmission observed among the Ashkenazim. Since Arg702Trp is not located in the LRR of Nod2, it is possible that it is not directly causative, but is in linkage disequilibrium with the causative variant. Consideration of ethnic specific haplotype associations will assist in defining the precise causative variant accounting for the observed association of Arg702Trp to CD.

**A putative functional polymorphism in the promoter of the prodynorphin gene is associated with cocaine dependence or abuse.** *A.C.H. Chen<sup>1</sup>, K.S. LaForge<sup>1</sup>, A. Ho<sup>1</sup>, P.F. McHugh<sup>1</sup>, S. Kellogg<sup>1</sup>, K. Bell<sup>1</sup>, R.P. Schluger<sup>1</sup>, S.M. Leal<sup>2</sup>, M.J. Kreek<sup>1</sup>.* 1) The Laboratory of Biology of Addictive Diseases; 2) The Laboratory of Statistical Genetics, The Rockefeller University, New York, NY.

The opioid peptide dynorphin has been demonstrated to play a role in modulating neurochemical responses to cocaine. Our laboratory and others have found that acute or chronic exposure to cocaine increases dynorphin gene expression in rats. Recently, a polymorphic 68-bp repeat within the promoter region of the human prodynorphin gene has been identified (Zimprich et al., 2000, J Neurochem.). This repeat is present in one, two, three, or four copies and contains a putative AP-1 transcription factor binding site. Previous in vitro evidence shows that alleles containing three or four copies are associated with an increase in stimulated promoter activity. We hypothesize that the 3 and 4 repeat alleles may be protective against cocaine dependence or abuse through a dynorphin-mediated mechanism. From a study of the genetics of addiction, 174 subjects were studied: controls with no history of substance abuse or dependence (n=91) and cases with a primary diagnosis (DSM-IV criteria) of cocaine dependence (n=61) or abuse (n=22). Primers were designed for polymerase chain reaction (PCR) to amplify the region of the prodynorphin gene containing the repeat element. All PCR products were sized on agarose gels and twenty samples were verified by direct sequencing. The association of cocaine dependence or abuse with alleles containing three or four repeats was examined. With data stratified by ethnicity, pooled Relative Risk with Mantel-Haenszel Chi square was calculated: Relative Risk = 0.59 (95% confidence interval 0.37 - 0.95),  $c^2_{(1)} = 4.14$ ,  $p = 0.042$ . Our results suggest that the 3 or 4 repeat alleles may confer a protective effect against cocaine dependence or abuse.

**Identification of a novel transition period in non-obese diabetic (NOD) mice by cDNA microarray.** *S.E.*

*Eckenrode, Q.G. Ruan, P. Yang, J.X. She.* Department of Pathology, Immunology and Laboratory Medicine, University of Florida, Gainesville, FL.

Type 1 diabetes is an autoimmune disease that afflicts more than 1 million Americans. In this disease, the insulin-producing beta cells of the pancreas are targeted for destruction by the body's own immune system. Two categories of genes are of great interest in type 1 diabetes: the genes that cause the disease and those that can be used to predict individuals at high risk for developing the disease. Microarray technology was employed to identify genes in both non-obese diabetic (NOD) mice, a mouse model that spontaneously develops diabetes, and NOD control strains, NOD.Idd3/Idd10 and NOD.B10 (<1% and 0% incidence of diabetes, respectively). A splenic cDNA library containing 11,520 clones was used to perform microarrays on the spleens of individual NOD and control mice at time points from 1 to 10 weeks of age. Data analysis of these microarrays revealed a transition period between 3 weeks and 6 weeks in the NOD mice. Sequencing the top 1,000 clones generated a list of 180 unique genes. Of the 48 genes that are up regulated, 12 are B cell related suggesting an expansion of the B cell population or sub-population in the NOD mice that is not seen in the control strains. Flow cytometry performed on splenic lymphocytes from NOD and NOD control mice at 3 and 6 weeks of age reveal that 3 week NOD mice have fewer CD21<sup>+</sup> B cells than either 6 week NOD or either control strains at 3 or 6 weeks of age. Further studies of the B cell population during this critical transition period will aid in our understanding of the diabetogenic process and help identify genes that may be used as molecular markers for disease prediction.

**Promoter region variants in G protein receptor kinase-3 (GRK3) are associated with bipolar disorder.** *T.B.*

*Barrett<sup>1</sup>, M. Alexander<sup>1</sup>, P. Keck<sup>2</sup>, S. McElroy<sup>2</sup>, A.D. Sadovnick<sup>3</sup>, R.A. Remick<sup>4</sup>, J.L. Kennedy<sup>5</sup>, E.E. Turner<sup>1</sup>, R.L. Hauger<sup>1</sup>, J.R. Kelsoe<sup>1</sup>.* 1) Department of Psychiatry, UCSD, La Jolla, CA, USA; 2) Department of Psychiatry, University of Cincinnati, Cincinnati, OH, USA; 3) Department of Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 4) Department of Psychiatry, St. Pauls Hospital, Vancouver, BC, Canada; 5) Centre for Addiction and Mental Health, Clarke Division, University of Toronto, 250 College St., R-31, Toronto, ON, Canada.

In a genome-wide linkage survey we have previously shown evidence indicating chromosome 22q12 contains a susceptibility locus for bipolar disorder (BPD) in the vicinity of GRK3. GRK3 is an excellent candidate risk gene for BPD since GRKs play key roles in the homologous desensitization of G protein-coupled receptor signaling. To identify mutations in GRK3 we sequenced the putative promoter region, exons, and flanking intron in 14 individuals with BPD. We found six variants in the promoter/5-UTR region, but no coding or obvious splice variants. Transmission disequilibrium data from two triad sets indicate two of the promoter/5-UTR variants, found as a linked haplotype, are associated with BPD in families of Northern European (NE) Caucasian ancestry but not in non-NE Caucasian or non-Caucasian families. In 329 NE Caucasian triads the transmission to non-transmission ratio was 25:7, chi-square = 10.1,  $p = 0.003$ . To confirm promoter activity we have cloned a 1.5 kb genomic region lying immediately upstream of the first coding exon into a luciferase reporter expression vector and transfected this construct into SK-N-MC neuroblastoma cells, demonstrating that this region has significant transcriptional activity. The possibility that the two variants associated with disease are mutations which effect transcription or translation will be studied by transfection of expression constructs into SK-N-MC cells. These data support the hypothesis that a dysregulation in GRK3 expression which alters signaling desensitization contributes to the development of BPD.

**C4AQ0 and C4BQ0 genotyping: association with systemic lupus erythematosus.** *X-Y. Man<sup>1,2</sup>, H-R. Luo<sup>1</sup>, X.P. Li<sup>2</sup>, Y-G. Yao<sup>1</sup>, C.Z. Mao<sup>2</sup>, Y-P. Zhang<sup>1</sup>.* 1) Lab. Cellular Molec. Evol., Kunming Inst. Zool., CAS, Kunming, Yunnan 650223, P.R. China; 2) Department of Dermatology, the Second Affiliated Hospital, Kunming Medical University, Kunming, 650101, China.

Systemic lupus erythematosus (SLE) is a multifactorial complex autoimmune disease characterized by various autoantibodies that recognize autoantigens. The association of C4 deficiency with SLE was previously well documented based on electrophoretic mobility of C4 protein in plasma, but no detailed gene analyses were performed on it. To investigate the association of C4 null genes C4AQ0 and C4BQ0 with SLE in Chinese, we have genotyped 113 patients and 104 normal people. C4 null genes were determined by a PCR procedure with sequence-specific primers (PCR-SSP). To further characterize whether the molecular basis of the defective C4A genes is due to 2bp insertion in exon29, which was previously identified in non-Chinese populations, we designed a pair of exon-specific primers to amplify the whole exon29 followed by direct DNA sequencing. The SLE patients' disease activity and damage were assessed using SLEDAI and SDI, respectively. Statistical analyses were carried out using SPSS software. The frequency of C4AQ0 allele is 15.04% (17/113) in SLE patients compared with 1.92% (2/104) in controls ( $P < 0.001$ ). There was no significance of C4BQ0 allele in SLE patients compared with the controls ( $P = 0.233$ ). SLE patients with C4AQ0 gene had an increased risk of acquiring serositis and arthritis compared with the other patients [For serositis, odds ratio (OR) 4.2, 95% CI 1.2-15.0,  $P = 0.036$ ; For arthritis, OR 2.41, 95% CI 0.64-9.12,  $P = 0.043$ ]. SLEDAI and SDI of SLE patients with and without C4AQ0 gene had no statistically significant difference. In all the 19 individuals with C4AQ0 gene, we didn't detect a 2-bp insertion in exon29 of C4 gene. These results suggested that deficiency of C4A is a risk factor for acquiring SLE in Southwest China, and this results in increased risk of serositis and arthritis in SLE patients. C4AQ0 had no association with SLEDAI and SDI. The genetic basis of C4A nonexpression in Southwest Chinese is not due to 2bp insertion in exon29, and further studies are required to verify it.

**Evidence that MeCP2 mediates transcriptional repression by the AS-IC domain.** *L.B.K. Herzing<sup>1</sup>, S.-J. Kim<sup>2</sup>, L. Villard<sup>3</sup>, E.H. Cook<sup>2</sup>, D.H. Ledbetter<sup>1</sup>*. 1) Dept of Human Genetics, Univ Chicago, Chicago, IL; 2) Dept of Psychiatry, Univ Chicago, Chicago, IL; 3) INSERM U491, Fac.deMedecine LaTimone, Marseilles, FR.

There is considerable phenotypic overlap between autism, Rett syndrome (RS) and Angelman syndrome (AS). We propose that the critical effects of mutations in the methyl-CpG binding protein *MeCP2*, the RS gene, are on imprinted genes, particularly on those implicated in other neurodevelopmental disorders such as autism. Improper decoding of mCpG imprint marks would result in changes in gene expression patterns, resulting in the RS phenotype. The proximal region of chromosome 15 contains a large domain of imprinted genes involved in brain development and function including the AS gene, *UBE3A*, and is a strong candidate region for containing a maternally expressed autism gene. We have previously characterized *ATP10C*, which maps adjacent to *UBE3A*, and also demonstrates imprinted, maternal expression in normal human brain. However, preliminary examination using semi-quantitative RT-PCR of parental specific *ATP10C* expression in fibroblast cell lines from RS patients suggests that the ratio of maternal:paternal expression differs between clonal lines expressing wild-type or mutant *MeCP2* protein. Furthermore, levels of *ATP10C* are considerably reduced in a RS lymphoblast (LB) cell line expressing mutant *MeCP2*. This residual expression is of paternal origin, as is the majority of expression detectable from an LB line carrying an AS-imprinting center (IC) mutation, suggesting that both AS-IC and *MeCP2* mutations result in loss of maternal *ATP10C* expression. Preliminary results also demonstrate that a paternally expressed antisense transcript overlapping *ATP10C* is present in normal LBs, and that loss of maternal *ATP10C* expression in LBs with AS-IC and *MeCP2* mutations is coordinate with a gain of expression of an additional, maternal *ATP10C* antisense transcript in these cells. Together, these results suggest that *MeCP2* mediates control of the maternally expressed genes on 15q11-13 through the AS-IC, and that loss of expression of these genes may contribute to chromosome 15-associated autism and the AS and RS phenotypes. This work is supported by the NIH, CAN and IRSA.

**Identification of two highly conserved protein coding genes from the Prader-Willi syndrome candidate region.** *Y-H. Jiang*<sup>1</sup>, *H. Li*<sup>1</sup>, *L.G. Shaffer*<sup>1</sup>, *J. Lehoczky*<sup>2</sup>, *A.L. Beaudet*<sup>1</sup>. 1) Dept. of Molecular & Human Genetics, Baylor College Medicine, Houston, TX; 2) Center for Genome Research, MIT, MA.

Prader-Willi syndrome (PWS) is a neurological disorder characterized by neonatal hypotonia, childhood obesity, hyperphagia, and hypogonadism. Most PWS patients have either a paternal derived 4 Mb deletion of 15q11-q13 or maternal UPD. There are two common centromeric deletion breakpoints, the distal breakpoint (Class II) lies between D15S541/S542 and D15S543; and central breakpoint (Class I) being centromeric to D15S541/D15S542. A 2 Mb region from central breakpoint to *IPW* was defined as PWS candidate region, and paternally expressed transcripts (*SNRPN*, *PAR-1*, *PAR-5*, *IPW*, *ZNF127*, *NDN*, *MAGEL2*, *snoRNA*) were identified from this candidate region. However, none of these genes are yet proven to be the gene responsible for the PWS.

To identify additional transcripts from PWS candidate region, a sequence-based BAC contigs from which draft sequences have been deposited by human genome project were constructed and several novel transcripts were identified. Two protein coding genes, *PWSR-1* and *PWSR-2*, are mapped close to the centromeric breakpoint. *PWSR-1* has 30 exons and *PWSR-2* has 3 exons. *PWSR-1* is deleted in PWS patients with Class I deletion and the class II deletion may lie within the BAC containing the *PWSR-1* gene. Biallelic expression for both genes is detected in lymphoblasts with either class I or class II deletion by RT-PCR and northern. The mouse homologues of both genes were identified and show 98% and 96% identity to human at amino acid level. The *PWSR-1* protein is highly expressed in CNS and homologous to a p53 inducible protein. Both genes are highly conserved in many different species including *Drosophila*, *C.elegans*. A CpG island is identified in BAC containing *PWSR-1* gene by sequence analysis and examination of methylation status and tissue-specific imprinting are ongoing. Targeting vector for *PWSR-1* gene was constructed and inactivation of this gene in mouse ES cells is underway. Analysis of mice with a null mutation of *PWSR-1* may shed a light on the role of *PWSR-1* in PWS.

**Variation at the calpain 10 gene implicated in Type 2 diabetes susceptibility, plays no role in the pathogenesis of polycystic ovary syndrome.** *L. Haddad<sup>1</sup>, J. Evans<sup>2</sup>, S. Franks<sup>1</sup>, M.I. McCarthy<sup>1</sup>*. 1) Imperial College, London, UK; 2) Department of Diabetes and Vascular Medicine, University of Exeter, Exeter, UK.

Polycystic ovarian syndrome (PCOS) affects less than 5% of women, and shows clear physiological and epidemiological overlap with type 2 diabetes. Recent studies also indicate shared genetic susceptibility factors. The calpain 10 (CAPN10) gene was recently identified as underlying the major diabetes genetic effect localised to chr. 2q in Mexican Americans (MA). In this study, we applied family-based association methods in our PCOS resources to determine whether the CAPN10 gene plays a wider role in insulin-resistant states. We studied 146 parent-offspring trios (all European) ascertained through symptomatic, ultrasound-confirmed PCOS probands [median (IQR) age: 32.4 (25.6-39.2)y; BMI 24.0 (16.7-31.3)kgm<sup>-2</sup>]. A further 223 PCOS subjects were available for intermediate trait analyses. We analysed CAPN10 variants (SNPs 43, 44, 19, 63) implicated in diabetes-susceptibility, using PCR-based assays and the transmission disequilibrium test (TDT). Homozygosity for the common allele at SNP43 was most strongly associated with MA type 2 diabetes, but no association was evident in PCOS ( $c^2=0.08$ ). Furthermore, we observed no excess transmission at SNP44 ( $c^2=0.78$ ), SNP19 ( $c^2=0.59$ ) or SNP63 ( $c^2=4.51$ , nominal  $p=0.028$  (NS after correction)). Multilocus TDT (with TRANSMIT) revealed reduced haplotype diversity (only 5 of 16 possible haplotypes were present at  $>1.2\%$ ), but none showed excess transmission ( $c^2=7.68$ ,  $p=0.18$ ) to affected offspring. Haplotype frequencies in all 369 PCOS subjects did not differ from those in  $>800$  European control chromosomes ( $p=0.57$ ). Finally, intermediate trait analysis (for BMI, WHR, lipids, fasting insulin/glucose) revealed no relationship with genotype in all 369 PCOS subjects. We conclude that there is no association between CAPN10 variation and PCOS in European subjects, and, therefore, no evidence that CAPN10 plays a general role in susceptibility to insulin-resistant states.

**Inheritance of specific haplotypes of the IL4R gene associated with type 1 diabetes in the HBDI families.** *D.B.*

*Mirel<sup>1</sup>, A.M. Valdes<sup>1</sup>, R.L. Reynolds<sup>1</sup>, H.A. Erlich<sup>1,2</sup>, J.A. Noble<sup>2</sup>.* 1) Roche Molecular Systems, Alameda, CA; 2) Children's Hospital Oakland Research Institute, Oakland, CA.

Over 50% of the genetic predisposition to type 1 diabetes, a multifactorial autoimmune disorder, has been attributed to the HLA region, where multiple loci (e.g., HLA-DRB1, -DQA1, -DQB1, -DPB1 and -A), contribute to the genetic risk. It has proved rather difficult to identify specific susceptibility genes outside of HLA, despite the discovery of linked regions. We have used 282 multiplex type 1 diabetes families from the Human Biological Data Interchange (HBDI) to perform analyses of linkage and association to disease. We examined the transmission of alleles of candidate genes by genotyping SNPs in cytokine and cytokine receptor genes, using a multiplex PCR and immobilized probe array hybridization system.

SNPs in the IL4R gene, encoding a subunit of the interleukin-4 receptor, have been shown to be associated with Th2-type inflammatory diseases such as atopic asthma. We have genotyped the HBDI cohort at eight SNPs within the IL4R coding region: I50V, N142N, E375A, L389L, C406R, S478P, Q551R, and S761P. As these SNPs are genetically very close and there is strong LD among them, we could infer the transmission of eight-locus haplotypes in families. We performed molecular haplotyping for a subset of the SNPs as necessary to resolve linkage phase, using allele-specific PCR and immobilized probe hybridization. The association of IL4R with type 1 diabetes was examined using the Transmission-Disequilibrium Test (TDT) method. TDT analysis of individual loci indicates that the majority allele of the E375A, L389L, C406R and S478P SNPs is transmitted significantly more than 50% ( $p < 0.05$ ) to affected children. Furthermore, TDT analysis of haplotypes shows a significant ( $p < 0.01$ ) under-transmission of a single haplotype. This one putatively "protective" haplotype is composed of the minor alleles of many of the eight IL4R SNPs, alleles that have been reported to be associated individually with Th2-mediated disease. We hypothesize that a risk factor for the Th1-mediated type 1 diabetes might be conferred by non-inheritance of Th2-associated IL4R alleles or haplotype(s).

**Mutation analysis and association studies of the neurofilament L, M and H genes in German Parkinson's disease patients.** *R. Krueger*<sup>1</sup>, *N. Rahner*<sup>2</sup>, *C. Fischer*<sup>3</sup>, *T. Schulte*<sup>4</sup>, *C. Holzmann*<sup>2</sup>, *J.T. Epplen*<sup>3</sup>, *L. Schoels*<sup>4</sup>, *O. Riess*<sup>2</sup>. 1) Neurology, University of Tuebingen, Tuebingen, Germany; 2) Medical Genetics, University of Rostock, Rostock, Germany; 3) Human Molecular Genetics, University of Bochum, Bochum, Germany; 4) Neurology, University of Bochum, Bochum, Germany.

Recent advances in the understanding of the genetic contribution to Parkinson's disease (PD) indicate an involvement of pathological protein aggregation and disturbed protein degradation:  $\alpha$ -synuclein (SNCA) and ubiquitin C-terminal hydrolase (UCHL1) are components of Lewy bodies (LB) in brains of PD patients and are mutated in some rare forms of familial PD. Neurofilaments are a major component of LB aggregations and are composed of three neuron-specific proteins with molecular weights of 61kDa (NF-L), 90kDa (NF-M) and 110kDa (NF-H). Therefore we performed a detailed mutation analysis of the coding regions of all three genes encoding subunits of neurofilament in a large sample of 328 German PD patients. Using single strand conformation polymorphism analysis followed by direct sequencing we found three silent DNA changes (G163A, C224T, C487T) in the NF-L gene in three unrelated patients. Concerning the NF-M gene we identified three amino acid (aa) substitutions in PD patients that were found at similar frequencies in controls: Ala475Thr, Gly697Arg and Pro725Gln. In one index patient of a family with autosomal-dominantly inherited PD we found an in-frame deletion leading to the loss of valine in position 830 of the NF-M gene. Although absent in 754 chromosomes of healthy controls, no cosegregation with the disease could be observed in our family. In the NF-H gene we identified three novel aa substitutions in index patients with familial PD: Ala314Val, Arg352Ser and Asn390Thr. Association studies in sporadic PD using polymorphisms of all three genes revealed no significant difference in the allelic and genotypic distribution between patients and controls. Thus our study provides no genetic evidence for an involvement of neurofilament in the pathogenesis of PD. However, since disease causing mutations are expected to be rare, further studies are required to determine the relevance of neurofilament in PD.

**Polymorphisms of the NOTCH4 gene and schizophrenia.** *T.A. Klempan<sup>1</sup>, J.M. Trakalo<sup>1</sup>, C.N. Pato<sup>2</sup>, M. Pato<sup>2</sup>, M.-H. Azevedo<sup>2</sup>, F.M. Macciardi<sup>1</sup>, J.L. Kennedy<sup>1</sup>.* 1) Neurogenetics, CAMH, Toronto, ON, Canada; 2) Department of Psychiatry, SUNY at Buffalo, NY.

The human NOTCH4 gene is a member of a family whose products are known to be involved in embryonic specification of neuronal cell fate in *Drosophila melanogaster*. The NOTCH4 locus lies between the class II and class III regions of the major histocompatibility complex at 6p21.3, a region previously seen to be associated with schizophrenia. A recent report has demonstrated a highly significant association of 3 different polymorphisms across the promoter region and first exon of NOTCH4 with schizophrenia in trios of British descent. We have examined the transmission of the two most significant polymorphisms (CTG repeat and MspI SNP) in a combined sample of 60 mixed Caucasian and 96 Portuguese families with schizophrenia. TDT-sTDT and GENEHUNTER were used to study transmission of alleles and haplotypes to affected offspring. While MspI alleles were transmitted randomly to affected individuals ( $p=0.626$ ), several CTG repeat alleles demonstrated biased, though non-significant, transmission (CTG-10,  $p=0.123$ ; CTG-11,  $p=0.117$ ). Of the ten haplotypes examined, two showed significantly biased transmission (CTG-10/2,  $p=0.029$ ; CTG-11/2,  $p=0.033$ ). Considering the previous positive report, our results lend support for a possible susceptibility locus in the region of NOTCH4. We are currently examining an expanded sample and a third polymorphism.

**Identification of Disease Gene Variants Based upon Gene-Gene Interactions.** *G.P. Larson, L. Geller, T. Krontiris.*  
Div Molecular Medicine, Beckman Res Inst City of Hope, Duarte, CA.

New methods are needed for the identification of pathogenic alleles of candidate genes that may increase cancer susceptibility. Such risk alleles are expected to be of low penetrance and may act alone or modify the effects of other genes. We describe a simple, efficient strategy for detecting relatively rare genetic variants associated with human disease in small sample sizes. The method is based on (1) allele-sharing of candidate genes by affected siblings and (2) the postulation of gene-gene interactions. Candidate gene pairs are chosen based upon previous evidence demonstrating genetic or biochemical interaction. This approach, which we call Disease Association by Locus Stratification (DABLS), first stratifies ASPs based upon allele sharing of both alleles at a microsatellite marker linked to candidate 1. A second stratification is then performed based upon microsatellite marker sharing at candidate 2. Subsets of ASP sharing both alleles at both loci are identified as screening targets. Utilizing this approach in a breast cancer affected sib pair cohort, we have identified two non-coding disease haplotypes of *CDKN1A* by virtue of *BRCA1* and *TP53* interactions. Our results indicate that an approach based upon allele-sharing and gene-gene interactions will be valuable not only in identifying risk alleles, but also in elucidating their mechanism of action.

**Association studies of genetic risk factors for autistic disorder on chromosome 7.** *P.A. McCoy<sup>1</sup>, Y. Shao<sup>1</sup>, E.R. Martin<sup>1</sup>, G.R. DeLong<sup>1</sup>, M.L. Cuccaro<sup>2</sup>, J.R. Gilbert<sup>1</sup>, M.A. Pericak-Vance<sup>1</sup>.* 1) Department of Medicine, Duke University Medical Ctr, Durham, NC; 2) W.S. Hall Psychiatric Institute, University of South Carolina, Columbia, SC.

Several genomic screens have indicated the presence of an autistic disorder (AutD) susceptibility locus within the distal long arm of Chromosome 7. Recent reports suggest two genes, WNT2 at 7q31 and RELN at 7q22, influence genetic risk in AutD. Both genes are also good functional candidates due to their involvement in development. WNT2 encodes a signaling protein that regulates cell growth and differentiation. RELN regulates neuronal migration during brain development. Using both the Pedigree Disequilibrium Test (PDT) and TRANSMIT (TMT), we tested for genetic association of two WNT2 variants in the 5'UTR and 3'UTR regions of WNT2 in 211 (multiplex and singleton) Duke AutD families. No significant association was found between AutD and the WNT2 genotypes. We also screened the coding region of WNT2 for two reported autism mutations (TG mutation in the signal domain of Exon 1 of WNT2 produced Leu5Arg and a CT mutation in Exon 5 produced Arg299Trp) and failed to identify these WNT2 mutations in our data set. Our data suggests that the WNT2 gene is not a major contributor to genetic risk in AutD.

In addition we examined the association of a 5'UTR polymorphism in RELN ((GCC)<sub>n</sub>) in a dataset (N=342 families) that included 252 Duke (multiplex and singleton) as well as 90 AGRE multiplex families. PDT and TMT analysis of the combined data found no evidence for association (p=0.12; p=0.09, respectively). However, examining the AGRE families independently resulted in support of association to RELN (p=0.0014 (PDT); p=0.02 (TMT)). Results in the overall Duke or subset by family type were not significant. Examining the allelic specific AGRE results showed association with the 8- and 10-repeat alleles. The previously reported AutD RELN association was with the longer triplet repeats (>10-repeat alleles). These data indicate that additional analysis of RELN is warranted in order to evaluate its role in AutD risk.

**Polysubstance abuse association genome scanning provides evidence for polygenic inheritance of common alleles at loci including BDNF and ADH.** *G.R. Uhl<sup>1,2</sup>, Q.-R. Liu<sup>1</sup>, D. Walther<sup>1</sup>*. 1) Molecular Neurology Branch, NIH/NIDA/IRP, Baltimore, MD; 2) Depts Neurol & Nsci, JHUSchool of Medicine.

Strong genetic contributions to drug abuse vulnerability are well documented, with much of this genetics overlapping with genetics for legal addictions. However, few chromosomal loci for substance abuse vulnerability alleles have been confirmed. We now identify chromosomal markers whose alleles distinguish drug abusers from controls in each of two samples, based on pooled sample SNP microarray and association analyses. Nine reproducibly-positive chromosomal regions defined by these markers and previous results from genome scans for ligal addictive substances were especially unlikely to have been identified by chance ( $P < 10^{-8}$ ). Positive markers identify the alcohol dehydrogenase (ADH) locus, the brain derived neurotrophic factor (BDNF) locus and seven other regions previously linked to nicotine or alcohol vulnerability. These data support polygenic contributions of specific common allelic variants to polysubstance abuse vulnerability.

**SLEB2 region in human SLE: locus-gene-mutation.** *L. Prokunina*<sup>1</sup>, *C. Castillejo-Lpez*<sup>2</sup>, *I. Gunnarsson*<sup>3</sup>, *L. Berg*<sup>4</sup>, *D. Tentler*<sup>1</sup>, *F. Öberg*<sup>1</sup>, *M. Alarcon-Riquelme*<sup>1</sup>. 1) Medical Genetics, Rudbeck Lab, Genetics and Pathology, Uppsala, Sweden; 2) Dept.of Cell and Molecular Biology, Lund University, BMC B13, 22184, Lund, Sweden; 3) Unit of Rheumatology, Karolinska Hospital,17176, Stockholm,Sweden; 4) MTC, Karolinska Institute,17176, Stockholm, Sweden.

In order to define the genetic component for Systemic Lupus Erythematosus (SLE), a complex autoimmune disease, we ran a genome scan for multicase families of Nordic origin (Iceland, Sweden and Norway). The locus SLEB2 was identified (Lindqvist, et al. *J Autoimm.* 14:169,2000). Further fine mapping has confirmed this locus and we have obtained a maximum multipoint Lod Score of 6.03 for markers D2S2585/D2S2985 (Magnusson et al. *Genomics*, 70:307, 2000). We have now used 8 SNPs in this region to construct haplotypes. We found a major haplotype segregating in multicase families (TDT test,  $p=0.00008$ ). We also analyzed 200 Swedish single case families and found the same major haplotype as in multicase families associated with SLE (TDT test  $p=0.00001$ ). Recombination analysis allowed us to significantly delimit the SLEB2 region. A candidate gene from the region is studied now. A functional SNP, associated with the disease is analyzed here.

**TGFA is a genetic modifier of Van der Woude Syndrome.** *T.M. Zuccherro, B.C. Schutte, S. Daack-Hirsch, J.C. Murray.* Dept Pediatrics, Univ Iowa, Iowa City, IA.

Van der Woude syndrome (VWS) is a common form of syndromic cleft lip and palate, accounting for approximately 2% of total cleft lip and palate cases. It is transmitted in an autosomal dominant pattern with at least 95% penetrance. Characteristics of VWS include cleft lip with and without cleft palate, isolated cleft palate, lower lip pits, hypodontia, and normal intelligence. Although a single gene locus for VWS has been mapped to 1q32-q41, occurrences of different forms of orofacial clefts within families and a previous report of a modifier locus on chromosome 17 (Sertie et al, 1999) suggest that this locus alone is not responsible for the manifestation of VWS. The presence of particular alleles at other loci may modify the severity of VWS in individual patients. Three excellent candidate genes are TGFA, MSX1, and TGFB3; these genes have been associated with nonsyndromic clefting in humans and TGFB3 and MSX1 have been shown to cause clefts in mouse knockout strains. We collected samples from 949 individuals in 129 families that have at least one member affected with VWS. To date, samples from both affected and unaffected individuals have been genotyped for a single polymorphism at each of the three candidate loci; Chi-square analysis was utilized to determine if particular alleles at these loci are associated with a particular cleft phenotype in our VWS population. No association was found at the MSX1 and TGFB3 loci. We found a significant association between an allele from the TGFA gene with the absence of lip pits in affected individuals ( $p=0.0007$ ). A significant association is also seen when compared to an unaffected internal family control population ( $p=0.01$ ) and an unaffected, unrelated control population (0.01). The results from an independent TDT (Transmission Disequilibrium Test) analysis are consistent with a role for the TGFA gene in modifying the lip pit phenotype ( $p=0.001$ ). Future studies will include exploring the mechanism for this association and genotyping additional alleles at these and other candidate loci.

**Mutations in the dystrophin gene are associated with sporadic dilated cardiomyopathy.** *J. Yan*<sup>1</sup>, *J. Feng*<sup>1</sup>, *C.H. Buzin*<sup>1</sup>, *J.A. Towbin*<sup>\*2</sup>, *S.S. Sommer*<sup>\*1</sup>. 1) Department of Molecular Genetics, City of Hope Medical Center, Duarte, CA; 2) Department of Pediatrics (Cardiology), Baylor College of Medicine, Houston, TX. \*These authors contributed equally to the work.

Dilated cardiomyopathy is the major indication for heart transplantation. Approximately 30% of all DCM is thought to be inherited, while 70% is sporadic. Mutations in the dystrophin gene have been associated with the uncommon X-linked form of dilated cardiomyopathy. We hypothesized that missense mutations and other less severe mutations might predispose to sporadic dilated cardiomyopathy. To test this hypothesis, we examined 22 patients with sporadic dilated cardiomyopathy by DOVAM-S (Detection of Virtually All Mutations-SSCP) (Liu et al, 1999. *BioTechniques* 26:932-942; Buzin et al, 2000. *BioTechniques* 28:746-753), a form of SSCP in which there is sufficient redundancy to detect virtually all mutations. Twenty-two kb of genomic dystrophin DNA was scanned in the 22 patients with sporadic DCM, including all 79 coding sequences and splice junctions, as well as six alternative exon 1 dystrophin isoforms. Three putative new mutations (IVS5+1 G>T, N2299T and F3228L) and six polymorphisms were identified. The splice site mutation IVS5+1 is predicted to cause skipping of exon 5, a region containing an actin binding site. In the missense mutation F3228L in exon 67, the amino acid phenylalanine is highly conserved in dog, mouse, chicken, Torpedo, dogfish, starfish, scallop, and amphioxus dystrophins. Screening of 141 control individuals failed to identify these 3 mutations, hinting that milder mutations in the dystrophin gene are associated with sporadic DCM, but clinical manifestation may require some environmental effector or a modifying gene. These mutations may have reduced penetrance and generally appear as *sporadic* DCM. Future studies are needed to confirm that mutations in the dystrophin gene are a frequent cause of DCM and to analyze families with these dystrophin mutations to search for environmental or genetic modifiers that may help to generate the disease phenotype.

**Fine mapping genes for Fc gamma receptor II and III in systemic lupus erythematosus.** C.A. Robertson, B.J. Morley, T.J. Vyse. Imperial College School of Medicine, Rheumatology Department, Hammersmith Campus, London, UK.

**Background** Human systemic lupus erythematosus (SLE) is a clinically heterogeneous autoimmune disorder, affecting primarily women. Autoreactive IgG antinuclear autoantibodies are a hallmark of the disease, and *in situ* formation of IgG immune complexes (IC) contributes to lupus glomerulonephritis. SLE is inherited as a complex trait, although the specific genes involved are largely unknown. Human genome-wide linkage analyses have mapped loci linked to SLE; several are orthologous with loci linked in murine models. One region, 1q23-24, is orthologous to murine susceptibility loci *Sle1*, *Lbw7*, *Nba2*, *Bxs3*. Candidate genes in this region include human IgG Fc gamma class II (*FCGR2A*, *2B*, *2C*) and III receptors (*FCGR3A*, *3B*). The receptors bind polymeric IgG and play a role in IC clearance and B cell signalling. A well-characterised polymorphism (H/R131) in *FCGR2A* influences receptor affinity: the low-binding allele (R131) is associated with SLE in some case control studies but not in others. It remains unclear if this polymorphism represents a true susceptibility allele.

**Methods** We have performed a family-based association study using a collection of 455 nuclear families of predominantly European Caucasian descent (86.8%). Genotyping of the *FCGR2A* H/R131 polymorphism was done with ARMS-PCR. We sequenced the promoter of *FCGR3B* and identified a novel polymorphism (-213G>T) which was typed using PCR/RFLP. Allelic association with SLE was examined by transmission disequilibrium testing (TDT) using TRANSMIT v3.5.

**Results** Transmission of *FCGR2A* H/R131 alleles did not vary significantly from expected values (families  $F=391$ ,  $n$  individuals=1897,  $P=0.267$ ); this was true regardless of renal status. No distortion in the transmission of *FCGR3B* -213G>T alleles was found among patients ( $F=274$ ,  $n=1396$ ,  $P=0.269$ ). It is unlikely that these polymorphisms represent SLE susceptibility alleles in European Caucasians.

We are currently genotyping additional polymorphisms at the *FCGR* locus in our family cohort and plan to define and analyse haplotypes.

**Evaluating resistin as a susceptibility gene for type 2 diabetes in the Finnish population.** *K. Silander*<sup>1</sup>, *C.M. Steppan*<sup>2</sup>, *K.L. Mohlke*<sup>1</sup>, *K.N. Lazaridis*<sup>1</sup>, *T.T. Valle*<sup>3</sup>, *T.A. Buchanan*<sup>4</sup>, *R.M. Watanabe*<sup>4</sup>, *M. Boehnke*<sup>5</sup>, *J. Tuomilehto*<sup>3</sup>, *R.N. Bergman*<sup>4</sup>, *M.A. Lazar*<sup>2</sup>, *F.S. Collins*<sup>1</sup>. 1) National Human Genome Research Institute, NIH, Bethesda, MD; 2) Dept. of Medicine and Genetics, University of Pennsylvania School of Medicine, Philadelphia, PA; 3) Dept. of Epidemiology and Health Promotion, National Public Health Institute, Helsinki, Finland; 4) Dept. of Medicine, Dept. of Preventive Medicine, and Dept. of Physiology and Biophysics, Keck School of Medicine, University of Southern California, Los Angeles, CA; 5) Dept. of Biostatistics, University of Michigan, Ann Arbor, MI.

Resistin, a hormone secreted by adipocytes, has been suggested to play a role in insulin resistance in mice (Steppan et al. 2001, *Nature* 409:307-312). The Finland-United States Investigation of NIDDM genetics (FUSION) study aims to identify genetic factors contributing to type 2 diabetes. To evaluate whether genetic variants in human resistin are associated with type 2 diabetes we screened a cohort of 64 unrelated Finnish patients for possible gain-of-function variants. We also assessed possible association with insulin sensitivity by screening a cohort of 35 obese insulin-sensitive individuals for loss-of-function variants. These individuals were selected from a sample of approximately 600 unaffected individuals based on the criteria of having a BMI > 30 kg/m<sup>2</sup> and a minimal model insulin sensitivity index > 0.53 min<sup>-1</sup>/pM. The controls were 14 normoglycemic individuals at least 70 years old. The exons and promoter region of the human resistin gene were screened for variants using dHPLC followed by sequencing. Several polymorphic sites were identified in the promoter region, 5'-untranslated region, intron 3 and 3'-untranslated region. However, we did not detect any coding region variations either in diabetic patients or in any of the other subjects screened. Although no association was apparent, we are currently typing a larger set of control individuals for the polymorphisms identified to determine whether the allele frequencies differ among type 2 diabetics, obese insulin-sensitive individuals and elderly controls.

**Splice variants of small conductance calcium-activated potassium channel gene *KCNN3/ SKCa3* cause dominant-negative suppression of SKCa currents.** *H. Tomita*<sup>1,2</sup>, *V. Shakkottai*<sup>1</sup>, *H. Wulff*<sup>1</sup>, *G. Sun*<sup>1</sup>, *S.G. Potkin*<sup>2</sup>, *W.E. Bunney*<sup>2</sup>, *K.G. Chandy*<sup>1</sup>, *J.J. Gargus*<sup>1,3</sup>. 1) Dept Physiology and Biophysics, Univ California, Irvine, Irvine, CA; 2) Dept Psychiatry and Human Behavior, Univ California, Irvine, Irvine, CA; 3) Division Human Genetics, Dept Pediatrics, Univ California, Irvine, Irvine, CA.

*KCNN3/ SKCa3* is a member of the small conductance calcium-activated potassium channels that mediate slow afterhyperpolarizations following the action potential in vertebrate neurons. In the brain, *SKCa3* is most abundantly expressed in the substantia nigra and the ventral tegmental area, sites giving rise to two of the major dopaminergic pathways, and it regulates the spontaneous firing pattern of midbrain dopaminergic neurons. Recently, a 4bp deletion in *SKCa3* was identified in a patient with schizophrenia. This rare heterozygous deletion caused a frame-shift mutation that results in a truncated protein encompassing the entire N-terminus and lacking the hydrophobic core and C-terminus. This mutant protein has been shown to suppress SK channel function in a dominant-negative fashion, which would be expected to enhance the release of dopamine in the brain.

Herein we report identification of two novel splice variants of *SKCa3*, which we refer to as *SKCa3-b* and *SKCa3-c*, both lacking the N-terminus and the first transmembrane segment. *SKCa3-b* is expressed in brain and muscle along with the native *SKCa3-a* transcript, while *SKCa3-c* is present abundantly in muscle and lymphoid tissue. The *SKCa3-b* and *SKCa3-c* proteins are non-functional, but when expressed in PC12 cells produce dominant-negative suppression of endogenous SKCa currents by coassembling with native subunits into non-functional tetramers. The level of SKCa channel function may, therefore, be regulated by these splice variants. Taken together, these findings strongly suggest that brain region-specific expression of *SKCa3* splice variants may regulate dopaminergic activities and could potentially be related to the pathogenesis of schizophrenia.

**Molecular dissection of the promoter of the Human *KCNN3* / *SKCa3* gene.** *G. Sun*<sup>1</sup>, *H. Tomita*<sup>1,2</sup>, *V. Shakkottai*<sup>1</sup>, *J.J. Gargus*<sup>1,3</sup>. 1) Dept Physiology and Biophysics, Univ California, Irvine, Irvine, CA; 2) Dept Psychiatry and Human Behavior, Univ California, Irvine, Irvine, CA; 3) Division Human Genetics, Dept Pediatrics, Univ California, Irvine, Irvine, CA.

*KCNN3* /*SKCa3* is a member of the gene family, *KCNN1 - 4*, encoding the small and intermediate conductance calcium-activated potassium channels. Long CAG-repeat alleles of this gene have been found to be over-represented in patients with schizophrenia in a number of population-based association studies, and this large, recently sequenced 160 kb gene (AF336797) maps to human chromosome 1q21, a region recently implicated in schizophrenia by linkage.

In an attempt to determine the mechanisms by which the expression of this gene is regulated, we subcloned the genomic fragment covering 2,261 bp of the 5'-flanking region of *KCNN3* into a promoterless pGL3-luciferase vector, where it produced orientation-dependent expression of the reporter gene in transiently transfected PC12 cells, cells which natively express the channel. A series of 5'-deletion constructs of the promoter region were obtained and used in a transfection assay. The region between -325 bp to -529 bp upstream of the first codon contained the critical promoter region. Computer analysis of this 204 bp region predicted the presence of several transcription factor binding sites, including: NFY, SP1, NF1, NKX25, and two MZF1 sites. This region has a GC box and a CAAT box, but no TATA box. Primer extension analysis identified two transcription initiation sites. Site-directed mutations in the 204 bp minimal promoter region cloned into the promoterless pGL3-luciferase reporter vector were produced. Mutations altering the NFY motif caused a significant reduction in expression derived from the 204 bp region when constructs were used to transfect PC12 cells, suggesting that this motif plays a substantial role in *KCNN3* expression in these cells.

**The identification of gene expression signatures in the PBMCs of patients with Systemic Lupus Erythematosus.**

*E.C. Baechler*<sup>1</sup>, *P.M. Gaffney*<sup>1</sup>, *W.A. Ortmann*<sup>1</sup>, *F.M. Batliwalla*<sup>2</sup>, *G. Karypis*<sup>3</sup>, *P.K. Gregersen*<sup>2</sup>, *T.W. Behrens*<sup>1</sup>. 1) Medicine, University of Minnesota, Minneapolis, MN; 2) Human Genetics, North Shore University Hospital, Manhasset, NY; 3) Computer Science, University of Minnesota, Minneapolis, MN.

Systemic Lupus Erythematosus (SLE) is a chronic autoimmune disease with a strong genetic component. SLE is characterized by unpredictable flares of disease activity and significant patient heterogeneity in drug response, severity of disease, and clinical symptoms. Here, we report our experience using Affymetrix microarrays to identify peripheral blood mononuclear cell (PBMC) gene expression signatures specific for SLE. In a first experiment, mRNA was isolated from the PBMCs of 11 SLE patients (with low levels of disease activity) and 11 healthy, age- and sex-matched controls. RNA probes were generated and hybridized to Affymetrix U95A GeneChips, followed by data analyses. This experiment identified 516 genes that differed significantly in their expression between SLE patients and controls ( $p < 0.05$  by unpaired T test). Among these were genes involved in cytokine and immune-cell signaling, a number of interferon-inducible genes, genes involved in calcium signaling pathways, as well as genes regulating the ubiquitin pathway of protein degradation. Hierarchical clustering clearly differentiated the patient profiles from the controls, and also identified at least 2 subgroups of SLE patients. A second experiment used polyA+ mRNA isolated from purified B and T cell populations, both at rest and after *in vitro* activation. This experiment identified 170 genes differentially expressed in resting B cells, 421 in resting T cells, and 244 in stimulated T cells (all at  $p < 0.05$  level). Once again, cluster analyses completely segregated SLE patients from controls, and many of the same genes identified in the PBMC experiment were also identified here. These results demonstrate that PBMC gene expression analysis can be used to identify deregulated pathways in SLE, and highlight the potential to identify patient sub-groups at the level of gene expression.

**MTHFR C677T and A1298C gene mutations, homocysteine, folic acid and vitamin B12 plasma levels and thrombosis in patients with systemic lupus erythematosus.** *H. Arrieta<sup>1</sup>, M.A. López<sup>1</sup>, A. Torre<sup>2</sup>, V. Valles<sup>3</sup>, M. Cardiel<sup>2</sup>, O.M. Mutchinick<sup>1</sup>.* 1) Dept de Genética; 2) Inmunología Reumatología; 3) Diabetes, Inst Nac Ciencias Médicas y Nutrición Salvador Zubirán, México, D.F.

**Background:** Thrombosis is considered a leading cause of morbidity and death in systemic lupus erythematosus (SLE). It is well known that the homozygous TT for the MTHFR C677T mutation produces a thermolabile enzyme that affects folate metabolism, homocysteine (Hc) remethylation in presence of methionine synthase and vitamin B12. The above induces a mild hyperhomocysteinemia (Hcy) that is a risk factor for thrombosis. **Objective:** To study the association of TT and CC genotypes for the MTHFR C<sup>677</sup>T and A<sup>1298</sup>C mutations, plasma levels of Hc, FA and B12, and daily intake of FA, B2, B6 and B12 with the risk of thrombosis in SLE. **Design:** Matched case-control study.

**Participants:** 35 patients with SLE and thrombosis (cases) and 70 with SLE without thrombosis (controls). **Methods:** Identification of the mentioned mutations by PCR and restriction enzyme analysis, plasma levels of Hc, FA and B12 by ELISA and the FA, B2, B6 and B12 intake by a food frequency questionnaire. .

**Results:** The frequency of TT genotype in cases was 14.7% and 11.4% in controls. We found only 1 homozygous for the C mutant allele in controls and none in cases. Correlation was not observed between TT and CC genotypes and plasma levels of Hc, FA and B12. No statistical differences were observed in daily intake of FA, B2, B6 and B12 vitamins among cases and controls. However, it was observed that the number of subjects with plasma level of FA below the median was significantly higher in cases than controls ( $P=0.035$ ).

**Conclusions:** The prevalence of the TT genotype of the C677T mutation in both groups of patients was significantly lower than the observed in diverse samples of normal Mexican populations studied by us. Our findings suggest that homozygous for the C677T and A1298C MTHFR mutations, plasma levels of Hc and B12 and current daily intake of FA, B2, B6 and B12 are not associated risk factors for thrombosis in SLE patients. Differences in FA plasma level most probably represents a spurious association.

**Identification of genetic polymorphisms in thymus-specific serine protease related to disease association with type 1 diabetes.** *B.A. Lie<sup>1</sup>, S. Johansson<sup>1</sup>, C.L. Bowlus<sup>2</sup>, J.R. Gruen<sup>3</sup>, F. Pociot<sup>4</sup>, J. Nerup<sup>4</sup>, E. Thorsby<sup>1</sup>, D.E.*

*Undlien<sup>1</sup>.* 1) Inst Immunology, National Hosp, Oslo, Norway; 2) Department of Internal Medicine, University of California Davis Medical Center, Sacramento, California 95817; 3) Department of Pediatrics, Yale University School of Medicine, 333 Cedar Street, New Haven, Connecticut 06520-8019; 4) Steno Diabetes Center, Gentofte, Denmark.

We have previously shown that there are additional genes in the HLA complex, besides the DR and DQ genes, involved in the development of type 1 diabetes by testing microsatellites spanning the extended HLA complex. The marker D6S2223, located in the extended HLA class I region, was strongly associated with type 1 diabetes when the haplotype was fixed for DR3-DQ2. The gene encoding thymus-specific serine protease (PRSS16) is located in this genetic region, where we believed PRSS16 to be the most likely candidate gene among the known genes. PRSS16 is exclusively expressed in thymus and has been suggested to be involved in positive selection of T cells in the thymus. Therefore, we screened the promoter, introns and exons of PRSS16 (11216 bp) by DHPLC and direct sequencing, and identified 22 (19 novel) polymorphisms. Three of the polymorphisms were located in exons, one SNP giving rise to the amino acid substitution, one silent SNP and a 15 bp deletion. To test for disease association in large data sets of type 1 diabetes families, we selected these polymorphisms together with seven others, based on their frequencies, patterns of linkage disequilibrium and their probability of being biologically functional. However, none of these polymorphisms showed significant association with type 1 diabetes with a strength comparable to that observed for D6S2223. Hence, it is unlikely that PRSS16 is involved in the development of type 1 diabetes.

**Imprinted expression from single copy *Snrpn* transgenes in mice.** *S.J. Chamberlain, C.I. Brannan.* Department of Molecular Genetics and Microbiology and the Center for Mammalian Genetics, University of Florida, Gainesville, FL.

The Prader-Willi syndrome (PWS) candidate genes as well as the Angelman syndrome (AS) candidate gene are regulated by an Imprinting Center (IC) located 5' and including the first exon of the *SNRPN* gene. The elements that are necessary for the IC have been defined by means of deletion mutations that have been mapped in humans and created in mice. We have sought to determine the minimal sequence sufficient to confer imprinting to a transgene. Previously, we have shown that an 85 kb murine *Snrpn*P1 clone, containing approximately 30 kb of 5' flanking DNA exhibited imprinted expression when present as a two copy transgene, but exhibited biparental expression as a single copy transgene. This suggests that this 85 kb P1 clone contains sequences able to confer imprinted expression, but not sufficient to in a copy-number independent manner. Therefore, we have sought to add more 5' flanking sequence to determine if we can obtain reliable single copy imprinting of a transgene. To obtain imprinted expression of a single copy transgene, we have isolated and injected three new BAC clones spanning the *Snrpn* locus. We have obtained several intact transgenic lines from each BAC on the FVB/NJ genetic background. We have transmitted the transgene maternally and paternally and prepared total brain RNA. We assayed expression of the transgene by Northern blot (avoids detection of the background, low level expression derived from the maternal FVB/NJ allele, which is only detectable by RT-PCR). We are able to distinguish expression of the transgene from expression of the endogenous gene by using a marked endogenous allele. We have found that single copy transgenes containing only 8 kb of upstream *Snrpn* sequence are expressed upon both maternal and paternal inheritance. In contrast, we found that single copy transgenes containing either 90 kb or 180 kb of upstream sequence are expressed upon paternal, but not maternal transmission. These data suggest that the relevant sequences for single copy imprinting lie within a 90 kb region upstream of *Snrpn*.

**Monozygotic twins discordant for the Beckwith-Wiedemann syndrome exhibit the same epigenetic defect at the 11p15 locus.** *C. Gicquel<sup>1</sup>, V. Gaston<sup>1</sup>, P. Sarda<sup>2</sup>, V. Soupre<sup>3</sup>, M.P. Vazquez<sup>3</sup>, Y. Le Bouc<sup>1</sup>.* 1) Laboratoire d'Endocrinologie - INSERM U515, Hopital Trousseau, AP-HP, Paris, France; 2) Service de Genetique Medicale et Foetopathologie, Hopital Arnaud de Villeneuve, Montpellier, France; 3) Service de Chirurgie Maxillo-faciale, Hopital Trousseau, AP-HP, Paris, France.

Monozygotic twinning occurs with relatively high frequency in Beckwith- Wiedemann syndrome (BWS). Most of monozygotic twins with BWS are female and in most cases the twins are discordant for the BWS phenotype. It has been suggested that the excess of female monozygotic twin pairs may be related to the process of X chromosome inactivation. We report here two pairs of female MZ twins, each discordant for BWS. In both cases, one twin showed typical BWS whereas the other did not. One pair of twins had a 47,XXX karyotype. The allelic status of the 11p15 region and the methylation status of the KCNQ1OT and H19 genes were investigated in DNA from peripheral blood cells by Southern-blot analysis. X chromosome inactivation was determined at the M27 locus (Xcen-p11.22) by Southern-blot analysis. Analysis of the 11p15 region showed the same epigenetic defect (almost complete demethylation of the KCNQ1OT gene) in both BWS twins and in normal twins. The X chromosome inactivation pattern was also similar in BWS patients and their unaffected twins. These data do not support an association between the expression of BWS and X chromosome inactivation. The hypothesis of a different tissue distribution of epimutated cells in the two twins is unlikely because of the complete demethylation of the KCNQ1OT gene and the absence of any clinical signs in the two unaffected twins. Further studies are necessary to establish the mechanism of discordant monozygotic twinning in BWS.

**Analysis of imprinting in the Silver Russell Syndrome candidate gene region at 7q31-qter.** *L. Bentley<sup>1</sup>, D. Monk<sup>1</sup>, E. Smith<sup>1</sup>, R. Edmonds<sup>1</sup>, M. Hitchins<sup>1</sup>, M.A. Preece<sup>2</sup>, P. Stanier<sup>1</sup>, G.E. Moore<sup>1</sup>.* 1) Maternal and Fetal Medicine, Imperial College, London, UK; 2) Institute of Child Health, University College London, London, UK.

Silver Russell syndrome (SRS) is characterised by pre- and postnatal growth restriction in association with other dysmorphic features including asymmetry and fifth finger clinodactyly. The syndrome is heterogenous, with a number of chromosomes implicated. However, maternal uniparental disomy for chromosome 7 (mat UPD7) has been demonstrated in up to 10% of cases. Two imprinted candidate regions on chromosome 7 have been identified by cytogenetic abnormalities on both the p and q arms. The first, defined by two unrelated maternally derived duplications of 7p11.2-p13 includes the reciprocally imprinted growth suppressing *GRB10* gene. Recently Hannula *et al.* (2001) reported a single case of segmental mat UPD7 of 7q31-qter. This defines the second candidate gene region that includes the imprinted gene cluster comprising of *MEST*, *COPG2* and *MIT1/LB9*.

Using 8 polymorphic repeat markers for the q arm, we systematically re-evaluated the possibility that segmental UPD7 may be present in 17 probands from our SRS cohort. In addition we have found that the *MEST* gene replicates asynchronously, a common feature of an imprinted gene domain. Using individual PAC and BAC clones from a contig of the region as FISH probes, we have delineated the extent of the asynchronous domain. The imprinting status of genes known to map within this region were assessed in monochromosomal somatic cell hybrids retaining individual chromosome 7s of known parental origin, in which the paternal expression of the *MEST 1* isoform was maintained.

**Microarray analysis of transcript expression in Prader-Willi syndrome.** *D.C. Bittel, Z. Talebizadeh, M.G. Butler.* Children's Mercy Hospital and University of Missouri-Kansas City School of Medicine, Kansas City, MO.

Prader-Willi syndrome (PWS) is characterized by infantile hypotonia, hypogonadism, hyperphagia, early onset of childhood obesity, a particular facial appearance and mental deficiency. PWS is caused by deficiency of genes located on the proximal long arm of chromosome 15. To date, several genes have been identified in the 15q11-q13 region including ZNF127, NECDIN, MAGEL2, SNURF-SNRPN, IPW, UBE3A, ATP10C, GABRA5, GABRB3, GABRG3, P and HERC2. ZNF127, NECDIN, MAGEL2, SNURF-SNRPN and IPW are expressed from the paternal chromosome and the lack of expression contributes to PWS. The other genes are either maternally expressed (UBE3A, ATP10C) or have biallelic expression. Deletion of paternal 15q11-13, maternal uniparental disomy (UPD) of chromosome 15 or in rare cases, imprinting center (IC) mutations are reported to cause PWS. The proximal portion of chromosome 15 which is critical for PWS contains approximately 4 million base pairs of DNA and may contain as many as 100 expressed sequences or genes. We have generated a custom cDNA microarray by mining the GenBank database for identification of PCR primer sequences from the proximal region of chromosome 15, performing PCR reactions and spotting the PCR products on glass slides. A total of 90 nonredundant genes and ESTs from the proximal long arm of chromosome 15 were spotted. Twenty- six of these have been mapped between the pTel and D15S122 anchor markers, 7 between D15S122 and D15S156, 10 between D15S156 and D15S165, 7 between D15S165 and D15S144, 12 between D15S144 and D15S118, 6 between D15S118 and D15S146, 8 between D15S146 and D15S117, 1 between D15S117 and D15S159 and the rest were either distal or not accurately mapped. Five micrograms of mRNA from actively growing control and PWS lymphoblastoid lines were labeled alternately with Cy3 (green) or Cy5 (red) and pooled for hybridization to the array. We compared and analyzed the expression of sequences from the proximal 15q region between control lymphoblasts and lymphoblasts derived from individuals with PWS caused by deletions, UPD and IC mutations.

**NTera2 as a Cell Culture Model for Brain-Specific Imprinting on Chromosome 15q11-q13.** C.J. GIULIANO, M. LALANDE. DEPARTMENT OF GENETICS AND DEVELOPMENTAL BIOLOGY, UNIVERSITY OF CONNECTICUT HEALTH CENTER FARMINGTON, CT.

Prader-Willi Syndrome (PWS) results from a physical or functional loss of paternally expressed genes in the chromosome 15q11-q13 region. Angelman syndrome (AS) results from mutation or absence of a maternally expressed gene, UBE3A. Genomic imprinting within the PWS/AS region is believed to be coordinately regulated by a bipartite imprinting center, implying that genomic imprinting is under regional control. There are differences in the regional distribution of non brain-specific and brain-specific transcripts in the PWS/AS region (Lee & Wevrick, 2000). Genes with broader tissue expression patterns are located in the more centromeric 15q11-q13 region; these include, ZNF127, NECDIN, MAGEL2, SNRPN, PAR5, PAR7, IPW, PAR1, and small nucleolar (sno) RNAs HBII85 and HBII13. In contrast, transcripts that show brain-specific expression are located in the more telomeric region; these include, UBE3A antisense (UBE3A-ATS), A005C48, and tandem repeats of the HBII52 snoRNAs. A complex pattern of alternative splicing is observed for the brain-specific genes, and these may be processed from one large transcript. The NTera 2 (NT2) cell line will be used as a model system to study the organization of the two expression domains. NT2 cells can be induced to differentiate into neurons by treatment with retinoic acid (RA). Expression of IPW, PAR5 and the HBII85 snoRNAs is observed throughout the process of neuronal differentiation, including in undifferentiated NT2 cells. This expression pattern is consistent with the presence of IPW, PAR5 and HBII85 in the domain with broader tissue expression. In contrast, expression of A005C48 and the HBII52 snoRNAs is not detected until 3 weeks after induction of neuronal differentiation, with high levels of expression evident in mature neurons. This pattern of expression is consistent with the localization of A005C48 and the HBII52 snoRNAs within the brain-specific domain. The *in vitro* system of neuronal NT2 cell differentiation may provide a powerful tool for studying the mechanism of brain-specific imprinting in the PWS/AS region. Reference: Lee, S. and Wevrick, R. (2000) American Journal of Human Genetics, 66: 848-858.

**Genetic mechanisms connecting disturbed early growth and type 2 diabetes: further evidence for imprinting at the insulin gene locus.** *N. Gharani*<sup>1</sup>, *S. Huxtable*<sup>1</sup>, *L.K. Li*<sup>2</sup>, *S. Humphries*<sup>2</sup>, *P. Hindmarsh*<sup>2</sup>, *M. McCarthy*<sup>1</sup>. 1) Imperial College; 2) UCL, London, UK.

There is growing evidence that the association between early growth and metabolic phenotypes in adults, is in part, due to the pleiotropic effects of genes modulating insulin secretion and/or action, and thereby contributing to variation in both fetal and adult phenotypes. One such locus is the insulin gene. Recent studies have shown that *INS*-VNTR-associated susceptibility to type 2 diabetes is preferentially-transmitted through paternal class III alleles, and is, by implication, mediated through imprinted mechanisms active in early life. We reasoned that similar imprinting effects modulating the known association between *INS*-VNTR class and early growth would provide further support for a common genetic mechanism. Therefore, we examined *INS*-VNTR genotypes of 191 European parent-offspring trios, each ascertained through unselected consecutive births. Measurements of infant weight, length and head circumference were available at 0, 6 and 12 months of age. Parental and cord-blood samples were genotyped for the -23Hph1 variant (as a surrogate for VNTR class), with ambiguities in the parental origin of fetal alleles resolved through additional *INS*-VNTR class I typing. The search for imprinting effects focussed on the 51 heterozygous infants, 21 of whom had inherited a paternal class I, and 30 a paternal class III. No differences were seen at birth, but, by 6 months, there was a clear divergence in growth patterns, with the paternal class III babies both lighter (weight SDS (SD): 0.03(1.02) vs 0.66(0.90),  $p=0.029$ ) and shorter (length SDS (SD): 0.13(1.00) vs 0.90(0.81),  $p=0.006$ ) than those with paternal class I. In this study, we found no evidence for a relationship between fetal VNTR genotype (I/I vs I/III vs III/III,  $p>0.32$ ) and parameters at birth, in contrast with previous ALSPAC data (though numbers were smaller). These data provide the first evidence that VNTR-associated effects on early growth, like those on diabetes, demonstrate parent-of-origin effects, lending additional support to a genetic contribution to the link between fetal and adult phenotypes.

**Identification and Characterization of Imprinting on Human Chromosome 14.** *C.J. Clarke, D.A. McFadyen, J. Shah, D.W. Cox.* Medical Genetics, University of Alberta, Edmonton, Alberta, Canada.

Genomic imprinting is known to significantly influence development, growth, and behavior in mammals. Imprinting has been directly linked to the etiology of several human disorders. Patients with both paternal and maternal uniparental disomy (UPD) for chromosome 14 have distinct phenotypes which have raised interest in possible imprinted regions on human chromosome 14.

To aid in the understanding of the phenotypes of UPD14 and 14q deletion patients we have performed an analysis using cell lines collected from patients with maternal UPD, paternal UPD or a deletion in 14q32. Using an RT-PCR based assay, we determined the imprinting status of 28 known genes and 67 ESTs located throughout human 14q32. This chromosomal region contains two previously identified reciprocally imprinted genes *GTL2* and *DLK1* and four associated imprinted transcripts *DAT*, *PEG11*, *antiPEG11*, *MEG8*. In our study, three novel paternally expressed transcripts were also identified, however, the function of the newly identified imprinted transcripts is unknown. This work provides the framework for further investigation into the function of these transcripts, their role in determining the phenotype in UPD14 patients, as well as the identification of additional imprinted genes in 14q.

**The human *LIT1* CpG island is a putative imprinting control element playing an essential role in Beckwith-Wiedemann syndrome.** *S. Horike, K. Mitsuya, M. Meguro, N. Kotobuki, A. Kashiwagi, T. Notsu, F. Ayabe, Y. Shirayoshi, M. Oshimura.* Department of Molecular & Cell Genetics, School of Life Science, Faculty of Medicine, Tottori University, Yonago, Tottori, Japan.

Imprinting defects at the human chromosome 11p15.5 lead to Beckwith-Wiedemann syndrome (BWS). The molecular mechanisms underlying genomic imprinting are unknown, but it is of particular interest in the context of coordinated regulation of neighbouring genes on the megabase scale. Two imprinting control elements (IC) that guide the allelic expression of neighbouring genes in the imprinting cluster, have been localized to the *H19/IGF2* locus and *KvLQT1/LIT1* locus in the human chromosome 11p15.5. It is thought that the imprinting of *H19/IGF2* locus is dependent upon an IC that acts as a chromatin insulator to interfere with enhancer-promoter interaction. We have previously shown that targeted deletion of a putative IC within the *KvLQT1/LIT1* locus abolished the *LIT1* transcription on the paternal allele, accompanied by activation of the multiple normally suppressed paternal alleles including *KvLQT1* and *p57<sup>KIP2</sup>*. We also have suggested that the IC within the *KvLQT1/LIT1* locus could have boundary functions in addition to being a promoter region for the *LIT1*, and this could be also true for the IC within the *H19/IGF2* as well. The similarities in the imprinting characteristics of these two ICs suggest that the imprinting element would be conserved in the heterologous chromosomal locations within one species, as well as in the orthologous regions between species. To test this hypothesis, we generated the modified chromosome harboring the *LIT1* locus, in that the *H19/Igf2* IC was inserted using chicken DT40 cells. Analysis of expression status of neighbouring genes in the *LIT1* locus using the modified chromosome is now ongoing. This work was supported by CREST of Japan Science and Technology Corporation (JST), and grants from the Mitsubishi Foundation, the Ministry of Health and Welfare of Japan and the Human Frontier Science Program Organization (HFSPO).

**Brain-specific processing of an imprinted transcript encompassing *Ipw* and the *Ube3a* antisense.** *M. Landers*<sup>1</sup>, *D. Bancescu*<sup>1</sup>, *C. Rougeulle*<sup>2</sup>, *H. Glatt-Deeley*<sup>1</sup>, *M. Lalande*<sup>1</sup>. 1) Genetics, UCHC, Farmington, CT; 2) Institut Pasteur, France.

Angelman syndrome is caused by the absence of a maternal contribution to the 15q11-q13 region. Most cases are due to a deficiency of *UBE3A/E6AP*, a gene with maternal-specific expression in brain. We have recently identified a paternal-specific transcript, *UBE3A-ATS*, that is also brain-specific and is antisense to *UBE3A*. Our hypothesis is that the *UBE3A-ATS* silences the paternal allele of *UBE3A* in brain although the mechanism of this interaction remains unknown. We characterized the upstream region of the mouse ortholog, *Ube3a-ATS*, in order to understand the regulation of its transcription in mouse brain. Strand-specific RT-PCRs were performed starting from the 3' region of *Ube3a*. Comparison of the nucleotide sequence of the genomic DNA and the RT-PCR products revealed that the ATS is contiguous with genomic DNA extending to 10 kb downstream of the *Ube3a* 3'-end. We detected two alternatively spliced ATS transcripts and identified eight exons spanning approximately 35 kb of genomic DNA further downstream. Three of these exons showed 82% homology to the exon G of the *Ipw* (*Hum. Mol. Genet.* 6:325) transcript. The genomic sequence also revealed a copy of the MBII52 small nucleolar RNA (snoRNA) embedded between *Ipw* exons G2 and G1 for one of the ATS transcripts. MBII52 snoRNAs are paternally expressed, brain-specific and processed from introns of the *Ipw* transcript (*PNAS* 97:14311). Consistent with these data, that suggest that *Ipw* and the *Ube3a-ATS* are part of the same transcript, we PCR-amplified a fragment from *Ipw* exons B to E by priming an RT from the contiguous region of ATS that overlaps the *Ube3a* 3'-end. We then used the P19 cell line, an *in vitro* model for neuronal differentiation, to analyze the expression of the paternal brain transcripts. *Ipw*, MBII52 snoRNAs and *Ube3a-ATS* are first detected at day 7 after induction of P19 cell differentiation. The temporal coincidence of these three transcriptional events during neurogenesis, together with the finding that both *Ipw* and *Ube3a-ATS* are under the control of the PWS-IC (*Genomics* 73:316), indicate that processing of *Ipw/Ube3a-ATS* in brain may play an important role in regulating the imprinting of *Ube3a*.

***NDN and MAGEL2 as candidate genes in Prader-Willi Syndrome.*** *S. Lee, S.L. Kuny, C. Walker, R. Wevrick.* Dept Medical Genetics, Univ Alberta, Edmonton, AB, Canada.

Prader-Willi syndrome (PWS) is a contiguous gene syndrome caused by the loss of imprinted, paternally expressed genes from human chromosome 15q11-q13. PWS is a neurobehavioural disorder characterized by neonatal hypotonia, hyperphagia and developmental delay. *NDN* and *MAGEL2*, members of the MAGE gene superfamily, are two adjacent, paternally expressed genes that are silenced in PWS. The mouse orthologues, *Ndn* and *Magel2*, are located within a region of conserved synteny on mouse chromosome 7. We have examined *Ndn* and *Magel2* in mouse P19 embryonic carcinoma cell lines. P19 cells can be induced to differentiate into neurons with the addition of retinoic acid and are thus an *in vitro* model of neurogenesis. We have found that the expression of *Magel2* RNA is repressed in P19 cells with the addition of retinoic acid, whereas *Ndn* expression is induced. The complementary expression pattern of these genes suggests that they have distinct roles in neurodevelopment despite their sequence similarities. The expression of *Ndn* and *Magel2* by RNA *in situ* hybridization in developing mouse embryos also suggests complementary roles in early nervous system development. *Ndn* expression begins around embryonic stage E9 and is distributed throughout the nervous system. *Magel2* expression begins around day E11, and confined mainly to the central nervous system. We hypothesize that the combined loss of *NDN* and *MAGEL2* may contribute to the neurological problems associated with PWS.

**Inheritance patterns of alleles in imprinted regions of the mouse genome at different stages of development.** A.K. Naumova<sup>1,4</sup>, S. Croteau<sup>1</sup>, C.M.T. Greenwood<sup>2,4</sup>, K. Morgan<sup>3,4</sup>. 1) Department of Obstetrics and Gynecology, Women's Pavillon, F3.36, Royal Victoria Hosp, Montreal, Quebec, Canada; 2) Department of Epidemiology and Biostatistics, McGill University and Research Institute of the McGill University Health Centre; 3) Department of Medicine, McGill University and Research Institute of the McGill University Health Centre; 4) Department of Human Genetics, McGill University, Montreal, Quebec, Canada.

Deviations from Mendelian 1:1 transmission ratio have been observed in mice and humans. With few exceptions the mechanism leading to transmission-ratio distortion (TRD) remains obscure. We proposed that a genomic imprinting mechanism plays a key role in the genesis of grandparental-origin dependent TRD (Naumova et al. 2001). To further test this hypothesis, we analyzed the transmission of grandparental alleles at three imprinted regions of the mouse genome known to contain genes required for embryo development. We found and replicated moderate (58%: 42%) TRD in favor of grandmaternal alleles in the imprinted region of maternal distal chromosome 12 among female offspring (326 grandmaternal alleles versus 238 grandpaternal alleles inherited, exact binomial  $p = 0.0062$ ). The region of maximal distortion on chromosome 12 was mapped distal to position 50 cM, and includes the imprinted genes *Meg3* and *Dlk1*. Comparison of transmission ratios at the distorted region of chromosome 12 among 3-week old mice with those in 3.5 d.p.c. and 7.5 d.p.c. embryos suggests that the distortion in favor of grandmaternal alleles is due to postimplantation embryo loss. The absence of grandparental-origin dependent TRD for maternal chromosomes 6 and 7 suggests that the relationship between TRD and imprinting is complex. Most likely multiple conditions are required for TRD to occur.

**Complementary patterns of histone H3 Lys9 and Lys4 methylation at the Prader-Willi imprinting center. J.**

*Wagstaff*<sup>1,2</sup>, *C.D. Allis*<sup>2</sup>, *Z. Xin*<sup>2</sup>. 1) Department of Pediatrics, University of Virginia, Charlottesville, VA; 2) Department of Biochemistry and Molecular Genetics, University of Virginia, Charlottesville, VA.

Prader-Willi syndrome (PWS) and Angelman syndrome (AS) are clinically distinct syndromes both caused by genetic alterations in the chromosome 15q11-q13 region. PWS is caused by lack of expression of paternally-expressed genes in this region; AS is caused by lack of a functional maternal allele of UBE3A, which is imprinted only in brain. A 4.3 kb region that includes the promoter and exon 1 of SNRPN, referred to as the PWS imprinting center (PWS-IC), is required for establishment of the paternal pattern of gene expression and DNA methylation throughout the PWS/AS region. This region shows cytosine methylation on the maternal allele in somatic cells. However, recent studies have shown that this DNA methylation is not present in human oocytes, but occurs after fertilization and therefore is not the gametic imprint (El-Maarri et al.(2001) Nature Genet. 27:341-4). We have analyzed other epigenetic modifications of this region in order to identify the gametic imprint. We have used chromatin immunoprecipitation to show that histone H3 methylated on Lys9, which has been associated with chromatin-based silencing in fission yeast and *Drosophila*, is associated preferentially with the silenced maternal promoter of SNRPN. Histone H3 methylated on Lys4 is associated preferentially with the active paternal promoters of SNRPN and NDN. In this region, histone H3 methylated on Lys9 and Lys4 correlate with alternative states of inactive and active chromatin, respectively. Methylation of histone H3 on Lys9 on the maternal allele of the PWS-IC is therefore a candidate gametic imprint for this region. Replacement of histone by protamine during spermatogenesis would provide a convenient means of erasing a maternal histone-based imprint.

**Role of DNA methylation and histone acetylation in silencing of imprinted genes in Prader-Willi syndrome.** K. Takano, M. Takahashi, A. Sudo, T. Wada, S. Saitoh. Department of Pediatrics, Hokkaido University School of Medicine, Sapporo, Japan.

Prader-Willi syndrome (PWS) is associated with silencing of several imprinted genes located in 15q11-q13. These genes are epigenetically silenced through genomic imprinting. We have previously demonstrated that the CpG island of *SNURF-SNRPN*, which is a key imprinted locus in 15q11-q13, is not only heavily methylated but is also hypoacetylated on the inactive maternally derived allele. We have extended the investigation of histone acetylation status to other imprinted loci including 4 paternally-expressed genes (*MKRN3*, *MAGEL2*, *NDN*, and *IPW*), and 2 maternally-expressed genes (*UBE3A*, and *ATP10C*). Lymphoblastoid cells from PWS and Angelman syndrome (AS) patients, and controls were subjected to a chromatin immunoprecipitation (ChIP) assay using anti-acetylated histone H3 and H4 antibodies. Parent-of-origin specific histone acetylation was not demonstrated in these loci except for at *SNURF-SNRPN*, even at the CpG island of genes where parent-of-origin specific DNA methylation had previously been demonstrated (ie., *MKRN3*, *MAGEL2*, *NDN*). The *UBE3A* promoter is biparentally unmethylated and was associated on both allele with hypoacetylated histones. The CpG island of *ATP10C* was also associated on both allele with hypoacetylated histones. To further elucidate the role of DNA methylation and histone acetylation in silencing of the imprinted genes, we treated the cells with 5-azadeoxycytidine (5-aza-dC), an inhibitor of DNA methylation, trichostatin A (TSA) that is a specific inhibitor of histone deacetylase, and a combination of both drugs. 5-aza-dC treatment induced expression of *SNURF-SNRPN* and *IPW*, but TSA alone failed to reactivate either gene consistently. A combination of 5-aza-dC and TSA did not further increase the expression level of either gene compared with 5-aza-dC alone, although it increased the histone acetylation level at the CpG island of *SNURF-SNRPN*. These results indicate that DNA methylation may play a major role in maintaining silencing of the imprinted genes in 15q11-q13.

**Molecular analysis of the cluster of imprinted gene on 11p15 in a cohort of BWS patients.** *S. Russo<sup>1</sup>, M. Mencarelli<sup>1</sup>, D. Milani<sup>2</sup>, F. Cavalleri<sup>1</sup>, A. Selicorni<sup>2</sup>, L. Larizza<sup>1,3</sup>.* 1) Molecular Biology, Institute Auxologico Italiano, Milan, Italy; 2) Genetic Department, I.C.P. Hospital, Milan, Italy; 3) Biology and Genetics Dept, University of Milan, Italy.

The Beckwith-Wiedemann syndrome (BWS) is the most common overgrowth syndrome mainly characterized by anterior abdominal wall defects, macroglossia and gigantism and associated with an increased susceptibility (7.5%) to a variety of childhood tumors including Wilms tumors, adrenocortical carcinoma and hepatoblastoma. Cytogenetic and molecular anomalies involving the 11p15.5 region, containing at least eight imprinted genes, point to this region, as the mainly involved in the aetiology of BWS. We collected a cohort of 26 patients affected by BWS: 11 of them filled all the major and minor clinical criteria of the syndrome, 9 had an intermediate phenotype and 6 showed only isolated hemihypertrophy, which is considered a very mild form of this syndrome. Among the 11 classical BWS 2 familial cases were identified. karyotype was normal in all the patients. Paternal segmental uniparental disomy within the of 11p15.5 region, investigated in all the patients by segregation of microsatellite markers, was found in 3 patients affected by classical BWS, in 1 with an intermediate phenotype and 1 with isolated hemihypertrophy. Analysis of methylation pattern of the imprinted gene H19 was found in a complete BWS patient, while mutation screening of the p57 coding region, performed by direct sequencing, did not evidence any alteration. IGF2 methylation pattern is in progress in all the patients. Our data confirm the incidence of 11pat UPD in 20% of BWS and point to this mechanism as responsible also for an incomplete clinical picture. Mutations of p57 gene and alteration of the H19 imprinting may be involved only in severe BWS form.

**Identification of parent-of-origin-specific *in vivo* footprints in the Prader-Willi syndrome imprinting center. S.**

*Rodriguez-Jato*<sup>1</sup>, *D.J. Driscoll*<sup>2,3</sup>, *T.P. Yang*<sup>1,3</sup>. 1) Dept. Biochem. & Molec. Biol., Univ. Florida, College of Medicine, Gainesville, FL; 2) Dept. Pediatrics, Univ. Florida, College of Medicine, Gainesville, FL; 3) Center for Mammalian Genetics, Univ. Florida, College of Medicine, Gainesville, FL.

The Prader-Willi and Angelman Syndromes (PWS/AS) region is located on human chromosome 15 q11-q13 and includes a cluster of imprinted genes that are coordinately regulated. Microdeletions in patients with imprinting mutation have defined an imprinting center (IC) which appears to control resetting of imprinting in the germ line and postzygotic maintenance of imprinting throughout the region. The IC is located 5' to the *SNURF-SNRPN* gene and has a bipartite structure, one component being involved in PWS and the other in AS. We are interested in identifying *cis*-acting elements that may mediate the IC function. Therefore we have performed *in vivo* footprint analysis with dimethylsulfate (DMS) and DNase I on the promoter region of the *SNURF-SNRPN* gene on lymphoblasts derived from PWS and AS patients. This region is located within the PWS-IC and shows differential DNase I hypersensitivity, DNA methylation and histone acetylation between the paternally- and the maternally-inherited alleles. DMS *in vivo* footprinting has identified a series of sequence-specific DNA-protein interactions within 85 bp that flank the transcription initiation site. Most of these footprints are specific to the transcriptionally active paternally-inherited allele, however one footprint is specific to the maternally-inherited allele. DNase I *in vivo* footprinting has shown that part of *SNURF-SNRPN* exon 1 and adjacent intronic sequences are protected from enzymatic cleavage specifically on the paternally-inherited allele. Additionally we have identified two footprints specific on the maternally-inherited allele in and upstream of exon 1. One or more of these parent-of-origin-specific *in vivo* footprints are likely to reflect the location *cis*-acting regulatory elements that play a role on transcriptional activation and/or repression of the *SNURF-SNRPN* gene. In addition, they may also act as *cis*-acting elements associated with IC function.

**Duplication of the early developmental regulator 3 locus, EDR3, in Cornelia de Lange syndrome. A.M.**

*Deshpande<sup>1</sup>, M.J. Nellissery<sup>1</sup>, X. Reveles<sup>2</sup>, S.L. Naylor<sup>2</sup>, L.G. Jackson<sup>3</sup>, I.D. Krantz<sup>4</sup>, R.M. Greenstein<sup>5</sup>, R.J. We have identified EDR3, a novel gene encoding member of the polycomb group (PcG) gene family. EDR3 maps to chromosome 3q26.2-q26.3, a region implicated in the pathogenesis of Cornelia de Lange syndrome (CDLS). This syndrome is typified by a characteristic facies with microbrachycephaly, synophrys, micrognathia and prominent philtrum as well as other abnormalities such as pre- and postnatal growth delay, mental retardation, hirsutism, delayed skeletal maturation and upper limb abnormalities. FISH and Southern analyses reveal that EDR3 is consistently duplicated in cell lines derived from CDLS patients, even in the absence of gross cytogenetic abnormalities. Analyses indicate that EDR3 is expressed during development in the craniofacial region, limbs, brain, heart and, liver. The gene has an ORF of 2895 bp and is organized into 16 exons. The EDR3 protein is similar to other members of the PcG family including human EDR1 and EDR2. Members of the PcG family regulate gene expression through protein-protein and protein-DNA interactions and play an important role in axial patterning of organisms through regulation of expression of homeotic genes. PcG protein function exhibits marked dosage sensitivity and alterations in gene copy number result in anterior or posterior transformations and developmental dysmorphogenesis. Based on the observed localization of the EDR3 gene, its consistent duplication in CDLS patients, and its expression pattern and potential role in development of tissues affected in CDLS, we propose that overexpression of EDR3 caused by increased gene copy number is responsible, at least in part, for the phenotype associated with CDLS.

**Transmission Disequilibrium Mapping in the Serotonin Transporter Gene (*SLC6A4*) Region in Autistic Disorder.**

*Leventhal*<sup>1,5</sup>, *E. Courchesne*<sup>3,6</sup>. 1) Laboratory of Developmental Neuroscience, Department of Psychiatry, University of Chicago, Chicago, IL; 2) Department of Human Genetics, University of Chicago, Chicago, IL; 3) Laboratory for Research on the Neuroscience of Autism, Children's Hospital Research Center, La Jolla, CA; 4) Developmental Disorders Clinic, Child and Adolescent Psychiatry, Department of Psychiatry, University of Chicago, Chicago, IL; 5) Department of Pediatrics, University of Chicago, Chicago, IL; 6) Department of Neurosciences, School of Medicine, University of California, San Diego, La Jolla, CA; 7) Department of Psychiatry, School of Medicine, University of California, San Diego, La Jolla, CA.

The serotonin transporter gene (*SLC6A4*) is a candidate gene in autistic disorder based on neurochemical and neuroendocrine studies and the efficacy of potent serotonin transporter inhibitors in reducing rituals and aggression. Two polymorphisms, 5-HTTLPR in the promoter region and a variable number of tandem repeat polymorphism (VNTR) in the second intron, were previously identified and suggested to modulate transcription. In the present study, we further investigated *SLC6A4* and its flanking regions by typing 20 single nucleotide polymorphisms (SNPs) and 7 simple sequence repeat (SSR) polymorphisms in 117 autism trios. When individual markers were analyzed by TDT, 7 SNP markers and 5 SSR markers from either *SLC6A4* or the bleomycin hydrolase gene (*BLMH*) showed nominally significant evidence of transmission disequilibrium. Four markers showed stronger evidence of transmission disequilibrium (TDTmax  $p=0.0005$ ) than 5-HTTLPR. Strong linkage disequilibrium (LD) among markers was found across the region. Thus, support is provided for the hypothesis that either *SLC6A4* itself is a susceptibility gene in autism, or is in linkage disequilibrium with another susceptibility locus (e.g. *BLMH*). Moreover, the specific variant(s) contributing to susceptibility in this region have yet to be elucidated and the strong LD over a large physical region may limit the resolution of fine mapping of loci for autism or other disorders within this gene and surrounding region.

**Dense mapping within the MHC suggests a complex pattern of haplotype associations with rheumatoid arthritis.**

*D. Jawaheer<sup>1</sup>, R. Graham<sup>2</sup>, W. Chen<sup>3</sup>, A. Damle<sup>1</sup>, N. Kohn<sup>1</sup>, T. Behrens<sup>2</sup>, J. Monteiro<sup>1</sup>, A. Begovich<sup>4</sup>, M.F. Seldin<sup>5</sup>, L. Criswell<sup>6</sup>, J.T. Elder<sup>7</sup>, K. Pillaipakkamnatt<sup>8</sup>, C. Amos<sup>3</sup>, P.K. Gregersen<sup>1</sup>.* 1) Div. Biology & Human Genetics, North Shore Univ Hosp, Manhasset, NY; 2) Ctr. for Immunology, Univ. of Minnesota, Minneapolis, MN; 3) Depts. of Epidemiology & Biomathematics, MDACC, Univ. of Texas, Houston, TX; 4) Roche Molecular Systems, Alameda, CA; 5) Biological Chemistry, UC Davis, Davis, CA; 6) Dept. of Medicine, UCSF, San Francisco, CA; 7) Univ. of Michigan, Ann Arbor, MI; 8) Dept. of Computer Science, Hofstra University, Hempstead, NY.

An initial analysis of 51 microsatellite markers across the HLA region in 257 multiplex families with rheumatoid arthritis (RA) was carried out to identify genetic factors preferentially transmitted with RA, using the single marker pedigree disequilibrium test (PDT). HLA-DRB1\*04 and flanking markers yielded highly significant transmission disequilibrium ( $p < 0.0005$ ) with RA. Several markers telomeric to HLA-DRB1 also displayed highly significant transmission disequilibrium with RA. The most striking of these associations was at the class III/class I border, 150 kb centromeric of HLA-B ( $p < 0.001$ ). A case control analysis of 257 RA probands and 383 controls confirmed these associations. Stratification using HLA-DRB1\*04 and/or markers in close linkage disequilibrium with DRB1\*04 suggests that a subset of these associations are due to effects independent of DRB1\*04. Some of these observations may reflect linkage disequilibrium with DRB1\*01, and others appear to reflect genes present on the common ancestral 8.1 haplotype (A1-B8-DR3). We have further developed an association mining program, based on the Apriori algorithm, to search for HLA marker combinations specifically enriched among RA patients. Overall, the data suggest a complex pattern of associations with particular HLA haplotypes, many but not all of which contain HLA-DRB1 alleles previously associated with RA. In addition, the data suggest the presence of susceptibility genes within the HLA region, outside of the HLA-DRB1 locus. Additional detailed case-control haplotype analysis will be required to fully elucidate these genetic associations.

**Family based association study (qTDT) on lipid abnormality-candidate genes on an isolated, admixed population.** Z. Han<sup>1</sup>, W. Li<sup>1</sup>, D. Shmulewitz<sup>1</sup>, S. Heath<sup>2</sup>, S. Auerbach<sup>3</sup>, M. Blundell<sup>1</sup>, T. Lehner<sup>1</sup>, J. Ott<sup>1</sup>, M. Stoffel<sup>1</sup>, J.M. Friedman<sup>1</sup>, J.L. Breslow<sup>1</sup>. 1) Starr Ctr Human Genetics, Rockefeller Univ, New York, NY; 2) Lab Mathematical Genetics, MSKCC, New York, NY; 3) HRSA, Department of Health & Human Services, New York, NY.

Traditional linkage analyses lack power and precision when applied to complex traits such as cholesterol (chol) level. Association may be more successful at identifying genes of small effect, but are often controversial due to problems such as population stratification (PS). Using quantitative TDT analysis, we examined 8 polymorphic sites, previously shown to be associated with abnormal lipid and lipoprotein levels, on the Kosrae Island where the population is an admixture of native Kosraeans and Caucasian from late 19th century. The 1102 individuals collected in this study were split into 223 nuclear families with total 1527 sibships. The traits studied included triglyceride (Tg), chol, apolipoprotein-AI (apoAI), apolipoprotein-AII (apoAII), apolipoprotein-B (apoB), body mass index (BMI) and blood pressure (BP) levels. The 8 markers were common polymorphisms in following candidate genes: apo AI-CIII-AIV gene cluster (apo CIII/SstI), apo AII (MspI), apo E (HhaI), cholesteryl ester transfer protein (CETP/TaqIB), cholesterol 7 $\alpha$ -hydroxylase (CYP7/BsaI), hepatic lipase (HL/DraI) and microsomal triglyceride transfer protein (MTP/HhpI). The method we used was QTDT program by Abecasis GR et al. When analyzed under a variance component model, the apoCIII/SstI was associated with Tg ( $p=0.0031$ ), and apoE/HhaI was associated with apoB level ( $p=0.0004$ , 0.0070 and 0.0285 for allele E4, E3 and E2). There was suggestive evidence for linkage of apoAII/MspI to systolic BP ( $p=0.0497$ ), and the linkage evidence was accounted for by adding association to the model. Our study has the advantages of reducing the likelihood of false-positive result from PS and increasing the chance of discovering relevant genetic factors due to a more homogenous environmental effect.

**A thorough linkage disequilibrium (LD) analysis in the human angiotensinogen gene (*AGT*).** *T. Nakajima*<sup>1</sup>, *T. Ishigami*<sup>2</sup>, *S. Umemura*<sup>3</sup>, *M. Emi*<sup>4</sup>, *J-M. Lalouel*<sup>2</sup>, *I. Inoue*<sup>1</sup>. 1) Division of Genetic Diagnosis, The Institute of Medical Science, The University of Tokyo, Tokyo, Japan; 2) Department of Human Genetics, University of Utah Health Sciences Center, Salt Lake City, UT; 3) Internal Medicine, Yokohama City University, Yokohama, Japan; 4) Department of Molecular Biology, Institute of Gerontology, Nippon Medical School, Kawasaki, Japan.

LD mapping for common diseases explicitly depend on the persistence of LD. To understand the organization of LD in the human gene promises to have great impact on the strategies for identifying candidate genes. *AGT* constitutes the locus that consistently has been associated with essential hypertension (EHT). Variants associated with EHT, T235 and A(-6), vary in frequency among major ethnic groups. Sequencing of angiotensinogen gene in nonhuman primates shows that the T235 and A(-6) variants are fixed in them. The protective M235 and G(-6) variants for EHT, that were in tight LD, are likely to have arisen during the course of human evolution. Haplotypes based on 21 SNPs in *AGT* showed that Caucasian and Japanese shared top four frequent haplotypes, even though the frequencies of them were quite different. In Caucasians G(-6)/M235 haplotype, protective haplotype for EHT, was very common ( $p=0.54$ ). Natural selection might result in the increased frequency of G(-6)/M235 haplotype in Caucasian. We also compared LD parameters  $D'$ ,  $r^2$ , and  $d^2$  based on the data from 861 possible marker pairs in *AGT*. An LD measure  $d^2$  is an appropriate choice for association studies. When compared between  $D'$  and  $d^2$ , the value of  $d^2$  varied widely in the marker pairs with  $D'=1$  or  $-1$ . In cases with  $D'=1$  or  $-1$ , the mean value of  $d^2$  is 0.21 and the proportion of marker pairs with  $d^2<0.1$  (insufficient LD for association studies) is 0.44. These results showed that about half of cases with complete LD in the value  $D'$  display insufficient LD ( $d^2<0.1$ ) for association studies. Another common measure  $r^2$  is compared with  $d^2$ .  $r^2$  and  $d^2$  were significantly correlated. In conclusion, an LD measure,  $r^2$ , is the better parameter than  $D'$  in considering strategies for identifying genes for common disease.

**Linkage disequilibrium mapping and haplotype analysis in the 15q11-q13 autism candidate region reveals suggestive association at *ATP10C* and *OCA2* in the CLSA families.** *E.L. Nurmi, T. Amin, Y. Bradford, M.M. Jacobs, J.L. Haines, J.S. Sutcliffe and the Collaborative Linkage Study of Autism.* Program in Human Genetics, Department of Molecular Physiology & Biophysics, Vanderbilt University, Nashville, TN.

Autism is a neurodevelopmental disorder with a complex genetic etiology. Observations of maternal duplications affecting chromosome 15q11-q13 in patients with autism and evidence for linkage and linkage disequilibrium to regional markers in chromosomally normal autism families suggest the existence of a susceptibility locus. We have screened the Collaborative Linkage Study of Autism families for a number of single nucleotide polymorphisms within a candidate region covering ~2 Mb and including the Angelman syndrome gene (*UBE3A*), another maternally-expressed gene *ATP10C*, a cluster of GABA<sub>A</sub> receptor subunit genes (*GABRB3*, *GABRA5* and *GABRG3*) and *OCA2*. Transmission disequilibrium test and haplotype analysis methods were applied to the study of these variants. We found suggestive evidence for association of individual polymorphisms and haplotypes at *ATP10C* and *OCA2*. We also detected highly significant increases in allele frequency at the *OCA2* locus in our autism families compared to a control group. *ATP10C*, encoding an aminophospholipid-transporting ATPase, has recently been shown to be imprinted with maternal-specific expression in human brain, thus making it an excellent candidate given the maternal-specificity of chromosomal duplications in association with autistic phenotypes. The *OCA2*, or *P*, gene encodes a putative tyrosine transporter, defects of which affect melanosomal production of melanin and result in hypopigmentation. *OCA2* is also expressed in the brain, where its role is less clear. Ongoing studies will seek to analyze additional polymorphisms and expand haplotype studies in a larger number of families.

**Is the BDNF gene associated with Bipolar Disorder?** *M. Neves-Pereira<sup>1</sup>, E. Mundo<sup>1,2</sup>, P. Muglia<sup>1</sup>, J.L. Kennedy<sup>1,2</sup>, F. Macciardi<sup>1,2</sup>.* 1) Neurogenetics Section, Clarke Division, CAMH, Toronto, ON., Canada; 2) Department of Psychiatry, University of Toronto, Toronto, ON, Canada.

Bipolar Disorder (BP) is a severe psychiatric disease that affects 1% of the population worldwide and it is characterized by recurrent episodes of mania and depression. BP has a strong genetic component with a complex mode of inheritance and heterogeneous clinical presentation. Brain Derived Neurotrophic Factor (BDNF) has been implicated in the pathogenesis of mood disorders. BDNF is reduced in depression and increases with antidepressant treatment. The aim of this study was to test for the presence of linkage disequilibrium between a dinucleotide (CA) polymorphism in the BDNF gene and BP. The CA repeat has 3 common alleles, and is located 1040bp upstream of the starting codon. Two hundred and eighty three triads in which bipolar probands were diagnosed with a semi-structured interview for DSM-IV Axis I diagnoses (SCID) were genotyped. Data was analysed with the Transmission Disequilibrium Test (TDT). Allele 3 was preferentially transmitted to the affected offspring (chi-square=5.765, p=0.02) suggesting that BDNF may confer susceptibility to BP. Future studies involving alternative phenotypes related to BP and other polymorphisms will be conducted to further assess the involvement of BDNF in BP.

**N-Methyl-D-Aspartate Receptor (GRIN1, GRIN2B) in schizophrenia: TDT and case-controls analyses. L.**

*martucci*<sup>1</sup>, *A. Wong*<sup>1</sup>, *J. Trakalo*<sup>1</sup>, *T. Cate*<sup>1</sup>, *F. Ajmar*<sup>2</sup>, *E. De Maria*<sup>2</sup>, *P. Mandich*<sup>2</sup>, *J.L. Kennedy*<sup>1</sup>, *F. Macchiardi*<sup>1</sup>. 1) Neurogenetics, Clarke Division, CAMH, Toronto, Ontario, Canada; 2) Department of Oncology, Biology and Genetics, University of Genova.

The N-Methyl-D-Aspartate Glutamate receptors (NMDAR) act in the CNS as regulators of the release of neurotransmitters such as dopamine, noradrenaline, acetylcholine and GABA. It has been suggested that a weakened glutamatergic tone increases the risk of sensory overload and of exaggerated responses in the monoaminergic system, which is consistent with the symptomatology of schizophrenia. We have focused on the study of two polymorphisms in GRIN1 and on one polymorphism in GRIN2B. NMDAR1/1 is a G/C substitution localized on the 5' untranslated region; NMDAR1/10 is an A/G substitution localized in exon 6 of GRIN1. There is a T/G substitution in the 3'UTR of GRIN2B. Minor allele frequencies in our sample were calculated to be 0.05, 0.2 and 0.4 respectively. We genotyped 41 nuclear families and 92 ethnically matched case-control pairs. Both samples were collected from the Toronto area. We tested the hypothesis that GRIN1 and GRIN2B polymorphisms were associated with schizophrenia using the Transmission Disequilibrium Test and comparing allele frequencies between cases and controls. The results are as follows: NMDAR1/1,  $c^2 = 0.333$ ,  $p = 0.57$ ; NMDAR1/10,  $c^2 = 0.429$ ,  $p = 0.51$ ; GRIN2B,  $c^2 = 1.19$ ,  $p = 0.2753$ . For the case-control sample: NMDAR1/1:  $c^2 = 0.013$ ,  $p = 0.908$ ; NMDAR1/10:  $c^2 = 0.544$ ,  $p = 0.461$ ; and GRIN2B:  $c^2 = 2.795$ ,  $p = 0.095$ . Although a slight trend was observed for the GRIN2B marker in the case-controls, no significant results were obtained. We are currently collecting additional samples to increase the power of the analyses.

**Haplotypic analysis of COMT polymorphisms and schizophrenia in two Chinese samples.** *V.C. Kodavali<sup>1</sup>, K. Xu<sup>3</sup>, M. Haraczak<sup>1</sup>, M. Cui<sup>3</sup>, T. Li<sup>3</sup>, B.Y. Xie<sup>3</sup>, W. Joel<sup>1</sup>, W.F. Tsoi<sup>4</sup>, N. Saha<sup>4</sup>, V.L. Nimgaonkar<sup>1,2</sup>.* 1) Departments of Psychiatry, University of Pittsburgh, Western Psychiatric Institute and Clinic, 3811 OHara Street, Pittsburgh, PA 15213, USA; 2) Departments of Human Genetics, University of Pittsburgh, Western Psychiatric Institute and Clinic, 3811 OHara Street, Pittsburgh, PA 15213, USA; 3) Guangzhou Psychiatric Hospital, Guangzhou, China; 4) Department of Psychiatry and Pediatrics, National University of Singapore, Singapore.

Catechol-O-methyl transferase (COMT) metabolizes catecholamines such as dopamine, adrenaline and nor-adrenaline. It exists in common high and low activity forms. The low activity form is the result of an amino acid substitution (val-108-met) which reduces the thermostability of the enzyme. Li et al (1996, 2000) reported that the high activity COMT allele, as well as related haplotypes are transmitted more often to patients with schizophrenia among Han Chinese case-control and case-parent samples. To replicate these findings, we have studied three COMT polymorphisms in Chinese cases from Singapore (n = 85), Guangzhou (n = 93) and adult controls (n = 85 and 91 respectively). The polymorphisms investigated were (186 C/T, exon 3), (408 C/G, exon 4) and 472 G/A (Val158Met). We did not find any significant allele or genotype-wise differences in either sample. We also used SNPDM software (Fallin and Schork, 2001) based on the EM algorithm to estimate and compare haplotype frequencies. Significant case-control differences were detected for one of four common haplotypes (186C, 408C, 472G) in the Singapore sample (overall differences in haplotype frequencies chi square = 15.8, p = 0.043). The implications of these findings will be discussed.

**Family-based association studies of schizophrenia in two independent samples with candidate genes DRD3 and NOTCH4.** *V.L. Nimgaonkar<sup>1,2,3</sup>, V.C. Kodavali<sup>1</sup>, S. Prasad<sup>4</sup>, A. Butler<sup>1</sup>, D.E. Downard<sup>1</sup>, F. Zhang<sup>1</sup>, S.N. Deshpande<sup>5</sup>, T. Bhatia<sup>5</sup>, J. Wood<sup>1</sup>, B.K. Thelma<sup>3,4</sup>.* 1) Department of Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh; 2) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh; 3) Indo-US Collaborative Study of Schizophrenia Genetics, New Delhi; 4) Department of Genetics, Delhi University, South Campus, New Delhi; 5) Department of Psychiatry, Dr Ram Manohar Lohia Hospital, New Delhi.

This study focuses on two putative genetic associations with schizophrenia. An association between the Ser9Gly polymorphism of the dopamine D3 receptor gene (DRD3) and schizophrenia have been reported by several research groups. It is not known whether the Ser9Gly polymorphism alone or a variation in linkage disequilibrium affects susceptibility to schizophrenia. Recently, Wei and Hemmings (2001), reported association of two polymorphisms at Notch4 with schizophrenia. To investigate these findings, we have genotyped four polymorphisms at DRD3 (DRD3,4: a di-nucleotide repeat, -712G/C, -205A/G and S9G) and five polymorphisms in Notch4 (AAGG, TAA, SNP1, SNP2 and CTG) in two independent case-parent samples from India (179) and US (235). The US sample also included a group of unscreened population based controls (n = 93). None of these polymorphisms showed any significant excess transmission of either allele in either population using TDT analysis. We analyzed transmission of haplotypes to cases. The haplotype 712G, -205A and Ser9 at DRD3 showed excess transmission in the US sample but not in the Indian sample ( $p = 0.006$ ). Our results suggest an association at DRD3, which varies by ethnicity.

**Use of DNA pools to assess allele frequencies of single nucleotide polymorphism (SNPs) at a type 2 diabetes mellitus (T2DM) susceptibility locus.** *M.A. Permutt, J.C. Wasson, S. Donelan, G. Skolnick, J. Lin, B.K. Suarez.*  
Washington University School of Medicine, St. Louis, MO.

Nominal evidence for linkage (Z score of 2.05,  $P < 0.05$ ) was observed on chromosome 20q12-13.1 in Ashkenazi Jewish multiplex families with T2DM. Combined analysis by the International T2DM Linkage Consortium has identified a peak at D20S107. To identify the gene(s) contributing to susceptibility in this region, linkage disequilibrium mapping is being employed. We determined that the most efficient, cost-effective method of genotyping SNPs was by the use of DNA pools with the PSQ96 Pyrosequencer and Allele Quantitation software. Accuracy of allele frequency estimation was assessed by mixing two different homozygous DNAs in various proportions at 5% increments. The observed vs. actual allele frequencies had a correlation coefficient of 0.9963. Pools of DNA from each of 150 diabetics and 150 non-diabetics were precisely assembled. With these pool sizes, differences between the groups of  $>7\%$  would be significant at the  $p < 0.05$  level, and could then be replicated with additional pools. To assess the actual genotype frequencies compared to those observed in the pools, each individual DNA was genotyped and the combined frequencies compared with those of the DNA pools. Four SNPs were tested for both cases and controls and the differences ranged from 0 to 1.7%. We are examining SNPs in one lod intervals around D20S107 containing 7.4Mb of DNA with 30 known or predicted genes ([www.ncbi.com](http://www.ncbi.com)). SNPs were selected from the SNP Consortium Database ([snp.cshl.org/](http://snp.cshl.org/)), although none of these SNPs had been previously validated. Examination of 11 of 15 of these SNPs revealed minor allele frequencies  $>20\%$ . Comparing allele frequencies between cases and controls, the greatest difference noted has been 7% ( $p=0.055$ ). We conclude that with this method we can rapidly and accurately determine differences in allele frequencies between cases and controls for a large number of SNPs across this chromosomal region.

**Family based and case-control associations serotonergic polymorphisms in Bipolar I Disorder.** *S. Ranade<sup>1</sup>, L.K. Brar<sup>1</sup>, V.C. Kodavali<sup>1</sup>, J. Wood<sup>1</sup>, H. Mansour<sup>1</sup>, B. Devlin<sup>1,2</sup>, D.J. Kupfer<sup>1</sup>, V.L. Nimgaonkar<sup>1,2</sup>.* 1) Department of Psychiatry, University of Pittsburgh School of Medicine, Western Psychiatric Institute and Clinic, Pittsburgh, Pennsylvania, USA; 2) Department of Human Genetics, University of Pittsburgh School of Medicine, Western Psychiatric Institute and Clinic, Pittsburgh, Pennsylvania, USA.

**Introduction:** The genetic factors contributing susceptibility to Bipolar Disorder I (BD I) are unknown. The mode of inheritance of BD I is complex and individual genetic susceptibility factors may contribute only a fraction of the liability. Therefore, we are presently conducting association studies using candidate gene polymorphisms. Since association studies are critically dependent on the choice of controls, we have employed unrelated as well as family based controls. **Methods:** We report on 80 nuclear families having a proband with BD I (DSM IV criteria), as well as available parents. Cord blood samples from local live births served as unrelated, unselected controls (n = 90). To enable haplotype-based analyses, five polymorphisms were analyzed at the serotonin 2A receptor (5-HT<sub>2A</sub>) and two polymorphisms for serotonin transporter (SLC6A4) loci. The HT<sub>2A</sub> markers included single nucleotide polymorphisms (Pro2, Thr25Asn, T102C, C516T and His452Tyr) while the SLC6A4 markers included an insertion/deletion polymorphism in the promoter sequence and variable number or tandem repeat polymorphism (VNTR) in the second intron. Associations with both genes have been suggested previously. **Results:** Significant transmission distortion was detected with the His452Tyr polymorphism (Transmission Disequilibrium Test,  $p < 0.005$ , 1 df). Haplotypes using the TC102, CT516 and Thr25Asn polymorphisms also displayed transmission distortion, but no case-control differences in genotype counts or allele frequencies were noted when the unrelated controls were analyzed. Our results support a plausible association of BD I with 5-HT<sub>2A</sub>. Analyses employing larger samples are warranted.

**Two-locus model of inheritance of multiple sclerosis in a large North American pedigree.** *E. Vitale<sup>1,6</sup>, S. Cook<sup>2</sup>, R. Sun<sup>1</sup>, C. Specchia<sup>3</sup>, K. Subramanian<sup>1</sup>, M. Rocchi<sup>4</sup>, D. Nathanson<sup>5</sup>, M. Schwalb<sup>1</sup>, M. Devoto<sup>3</sup>, C. Multiple sclerosis (MS) is a chronic inflammatory demyelinating disease of the central nervous system (CNS) with a probable immune-mediated pathogenesis. Strong evidence supports the hypothesis that MS is determined by genetic and environmental factors, but these factors remain largely undefined. Several studies have shown association of MS with the HLA class II region, specifically DR15, DQ6. However, there is no convincing evidence of a common susceptibility locus. We have identified a pedigree of Pennsylvania Dutch extraction, in which MS segregates with an autosomal dominant inheritance pattern. We have collected blood samples from 18 family members, seven of whom show typical signs of MS lesions by MRI. The 18 individuals were serotyped for HLA class I and II and analyzed by a genome wide screen for linkage analysis. We have found evidence for suggestive linkage to markers on 12p12 with a maximum multipoint lod-score of 2.71 conditional on the presence of DR15, DQ6. The significance of the association of MS with both the HLA-DR15 allele and the chromosome 12p12 haplotype was further tested by contingency table analysis. This results in a chi-square of 16 and a p-value of 0.00011 from Monte Carlo simulation analysis. A potentially interesting gene in the critical region is GD3 synthase which is part of the sialyltransferase family characterized by having the sialyl motif and a key regulatory domain that controls the ganglioside biosynthesis pathway. In search for a mutation we sequenced the 4 exons and part of the intronic sequences characterizing GD3 gene, and we found a SNP at position +30 of a splice donor site of intron 3 in our patients. We are in the process of assaying this change.

**Genetic Analysis of the CTLA-4/CD28 Gene Region in Type I Diabetes.** *M. Barreto<sup>1</sup>, A. Vicente<sup>1</sup>, T. Vassilevskaya<sup>1,2</sup>, N. Duarte<sup>1</sup>, L. Gardete-Correia<sup>2</sup>, J. Boavida<sup>2</sup>, R. Duarte<sup>2</sup>, F. Raposo<sup>2</sup>, J. Mendes<sup>2</sup>, C. Penha-Gonçalves<sup>1</sup>, D. Holmberg<sup>1</sup>.* 1) Instituto Gulbenkian Ciência, Oeiras, Portugal; 2) Associação Protectora dos Diabéticos de Portugal.

Insulin Dependent Diabetes Mellitus (IDDM) is a polygenic disease, characterized by the autoimmune destruction of the insulin-producing  $\beta$  cells within the pancreatic islets. The objective of this study is the identification and characterization of genes involved in the etiology of IDDM, focusing on the IDDM12 susceptibility region on 2q33-34. Although linkage and/or association of IDDM to this locus has been reported, the gene(s) involved have not yet been identified. Two strong candidate genes map to this area, CD28 and CTLA-4, which are part of the co-stimulatory system involved in the activation of T cells. It is widely accepted that dysregulation of co-stimulation contributes to the initiation and maintenance of autoimmunity due to activation of self-reactive T cells. To further define the IDDM12 susceptibility region, we performed a genetic screening using 11 polymorphic markers in the 2q33-34 chromosomal region, in a Portuguese population sample of 120 patients and 150 matched controls. We have confirmed a significant association of the disease with markers within the CTLA-4 gene (a SNP involving an A to G transition in the promoter ( $p = 0.021$ ) and a microsatellite marker in the 3' UTR ( $p < 0.001$ )). We also noticed that the longer alleles at the dinucleotide repeat located in the 3' UTR are associated with increasing risk for IDDM. None of the other 7 markers tested, spanning the region around and between CTLA-4 and CD28, showed any association.

**Evidence for association of the BCL3 gene in 98 Brazilian nonsyndromic clefting patients using the transmission disequilibrium test (TDT).** D.A. Gaspar<sup>1,2</sup>, R.C. Pavanello<sup>1,2</sup>, B.C. Araujo<sup>3</sup>, M. Andre<sup>4</sup>, S. Steman<sup>5</sup>, S.R. Matioli<sup>2</sup>, M.R. Passos-Bueno<sup>1,2</sup>. 1) Centro de Estudos do Genoma Humano; 2) Depto de Biologia, IBUSP; 3) HMJ; 4) FOU SP; 5) FMUSP, Sao Paulo, Brasil.

Nonsyndromic cleft lip with or without cleft palate (NSCL/P) is a common malformation with an incidence of at least 1 in 1000 caucasian live births. The inheritance of CL/P is complex and approximately 20 genes interacting multiplicatively along with environmental factors have been considered as responsible for this phenotype. Stein *et al.* . 1995 (Am J Hum Genet 57:257-272), using linkage analysis in multiplex families, first presented evidence that the BCL3 gene or a nearby locus at 19q13.2 might be involved with NSCL/P. Some other studies based on association analysis between 19q13.2 markers and NSCL/P also supported this idea. In this study, we analysed two markers from 19q13.2 region (D19S178 and an intragenic marker in BCL3) in 98 families with at least one NSCL/P patient (45 familial cases and 53 isolated families). Smoking habits were assessed in 72 mothers of NSCL/P patients (23 smokers; 49 nonsmokers). The TDT test showed a significant excess transmission of the 131bp allele (54 alleles transmitted vs. 35 nontransmitted; P=0.04) at the BCL3 locus while the 167 bp allele of D19S178 (5 alleles transmitted vs. 15 nontransmitted; P=0.025) was under-represented in NSCL/P patients. A specially developed TDT test based on random permutations considering the two loci simultaneously was applied to these data and we observed that one haplotype (BCL3/D19S178: 131bp/169bp) was more frequently transmitted to NSCL/P patients (15 haplotypes transmitted vs. 6 nontransmitted; P=0.052), suggesting a marginal association between BCL3 gene and NSCL/P in our sample. A preliminary analysis did not suggest an interaction of smoking and the BCL3 locus in the predisposition of clefting in our families. Our analysis, if taken together with other studies, further supports that the BCL3 gene or a nearby locus might play a role in the predisposition of NSCL/P, but probably in a small proportion of cases. **The role of human circadian clock genes in bipolar disorder.** *C.M. Nievergelt, D.F. Kripke, J.R. Kelsoe.* Dept Psychiatry, 0603, Univ California, San Diego, La Jolla, CA.

Bipolar disorder is a complex genetic human disease with strong evidence for heritability and has been a major focus of linkage studies in psychiatry. Linkage reports have implicated fairly broad genomic regions, thus making gene identification a challenging project. An alternative to whole-genome surveys is the analysis of specific candidate genes. Bipolar disease is suspected to be associated with malfunctions of the circadian system, which regulates individual circadian rhythms and enables the adaptation to a daily 24-hour cycle and seasonal changes. Several human clock genes have been identified and localized and a comparison with linkage hotspots for bipolar disorder has revealed close correspondences.

One of the most promising candidates, human cryptochrome 1 (hCRY1; located on 12q23 q24.1) was analyzed here. Linkage of bipolar disorder to 12q has been reported by several groups. Using two hCRY1 flanking microsatellite markers, linkage analysis revealed slightly positive LOD scores under a dominant transmission model with medium penetrance in 23 out of 52 genotyped bipolar families. Affected subjects from these families and controls (n=28) were screened for mutations by sequencing 13 kb (13%) of the genomic sequence. We identified a total of 16 single nucleotide polymorphisms (SNPs) and a 3bp insertion in the promoter region (2 SNPs), the 5' and 3' untranslated regions (4 and 2 SNPs, respectively), and the 12 exons and their flanking regions (1 and 8, respectively). However, no mutations with functional impact in exonic regions were found. SNP frequencies ranged between 0.02 and 0.37. These SNPs will be useful for linkage disequilibrium studies of this gene in bipolar disorder. Such studies are now underway in a set of 150 parent proband triads.

We are also now employing a similar strategy for several other human clock genes that map to regions reportedly linked to bipolar disorder.

**Possible relationship between the van der Woude syndrome (vWS) locus and nonsyndromic cleft lip with or without cleft palate.** *C. Houdayer<sup>1</sup>, C. Bonaiti Pellié<sup>2</sup>, C. Erguy<sup>1</sup>, V. Soupre<sup>3</sup>, L. Bürglen<sup>4</sup>, R. Couderc<sup>1</sup>, MP.*

*Vazquez<sup>3</sup>, M. Bahuau<sup>1,3</sup>.* 1) Biochimie Biol Moleculaire, Hosp Trousseau, Paris, France; 2) INSERM U521, IGR, Villejuif, France; 3) Chirurgie Maxillo Faciale et Plastique, Hosp Trousseau, Paris, France; 4) Génétique Médicale, Hosp Trousseau, Paris, France.

Cleft lip with or without cleft palate (CL/P) is one of the commonest congenital malformation conditions in humans which may be part of a defined syndrome, sequence or association, although most individual or familial cases present as an isolated (nonsyndromic) malformation defect (NSCL/P). Inheritance is generally regarded as multigenic although, in some families, NSCL/P seemingly segregates as a monogenic trait. On the other hand, van der Woude syndrome (vWS) is a rare autosomal dominant with cardinal features of lower-lip pits (LLP) and CL/P or cleft palate (alone). Since none of these traits is present in all mutation carriers, some individual or familial vWS cases, especially those lacking LLP, are indiscernible from NSCL/P, raising the question whether allelic variation at the vWS locus could underlie NSCL/P. This question was addressed using parametric linkage (LOD score) analysis in 21 multiplex NSCL/P families based on a tightly linked microsatellite marker (D1S3753), and nonparametric analysis using the transmission/disequilibrium test (GTDT) in 106 NSCL/P triads and selecting markers D1S205, D1S491, and D1S3753. No evidence for linkage of NSCL/P to vWS was found on the 21 families using the LOD score approach. In contrast, TDT yielded a significant P value of 0.04 for D1S205, supporting involvement of vWS in NSCL/P in a complex, modifying/polygenic manner rather than as a monogenic/major disease locus.

**Cloning and Expression Analysis of a Novel Candidate Gene for Bipolar Disorder and Schizophrenia on Human**

**Chromosome 18p11.2.** *L.D. McNabb<sup>1</sup>, J.C. Friedland<sup>1</sup>, T.A. Gieringer<sup>2</sup>, K. Rojas<sup>3</sup>, J. Overhauser<sup>3</sup>, G. Smith<sup>4</sup>, G. Golden<sup>4</sup>, S. Arnold<sup>2</sup>, T.N. Ferraro<sup>1,2</sup>, W.H. Berrettini<sup>1,2</sup>, R.J. Buono<sup>2</sup>.* 1) Department of Pharmacology, University of Pennsylvania, Philadelphia, PA; 2) Department of Psychiatry, University of Pennsylvania, Philadelphia, PA; 3) Department of Biochemistry and Molecular Pharmacology, Thomas Jefferson University, Philadelphia, PA; 4) VAMC, Coatesville, PA.

A locus on human chromosome 18p11.2 has been identified through linkage and association studies as containing a possible candidate gene for bipolar disorder and/or schizophrenia. cDNA selection and direct sequencing have identified several novel DNA sequences that are likely to be expressed. One sequence in particular, 1B10, is in close proximity to a microsatellite marker (D18S53) that has been linked with schizo-affective illness. A 3.9 kilobase cDNA clone was identified using PCR analysis with primers specific to 1B10. This clone, named 22444, was expressed only in brain tissue, and contained the entire 1B10 sequence, as well as D18S53 in the 3 prime untranslated region. Rabbit polyclonal antibodies generated against the predicted amino acid sequence of clone 22444 were used in western blots to identify a protein from human tissues. The predicted amino acid sequence of 22444 leads to the formation of a 14 kilodalton protein; however, polyclonal serum #1363 recognizes a specific 20 kilodalton protein in human brain tissue. This protein is not detected by western blot analysis in peripheral tissues, which is in agreement with the PCR findings. We are currently using this polyclonal antibody to isolate the 30 kilodalton protein for sequencing in order to provide evidence that 22444 is translated into protein. In addition, mutation scanning of the DNA sequence is ongoing to identify variants found in ill versus well individuals. This research was supported by a NARSAD Young Investigator Award to RJ Buono.

**Analysis of a missense mutation in the catatonic schizophrenia candidate gene WKL1 in bipolar affective disorder and schizophrenia patients from Denmark and the Faroe Islands.** *M.D. Lundorf<sup>1</sup>, T.H. Jorgensen<sup>2</sup>, H.N. Buttenschoen<sup>2</sup>, A.G. Wang<sup>3,4</sup>, M. Vang<sup>3</sup>, T.A. Kruse<sup>5</sup>, O. Mors<sup>2</sup>, H. Ewald<sup>1,2</sup>.* 1) Department of Biological Psychiatry, Institute for Basic Psychiatric Research, Risskov, Aarhus, Denmark; 2) Department of Psychiatric Demography, Institute for Basic Psychiatric Research, Psychiatric Hospital in Aarhus, DK-8240 Risskov, Denmark; 3) Department of Psychiatry, National Hospital, Torshavn, Faroe Islands; 4) Copenhagen University Hospital, Denmark; 5) Department of Clinical Biochemistry and Genetics, Odense University Hospital, Denmark.

Genetic mapping studies, investigations of cytogenetic abnormalities and direct examination of candidate genes suggest that chromosome 22q may harbour risk genes for schizophrenia as well as bipolar affective disorder. Patients from a genetic isolate of the Faroe Islands were typed for 35 evenly distributed polymorphic markers on 22q in a search for shared risk genes in the two disorders. A region on 22q13.3 showed increased sharing of haplotypes in bipolar and schizophrenic patients. Of particular interest is a segment close to the WKL1 gene recently suggested to harbour a missense mutation in individuals with catatonic schizophrenia. We evaluated this mutation by a primer extension assay in 13 bipolar affective disorder patients, 11 schizophrenic patients and 40 controls from the Faroe Islands. Furthermore, the polymorphism was tested in 79 bipolar affective disorder patients and 84 controls from Denmark. However, we did not detect the mutation in any of the 454 chromosomes tested. This suggests that the WKL1 missense mutation is very rare in, or absent from, the Danish and Faroese populations and it is not associated with schizophrenia or bipolar affective disorder in our samples.

**Testing Autism Candidate Genes on Chromosome 7.** *H.B. Hutcheson<sup>1</sup>, Y. Bradford<sup>1</sup>, S.E. Folstein<sup>2</sup>, M.B. Gardiner<sup>1</sup>, J. Piven<sup>3</sup>, S.L. Santangelo<sup>2,4</sup>, J.S. Sutcliffe<sup>1</sup>, V. Vieland<sup>5</sup>, T.H. Wassink<sup>6</sup>, J.L. Haines<sup>1</sup> and Collaborative Linkage Study of Autism (CLSA).* 1) Program in Human Genetics, Vanderbilt University Medical Center, Nashville, TN; 2) Department of Psychiatry, New England Medical Center/Tufts University School of Medicine, Boston, MA; 3) Neurosciences Hospital, University of North Carolina School of Medicine, Chapel Hill, NC; 4) Harvard University School of Public Health, Boston, MA; 5) Division of Statistical Genetics, University of Iowa Colleges of Public Health and Medicine, Iowa City, IA; 6) Psychiatry Research, University of Iowa College of Medicine, Iowa City, IA.

Based on previous genetic and cytogenetic studies performed in autism, evidence points to the existence of one or more autism genes residing on chromosome 7q (115cM-149cM on the Marshfield map). However, further localization using linkage analysis has proven difficult. To overcome this problem, we examined our Collaborative Linkage Study of Autism (CLSA) dataset to identify only the families potentially linked to chromosome 7. 47 from a total of 86 families were identified and 17 markers were used to generate chromosomal haplotypes. We performed recombination breakpoint analysis to determine if any portion of the chromosome was predominately shared. The preponderance of these data identified a 6 cM region between D7S501 and D7S2847 as being most commonly shared. Additional markers at 1 cM intervals within this region were genotyped and association and recombination breakpoint analysis was performed. Although no significant association was found, the preponderance of the recombination breakpoint data points to a shared region between D7S496-D7S2418 (120 cM-123 cM) encompassing about 4.5 Mb of genomic DNA with over 50 genes. Multiple neuronally expressed genes, such as KIAA0716 and Leucine Rich Repeat Protein, have been prioritized for analysis. A minimum of five single nucleotide polymorphisms (SNPs) was examined in these genes but none of the analyses resulted in any significant allelic or haplotypic associations. Thus we conclude that these two genes are not involved in autism and examination of additional genes in this region is needed and underway.

**Genetic analysis of tryptophan hydroxylase gene polymorphisms in a chromosome 11p15 candidate region for autism.** *M.M. Jacobs, E.L. Nurmi, Y. Bradford, T. Amin, J.L. Haines, J.S. Sutcliffe and the Collaborative Linkage Study of Autism.* Program in Human Genetics, Department of Molecular Physiology & Biophysics, Vanderbilt University, Nashville, TN.

Reports of serotonergic abnormalities in both autistic probands and their relatives and an elevated prevalence of depression, anxiety, and obsessive-compulsive disorder in relatives of autistic subjects may reflect an underlying involvement of the molecular mediators of serotonergic neurotransmission in the pathogenesis of autism. Further, drugs that alter serotonin signaling can be used to treat anxiety, social phobia, and obsessive-compulsive disorder in both autistics and in the general population. A genomic linkage screen and follow-up analysis of the Collaborative Linage Study of Autism families identified a candidate region on chromosome 11p with a peak two-point LOD score of 2.04 at marker D11S1999 at 17 cM. Tryptophan hydroxylase (TPH) catalyzes the rate-limiting step in the synthesis of serotonin; its gene is located nearby D11S1999 at ~21 cM and is therefore an attractive functional candidate for involvement in autism susceptibility. In order to analyze *TPH* as a candidate gene to account for genetic linkage to this region, we have selected single nucleotide polymorphisms (SNPs) within the transcriptional unit. SNPs were genotyped in a subset of the CLSA families and analyzed using a variant of the transmission disequilibrium test, which is appropriate for use with sibpair datasets. Initial analysis of one SNP within intron 2 and two others flanking the transcriptional unit does not show evidence for allelic association. Other functional candidate genes within a broader region around D11S1999 include the dopamine D4 receptor, tyrosine hydroxylase, and secretin. Ongoing studies seek to analyze additional polymorphisms in *TPH* and other positional candidates individually and within haplotypes to investigate potential association of gene variants with autistic disorder.

**The HLA/TNFA region is linked to leprosy clinical subtypes.** *M.T. Mira*<sup>1</sup>, *A. Alcaïs*<sup>2</sup>, *N.V. Thuc*<sup>3</sup>, *T. Huong*<sup>3</sup>, *M.C. Phuong*<sup>3</sup>, *L. Abel*<sup>2</sup>, *E. Schurr*<sup>1</sup>. 1) Centre for Host Resistance, McGill University, Montreal, Quebec, Canada; 2) INSERM, U 550, Hopital Necker, Paris, France; 3) Hospital for Dermato-Venereology, Ho-Chi-Minh City, Vietnam.

Leprosy is a chronic infectious disease caused by *Mycobacterium leprae*. The disease presents as a spectrum of clinical manifestations ranging from paucibacillary (PB), tuberculoid forms to multibacillary (MB), lepromatous forms. We have enrolled 20 mixed PB and MB multiplex nuclear families from South Vietnam for a genetic study of leprosy susceptibility. These families have been used in a previous linkage study that identified the NRAMP1 region as one important factor controlling primary steps of host responsiveness to infection by *M.leprae*. In the present study, our objective was to evaluate linkage of additional candidate regions to leprosy susceptibility. DNA samples were genotyped for biallelic single-nucleotide polymorphisms (SNPs) and for highly informative microsatellite markers closely linked to the vitamin D receptor encoding gene (VDR, chromosome 12q13), the tumour necrosis factor alpha gene (TNFA) located within the HLA complex (HLA/TNFA, chromosome 6p21), the TNFA-receptor 1 and -receptor 2 genes (TNFR1, chromosome 12p13 and TNFR2, chromosome 1p36), as well as for informative markers within the cytokine gene cluster on chromosomal region 5q33-q35. Genetic model-free sib-pair linkage analysis was performed using the MLB method that allowed simultaneous consideration of PB and MB siblings within the same family. No significant linkage was found between any of the candidate gene regions and leprosy per se. Conversely, we observed significant linkage between leprosy clinical subtypes and the HLA/TNFA region (corrected multipoint p-value =  $8 \times 10^{-4}$ ). The estimated proportion of parental haplotypes shared by two concordant sibs (both PB or both MB) was 0.77. The estimated proportion of haplotypes shared by discordant sibs (one PB and one MB) was 0.23. These results support the general concept that NRAMP1 and other innate resistance genes control initial steps in leprosy pathogenesis, while HLA/TNFA linked immune response genes determine the specific clinical manifestations of the disease.

**Lack of Association Between HoxA1, HoxB1, Reelin and WNT-2 Gene Variants and Autism in 110 Multiplex Families.** *J. Li<sup>1</sup>, H.K. Tabor<sup>1</sup>, L. Nguyen<sup>1</sup>, C. Gleason<sup>1</sup>, L.J. Lotspeich<sup>2</sup>, D. Spiker<sup>2</sup>, N. Risch<sup>1</sup>, R.M. Myers<sup>1</sup>.* 1) Dept Genetics, Stanford Univ. School of Medicine; 2) Psychiatry and Behavioral Sciences, Stanford Univ, Stanford, CA 94305.

Autism is a severe neurodevelopmental disorder characterized by marked social deficits, delay and deviance in language development and communication skills, and a restricted range of stereotypical, repetitive behaviors and limited interests. The etiology of autism is largely unknown. However, family and twin studies have provided compelling evidence for a strong genetic component in most idiopathic cases. Several recent candidate gene studies separately suggested that the HoxA1, HoxB1, Reelin and WNT-2 genes play a role in susceptibility to autism. To determine whether these findings could be replicated, we screened these genes for DNA polymorphisms by sequencing all exons and adjacent intronic regions in 24 individuals with autism. We identified one single base substitution variant in HoxA1, a common haplotype in HoxB1 comprising three single nucleotide polymorphisms (SNP), a polymorphic trinucleotide repeat in the 5' Untranslated Region (UTR) of Reelin, and four common SNPs in WNT-2, of which one is in the 5' UTR, and three are in the 3' UTR. We genotyped all these polymorphisms in 110 multiplex families with autism, and applied the Transmission Disequilibrium Test to detect possible association of these variants to autism. Our results demonstrated no deviation from the null hypothesis of no association. We have also separately examined transmissions (i) within individual mating types, (ii) for paternal versus maternal alleles, (iii) to affected versus unaffected children, and (iv) for transmission to affected boys versus girls. None of these subsets revealed significant deviation from the null expectation. Our interpretation of these findings is that it is unlikely that HoxA1, HoxB1, Reelin and WNT-2 play a significant role in the genetic predisposition to autism.

**The N-Methyl-D-Aspartate receptor subunit 2B gene (GRIN2B) is not linked to Bipolar Disorder: evidence for specificity of the role of GRIN1.** *E. Mundo<sup>1</sup>, N. Prociw<sup>1</sup>, N. King<sup>1</sup>, F. Ajmar<sup>2</sup>, E. De Maria<sup>2</sup>, P. Mandich<sup>2</sup>, F.*

*Macciardi<sup>1</sup>, J.L. Kennedy<sup>1</sup>.* 1) Neurogenetics Section, CAMH, Clarke Site, Department of Psychiatry, University of Toronto, Toronto, Ontario, Canada; 2) Department of Oncology, Biology, and Genetics, University of Genova, Genova, Italy.

The glutamate system has been involved in the pathogenesis of schizophrenia (Carlsson et al, 1999) and the most common mood stabilizers used to treat Bipolar Disorder (BP) appear to act via the glutamate system (Dixon and Hokin, 1997; Loscher, 1999). The N-Methyl-D-Aspartate (NMDA) receptor subtype of the glutamate-gated ion channels is composed of different combinations of sub-units (Monyer et al, 1992). In a recent family-based association study, we reported a significant association, confirmed by a haplotype analysis, between the N-Methyl-D-aspartate receptor subunit 1 gene (GRIN1) and BP (Mundo et al, 2001). The aim of the present study was to investigate the same sample for the presence of linkage disequilibrium between the gene encoding for the subunit 2B of the N-Methyl-D-aspartate receptor (GRIN2B) (Mandich et al, 1994) and BP. One hundred and eighteen BP I or BP II probands with their living parents were studied. Diagnoses were assessed by a structured interview for DSM-IV (APA, 1994) (SCID-I). Genotyping data of the BstYI (G/T) polymorphism of the GRIN2B were analyzed using the Transmission Disequilibrium Test (TDT) (Spielman et al, 1993). Sixty-one triads had heterozygous parents and were suitable for the final analyses. The two alleles of the BstYI polymorphism were transmitted to the probands with similar frequency ( $\chi^2=0.610$ ,  $df=1$ ,  $p=0.435$ ). These negative results for the GRIN2B appear to confer specificity to the GRIN1 as a susceptibility marker for BP. Further investigations on larger samples and on alternative phenotypes related to BP (e.g., response to mood stabilizers) are warranted.

**Dopamine system genes, sensation seeking, and the risk for substance use disorders.** *M.M. Vanyukov<sup>1,2,3,5</sup>, B.S. Maher<sup>4,5</sup>, R.E. Ferrell<sup>2,5</sup>, L. Kirisci<sup>1,3,5</sup>, H.F. Simkevitz<sup>1,5</sup>, G.P. Kirillova<sup>1,5</sup>, B. Devlin<sup>3,5</sup>, M.L. Marazita<sup>1,2,4,5</sup>, R.E. Tarter<sup>1,3,5</sup>.* 1) Center for Education and Drug Abuse Research (CEDAR), Dept. of Pharmaceutical Sciences; 2) Dept. of Human Genetics; 3) Dept. of Psychiatry; 4) School of Dental Medicine; 5) University of Pittsburgh, Pittsburgh, PA.

The reward pathways for different drugs share the structures of the brain comprising the mesocorticolimbic dopaminergic system (Koob & Le Moal, *Neuropsychopharmacology* 24:97-129, 2001). Dopaminergic mechanisms are also involved in natural reward, especially under conditions of novelty. There are data indicating that mesolimbic dopamine neurons code for stimuli with high motivational impact due to their novelty, rather than for generic motivational salience (Bassareo & Di Chiara, *J Neurosci* 17:851-861, 1997). The relationship between parental substance use disorder (SUD) and offspring's risk for SUD is in part mediated by offspring's sensation (novelty) seeking (Kirillova et al., *J Child Adol Substance Abuse*, in press). We applied the transmission/disequilibrium test for quantitative traits (QTDT) to the relationship between dopamine system genes (dopamine transporter and dopamine D2, D4, and D5 receptor genes) and the scales of Zuckerman's Sensation Seeking Questionnaire (SSQ) and the risk for SUD in a sample of Caucasian boys and their parents. Significant associations were detected between a microsatellite polymorphism at the dopamine D2 receptor gene and all four SSQ scales. A QTDT analysis of the single factor derived from the scales, however, showed its significant association with a VNTR at the dopamine transporter (DAT1) gene. Controlling the SSQ scales for the common factor did not affect their associations with the DRD2 gene, indicating independent contributions of the two genes to the common sources of variance in the scales. A QTDT analysis of a quantitative index of the liability to SUD derived for 10-12 year old boys using item response theory (Vanyukov & Tarter, *Drug Alcohol Dep* 59:101-123, 2000) showed a trend toward an association with the DAT1 polymorphism. This trend is consistent with significant differences observed for this polymorphism between adult SUD and control males.

**Polymorphisms of interferon gamma (*IFNG*) contribute to gender-based differential susceptibility to MS.** B.G. Weinshenker<sup>1</sup>, O.H. Kantarci<sup>1</sup>, A. Goris<sup>6</sup>, S. Heggarty<sup>4</sup>, M.G. Marrosu<sup>7</sup>, C. Graham<sup>4</sup>, S. Hawkins<sup>5</sup>, E. Atkinson<sup>2</sup>, M. de Andrade<sup>2</sup>, K. Vandebroek<sup>3</sup>. 1) Dept Neurology, Mayo Clinic, Rochester MN; 2) Dept of Health Sciences Research, Mayo Clinic, Rochester MN; 3) School of Pharmacy, Queen's University of Belfast, Belfast UK; 4) Dept of Medical Genetics, Queen's University of Belfast, Belfast UK; 5) Dept of Neurology, Royal Victoria Hospital, Belfast UK; 6) Rega Institute for Medical Research, University of Leuven, Belgium; 7) Dept of Neuroscience, University of Cagliari, Cagliari, Italy.

Multiple sclerosis (MS) is a complex disease that is twice as common in women than men. *IFNG* is a T helper 1 cytokine, the expression of which increases preceding exacerbations of MS. Expression of *IFNG* is higher in women than in men with diverse inflammatory and infectious diseases, including MS. An intron 1 microsatellite is associated with *IFNG* expression. We tested this and other novel intragenic polymorphisms of *IFNG* uncovered by dideoxyfingerprinting for population and family-based association with susceptibility to MS. We found that the frequency of the 12 CA-repeat allele or of the 12/12 genotype was lower in men with MS compared to controls. The odds ratios for carriers of the 12 repeat allele was 0.26 (95% CI: 0.10-0.69) in Olmsted County, MN and 0.15 (0.03-0.79) in Sardinia (DR3/4-, low risk by MHC). For those with the 12/12 repeat genotype, the odds ratio was 0.16 (0.04-0.68) in Olmsted County, 0.06 (0.01-0.49) in Sardinia (DR3/4-) and 0.38 (0.16-0.92) in Northern Ireland. Similar findings were observed for the G allele of an exon 4 position 325 (untranslated region) G/A single nucleotide polymorphism that is in linkage disequilibrium with the 12 CA-repeat allele of the microsatellite in Olmsted County. The 12 repeat allele was transmitted less frequently than expected from heterozygous parents to affected Sardinian DR3/4- men but not women. A subsequent linkage disequilibrium survey using multiple microsatellites localized the responsible locus to a 94-kb interval immediately surrounding *IFNG*. The lower frequency of the high expression alleles of *IFNG* in men destined to develop MS may explain the relative protection of men from MS.

**Analysis of GABAA receptor subunit genes in Alcohol Dependence and Obsessive-Compulsive Disorder.** *M. Radel, R. Vallejo, R. Aragon, J.C. Long, M. Virkkunen, D. Goldman.* Lab Neurogenetics, NIAAA/NIH, Rockville, MD.

The major objective of this study was to evaluate, using polymorphism detection and linkage strategies, the role of genetic variation of GABAA receptor genes in the genetic susceptibility to alcohol dependence (AD). In addition, the role of GABRG2 in the genetic susceptibility to obsessive-compulsive disorder (OCD), a severe anxiety disorder, was analyzed. Sequence variants of the GABRA1, GABRA6, GABRB2 and GABRG2 genes, on chromosome 5q, and of GABRB1 on 4p, were detected by pDHPLC. The sensitivity and specificity of this novel method was first tested in double-blind fashion across 9 known single nucleotide polymorphisms (SNPs). Putative variants were confirmed and characterized by automated sequencing. A panel of six SNPs at the 5q cluster was selected for linkage and association studies and genotyped blind to diagnosis by PCR-RFLP. For AD, two psychiatrically interviewed samples from population isolates were used: A Southwestern American-Indian (SWAI) tribe (N=433) and a Finnish sample (N=473). There was no deviation of genotypic distributions from Hardy-Weinberg (HW) equilibrium. Association of GABRB2 and GABRA6 alleles with AD was detected in both samples. Sib-pair linkage of GABRG2 to AD was detected in the Finns. Linkage disequilibrium (LD) between alleles at the six loci did not vary as a simple function of distance, and normalized LD coefficients varied between them. The trimmed haplotype analysis showed evidence of linkage of 5q GABAA haplotypes to AD. These results are consistent with genetic variation at or near the 5q GABAA cluster conferring differential susceptibility to alcohol dependence. To investigate the role of the GABRG2 gene in OCD, subjects and controls from the US (N=96) and Italy (N=92) were genotyped blind to diagnoses for two GABRG2 SNPs. There was no H-W deviation. Population association was detected between alleles at both SNPs and OCD in both samples. These results suggest that either these polymorphisms alter function, or that they are in linkage disequilibrium with a functional variant that confers increased genetic vulnerability to OCD.

**Association study of SNPs for the FCHL locus on 1q21.** *P. Pajukanta*<sup>1</sup>, *M.-R. Taskinen*<sup>2</sup>, *J.S. Sinsheimer*<sup>1,3</sup>, *J.S. Bodnar*<sup>1</sup>, *A.J. Lysis*<sup>1</sup>, *L. Peltonen*<sup>1,4</sup>. 1) Dept of Human Genetics, UCLA, USA; 2) Dept of Medicine, University of Helsinki, Finland; 3) Dept of Biomathematics, UCLA, USA; 4) Dept of Molecular Medicine, National Public Health Institute, Finland.

Familial combined hyperlipidemia (FCHL) is a common familial lipid disorder predisposing to coronary heart disease. Despite intensive efforts, the etiology of FCHL has remained unknown. We previously identified a locus for FCHL on human chromosome 1q21-q23 in 31 Finnish FCHL families. The finding has been replicated in FCHL families from other, more heterogeneous populations, and the same 1q21 region has also been linked to non-insulin-dependent diabetes mellitus (NIDDM) in several studies, suggesting a partially shared genetic background for FCHL and NIDDM. Interestingly, a locus for combined hyperlipidemia (Hyplip1) in mouse was mapped to a region on chromosome 3 that was potentially orthologous to human chromosome 1q21. Fine mapping of the Hyplip1 gene assigned the human counterpart 10 Mb of the peak linkage markers to FCHL on 1q21. To determine whether the same gene is responsible for hyperlipidemia in both human and mouse, exons, introns, and the promoter region of the human Hyplip1 gene were sequenced in 61 Finnish FCHL families. We found 20 single nucleotide polymorphisms (SNPs): Ten in the promoter, one in an intron and nine in the last exon. None of the variants resulted in an amino acid change and all of them were relatively rare (allele frequencies < 0.1). Two-point and multipoint association analyses of the most common SNPs in 61 extended Finnish FCHL families revealed no evidence for association, indicating that the Hyplip1 gene is unlikely the causative FCHL gene. To analyze other regional candidate genes on 1q21-23, we genotyped 33 SNPs for 19 positional candidate genes in the region of the peak linkage markers, including apolipoprotein A2, upstream stimulatory factor 1, and retinoid X receptor gamma. Significant evidence for both linkage and association in Finnish FCHL families was obtained with some of the analyzed SNPs. We are currently analyzing these FCHL-associated SNPs in the representative population samples from Finland to identify the FCHL-associated variant.

**Analysis of the gene RAY1(FAM4A1/ST7)at a translocation breakpoint region on 7q31.3 in an autism patient reveals a complex multigene system.** *J.B. Vincent<sup>1,2</sup>, E. Petek<sup>3</sup>, S. Thevarkunnel<sup>1</sup>, J. Cheung<sup>1</sup>, S.W. Scherer<sup>1</sup>.* 1) Dept Genetics, Hosp Sick Children, Toronto, ON, Canada; 2) Dept. of Psychiatry, University of Toronto, ON, Canada; 3) Institute for Medical Biology and Human Genetics, University of Graz, Graz, Austria.

We recently identified a novel gene, RAY1 (FAM4A1), which spans a translocation breakpoint at 7q31.3 in a patient with autism. This gene has also recently been reported to be a suppressor of tumorigenicity, ST7. We have analysed this locus in more detail and revealed a multigene system that includes two novel non-coding anti-sense genes (RAYNC1 and RAYNC2) and a non-coding sense-strand gene (RAYNC3) that overlap with the coding RAY1 transcript. RAYNC1 overlaps with the RAY1 exon 1 and putative promoter and has several different polyadenylation sites. RAYNC2 spans from RAY1 intron 9 to intron 1, and has multiple isoforms. RAYNC3 spans from RAY1 intron 10 to exon 13 and includes RAY1 exons 11, 12 and 13, as well as at least six other intervening exons. Comparative sequence analysis between human and mouse genomic sequence at this locus has also revealed a number of intronic and intragenic regions that show a high degree of intra-species conservation. We have screened all exons of RAY1, RAYNC1, RAYNC2 and RAYNC3 for sequence variants in over 90 unrelated autism probands from multiplex families, and identified a number of polymorphisms and mutations. We have also identified a second autism patient with a chromosome 5:7 translocation mapping to the same cytogenetic band, 7q31.3, as the first patient. We have localized the breakpoint to a single BAC clone to which no genes have been mapped. We postulate that the non-coding genes around RAY1 are likely to be either cis-regulatory RNAs, particularly RAYNC1 which spans RAY1 promoter and exon 1, or may be evidence of promiscuous transcription, resulting in junk RNA.

**Identification of genes differentially expressed in wildtype and Fmr1 knockout mouse barrel cortex. W.T.**

*O'Donnell<sup>1</sup>, K. Zito<sup>2</sup>, B. Burbach<sup>2</sup>, K. Svoboda<sup>2</sup>, S.T. Warren<sup>1</sup>*. 1) Biochemistry, Genetics, and Pediatrics, Emory Univ Sch Med, Atlanta, GA; 2) Cold Spring Harbor Laboratory, Cold Spring Harbor, NY.

Fragile X syndrome is an X-linked dominant disorder caused by the absence of Fragile X Mental Retardation Protein (FMRP). Fmr1 knockout mice exhibit a cognitive and behavioral phenotype consistent with the human disorder, and show delayed dendritic spine maturation. Thus, at the cellular level, there is a difference between wildtype and knockout neurons. To investigate this difference *in vivo*, we sought to identify genes whose total expression levels are different between WT and KO mice. The following experiment was run in triplicate: the barrel cortices from 10 WT and 10 KO congenic c57BL/6 mice were dissected out during a critical period in neural development: P11-13. RNA was isolated from this tissue and used to probe oligonucleotide microarrays. Of the over 25,000 genes probed, 45% were present in the mouse barrel cortex. Four genes showed a substantial and consistent difference in expression between WT and KO in all three replicates. Real time, quantitative PCR was performed on three of these candidates and confirmed the change. We then used the available public databases to determine the identities of the differentially expressed genes: two of the genes are unknown ESTs (one overexpressed and one underexpressed in KO), the third is Fmr1, and the fourth is the beta chemokine exodus-2. Fmr1 expression is present in KO barrel cortex, but is much less abundant than in WT. This finding is not unexpected and provides an internal control for the experiment because of presumed nonsense mediated decay of Fmr1 knockout transcript. Exodus-2 is also less abundant in KO tissue. Though exodus-2 has not been shown to be involved in the developing mouse brain, recent findings have implicated cytokines in neural development.

**Variation in UCP3 is associated with multiple metabolic features in Caucasian females.** *C.M. Damcott<sup>1</sup>, E. Feingold<sup>1</sup>, S.P. Moffett<sup>1</sup>, J.A. Marshall<sup>2</sup>, R.H. Hamman<sup>2</sup>, J.M. Norris<sup>2</sup>, R.E. Ferrell<sup>1</sup>*. 1) Univ. of Pittsburgh; 2) Univ. of Colorado School of Med.

The uncoupling proteins (UCP) are a family of mitochondrial transport proteins that promote proton leakage across the inner mitochondrial membrane, uncoupling proton transfer from ATP production and releasing energy as heat. UCP3 is a member of this family uniquely expressed in skeletal muscle, a major tissue of thermogenesis. Gene expression studies in rodents suggest a role for UCP3 in energy metabolism, alterations in lipid, glucose, and insulin levels, and fuel substrate management. The UCP3 gene maps to human chromosome 11q13, a region linked to variation in obesity and REE. We tested the hypothesis that variation in the UCP3 gene is associated with aspects of obesity and/or diabetes mellitus in a sample of Caucasian females (n=223) from the San Luis Valley Diabetes Study. Resequencing of roughly 1kb 5' of exon 1 of UCP3 identified a C/T polymorphism at -55 bp. This variation was significantly associated with HOMA IR (p=0.01), a measure of insulin resistance, and marginally associated with triglycerides (TG; p=0.068). The C homozygotes have lower HOMA IR indexes (~3 units) and TG (~16 mg/dl). A second polymorphism in UCP3, a T/C silent substitution in codon 210 of exon 5, is also associated with HOMA IR (p=0.046) and TG (p=0.047). Presence of the C allele confers lower HOMA IR indexes (~3 units) and TG (~26 mg/dl), similar to C/C individuals at the -55 site. The linkage disequilibrium between these two variants suggests that the exon 5 C allele and the -55 C allele are marking a functional change in UCP3 affecting insulin resistance and TG levels. The exonic variant is also associated with fat mass measured by DEXA (p=0.002), percent body fat (p=0.018), and fasting free fatty acids (FFA; p=0.022). On average, T/T homozygotes exhibit a 5 kg higher fat mass, a 3% greater body fat, and increased FFA (+84 mol/l). Association of the exon 5 variant with these phenotypes, independent of the -55 variation, suggest the presence of additional functional variation in the UCP2/UCP3 region. This supports a role of UCP3 in regulating body weight, energy expenditure, lipid metabolism, and insulin action.

**Genotyping Single Nucleotide Polymorphisms in Four Different Amplicons in Diabetes.** *M.L. Robinson<sup>1</sup>, G. Wu<sup>1</sup>, S. Babu<sup>2</sup>, C. Roberts<sup>2</sup>, F. Bao<sup>2</sup>, P.R. Fain<sup>2</sup>.* 1) Applied Genomics and Molecular Genetics, Transgenomic Inc., Omaha, NE; 2) Barbara Davis Center for Childhood Diabetes, University of Colorado Health Sciences, Denver, CO.

Single nucleotide polymorphisms (SNPs) are very useful markers for linkage disequilibrium studies aimed at the discovery of disease genes. Although a large number of SNPs have been identified and a high-density SNP map has been developed, cost effective methods for high-throughput SNP genotyping are lacking. As part of an effort to identify a susceptibility gene for type 1 diabetes, which maps to human chromosome 10q25.1, over 100 SNPs within a 125 kb interval at 10q25.1 were identified by direct sequencing of genomic DNA from 4 affected and unaffected family members. We designed and optimized primers to amplify 4 different amplicons which contain SNPs showing maximum linkage disequilibrium with the disease locus (IDDM17). Patients with known genotypes for each of the 4 SNPs were genotyped using a new primer extension protocol for the Transgenomic WAVE® DHPLC System. This is a rapid and inexpensive protocol suitable for high throughput genotyping.

**Epigenetic sequencing analysis of a H19-DMR reveals parent-of-origin independent methylation.** *T. Enklaar, M. Oswald, D. Prawitt, B. Zabel.* Children's Hospital , University of Mainz, Mainz, Germany.

Parent-of-origin specific DNA-methylation plays an important role in the process of controlling monoallelic expression of imprinted genes. For the human H19 gene two differentially methylated regions (DMRs) are known, residing around the promoter of the gene (DMR1) and in a region of 400bp direct repeats starting -2kb upstream of the H19 transcription start site (DMR2). They were frequently analyzed in order to find an association of a pathological methylation pattern with loss of imprinting implicated in diseases like Beckwith-Wiedemann-syndrome, Wilmstumour and colorectal cancer. The majority of previous investigations relied on the use of methylation-sensitive restriction enzymes like HpaII and SmaI detecting up to three restriction sites in each DMR. The sequencing of bisulfite treated DNA on the other hand reveals the methylation status of every single CpG-dinucleotide in the amplified region and allows to discriminate directly between the two parental alleles if single nucleotide polymorphisms are available. Thus, LOI of H19 in Wilmstumours and colorectal cancer was linked to hypermethylation of the DMR -2kb upstream of H19. Analysis of the H19 methylation status in Beckwith-Wiedemann-syndrome cases was up to now focused on the HpaII- and SmaI sites of the H19-promoter region revealing infrequent hypermethylation. We examined all involved CpG-dinucleotides of both differentially methylated regions in DNA of BWS patients and controls by bisulfite sequencing. Almost all CpGs near the H19 promoter, including the HpaII- and SmaI-sites showed parent-of-origin independent methylation. The degree of demethylation of the paternal allele as well as hypermethylation of the maternal allele was found to be highly variable. These studies suggest that silencing of the paternal H19 allele may not be directly related to methylation of DMR1 or seems to require only low levels of differential promoter methylation.

**Epigenetic differences between the parental alleles of *Ndn* (necdin), an imprinted gene in the Prader-Willi Syndrome region.** *M.L. Hanel, R. Wevrick.* Medical Genetics, University of Alberta, Edmonton, Alberta, Canada.

Imprinted genes are expressed unequally on the two alleles depending on the parental origin. The neurobehavioural disorder Prader-Willi Syndrome (PWS) results from loss of the paternal complement of the chromosome region 15q11-q13 including *NDN* and other paternally expressed genes in this region. Mouse *Ndn* is located in the region of conserved synteny on chromosome 7 with the human PWS region. To investigate possible mechanisms for establishing and maintaining imprinting, we have studied *Ndn* for allele-specific methylation and chromatin conformation. We found that in brain, where necdin is expressed, the maternal allele is relatively hypermethylated compared with the paternal allele. In liver and heart, where necdin is not expressed, DNA methylation levels are low on both alleles. A distinctive but unstable maternal methylation pattern persists from the gametes until before the blastocyst stage (around implantation) and is then lost by the blastocyst stage where low levels of methylation are present on most paternal and maternal DNA strands. This suggests that for *Ndn*, DNA methylation may initially preserve a gametic imprint during preimplantation development, but that other epigenetic factors maintain the imprint later in embryonic development.

We are now analyzing the region for allele-specific differences in chromatin structure through DNase I sensitivity assays. Increased DNase I sensitivity is associated with an open chromatin conformation. In brain, the methylated, inactive maternal allele was more resistant to DNase I than the unmethylated, active paternal allele in the promoter region. In liver, both alleles were relatively resistant to digestion. Preliminary results in a search for allele-specific DNase I sensitivity outside the promoter region show that increased DNase I sensitivity on the paternal allele was detected at least 4 kb upstream of *Ndn*. In summary, allele-specific differences in DNA methylation and chromatin conformation are not evident in non-expressing tissues. However, methylation and chromatin conformation appear to be involved in allele-specific expression of *Ndn* in brain.

**Association between heteroplasmy of A3243G mutation and SNP in ND1 gene in 109 MELAS patients. J.**

*Akanuma<sup>1</sup>, T. Kinoshita<sup>1</sup>, H. Komaki<sup>1</sup>, I. Nonaka<sup>2</sup>, Y. Goto<sup>1</sup>.* 1) Mental Retardation/Birh Def, National Inst Neuroscience (NCNP), Kodaira, Tokyo, Japan; 2) National Center Hospital for Mental, Nervous and Muscle Disorders, NCNP.

Mitochondrial myopathy, encephalopathy, lactic acidosis and stroke-like episodes (MELAS) is often associated with an A3243G mutation in tRNA-Leu(UUR) region of mtDNA. The patients with the mutation exhibit variable and multisystemic clinical manifestations, which are thought to be caused by different proportion (heteroplasmy) and distribution of the mutant mtDNA in the tissues. It is very important to know whether the mtDNA genome with A3243G mutation has a replicative advantage over wild-type one, because it may be closely related with the severity and the progression of the disease. In this study, we analyzed the single nucleotide polymorphism (SNP) other than A3243G mutation to know the possible involvement in the heteroplasmy of the mutant. We studied 109 DNA samples extracted from the muscles of MELAS patients carrying A3243G mutation. In order to quantify the mutation rapidly and accurately, we devised a real-time PCR amplification method using two fluorogenic probes in a single tube. The proportion of mutant mtDNA in these patients ranged from 7.5% to 100%. Then we selected 15 from 109 patients and divided them into two groups; one is high percentage level of the mutation group (10 patients; almost 100% of mutant DNA) and the other is low percentage level group (5 patients; from 7.5% to 43.6% of mutant DNA). We investigated the total mtDNA sequence of both groups and compared the SNPs. In result, total 194 SNPs were detected in both groups. We summarized these data in each group with radar chart divided into 16 functional units of mtDNA. The pattern of chart of 16S rRNA and ND1 gene appeared to be different between the groups. Then we screened the SNPs of the 16S rRNA and ND1 genes in all 109 patients. Several SNPs in ND1 gene were found to be accompanied with the high percentage level group more frequently in statistical significance. We conclude that the several SNPs in ND1 gene in mtDNA are related to the replicative advantage of mtDNA carrying A3243G.

**Pathogenic mechanism of mitochondrial tRNA<sup>Ser(UCN)</sup> 7511 mutation associated with non-syndromic deafness.**

*M.X. Guan*<sup>1</sup>, *X.M. Li*<sup>1</sup>, *N. Fischel-Ghodsian*<sup>2</sup>, *R. Friedman*<sup>3</sup>. 1) Div Human Genetics, Children's Hosp Medical Ctr, Cincinnati, OH; 2) Department of Pediatrics, Cedar-Sinai Medical Center, Los Angeles, CA; 3) House Ear Institute, Los Angeles, CA.

Hearing loss is one of the most common human sufferings, affecting one in 1000 children. Despite the recent progress in molecular characterization of deafness, the biochemical and molecular pathogenic mechanisms underlying the maternally inherited deafness remain poorly understood. Recently, an African-American family with maternally inherited nonsyndromic hearing loss has been found to be associated with the mitochondrial T7511C mutation in the tRNA<sup>Ser(UCN)</sup> gene, which is commonly related to deafness. In addition, homoplasmic mutations T3308C in the ND1 gene and T5655C in the tRNA<sup>Ala</sup> gene have been found in all members of this pedigree and also in some controls. To understand the pathogenic mechanisms of these mtDNA mutations, a biochemical analysis has been carried out of transmitochondrial cell lines, constructed by transferring mitochondria from lymphoblastoid cell lines derived from deaf individuals with mtDNA mutations or from controls lacking mutations, into human mtDNA-less (r<sup>0</sup>) cells. A significant decrease in the amount of tRNA<sup>Ser(UCN)</sup> and rate of mitochondrial protein synthesis and oxygen consumption was observed in the five mutant cell lines, when compared with control cell lines. These observations suggest that the T7511C mutation in the tRNA<sup>Ser(UCN)</sup> gene is a primary mutation responsible for deafness phenotype and that T3308C and T5655C mutations play synergistic roles in the biochemical defect leading to deafness phenotype.

**DNA microarrays as a method to monitor changes in mitochondria-related gene expression in patients with OXPHOS defects and/or mitochondrial cardiomyopathy.** *J. Geurts<sup>1</sup>, B. van den Bosch<sup>1</sup>, L. Jacobs<sup>1</sup>, K. van der Kuijl<sup>1</sup>, S. van der Vlies<sup>1</sup>, I. de Coo<sup>2</sup>, H. Scholte<sup>2</sup>, J. Nijland<sup>2</sup>, T. Meitinger<sup>3</sup>, V. Tiranti<sup>4</sup>, M. Zeviani<sup>4</sup>, H. Smeets<sup>1</sup>.*

1) Department of Genetics and Cell Biology, University of Maastricht, The Netherlands; 2) Department of Biochemistry and Child Neurology, Erasmus University Rotterdam, The Netherlands; 3) Department of Medical Genetics, Ludwig-Maximilians University, Munich, Germany; 4) Division of Biochemistry and Genetics, National Neurological Institute C. Besta, Milan, Italy.

One of the most important functions of mitochondria is the production of ATP by the process of oxidative phosphorylation (OXPHOS). OXPHOS defects become clinically manifest if the ATP production gets below a tissue-specific threshold level. Based upon energy consumption, the organs most likely to be affected are the central nervous system, skeletal and cardiac muscle, pancreatic islets, liver and kidney. In the case of the heart, OXPHOS defects may lead to hypertrophic, dilated or hypertrophic dilated cardiomyopathy, often as part of specific syndromes, but also as the sole expression of the defect. The 16 kb mitochondrial DNA encodes only 13 of the proteins involved in OXPHOS. The vast majority of mitochondrial proteins are encoded by the nuclear genome. To characterize the changes in expression of mitochondrial DNA- and nuclear DNA-encoded genes involved in the molecular pathogenesis of mitochondrial disease and mitochondrial cardiomyopathy in particular, we have developed a human mitochondrial DNA microarray encompassing approximately 600 mitochondria-related genes. This mitochondrial microarray is ideally suited for expression profiling experiments using patient-derived fibroblast cell lines and (cardiac) muscle biopsies. At this moment, biological material is available for different groups of patients with (1) complex I and/or complex I and IV deficiencies, (2) different mitochondrial mutations e.g MELAS, MERRF, NARP, Pearson syndrome, CPEO, LHON, Leigh syndrome and (3) mitochondrial cardiomyopathy. Results from initial experiments will be presented.

**The influence of mtDNA background on the disease process: a new primary Leber's Hereditary Optic Neuropathy mtDNA mutation requires European haplogroup J for expression.** *M.D. Brown<sup>1</sup>, O.A. Derbeneva<sup>2</sup>, Y. Starikovskaya<sup>2</sup>, J. Allen<sup>1</sup>, R.I. Sukernik<sup>2</sup>, D.C. Wallace<sup>1</sup>.* 1) Center for Molecular Medicine, Emory University School of Medicine, Atlanta, GA; 2) Institute of Cytology and Genetics, Russian Academy of Sciences, Novosibirsk, Siberia, Russia.

Lebers Hereditary Optic Neuropathy (LHON) is a form of blindness caused by mitochondrial DNA (mtDNA) mutations. Three mutations, 3460A, 11778A, and 14484C, account for 90% of LHON worldwide and are designated "primary" mutations. Primary mutations strongly predispose carriers to LHON, are not found in controls, are all in Complex I genes, and do not co-occur with each other. Previously, we demonstrated that the 11778A and 14484C mutations occurred more frequently than expected in association with European mtDNA haplogroup J (found in 9% of European-derived mtDNAs), suggesting a synergistic interaction among mtDNA mutations increased the probability of disease expression. Here, we report a new primary LHON mtDNA mutation, 10663C, affecting a Complex I gene. This mutation was homoplasmic in 3 Caucasian LHON families, all of which belonged to haplogroup J. These 3 families were the only haplogroup J-associated LHON families (out of 17) that did not harbor a known, primary LHON mutation. Comprehensive phylogenetic analysis of haplogroup J using complete mtDNA sequences demonstrated that the 10663C variant has arisen 3 independent times on this background. This mutation was not present in over 200 non-haplogroup J European controls, 74 haplogroup J patient and control mtDNAs, or 36 putative LHON patients without primary mutations. A partial Complex I defect was found in 10663C-containing lymphoblast and cybrid mitochondria. Thus, the 10663C mutation has occurred three independent times, each time on haplogroup J and only in LHON patients without a known LHON mutation. This makes the 10663C mutation unique among all pathogenic mtDNA mutations in that it appears to require the genetic background provided by haplogroup J for expression. These results provide further evidence for the predisposing role of haplogroup J and for the paradigm of "mild" mtDNA mutations interacting in an additive way to precipitate disease expression.

**Novel mtDNA C11777A Mutation in Leigh Syndrome Changes the Same Acid As G11778A Mutation in LHON.**

*H. Komaki*<sup>1</sup>, *H. Iwata*<sup>3</sup>, *T. Takahashi*<sup>4</sup>, *J. Akanuma*<sup>1</sup>, *I. Nonaka*<sup>2</sup>, *Y. Goto*<sup>1</sup>. 1) Mental Retardation/Birth Def, National Inst Neuroscience, NCNP, Kodaira, Tokyo, Japan; 2) Ultrastructural Research, National Institute of Neuroscience, NCNP, Tokyo, Japan; 3) Pediatrics, Shinshiro City Hospital, Aichi, Japan; 4) Pediatrics, School of Medicine, Keio University, Tokyo, Japan.

Leigh syndrome (LS) is a heterogeneous disease, and defects in both mtDNA and nuclear DNA are reportedly involved in the pathogenesis of LS. However, in more than half of LS patients, the pathogenesis cannot be identified. A novel mtDNA C11777A mutation was identified in two unrelated patients out of 62 LS patients. Clinical symptoms including psychomotor retardation, abnormal signals on brain MRI, and hyperlactic acidemia were compatible with LS, but the clinical courses are relatively mild. Optic neuropathy was not detected. This mutation converted a highly evolutionary conserved arginine to a serine at codon 340 in the ND4 gene of complex I. The codon was also converted by a G11778A mutation, the most common mutation in LHON, but the amino acid replacement was different. This mutation existed in a heteroplasmic condition and did not detected 215 normal individuals and one patient's mother. No ragged-red or COX deficient fibers were detected by histopathologic studies of muscle biopsy. Spectrophotometric assays of skeletal muscle mitochondria showed significantly decreased activities in rotenone-sensitive NCCR with normal activities in SCCR and COX. ATP synthesis of myoblasts was significantly decreased when pyruvate/malate and glutamate/malate were used as substrates. ATP synthesis was normal when succinate and TMPD/ascorbate were used. These findings confirmed isolated complex I deficiency in their muscle. However, ATP synthesis of fibroblasts in one patient was normal, suggesting tissue-specific manner. It is noted that the phenotype of LHON patients is quite different from that the present cases despite the same amino acid substitution. These above findings indicate that this novel mutation caused a defect in energy production resulting in neuromuscular disease without optic neuropathy. Because the mean onset of LHON with 11778 mutation is their twenties, 11777 mutation may produce optic neuropathy in later life.

**Cloning and characterization of human *GTPBP3* gene, encoding a mitochondrial GTP binding protein.** X.M. Li, M.X. Guan. Human Genetics, Children's Hospital Med. Center, Cincinnati, OH.

*MSS1* in the yeast *Saccharomyces cerevisiae* encodes a mitochondrial GTP binding protein involved in the expression of *COX1* subunit of cytochrome c oxidase. *mss1* mutants manifest their respiratory-deficient phenotype only when coupled with a mitochondrial P<sub>R</sub><sup>454</sup> mutation, analogous to the deafness-linked A1555G mutation in the human mitochondrial 12S rRNA gene. Based on the available human EST sequences homologous to yeast *MSS1*, we have isolated full length cDNAs of human *GTPBP3* by use of SMART<sup>TM</sup> RACE cDNA amplification. *GTPBP3* gene (GeneBank accession no. AF360742) encodes a predicted protein with 493 amino acids, sharing a high identity to yeast *Mss1p*. This deduced protein contains the typical mitochondrial target sequence and three conserved domains: two GTP binding domains GTP1/OBG, and P21<sup>RAS</sup> as well as the SH3 domain, which is involved in protein-protein interaction. The coding region of this gene spans 8 exons, located at chromosome 19. Human *GTPBP3* gene is ubiquitously expressed as multiple transcripts. The ratio of different transcripts varies in several different tissue types. *GTPBP3*-GFP fusion experiment showed that *GTPBP3* is localized in mitochondrion. Additionally, the human *GTPBP3* can functionally complement the mutational phenotypes of yeast *mss1*. This suggested that human *GTPBP3* is the homolog of yeast *MSS1* and may be involved in the phenotypic expression of human deafness-linked A1555G mutation.

**Mitochondrial respiratory chain complex II mutations and the development of hereditary paragangliomas in the head and neck region.** *P.E. Taschner*<sup>1</sup>, *C.J. Cornelisse*<sup>2</sup>, *P. Devilee*<sup>1,2</sup>. 1) Dept Human/Clinical Genetics, Leiden Univ Medical Ctr, Leiden, Netherlands; 2) Dept Pathology, Leiden Univ Medical Ctr, Leiden, Netherlands.

Hereditary paragangliomas are usually benign slow-growing tumors, which arise from paraganglia, cell clusters of neuroectodermal origin. The most prominent paraganglion in the head and neck region is the carotid body, a chemoreceptive organ, which monitors arterial oxygen and maintains homeostasis. The occurrence of hereditary paragangliomas has been linked to at least three different loci: PGL1 on chromosome 11q22-q23, PGL2 on chromosome 11q13, and PGL3 on chromosome 1q21. Most families with hereditary paraganglioma are linked to the PGL1 locus. The inheritance pattern in these families is autosomal dominant with maternal imprinting. Recently, the PGL1 and PGL3 loci have been identified as the SDHD and SDHC genes, respectively, which encode the two membrane anchor proteins of mitochondrial respiratory chain complex II. Loss of the normal allele in paragangliomas suggests that the presence of these mitochondrial proteins is required to suppress tumor development. We hypothesize that mutations in the complex II membrane anchor genes result in abnormal oxygen sensing and interfere with normal development and maturation of the carotid body. Hyperplastic growth of the carotid body occurs, probably followed by additional somatic changes leading to monoclonal foci of tumor cells. The involvement of complex II in the development of paragangliomas provides evidence that mitochondria play a more important role in cellular oxygen sensing than suggested in current theories. This research is supported by the Dutch Cancer Society (KWF 98-1721).

**A Common mtDNA variant may be a susceptibility factor in 3 multifactorial diseases.** *J. Poulton<sup>1</sup>, V. Macaulay<sup>2</sup>, K. Livesey<sup>3</sup>, N. Wareham<sup>4</sup>, E. Parker<sup>1</sup>, D. Phillips<sup>5</sup>, D. Simmons<sup>6</sup>, B. Mayosi<sup>7</sup>, S. Khogali<sup>8</sup>, K. Robson<sup>3</sup>.* 1) University of Oxford Dept Paediatrics, John Radcliffe Hospital, Oxford OX3 9DU, UK; 2) University of Oxford Dept Statistics; 3) University of Oxford WIMM; 4) University of Cambridge; 5) MRC Environmental Epidemiology Unit, Southampton, UK; 6) University of Melbourne, Australia; 7) University of Oxford Dept Cardiovascular Medicine; 8) University of Birmingham, UK.

Type 2 diabetes and dilated cardiomyopathy (DCM) are important multifactorial conditions. Haemochromatosis is an autosomal recessive disorder with incomplete penetrance. Diabetes, cardiomyopathy and liver failure are all features of mitochondrial disease. Hence mtDNA variants may play a role in type 2 diabetes, DCM and haemochromatosis. The common 16189 variant lies near to control sequences in human mtDNA. **Diabetes Studies** 1. *Case control study* in 417 European diabetics and 427 controls. 16189 variant increased in diabetics, OR=1.67(p=0.037, 95%CI 1.0-2.6). 11/11 individuals with both paternal family history of diabetes and variant were diabetics OR= . 2. *Hyperinsulinaemia* associated with: the 16189 variant in 2 European populations (p=0.015) length variation due to 16189 variant among 190 Polynesians (p=0.008). 3. *16189 variant & thinness*: associated with: Decreased Ponderal Index at birth in 'changers' with the 16189 variant (p=0.007) in a birth cohort of 885. High placental to birth weight ratio, acute insulin response & glucose effectiveness in an Australian birth cohort of 160 individuals (p=0.025, 0.022, 0.005) **DCM study** The 16189 variant is associated with increased risk of DCM in Caucasians & Africans (p=0.01; OR=2.15 [95% CI 1.16-3.98] and p=0.036 OR=4.51 (95%CI 1.03-19.65, ) respectively). **Haemochromatosis study** The 16189 variant is present in 19/113 (17.9%) of individuals expressing the haemochromatosis phenotype who are homozygous for the C282Y allele compared with 8.8% of controls (p=0.01). The 16189 variant may influence penetrance. The 16189 variant per se may subtly affect mitochondrial function as 1) founder effect excluded 2) associations between 4 phenotypes in a total of 8 populations.

**Rescue of the frataxin knockout mouse embryonic lethal phenotype by human YAC and BAC transgenesis.** *M. Pook<sup>1</sup>, S. Al-Mahdawi<sup>1</sup>, C. Carroll<sup>1</sup>, M. Cossee<sup>2</sup>, H. Puccio<sup>2</sup>, L. Lawrence<sup>1</sup>, P. Clark<sup>1</sup>, M. Lowrie<sup>1</sup>, J. Bradley<sup>3</sup>, J.M. Cooper<sup>3</sup>, M. Koenig<sup>2</sup>, S. Chamberlain<sup>1</sup>.* 1) Cell & Molecular Biology, Leukocyte Biology and Biological Structure & Function, BMS, Imperial College School of Medicine, London, UK; 2) IGBMC, CNRS/INSERM Universit Louis Pasteur, Hopitaux Universitaires de Strasbourg, 67404 Illkirch, France; 3) University Dept. of Clinical Neurosciences, Royal Free and University College Medical School, London, UK.

Friedreichs ataxia (FRDA) is an autosomal recessive progressive neurodegenerative disorder caused by decreased expression of the nuclear encoded mitochondrial protein, frataxin. Previous studies have suggested involvement of mitochondrial iron accumulation and iron-sulphur enzyme deficiencies in FRDA pathogenesis, and embryonic lethality of homozygous *Frda* knockout mice has indicated a role for frataxin in development. To study FRDA pathogenesis in more detail, mouse models that demonstrate reduced levels of frataxin function are required. As an initial test for the feasibility of re-introducing functional human frataxin into a null mouse, we have established three YAC and two BAC wild-type human FRDA transgenic lines, containing different amounts of human genomic DNA (140kb to 370kb) flanking an intact FRDA gene. To date, one YAC (370kb) and both BAC (140kb and 180kb) transgenic lines have been crossed with heterozygous *Frda* knockout mice. Phenotypically normal offspring that express only human frataxin, and no endogenous mouse frataxin, have been identified from all three lines. The human frataxin is expressed in the appropriate tissues at levels comparable to the endogenous mouse frataxin, and it is correctly processed and localised to mitochondria. Biochemical analysis of heart tissue shows preservation of mitochondrial respiratory chain function. Thus, we have demonstrated that human frataxin can effectively substitute for endogenous murine frataxin in the null mutant. These studies are of immediate consequence for the generation of FRDA transgenic mouse models and further contribute to the accumulating knowledge of human-mouse functional gene replacement systems.

**Gene expression alterations in tau-deficient mice.** *F. Oyama*<sup>1,2</sup>, *S.E. Kotliarova*<sup>2</sup>, *A. Harada*<sup>3</sup>, *M. Ito*<sup>4</sup>, *Y. Ueyama*<sup>4,5</sup>, *N. Hirokawa*<sup>3</sup>, *N. Nukina*<sup>2</sup>, *Y. Ihara*<sup>1,6</sup>. 1) Neuropathology, Grad Sch Med, Univ Tokyo, Tokyo, Japan; 2) Molecular Neuropathology Group, RIKEN Brain Science Institute, Saitama, Japan; 3) Cell Biology and Anatomy, Grad Sch Med, Univ Tokyo, Tokyo, Japan; 4) Central Institute for Experimental Animals, Kanagawa, Japan; 5) Pathology, Sch Med, Tokai Univ, Kanagawa, Japan; 6) CREST, Saitama, Japan.

Tau, a microtubule-associated phosphoprotein, plays an important role in determining and maintaining neuronal morphology. Its hyperphosphorylated form is the major constituent of paired helical filaments (PHF) in Alzheimers disease (AD). Recently a number of exonic and intronic mutations in the tau gene were identified in the patients affected by frontotemporal dementia and parkinsonism linked to chromosome 17 (FTDP-17). This disease is characterized by extensive neuronal loss in certain regions associated with PHF-like fibril formation. Thus, this is definite genetic evidence that tau can kill the neuron. To find an as yet unidentified role of tau in vivo, we used oligonucleotide DNA arrays profiling ~11000 mRNAs to see how the gene expression is altered in the brain from tau-deficient mice at 1 and 8 weeks of age, compared with control mice at the same ages. This microarray screening suggested that 19 and 74 genes are significantly changed at 1 and 8 week aged tau-deficient mice, respectively. To confirm the data by the microarray we performed quantitative RT PCR or ribonuclease protection assay. We found that the levels of mRNAs encoding the transcription factors, inflammatory proteins, cytokines, chemokines and growth factors are markedly increased at 8 weeks of age in the brain of tau deficient mice, while the expressions of suggested genes were not significantly altered at 1 week of age. These results indicate that tau-deficiency directly or indirectly leads to overexpression of a distinct set of genes involved in transcription and inflammation at 8 weeks of age.

**Characterization of the Kelch-like 1 (KLHL1) protein.** *Y. He, J. Nemes, M.D. Koob.* Inst Human Genetics, U of MN, Minneapolis, MN.

The KLHL1 protein is encoded by the sense mRNA of the sense/antisense transcriptional unit at the spinocerebellar ataxia type 8 (SCA8) locus on chromosome 13. We have previously reported that both the KLHL1 sense and antisense transcripts are evolutionarily conserved and are primarily expressed in brain tissues in both mouse and man. We have now begun characterization of the KLHL1 protein to determine what function this protein serves, with the ultimate goal of determining if disruption of KLHL1 function plays a role in the neuropathology of SCA8. Based on our results to date, we are hypothesizing that KLHL1 is an actin-organizing protein that is involved in either establishing or maintaining portions of the actin-cytoskeleton of the neurons in which it is expressed. Analysis of the predicted amino acid sequence of KLHL1 indicates that it contains a POZ protein-protein interaction domain that may allow KLHL1 to multimerize, and a potential actin-binding domain consisting of six KELCH repeat units. In order to experimentally determine if KLHL1 has these predicted properties, we over-expressed and purified the amino-terminal fragment of KLHL1 containing the POZ domain using an *E. coli* expression system. We found that this protein fragment does, as expected, form multimers with itself. We were also able to demonstrate that KLHL1 binds actin *in vivo* by co-immunoprecipitating actin from mouse brain protein-extracts using a purified rabbit polyclonal antibody raised against this KLHL1 fragment. Preliminary immunohistochemistry using the KLHL1 polyclonal antibody and a primary culture of mouse granule cells indicates that KLHL1 is primarily localized to actin-rich neuronal structures (e.g., growth cones and synaptic junctions). We are continuing to confirm and expand these cellular and subcellular localization studies using newly developed KLHL1 monoclonal antibodies.

**Muscleblind localizes to nuclear foci of aberrant RNA in myotonic dystrophy (DM) types 1 and 2.** *C.A. Thornton<sup>1</sup>, A. Mankodi<sup>1</sup>, C. Urbinati<sup>2</sup>, R. Moxley<sup>1</sup>, V. Sansone<sup>1</sup>, M. Swanson<sup>2</sup>.* 1) Univ Rochester, Rochester, NY; 2) Univ Florida, Gainesville, FL.

There is locus heterogeneity in DM. DM1 is caused by expansion of a CTG repeat in the DMPK gene on chr. 19. DM2 is linked to chr. 3. Pathogenic effects in DM1 are likely mediated, at least in part, by the expanded CUG repeat in mutant mRNA. The mutant transcripts are retained in the nucleus in multiple foci. Various proteins interact with CUG repeats in vitro, but none have been shown to interact in vivo. We investigated the possibility that DM2 is caused by expression of a CUG repeat or related sequence. RNase protection with a CAG-29 probe showed an expanded CUG repeat in DM1 but not in DM2 or normal controls (n=4 in each group, myoblast RNA). However, FISH using CAG probes on sections of muscle tissue showed nuclear foci in DM2 similar to those in DM1. Nuclear foci were present in muscle tissue from all patients with symptomatic DM1 (n=9) or DM2 (n=9) but not in disease or healthy controls (n=23). Foci were not seen with CUG- or GUC-repeat probes. Foci in DM2 were distinguished from DM1 by lower stability of the probe-target duplex, suggesting that a sequence related to CUG repeats accumulates in the DM2 nucleus. Furthermore, muscleblind, homologue of a protein required for muscle development in *Drosophila*, localized to the nuclear foci in both DM1 and DM2. In contrast to previous studies showing hundreds of RNA foci per nucleus in DM1 myoblasts, we found 1 to 3 foci per nucleus in muscle tissue from DM1 and DM2 patients. The foci did not associate with a specific nuclear structure, as determined by markers for nucleoli, coiled bodies, PML bodies, or perinucleolar complex. To identify proteins that interact with expanded CUG repeats in vivo, we examined muscle from transgenic mice that express expanded CUG repeats. Among 9 proteins examined, including 7 dsRNA binding proteins and CUGBP1, only muscleblind colocalized with foci of expanded CUG repeats. These results support the idea that nuclear accumulation of mutant mRNA is pathogenic in DM1, suggest that a similar disease process occurs in DM2, and point to a role for muscleblind in the pathogenesis of both disorders.

**Genotyping microarray (gene chip) for the *ABCR* (*ABCA4*) gene.** R. Allikmets<sup>1</sup>, A. Hutchinson<sup>1</sup>, K. Jaakson<sup>2</sup>, M. Külm<sup>2</sup>, H. Pavel<sup>2</sup>. 1) Dept Ophthalmology, Columbia Univ, New York, NY; 2) Asper, Ltd., Tartu, Estonia.

Variants in the *ABCR* (*ABCA4*) gene have been associated with at least five distinct macular degeneration phenotypes, including Stargardt disease (STGD), cone-rod dystrophy (CRD), and age-related macular degeneration (AMD). Comparative genetic analyses of *ABCR* variation have been complicated due to high allelic heterogeneity of the gene and differences in screening methods. To overcome these limitations, we designed a genotyping microarray (gene chip) for *ABCR*, which includes all >320 variants currently described in this gene, allowing for the detection of all known *ABCR* variants in a DNA sample in one simple reaction. The ABCR320 chip was constructed by the allele-specific primer extension (APEX) technology (described at: <http://www.asper.ee>). Every sequence change described in the *ABCR* gene was included on the chip by synthesis and application of allele-specific oligonucleotides. Screening of 150 STGD patients and 100 controls, previously analyzed by us with the SSCP technology, was performed to validate the ABCR320 chip. The microarray yielded >90% effective in determining the existing genetic variation, and proved to be comparable to direct sequencing in that it yielded many sequence changes that had gone undetected by SSCP. Moreover, the cost of screening was below 25 cents per genotype, which is at least five times less expensive than similar service currently available by any comparable technique and/or provider. The ABCR320 genotyping microarray represents the most cost-effective and comprehensive screening tool for genetic variation in one gene. This is the first instance where a gene chip is made available for the genotyping of patients with eye disease(s), including STGD/FFM, CRD, RP, and AMD. Latest results from screening patients with these phenotypes will be presented at the meeting. The ABCR chip serves as a prototype for the next generation of screening and diagnostic tools in ophthalmic genetics, and will serve as a bridge between clinical and scientific research.

**Haplotype Analysis of b-Thalassemia in Iran.** *N. Ghobadi*<sup>1</sup>, *T. Parsa*<sup>1</sup>, *B. Moghimi*<sup>2</sup>, *A.R. Noorian*<sup>2</sup>, *S. Teimourian*<sup>3</sup>, *H. Najmabadi*<sup>4</sup>. 1) Department of Genetics, University of Welfare & Rehabilitation, Evin, Tehran, Tehran, Iran; 2) Tehran University of Medical Sciences, School of Medicine, Tehran, Iran; 3) Institute of Biochemistry and Biophysics (IBB), Tehran University of Sciences, Tehran, Iran; 4) Dept Molecular Biol, Torrance, CA.

Beta thalassemia is the most common genetic disorder in Iran. Over 25 mutations have been identified so far. The objective of this study is to perform haplotype analysis of these mutations in order to determine their origin and historical background. So far we have studied 34 b-thalassemia individuals with confirmed mutations IVSII-1, C44, C8, C22 and FR36-37. We constructed a related haplotype for each mutation type in six polymorphic loci (Xmn 1, Hind III G/g, Hind II/3`wb, Rsa 1/b, Ava II/b and Hinf 1/b). Our results indicate that majority of individuals with IVS II-1, C8, C22 and FR36-37 mutations have two haplotypes while C44 mutation showed one haplotype.

**Variant Analysis of the ABCR (ABCA4) Gene in an AMD Patient Population.** *J.R. Gilbert<sup>1</sup>, S. Schmidt<sup>1</sup>, E. Postel<sup>1</sup>, C. Allen<sup>1</sup>, W. Scott<sup>1</sup>, A. Agrawal<sup>2</sup>, M. Hogan<sup>2</sup>, J. Haines<sup>2</sup>, M.A. Pericak-Vance<sup>1</sup>.* 1) Dept Medicine, Ctr Human Gen, Duke Univ, Durham, NC; 2) Program in Human Genetics, Vanderbilt Univ, Nashville, TN.

Age-related macular degeneration (AMD) is the most common cause of severe vision loss among individuals over age 50 in the U.S. The etiology of this devastating disease is unknown. Evidence implicates a combination of genetic, environmental, and biological factors in the pathogenesis of AMD. Variants in the gene encoding ABCR (ABCA4), a photoreceptor-specific ATP-binding cassette transporter, have been implicated in the etiology of AMD in some patients and families. We have begun a complete analysis of the ABCA4 gene in a large cohort of AMD families and age and sex matched controls. Two clinical subtypes of advanced AMD have been described and are referred to as an exudative (wet) form characterized by choroidal neovascularization (CNV) and a dry form characterized by geographic atrophy. Vision loss may be severe with either form. Individuals were considered unaffected if they were classified as grade 1 (no or small (<63  $\mu$ m) drusen) or grade 2 (non-extensive intermediate (>63  $\mu$ m) drusen). Individuals with extensive intermediate or any large (>125  $\mu$ m) soft drusen were classified as grade 3 and considered affected. Similarly, those with the more advanced findings of geographic atrophy (grade 4) or exudative lesions (grade 5) were considered to suffer from AMD. Initial analysis has begun with 194 individuals from 67 families. These individuals were grouped into 45 pools for rapid processing. All 50 exons of the ABCR gene including the promoter region have been subjected to mutation screening with denaturing high-performance liquid chromatography (DHPLC). Variants have been detected in multiple families for exons 3, 6, 12, 25, 29, 33, 41, 44, and 50. Variants have been detected in single families for exons 8, 30, 37 and other exons. Many families show multiple changes within the same family. A full cataloging of variants in all exons and the promoter of ABCA4 in these families will be presented.

**Gene-based screening for Y-chromosome deletions in Taiwanese men presenting with spermatogenesis failure.** *P. Kuo*. Dept OB/GYN, National Cheng-Kung Univ Hosp, Taiwan, Republic of China.

**Objective:** To develop a protocol for gene-based screening of Y chromosome deletions in men with spermatogenic failure. **Materials and Methods:** Two hundred and two infertile men presenting with severe oligozoospermia and non-obstructive azoospermia. Fifteen gene-specific markers were applied for screening of Y chromosome deletion status. Three genes are located in the AZFa region: DFFRY, DBY, and UTY. Four genes are located in the AZFb region: EIF1AY, PRY (multiple copies, also s in 4A and 6E), TTY2 (multiple copies, also in 4A) and RBM1. Three genes are located in the AZFc region: DAZ, BPY2, and CDY1. We also screened 5 genes beyond AZF region: TB4Y, BPY1, CDY2, XKRY and SMCY. A multiplex polymerase chain reaction (PCR) amplification system was developed to facilitate rapid screening. Another set of 24 STS markers was also used in all patients in order to define the position and extent of deletion. This part of experiment included 13 markers from interval 5 (sY81, sY82, sY84, sY88, sY182, sY94, sY95, sY97, sY102, sY105, sY109, sY 117, and sY127) and 11 markers from interval 6 (sY 143, sY164, sY134, sY138, RBM1 gene, sY147, sY149, sY153, sY 277, sY283, SPGY). **Result(s):** Of 180 patients evaluated, 19 were found to harbor deletions of one or more genes including DFFRY, DBY, RBM1, DAZ, CDY1 and BPY2. The deletion frequency in this series was 10.6%. Only 16 out of 19 gene-deleted patients were found to have deletions by the second round of STS screening. The 3 patients (case 1-3) in whom the deletion failed to be detected by STS markers harbor deletions of DFFRY and DBY gene, respectively. Except for these three cases, the positions and extents of deletion interval of 16 Y-deleted patients were compatible between the 2 methods. **Conclusion:** Gene-based multiplex PCR screening provides a rational alternative to detect deletion status of Y chromosomal genes in infertile men. As compared with approach based on anonymous STS markers, it provides more rational tool for genotype/phenotype correlations.

**Mutation analysis of UBE3A gene in Angelman syndrome patients.** *G.A. Molfetta*<sup>1,2</sup>, *W.A. Silva-Jr*<sup>3</sup>, *J. Wagstaff*<sup>2</sup>, *J.M. Pina-Neto*<sup>1</sup>. 1) Dept Genet, Sch Medicine, Ribeirao Preto - USP, Brazil; 2) Dept Biochem Molec Genet, Sch Medicine, University of Virginia, USA; 3) Molec Biol Lab, Cellular Therapy Center, Blood Center, Sch Medicine, Ribeirao Preto - USP, Brazil.

Angelman syndrome (AS) is a clinical condition characterized mainly by congenital hypotonia, delayed neuropsychomotor development, severe mental deficiency, loss of speech, bursts of inappropriate laughter, seizures and ataxia. Different genetic mechanisms can result in loss of expression of the gene responsible for AS: 70% are maternal 15q11-13 deletions; 7-9% are imprinting defect at the 15q11-13 region; 3-5% show paternal uniparental disomy (UPD); 4-8% present mutations in the UBE3A gene and 10-15% have no deletion, imprinting defect, UPD or UBE3A mutation. The UBE3A gene (E6-AP ubiquitin-protein ligase) is the elected gene for AS because it suffers tissue-specific imprinting in brain tissue and some point mutations in this gene lead to AS. The aim of this work was to screen for mutations in the UBE3A gene in 63 patients suspected of having AS with normal molecular analysis. We used the SSCP technique to screen for mutations in all the 16 exons from the UBE3A gene. When an abnormal shift was found the DNA sequencing was carried out and the sequences were compared with GenBank access U84404. We found that 5 cases showed abnormal shifts by SSCP. Performing the DNA sequencing we found that 3 cases had sequence variants inherited from the father and therefore not pathogenic: 1118G®A (A178T), 1003A®T (A139A) and 3UTR del114bp, the last one having already been reported. One case showed a T®C at position 9 of the intron 12 and another case showed a 3UTR dup4bp. Parental samples of this last patient were not available but we believe this is not a mutation because the abnormality is located at the 3UTR region, which has already been shown to have only benign variants. We concluded that the molecular approach here described is useful to detect abnormalities in the UBE3A gene. We would like to reinforce the use of this methodology associated with a more stringent clinical criteria, in order to better select patients that would be submitted to this molecular investigation. Supported by: FAEPA, FAPESP.

**Mutational analysis of AIRE gene in APS2 patients.** *R. Mango<sup>1</sup>, S. Guarino<sup>1</sup>, R. D'Apice<sup>1</sup>, F. Amati<sup>1</sup>, F. Sangiuolo<sup>1</sup>, P. Pozzilli<sup>2</sup>, G. Bottazzo<sup>3</sup>, A. Crinò<sup>3</sup>, R. Buzzetti<sup>4</sup>, G. Novelli<sup>1</sup>.* 1) Dept. of Biopathology, Tor Vergata University, Rome, Roma, Italy; 2) Dept. of Internal Medicine, Tor Vergata University, Rome, Italy; 3) Ospedale Bambino Ges, Rome, Italy; 4) Dept. of Internal Medicine, La Sapienza University, Rome, Italy.

Autoimmune polyendocrine syndrome, type II; (APS2, OMIM 269200), is characterized by adult onset adrenal failure associated with type I diabetes and/or hyperthyroidism. APS2 is believed to be polygenic, characterised by dominant inheritance and association with HLA DR3. In the effort to identify genes involved in this syndrome, we decided to perform a mutational analysis of the coding region the autoimmune regulator (AIRE) gene in a group of 29 patients. AIRE gene represents the causative gene for APECED (autoimmune polyendocrinopathy-candidiasis ectodermal dystrophy) or APS1 (OMIM 240300). All fourteen exons of AIRE gene, were amplified from genomic DNA with primers located in respective flanking introns and analysed with DHPLC. We detected an heteroduplex peak in a patient, the following sequencing reaction showed a C®T transition at 717nt that resulted in a silent mutation. However this mutation was absent in a group of 50 controls. The same patient showed a C®A transversion in intron 7 (IVS7 41 C®A). An additional polymorphism was detected in intron 10 (IVS10 5G®A) in three patients. This variant was also detected in the control group. These results rule out the role of AIRE gene in etiology of autoimmune polyendocrine syndrome type II.

**The Arginine to Tryptophan Mutation in Codon 394 of the Wilms' Tumor Gene (R394W), a Mutation Hotspot for Denys-Drash (DDS) and Frasier syndromes (FS), is Uncommon in Primary Sporadic Focal Segmental Glomerulosclerosis (FSGS).** *S.M. Orloff<sup>1</sup>, S.K. Iyengar<sup>1</sup>, W. Briggs<sup>3</sup>, R. Dart<sup>3</sup>, S. Kobert<sup>3</sup>, M. Mokryzcki<sup>3</sup>, D. Vlahov<sup>3</sup>, P. Kimmel<sup>3</sup>, T. Ahuja<sup>3</sup>, J. Berns<sup>3</sup>, E. Simon<sup>3</sup>, M. Smith<sup>3</sup>, H. Trachtman<sup>3</sup>, M. Michel<sup>3</sup>, C. Winkler<sup>2</sup>, J.R. Schelling<sup>1</sup>, J.R. Sedor<sup>1</sup>, J.B. Kopp<sup>2</sup>.* 1) Epidemiology and Biostatistics and Medicine, Case Western Reserve Univ, Cleveland, OH; 2) NIH-NIDDK, Bethesda, MD; 3) Other.

Heterozygous mutations in the Wilms' tumor (WT1) gene are associated with early onset, diffuse mesangial sclerosis (DMS) and FSGS as part of DDS and FS. Based on evidence from rare DDS and FS patients, we hypothesized that WT1 mutations occur in sporadic, more common, forms of glomerular scarring, and confer risk to progressive nephropathy. To test our hypothesis, patients with primary FSGS enrolled in a multi-center study were screened for the R394W WT1 mutation, which functions in trans to inhibit wild type WT1 function. Our study is largest mutation analysis conducted to determine if variants at WT1 cause idiopathic FSGS. Cases, recruited at 13 US Medical centers, were African American (AA) (62F, 109M), Caucasian (15F, 29M), Hispanic (4F, 6M) or Asian (3F) with primary renal disease (idiopathic, heroin, HIV and collapsing FSGS). AA controls (143M, 50F) were HIV seropositive, with HIV duration > 8 years, with no clinical evidence of renal disease as demonstrated by serum creatinine < 1.5mg/dl and urine protein/creatinine < 0.05. The 224 base pair (bp) exon 9 product was digested with Hpa II. Hpa II digested, wild type, arginine-containing, alleles generate fragments of 118 and 106 bps, while the mutation-bearing alleles were undigested. We found only one case and one control that carried the homozygous R394W mutation, and no heterozygotes. We conclude that the WT1 R394W mutation is not common in sporadic FSGS and the presence of this mutation in a control suggests it is insufficient to cause disease. Further mutation analyses of WT1 may identify nephropathy risk alleles.

**Alpha 1- antichymotrypsin gene analysis in allergic asthmatic children.** *C. Quinzii, C. Bombieri, G. Malerba, P.F. Pignatti.* Section of Biology & Genetics, DMIBG, University of Verona, Verona, Italy.

Asthma is a complex disease, phenotypically heterogeneous, associated with intermittent respiratory symptoms, bronchial hyperresponsiveness (BHR), atopy and reversible airflow obstruction. This disease results from exposure to environmental factors in genetically susceptible individuals. Linkage analysis and transmission disequilibrium test on chromosome 14 markers in 189 families (847 individuals) with asthmatic children suggested that alpha 1-antichymotrypsin gene (AACT) or a closely located gene may be involved in susceptibility to allergic asthma, in particular to BHR (*J Allergy Clin Immunol* 2000; 107:654). We now report an analysis for AACT gene mutations in a sample of 19 asthmatic children from North East Italy, characterized for atopy, hyperresponsiveness to metacholine, total serum IgE levels, skin prik test (SPT), and clinical asthma, and selected for the presence of BHR positivity among the above cited patients, and in 18 healthy controls tested for the same phenotypes. Denaturing gradient gel electrophoresis (DGGE) was performed for exons 1, 3, 4 and 5 and their intronic flanking regions; direct sequencing is being performed for exon 2. DGGE screening showed the presence of a mutation in 1 asthmatic patient and in 2 control subjects, respectively. At the moment only one of the mutations is characterized: a newly described mutation 834 A@C in exon 3 (Ala 249 Ala), of one control subject. Sequencing of the other two mutations, and of exon 2 is proceeding. Presently available data do not indicate an association between alpha 1-antichymotrypsin mutations and allergic asthma in addition to the Thr-15Ala polymorphism previously reported.

**Increased noise as an effect of haploinsufficiency of the tumor suppressor gene Neurofibromatosis type 1 in vitro.**

*D. Kaufmann*<sup>1</sup>, *S. Schrank*<sup>2</sup>, *H. Gruler*<sup>2</sup>, *W. Vogel*<sup>1</sup>, *R. Kemkemer*<sup>2</sup>. 1) Dept of Human Genetics, University of Ulm, D 89070 Ulm, Germany; 2) Dept of Biophysics, University of Ulm, D 89070 Ulm, Germany.

In human diseases related to tumor suppressor genes, it is suggested that only the complete loss of the protein results in specific symptoms such as tumor formation, whereas simple reduction of protein quantity leading to haploinsufficiency essentially does not affect cellular behavior. Using a model of gene expression it was presumed that haploinsufficiency is related to an increased noise in gene expression also in vivo (Cook et al.1998). Here, we demonstrate that haploinsufficiency of the tumor suppressor gene Neurofibromatosis type 1 (NF1) results in an increased variation of dendrite formation in cultured NF1 melanocytes. These morphological differences between NF1 and control melanocytes can be described by a mathematical model where the cell is considered as a self-organized automaton. The model describes the adjustment of the cells to a set point and introduces some noise into that process. It fits the experimental data of control and NF1 melanocytes. In the cells haploinsufficient for NF1 we found an altered signal-to-noise ratio detectable as increased variation in dendrite formation in 2 out of 3 investigated morphological parameters. We also suggest that in vivo NF1 haploinsufficiency results in an increased noise in a cellular regulation and that this effect of haploinsufficiency might be found also in other tumor suppressors.

**A common P-glycoprotein polymorphism is associated with nortriptyline-induced postural hypotension in patients treated for major depression.** *M.A. Kennedy<sup>1</sup>, R.L. Roberts<sup>1</sup>, R.T. Mulder<sup>2</sup>, P.R. Joyce<sup>2</sup>*. 1) Department of Pathology, Christchurch School of Medicine, University of Otago, Christchurch, New Zealand; 2) Department of Psychological Medicine, Christchurch School of Medicine, University of Otago, Christchurch, New Zealand.

The human multi-drug resistance gene *ABCB1* encodes the P-glycoprotein (P-gp) that regulates movement of many substances across the blood-brain barrier. Evidence from a knockout mouse lacking P-gp (Uhr et al. 2000; *Neuropsychopharmacology* 22,380-387) suggests that the TCA amitriptyline and its metabolites are substrates for P-gp. In these mice penetration of amitriptyline, but not the SSRI fluoxetine, into the brain is enhanced. We reasoned that polymorphisms of P-gp may affect responses of patients to antidepressant drugs. A polymorphism of *ABCB1* (3435C>T) was recently correlated with expression levels and in vivo function of P-gp (Hoffmeyer et al. 2000; *PNAS* 97,3473-3478). We developed a DNA test for this SNP, and genotyped 165 Caucasian patients with major depression enrolled in a randomized antidepressant treatment trial of nortriptyline and fluoxetine. We observed a significant association between nortriptyline-induced postural hypotension (NIPH) and 3435C>T (chi-square = 6.75, df = 2.73, p=0.034). Of nortriptyline-treated patients, 25% (4 of 16) who were TT and 7% (3 of 43) who were heterozygous suffered symptomatic NIPH. None of the 17 patients who were CC and no fluoxetine-treated patients experienced postural hypotension. Our results suggest that presence of one or more T alleles at the 3435C>T polymorphism of *ABCB1* is a risk factor for occurrence of NIPH.

**Investigation of relation of NOD2 mutations to treatment response to infliximab and clinical course of Crohn's Disease.** *J. Hampe<sup>1</sup>, S. Mascheretti<sup>1</sup>, J. Grebe<sup>1</sup>, P.J.P. Croucher<sup>1</sup>, K. Huse<sup>2</sup>, H. Frenzel<sup>1</sup>, S. Nikolaus<sup>1</sup>, S. Schreiber<sup>1</sup>.* 1) General Internal Medicine, University Kiel, Kiel, Germany; 2) Institute for Molecular Biotechnology Jena, Germany.

Genetic predisposition to inflammatory bowel disease (IBD) has been demonstrated by epidemiological and linkage studies. Genetic linkage of IBD to chromosome 16 has been previously observed and replicated in independent populations. Recently, NOD2 has been identified as the first susceptibility gene for Crohn's Disease on chromosome 16 in four different populations. NOD2 has a strong influence on the activation of NFkB.

We investigated the influence of three mutations in the leucine-rich region of the NOD2 gene on treatment response to infliximab (Anti-TNF-alpha antibody) in a cohort of 93 patients treated in a controlled clinical trial. The influence of NOD2 variants on the natural course of disease was investigated in 180 prospectively and 200 retrospectively characterized German Crohn's Disease patients.

No significant association of NOD2 variants with the response to infliximab treatment was found. Further investigation is needed to define the influence of NOD2 variation of treatment response and clinical course of Crohn's Disease.

**MAPPING OF GENES IN THE AUTISTIC DISORDER REGION ON CHROMOSOME 15q11-q13.** *S.J. Kim, M.M. Menold, J. Stajich, M.A. Pericak-Vance, J.R. Gilbert.* Department of Medicine and Center for Human Genetics, Duke University Medical Center, Durham, NC 27710.

Chromosome 15q11-q13 has been implicated in the genetic etiology of autistic disorder (AutD). To identify candidate AutD genes, a physical contig map was generated from the GABRB3 receptor to the OCA2 gene. To characterize AutD candidate genes within the genomic contig, 28 BAC, PAC and P1 clones containing numerous rare restriction sites were analyzed using Island Rescue PCR (IR-PCR). 150 EagI, BssHII and SacII related CpG island sites were cloned, sequenced and analyzed. BAC/PAC sequencing and multiple comparison analysis have identified 83 unique clones. All IR-PCR clones had the characteristics of 5' end of gene or promoter sequence. 45 unique CpG islands met full CpG island criteria. 31 CpG island clones were mapped onto the human genomic draft contigs spanning the region from GABRB3 gene to the APBA2 gene. 14 CpG clones including GABRG3 and APBA2 showed expression in human fetal brain tissue. mRNA homology searching results performed by BLAST analysis for 31 CpG island clones included known GABRG3 gene, APBA2 gene and E1-E2 ATPase gene as well as 16 ESTs. 13 IR-PCR clones were very close to CpG island criteria. 25 IR-PCR clones did not meet CpG island criteria. 13 clones showed expression in human fetal brain tissue. 9 clones showed a homology to ESTs. Transcript map in this region was generated with CpG island gene markers along the contig. Five known genes including GABAA receptor subunits, APBA2, and numerous ESTs colocalized with CpG islands in this region and are candidates with AutD gene(s). Currently, we are investigating CpG island SNPs in this region for association with AutD. This island rescue system will allow us to investigate the methylation status and alterations of genes within the AutD region in tissues.

Program Nr: 2353 from the 2001 ASHG Annual Meeting

**Genetic analysis of attention network efficiency.** *J.A. Fossella, J. Fan, Y. Wu, T. Sommer, D. Pfaff, M.I. Posner.*  
Sackler Institute for Developmental Psychobiology, Department of Psychiatry, Weill Medical College, Cornell University, New York, NY.

Attention can be viewed in terms of neural networks that carry out specific functions. Each of these networks appears to be modulated by somewhat different neuromodulatory system. Studies of alert monkey suggest that the effectiveness of alerting produced by a warning signal can be eliminated by drugs that block noradrenaline. The executive network involves the anterior cingulate, which is modulated by dopamine from the ventral tegmental area. Our genetic analysis seeks to determine the contributions of noradrenergic and dopaminergic genetic variation to the efficiency of alerting and executive networks, respectively. As a first step, the heritability of both networks was determined. The Attention Network Task (ANT) was administered to 26 MZ twins and 26 age matched and same sex DZ twins. For the executive network (incongruent minus congruent RTs) the MZ twins showed a correlation of (0.73) and the DZ twins of (0.28). For this network the heritability was estimated ( $h^2 = 0.90$ ). For alerting, both MZ twins (.46) and DZ twins (.37) showed high correlations producing a much lower estimate of heritability ( $h^2 = 0.18$ ). ANT data have also been collected for a population of normal subjects ( $N = 200$ ). PCR-RFLP analysis of buccal swab DNA was used to detect variation in genes involved in dopaminergic and noradrenergic signaling. Results relating polymorphisms in these genes to the appropriate networks using ANT RTs will be presented.

**Chromosome 21 Promoter Activity and Polymorphism Effects.** *S.L. Coleman, C.A. Guy, B. Hoogendoorn, S.K. Smith, M.C. O'Donovan, P.R. Buckland.* Psychological Medicine, UWCM, Cardiff, Wales.

Chromosome 21 was the first chromosome to be completely sequenced and for this reason was chosen to identify putative promoters using the NCBI database. A total of 70 putative promoters were identified of which 50 were optimised for PCR. In order to confirm that the sequences identified were promoter regions all 50 PCR products were pooled in equal concentrations, ligated into a pGL3 T-vector and transformed. Sequencing identified 20 clones with the correct insert orientation. The pGL3 vector permits a simple luciferase assay to be carried out on cells that are transfected with pGL3 plasmids containing the test promoter, where the luciferase activity can be read in a luminometer. In comparison to the negative control of basic-pGL3, 90% were proven to have promoter activity in the three cell lines transfected (HEK 293t, JEG-3 and TE 671) and 20% showed higher promoter activity than the control pGL3-SV40. Due to the successful identification of promoter regions in the initial findings the original 50 putative promoters were screened with DHPLC for common polymorphisms using a screening set of 16 individuals. Of the 50 putative promoters 29 were identified as heterozygous. Each allele of the polymorphism was cloned into pGL3 and again transfected into the 3 cell lines. The luciferase activity for each allele was compared with its pair to see the effect of the polymorphism on promoter activity, with significant differences identified.

**Identification of a Molecular Variant at the Promoter Region of Human Reelin Gene and Association Study with Schizophrenia.** *C.H. Chen<sup>1,2</sup>, M.L. Chen<sup>1</sup>, S.Y. Chen<sup>3</sup>, C.H. Huang<sup>2</sup>*. 1) Dept Psychiatry, Tzu-Chi General Hosp, Hualien City, Taiwan; 2) Institute of Human Genetics, Tzu Chi University, Hualien, Taiwan; 3) Department of Life Sciences, Tzu Chi University, Hualien, Taiwan.

Reelin protein is essential for embryonic brain development as guiding the normal neuron migration and correcting cortical lamination. Recent studies indicated that reduction of reelin expression in the brain might be a vulnerability factor in schizophrenia. We hypothesized that functional polymorphism at the promoter region of the reelin gene might confer genetic susceptibility for schizophrenia. We searched for molecular variants at the promoter region of human reelin gene using single strand conformation polymorphism analysis, PCR direct sequencing and restriction fragment length polymorphism analysis in a cohort of Chinese schizophrenic patients from Taiwan. A G to C single nucleotide polymorphism at nucleotide position 888 upstream from translation initiation site was identified. This polymorphism was found to alter the Sp1 and/or hsp70.2 transcription factor binding sites by computer analysis. Further case control association study, however, did not reveal differences of genotype and allele frequency distributions between schizophrenic patients and comparison subjects. Our data suggest that this polymorphism at the promoter region of the reelin gene is not associated with schizophrenia, and there might be other factors that account for the decreased reelin expression in the brain of schizophrenic patients.

**Defective Inhibition of b-Catenin Signaling in Variants of SOX1 from Spina Bifida Patients.** *J.S. Nye<sup>1,4</sup>, L. Kan<sup>1</sup>, J. Luo<sup>1</sup>, V. Reddy<sup>1</sup>, S.G. Guy<sup>1</sup>, Z. Gu<sup>1</sup>, M. Matsumata<sup>2</sup>, Y. Kamachi<sup>2</sup>, J. Charrow<sup>1,4</sup>, J.F. Sarwark<sup>1,4</sup>, H. Kondoh<sup>2</sup>, M.C. Speer<sup>3</sup> and NTD Collaborative Group.* 1) Northwestern Univ Medical Sch, Chicago, IL; 2) Institute of Molecular and Cellular Biology, Osaka University, Osaka 565, Japan; 3) Center for Human Genetics, Duke University Medical School, Durham NC 27710, USA; 4) Childrens Memorial Hospital, Chicago IL.

Multiple genes are likely to contribute to the risk of neural tube defects (NTDs), but few genetic risk factors have been identified. Since deletions of a critical region of chromosome 13q33-34 are associated with NTDs, this region may contain one or more genes that are defective in patients with normal karyotypes. SOX1 is a Sry-class transcription factor encoded on 13q34 that is expressed in the neural plate, promotes neural development in model systems, and contains short imperfect repeats encoding one polyglycine and four polyalanines. Here we identify in-frame insertions and deletions in spina bifida patients and controls in these repetitive regions, revealing that the SOX1 protein is highly variable. Unique variants and genotypic combinations were identified in patients, but these were too rare to test for their contribution to risk. However, two of the alleles found in patients were defective in their ability to suppress b-catenin signal transduction, despite their ability to bind b-catenin and their ability to activate a target of group B SOX proteins, the d-crystalline promoter. These two variant SOX1 proteins functioned as dominant negatives when combined with wildtype proteins. Other variants showed a spectrum of activity in suppressing b-catenin signaling. These data suggest that defective modulation of b-catenin signaling may exist in individuals with spina bifida carrying certain SOX1 variants. Since numerous studies have shown that b-catenin signaling and the Wnt/wg pathway are critical for early neural development, these observations imply that variant forms of SOX1 may contribute to neural tube defects. Supported by the NICHD and NINDS.

**SNP analysis of candidate genes for isolated cleft lip and palate.** *R. Ingersoll<sup>1</sup>, S. Rowe<sup>1</sup>, M. Campbell<sup>1</sup>, L. Kasch<sup>1</sup>, I. McIntosh<sup>1</sup>, T. Beaty<sup>2</sup>, A.F. Scott<sup>1</sup>.* 1) Institute of Genetic Medicine, Johns Hopkins University School of Medicine; 2) Department of Epidemiology, School of Public Health, Johns Hopkins University.

We are investigating the genetics of non-syndromic cleft lip and palate by identifying single nucleotide polymorphisms (SNPs) in candidate genes identified by linkage analysis, animal models or presumed function. SNPs are identified in coding region, 3' UTR and promoter sequences by PCR amplification and direct sequencing of DNAs from unrelated parents of 15 probands. We are taking advantage of the increasingly complete human genome sequence and NCBI resources such as OMIM, LocusLink and Map Viewer to identify genes and genomic sequence. Sequences are aligned manually and visually inspected for differences. As of June 2001, PCR primers have been designed for 408 exons from 44 genes. Three genes have been completely sequenced (45 amplicons) and 20 additional exons have been completed from other genes. A total of 92 SNPs have been identified of which 18 occur in exons and eight of which result in amino acid changes. Allele frequencies will be determined for each SNP in a collection of trios obtained through a proband with a non-syndromic oral cleft (cleft lip with or without cleft palate and cleft palate only). Previous studies of these case-parent trios have shown evidence of linkage in the presence of disequilibrium for several candidate genes, in particular MSX1 and TGFB3. Both of these genes have been screened and a number of novel SNPs were identified.

**An association study of SNAP-25 alleles shows evidence for biased paternal inheritance in Attention Deficit Hyperactivity Disorder.** V. Kustanovich<sup>1</sup>, B. Merriman<sup>1</sup>, L. Crawford<sup>1</sup>, S. Smalley<sup>2</sup>, S. Nelson<sup>2</sup>. 1) Dept Human Genetics, Univ California, Los Angeles, Los Angeles, CA; 2) UCLA Center for Neurobehavioral Genetics, UCLA, Los Angeles, CA.

**Research Goals:** Attention Deficit Hyperactivity Disorder (ADHD) is one of the most common childhood neuropsychiatric disorders with an estimation of 3%-10% of school age children affected worldwide. Although the biological basis of this disorder is unknown, there is persuasive evidence that susceptibility to ADHD is in part genetically inherited. A recently implicated gene is the synaptic vesicle docking fusion protein, synaptic-associated protein of 25 kDa (SNAP-25). SNAP-25 has been shown to be causal in the hyperactive behavior of the mouse mutant *coloboma* (Cm/+). We have sought to define a possible association between this gene and ADHD.

**Methods:** All child and adolescent probands were assessed by direct interview using the K-SADS-PL. All adult probands and parents were assessed by direct interview with the SADS-LA-IV. Parental reports of child symptoms were obtained and, for children older than 8 years old, self-reports of symptoms were also obtained. In all cases, the structured interviews were supplemented with teacher and parent rating scales. Experienced clinical psychologists, trained on instruments of ADHD diagnosis, carried out all the interviews. We have implemented a fluorescence polarization template directed incorporation assay of single nucleotide polymorphisms (SNPs) in order to genotype over 550 individuals. Genotypes were gathered by AlleleCaller. Mendelian inheritance was verified by CheckMendel and TDT analysis was performed by TDT-SNPster.

**Results:** Here we report the confirmation of a genetic association between ADHD and two polymorphisms of SNAP-25 (T1065G and T1069C). We have tested and confirmed this association within multiplex families within our sample by the transmission disequilibrium test ( $c^2 = 4$ ,  $P = 0.045$ ). Further, we find convincing evidence of a paternal transmission bias of the SNAP-25 haplotype to affected children ( $c^2 = 9$ ,  $P = 0.003$ ).

**Codon 12 polymorphism of the peroxisome proliferator-activated receptor  $\gamma$  gene is not associated with body mass index or breast cancer.** A. Memisoglu<sup>1</sup>, S.E. Hankinson<sup>1,2</sup>, J.E. Manson<sup>2,3</sup>, G.A. Colditz<sup>1,2</sup>, D.J. Hunter<sup>1,2</sup> and Nurses Health Study. 1) Epidemiology, Harvard School of Public Health, Boston, MA; 2) Channing Laboratory, Dept. of Medicine, Harvard Medical School and Brigham and Women's Hospital, Boston, MA; 3) Preventive Medicine, Dept. of Medicine, Harvard Medical School, Boston, MA.

Estrogen-induced cell proliferation is thought to underlie breast carcinogenesis. In addition to its role in the transcriptional regulation during adipocyte differentiation, studies indicate that the peroxisome proliferator-activated receptor $\gamma$  (PPAR $\gamma$ ) transcription factor is involved in transcriptional regulation of aromatase, a key enzyme in estrogen biosynthesis. Specific agonists for PPAR $\gamma$  induce differentiation and suppress markers of malignancy in breast cancer cells suggesting that PPAR $\gamma$  may be involved in breast carcinogenesis. The proline to alanine polymorphism in codon 12 (Pro12Ala) of PPAR $\gamma$  affects PPAR $\gamma$ 's DNA binding and transactivation ability. Here we determined the association of the Pro12Ala PPAR $\gamma$  polymorphism with breast cancer in a case-control study nested within the Nurses Health Study. 725 incident cases of breast cancer and 953 matching controls were included and no association was observed between PPAR $\gamma$  Pro12Ala polymorphism and breast cancer (odds ratio of 1.08 (0.85-1.38) for variant allele carriers compared to non-carriers). Further, serum levels of estrone sulfate, estrone, estradiol, testosterone and androstenedione were similar among PPAR $\gamma$  genotypes. In contrast to some reports, BMI of individuals in this study did not vary with PPAR $\gamma$  genotype. However, an association between PPAR $\gamma$  genotype and age at menarche was observed. Mean age of menarche for homozygous individuals bearing only the variant alanine allele was 13.32 years compared to 12.49 and 12.52 years for heterozygotes and homozygotes bearing only the common proline allele, respectively ( $p=0.005$ ). Thus, although an association between the Pro12Ala PPAR $\gamma$  polymorphism and plasma estrogens or breast cancer risk was not observed, this genetic variant may alter estrogen-dependent developmental programs such as the timing of menarche.

**The (TG)<sub>n</sub> promoter polymorphism in the NRAMP1 gene and susceptibility to sarcoidosis.** *T.A. Wischmeijer<sup>1</sup>, C. Bombieri<sup>1</sup>, M. Luisetti<sup>2</sup>, P.F. Pignatti<sup>1</sup>.* 1) Section of Biology & Genetics, DMIBG, University of Verona, Verona, Italy; 2) Inst. Respiratory Diseases, IRCCS, S.Matteo, University of Pavia, Pavia, Italy.

Sarcoidosis is a multisystem granulomatous disorder of unknown etiology, that may represent an immunologic response to an exogenous agent in a genetically susceptible individual. The human natural resistance-associated macrophage protein 1 (NRAMP1) gene encodes a pH-dependent divalent cation transporter involved in macrophage function. A functional repeat polymorphism in the promoter of NRAMP1 has been described. In different populations, allele 2 occurs at an allele frequency of about 0.20-0.25 and has been correlated to infectious disease susceptibility. Allele 3 occurs at an allele frequency of about 0.75-0.80, and has been associated with susceptibility to autoimmune disease. The other described alleles are rare (allele frequencies less than 0.001). In a report on a case-control study in African American sarcoidosis patients, Maliarik et al. (*Am J Respir Cell Mol Biol* 2000;22:672-675) suggested that allele 2 may decrease susceptibility to sarcoidosis. We performed a case-control association study in 51 Italian sarcoidosis patients and 80 Italian control subjects, to test whether the (TG)<sub>n</sub> promoter polymorphism in NRAMP1 is associated with susceptibility to sarcoidosis. Individuals with genotype 3,3 were more common in sarcoidosis: 29/51 (57%) vs. 33/80 (41%) in controls. The difference is not statistically significant. Of 102 alleles of sarcoidosis patients, we found 22/102 (22%) alleles 2 and 77/102 (75%) alleles 3. There were 3/102 (3 %) other alleles. In 160 control alleles 50/160 (31%) could be identified as allele 2 and 107/160 (67%) as allele 3. We found 3/160 (2%) other alleles in the control group. In accordance with Maliarik et al., we found a decreased frequency of allele 2 in sarcoidosis patients compared to controls. However, we can't support the hypothesis of a protective effect of allele 2, since the results in our population are not statistically significant.

**Association study of polymorphisms in the glutamate receptor genes, *GRM2* and *GRIK1* with Japanese schizophrenia.** H. Shibata<sup>1</sup>, A. Joo<sup>1</sup>, Y. Fujii<sup>1</sup>, A. Tani<sup>1</sup>, C. Makino<sup>1</sup>, N. Hirata<sup>1</sup>, R. Kikuta<sup>1</sup>, H. Ninomiya<sup>2</sup>, H. Kawasaki<sup>2</sup>, N. Tashiro<sup>2</sup>, Y. Fukumaki<sup>1</sup>. 1) Research Center for Genetic Information, Medical Institute of Bioregulation, Kyushu University, Fukuoka, JAPAN; 2) Department of Neuropsychiatry, Graduate School of Medical Sciences, Kyushu University, Fukuoka, JAPAN.

Upon the glutamatergic dysfunction hypothesis for schizophrenia, glutamate receptor genes are strong candidates for susceptibility genes of the disorder. We screened polymorphisms in two glutamate receptor genes: the metabotropic glutamate receptor type 2 gene, *GRM2* and the kainate receptor type 1 gene, *GRIK1*, and examined putative association of the polymorphisms with schizophrenia. We recruited both schizophrenics (n = 213) and healthy controls (n = 220) from Kyushu area in Japan. All specimens are unrelated and ethnically Japanese. We identified 13 SNPs (ten missense, one synonymous, two in the noncoding exon) in the entire exons and four polymorphisms (one SNP and three indels) in the 5' upstream region of *GRM2* by PCR-SSCP and direct sequencing. We genotyped the entire samples of both schizophrenics and controls for all the 17 polymorphic sites. The observed frequencies of the polymorphisms were low (< 2 %) both in schizophrenics and controls. There is no significant differences in allele frequencies of all tested polymorphisms in *GRM2*. We also identified six SNPs (three missense, three synonymous) in the entire exons of *GRIK1* by the same methods. Since only three SNPs (one missense, two synonymous) among the six were commonly observed in the polymorphism scanning process (> 7 %), the extensive genotyping for the three major SNPs in *GRIK1* was performed against the entire samples of schizophrenics and controls. From the observed allele frequencies, we estimated haplotype frequencies of the three SNPs using the EH program. There is no significant association of schizophrenia with the SNPs and their haplotypes in *GRIK1* locus. Therefore, we conclude that neither *GRM2* nor *GRIK1* plays a major role in schizophrenia pathogenesis in the Japanese population.

**Major structural polymorphisms in the nicotinic acetylcholine receptor  $\alpha$ -7 Subunit (CHRNA7) partial duplication on chromosome 15q13-q14.** *B.P. Riley<sup>1</sup>, M. Williamson<sup>2</sup>, D. Collier<sup>3</sup>, H. Wilkie<sup>3</sup>, A. Makoff<sup>3</sup>.* 1) Dept. of Psychiatry, Virginia Commonwealth Univ., Richmond, VA; 2) Department of Paediatrics, University College London Medical School, London, UK; 3) Division of Psychological Medicine, Institute of Psychiatry, De Crespigny Pk., London, UK.

We have reported evidence of linkage and haplotype transmission disequilibrium between schizophrenia and markers in the region of CHRNA7 and its nearby partial duplication. The 95-99% identity between gene and duplication, and between the multiple copies of novel exons associated with the duplication, necessitated the identification of unique positions in this complex region of chromosome 15q13-q14. We identified five distinct sequences, four of which map to 15q13-q14, from 5'-RAGE clones: those representing the gene and duplication, two distinct versions of the novel exons, and an unknown kinase gene mapped to chromosome 3 from which most but not all of the novel exons originate. The physical map assembled from these clones reveals two kinds of variation involving major structural differences. First, the partial duplication is polymorphic. Second, where present, it can exist in either orientation. Finally, a number of previously identified sequence variants, including a 2 bp deletion in exon 6, exist in the duplication. We are currently developing assays to determine the copy number and orientation of the partial duplication using real time PCR and multicolor FISH in order to obtain detailed genotypes and haplotypes of variants in the region in our family sample.

**Analysis of the Leptin receptor SNP, GLN223ARG, in anorexia nervosa.** *D.W. Meechan<sup>1</sup>, N.D. Quinton<sup>2</sup>, L.F. Pieri<sup>3</sup>, K.M.O. Brown<sup>4</sup>, H.E. Eastwood<sup>4</sup>, A.I.F. Blakemore<sup>5</sup>*. 1) Biomedical Research Centre, Sheffield Hallam University, Sheffield, S1 1WB UK; 2) School of Biomedical Sciences, University of Leeds, Leeds, LS2 9JT, UK; 3) Yorkshire Centre Eating Disorders, Seacroft Hospital, Leeds, UK; 4) Molecular Medicine Unit, University of Leeds, St James Hospital, Leeds, UK; 5) Imperial College of Science, Technology and Medicine, Kennedy Galton Centre, Level 8V, Northwick Park Hospital, Watford Road, Harrow, HA1 3UJ, UK.

Anorexia nervosa is a complex disorder of unknown aetiology, characterised by abnormal eating and purging behaviours with the express aim of reducing body weight. Leptin, a cytokine expressed and secreted by the adipose tissue, is involved in the regulation of body weight. Recent reports have indicated that leptin levels are reduced in underweight anorexic patients and these levels correlate with decreased body mass index (BMI). During recovery, leptin levels progressively increase to reach higher than expected levels for the body weight.

We, and others, have shown an association between the leptin receptor SNP, GLN223ARG, and fat mass, body mass index (BMI) and leptin levels in Caucasian post-menopausal women. The aim of this study was to determine whether this association could also be found in young female, Caucasian control subjects and whether this SNP is associated with anorexia nervosa. 175 subjects with anorexia nervosa (divided into bingeing/purging and restricting anorexics) were recruited from the Yorkshire Centre for Eating Disorders at Seacroft Hospital. 145 controls were recruited from the University of Leeds. In both cohorts, genotype and allele frequencies for GLN223ARG, did not differ significantly from published frequencies. There was no significant difference in genotype frequency between the control and the anorexic cohorts or between restricting and bingeing subjects with anorexia and there was no correlation with BMI in patients or controls. This may reinforce existing evidence that this SNP is associated with adiposity in middle-aged, but not young subjects.

**Association study of SNPs in 26 candidate genes involved in blood pressure variation in an isolated population.** *L. Jin*<sup>1,2,3</sup>, *Z. Jiang*<sup>2,3</sup>, *J. Shi*<sup>3</sup>, *H. Chen*<sup>2</sup>, *J.M. Akey*<sup>1</sup>, *W. Huang*<sup>3</sup>. 1) Environmental Health, University of Cincinnati, Cincinnati, OH; 2) Institute of Genetics, Fudan University; 3) National Human Genome Center at Shanghai.

Twenty-six candidate genes implicated in blood pressure (BP) regulation were selected, fifteen from candidate regions based on whole genome scanning and linkage disequilibrium analyses and eleven based on their biological functions. We identified 286 SNPs in the promoter regions, exons, and intron-exon junctions of these genes (124kb in length) by sequencing 80 individuals with blood pressure chosen from the two tails of the blood pressure distribution in an isolated Chinese population. Approximately 21 SNPs detected in 9 genes showed significant allele frequency differences between the high and low BP groups. Extended genotyping in larger samples showed that the association between four genes and BP remained. The genetic diversity of this isolated population is generally smaller compared to African and European populations. The majority of the SNPs found in this study are absent in the African and European populations challenging the rationale of the recent SNP discovery effort. Further analyses showed that no population expansion or population stratification was present in this population, while evidence for natural selection is also absent in all the genes studied except one.

**Functional analysis of promoter variants in the  $\alpha 7$  nicotinic receptor gene in normal and schizophrenic individuals.** *J.M. Gault<sup>1</sup>, J. Logel<sup>2</sup>, C. Drebing<sup>1</sup>, J. Hopkins<sup>2</sup>, M. Short<sup>2</sup>, R. Vianzon<sup>1</sup>, D. Venn<sup>1</sup>, K. Walton<sup>1</sup>, R. Berger<sup>1</sup>, B. Sullivan<sup>1</sup>, M. Maslak<sup>2</sup>, M. Robinson<sup>1</sup>, R. Freedman<sup>1,2</sup>, S. Leonard<sup>1,2,3</sup>.* 1) Dept Psychiatry, Univ Colorado Health Sci Ctr, Denver, CO; 2) VA Medical Center, Denver, CO; 3) Dept Pharmacology, Univ Colorado Health Sci Ctr, Denver, CO.

The  $\alpha 7$  neuronal nicotinic receptor subunit (CHRNA7) has an important role in the P50 auditory gating deficit found in many schizophrenics as shown by pharmacological investigation in humans and rodents. Samples from 167 controls and 192 schizophrenics of Caucasian (64%), African American (32%) and Hispanic (4%) descent were analyzed for proximal promoter mutations. Sequence and single strand conformational polymorphism (SSCP) analysis identified 11 unique single bp variants, 11 different combinations of double bp variants and 2 individuals with multiple base insertions in the 231bp promoter region upstream of the ATG translation start site. Functional analysis of 8 polymorphisms, using a luciferase reporter gene assay in transfected SHSY-5Y neuroblastoma cells, shows a statistically significant drop in the transcriptional activity of 8 to 38% for 6 of the 8 variants examined ( 86C@T, 92G@A, 143G@A, 178delG, -194G@C, and 241A@G). These six variants were more prevalent in schizophrenics than controls (controls 15% vs. schizophrenics 26%,  $p=0.0137$ ). The most frequent variant, 86 C@T, decreases promoter activity by 18% ( $p<0.0001$ ) and is associated with schizophrenia ( $p=0.0288$ ) in a sample of combined ethnic groups. The controls with no variants have a significantly lower mean P50 ratio than controls in whom a promoter variant was found ( $p=0.0001$ ). These results suggest that some  $\alpha 7$  promoter variants may be functional and are related to the auditory gating phenotype.

**Coronary atherosclerosis: correlation of the FGF2 gene-expression to genetic variants in the 5UTR.** *P. Greiser<sup>1</sup>, U. Schagdarsurengin<sup>1</sup>, S. Schulz<sup>1</sup>, T. Süß<sup>2</sup>, A. Kabisch<sup>3</sup>, D. Rehfeld<sup>2</sup>, U. Müller-Werdan<sup>2</sup>, B.M. Taute<sup>2</sup>, K. Werdan<sup>2</sup>, I. Hansmann<sup>1</sup>, C. Gläser<sup>1</sup>.* 1) Inst Human Genetics, Univ Halle, Halle, Germany; 2) Dep Intern Med, Univ Halle, Halle, Germany; 3) Inst Transf Med/Bloodbank, Univ Halle, Halle, Germany.

The potent cytokine FGF2 is involved in the proliferative response to vascular injury of many cell types like monocytes/macrophages, fibroblasts, vascular smooth muscle and endothelial cells and is suggested as an important candidate gene for CAD. The C223T polymorphism of its exon1, located in the 5' untranslated region (5UTR) in the functionally important internal ribosome entry site, modifies the calculated mRNA folding-structure and is regarded to influence the transcription and translation. We included 152 probands (118 males, 49.92y, SD 9.02) with angiographically proven coronary state (91 CAD, 61 controls with unaffected coronary vessels), determined their C223T genotypes (SSCP) and detected their in vivo FGF2 mRNA-expression in monocytes (competitive RT-PCR). **Results:** We found significantly higher expression levels in the CAD patients compared to the coronary controls (1.19ag/U vs. 0.86ag/U,  $p < 0.03$ ). Analyzing all probands the highest expression was detected in the frequent wildtype carrier CC (frequency 0.82,  $n = 125$ ) with 1.13ag/U whereas the T-allele carriers showed lower levels (CT,  $n = 25$ , genotype frequency 0.17, expression 0.77ag/U) (TT,  $n = 2$ , genotype frequency 0.01, expression 0.25ag/U) ( $p < 0.015$ ). The same tendency was found in both subgroups (CAD: CC/CT/TT 1.28/0.77/0.30ag/U,  $p < 0.02$ ; controls CC/CT 0.89/0.77ag/U, n.s.).

**Conclusion:** In general the frequent wildtype carriers (CC) are characterized by a high level of the FGF2 gene-expression in monocytes, a crucial cell system in the atherosclerosis development. CAD is associated with an additional 43% up regulation in CC carriers. T-allele carriers seem to be unable to realize such a regulation: independent of the coronary findings both CAD patients and controls had comparable and lower FGF2 mRNA-levels, and the lowest showed homozygous TT carriers. Our results suggest that the cellular FGF2 expression could be a sufficient risk marker dependent on C223T gene-constellation.

**Heterozygosity for a surfactant protein C mutation causes familial usual interstitial pneumonitis in adults and cellular interstitial pneumonitis in children.** *A. Thomas<sup>1,5</sup>, K. Lane<sup>1,5</sup>, J. Loyd<sup>1,5</sup>, M. Prince<sup>2,5</sup>, C. Markin<sup>1,5</sup>, J. Johnson<sup>3,5</sup>, J. Haines<sup>4,5</sup>, M. Stahlman<sup>2,5</sup>, J. Phillips III<sup>2,5</sup>.* 1) Department of Medicine; 2) Department of Pediatrics; 3) Department of Pathology; 4) Department of Molecular Physiology and Biophysics; 5) Vanderbilt University School of Medicine, Nashville, TN.

Idiopathic pulmonary fibrosis (IPF) is a fibrotic, destructive lung disease of unknown cause. A familial occurrence of the disease (FIPF) has been reported in up to 25% of cases. A mutation in the gene (SFTPC) encoding surfactant protein C (SP-C) has recently been described in an infant and mother with interstitial lung disease. We hypothesized that FIPF is caused by a mutation in SFTPC. In one large FIPF family, we performed a mutational and expression analysis of SP-C by genetic linkage, dideoxy-fingerprinting (ddF), sequencing, and immunohistochemistry. This family contains 14 affected members with interstitial lung disease, including adults with usual interstitial pneumonitis (UIP) and children with cellular interstitial pneumonitis (CIP). All affected family members shared the same polymorphic marker located near SFTPC. Linkage analysis generated a lod score of 4.33. DNA from all affected individuals studied shared an abnormal ddF pattern. Sequencing of this region revealed an Exon 5+128 T to A transversion that was present in the DNA of all 6 affected family members studied and 2 obligate carriers by restriction enzyme analysis, but in none of 88 control chromosomes. This mutation substitutes a glutamine for a highly conserved leucine residue that is predicted to hinder post-translational clipping of SP-C precursor (proSP-C), which would cause its retention in the endoplasmic reticulum. Staining for proSP-C by immunohistochemistry in lung tissue from an affected individual revealed dysplastic, proliferating type II alveolar cells with abundant intracellular proSP-C. Our findings show that a SFTPC mutation segregates with FIPF. The presence of UIP and CIP in affected relatives sharing this mutation indicates that these diseases may represent pleiotropic manifestations of the same central pathogenesis.

**Delineation of the Mechanism of Glycine N-methyltransferase Gene Control in Liver Cancer.** *Y.A. Chen<sup>1</sup>, C.-M. Lee<sup>1</sup>, Y.-P. Shih<sup>1</sup>, T.-L. Tseng<sup>2</sup>, K.H. Buetow<sup>2</sup>.* 1) Inst Public Health, Natl Yang-Ming Univ, Taipei, Taiwan; 2) Laboratory of Population Genetics, Division of Cancer Epidemiology and Genetic, NCI, Bethesda, MD. 20892, USA.

Glycine N-methyltransferase (GNMT) is not only an enzyme regulating the concentration of the methyl-group donor, S-adenosylmethionine, but also is the 4S polycyclic aromatic hydrocarbon-binding protein participating in the detoxification pathway of cells. Previously, we reported that the expression of GNMT was diminished in human hepatocellular carcinoma (HCC) cell lines and tissues. Genotypic study and liver cancer susceptibility analyses showed that the average of odds ratio for people who possess risk genotypes of GNMT to develop HCC was 1.37~3.97 (see Dr. Tzu-Ling Tseng's abstract in this meeting). In addition, all five HCC cell lines including HA22T, Hep 3B, HuH-7, Sk-Hep1 and PLC/PRF-5 had homozygous genotypes on the polymorphism markers in the promoter region while two hepatoblastoma cell lines (HuH-6 and HepG2) were heterozygous on GNMT gene. Methylation-sensitive restriction endonuclease digestion and PCR amplification demonstrated that among 7 cell lines mentioned above, the upstream control region of GNMT gene was methylated in 4 cell lines (HA22T, Sk-Hep1, PLC/PRF-5 and HuH-6). The GNMT upstream promoter region was subcloned to a vector-pGL3-Basic containing the luciferase gene. Plasmid DNA from the resultant plasmid-pGNMT1.8k was used to transfect different cell lines and showed that the luciferase activity ratios of pGNMT1.8k vs. pGL3-Basic were 18.7 for HepG2 and 2.0 for a subclone of HepG2 that expresses HBV viral antigens (MS-G2). The interaction between GNMT gene control and HBV was further investigated by cotransfection experiment. In comparison with the cells cotransfected with vector DNA, the luciferase activity decreased 67% in the cells cotransfected with pGNMT1.8k and a plasmid containing HBV full genome-pHBV1.3-Bcl. Therefore, loss of heterozygosity, DNA methylation and HBV infection may contribute to the down-regulation of GNMT gene expression during the tumorigenesis of liver.

**Characterization of the Aryl Hydrocarbon Receptor Repressor Gene and Association of Its Pro185Ala**

**Polymorphism with Micropenis.** *H. Fujita*<sup>1</sup>, *R. Kosaki*<sup>2</sup>, *H. Yoshihashi*<sup>1</sup>, *T. Ogata*<sup>1</sup>, *N. Matsuo*<sup>1</sup>, *K. Kosaki*<sup>1</sup>. 1) Dept of Pediatrics, Keio University School of Medicine, Tokyo, Japan, 160-8582; 2) Dept of Genetics, Saitama Children's Medical Center, 2100 Magome, Iwatsuki, Japan, 339-8551.

In utero exposure to dioxins affects male external genital development in rodents. The effects of dioxins are mediated via the aryl hydrocarbon receptor (AHR) and its binding protein, aryl hydrocarbon receptor nuclear translocator (ARNT). In mice, aryl hydrocarbon receptor repressor (AHRR), which binds to ARNT in competition with AHR, plays a critical negative regulatory role in mice AHR signalling. We attempted to characterize the human AHRR gene and investigate the relationship between AHRR polymorphisms and the incidence of micropenis, a phenotype of demasculinization. We identified and characterized the human homolog of mouse AHRR, taking advantage of the publicly available draft version of the human genome sequence. The deduced sequence for human AHRR (715 residues) and the mouse AHRR protein exhibited 81 % sequence homology to each other. Radiation hybrid mapping revealed that AHRR was located on 5pter. This location was syntenic to chromosome 13 in mouse genome according to the mouse-human homology map. We then detected an AHRR protein polymorphism by the direct sequencing of pooled human genomic DNA. Pro185Ala polymorphism was identified between the PAS-A region and the highly conserved arginine/cysteine-rich RCFRCRL/VRC region, which may affect the inhibitory action of AHRR on AHR signalling by altering the heterodimerization of AHRR and ARNT or by altering DNA binding. We evaluated the association between the polymorphism and the presence or absence of micropenis ( $< 2.5SD$ ) in patients with micropenis and control subjects. Forty-six percent (27/59) of patients with micropenis and 27% (22/80) of the controls were homozygous for 185Pro; this difference in frequencies was significant ( $P = 0.03$ ). This result indicates that the homozygosity for the 185Pro allele of AHRR may increase the susceptibility of a fetus to the demasculinizing effects of dioxin exposure in utero, presumably through the diminished inhibition of AHR-mediated signalling.

**Valproic acid exposure alters gene expression in rat embryos: mechanism of teratogenicity and relationship to autism spectrum disorders.** C.J. Stodgell, S. Gnall, P. Rodier. Dept OB/GYN, Univ Rochester School of Medicine, Rochester, NY.

Valproic acid (VPA) exposure during pregnancy is associated with physical malformations and behavioral deficits, developmental delays and autism. Some of these terata can be reproduced in rats by in utero exposure to VPA. *Hoxa1* knockout mice display brainstem and craniofacial deficits similar to those seen in VPA-exposed rats and in cases of autism. In humans, *HOXA1* has been linked to increased susceptibility to autism and autistic behaviors. We postulated that interference with expression of *HOXA1* and other genes might be a mechanism of VPAs teratogenicity. To test this, we exposed rat embryos to a teratogenic dose of VPA or saline (control) during the period of *Hoxa1* expression (i.e., day 10.5-13.5 of gestation). At all of these times, VPA significantly increased the expression of *Hoxa1* relative to expression seen in saline-treated controls. VPA also induced abnormal expression of the gene prior to day 10.5 and as late as day 14, both times when *Hoxa1* is not expressed. By day 15, *Hoxa1* expression had ceased in controls, and could not be induced by VPA. In day 12 embryos, we compared the effects of exposure to a teratogenic analog of VPA (4-yn) or a nonteratogenic form (IE-VPA). 4-yn significantly ( $p < 0.005$ ) increased *Hoxa1* expression at 2, 4, 6 and 24 hours post-treatment compared to age-matched, saline-treated controls. IE-VPA did not alter expression of *Hoxa1* at any time point. DNA microarrays (Affymetrix RAT34A) were also used to examine the effect that VPA, 4-yn and IE-VPA had on expression of genes in embryos treated on day 12. Expression of several transcription factors, cell cycle and signal transduction genes were affected by VPA and 4-yn, and were not affected by IE-VPA exposure. These data suggest that VPA's effect on gene expression is a mechanism of VPA's teratogenicity, and they offer one explanation for why VPA exposure increases the risk of autism.

**Single-genome analysis of the expanded GAA triplet-repeat sequence indicates a very high mutation load *in vivo* and a distinct contraction bias.** S. Bhatti<sup>1</sup>, R. Clark<sup>1</sup>, T. Ashizawa<sup>2</sup>, S.I. Bidichandani<sup>1</sup>. 1) Biochemistry & Molecular Biology, University of Oklahoma Health Sciences Center, Oklahoma City, OK; 2) Neurology, Baylor College of Medicine, Houston, TX.

Friedreich ataxia (FRDA) is caused by abnormal expansion of a GAA triplet-repeat (GAA-TR) sequence in the first intron of the frataxin gene. Normal and mutant chromosomes have 6-60 and 100-1700 repeats, respectively. The expanded GAA-TR is known to be unstable in somatic and germ cells. To enable a detailed characterization of somatic instability we used a small-pool PCR (SP-PCR) assay that detected alleles ranging from 7-1677 repeats with single-genome resolution. Over 1000 individual leukocyte genomes were analyzed from five heterozygous carriers of expanded alleles with 798-1088 GAA triplets (progenitor allele sizes were determined by genomic Southern analysis). We detected a striking degree of somatic variability *in vivo*, with mutation loads (the proportion of alleles that differed significantly from the progenitor allele) ranging between 0.89-0.97 for the various expansions. Extreme changes in repeat length were identified; contractions and expansions up to 24% and 154% of the original progenitor allele length were seen. There was a distinct bias towards contraction, with a significant correlation between the proportion of contracted alleles and the length of the progenitor allele ( $r^2 = 0.82$ ). The mutational spectrum revealed two types of changes: small mutations (<5% of allele length) with equal prevalence of contractions and expansions, and large mutations (>15% of allele length) among which contractions were 2-3 times more frequent. This bias towards contraction is in contrast with the expansion bias displayed by similar alleles of the CTG triplet-repeat in myotonic dystrophy. Additionally, SP-PCR analysis of serially passaged lymphoblastoid cells also showed increasing mutation loads upon serial passaging and a preponderance of large contractions. In addition to the mechanistic implications of the deletional bias, these findings suggest the possible role of cellular development and proliferative capacity in mediating somatic instability of the GAA triplet-repeat.

**Unexpectedly low prevalence of Friedreich ataxia in the Mexican population.** *S.I. Bidichandani<sup>1</sup>, R.M. Clark<sup>1</sup>, S. Bhatti<sup>1</sup>, E. Alonso<sup>2</sup>, P. Yescas<sup>2</sup>, A. Rasmussen<sup>2</sup>.* 1) Biochemistry & Molecular Biology, University of Oklahoma Health Sciences Center, Oklahoma City, OK; 2) Neurogenetics, Instituto Nacional de Neurologia y Neurocirugia Manuel Velasco Suarez, Mexico City, Mexico.

Friedreich ataxia (FRDA) is an autosomal recessive disease characterized by neurodegeneration, cardiomyopathy and diabetes. Over 95% of FRDA patients are homozygous for an abnormal expansion of a polymorphic GAA triplet repeat sequence in the first intron of the frataxin gene. Normal and mutant chromosomes have 6-60 and 100-1700 triplet repeats, respectively. In the Indo-European and North African populations, FRDA is the most common inherited ataxia, accounting for at least 50% of all recessive and sporadic ataxias. Almost 1% of the chromosomes in these populations carry pathologic GAA triplet-repeat expansions (>100 triplets), resulting in the observed disease incidence of 1-2 / 50,000. The expanded alleles in turn originate from long normal (LN) alleles (>12 triplets) which account for 10-15% of all Indo-European and North African chromosomes. In contrast, East Asians (from Japan, China, and South East Asia) and Native Americans have a significantly lower frequency of LN alleles (<2%), and consequently have a very low incidence of FRDA. No such data exists for the Mexican population. We analyzed a cohort of 88 patients with recessive (n = 36) and sporadic (n = 52) ataxia from Mexico and found only 5 individuals (5.7%) who were homozygous for pathologic GAA triplet-repeat expansions, consistent with the diagnosis of FRDA. Three of them were sporadic, and 2 were recessive cases. This indicates that FRDA represents a minority of all Mexican recessive and sporadic ataxia patients, significantly lower than the frequency observed in the Indo-European and North African populations. The lower prevalence of FRDA among Mexicans could stem from a lower frequency of LN alleles. Of the 176 chromosomes analyzed, we observed only 10 LN alleles (5.7%), representing a significantly lower frequency of LN alleles. These data have important epidemiological implications concerning the incidence of FRDA in Mexico, and in the U.S. among individuals of Mexican origin.

**Molecular analysis of a fragile X family with two females homozygous for a premutation.** *F.B. Essop<sup>1</sup>, J. Greenberg<sup>2</sup>, D. Basel<sup>2</sup>, A. Krause<sup>1</sup>.* 1) Department of Human Genetics, School of Pathology, South African Institute for Medical Research and University of the Witwatersrand, Johannesburg, South Africa; 2) Department of Human Genetics, University of Cape Town Medical School, Observatory, South Africa.

Fragile X syndrome (FRAXA) is the most common inherited cause of mental retardation. The disorder affects 1 in 5000 males. Fragile X results from the inheritance of an unstable DNA repeat (a CGG triplet repeat in the 5'-untranslated region of the FMR-1 gene) capable of expanding with successive generations. Normal individuals have 5-50 repeats, a premutation carrier 50-200 repeats and affected individuals have more than 200 CGG repeats. Repeat sizes from 40 to 60 repeats are considered to be a grey area/intermediate range. Alleles in this range may be transmitted stably or show instability. The clinical significance of carrying an allele in this intermediate size range is unclear, particularly for the smaller premutation sizes, but there may be an increased risk of expansion in the future generations.

We describe an interesting family in which two sisters are homozygous for a premutation (PM). Sister 1 (S1) has repeat sizes of 51 and 69 and sister 2 (S2) has repeat sizes of 51 and 57. The sisters inherited a premutation allele from each of their parents. The father carries an allele of 51 repeats and the mother carries alleles of sizes 29 and 57 repeats. S1 has a son affected with FRAXA. S2 has 4 children. In only one of them (a daughter) has her PM expanded to 67 repeats. Clinically the sisters are normal. To determine which allele of S2 underwent expansion, linked marker analysis using microsatellite markers DXS548 and FRAXAC2 was undertaken. The 57 allele in S2 was shown to have expanded.

Molecular detection for fragile X was undertaken by PCR and Southern blotting. This is the first South African report of females homozygous for a premutation and the fourth case in the literature.

**Comparison of the CAG-expansion content of the human and mouse genome using 2-D Repeat Expansion Detection (2D-RED).** *K.A. Benzow, M.D. Koob.* Inst Human Genetics, Univ Minnesota, Minneapolis, MN.

We have used two-dimensional Repeat Expansion Detection (2D-RED), a method that we have described previously, to analyze the approximate size and number of CAG expansions in the genomic DNA of both humans and mice. We consistently detect only five genomic fragments that generate RED signals of 30 CAG repeats (RED30) or greater in typical human genomic DNA samples. We have identified the source of these signals to be the androgen receptor gene (AR, RED30), the ataxin-1 gene (SCA1, RED30), the AF-9 gene (RED40), and the "background" CAG expansions MN1 and ERDA (RED50 and greater, present in almost half of the samples analyzed). When we used the same 2-D RED conditions to assay genomic DNA from standard laboratory mouse strains, however, we found that essentially all genomic size fractions generated RED30 or greater signals and that three size fractions generated RED90 or greater signals. We used our RAPID cloning method to identify the mouse genomic sequence that generated the largest RED signal and found that it was a stretch of 101 pure CAG repeats interrupted in 28 positions by GAG and in one position by GGA (i.e., 130 CAG repeats with 31 nucleotide changes). This polymorphic sequence is in the promoter region of the mouse cathepsin S (CatS) gene. RAPID cloning of sequences that generated some of the smaller signals identified both pure CAG repeat tracts and another CAG/GAG mixed tract similar to that in the CatS promoter. By reanalyzing the mouse genomic DNA using more stringent 2D-RED conditions, we were able to eliminate the signal from these CAG/GAG mixed sequences and detected only numerous RED30 size fractions and a single RED40 signal (mouse AF9). Our results indicate that genomic DNA from common lab strains of mouse 1) has more small, pure CAG expansions in the 20-30 repeat size range than does the human genome, 2) has many minimally interrupted repeats not seen in human genomic DNA, but 3) does not have large uninterrupted repeats found in many human genomic samples. These results are consistent the hypothesis that CAG expansions may be generated or repaired in a different manner in mice and in man.

**Resistance of an expanded polyglutamine repeat androgen receptor to 26S proteasome degradation results in amino-terminal fragment formation.** *I.F.M. Andriola<sup>1</sup>, C.K. Bailey<sup>1,2</sup>, D.E. Merry<sup>1</sup>*. 1) Dept. Biochem & Molec Pharm, Thomas Jefferson Univ, Philadelphia, PA; 2) Univ of Pennsylvania, Neuroscience Graduate Group, Philadelphia, PA.

Proteolysis is essential for execution of many cellular functions, including the removal of incorrectly folded or damaged proteins. For this purpose the 26S proteasome is the major proteolytic system of the nuclear and cytoplasmic compartments of eukaryotic cells, responsible for the degradation of many cellular proteins. Increasing evidence indicates that altered protein handling leads to impairment of proteasome activity, thus contributing to neuronal cell death in several neurodegenerative diseases. We have observed polyglutamine repeat length dependent proteolysis of the androgen receptor, coupled with cell death in a cell culture model of spinal and bulbar muscular atrophy (SBMA). Inhibition studies have revealed that the fragment production depends on the activity of the 26S proteasome. The proteasome inhibitors lactacystin and the highly specific epoxomicin can effectively block the production of amino-terminal fragments of AR. This "proteolysis" results in the production of a repeat containing amino-terminal AR fragment. Fractionation of expanded AR-expressing cells indicated that the repeat-containing amino-terminal fragment is exclusively nuclear. These results indicate that the presumptive proteolytic AR fragment represents the inefficient degradation of the expanded repeat AR, rather than the site-specific cleavage by another protease. The finding of a specific location within the expanded repeat AR protein resisting proteasome degradation indicates a specific structural site of proteasome failure. Furthermore, the overexpression of the molecular chaperons Hsp70 and Hsp40 eliminates amino-terminal fragment formation even while promoting AR degradation. This indicates that chaperone-mediated folding to a native AR conformation stably prevents the conformational change that blocks processive AR proteasome degradation. These results suggest that dysfunction of the ubiquitin-proteasome pathway may be involved in cell death induced by an expanded polyglutamine AR.

**Identification of a boundary between imprinted Prader-Willi syndrome genes and 3 adjacent non-imprinted genes.** *J.H. Chai*<sup>1</sup>, *J.M. Greally*<sup>2</sup>, *J. Dunai*<sup>2</sup>, *D.P. Locke*<sup>3</sup>, *T. Ohta*<sup>1</sup>, *E.E. Eichler*<sup>3</sup>, *R.D. Nicholls*<sup>1</sup>. 1) Univ. Pennsylvania, Philadelphia, PA; 2) Albert Einstein Coll. Med., New York, NY; 3) Case Western Reserve Univ., Cleveland, OH.

Prader-Willi syndrome (PWS) shows loss of function of paternally expressed genes in a 2 Mb imprinted domain of human chromosome 15q11-q13 or the homologous mouse 7C, with imprinting controlled in *cis* by an imprinting center (IC). Previous studies identified an imprinted, intronless gene cluster ~1 Mb from the IC and a flanking non-imprinted gene, *SRAI*, at an unknown distance. To characterize this region further, we searched for CpG islands near *SRAI* and identified 2 novel genes, *MNCb-2146* (*M2146*; 7 exons) and *MNCb-2146-LIKE* (*M2146L*; 5 exons). A (GCG)<sub>n</sub> coding polymorphism in *M2146L* exon 1 varies from n=6-10 (mean 7-8) in 30 individuals of European and Asian origin. While the functions are unknown, the human and mouse 329 amino acid (aa) M2146L or 360 aa M2146 polypeptides show 99% or 96% identity, respectively, with 43% identity for the paralogous pairs. Human *M2146L* expresses 2.2- and 7.5-kb mRNAs, the latter greatly enriched in brain, which arise from alternate polyA site usage. Similar *M2146l* mRNAs occur in mouse brain and heart, while human *M2146* expresses 5- and 1.9-kb transcripts, the latter enriched in brain and muscle. FISH using 4 BAC probes identifies the order tel-*Sra1*-*M2146*-*M2146l*-IC-cen in normal and Tg<sup>PWS</sup> mouse fibroblasts, with all 4 genetic loci deleted in Tg<sup>PWS</sup> mice. RT-PCR analysis with Tg<sup>PWS</sup> and Tg<sup>AS</sup> mouse brain and human PWS and AS imprinting mutations demonstrates that *M2146* and *M2146L* are expressed from both parental alleles, and hence are non-imprinted. Large duplicons map between non-imprinted and imprinted domains in human, with a 150-200 kb region with >80 kb composed of a high density of L1 repeats in mouse, which may form a boundary separating the 2 domains. Among alternative hypotheses, the Sp1 transcription factor (TF) can protect CpG islands from methylation, and as multiple consensus Sp1 sites occur in the promoters of the 2 new genes, Sp1 might protect from *de novo* methylation on the maternal allele and play a role in generating the non-imprinted/imprinted boundary.

**Large fragile X premutatin alleles may often contain two AGG interruptions.** *S.L. Nolin, G.E. Houck, Jr., A.D. Gargano, W.T. Brown.* Human Genetics Dept, NYS Inst Basic Research, Staten Island, NY.

Fragile X syndrome, a common cause of inherited mental retardation, is associated with a CGG repeat expansion within the FMR1 (fragile X mental retardation 1) gene. In the normal population, AGG triplets are usually present at regular intervals within the repeat region, most commonly at positions 10 and 20. AGG interruptions are thought to stabilize the region by preventing slippage during DNA replication. In families with fragile X, however, a different pattern of AGG interruptions has been observed. Several groups have used a variety of techniques to analyze the repeat organization in fragile X premutation males and observed either a single or no AGG interruption in the 5 end of the repeat and long tracts of uninterrupted CGG repeats in the 3 end. We have developed a procedure for sequencing the repeat that allowed us to examine the alleles in 20 premutation males with repeats ranging from 90 to 150. In contrast to the results of earlier studies, sequence analysis revealed that seven males had no AGG, seven had one AGG, and six had two AGG interruptions in the 5 end of the repeat. These results suggest that two AGG interruptions may be a common finding in males with large premutation alleles. If this proves to be the case in males, two AGG interruptions may also be observed in some premutation females, particularly in those whose offspring seem less likely to undergo expansion to a full mutation.

**Nuclear localization and dominant-negative suppression by a mutant SKCa3 N-terminal channel fragment identified in a patient with schizophrenia.** *M.J. Miller<sup>1</sup>, H. Rauer<sup>1</sup>, H. Tomita<sup>1</sup>, H. Rauer<sup>1</sup>, J.J. Gargus<sup>1,2</sup>, G.A. Gutman<sup>3</sup>, M.D. Cahalan<sup>1</sup>, K.G. Chandy<sup>1</sup>.* 1) Physiology and Biophysics, University of California, Irvine, Irvine, CA; 2) Division of Human Genetics, Department of Pediatrics, University of California, Irvine, Irvine, CA; 3) Department of Microbiology and Molecular Genetics, University of California Irvine, Irvine, CA.

The small-conductance calcium-activated K<sup>+</sup> channel gene SKCa3 / KCNN3 maps to 1q21, a region strongly linked to schizophrenia. Recently, a 4 bp deletion in SKCa3 was reported in a patient with schizophrenia. This frame-shift mutation would truncate the protein at the end of the N-terminal cytoplasmic region (SKCa3D). We generated a GFP-SKCa3 N-terminal construct (SKCa3-1/285) that is identical to SKCa3D except for the last two residues. Using confocal microscopy we demonstrate that SKCa3-1/285 localizes rapidly and exclusively to the nucleus of mammalian cells like several other pathogenic polyglutamine containing proteins. This nuclear targeting is mediated in part by two polybasic sequences present at the C-terminal end of SKCa3-1/285. In contrast, full-length SKCa3, SKCa2 and IKCa1 polypeptides are all excluded from the nucleus and express as functional channels. When over-expressed in human Jurkat T cells, SKCa3-1/285 can suppress endogenous SKCa2 currents, but not voltage-gated K<sup>+</sup> currents. This dominant negative suppression is most likely mediated through the co-assembly of SKCa3-1/285 with native subunits and the formation of non-functional tetramers. The nuclear localization of SKCa3-1/285 may alter neuronal architecture, and its ability to dominantly suppress endogenous SKCa currents may affect patterns of neuronal firing. Together, these two effects may play a part in the pathogenesis of schizophrenia and other neuropsychiatric disorders.

**A 33 CAG-repeat allele causes ataxia in a patient with a de novo mutation at the SCA2 locus.** *A.O. Rasmussen, M. Languren, M.E. Alonso-Vilatela, P. Yescas-Gómez.* Department of Neurogenetics, Instituto Nacional de Neurologia y Neurocirugia, Mexico City, Mexico.

The autosomal dominant spinocerebellar ataxias (ADCA) are a clinically and genetically heterogeneous group of disorders, caused by the expansion of unstable microsatellite repeats in several genes. Spinocerebellar ataxia type 2 (SCA2) is the most prevalent cause of ADCA in Mexican population, accounting for almost 50% of all cases. A large cohort of ataxia patients has been studied at the Instituto Nacional de Neurologia y Neurocirugia in Mexico City, including 75 sporadic cases. Among these, we identified a 40 year-old female with a very slowly progressive cerebellar ataxia (age at onset: 16) and negative family history. Clinical and laboratory information outruled acquired causes of ataxia, as well as Vitamin E-deficiency. Molecular analysis of the SCA2 gene demonstrated that she is a heterozygote for this locus with a normal 22-CAG repeat allele, and a 33 CAG-repeat allele. The analysis was extended to her parents, the father is a normal 22 CAG-repeat homozygote while her mother carries a long-normal allele. On clinical examination, both are healthy at the ages of 65 and 62 respectively. The proband has a 10 year old son whom she refused to be tested. This case supports a previous observation that SCA2 alleles with only 33 CAG repeats can be enough to cause disease, and the result of de novo expansions of longer-than-usual SCA2 alleles. Supported by CONACYT 37090-M.

**Screening of maternal uniparental disomy of chromosome 7 in pre- and postnatal growth retardation of unknown etiology.** *K. Hannula<sup>1</sup>, M. Lipsanen-Nyman<sup>2</sup>, P. Kristo<sup>1</sup>, I. Kaitila<sup>3</sup>, K.O.J. Simola<sup>5</sup>, H.L. Lenko<sup>6</sup>, P. Tapanainen<sup>7</sup>, C. Holmberg<sup>2</sup>, J. Kere<sup>1, 4</sup>.* 1) Dept Medical Genetics, Univ Helsinki; 2) Hospital for Children and Adolescents, Univ Helsinki; 3) Clinical Genetics Unit, Univ Helsinki; 4) Finnish Genome Center, Univ Helsinki; 5) Dept Clinical Genetic, Tampere Univ Hospital; 6) Dept Pediatrics, Univ Tampere; 7) Dept Pediatrics, Univ Oulu, Finland.

Many short-statured children lack an etiologic explanation for their growth retardation. Uniparental disomy (UPD), the inheritance of both chromosomes of a chromosome pair from only one parent, is associated with short stature for many chromosomes. Maternal UPD of chromosome 7 (matUPD7) is observed in 10% of Silver-Russell syndrome (SRS) cases. SRS is an extreme syndrome of intrauterine growth retardation (IUGR) and slight dysmorphic signs. MatUPD7 has also been reported in patients with only slight dysmorphic features and pre- or postnatal short stature. The aims of this study were to study the role of matUPD7 in growth failure of unknown etiology and SRS, and to evaluate the efficiency of testing for matUPD7 as a diagnostic tool. The patient cohort included 205 children with short stature of unknown etiology: 39 SRS cases, 91 patients with IUGR and subsequent postnatal short stature, and 75 patients with postnatal growth retardation (PNGR) only. MatUPD7 was screened for by genotyping DNA from the patient and parents with 13 chromosome-7-specific microsatellite markers. Six matUPD7 cases were observed (3%, 6/205) exclusively among 39 SRS patients (15%, 6/39). IUGR and/or PNGR patients with dysmorphic features did not reveal matUPD7 cases. All six matUPD7 patients have mild SRS signs and they have additional features not regarded as typical of SRS: excessive sweating, severe feeding difficulties, and speech delay. MatUPD7 cases seem to form a distinct entity among SRS cases. Our results indicate that matUPD7 is predominantly observed among SRS patients and matUPD7 is not a common cause for growth retardation. From a clinical perspective, screening of matUPD7 should be focused on patients with severe IUGR, features of SRS, speech difficulties, and poor feeding.

**Strong candidate region adjacent to D15S113 responsible for imprinting mechanism of Prader-Willi syndrome.**

*S. Ninomiya, Y. Yokoyama, C. Inoue, S. Yamashita, T. Une, M. Teraoka, Y. Seino.* Dept Pediatrics, Okayama Univ Graduate Sch of Medicine and Dentistry.

Prader-Willi syndrome (PWS) results from the loss of expression of one or more paternally expressed genes on human chromosome 15q11-q13. Most cases are due to a paternal deletion or maternal uniparental disomy (UPD) and rare cases have imprinting mutation. Here we report an atypical PWS case in which deletion was not detected but very small region, D15S113, CA repeat marker, had maternal hetero UPD. Clinical summaries: The patient, 18-year-old boy, was born after 40 weeks of gestation as the offspring of healthy parents with no consanguinity. He showed microcephaly, short neck, webbed neck, low set of ears, down slanting palpebral fissurae, bilateral convergent strabismus, bilateral second to fifth fingers skinny syndactyly, and cryptorchism. He had moderate mental retardation. His hyperphagia has been remarkable since about 12-year-old. His clinical features did not completely satisfy the PWS diagnostic criteria. Cytogenetics: The chromosomal analysis using high resolution banding by GTG banding method showed no deletion of 15q11-q13 and the fluorescent in situ hybridization (FISH) using a probe of SNRPN also revealed no deletion. Molecular analysis: Genomic DNA was extracted by the standard method. Highly polymorphic CA repeat markers within 15q11-q13 and other 15q regions were analyzed by PCR. Primer loci were D15S11, D15S128, D15S122, D15S210, D15S113, D15S1234, GABRB3, D15S165, D15S126, D15S153, D15S211 and D15S127. It demonstrated biparental inheritance at two loci within 15q11-q13 (D15S11 and D15S1234) and at two loci distal to 15q13 (15S126 and 15S211). Remarkable interestingly only one locus, D15S113, within 15q11.2-q12 showed maternal hetero UPD. The DNA methylation pattern of the patient using by SNRPN probe was normal. Conclusion: The result of partial maternal hetero UPD in this study suggests that a gene (genes) or an important unit of imprinting mechanism for PWS exists surrounding the narrow UPD region. In addition this suggests the UPD in very small region may be one of the cause of congenital multiple malformations.

**Molecular rescue by mitotic recombination as an explanation for recurrence of 11q- Jacobsen syndrome in two brothers.** *M.M. Haag<sup>1</sup>, L.S. Beischel<sup>1</sup>, C.L. McCann<sup>1</sup>, J.F. Reynolds<sup>1</sup>, S.M. Phillips<sup>1</sup>, M.L. Tunby<sup>1</sup>, J.C. Hansen<sup>2</sup>, J.P. Johnson<sup>1</sup>.* 1) Shodair Children's Hospital, Helena, MT; 2) Medical Associates, P.C., Bozeman, MT.

The 11q- syndrome (Jacobsen syndrome) involves characteristic but variable features including trigonocephaly, psychomotor retardation, cardiac anomalies, and thrombocytopenia. Most cases are de novo, resulting from deletions at 11q23 or distal. Inheritance of an expanded CCG repeat at the folate-sensitive fragile site, FRA11B, has been implicated in generation of the chromosome breakpoint in some Jacobsen syndrome patients. We describe the first family, to our knowledge, with recurrent 11q24-qter deletion in two brothers. Both presented at birth with thrombocytopenia and minor anomalies. The older brother was mosaic for an 11q- cell line (~10% normal). Molecular analysis shows that the breakpoints are near D11S4958 (11q23.3), distal to FRA11B, and that the deletion is identical and of maternal origin in both boys. Parental lymphocyte chromosomes were normal with no expression of a folate-sensitive fragile site under stressed culture conditions. However, mother is homozygous for all loci within the deleted region in her sons, and likely has uniparental disomy (UPD) for this region. We suggest that a grandparental chromosome has an 11q fragile site distal to FRA11B, and that mother experienced rescue from the 11q- syndrome by mitotic recombination. This resulted in uniparental disomy with tissue limited mosaicism for a deleted cell line to account for her two affected sons. We propose that the tissue limited rescue phenomenon also occurred in her mosaic son. The low level of normal cells in the older son did not allow molecular confirmation. The presumed post-zygotic segmental UPD in the mother may be another example of somatic recombination, a mechanism identified by loss of heterozygosity, as observed in certain cancers and in the segmental UPD 11p in Beckwith-Wiedemann syndrome. Here, we show this mechanism in recurrent Jacobsen syndrome. Other cases of familial recurrence of a chromosome abnormality in a syndrome may be candidates for this approach to identify mitotic recombination and UPD.

**Genetic Testing for BWS: Introduction of a Simple Quantitative Method for UPD Detection.** *C. Wei<sup>1</sup>, R. Weksberg<sup>2</sup>, L. Steele<sup>1</sup>, T.L. Stockley<sup>1</sup>, C. Shuman<sup>2</sup>, P.N. Ray<sup>1</sup>.* 1) Paediatric Laboratory Medicine, Hospital for Sick Children, Toronto, Ontario, Canada; 2) Division of Clinical and Metabolic Genetics, Hospital for Sick Children, Toronto, Ontario, Canada.

Beckwith-Wiedemann syndrome (BWS) is an overgrowth syndrome characterized by pre- and/or postnatal overgrowth, neonatal hypoglycemia, hemihyperplasia, abdominal wall defect and increased risk of childhood tumors. The imprinted region of chromosome 11p15.5 is involved in pathogenesis of BWS. Several molecular mechanisms have been identified including paternal uniparental disomy (UPD) of chromosome 11p15.5, paternal duplication or maternal translocation, imprinting defects at KvDMR1, and p57KIP2 mutation. Molecular diagnosis for BWS is optimal for patient management and accurate genetic counseling for the family. Paternal UPD of chromosome 11p15.5 is reported to account for approximately 20% of sporadic BWS cases. We have developed a multiplex PCR-based assay using microsatellite markers on chromosome 11 to detect paternal UPD in BWS patients. In 125 BWS probands tested, we detected chromosome 11p15 UPD in 21 cases, 16 of which were confirmed to be paternal in origin. Consistent with the literature, mosaicism was seen in all BWS patients with UPD, supporting the hypothesis that UPD arises at 11p15 from post-zygotic recombination between paternal and maternal chromosomes. The level of mosaicism detected varies between patients and specimen types (ie, whole blood, skin fibroblasts, and lymphoblasts). The lower limit of detection of UPD using this assay is 20% based on experimental variation detected in normal samples. In addition to UPD detection, this assay also detected 5 cases of paternal duplication of 11p15. Four of these cases showed two paternal alleles and one maternal allele at informative loci, indicating partial trisomy of 11p15 resulting from a paternal balanced translocation. One case with de novo 11p15 duplication was confirmed to be paternal in origin. In summary, we have shown that this quantitative multiplex PCR-based method is accurate and sensitive to detect paternal UPD as well as duplication of 11p15 in BWS patients.

**Methylation analysis of maternal and paternal uniparental disomy of human chromosome 14.** A.A. Wylie<sup>1</sup>, P.D. Cotter<sup>2</sup>, B. Williford<sup>3</sup>, P.R. Papenhausen<sup>3</sup>, R.L. Jirtle<sup>1</sup>. 1) Radiation Oncology, Duke University, Durham, NC; 2) Division of Medical Genetics, Childrens Hospital Oakland, CA; 3) Department of Cytogenetics, LabCorp Inc., Research Triangle Park, NC.

Abnormal phenotypes associated with uniparental disomy (UPD) have implied the presence of imprinted genes on a number of chromosomes. These include distinct clinical abnormalities associated with both maternal and paternal UPD of the long arm of human chromosome 14. The only imprinted genes identified to date on human chromosome 14 are the paternally expressed DLK1 and maternally expressed GTL2. As a first step in establishing if abnormal expression of DLK1 and/or GTL2 underlies the clinical phenotype observed in either maternal or paternal UPD14, we determined whether the DLK1/GTL2 imprinted locus is contained within the proposed chromosome 14 uniparental disomic region. A parent-of-origin dependent, differentially methylated region (DMR) lies immediately upstream of GTL2 and is proposed to regulate the imprinted expression of both DLK1 and GTL2. Using bisulfite sequencing for methylation analysis of this DMR, we determined the status of both the maternal and paternal alleles in normal controls and patients reported to have UPD14. Normal control samples analysed using this approach were differentially methylated and contained both methylated and unmethylated alleles. In contrast, paternal UPD samples contained only methylated alleles and maternal UPD samples contained only unmethylated alleles, consistent with their UPD status. These data indicate that for the samples analysed the DLK1/GTL2 locus is contained within the proposed region of uniparental disomy and abnormal expression of these genes may underly the clinical phenotype of maternal and/or paternal UPD14. In order to allow rapid analysis of future samples, a UPD14 methylation specific PCR (MSP) assay was also developed. This assay eliminates the need for parental DNA samples, does not require microsatellite marker analysis and will identify both maternal or paternal UPD in a single assay.

**Primary open-angle glaucoma GLC1A mutation testing in clinical practice.** *M.A. Aldred<sup>1,3</sup>, L. Baumber<sup>1,3</sup>, A. Hill<sup>2</sup>, K. Goh<sup>2</sup>, W. Karwatowski<sup>2</sup>, R.C. Trembath<sup>1,3</sup>.* 1) Leicestershire Genetics Centre, Leicester Royal Infirmary, Leicester, UK; 2) Department of Ophthalmology, Leicester Royal Infirmary, Leicester, UK; 3) Division of Medical Genetics, University of Leicester, Leicester, UK.

Primary open angle glaucoma (POAG) affects 1% of people over age 40. Early detection and treatment can prevent blindness, but the disease is often symptomless until a late stage. Positive family history is an important risk factor, but only ~50% of at-risk individuals take up free eye tests. Previous studies indicate that ~5% of POAG results from mutations in the GLC1A gene, raising the possibility of identifying individuals genetically predisposed to glaucoma. We collected DNA samples from 426 predominantly Caucasian POAG patients unselected for family history and sequenced exon 3 of GLC1A, where most mutations cluster. The Q368X mutation was found in 6 patients (1.4%). No other mutations were identified. It is unclear whether this reflects sampling error, or whether the prevalence of GLC1A mutations in this cohort is lower than in other populations. Genetic and glaucoma screening was offered to first-degree relatives of these 6 probands and of age/sex matched mutation-negative controls. Of 11 proband relatives, 3 carried Q368X, one of whom already had glaucoma. 8 were mutation negative, of which 2 were under treatment for glaucoma. Of 5 control relatives, all were mutation and glaucoma negative. We have thus identified 2 unaffected mutation carriers who may be at increased risk of developing glaucoma in later life. Upon review, the two mutation-negative relatives are not thought to have glaucomatous damage, but we caution against changing glaucoma surveillance regimens in such individuals.

**Identification of new FANCA mutations in Tunisian patients.** C. Bouchlaka<sup>1</sup>, K. Dellagi<sup>1</sup>, S. Abdelhak<sup>1</sup>, For the Tunisian Fanconi Anemia Study Group\*<sup>2,3,4,5,6</sup>. 1) Immunology Dept, Institut Pasteur, Tunis, Tunisia; 2) C.H.U.Aziza Othmana, Tunis; 3) C.H.U.Habib Bourguiba, Sfax; 4) C.H.U.Farhat Hached, Sousse; 5) CNGMO, Tunis; 6) Hopital de Kairouan.

Fanconi anemia (FA) is a genetically heterogeneous autosomal recessive rare disease. Five genes (FANCA, FANCC, FANCE, FANCG and FANCF) have been identified, and one (FANCD) have been solely localized. Forty patients belonging to thirty-one families from different geographical areas of Tunisia were investigated. Haplotype analysis and homozygosity mapping allowed us to assign Tunisian patients to FAA complementation group. Search for mutations was started by screening all the patients for the already described recurrent mutations (1263delF, 1115-1118del and 4267-4404del) found within FANCA in exons 13, 38 and 43 respectively. These mutations were identified in multiple unrelated patients from different populations. No one of these recurrent deletions nor other mutations were observed in these exons for our population. Screening for mutations in the remaining 40 exons of the FANCA gene and their flanking intronic sequences was performed using genomic DNA amplification and direct sequencing. Preliminary investigation allowed the identification of three novel mutations within FANCA gene. Two small homozygous deletions occurred in exon 17 (1693delT) and exon 19(1784-1788del) respectively resulting in a frame shift and a premature stop codon. These mutations may lead to the production of a truncated protein. The third mutation is an A to T transversion at position 166 within intron 24. This mutation leads to the production of an uncorrectly spliced mRNA with an insertion of 166 bp. Our results show the heterogeneity of the mutations affecting Tunisian FA patients.

**Variant patterns of intron 22 inversion in factor VIII gene in Indian hemophiliacs. *G.R. Chandak, M. Idris, K. Radha Mani.* Centre for Cellular Molecular Biology, HYDERABAD, Andhra Pradesh, India.**

**Hemophilia A is a common coagulation disorder resulting from an inherited deficiency of factor VIII. The disorder is inherited as X-linked recessive trait with a significant proportion of cases (20-30%) due to de novo mutations in the FVIII gene located at Xq28. Recurrent DNA inversion of intron 22 in the FVIII gene accounts for more than 40% of cases with severe Hemophilia-A. The inversion occurs between a region of intron 22 (int22h) and one of two homologous copies of this region (int22h-2 and int22h-3), located 300 to 400 kb telomeric to the FVIII gene. A BclI digestion of genomic DNA followed by Southern Hybridizations using p542.16 probe detects the disruption of factor VIII gene by showing a change in the characteristic three-band pattern (21.5 Kb, 16.0 Kb and 14.0 Kb bands). Different variants have been reported in the pattern of this inversion. We report 3 Indian families each with characteristic atypical pattern of inversion. All three patients had severe hemophilia-A, however their inhibitor status was not known. Family I showed an additional 23.5 Kb band whereas family II showed a 20 Kb band apart from the normal three bands. The normal pattern of 21.5 Kb, 16.0 Kb and 14.0 Kb was altered to 17.5 Kb, 16.0 Kb and 14.0 Kb in family III. Subsequent analysis using XbaI restriction fragment length polymorphism has shown variable copy number of int22h apart from the normal three copies. Further analysis has also been performed to analyse the associated inversion junction. The detailed analysis of these families in the light of these results will be presented. These patients and the variant inversions further stress on the association of int22h with Xq28 instability.**

**Molecular genetic analysis of Fanconi anaemia in Black South Africans.** A. Krause<sup>1</sup>, F. Essop<sup>1</sup>, L. Wainwright<sup>2</sup>, J. Poole<sup>3</sup>, C. Mathew<sup>4</sup>. 1) Department of Human Genetics, South African Institute for Medical Research, Johannesburg, South Africa; 2) Department of Paediatrics, Chris Hani Baragwanath Hospital, University of the Witwatersrand, Johannesburg, South Africa; 3) Department of Haematology and Oncology, New Johannesburg Hospital, University of the Witwatersrand, Johannesburg, South Africa; 4) Division of Medical and Molecular Genetics, GKT School of Medicine, Guy's Hospital, London, United Kingdom.

The Fanconi anaemias (FA) are a group of autosomal recessive genetic disorders characterised clinically by progressive bone marrow failure, skeletal deformities, early occurrence of malignancies and a predisposition to neoplasia. Spontaneous chromosome breakage is a feature of FA. Mutation screening is generally difficult because of marked genetic heterogeneity. In the South African Black population, the most common mutation is a 7bp deletion in exon 5 (637-643del) of the FA Complementation Group G gene. DNA analysis on Black patients with FA showed 85% to be homozygous for the FANCG mutation. This mutation is highly likely to have had a single origin, as evidenced by its tight association with the C allele of a SNP at IVS1+77 in the FANCG gene. The 7bp deletion was detected on 3/600 chromosomes from unaffected individuals, giving a carrier rate of 1/100. The birth rate for all FA in Black patients in SA is estimated to be 1/20 000, one of the highest rates in the world. The majority (19/20) of these cases are still not being diagnosed. The presence of a single common mutation allows for rapid diagnostic testing in this group, with possibilities for preclinical, prenatal and carrier testing in the majority of Black South African families.

**Correlation of SMN and NAIP gene deletions with the phenotype of Spinal Muscular Atrophy in Indian patients.**  
*M. Idris<sup>1</sup>, M. Nair<sup>2</sup>, G.R. Chandak<sup>1</sup>.* 1) Centre for Cellular and Molecular Biology, Hyderabad, Andhra Pradesh, India; 2) Shri Chitra Thirunal Institute of Medical Sciences, Trivandrum, Kerala, India.

The spinal muscular atrophies (SMAs) form a heterogeneous group of diseases inherited as autosomal dominant, autosomal recessive, or X linked recessive traits. Three candidate genes have been identified and shown to be deleted in SMA patients: the Survival Motor Neuron gene (SMN), the Neuronal Apoptosis Inhibitory Protein gene (NAIP) and the XS2G3 cDNA. In this report, we present the molecular analysis of the SMN exons 7 and 8 & NAIP exons 5 and 13 in 16 Indian patients with a clinical diagnosis of SMA. Exons 7 and 8 of SMN were homozygously deleted in all 10 SMA type I patients, three Type II patients and one out of three Type III patient. Exon 5 of NAIP gene was homozygously deleted in seven Type I patients only. None of the type II and III patients had deletion in exon 5 and 13 of NAIP gene. In an attempt to establish the genotype-phenotype correlation, it was noted that all SMA type I patients with a deletion in both SMN and NAIP had serious breathing difficulties and expired during the first six months of life whereas the remaining with a deleted SMN but intact NAIP needed respiratory support only after the first year of life. Homozygous deletion of exon 5 of NAIP was detected in a fetus during prenatal diagnosis in a couple. They had an earlier child who expired at the age of 6 months with a clinical diagnosis of type I disease. However, no deletion of SMN gene at exons 7 and 8 and exon 13 of NAIP gene was noted. None of the parents showed homozygous deletion of exon 5 in the NAIP gene. Q-PCR analysis did show variable copy number in the parents but no deletion of any copy of NAIP gene could be detected. This led to diagnostic dilemma and brings in ethical and social issues. The present findings support the hypothesis that SMN deletion plays an important role in the development of SMA and suggest that combined deletion of both SMN and NAIP may be relevant for determining the disease severity. However, the role of isolated NAIP deletion in the causation of phenotype of SMA may need to be investigated.

**Connexin 26 mutations in Iranian patients with autosomal recessive nonsyndromic sensorineural hearing loss.** *S. Sahebjam<sup>1</sup>, N. Kouchakian<sup>1</sup>, S. Arzhangi<sup>1</sup>, K. Kahrizi<sup>1</sup>, M. Menzens<sup>2</sup>, R.J.H. Smith<sup>2</sup>, H. Najmabadi<sup>1</sup>.* 1) Genetics Research Center, University of Welfare Sciences, Tehran, Tehran, Iran; 2) Molecular Otolaryngology Research Laboratories, Department of Otolaryngology Head and Neck Surgery, University of Iowa; Iowa, IA United States.

Hereditary hearing loss is an extremely common disorder. About 70% of hereditary deafness is non-syndromic. Autosomal recessive forms make up about 85% of these cases. Many deafness genes exist, but the most common cause of hereditary hearing loss in many different populations is the mutations of connexin 26 (GJB2), which mainly lead to autosomal recessive non-syndromic hearing loss (ARNSHL). This study is aimed to investigate the mutations of connexin 26 gene (GJB2); found in patients with autosomal recessive nonsyndromic sensorineural hearing loss in the Iranian population. Fifty-five unrelated patients were studied and GJB2 mutations were found in 22 (20%) chromosomes with the 35delG mutation standing first. R127H, W24X, and R184P were the other GJB2 mutations detected. The relative frequency of connexin 26 mutations is much less than reports of other populations. This raises the possibility that mutations located in other loci be the major cause of ARNSHL in Iranian patients.

**Variable phenotype in monozygotic twins with Duchenne Muscular Dystrophy. *K. Radha Mani, G.R. Chandak.* Centre for Cellular and Molecular Biology, Hyderabad, Andhra Pradesh, India.**

Duchenne and Becker Muscular Dystrophy are X-linked recessive allelic neuromuscular disorders where affected individuals typically have pseudohypertrophy of calf muscles with development of secondary atrophy and contraction and cardiac or respiratory muscle involvement in the later stages. The disease is caused by mutation in the DMD gene and approximately 65% of patients have intragenic deletions, the rest have point mutations or duplications. We report an interesting case of monozygotic twins with variable phenotype on a similar genetic background. The patients presented to us at the age of 12 years, with one of them almost immobilized with an age of onset at 4 years (Twin I) whereas the other fairly mobile with an age of onset only at the age of 8 years (Twin II). Although both had similar pseudohypertrophy of the calf muscles but the twin I had comparatively flabby muscles consistent with degenerating muscles. The CPK levels were 28,000 and 13,000 respectively for twin I and twin II. Cytogenetic study for both was consistent with a male karyotype with a normal banding pattern. DNA fingerprinting using a 10-loci microsatellite showed similar profile and matched with the parents thus confirming paternity. Deletion analysis of the DMD gene showed exon 49-50 deletion out of 25 exons analysed. Analysis of entire DMD gene using cDNA probes failed to show any other missing or abnormal restriction fragment. Both twins showed deletion of 1.6 Kb and 3.7 Kb fragments on a HindIII blot hybridized with cDNA 8 of the DMD gene. Neither the mother nor the relatives showed this deletion suggesting the deletion to be a new mutation in this pair of monozygotic twin. Two possible explanations can be advanced to account for this variability on a seemingly similar genetic background. This may be an evidence for somatic mosaicism or it may suggest the presence of other factors modulating the severity of the DMD phenotype.

**Homozygosity for the V37I Connexin 26 mutation in 3 unrelated children of Asian background with sensorineural hearing loss.** *P.M. Fortina<sup>1</sup>, L. Bason<sup>2</sup>, T. Dudley<sup>3</sup>, K. Lewis<sup>3</sup>, U.K. Shah<sup>4</sup>, W. Potsic<sup>4</sup>, I.D. Krantz<sup>2</sup>.* 1) Division of Clinical Pathology; 2) Division of Human Genetics and Molecular Biology; 3) Division of Audiology; 4) Division of Otolaryngology, The Children's Hospital of Philadelphia and The University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania.

Mutations in Connexin 26 (Cx26) account for approximately 20% of all childhood deafness and approaches 50% in documented recessive cases of sensorineural hearing loss (SNHL). Two mutations in particular, 35delG and 167delT, account for more than 90% of reported mutations in this gene and several mutations predominate in specific ethnic populations (167delT in Ashkenazi Jews and 235delC in Japanese individuals). The V37I amino acid change was initially reported as a polymorphism by Kelley et al (*Am J Hum Genet* 62:792-799, 1999) when it was seen in a heterozygous state in a sample from a control group. Subsequently Rabionet et al (*Hum Genet* 106:40-44, 2000) found the same change in a homozygous state in an individual with hearing loss and not in 100 control samples. All individuals tested in the Rabionet study were described as "Spanish" or "Italian", while the ethnic background of the individual reported by Kelley et al was not specified. We have identified 3 unrelated individuals homozygous for the V37I mutation with sensorineural hearing loss. Patient 1 has a 40-50 dB bilateral SNHL with increase in severity in the higher frequencies, patient 2 had a 55-60 progressing to 70-100 dB bilateral SNHL over 4 years (from 2-6 years), and patient 3 has a bilateral high frequency hearing loss starting at 2000 Hz and increasing to 40-60 dB at 4000 Hz. Patient 2 is the oldest of the 3 patients. It is unclear if this mutation predisposes to progression of hearing loss. One individual is of Philippine ancestry, and the other 2 are of Chinese background, raising the possibility that this mutation may be more frequent amongst Asian populations. Further screening of controls of Philippine and Chinese background is being undertaken to determine the carrier status of this mutation in these populations.

**Long QT syndrome:reduced penetrance in heterozygotes.** *H.E. Hughes<sup>1</sup>, A. Murray<sup>2</sup>, L. Emmerson<sup>1</sup>, R. Evans<sup>1</sup>, W. Reardon<sup>3</sup>, S. Jeffery<sup>2</sup>.* 1) Institute of Medical Genetics, Univ Hosp Wales, Cardiff, Wales; 2) Medical Genetics Unit, St. George's Hospital, London; 3) National Centre for Medical Genetics, Dublin, Ireland.

Long QT syndrome is recognized as a genetically heterogeneous disorder characterized by syncopal episodes. A number of different loci and gene mutations have been delineated - the first being KVLQT1, also known as KCNQ1. The phenotype usually is expressed in the heterozygous state (Romano-Ward syndrome). In the one well-recognized recessive phenotype (Jervell and Lange-Nielsen syndrome), caused by a homozygous mutation in the above gene, arrhythmia is associated with deafness. We report a large kindred where the proband, the product of a first cousin marriage, presented with repeated syncopal attacks at the age of 4 years. Both the proband and her asymptomatic brother, now aged 16 years, were shown to have prolonged QT interval and molecular analysis revealed a homozygous G269S mutation in exon 5 of the KVLQT1 gene. The proband, now deceased, was not known to have a hearing problem and audiometric testing of the brother shows no evidence of a hearing loss. Molecular analysis of extended family members over three generations has identified 8 other heterozygous carriers, the eldest of whom is 81 years of age. Six of these individuals, as well as the homozygous brother, have a significantly prolonged QT interval but none has a history of recurring syncope. Of the six heterozygotes who have had audiometric testing, four have normal hearing. However, other factors, such as industrial exposure and the possibility of another dominant gene, influence the development of hearing loss in this family. Two heterozygotes and other relatives who have tested negative for the above mutation have documented audiometric abnormalities. Reduced penetrance in heterozygotes in this family supports the suggestion that gene mutations for long QT syndrome are more common in the population than has been appreciated to date. This has implications for counselling and management of identified families. Furthermore, the family provides additional evidence that a homozygous mutation in this gene is not necessarily associated with a significant hearing loss in childhood.

**Mutations in the Cx26 and CDH23 gene cause indistinguishable profound congenital hearing loss in a large Dutch family.** *H. Kremer<sup>1</sup>, P. Van Hauwe<sup>1,2</sup>, L.H. Hoefsloot<sup>2</sup>, A. de Brouwer<sup>1,2</sup>, R. Pennings<sup>1</sup>, A. Deutman<sup>3</sup>, L.M. Astuto<sup>4</sup>, W.J. Kimberling<sup>4</sup>, J.M. Bork<sup>5</sup>, C.W.R.J. Cremers<sup>1</sup>, F.P.M. Cremers<sup>2</sup>.* 1) Dept. Otorhinolaryngology, UMC Nijmegen, Nijmegen, The Netherlands; 2) Dept. Human Genetics, UMC Nijmegen, Nijmegen, The Netherlands; 3) Dept. Ophthalmology, UMC Nijmegen, Nijmegen, Netherlands; 4) Gene Marker Laboratory, Boystown National Research Hospital, Omaha, NE USA; 5) Laboratory of Molecular Genetics, NIH, Rockville, MD USA.

In 1989, we ascertained a large family with apparent autosomal recessive non-syndromic childhood deafness. A genome wide scan with 300 polymorphic markers was not successful. Later, analysis of candidate loci for DFNB revealed genetic heterogeneity. In one branch (A) of the family the 35delG mutation in the Cx26 gene is homozygously present. In two other branches (B and C) the DFNB12 locus is involved. Testing patients of the branches B and C for mutations in the CDH23 gene revealed that the D2148N mutation is homozygously present in branch B and heterozygously in branch C. The D2148N mutation was not present in 100 control individuals but was detected heterozygously in another DFNB12 family corroborating its pathogenic nature. Further analysis of the CDH23 gene in order to find the second mutation in branch C is ongoing. Audiometric evaluation of the Cx26-related and CDH23-related hearing loss revealed no significant differences. Since mutations in the CDH23 gene also can cause USH1D with a variable retinal phenotype the patients with the CDH23 mutation will undergo ophthalmologic examination in order to contribute to the phenotype-genotype correlation of mutations in the CDH23 gene. Although the pedigree of the family initially suggested that it was ideal for the identification of a locus involved in autosomal recessive deafness, the data presented here illustrate the pitfalls in studying genetically heterogeneous hereditary hearing loss.

**Genetic Evidence for Digenic Inheritance of Non-Syndromic Deafness Involving the Connexin 26 Locus.** *W.E. Nance<sup>1</sup>, M. Tekin<sup>1</sup>, K.O. Welch<sup>2</sup>, X.J. Xia<sup>1</sup>, X.Z. Liu<sup>1</sup>, A. Pandya<sup>1</sup>, K.S. Arnos<sup>2</sup>*. 1) Dept Human Genetics, Virginia Commonwealth Univ, Richmond, VA; 2) Dept Biology, Gallaudet University, Washington, DC.

Mutations in the *GJB2* (Connexin26/Cx26) gene are known to account for greater than 50% of recessive non-syndromic deafness in certain populations. More than 50 different mutations in the single coding exon of the Cx26 gene have been reported. However, a substantial number of deaf individuals (1-10% of the screened deaf population) have been reported to carry a single heterozygous mutation in this gene. Mutations in the regulatory region of Cx26 or a second gene have been suggested as the cause for hearing loss. Screening for Cx26 mutations in a nationwide repository of deaf probands revealed two families, of the type shown in Fig.1, in whom the Cx26 mutations were not sufficient to explain deafness in all individuals. A second deafness gene, interacting with Cx26, has remained the most parsimonious explanation for hearing loss in these individuals. Screening for mutations in the Cx30 and Cx31 has been negative to date. We are continuing our search for mutations in other genes causing NSDF. The family structures and our data strongly support the hypothesis that Cx26 interacts with a second deafness gene. Now that an increasing number of specific forms of genetic deafness can be identified by molecular techniques, it is apparent that the analysis of marriages among the deaf will provide a previously unexploited technique for identifying epistatic interactions among genes for deafness. No matter how rare they are, assortative mating tends to amplify the frequency of genes that interact with Cx26, just as this mechanism specifically increases the frequency of Cx26 deafness itself.

**Molecular study of connexin 31 gene in nonsyndromic hearing impairment.** *E. Sartorato*<sup>1</sup>, *F. Alexandrino*<sup>1</sup>, *A. Maciel-Guerra*<sup>2</sup>. 1) Laboratorio de Genetica Humana - CBMEG, UNICAMP, Campinas - SP, Brazil; 2) Departamento de Genetica Medica - FCM, UNICAMP, Campinas - SP, Brazil.

Congenital deafness occurs in approximately 1 in 1000 live births. In developed countries half of this hearing loss is genetic. However, in Brazil the majority of cases of hearing loss are due to environmental factors, such as congenital infections (mainly rubella), perinatal anoxia, kernicterus and meningitis. There has been enormous progress in nonsyndromic deafness research during the last five years, with the identification of over 70 loci, and 19 genes. Among these, three connexin genes are related to either autosomal dominant or recessive hearing impairment (GJB2, connexin 26; GJB6, connexin 30; GJB3, connexin 31). Mutations in GJB2 account about 50% of all congenital cases of hearing impairment. The analysis of deaf patients lead to the identification of a missense mutation in a family with dominant hearing impairment in the connexin 30 gene. Mutations in GJB3, connexin 31 (Cx31) have been associated with a dominant and recessive form of deafness, as well as, several cases of erythrokeratoderma variabilis (EK). Eighteen nonsyndromic hearing loss families without mutations in the GJB2 were screened for mutations in the GJB3 gene. Besides other alterations a novel dominant mutation in GJB3 was found in a patient with pre-lingual severe deafness. Only two dominant mutations in the GJB3 gene were described before in families characterized by bilateral high-frequency hearing impairment.

**Mutations in the TMPRSS3 gene are a rare cause of childhood non-syndromic deafness in Caucasian patients.** *M. Wattenhofer<sup>1</sup>, S. Alwan<sup>1</sup>, C. Rossier<sup>1</sup>, R. Rabionet<sup>2</sup>, B. Montserrat-Sentis<sup>2</sup>, M.L. Arbones<sup>2</sup>, X. Estivill<sup>2</sup>, A. Pampanos<sup>3</sup>, T. Iliades<sup>3</sup>, M.B. Petersen<sup>3</sup>, M.V. Di Iorio<sup>4</sup>, A. Pasquadibisceglie<sup>4</sup>, M. D'Amelio<sup>4</sup>, P. Gasparini<sup>4</sup>, H-H.M. Dahl<sup>5</sup>, L. Dougherty<sup>6</sup>, H.S. Scott<sup>6</sup>, S.E Antonarakis<sup>1</sup>.* 1) Medical Genetics, University of Geneva School of Medecine, CH; 2) Medical & Molecular Genetics Center, Institut de Recerca Oncologica: Barcelona, Sp; 3) Institut of Child Health: Athens, Gr; 4) Medical Genetics Service, IRCCS-CSS: Rotondo, I; 5) The Murdoch Institute, Royal Children's Hospital, Melbourne, Aus; 6) Genetics and Bioinformatics Division, WEHI, Melbourne, Aus.

About 50% of early-onset deafness cases are genetic and 50% of the recessive cases are due to mutations in the GJB2 gene. The TMPRSS3 gene which encodes a potential transmembrane serine protease, is mutated in the families used to describe both the DFNB10 and DFNB8 loci on chromosome 21 (Scott et al., Nat Genet:27, 59-63, 2001). To determine if TMPRSS3 mutations are an important contributor to the etiology of childhood deafness, we performed SSCP screening of all 13 exons and intron-exon junctions and/or sequencing of DNAs of non-syndromic recessive deaf patients negative for GJB2 gene mutations. A total of 455 such unrelated patients (99 Spanish, 198 Italian, 93 Greek and 65 Australian) were enrolled in the study. Pathogenic mutations have been found in only two patients. A deletion of nucleotide 207C in exon 4 has been found in homozygosity in one Spanish patient resulting in a truncation of the TMPRSS3 protein after the transmembrane domain. A Greek patient is compound heterozygote for del 207C and D103G substitution. D103 is located in the LDLR domain and is well conserved in all examined LDLR domains. In addition, several common known exonic polymorphisms were found (V53I, G111S, I253V) as well as a series of intronic changes. Two new exonic polymorphisms that change amino acids have also been found: D173N and A426T. These results indicate that mutations in TMPRSS3 do not substantially contribute to the non-syndromic deafness in the Caucasian population. The frequency of TMPRSS3 mutations in our sample is 0,44% and is estimated to be 0,2 % in the general Caucasian childhood deafness population.

**The incidence of GJB2 mutations in prelingual deafness in the Greek population.** A. Pampanos<sup>1</sup>, T. Iliades<sup>2</sup>, N. Voyiatzis<sup>2</sup>, N. Eleftheriades<sup>2</sup>, V. "Demokritos", Athens, Greece; 7) JF Kennedy Inst, Glostrup, Denmark; 8) Univ of Ioannina, Greece.

Mutations in the gene encoding the gap-junction protein connexin 26 (GJB2) on chromosome 13q11 have been shown as a major contributor to prelingual, sensorineural, non-syndromic deafness. One specific mutation, 35delG, has accounted for the majority of the mutations detected in the GJB2 gene in Caucasian populations. A carrier frequency of the 35delG mutation of 3.5% has previously been reported in the Greek population. In a collaboration with the major referral centers for childhood deafness in Greece, patients were examined by an extensive questionnaire to exclude syndromic forms and environmental causes of deafness and by allele-specific PCR for the detection of the 35delG mutation. When syndromic forms and environmental cases were excluded, the 35delG mutation was found in 48.6% of the chromosomes in 36 familial cases (16 homozygotes and 3 heterozygotes) and in 32.4% of the chromosomes in 111 sporadic cases (32 homozygotes and 8 heterozygotes). Patients heterozygous for the 35delG mutation were analyzed by direct genomic sequencing of the coding region of the GJB2 gene, which revealed the W24X (2 alleles), L90P (2 alleles), 291insA (1 allele), and R184P (1 allele) mutations. In 5 35delG heterozygotes, no second GJB2 mutation could be detected. We conclude that GJB2 mutations are responsible for a large proportion of prelingual, non-syndromic deafness in the Greek population, and that allele-specific PCR is an easy screening test for the common 35delG mutation.

**Pendred syndrome mutations in the PDS gene cause a loss of iodide transport function and protein**

**mislocalisation.** *J.P. Taylor<sup>1</sup>, R. Metcalfe<sup>2</sup>, A.P. Weetman<sup>2</sup>, P.F. Watson<sup>2</sup>, R.C. Trembath<sup>1</sup>.* 1) Genetics, University of Leicester, Leicester, Leicestershire, United Kingdom; 2) Division of Clinical Sciences, University of Sheffield, Sheffield, United Kingdom.

Pendred syndrome is an autosomal recessive disorder with a variable phenotype, classically characterised as the association between hearing loss and thyroid goitre. This syndromic form of deafness is caused by mutations in the *PDS* gene, encoding an iodide/chloride transporter protein. Pendrin is located at the apical membrane of the thyroid follicle cells where it is hypothesised to be responsible for iodide efflux into the colloidal space. It is also expressed within distinct regions of the inner ear, although its role here is yet to be defined.

Over 50 mutations located throughout 18 of the 20 coding exons, have been reported and associated with a wide spectrum of phenotypes. To aid understanding of the genotype-phenotype correlation we studied the molecular mechanism by which 8 *PDS* mutations, previously identified within our patient cohort, relate to thyroid dysfunction in Pendred syndrome. The ability of wild-type and mutant pendrin to efflux iodide was assayed in HEK293 cells transiently transfected with GFP-tagged *PDS* constructs and NIS, the sodium iodide symporter expressed in the thyroid and responsible for iodide influx. All mutations studied caused a complete or partial loss of transport function in this system. At a cellular level, localisation studies of the mutant pendrin proteins revealed that some fail to reach the cell membrane and are, instead, retained within the endoplasmic reticulum. Mutations leading to a non-functioning, mislocalising protein are associated with a variable patient phenotype, indicating that genetic background and or environmental factors play a significant role in determining the extent of the clinical disorder. Of particular interest, the mutations 1337A>G and 1229 C>T both showed complete loss of iodide transport function, yet in the homozygous state in humans are associated with normal thyroid function, confirming a level of redundancy for pendrin within the thyroid gland.

**The osteogenesis imperfecta mouse (*oim*) thoracic aorta has decreased biomechanical integrity associated with reduced collagen content and increased pyridinoline crosslinks.** C.L. Phillips<sup>1</sup>, B.J. Pfeiffer<sup>1</sup>, R.A. Bank<sup>2</sup>, C.L. Franklin<sup>3</sup>. 1) Dept Biochemistry/Child Health, Univ Missouri, Columbia, MO; 2) TNO Prevention & Health, Leiden, The Netherlands; 3) Dept Veterinary Pathobiology, Univ Missouri, Columbia, MO.

Molecular defects in type I collagen (COL1A1 or COL1A2 genes) can impact mineralized as well as non-mineralized tissues. The primary load bearing components of the aorta are elastin and collagen. Using the osteogenesis imperfecta model mouse [*oim*, homozygous null for a COL1A2 gene, synthesizing only homotrimeric type I collagen,  $[a1(I)]_3$ , instead of normal heterotrimeric type I collagen,  $[a1(I)]_2 a2(I)$ ] we demonstrated that homozygote *oim* mouse aortas have significantly reduced breaking strength and decreased stiffness (incremental elastic modulus) as compared to wildtype (+/+) mouse aortas, with the greatest effect circumferentially and in the descending thoracic aorta. To determine if the decreased biomechanical integrity is associated with alterations in collagen content and/or collagen crosslinking we quantitated total collagen and non-reducible pyridinoline crosslinks in aortic tissues. Both ascending and descending portions of the *oim* thoracic aorta had significantly reduced collagen content relative to +/+ ascending and descending aortas. Yet, the ascending *oim* aorta had significantly *increased* levels of the non-reducible crosslink, hydroxylysylpyridinoline (H-Pyr) [ $0.541 \pm 0.036$  H-Pyr/collagen molecule] as compared to +/+ ascending aorta [ $0.365 \pm 0.032$  H-Pyr/collagen molecule,  $p = 0.005$ ]. The descending *oim* aorta also had increased H-Pyr as compared to +/+ descending aorta, though it was not significant,  $p = 0.077$ . The non-reducible crosslink, lysylpyridinoline, was not detectable. These findings suggest that the absence of pro $\alpha 2(I)$  collagen chains significantly weakens the *oim* thoracic aorta and that the reduced biomechanical properties of the *oim* aorta maybe due in part to decreased collagen content. Moreover, these studies suggest a potential compensatory protective mechanism via increased collagen crosslinking that may stabilize the vascular matrix when there is reduced and/or abnormal type I collagen present.

**Linkage disequilibrium suggests a common origin for Middle Eastern populations of connexin 26 (GJB2) mutations leading to deafness.** *H. Shahin*<sup>1, 2</sup>, *T. Walsh*<sup>3</sup>, *T. Sobe*<sup>2</sup>, *M-C. King*<sup>3</sup>, *K.B. Avraham*<sup>2</sup>, *M. Kanaan*<sup>1</sup>. 1) Dept of Life Sciences, Bethlehem Univ, Palestinian Authority; 2) Dept of Human Genetics and Molecular Medicine, Tel Aviv Univ, Israel; 3) Depts of Medicine and of Genomic Sciences, Univ Washington, Seattle WA.

Mutations in GJB2 are the most frequent known cause of genetic deafness. In most populations, the most common GJB2 mutant alleles are 35delG and 167delT. To explore the origins of these mutations and the historic demography of the Middle Eastern populations in which they occur, we identified SNPs 5-prime of GJB2 (-3558 T/C) and 3-prime of GJB2 (+1749 T/C, relative to ATG=+1 on genomic sequence). The SNPs are separated by 5.3 kb. We genotyped unrelated Palestinian and Israeli deaf probands with known GJB2 mutations and Palestinian and Israeli hearing controls. Allele frequencies among hearing controls at (-3558) were 0.86/0.14 in Israelis and 0.74/0.26 in Palestinians and at (+1749) were 0.88/0.12 in both populations. The most frequent (-3558)(+1749) haplotype, TT, had frequencies of 0.65 among Palestinian and 0.74 among Israeli hearing controls.

GJB2 167delT occurred exclusively on the TT haplotype in both populations. GJB2 35delG also occurred most frequently on the same haplotype in both populations. However, the consensus 35delG haplotype (C at -3558 and T at +1749) was relatively uncommon among both Palestinian and Israeli hearing controls (frequencies 0.27 and 0.14, respectively). Linkage disequilibrium (LD) measured by the Yule coefficient over 3.6 kb between the 5-prime SNP and 35delG was 0.83 among Palestinians and 0.82 among Israelis; LD over 1.7 kb between 35delG and the 3-prime SNP was 1.0 in both populations. The observations that the consensus 35delG haplotype was (a) the same in the two deaf populations and (b) relatively rare in each suggest that GJB2 35delG occurred once in a population ancestral to present communities in the Middle East. Similar LD values among Palestinians and Israelis between sites of deafness-associated GJB2 mutations and adjacent SNPs further support the antiquity and common shared origin of the mutant alleles.

**Low Frequency and Unique Spectrum of Connexin 26 (Cx26) Mutations in Mongolia: Role of Relaxed Selection and Assortative Mating.** A. Pandya<sup>1</sup>, X.J. Xia<sup>1</sup>, R. Erdenetungalag<sup>2</sup>, M. Tekin<sup>1</sup>, T.W. White<sup>3</sup>, J. Radnaabazar<sup>2</sup>, B. Dangaasuren<sup>2</sup>, W.E. Nance<sup>1</sup>. 1) Dept Human Genetics, Medical Col Virginia, Richmond, VA; 2) Dept Human Genetics and Human Reproduction, Maternal and Child Health, Ulaanbaatar, Mongolia; 3) State Univ New York, Stony Brook, NY.

Cx26 mutations account for 20-40% of all prelingual deafness. Heterosis, founder effects and mutation hot spots have been suggested to explain the high frequency of Cx26 deafness. Alternatively, we have proposed that Cx26 deafness may have been specifically amplified during the past 200-300 years by relaxed selection and assortative mating in some but not all parts of the world. To search for such correlations, we measured the frequency of Cx26 deafness in 316 deaf probands, and obtained measures of the genetic fitness and marriage patterns in 160 deaf adults from Mongolia. Since there is no "Deaf culture" or a long tradition of intermarriage among deaf in Mongolia, we expected the genetic fitness, assortative mating and frequency of Cx26 deafness to be low in this country. A survey of 160 deaf adults from Ulaanbaatar city revealed an assortative mating rate of 0.375, much lower as compared to 0.86 in the USA. An overall genetic fitness rate of 0.6 was observed compared to 0.8 for deaf in the USA. Of the 316 probands screened for mutations at the Cx26 locus, 43 had bi-allelic changes. However, only 4 carried both mutations that were definitely pathogenic, accounting for 2-4% of deafness in Mongolia, which is significantly lower than in Caucasian populations. 235delC was the most prevalent mutation (1.6% of alleles), and 35delG was only noted as a heterozygous change in 3 probands (0.5% of alleles). 39 probands had the V27I + E114G double mutation occurring in cis, with 3 being homozygous for double mutation. In vitro functional studies in a xenopus oocyte system revealed loss of intercellular conductance to  $\approx$  95% of WT constructs suggesting a pathogenic role for the double mutant. However, the presence of this change in one normal control raises issue about its clinical relevance role in causing hearing loss.

**Candidate screening for non-syndromic recessive auditory neuropathy.** *R.J. Rogers<sup>1</sup>, P.M. Kelley<sup>1</sup>, B.J.B. Keats<sup>2</sup>, A. Starr<sup>3</sup>, K. Kirschhofer<sup>4</sup>, S.M. Leal<sup>5</sup>, E.S. Cohn<sup>1</sup>, W.J. Kimberling<sup>1</sup>.* 1) Center for Hereditary Communication Disorders, Boys Town National Research Hospital, Omaha, NE 68131; 2) Department of Genetics, LSU Health Sciences Center, New Orleans; 3) Department of Neurology, University of California, Irvine; 4) Department for Oto-Rhino-Laryngology, University of Vienna, Vienna, Austria; 5) Laboratory of Statistical Genetics, The Rockefeller University, New York.

Auditory neuropathy (AN) is a type of hearing loss characterized by absent or abnormal auditory brainstem response with normal outer hair cell function. These individuals generally have poor speech reception out of proportion to the degree of hearing loss and have disappointing results with hearing aids. Most AN cases have an associated peripheral neuropathy, however there is a non-syndromic form which is less common and inherited as an autosomal recessive. In order to find the gene responsible for a type of non-syndromic recessive auditory neuropathy (NSRAN), a genome screen was initiated and linkage analysis was performed on a group of four NSRAN families using LINKAGE program version 5.1 (Lathrop et al. 1984). LOD scores were generated using MLINK for 2-point analyses and LINKMAP for multipoint analyses. Multipoint linkage analysis produced a maximum LOD score of 3.47, while 2-point linkage analysis gave a maximum LOD score of 2.908. Screening of a candidate gene revealed mutations, which we believe are pathologic. Since approaches to treatment and remediation differ between AN and non-AN groups, these findings have important implications for diagnosis, newborn screening, and prognostication. This study emphasizes that audition is a complex phenomenon whose processes can be dissected by modern methods of audiologic analysis.

**Identification and functional analysis of amino acid variants in the connexin26 (GJB2) gene.** *R. Rabionet<sup>1</sup>, E. Thönnissen<sup>2</sup>, A. Bosch<sup>1</sup>, B. Montserrat-Sentís<sup>1</sup>, N. López-Bigas<sup>1</sup>, A. Borragán<sup>3</sup>, M.L. Arbonés<sup>1</sup>, K. Willecke<sup>2</sup>, X. Estivill<sup>1</sup>.* 1) CGMM, Cancer research institute, Avia Castelldefels, Km 2.7, Barcelona, Spain; 2) Institut für Genetik, Universität Bonn, Römerstr. 164, 53117 Bonn, Germany; 3) Centro de Foniatría y Logopedia, Santander, Spain.

Frameshift mutations are the most common defects in the connexin26 gene (GJB2) causing congenital deafness. A large number of amino acid changes have been described, some leading to autosomal dominant hearing loss (W44S, W44C, and I20T). Other amino acid changes cause syndromic hearing impairment with skin disease and autosomal dominant transmission (G59A, D66H). A large number of changes have been detected in patients that have recessive hearing impairment (Connexin-Deafness Homepage <http://www.iro.es/deafness>). The functional consequences of these mutations are largely unknown. We have identified two amino acid changes (G21R and R75Q) that have an autosomal dominant pattern of hearing loss transmission, other changes inherited in an autosomal recessive fashion (L90P, P173R, M1V, R143W) and other changes of uncertain clinical consequences (M34T, R127H, V95A). Functional analysis by dye transfer experiments in HeLa cells stably transfected with the wild type or mutated GJB2 coding region, on some GJB2 mutations, such as M34T, R127H, or R184P showed that mutations M34T or R184P have a reduced functionality. In contrast, mutation R127H, which had been proposed as a dominant mutation, since it was detected in a subject with a dominantly inherited deafness, is in fact as functional as the wild type connexin, and thus, it is probably a polymorphism. This is supported by the identification of additional families and the absence of segregation with hearing impairment. We are also performing new functional studies for G21R, R75Q, V95A and A149T, also by dye transfer in HeLa cells. Acknowledgements: RR is supported by a BEFI grant (98/9207). The study has been supported by a grant from the Botin Foundation and the FISS (Spanish Ministry of Health).

**Mutational analysis of Peroxiredoxin IV (Prx-IV): exclusion of a positional candidate for multinodular goiter.** *E. Giardina*<sup>1</sup>, *F. Capon*<sup>1</sup>, *S. Sciacchitano*<sup>2</sup>, *R. Bruno*<sup>3</sup>, *V. Tassi*<sup>4</sup>, *V. Trischitta*<sup>4</sup>, *S. Filetti*<sup>5</sup>, *B. Dallapiccola*<sup>2,6</sup>, *G. Novelli*<sup>1</sup>.  
1) Department of biopathology, "Tor Vergata" University of Rome; 2) Department of Experimental Medicine and pathology, University "La Sapienza" of Rome; 3) Hospital of Tinchì, MT, Italy; 4) Endocrinology Unit CSS-IRCCS San Giovanni Rotondo (FG), Italy; 5) Department of Experimental Medicine, University of Catanzaro, Italy; 6) CSS-Mendel Institute, Rome, Italy.

Multinodular goiter (MNG) is a common disorder characterized by an enlargement of the thyroid, occurring as a compensatory response to hormonogenesis impairment. We recently assigned an MNG locus to chromosome Xp22 (MNG2, OMIM \*300273), in a region containing the peroxiredoxin IV (Prx-IV) gene. Prx-IV, previously known as AOE372, belongs to a family of antioxidant enzymes, regulating intracellular concentration of reactive oxygen species, including hydrogen peroxide. H<sub>2</sub>O<sub>2</sub> concentration is critical in thyroid tissue, where it is utilized for thyroxine synthesis. In this study, we screened Prx-IV as a positional candidate gene for the MNG2 locus. We sequenced the gene 7 coding exons in 2 patients and 2 unrelated controls. We identified two adjacent polymorphisms within intron 1, but failed to detect any mutation within the coding sequence. On the whole, our data exclude the involvement of Prx-IV in MNG pathogenesis. Work funded by the Italian Telethon (Grant E1031).

**FSHD Myoblasts Possess Reduced Resistance to Oxidative Stress.** *K.A. Barrett<sup>1,2</sup>, R. Tawil<sup>2</sup>, R.C. Griggs<sup>2</sup>, D.A. Figlewicz<sup>1,2</sup>.* 1) Dept Neurobiology & Anatomy, Univ Rochester, Rochester, NY; 2) Dept Neurology, Univ Rochester, Rochester, NY.

Facioscapulohumeral muscular dystrophy (FSHD), the third most common muscular dystrophy, is inherited in an autosomal dominant manner. A variable deletion in a repeat region (D4Z4) of chromosome 4q35 has been associated with the disorder, however, the pathogenesis of FSHD has yet to be established. Myoblasts from FSHD patients possess a necrotic appearing morphology, with a swollen cytoplasm and perinuclear vacuoles. Highly confluent cells appear to lack the organization of normal myoblasts, and FSHD cells fuse to form disorganized, swollen myotubes. Although necrotic appearing cells can be found in cultures of normal myoblasts, a larger percentage of FSHD cells possesses the phenotype ( $2.6 \pm 1.5\%$  for normals, and  $15.7 \pm 6.1\%$  for FSHD,  $p=0.046$ ,  $n=4$ .), controlling for cell density and replicative age. Preliminary observations indicate that this phenotype can be elicited in normal cells exposed to the superoxide anion generator, paraquat. Additionally, previous studies have demonstrated an increased susceptibility of FSHD myoblasts to paraquat relative to normal and disease control (other myopathies) cells. The cyclin dependent kinase (cdk) inhibitor, p21, appears to be upregulated in FSHD cells under normal growth conditions (22.2% of FSHD myoblast nuclei stain strongly positive for p21 compared to 14.2% of normal myoblast nuclei,  $p=0.004$ ,  $n=4$ .); a similar phenomenon in fibroblasts was associated with oxidative stress. Rescue from oxidative stress was attempted by exposing normal and FSHD myoblasts to the membrane permeable anti-oxidant, glutathione ethyl ester (GSH-OEt). Low concentrations of GSH-OEt (0.89mM) achieved full rescue of normal cells exposed to 20mM paraquat. In contrast, GSH-OEt was unable to rescue FSHD cells exposed to 10mM paraquat; the viability of FSHD myoblasts in test wells (containing paraquat plus GSH-OEt) was equivalent to that in wells containing paraquat alone. The current study demonstrates an enhanced irreversible vulnerability of FSHD myoblasts to oxidative stress, suggesting a biochemical marker for FSHD early in myocyte development.

**A KO mouse model for SURF-1 deficiency.** *A. Agostino, L. Valletta, V. Tiranti, P. Corona, M. Zeviani.* Molecular Neurogenetics, Neurological Institute, Milan, MI, Italy.

Loss-of-function mutations of SURF1 cause Leigh syndrome and isolated, generalized COX deficiency in humans. A constitutive KO mouse for SURF1 was generated by replacing exons 3-5 of the murine gene with a Neo cassette. Two independent heterozygous Surf1<sup>+/-</sup> ES cell clones were used to generate three 100% Surf1<sup>+/-</sup> germline chimaeras. Several Surf1<sup>+/-</sup> F1 heterozygous animals were mated together to produce F2 litters. We obtained only three at-term Surf1<sup>-/-</sup> pups out of approximately 150 F2 individuals, suggesting that the KO Surf1<sup>-/-</sup> genotype is embryolethal in most of the cases, at least in our experimental conditions. No Surf1 specific cross-reacting material was detected in fibroblasts from two Surf1<sup>-/-</sup> individuals, and from several organs of a third Surf1<sup>-/-</sup> individual sacrificed at one month after birth. In this animal, COX activity was 40% and 10% of the controls means in muscle and liver homogenates, respectively. The other respiratory chain complexes were normal. This result indicates a function for murine Surf1 specifically related to COX. Brain and muscle histology were both normal. Body growth rate appeared markedly delayed in all three Surf1<sup>-/-</sup> animals and body weight has remained stably reduced in the two KO animals that reached adulthood, compared to age-matched controls. At 5 months after birth, no overt neurological abnormalities have been detected in both. We are currently carrying out further studies on the phenotypic characterization of the KO <sup>-/-</sup> animals, the expression of the surf1 gene cluster in <sup>-/-</sup> and <sup>-/+</sup> individuals, and identification of the embryonal stage of <sup>-/-</sup> lethality .

**Human cationic trypsinogen gene: a new paradigm of disease-associated genes resulting in a “gain-of-function” condition.** *T. Montier, J.M. Chen, C. Férec.* INSERM-EMI 01 15, Etablissement Français du Sang-Bretagne, Université de Bretagne Occidentale, and Centre Hospitalier Universitaire, 46 rue Félix Le Dantec, 29275 Brest, France.

A first classification of mutations is into “loss-of-function” vs “gain-of-function” mutations. It is widely accepted that “gain-of-function” is likely when only a specific mutation in a gene produces a given pathology. However, the identification of multiple, pancreatitis-associated “gain-of-function” mutations in the human cationic trypsinogen gene (PRSS1) is modifying this classical perception.

To date, at least five missense mutations—A16V, D22G, K23R, N29I, and R122H—in the PRSS1 gene have been found to be associated with hereditary or/and sporadic pancreatitis, a much wider mutational spectrum than previously thought with respect to a “gain-of-function” condition. This surprising finding appears to lie in the complicated biogenesis of trypsin and the complex regulation of trypsin(ogen) activation/inactivation: A16V affects the signal peptide cleavage site, D22G and K23R affect the activation peptide cleavage site, R122H disrupts the important R122 autolysis site, and N29I enhances zymogen autoactivation or increases trypsin stability, all of which resulting in an enhanced trypsin activity within the pancreas. Clearly, “gain-of-function” of trypsin can occur through a variety of mutations that affect different amino acid residues with important biological significance. This will make PRSS1 mutations a unique example showing that the spectrum of “gain-of-function” mutations in a gene is not always restricted. Moreover, unlike some genes, where one or two mutations cause a “gain-of-function” condition but other mutations produce different syndromes, the PRSS1 gene may be only associated with a “gain-of-function” condition. This is because on one hand, trypsin appears to perform no function other than alimentary digestion. On the other hand, deficiency resulting from any “loss-of-function” mutations in PRSS1 will not produce a disease due to the existence of multiple functional trypsinogen genes.

**Type II collagen is abnormally processed in spondyloepiphyseal dysplasia tarda (SEDL) cartilage.** *G.E. Tiller<sup>1</sup>, C.E. Baird<sup>1</sup>, M.A. Weis<sup>2</sup>, D.R. Eyre<sup>2,3</sup>.* 1) Dept of Pediatrics, Vanderbilt Univ School of Medicine, Nashville, TN; 2) Dept of Orthopedics, Univ of Washington, Seattle, WA; 3) Dept of Biochemistry, Univ of Washington, Seattle, WA.

Spondyloepiphyseal dysplasia tarda (SEDL) is an X-linked skeletal dysplasia characterized by disproportionate short stature and early-onset osteoarthritis. The SEDL gene is located at Xp22.2, and encodes a 140 amino-acid protein provisionally named sedlin. In addition, a transcribed retropseudogene exists on chromosome 19. Mutational analysis of the SEDL gene in SEDL patients has revealed a recurrent splice mutation, IVS3+5G®A, which is predicted to eliminate the translational start site. In order to assess the effects of the mutation on gene expression, immunohistochemical analysis of cultured fibroblasts using an anti-sedlin antibody was performed. Control fibroblasts demonstrated a perinuclear staining pattern, suggestive of ER or Golgi localization, whereas SEDL fibroblasts demonstrated no staining above background. We have also performed biochemical analysis of articular cartilage from a 50-year old SEDL male with this mutation. Electrophoresis of type II collagen CNBr peptides revealed retarded migration of all major peptides, which was comparable to that seen in tissue from SED congenita patients with type II collagen gene (COL2A1) mutations, and more extensive than that seen in patients with idiopathic osteoarthritis. These results are consistent with post-translational overmodification of type II collagen  $\alpha$ -chains. These data suggest that the common IVS3+5G®A mutation in the SEDL gene is a null allele; the retropseudogene on chromosome 19 is transcribed but not translated; and type II collagen undergoes aberrant post-translational modification in SEDL chondrocytes. Our data support the hypotheses that sedlin serves a role in trafficking of extracellular matrix components within chondrocytes, and that overmodification of type II collagen may be responsible in part for the SEDL phenotype.

**Fibrillin-1 Abnormalities in Fibroblast Cultures From First Degree Relatives of Patients with Systemic Sclerosis.**

*D.D. Wallis, F.K. Tan, F.C. Arnett, D.M. Milewicz.* Dept of Internal Medicine, Univ Texas-Houston Medical School, Houston, TX.

Systemic sclerosis (SSc) is a multisystem disease characterized by visceral and cutaneous fibrosis, autoantibodies, and microvascular abnormalities. We have previously shown that fibroblast cultures from systemic sclerosis (SSc) patients assemble fibrillin-1 containing microfibrils that are more sensitive to degradation than microfibrils assembled by control cells. In addition, FBN1 polymorphisms (SNPs) have been found to be associated with SSc in two populations. We sought to determine if fibrillin-1 microfibril instability could be detected in fibroblast cultures from 1<sup>st</sup> degree relatives of SSc patients. Fibrillin-1 is synthesized as a proprotein and after secretion and proteolytic processing, it multimerizes into matrix structures termed microfibrils. Fibroblasts were explanted from the skin of unaffected 1<sup>st</sup> degree relatives (N=22), of SSc patients (N=12), and age matched controls (N=14). After the cells were metabolically labeled with [<sup>35</sup>S] cysteine for 3 hours, then incubated without label present. The media, cellular lysate, and ECM components were harvested at 24 and 96 hours. The amount of fibrillin-1 in the ECM was quantified on triplicate experimental sets after SDS-PAGE using a Molecular Dynamics Storm 860 imager and a ratio was established using an intracellular protein as a control. Statistical analysis was performed with the Mann-Whitney U test. Analysis of the cellular lysates and medium showed efficient secretion and proteolytic processing from fibrillin-1 in the fibroblast cultures of the 1<sup>st</sup> degree relatives. In contrast, assessment of the amount of fibrillin-1 in the ECM of fibroblasts from 1<sup>st</sup> degree relatives indicated that the amount of fibrillin-1 was significantly lower at 24 hours ( $p < 0.0001$ ), and at 96 hours ( $p = 0.0001$ ) as compared with controls, although a pattern of inheritance of this abnormality could not be determined. These studies indicate that decreased fibrillin-1 incorporation into the ECM is apparent in the cultures from unaffected 1<sup>st</sup> degree relatives of patients with SSc, which supports the hypothesis that the abnormalities in fibrillin-1-containing microfibrils in SSc have a genetic basis, but other genetic or environmental factors are required for the SSc phenotype.

**Identification of a Locus for Anophthalmia on Chromosome 3q, with Delineation of a 2.3 Megabase Candidate**

**Interval.** *A. Male*<sup>1</sup>, *A. Davies*<sup>1</sup>, *A. Bergbaum*<sup>1</sup>, *J. Keeling*<sup>3</sup>, *L. Grace*<sup>4</sup>, *D. Fitzpatrick*<sup>5</sup>, *C. Mackie Ogilvie*<sup>1</sup>, *J. Berg*<sup>2</sup>. 1) The Genetics Centre, Guy's Hospital, London; 2) Division of Medical and Molecular Genetics, GKT School of Medicine, London; 3) Department of Paediatric Pathology, Royal Hospital for Sick Children, Edinburgh; 4) Department of Clinical Genetics, Western General Hospital, Edinburgh; 5) MRC Human Genetics Unit, Western General Hospital, Edinburgh.

Anophthalmia occurs in 3-6 per 100,000 individuals, either in isolation or as a part of a dysmorphic syndrome. In most cases of anophthalmia no cause is identified; however, there are autosomal recessive and X-linked forms of the disease. We have identified two dysmorphic children with bilateral anophthalmia in association with a chromosomal deletion involving distal chromosome 3q. Both patients have bilateral anophthalmia in association with intra-uterine growth retardation, microcephaly, a broad forehead and triangular face. The first patient has a complex karyotype with a translocation between chromosomes 3 and 7 and a deletion of a small segment of chromosome 3 (3q26-q28). The second patient had additional features of partial agenesis of the corpus callosum, abnormal neuronal migration, midline cleft palate, a laryngeal cleft, 13 pairs of ribs and micropenis. He has an interstitial deletion involving a small region of distal chromosome 3q that is not yet fully defined. We have identified BACs known to map to distal 3q from the Ensembl database, and have used fluorescence in-situ hybridization to determine the minimum deleted region common to both patients. The minimum deleted interval identified to date is between clones RPC11-134F2 and RPC11-430L16, an interval of approximately 2.3 million base pairs. We hypothesise either that haploinsufficiency for a gene in this interval is sufficient to cause anophthalmia, or that the chromosomal deletion is unmasking a recessive gene for anophthalmia on chromosome 3q. Our candidate interval contains 12 known genes and 7 novel predicted transcripts, but excludes the HRY gene which was previously a strong candidate. Further characterisation of the candidate interval is in progress.

**Development of a cDNA microarray to study muscular dystrophy.** *T. Tsukahara*<sup>1</sup>, *H. Nagasawa*<sup>2</sup>, *K. Arahata*<sup>1, 3, 4</sup>. 1) Dept Neuromuscular Research, National Institute of Neuroscience, NCNP, Tokyo, Japan; 2) Ebara Co., Kanagawa, Japan; 3) CREST, JST, Tokyo, Japan; 4) Dr. Kiichi Arahata passed away on December 20, 2000.

Defects of plasma membrane or extracellular matrix associated proteins, dystrophin or laminin alpha 2 and so on, due to fragile sarcolemma and muscular dystrophy have been identified. However, there are some muscular dystrophy genes whose products are not associated with the plasma membrane. In particular, deficiencies in two nuclear membrane associated proteins, emerin and lamin A/C, result from Emery-Dreifuss muscular dystrophy, EDMD. Moreover, genes for some cytosolic enzymes, calpain 3 and myotonin protein kinase are also responsible genes for muscular dystrophy. However, the relationship between abnormalities in these genes and muscular dystrophy is unclear. Recently, the characterization of pathological features by a comprehensive examination of gene expression in the patients tissue has become possible. To clarify the gene expression profile and to help therapeutic studies, we developed a human muscle cDNA microarray.

To develop a low-background microarray, we constructed a highly nonredundant human singleton database for virtual cDNAs expressed in skeletal or cardiac muscle. The database was constructed from public sequence data, and then homologous sequences with rRNA and with mtDNA, and with repetitive sequences were excluded to increase the reliability of each probe. PCR primers were designed as amplification lengths of 450-550bp in the vicinity of 3 ends of each singleton. Each fragment of genes in the database was amplified with specific primers and muscle cDNA pools, cloned and confirmed by sequencing. 1536 clones were then amplified, purified and spotted on a CMT-GAPS coated slideglass to make microarrays.

To confirmed sensitivity and reproducibility of our microarray, RNAs were labeled and then analyzed by using tyramide signal amplification system and the ScanArray 5000. One microgram of total RNA was enough to analyze, and our microarray showed low background and good resolution. This microarray was considered to be a suitable device for gene expression analysis of the muscular disease with biopsied samples.

**Al-Aqeel Sewairi Syndrome, A new autosomal recessive disorder with multicentric osteolysis and arthritis with a novel mutation of matrix metalloproteinase 2 gene (MMP-2).** *W.M. Al sewairi<sup>1</sup>, A.I. Al-Aqeel<sup>1</sup>, R.J. Desnick<sup>2</sup>, J.A. Martigenetti<sup>2</sup>.* 1) Departement of Pediatrics, Riyadh Military Hospital , Riyadh, Sauda Arabia; 2) Departement of Human Genetics, Mount Siani School of Medicine, New York, USA.

We reported an autosomal recessive multicentric osteolysis in a Saudi Arabian family with distal arthropathy of the metacarpal, metatarsal and interphalangeal joints, which eventually progressed to the proximal joints and resulted in ankylosis and generalized osteopenia. In addition, they had large, painful to touch palmar and plantar pads and mild dysmorphic facial features including proptosis, a narrow nasal bridge, bulbous nose and micrognathia. Using a genome-wide search for homozygous-by-descent microsatellite markers from 6 members of this family, localized the disease gene to chromosome 16q12-21 with a LOD score of 4.59. Haplotype analysis with additional markers narrowed the critical region to 1.2 cM between markers D16S3032 and D16S3140 and identified the matrix metalloproteinase 2 (MMP-2 , gelatinase A, collagenase type IV, EC 3.4.24.24) gene as a disease candidate. All affected individuals were homoallelic for a nonsense mutation (TCA>TAA) in codon 244 of exon 5, predicting the replacement of a tyrosine residue by a stop codon in the first fibronectin type II domain (Y244X) leading to no MMP-2 enzyme activity in serum and/or fibroblast of affected individuals. In conclusion: The discovery that deficiency of this well characterized gelatinase/collagenase results in an inherited form of an osteolytic and arthritic disorder provides invaluable insights for the understanding of osteolysis and arthritis and the in vivo function of MMP-2.

**Truncating FgfR2 exon IIIc mutation in a familial form of Jackson-Weiss syndrome.** V. El Ghouzzi, E. Lajeunie, T. Hirtzig, J. Bonaventure, A. Munnich, M. Le Merrer. Human Genetics, Hopital Necker Enfants Malades, Paris, France.

Originally described in a large Amish family, Jackson-Weiss syndrome is a craniosynostosis syndrome with midface hypoplasia, hypertelorism, proptosis, foot abnormalities including broad great toes, partial syndactyly of the second and third toes and fusion of tarsal and metatarsal bones. All hitherto reported mutations are missense substitutions occurring within the third Ig-like loop of FgfR2 gene. Here, we report on severe bicoronal craniosynostosis with facial and foot abnormalities typical of the Jackson-Weiss syndrome in a mother and her son carrying a FgfR2 mutation in the alternatively spliced exon 9 which is specific for the IIIc isoform of the receptor. Sequencing this exon revealed heterozygosity of both patients for a two nucleotide deletion at codon 320 (958delAC) causing a frameshift and a premature termination codon at position 324. Surprisingly, semi-quantitative RT-PCR analysis of the patient fibroblasts revealed a 2-fold decreased expression of FgfR2 IIIc, suggesting that the mutation triggered mRNA instability of this isoform. As this mutation could cause ectopic expression of the FgfR2 IIIb isoform, expression of this isoform was investigated in patient fibroblasts but not found. Because no osteoblastic cells of the patients were available, it was not possible to test whether the mutation caused re-expression of FgfR2 IIIb in the calvaria. To our knowledge, this is the first report of a non sense mutation in FgfR2 associated with a craniosynostosis phenotype. Based on a recent FgfR2-IIIc +/- mouse model, we suggest that an heterozygous nonsense mutation in the FgfR2 IIIc isoform would cause a splicing switch resulting in a gain-of-function mutation.

**A Novel CBFA1 mutation in an Italian family CCD with skeletal myopathy.** *C. Casali<sup>1</sup>, F. Cricchi<sup>1</sup>, M. Spadaro<sup>1</sup>, L. Benedetti<sup>1</sup>, G. DiGiacinto<sup>1</sup>, G.A. Amabile<sup>1</sup>, A. Tessa<sup>2</sup>, F.M Santorelli<sup>1, 2</sup>.* 1) Inst Clinica Malattie Ner Men, La Sapienza Univ, Rome, Rome, Italy; 2) Molecular Medicine Unit, IRRCS Ospedale Pediatrico Bambino Ges, Rome, Italy.

Cleidocranial dysplasia (CCD) is a skeletal disorder characterized by large fontanelles, hypoplastic or aplastic clavicles, dental anomalies, and short stature. We studied a two-generation Italian family with a classic CCD phenotype in two patients, father and daughter. Interestingly they also presented clinical, EMG and morphologic signs of skeletal myopathy. We identified a novel CBFA1 mutation in exon 1 (c.398G>A) resulting in the replacement of tryptophan 116 by a stop codon (W116X). A diagnostic polymerase chain reaction-restriction fragment length polymorphism (PCR-RFLP) analysis was used for rapid detection of the novel mutation in the proband and his relatives using the endonuclease BfaI. The novel mutation is likely to be pathogenetic because of the following considerations: 1) the W116X segregated in affected family members; 2) it was not found in 150 control chromosomes; 3) it occurs in the highly conserved CBFA1 runt domain, resulting in premature translation termination. Our findings expand the list of CBFA1 allelic variants in CCD. The CBFA1 gene encodes a transcription factor required for osteoblast cell fate commitment. Identified mutations mostly reside within the DNA-binding runt homology domain. As in other cases, it is possible that the W116X mutation abolishes the DNA-binding ability of the transcription factor CBFA1, affecting protein function and leading to reduced function. Loss-of-function of one allele might result in delayed intramembranous and endochondral ossification since both these pathways have in common osteoblast cell fate commitment and differentiation as a final step in matrix ossification. If this relates to the muscular disorder in the propositus will require further studies.

**Genetic mapping and characterization of an autosomal recessive mouse mutation resulting in skeletal defects and male infertility.** *K.N. Bromfield<sup>1</sup>, I.J. Karolyi<sup>1</sup>, A.M. Wenglikowski<sup>1</sup>, D. Dolan<sup>2</sup>, G. Dootz<sup>2</sup>, A.A. Finnegan<sup>3</sup>, L.D. Siracusa<sup>3</sup>, S.A. Camper<sup>1</sup>.* 1) Human Genetics, University of Michigan Medical School, Ann Arbor, MI; 2) Otolaryngology, University of Michigan Medical School, Ann Arbor, MI; 3) Department of Microbiology and Immunology, Kimmel Cancer Center, Jefferson Medical College, Philadelphia, PA.

A spontaneous mutation resulting in growth insufficiency appeared in the progeny of a female DBA.B6-A<sup>hvy/a</sup> and her father, a DBA/2J male, at the N3 backcross generation. Further breeding demonstrated that the growth impairment was genetic and consistent with recessive inheritance. Mutant males are sterile, but mutant females are semi-fertile. There are no obvious neurological problems in the mutants but they exhibit hind leg clasping when held by the tail.

The growth impairment is detectable by weaning. Adult male and female mutants weigh approximately 75% of their normal littermates. Thyroid hormone levels are normal. Alcian blue and alizarin red staining reveals skeletal abnormalities in the mutant mice, including shortened skull, reduced vertebral bodies, flattened iliac crests, shortened fore and hind limbs and enlarged joints. The number of vertebrae and ribs is normal. These results suggest that the growth insufficiency is due to a developmental defect of bone or cartilage.

Mutant testes are only 25% the size of normal adult testes, although seminal vesicles are normal. Histology reveals small seminiferous tubules, no evidence of sperm maturation, and reductions in germ cells and Sertoli cells.

The karyotype of mutants is normal. To determine the genetic map location of the mutant locus, mutant females were crossed to *Mus castaneus* and 100 F1 intercross progeny were collected. Although growth insufficiency is less obvious among the intercross progeny, both it and male hypogonadism are fully penetrant. Pools of DNA from either mutant mice or their normal littermates were composed, and a genome scan with polymorphic markers revealed an association of the phenotype with distal chromosome 9. Analysis of positional candidate genes is in progress.

**CONTINUED GENETIC INVESTIGATION OF PATIENTS WITH PRESUMED DEFECTS IN THE GH-IGF-1 AXIS: GENOTYPE:PHENOTYPE CORRELATIONS.** *M.E. Ahearn, L. Gayol, E. Estrella, E. Volz, H. Basterrichea, M. Silverman, A. Davis, L. Baumbach.* Pediatrics, Univ Miami Med Sch, Miami, FL.

An increasing percentage of unexplained growth retardation are due to detectable genetic abnormalities, many of which occur in genes which encode proteins and/or factors in the GH-IGF-1 axis. The further understanding of the molecular basis of short stature syndromes will lead to design of better management and treatment modalities. We have completed molecular studies of the Pit-1 and Prop-1 loci in a cohort of short stature patients who have either isolated or multiple pituitary hormone deficiency and of the growth hormone receptor (GHR) gene in patients with suspected growth hormone insensitivity syndrome. Ten individuals representing six families were studied for Pit-1 mutations, 12 individuals in six families for Prop-1 mutations, and four probands in four families for GHR mutations. Possible mutations were evaluated through exon-specific PCR, SSCP and DNA sequencing of SSCP variants. Known mutations for each of these genes were included as positive controls. Evaluation of Pit-1 mutations has revealed a novel SSCP variant found in exon 5 in a consanguineous family with classical Pit-1 phenotype. We are awaiting DNA sequencing results, however, mutations in this exon have never been reported. The remaining five families, who did not display classical Pit-1 phenotypes, did not have detectable Pit-1 abnormalities. Screening for Prop-1 mutations focused initially on detection of a recurrent 2bp deletion mutation in exon 2, which will followed by complete SSCP analysis of the Prop-1 locus. To date, one family displaying a classical Prop-1 phenotype, carries the 2bp del mutation. The entire GHR locus was screened for possible mutations, and to date, no mutations were found in the patients studied, who did not have classical Laron syndrome. These combined results suggest that mutations in these loci will be most often found in patients with classical presentations, and that patients with variant phenotypes may well be due to mutations in-yet to be identified growth regulatory genes.

**Identification of novel mutations in the COL1A1 gene.** *V. Kucinskas, E. Benusiene, D. Kasperaviciute, R. Slibinskas.* Human Genetics Ctr, Vilnius Univ, Vilnius, Lithuania.

Osteogenesis imperfecta (OI) is a generalized disorder of connective tissue characterized by an increased fragility of bones and also manifested in other tissues containing collagen type I, by blue sclera, hearing loss, dentinogenesis imperfecta, hyperextensible joints, hernias and easy bruising. OI is dominantly inherited and results from mutations in one of the two genes (COL1A1 and COL1A2) for the type I procollagen. Recognising the molecular background of OI is helpful in proper diagnosis and, as a result, leads to an improvement of genetic counselling for the families at risk.

The aim of this study was to determine mutations which cause osteogenesis imperfecta (OI) in Lithuanian patients to better postnatal and prenatal diagnosis.

Thirteen familial and eight sporadic dominant OI cases (out of 110 recorded in the Lithuanian OI database) were available for molecular genetic testing. The segregation of OI-linked COL1A1 and COL1A2 loci was analysed using RFLP within or close to the genes. Comparison of phenotypic features with the concordant collagen locus showed that in three pedigrees Sillence OI type I segregated with the COL1A1 locus, while in two pedigrees Sillence OI type I and OI type IV segregated with the COL1A2 locus. In eight remaining pedigrees the data available were insufficient for the identification of a definite OI-linked COL1A locus. DNA heteroduplex analysis based screening for mutations in 30 exons of the COL1A1 gene was performed in probands from 11 OI families and 8 sporadic OI cases. The results showed the presence of nucleotide sequence changes segregating with the OI phenotype in seven probands. Using direct DNA sequencing seven mutations were identified. Out of them, six mutations appeared to be novel: E500X, c.2046-2047insCTCTCTAG, c.1668delT, c.1667-1668insC, IVS19+1G>A, IVS20-2A>G (nucleotides are numbered from the first base of the start codon).

**Cleidocranial dysplasia phenotype and correlations with CBFA1/RUNX mutations.** *K.L. McBride, D. Napierala, Y. Chen, G. Zhou, B. Lee.* Human and Molecular Genetics, Baylor College of Medicine, Houston, TX.

Cleidocranial dysplasia (CCD) is a dominantly inherited skeletal dysplasia with high penetrance and variable expressivity, characterized by delayed endochondral and intramembranous ossification. We and other groups previously reported that mutations in the osteoblast-specific transcription factor CBFA1 cause CCD. The CBFA1 protein consists of an N-terminal stretch of polyglutamine/polyalanine repeats, a runt domain homologous with the *Drosophila* runt gene, and a proline/serine/threonine rich activation domain. The majority of mutations are missense and affect the runt domain, abolishing DNA binding to a target OSE2 sequence. These and other mutations which result in premature termination of the protein in the runt domain produce the classic CCD phenotype by abolishing transactivation by the mutant protein and hence haploinsufficiency of the normal gene.

The objective of the current study was to describe further mutations of the CBFA1 gene associated with CCD and correlate with the respective phenotype. We performed PCR amplification of genomic DNA for CBFA1 gene and sequenced all of its 8 exons. We analyzed for previously undescribed mutations in 27 unrelated patients.

A total of 10 mutations in 10 individuals were identified. There were 3 missense mutations in the runt domain, R190P, R193L, and Q209H, and two frameshifts, 542delG and 867insC. There was one deletion (243del18) in the polyQ/A. Two nonsense mutations (Q284X, Q292X) and two frameshift mutations (961delG, 1224insC) occurred in the PST domain. No mutation types recurred in different families. The frameshift mutation 542delG occurred in a patient with CCD and multiple fractures. Cohort patients had clinical expressions ranging from isolated dental anomalies to severe CCD with fractures. The location of the mutations also correlates well with alteration of multiple interacting domains.

In conclusion, our data demonstrate that variable loss of CBFA1 function may be associated with a spectrum of classic CCD, CCD with osteopenia and fractures, and isolated dental anomalies.

**Identification of genetic loci that modify tooth and bone phenotypes.** *T.C. Hart<sup>1,3</sup>, M.L. Marazita<sup>2,3</sup>, Y. Zhang<sup>1</sup>, M.C. Gorry<sup>1</sup>, M.E. Cooper<sup>2</sup>, J.J. Marks<sup>1</sup>, J.T. Wright<sup>4</sup>.* 1) Dept. Oral Med/Pathology, Univ Pittsburgh Sch Dental Med, Pittsburgh, PA; 2) Dept. Oral & Max Surg, Univ Pittsburgh SDM, Pittsburgh, PA; 3) Dept. Human Gen, Univ Pittsburgh Grad Sch Public Health, Pittsburgh, PA; 4) Dept. Pediatric Dentistry, Sch Dentistry, Univ North Carolina, Chapel Hill, NC.

Tricho dento osseous syndrome (TDO) is an autosomal dominant condition that results from a 4 bp deletion mutation of the distal-less 3 gene (DLX3). We have identified 7 extended families segregating TDO. All 52 TDO affecteds share a common haplotype surrounding the same DLX3 mutation, suggesting it is inherited from a common ancestor. TDO is characterized by variable hair, teeth and bone expression. Thickness of the cranial bones measured radiographically at glabella (mean TDO affected = 9.78 mm; unaffected 7.5 mm) and nuchal crest (mean TDO= 17.3 mm; unaffected 13.3 mm) are significantly increased in TDO affecteds ( $p=0.02$  and  $0.01$  respectively). Tooth size (mean width TDO =11.5 mm, unaffected=13.5 mm) and enamel thickness (mean TDO = 0.42 mm, unaffected 1.5 mm) are significantly reduced in affecteds ( $p=0.0001$ ) compared with unaffected individuals. As TDO affected individuals share a common DLX3 mutation, we hypothesized that the clinical variability associated with tooth and bone traits is due to modifying genes. Segregation analyses of tooth length (TL), width (TW), bone nuchal crest width (NCW), & glabella width (GW) phenotypes are consistent with genetic transmission. To identify modifying genes for tooth and bone findings, we performed linkage studies. Using a candidate gene approach we identified support for genetic modifiers. The transcription factor DLX5 was significantly linked to TL ( $p<0.001$ ), TW ( $p=0.01$ ), GW ( $p=0.007$ ), & NCW ( $p=0.04$ ). Osteocalcin, was linked to TL ( $p<0.001$ ) and TW ( $p<0.001$ ), but not to bone measures. We tested the utility of a high density genome wide scan to detect linkage relationships for modifying genes. Linkage was detected for genetic loci  $> 2cM$  from the DLX5 locus with TL ( $p <0.001$ ), TW ( $p <0.001$ ) and NCW ( $p= 0.001$ ). These data suggest that linkage studies of families segregating TDO provide a unique human model to identify genetic modifiers of tooth and bone phenotypes. NIDCR DE10804.

**Camurati-Engelmann disease: New mutations in the latency-associated peptide of the transforming growth factor b-1 gene.** *S.R. Mumm<sup>1,2</sup>, S. Obrecht<sup>1</sup>, M.N. Podgornik<sup>2</sup>, M.P. Whyte<sup>1,2</sup>*. 1) Division of Bone & Mineral Diseases, Washington University School of Medicine and Barnes-Jewish Hospital Research Institute, St Louis, MO; 2) Center for Metabolic Bone Disease and Molecular Research, Shriners Hospital for Children, St. Louis, MO.

Camurati-Engelmann Disease (CED), also called progressive diaphyseal dysplasia, is an autosomal dominant disorder characterized by painful spreading hyperostosis of the diaphyses of major long bones beginning in childhood. Mutations in the latency-associated peptide (LAP)/transforming growth factor b-1 (TGFb-1) gene have been implicated as the cause of CED in reports of several Japanese and European patients. The LAP and TGFb-1 are co-expressed from the same gene as a single peptide, which is subsequently cleaved into separate LAP and TGFb-1 proteins. A dimerized LAP remains noncovalently bound to a dimerized secreted TGFb-1, presumably keeping the latter inactive. We have sequenced the coding region of the LAP/TGFb-1 gene in 8 unrelated CED patients (3 sporadic, 5 familial), identifying mutations in all but one sporadic case diagnosed elsewhere. In 4 of these probands, previously reported mutations were documented in exon 1 (9 bp insertion causing a 3 Leu insertion in a poly-Leu region) and in exon 4 (Arg218His, Arg218Cys). In the remaining 3 cases, new mutations were identified. The novel mutations include a dinucleotide change in exon 4 (Cys223Ser) at a critical residue involved in disulfide bonding and tertiary structure of the LAP; a previously reported single nucleotide mutation results in the same amino acid change (Cys223Ser). The second was a C to T transition in exon 2 (C463T) causing an arginine to cysteine change (Arg156Cys); one may speculate that this newly created Cys residue could also interfere with disulfide bonding and tertiary structure. The new mutations were not detected in 168 LAP/TGFb-1 alleles from unaffected individuals, showing the changes are mutations and not polymorphisms. Hence, all 7 of the mutations identified to date causing CED are located in the LAP; none are found within TGFb-1. This finding suggests the underlying defect in CED is control, at the protein level, of an intact TGFb-1.

**Targeted disruption of *Cacp* in the mouse resembles human Camptodactyly-Arthropathy-Coxa vara-Pericarditis syndrome (CACP) and provides insight into this disease's pathogenesis.** *J. Marcelino*<sup>1</sup>, *Y. Gong*<sup>1</sup>, *M. Baker*<sup>2</sup>, *M. Warman*<sup>1</sup>, *J. Carpten*<sup>2</sup>. 1) Dept Genetics, Case Western Reserve Univ, Cleveland, OH; 2) National Human Genome Research Institute, NIH, Bethesda, MD.

We have previously reported mutations in *CACP*, which encodes a large, multi-domain, secreted glycoprotein, as the cause of the autosomal recessive disorder Camptodactyly-Arthropathy-Coxa vara-Pericarditis syndrome (CACP). Patients with CACP have congenital or childhood-onset camptodactyly and develop a childhood-onset arthropathy characterized by a non-inflammatory synovial cell hyperplasia. To understand how mutations in *CACP* lead to joint failure, we targeted the *Cacp* gene in mice. Homozygous knock-out mice are viable and fertile. We performed histological analyses on the knee joints of wild-type, heterozygous, and homozygous mice at 15, 30, and 60 days of life. While the wild-type and heterozygous joints appeared normal, the homozygous joints revealed hyperplasia of the synovium, similar to that which has been described in biopsies from CACP patients. Homozygous knock-out mice also had abnormalities of their articular cartilage. The superficial zone of the cartilage appeared thickened and depleted of chondrocytes, and the articular surface had accumulated a layer of eosinophilic-staining material. Although signs of camptodactyly or arthropathy were not apparent in the homozygous knock out mice at 60 days of life, several animals developed swollen ankles and camptodactyly of their hind paws by 6 months of age. We conclude that the *Cacp* knock-out mice have features which resemble human CACP. The cartilage pathology we observed in these mice may also be present in CACP patients, but not appreciated because patients have not had articular cartilage biopsies. This animal model for CACP should permit us to explore potential roles for the CACP in joint homeostasis, such as the lubrication of articulating surfaces and the regulation of intimal cell growth.

**Identification of the gene resulting in the high bone mass trait linked to 11q13.** *R.D. Little<sup>1</sup>, J. Carulli<sup>1</sup>, R. Del Mastro<sup>1</sup>, J. Dupuis<sup>1</sup>, M. Osborne<sup>1</sup>, C. Root<sup>1</sup>, S.P. Manning<sup>1</sup>, P. Swain<sup>1</sup>, S-C. Zhao<sup>1</sup>, B. Eustace<sup>1</sup>, M.M. Lappe<sup>1</sup>, L. Spitzer<sup>1</sup>, S. Zweier<sup>1</sup>, K. Braunschweiger<sup>1</sup>, M.G. FitzGerald<sup>1</sup>, K.M. Allen<sup>1</sup>, S. Recker<sup>2</sup>, P. Van Eerdewegh<sup>1</sup>, R.R. Recker<sup>2</sup>, M. Johnson<sup>2</sup>.* 1) Human Genetics, Genome Therapeutics Corp, Waltham, MA 02453; 2) Osteoporosis Research Centre, Creighton University, Omaha, NE 68131.

Osteoporosis is a complex disease that affects over 10 million people in the U.S. and results in 1.5 million fractures every year. In addition, the high prevalence of osteopenia (low bone mass) in the general population places a large number of people at risk for developing the disease. In an effort to identify genetic factors influencing bone density, we characterized a family with individuals that possess exceptionally dense bones but are otherwise phenotypically normal. This autosomal dominant high bone mass trait (HBM) was originally localized to a 30 cM region on chromosome 11q12-13 by linkage analysis. In order to narrow the genetic interval we extended the pedigree and typed additional microsatellite markers. Linkage analysis resulted in a peak LOD score of 10.1 and a refinement of the interval to less than 3 cM. In order to identify candidate HBM genes, a physical map spanning the critical interval was developed and genomic sequencing of 15 BACs was performed. Comparative DNA sequencing was then used to identify polymorphisms in the HBM candidate genes. From our survey of 231 exons in 17 genes, a single polymorphism was identified that was only present in affected members of the HBM family and not in an ethnic diversity panel of ~1000 individuals. Inhibitors of bone resorption are the most common therapies for osteoporosis. However, the extent of bone loss may far exceed the amount that can be restored by these treatments, making stimulation of bone formation by specific osteogenic agents a potentially valuable adjunct therapy. Our findings suggest that the HBM mutation confers a unique osteogenic activity in bone remodeling, and that the HBM protein represents a novel therapeutic target for the treatment of osteoporosis.

**Physical Mapping of CHH Region and Mutation Analyses in RMRP Gene Among Amish and Non Amish**

**Patients.** *P.K. Jain*<sup>1</sup>, *S. Chandrashekarappa*<sup>2</sup>, *I. Makalowska*<sup>3</sup>, *C.A. Francomano*<sup>1</sup>. 1) Laboratory of Genetics, NIA, Baltimore, MD; 2) GMBB, NHGRI, NIH, Bethesda, MD; 3) GTB, NHGRI, NIH, Bethesda, MD.

Cartilage Hair Hypoplasia is an autosomal recessive disorder prevalent among the Old Order Amish in the United States and the Finish population, although sporadic cases exist in other populations as well. The CHH phenotype is characterized by short stature; sparse, fine hair and other associated features including deficient erythropoiesis, abnormal cellular immunity, aganglionic megacolon and increased risk of certain malignancies. The CHH locus was previously localized to approximately 1.5cM between D9S163 and D9S 1791. In the Amish population, we narrowed the critical region to less than a megabase between the markers D9S163 and D9S1804. We identified seven RPCI-11 library clones ( 182-N-22, 201-P-13, 395-N-21, 156-G-4, 331-F-9, 112-J-3 and 327-I-3) and one Research Genetics library clone 167-M-7 which constitute the contig of the critical region. We mapped several ESTs/Genes and markers within this region. One mapped EST (Accession No. N36356, Lod Score 8.30, distance 33cRS from SHGC33250 on Stanford G3 panel) within the region from Melanocyte library had more than 96% identity with the RMRP (RNA component of Mitochondrial RNA-Processing Endoribonuclease) gene. This gene is within the RPCI-11 library BAC clone 331-F-9 and Research Genetics BAC clones 98-A-4 and 468-J-10. The RMRP gene is encoded in the nucleus and transported to mitochondria and plays a role in RNA primer metabolism in mitochondrial DNA replication. Recently, mutations in this gene have been found among CHH patients (Maaret Ridanpaa et al; cell 104,195-203, 2001). We have screened the RMRP gene in our 15 patients from Amish population and 13 non-Amish patients and found that the mutation 70 A-->G is the more common mutation among our populations representing more than 75% alleles. Thus we conclude that in clinical practice this mutation should be screened first among CHH patients, but before making this, as a regular practice larger number of patients need to be studied.

**Missense Mutations in COL2A1 Which Alter Amino Acids Other Than Triple Helical Glycines in Type II**

**Collagen.** A.J. Richards<sup>1</sup>, J. Morgan<sup>2</sup>, H. Hughes<sup>2</sup>, C. Tysoe<sup>2</sup>, F.M. Pope<sup>2</sup>, A. Bird<sup>3</sup>, M.P. Snead<sup>4</sup>. 1) Pathology Department, Cambridge University, Cambridge, UK; 2) University Hospital of Wales, UK; 3) Moorfields Eye Hospital, London, UK; 4) Addenbrooke's NHS Trust, Cambridge, UK.

We have recently described a type II collagen R365C mutation in two sporadic cases of Stickler syndrome<sup>1</sup> (arthropathopathy). We have now detected a third instance of this mutation in a small family. We compare and contrast the resulting phenotypes to a large family, with an unclassified chondrodysplasia<sup>2</sup>, where a novel mutation (G1105D) is sited in a conserved region of the type II collagen C-propeptide. Unlike these first two cases where premature arthropathy is a feature, a COL2A1 L467F mutation<sup>1</sup> produces a predominantly ocular phenotype.

All affected individuals with the R365C mutation had the congenital membranous vitreous anomaly. Six individuals had suffered retinal detachment. The oro-facial phenotype showed moderate to mild midfacial and nasal hypoplasia. All had mild to moderate sensorineural hearing loss. Joint laxity was largely absent but degenerative arthropathy was severe in the 3 patients over 40yrs of age.

In a large family with a G1105D mutation, affected individuals exhibited a loose liquescent gel without the vitreous anomaly seen in the R365C patients. Some affected individuals showed early degenerative changes in the hips and patellae. Around the time of puberty, brachydactyly, due to abnormal phalangeal epiphyseal development became evident, and was a common feature in this family.

The family with a L467F change all had an "afibrillar" vitreous<sup>1</sup>. Retinal detachment and blindness was common resulting in a severe ocular phenotype. Referred with a diagnosis of Stickler syndrome, the hearing loss, arthropathy and midfacial hypoplasia were uniformly mild or absent in all affected individuals so that dominant rhegmatogenous retinal detachment (DRRD) might be a more appropriate description.

**Molecular diagnosis of SHOX abnormalities in Leri-Weill dyschondrosteosis.** *A.R. Zinn<sup>1</sup>, F. Wei<sup>1</sup>, H. Chen<sup>1</sup>, L. Zhang<sup>1</sup>, P. Marttila<sup>2</sup>, J.L. Ross<sup>3</sup>.* 1) McDermott Ctr Human Growth/Dev, Univ Texas SW Medical Sch, Dallas, TX; 2) Esoterix Endocrinology, Calabasas Hills, CA; 3) Dept. of Pediatrics, Thomas Jefferson University, Philadelphia, PA.

**INTRODUCTION:** Leri-Weill dyschondrosteosis (LWD, MIM 127300) is a dominant skeletal dysplasia characterized by short stature, mesomelia, and Madelung deformity. Mutations or deletions resulting in haploinsufficiency of the Xp/Yp pseudoautosomal gene SHOX have been identified in 60-80% of LWD cases in previous studies. We sought to determine the frequency and nature of SHOX abnormalities in a large number of U.S. LWD subjects. **METHODS:** We collected 29 unrelated families with one or more members having LWD (59 affecteds total) and tested at least one affected individual from each family for SHOX abnormalities. We used FISH to detect SHOX deletions and denaturing HPLC and/or direct sequencing to detect point mutations in the SHOX coding region. **RESULTS:** SHOX deletions were present in 23 families (79%) with a total of 44 affecteds (75%). Point mutations that cosegregated with the LWD phenotype were present in 5 families (17%) with a total of 13 affected (22%). These included frameshift, nonsense, and missense mutations that are all predicted to alter critical regions of the SHOX protein. We did not detect a SHOX deletion or point mutation in one family with two affected sisters. However, analysis of multiple intragenic single-nucleotide polymorphisms failed to demonstrate heterozygosity, suggesting that these women are hemizygous for a SHOX deletion too small to detect by FISH. We are attempting to confirm this deletion by Southern blotting and by segregating SHOX alleles using somatic cell hybrids. **CONCLUSIONS:** SHOX abnormalities are present in 96-100% of LWD patients. Deletions are more common than point mutations. SHOX abnormalities can be identified in nearly all LWD patients using a combination of molecular, cytogenetic, and genetic methods. We found no evidence for locus heterogeneity in LWD.

**Langer mesomelic dysplasia: clinical features and SHOX mutational analysis.** *J.L. Ross<sup>1</sup>, C. Scott<sup>2</sup>, P. Marttila<sup>3</sup>, F. Wei<sup>4</sup>, A.R. Zinn<sup>4</sup>.* 1) Dept Pediatrics, Thomas Jefferson Univ, Philadelphia, PA; 2) A.I. DuPont Children's Hospital, Dept Pediatrics, Jefferson Univ, Philadelphia, PA; 3) Esoterix Endocrinology, Calabasas Hills, CA; 4) McDermott Ctr Human Growth/Dev, Univ of Texas SW Medical Sch, Dallas, TX.

**INTRODUCTION:** Langer type mesomelic dysplasia (LMD, MIM 249700) is thought to be due to homozygous SHOX loss of function mutations. Radiologic findings include severely shortened long bones of the limbs, Madelung deformity, varus deformity of the humeral head, angulation of the radial shaft and distortion of the carpals, short femoral neck, and hypoplastic or absent proximal half of fibula. Homozygous SHOX deficiency was recently reported in a young Langer boy. We present the results of a detailed evaluation of four adults with LMD. **METHODS:** Each subject had careful auxological measurements as well as molecular examination of SHOX. **RESULTS:** Four LMD adults (including one sib pair) were evaluated (2 males, 2 females, ages 33-85 years). Mean height z-scores of the males and females were similar:  $-6.6 \pm 0.5$  vs.  $-6.1 \pm 0.9$ . All subjects had severe mesomelia: mean arm span z-score =  $-8.5 \pm 0.4$ , mean lower leg length z-score =  $-7.1 \pm 2.7$ , evidence of hypoplastic fibulae, and all had Madelung wrist deformity. Hands and feet were relatively normal-sized, and facies were normal without dysmorphic features. Deletion of one SHOX allele in the sibs with LMD was detected by FISH. A missense mutation in one SHOX allele was detected by sequencing in the other unrelated LMD woman. The remaining SHOX alleles are being analyzed. **CONCLUSION:** LMD was previously associated with complete deficiency of SHOX. Our LMD patients also show SHOX abnormalities, although we have not yet proved homozygosity. The resulting mesomelia is severe and is associated with severe short stature and Madelung deformity. The target bones of SHOX action appear to be specific with relative sparing of the hands, feet, and facies. Interestingly, the fibula is markedly abnormal in LMD but spared with SHOX haploinsufficiency. Males and females are similarly affected. Future studies are aimed at elucidating the mechanism of LMD.

**Molecular and protein studies of spondyloepiphyseal dysplasia tarda (SEDТ). X. Zhang<sup>1</sup>, S. Obrecht<sup>1</sup>, M.P. Whyte<sup>1,2</sup>, S. Mumm<sup>1,2</sup>.** 1) Division of Bone and Mineral Diseases, Washington University School of Medicine and Barnes-Jewish Hospital Research Institute, St. Louis, MO; 2) Center for Metabolic Bone Disease and Molecular Research, Shriners Hospital for Children, St. Louis, MO.

Spondyloepiphyseal dysplasia tarda (SEDТ) is an X-linked disorder that presents during childhood with back pain and short stature in boys, caused by vertebral malformation and degenerative changes involving the spine and major joints. The underlying defect is mutation in a gene designated *sedlin*. We have previously described two large SEDТ kindreds with either 2 or 5 base pair deletions in the *sedlin* gene. We now report on a unique splice site mutation in an African-American male with SEDТ. This mutation changes the splice acceptor site at exon 6 from the canonical AG to AC, which likely would prevent mRNA splicing at this site. This is the 3'-most mutation reported for SEDТ, but causes the classical symptoms of the disease.

To begin to understand the cellular function of *sedlin*, we have initiated expression studies and have made a *sedlin* antibody. The *sedlin* cDNA was expressed from an in-vitro translation system as an approximately 14 kD protein; this is consistent with the size predicted from the open reading frame for the protein without post-translational modifications. The *sedlin* antibody was generated with a *sedlin*-specific peptide in rabbits, and was shown to recognize the in-vitro translated protein by Western blot analysis. Endogenously-expressed *sedlin* was also identified as a 14 kD protein in SAOS cells, by Western blot. This results supports the notion that *sedlin* protein does not undergo significant post-translational modification. We have previously shown by Northern blot analysis that *sedlin* mRNA is expressed ubiquitously in a variety of tissues that we examined. In our preliminary Western blot experiments, however, the *sedlin* protein doesn't appear to be ubiquitously expressed. This may help explain why disease-causing mutations in the *sedlin* gene only appear to affect endochondral bone formation.

**A missense mutation in a calcium-channel gene causes SCA in a four generation family also with hemiplegic migraine.** *I. Alonso<sup>1,2</sup>, A. Tuna<sup>3</sup>, J. Coelho<sup>1</sup>, J. Barros<sup>3</sup>, J. Sequeiros<sup>1,2</sup>, I. Silveira<sup>1,2</sup>, P. Coutinho<sup>4</sup>.* 1) Unigene, IBMC - Univ Porto, Porto, Portugal; 2) Lab. de Genética Médica, ICBAS - Univ Porto, Porto, Portugal; 3) Hospital de St. António, Porto, Portugal; 4) Hospital de So Sebastião, Feira, Portugal.

Familial hemiplegic migraine (FHM) is a neurological disorder, characterized by episodes of migraine with hemiparesis or other neurological focal deficits, inherited in an autosomal dominant form. FHM can also be associated with fever, confusion, coma or ataxia. Seven different missense mutations in a gene that encodes a subunit of a neuronal calcium channel cause FHM. Mutations disrupting this gene are also involved in episodic ataxia type 2 (EA2), whereas expansion of a CAG repeat causes spinocerebellar ataxia type 6 (SCA6). We ascertained 29 individuals from a four-generation family, comprising 14 patients with multiple and different phenotypes of progressive cerebellar ataxia, hemiplegic migraine, focal neurological deficits and coma triggered by minor head trauma, dominantly inherited. We have (1) assessed CAG repeat size at the SCA6 locus; (2) performed linkage analysis with chromosome 19p markers D19S1150, D19S840 and D19S226 and (3) screened our family for mutations in the CACNA1A gene. Polymorphism detection was performed by PCR amplification, single strand conformational polymorphism (SSCP) analysis and sequencing. Expansions of the CAG repeat were not present in any of these patients. Linkage analysis was performed and showed positive lod scores to chromosome 19p markers. SSCP and sequencing detected a G-to-A substitution in exon 13 of the CACNA1A gene, resulting in an arginine to glutamine change at codon 583, previously described. This mutation is present in all 12 living patients and also in one at-risk individual. In conclusion, the same missense mutation in the CACNA1A gene gives rise to varied clinical syndromes of permanent ataxia, hemiplegic migraine and episodes of focal deficits or coma triggered by minor head trauma.

**Mutation spectrum and genotype-phenotype correlation of MECP2 in 100 Japanese patients with Rett syndrome.**

*T. FUKUDA<sup>1</sup>, T. Matsuichi<sup>2</sup>, R. Morishita<sup>1</sup>, Y. Yamashita<sup>2</sup>, I. Ohmori<sup>3</sup>, I. Horiuchi<sup>3</sup>, K. Kuwajima<sup>4</sup>, H. Nitta<sup>5</sup>, H. Yamagata<sup>1</sup>, I. Kondo<sup>1</sup>.* 1) Dept. of Hygiene, Ehime Univ. School of Med., Onsen-gun, Ehime, Japan; 2) Dept. of Pediatrics, Kurume Univ. School of Med., Fukuoka, Japan; 3) Dept. of Child Neurology, Okayama Univ. School of Med., Okayama, Japan; 4) Dept. of Pediatrics, Ibaraki Pref. Handicapped Children's Center, Ibaraki, Japan; 5) Niigata Pref. Hamagumi Handicapped Children's Center, Niigata, Japan.

Rett syndrome (RTT) is an X-linked dominant neurodevelopmental disorder characterized by cognitive and adapted regression with autistic behavior, stereotypic hand movements, epilepsy and ataxia. Over 120 different mutations in the methyl-CpG binding protein 2 (MECP2) have been reported in patients with RTT, but the genotype-phenotype correlation has not been established. We have studied MECP2 mutations in 136 patients with RTT and 36 different mutations were detected in 100 patients. Common mutations were four missense mutations (R133C, P152R, T158M and R306C) detected in 34 cases and four nonsense mutations (R168X, R255X, R270X and R294X) detected in 37 cases. Comparing phenotypes in patients with the common MECP2 mutations, three mutations (R133C, R306C and R294X) were more frequently detected in patients with atypical RTT phenotypes. In particular, patients with R133C had the mildest clinical features; 4 in 7 patients with R133C had preserved speech variant type of RTT. Most patients with other common mutations (T158M, R168X, R255X and R270X) and frameshift mutations with deletion/insertion in C-terminal regions had typical form of RTT. A patient with a truncating mutation in 5' region of functional domains had congenital form of RTT. Influence of skewed X-inactivation detected in MECP2 region could be neglected in most patients with RTT. These results suggest that there is genotype-phenotype correlation of MECP2 in patients with RTT, although large scale study of adults patients with RTT needs to determine more precise influence of MECP2 mutations in clinical natural history and phenotypes.

**Genetic heterogeneity and functional candidate gene analysis in Joubert syndrome.** *C.L. Bennett<sup>1</sup>, I.P. Blair<sup>2</sup>, R.R. Gibson<sup>1</sup>, P.F. Chance<sup>1</sup>.* 1) Dept Pediatrics, Univ Washington, Seattle, WA; 2) Garvan Institute of Medical Research, Sydney, Australia.

Joubert syndrome (JS) is a rare autosomal recessive malformation syndrome involving agenesis or dysgenesis of the cerebellar vermis with accompanying brainstem malformations. The disease is also characterized by hypotonia, developmental delay, abnormal respiratory patterns, and abnormal eye movements. The biochemical and molecular mechanisms underlying the JS are unknown. JS is clinically heterogeneous and linkage analyses indicate that there is genetic heterogeneity. Recently, homozygosity mapping identified a Joubert locus on chromosome 9q34 in a consanguineous family of Omani origin and excluded the same locus in a second Iranian pedigree (Saar et al. *AJHG* 1999). We undertook haplotype analyses in 26 Joubert pedigrees including three consanguineous families, using markers that define the locus on chromosome 9q34. We found no evidence of homozygosity for markers in the 9q34 region in these JS pedigrees suggesting that other loci are yet to be identified. A second locus for JS was more recently suggested following the identification of a chromosome 17p11.2 deletion in a patient with features of the Smith-Magenis syndrome and JS (Natacci et al. *AJMG* 2000). The possibility that the JS-like phenotype seen in this individual was due to the unmasking of a recessive JS allele on the non-deleted chromosome was proposed. We undertook haplotype analyses in the 26 Joubert families mentioned above with markers spanning the 17p11.2 deleted region. We found no evidence for homozygosity in this interval in these pedigrees. We suggest that the majority of JS patients do not have a mutant gene in 9q34 or 17p11.2. More directly, we have been able to exclude EN1, EN2 and FGF8 as functional candidate genes by mutation analysis and *BARHL1* by fine mapping exclusion in our cohort of Joubert families. Other strong candidates await investigation including *GBX2*, *MATH1*, *PAX2*, and *PAX5*.

**MECP2 TRANSCRIPTION ANALYSIS AND X-INACTIVATION PATTERN IN A RETT GIRL BRAIN TISSUE.** *F. Gualandi<sup>1</sup>, E. Manzati<sup>1</sup>, S. Bigoni<sup>1</sup>, M. Vacca<sup>2</sup>, M. D'Esposito<sup>2</sup>, G. Hajek<sup>3</sup>, M. Zappella<sup>3</sup>, E. Calzolari<sup>1</sup>, A. Ferlini<sup>1</sup>.* 1) Dept Exp Diagn Medicine, Medical Genetics Section, Ferrara, Italy; 2) IIGB-CNR, Napoli, Italy; 3) Neuropsichiatria Infantile, University of Siena, Italy.

A variety of different MeCP2 mutations have been identified in Rett syndrome (RTT) patients. Furthermore, many mutations, some of these exclusively, have been identified in a relevant number of FRAXA negative, X-linked aspecific mental retardation (X-AMR). Nevertheless, the true pathogenetic mechanism responsible for RTT phenotype(s) as well as the reason why some mutations are associated with X-AMR, remain still obscure. A clear genotype/phenotype correlation has not been established and the non-random X- inactivation remains the more convincing mechanism possibly underlying the diversity in the clinical features. However, the X-chromosome methylation pattern has only been evaluated in lymphocytes, raising the question as to how these cells can be representative of the brain scenario. In order to further examine the role of X-inactivation in RTT we performed transcription as well as X-inactivation HUMARA in a post-mortem sample (temporal cortex) from a RTT girl. Mutation detection in this patient revealed the presence of a R106W missense mutation. Gene-specific semiquantitative RT-PCR of MeCP2 RNA showed the normal transcript in RS brain cortex in amounts comparable to that in two control brains (a male temporal cortex and a female frontal cortex). However, direct sequencing of this transcript in RTT brain revealed only the mutated allele. X-inactivation studies on brain-derived DNA showed a clear skewed X inactivation (98 vs 2). These findings represent the first report on X-inactivation studies in RTT brain and show the occurrence of an extremely skewed inactivation at least in the tissue sample analysed. This evidence is not supporting the haploinsufficiency hypothesis and might be compatible with a loss of function pathogenetic mechanism. Acknowledgement The Italian Association for Rett Syndrome support (AIRETT, <http://www.airett.it/>) is gratefully acknowledged. The work has also been partially supported by the European Union Grant FINGER, QLG2-CT-1999-00920 (to AF).

**Gene expression profiling identifies RNA regulation defects in Amyotrophic Lateral Sclerosis muscle.** *K. Bouri*<sup>1</sup>, *D. Escolar*<sup>1</sup>, *R. Mandler*<sup>2</sup>, *C. Brandoli*<sup>1</sup>, *Y-W. Chen*<sup>1</sup>, *E. Pegoraro*<sup>3</sup>, *C. Angelini*<sup>3</sup>, *E.P. Hoffman*<sup>1</sup>. 1) Center for Genetic Medicine, Children's National Medical Center, Washington, DC; 2) Department of Neurology, George Washington University, Washington, DC; 3) Department of Neurology and Psychiatric Sciences, University of Padova, Italy.

Amyotrophic lateral sclerosis (ALS) is a devastating neurodegenerative disease affecting upper and lower motor neuron and atrophy of affected muscles that leads to paralysis and finally death. We tested the hypothesis that muscle shows ALS specific changes not shared with other denervation or dystrophic states. In order to identify genes that are differentially expressed as a result of ALS, we performed expression profiling of 12,000 genes in ALS patients, juvenile ALS, Charcot-Marie-Tooth (CMT) and control muscles using oligonucleotide microarray (Affymetrix). Patients muscle samples were processed individually on a custom muscle chip (cnHuMuscleA, Affymetrix) and compared to normal control muscles. Most differentially-regulated genes are involved in established pathways of mitochondrial metabolism, nerve degeneration/regeneration processes and growth factor signaling. Interestingly, we identified a gene that is specifically down regulated in adult and juvenile ALS, this gene belongs to a family of RNA metabolism gene processes and ribosomal DNA transcription. We have also identified an ALS specific gene involved in L-Serine biosynthesis, which plays an important role in development and function of the central nervous system. We hypothesize that these genes are involved in stabilizing the neuromuscular junction, and a reduction of these genes in ALS would disrupt the integrity of the NMJ and the ability to reinnervate the muscle after mild denervation, which leads to further damage.

**Spastin, a AAA protein involved in autosomal dominant spastic paraplegia, interacts dynamically with microtubules.** *A. Errico, A. Ballabio, E.I. Rugarli.* TIGEM, Naples, Italy.

Hereditary spastic paraplegia (HSP) comprises a heterogeneous group of neurodegenerative diseases characterised by degeneration of the corticospinal tracts. The gene responsible for the most frequent form of autosomal dominant HSP (SPG4) encodes a 616 amino acid protein, spastin, belonging to the AAA proteins family. The AAA family is characterised by the presence of a highly conserved module with ATPase activity named AAA cassette. Among the members of the AAA family, spastin has higher homology with SKD1, a protein involved in endosomal trafficking, and katanin, responsible for microtubule severing at the centrosome. Interestingly, almost all the missense mutations found in spastin fall into the AAA functional domain. In order to study spastin biological function, we performed subcellular fractionation and immunofluorescence (IF) experiments on transfected cells. These experiments showed that spastin has a cytoplasmic localisation and that its overexpression leads to the formation of aggregates. Interestingly, when a low level of expression is obtained, the protein is localised in the region of the centrosome. To investigate if the ATPase activity could modulate the protein localisation, we produced constructs to express a truncated spastin, lacking the AAA cassette, or a missense mutation predicted to block ATP hydrolysis. IF experiments with these constructs revealed a characteristic filamentous pattern, partially co-localising with alfa-tubulin, and sensible to nocodazole treatment. Furthermore, the distribution of microtubules in transfected cells is altered. The overexpression of all the missense mutations found in patients gave similar results, leading us to postulate that these mutations affect ATP hydrolysis. In conclusion, we have demonstrated that spastin interacts dynamically with microtubules and that this interaction is regulated by ATP hydrolysis. Because of the homology with katanin, we are investigating a possible role of spastin in microtubules severing. These results have important implications for understanding pathogenesis of the axonal degeneration in HSP due to spastin mutations.

**Characterization of gigaxonin, the defective protein in Giant Axonal Neuropathy.** *P. Bomont, M. Koenig.* Institut de Genetique et de Biologie Moleculaire et cellulaire, Strasbourg, France.

Giant Axonal Neuropathy (GAN, OMIM 256850), a severe, autosomal recessive sensorimotor neuropathy affecting both the peripheral nerves and the central nervous system, corresponds to a generalized disorganization of the cytoskeletal intermediate filaments, with neurofilaments predominantly affected.

We localized the GAN locus on chr 16q24.1 (Eur J Hum Genet 2000, 8: 527-534), identified the defective gene by a bioinformatic approach, and cloned the full cDNA by screening a human brain cDNA library (Nature Genetics 2000, 26: 370-374). We have now identified 18 distinct mutations including nonsense mutations in consanguinous families, frameshift and missense mutations, distributed through the 11 exons of the gene. RT-PCR, done on multiple mouse tissues with the orthologue EST indicated ubiquitous expression.

We are now studying the function of the corresponding protein gigaxonin, and looking for its implication in the intermediate filaments organization. Gigaxonin is composed of an amino-terminal BTB/POZ domain followed by six Kelch repeats, which are predicted to adopt a b-propeller shape. No orthologue protein to gigaxonin was present in databases. Since the highest identities among the proteins carrying both a BTB and a Kelch domain ranged only from 22 to 27%, gigaxonin represents a novel and distinct member of this family. We produced both polyclonal and monoclonal antibodies raised against three different peptides and against the N-terminal part of the protein. Gigaxonin localized in the cytoplasm of both COS and HeLa cells in transfection experiments, as revealed by immunofluorescence. Gigaxonin did not colocalize with any of the intermediate filaments, microtubules or microfilaments networks. Experiments with the endogenous gigaxonin are in progress. We detected gigaxonin by western blot and by immunoprecipitation experiments. The search of the putative partners of gigaxonin should provide indications about its function.

Nasu-Hakola disease is a rare autosomal recessive disorder characterized by presenile dementia and bone cysts. Most patients have been found in Finland and Japan. A founder mutation in *TYROBP*, also known as *DAP12*, was found in Finnish Nasu-Hakola disease patients and a different mutation was found in a Japanese patient. *DAP12* was originally identified as an activating co-receptor of natural killer cells. To further delineate genetic basis of Nasu-Hakola disease, we studied 8 independent Japanese families with Nasu-Hakola disease to search for a mutation in *TYROBP*. In 7/8 families, we found a homozygous 144delC mutation, which was the same as the one originally described. Haplotype analysis suggested a common founder for this mutation. Neuropathology of Nasu-Hakola disease has been recognized as a white matter degenerative disease with spheroids. The relationship between the gene mutation and the neuropathology has not been previously studied. We investigated the distribution *TYROBP* protein in the normal brain by immunohistochemistry. *TYROBP* was expressed predominantly in microglia in the white matter and in some neurons in the cortex. In the patient brains we characterized the microglial cells and observed them to be positive with RCA-1 and CD68 but almost negative with ionized calcium binding adaptor molecule-1(Iba-1). This contrasts with other leukodystrophies that we investigated (adrenoleukodystrophy and metachromatic leukodystrophy), in which microglia were positive with Iba-1. These findings suggest that a mutation in *TYROBP* results in brain pathology with altered reactivity in the microglial function.

**Clinical and molecular characterization of Alexander disease patients.** *J.R. Gorospe<sup>1</sup>, S. Naidu<sup>2</sup>, A. Johnson<sup>3</sup>, G. Raymond<sup>2</sup>, O. Ayuste<sup>4</sup>, V. Puri<sup>5</sup>, S. Jenkins<sup>6</sup>, R. Pedersen<sup>7</sup>, D. Lewis<sup>8</sup>, P. Knowles<sup>9</sup>, E. Hoffman<sup>1</sup>.* 1) Center for Genetic Medicine, Children's National Med Ctr, Washington, DC; 2) Kennedy Krieger Institute, Baltimore, MD; 3) Department of Pathology, Albert Einstein College of Medicine, Bronx NY; 4) Downers Grove IL; 5) Norton Healthcare, Louisville KY; 6) Department of Neurology, Children's Hospital Oakland, Oakland CA; 7) Department of Pediatrics - Neurology Service, Tripler Army Medical Center, Honolulu HI; 8) Department of Pediatrics - Neurology Division, Duke University Medical Center, Durham NC; 9) T.C. Thompson Children's Hospital, Chattanooga TN.

Alexander disease is a slowly progressive childhood disorder of the CNS variably manifested by bulbar signs, seizures, ataxia, and macrocephaly. MRI commonly reveal predominantly frontal leukoencephalopathy. Until recently, diagnosis could only be afforded by brain biopsy, where the presence of Rosenthal fibers was considered diagnostic. Mutations in the GFAP gene were recently found in 10 biopsy-proven patients (Brenner et al., *Nature Genetics* 27: 117). Here, we studied 22 patients whose history, physical examination and MRI findings were suggestive of Alexander disease. Sequencing the entire coding region revealed 11 patients (50%) with mutations in GFAP. Age of onset in mutation-positive patients ranged from 2m to 9y. Infantile patients typically presented with seizures and macrocephaly, while older onset patients presented with variable symptoms, including normocephaly, intractable vomiting, and failure to thrive after a relatively unremarkable early childhood. With advancing age, patients developed speech abnormalities, dysphagia, cognitive deficits, and uncoordinated movements, with/without seizures. All the identified mutations involved sporadic single amino acid heterozygous changes: M73R (1), R79G (1), R79H (2), R88C (2), R239C (1), Y242D (1), E373X (1), R416W (2). Most were novel mutations, suggesting that complete screening of the GFAP gene is required for accurate diagnosis. In conclusion, GFAP mutation-positive Alexander disease patients show a variable clinical phenotype. Additionally, patients with a predominantly frontal leukoencephalopathy should be tested for mutations in the GFAP gene.

**Infantile Alexander Disease: spectrum of GFAP mutations and genotype-phenotype correlation.** *O. Boespflug-Tanguy*<sup>1</sup>, *D. Rodriguez*<sup>2,3</sup>, *F. Gauthier*<sup>1</sup>, *E. Bertini*<sup>4</sup>, *G. Uziel*<sup>5</sup>, *R. Surtees*<sup>6</sup>, *S. N'Guyen*<sup>7</sup>, *C. Goizet*<sup>8</sup>, *A. Gelot*<sup>2</sup>, *JM. Pedespan*<sup>8</sup>, *M. Dautigny*<sup>3</sup>. 1) Fac de Medecine, Inserm U384, Clermont-Ferrand, France; 2) Hopital Saint Vincent de Paul, Paris; 3) URA CNRS 1488, Paris; 4) Ospitale Bambino Di Jesu, Roma, Italy; 5) Istituto Carlo Besta, Milano, Italy; 6) Institute of Child Health, University College, London, UK; 7) University Hospital Nantes, France; 8) University Hospital Bordeaux, France; 9) Hospital Clinico San Borja Arriaran, Santiago, Chile; U. Birmingham, Alabama and U. Wisconsin, Madison, USA.

Alexander disease (AD) is a leukoencephalopathy characterized by the presence of Rosenthal fibers (RF) in astrocytes. RF are cytoplasmic inclusions containing the intermediate filament protein GFAP. In infantile cases, the disease begins during the first 2 years of life with macrocephaly, psychomotor regression, seizures leading to death within the first decade. MRI is useful for diagnosis showing white matter signal changes with a rostrocaudal gradient, basal ganglia and thalamic abnormalities. Most of AD are sporadic. The genetic origin of this disease was still controversial when RF were found in the brain of mice overexpressing human GFAP. Heterozygous, de novo, GFAP missense mutations were found in 12 of 13 patients affected by a neuropathologically proven AD. We investigated a new series of 16 patients with heterogeneous clinical symptoms but neuroimaging abnormalities suggestive of AD. Missense, de novo, GFAP mutations, restricted to exons 1 and 4, were found in 15 cases including patients without macrocephaly and a slowly progressive white matter disease. Ten patients had previously described arginine mutations (5 R79H; 4 R239C and 1 R239H), but the other 5 had 3 novel mutations including arginine (2 R88C, 1 R88S) or non-arginine residues (L76F; N77Y), with a correlation according to the clinical severity. All mutations are located in the rod domain of the GFAP. These results confirm that dominant GFAP mutation is a reliable molecular marker for the diagnosis of infantile AD, including prenatal diagnosis to detect cases of germinal mosaicism.

**Ataxia with primary vitamin E deficiency (AVED): clinical, biochemical and molecular study in Italian patients.**  
*C. Gellera, R. Mineri, M. Rimoldi, D. Vacca, A. Castucci, B. Castellotti, F. Taroni, S. DiDonato, C. Mariotti.* Divisione di Biochimica e Genetica, Istituto Neurologico C Besta, Milan, Italy.

AVED is a rare autosomal recessive neurodegenerative disorder due to mutations in the  $\alpha$ -tocopherol transfer protein ( $\alpha$ -TTP) gene located on 8q13. AVED patients present an impaired ability to incorporate  $\alpha$ -tocopherol into VLDL secreted by the liver. Vitamin E is a potent lipid-soluble antioxidant, especially effective in scavenging peroxy radicals in cell membranes. In AVED patients, plasma levels of vitamin E are usually less than 10% of controls. The disease has a juvenile onset and is most frequent in North-African and Mediterranean populations. The neurological phenotype is very similar to that observed in patients affected with Friedreich's ataxia (FRDA), the most common hereditary ataxia. Unlike FRDA, however, cardiac involvement and impairment of glucose metabolism are very unusual in AVED patients. Progression of neurological deficits can be prevented by daily supplementation of high doses of vitamin E.

We studied 13 ataxic patients from 11 families of Italian origin, who exhibited very low plasma levels of vitamin E (range 0.11 - 0.33 mg%; nv,  $1.22 \pm 0.23$  mg%). Age at onset ranged from 4 to 27 y. None of them presented cardiomyopathy or diabetes. We identified pathogenic mutations in 21/22 alleles. Two mutations, 744delA and 513insTT, were found to be prevalent. These mutations accounted for 70% of the mutated alleles (16/22). The 744delA mutation had been previously described in the majority of patients of Mediterranean origin, while the 513insTT had been found in patients of North European origin. We also identified two novel mutations: a homozygous 210insTA identified in a patient from consanguineous parents and a Gly246Arg missense mutation found in a compound heterozygous patient carrying the 513insTT on the other allele. The characterization of AVED patients is particularly relevant because early treatment with vitamin E can delay the progression of the disease. Moreover, the treatment of presymptomatic subjects in characterized families could potentially prevent the development of neurological deficits.

**The effects of  $\alpha$ -synuclein expression on gene expression profiles in familial Parkinson's disease.** *B.A. Chase<sup>1</sup>, L. Avery<sup>2</sup>, Z.K. Wszolek<sup>3</sup>, K. Markopoulou<sup>2</sup>.* 1) Dept of Biology, Univ Nebraska, Omaha, NE; 2) Dept of Neurological Sciences, Univ of Nebraska Medical Center, Omaha, NE; 3) Dept of Neurology, Mayo Clinic, Jacksonville, FL.

Mutations in  $\alpha$ -synuclein (G209A, G88C) are associated with Parkinson's disease (PD). The function of normal  $\alpha$ -synuclein is presently unknown.  $\alpha$ -Synuclein is identified in aggregates - Lewy bodies (PD) and amyloid plaques (Alzheimer's disease), yet mutations have only been found in familial PD. In familial PD with the G209A mutation, there is considerable phenotypic variability including age of onset, disease severity and duration and neuropathology. We have found that in familial PD, the expression of the G209A allele is significantly reduced or absent. To gain insights into the role(s) of  $\alpha$ -synuclein and its expression status in neurodegeneration we used cDNA microarrays to profile gene expression as a function of G209A  $\alpha$ -synuclein allele expression status. We assayed the expression of approximately 3500 genes in cell lines established from members of a large kindred with PD. To assess the effects of differential  $\alpha$ -synuclein expression on the expression of other genes we compared symptomatic individuals not expressing the G209A allele to asymptomatic individuals who did not express the G209A allele, but were older than the mean age of disease onset for their generation, and to individuals who were asymptomatic, did express the G209A allele, and were younger than the mean age of onset for their generation. We find that the expression of a large number of genes is differentially affected as a function of the expression of the  $\alpha$ -synuclein mutant allele. Here, we focus on two sets of genes, one involved in energy and one in the proteasome pathway. For example, the expression of different subunits of the mitochondrial ATP synthase and NADH dehydrogenase, E3 ubiquitin ligase and ubiquitin conjugating enzyme E2 are overexpressed in the absence of the expression of the G209A allele. These findings support the hypothesis that the status of  $\alpha$ -synuclein gene expression plays a role in neurodegeneration and that the  $\alpha$ -synuclein gene functions in networks affecting multiple aspects of cellular function.

**A novel myelin protein zero mutation associated with Charcot-Marie-Tooth type II disease.** *E. Di Maria<sup>1</sup>, D. Cassandrini<sup>1</sup>, P. Balestra<sup>1</sup>, F. Manganelli<sup>2</sup>, L. Santoro<sup>2</sup>, F. Ajmar<sup>1</sup>, P. Mandich<sup>1</sup>, E. Bellone<sup>1</sup>.* 1) Dept. of Neurological Sciences and Vision, University of Genova, Genova, Italy; 2) University of Napoli Federico II.

Charcot-Marie-Tooth type II disease (CMT2) is a typical peroneal muscular atrophy syndrome and is characterised by normal or slightly reduced nerve conduction velocities with signs of axonal degeneration. CMT2 is genetically heterogeneous: linkage to 1p35-p36 (CMT2A), 3q (CMT2B) and 7p (CMT2D) loci has been reported for the autosomal dominant disease; however, the majority of CMT2 families do not link to any of the reported loci. Mutations of the myelin protein zero (MPZ) gene were found associated with demyelinating forms of hereditary neuropathies such as CMT1B, Dejerine-Sottas syndrome and congenital hypomyelination. So far, few CMT2 cases were found to be caused by point mutations in the MPZ (see CMT Mutation Database, <http://molgen-www.uia.ac.be/CMTMutations/>).

We report a family in which three members are affected with a late-onset peripheral neuropathy. The index patient is a 68 years old male who presents with pronounced distal muscle weakness of inferior limbs, bilateral *pes cavus* and absence of deep tendon reflexes. Electrophysiological findings were suggestive of an axonal form of peripheral neuropathy, thus allowing the diagnosis of CMT type 2. At the clinical and electrophysiological examination, two other family members (first cousins of the proband) resulted to be affected. MPZ gene direct sequencing revealed a heterozygous T/A transversion in the exon 3 of the gene, predicting an Asp103Glu aminoacid substitution in the extracellular domain of the protein. This variant was not found in unaffected relatives and in 100 normal chromosomes. This finding confirms the role of protein zero in axonal neuropathies and further suggests that the assessment of the MPZ gene should be included in the molecular diagnostic protocol of CMT2 patients.

(The laboratory is a member of the European CMT Consortium; partially granted by Ministero della Sanit to PM, MURST to FA).

**An hPer2 Phosphorylation Site Mutation in Familial Advanced Sleep-Phase Syndrome.** *Y. Fu*<sup>1</sup>, *C.R. Jones*<sup>2</sup>, *K. Toh*<sup>3</sup>, *D. Virshup*<sup>4</sup>, *L.J. Ptacek*<sup>5</sup>. 1) Neurobiology and Anatomy, Univ Utah, SLC, UT; 2) Department of Neurology, Univ Utah, SLC, UT; 3) Department of Human Genetics, Univ Utah, SLC, UT; 4) Department of Pediatrics, Univ Utah, SLC, UT; 5) Howard Hughes Medical Institute, Univ Utah, SLC, UT.

Advanced Sleep Phase Syndrome (ASPS) is manifest by early sleep preference and early morning awakening. It is very common in elderly people who tend to sleep and wake earlier than when they were younger. Familial advanced sleep phase syndrome is an autosomal dominant circadian rhythm variant that is similar although much more severe than the ASPS of aging; affected individuals are "morning larks" with a 4 hour advance of the sleep, temperature and melatonin rhythms. We now report localization of the FASPS gene near the telomere of chromosome 2q. A strong candidate gene (hPer2), a human homolog of the period gene in *Drosophila*, maps to the same locus. Affected individuals have a serine to glycine mutation within the casein kinase I (CKI) binding region of hPER2, that causes hypophosphorylation by CKI in vitro. Thus, a variant in human sleep behavior can be attributed to a missense mutation in a clock component, hPER2, that alters the circadian period. We have now expanded our collection of families and are looking for other hPer2 gene mutations. In addition, other candidate circadian rhythm genes are being screened for mutations in probands who don not have hPer2 mutations.

**Gene Expression Profiling in Infantile SMA Muscle.** *C. Brandoli<sup>1</sup>, K. Bouri<sup>1</sup>, D.M. Escolar<sup>1</sup>, Y-W. Chen<sup>1</sup>, S. Servidei<sup>2</sup>, E.P. Hoffman<sup>1</sup>.* 1) Research Center for Genetic Medicine, Children's National Medical Center, Washington, DC; 2) Institute of Neurology, Catholic University of Rome, Italy.

Spinal Muscular Atrophy (SMA) is an autosomal recessive neuromuscular disease occurring 1 in 10,000 newborns. While the primary pathological feature of SMA has long been considered to be the loss of the cell bodies of a-motor neurons in the anterior horn of the spinal cord, increasing evidence points to additional primary defects of the end target of the motor neurons, namely skeletal muscle. SMA is caused by reduction of the expression of the survival of motor neuron (SMN) gene, which is thought to regulate a series of downstream mRNAs, which have not yet been defined. We used gene expression profiling of biopsies from infantile SMA patients to define the pathophysiological mechanisms involved in the onset and progression of the disease. Expression profiling was done on five muscle biopsies from SMA type I patients and compared to age/sex matched normal controls. 70 genes of 15,000 studied showed more than 2-fold-up or down regulation in SMA patient muscle. The most interesting group of down-regulated genes involved transcription factors with 24-fold under expression of a specific Zinc finger protein; similar proteins have recently been shown to interact with SMN and co-localizes with SMN in subnuclear structures. We found a number of genes, typically overexpressed during denervation, which were either downregulated (c-fos, jun-B, NF-IL6) or upregulated (IGF-II) in SMA muscle. We developed a model where nerve/muscle interaction is disrupted in SMA, where some compensatory re-innervation signaling pathways are lost due to SMN depletion, while other pathways are retained but insufficient to sustain or re-establish innervation. Our finding of dramatic down-regulation of a Zinc finger protein suggests that this protein fails to associate with gems, inhibits splicing or activation of other transcription factors which are up-regulated during normal muscle denervation. The loss of muscle molecular response triggers a secondary mechanism of re-innervating signals to the nerve: degenerating motor neurons are unable to respond to the signals and inappropriate cell death occurs.

***Atlastin* gene analysis in early onset hereditary spastic paraplegia.** D.M. Alvarado<sup>1</sup>, L. Ming<sup>1</sup>, P. Hedera<sup>1</sup>, S. Rainier<sup>1</sup>, X. Zhao<sup>1</sup>, W. Raskind<sup>2</sup>, T. Bird<sup>3</sup>, J.K. Fink<sup>1,4</sup>. 1) Department of Neurology, University of Michigan, Ann Arbor, MI; 2) Department of Medicine, University of Washington, Seattle, WA; 3) Department of Neurology, University of Washington, Seattle, WA; 4) Geriatric Research Education Clinical Center, Ann Arbor Veterans Affairs Medical Center.

Hereditary spastic paraplegia (HSP) is a group of disorders characterized by progressive lower extremity spastic weakness. 7 loci for "uncomplicated" autosomal dominant HSP (ADHSP) have been identified. These forms of "uncomplicated" HSP are clinically similar although differ in the average age of symptom onset. Symptoms begin before age 11 yrs.(on average) in ADHSP linked to chr. 12 (SPG10), 14 (SPG3), and 19 (SPG12); and after age 20 yrs. (on average) in ADHSP linked to chr. 2p (SPG4), 2q (SPG13) 8 (SPG8), and 15(SPG6). Recently (*Zhao et al, ASHG abstract 102*), we discovered disease-specific missense mutations in a novel GTPase (designated *atlastin*) in each affected subject from 3 families with chr.14q-linked ADHSP in which symptoms began before age 10 years.

In the present study, we investigated the frequency of *atlastin* gene mutations in childhood onset ADHSP. We sequenced each *atlastin* exon in affected subjects from 11 ADHSP kindreds in which the disorder began in childhood. Small family size (9 kindreds)precluded linkage analysis; 1 early onset ADHSP kindred had lod score to the SPG3 locus »1.0. We also analyzed samples from subjects from 2 small ADHSP kindreds with later symptom onset (6-52 years) but for whom lodscore = 1.0 suggested possible linkage to the chr. 14q SPG3 locus.

We found disease-specific *atlastin* mutations in 2 of 10 early onset ADHSP kindreds that were not pre-selected for linkage to SPG3. Both families had the same mutation (codon 239 Arg@Cys) which was previously identified in affected subjects from an ADHSP kindred linked to the SPG3 locus. These observations suggest that 20% of early onset ADHSP kindreds have *atlastin* coding sequence mutations.

**Missense mutation in TSC2 associated with an unusually mild form of tuberous sclerosis.** *D. D'Agostino<sup>1</sup>, F. Dubeau<sup>1</sup>, A. Al-Asmi<sup>1</sup>, S. Bourgoin<sup>2</sup>, M. Labuda<sup>2</sup>, S. Mercho<sup>1</sup>, F. Andermann<sup>1</sup>, M. Pandolfo<sup>2</sup>, D.J. Kwiatkowski<sup>3</sup>, E. Andermann<sup>1</sup>.* 1) Montreal Neurological Institute and Hospital, McGill University, Montreal, PQ, Canada; 2) Centre Hospitalier de l'Université de Montréal, Montréal, PQ, Canada; 3) Brigham and Women's Hospital, Boston, Harvard University MA.

Tuberous sclerosis is an autosomal dominant disorder characterized by hamartomata in various organs, including skin, brain and kidneys, caused by TSC1 (9q34) or TSC2 (16p13.3) mutations. Familial cases are equally distributed between TSC1 and TSC2. The majority of sporadic patients have TSC2 mutations. The disease phenotype is milder in sporadic TSC1 patients (Dabora et al., 2001).

We report a large extended kinship with exceptionally mild TSC2.

Field trips were carried out to examine the family members and to collect blood samples. We reviewed medical records and brain imaging data (MRI). 55 subjects were genotyped for markers linked to the loci for familial partial epilepsy with variable foci (22q11), TSC1 (9q34) and TSC2 (16p13). We defined the affected status by coexistence of epilepsy and skin lesions. Two point lod scores were calculated using the MLINK program.

Of 65 individuals examined, 18 had epilepsy. In most patients, seizures were well controlled by medication and became milder or resolved at older ages. All assessed individuals with epilepsy had hypopigmented macules on the limbs and trunk. An additional 12 family members had only hypopigmented macules. No facial angiofibromas, periungual fibromas or retinal hamartomas were found. MRI, available in 7 patients, showed left frontal sub-ependymal giant cell astrocytoma and sub-ependymal nodules in one patient each. 1/5 screened individuals had renal angiomyolipoma. No rhabdomyoma was revealed by echocardiography. Penetrance of epilepsy was about 60%. The penetrance of hypopigmented macules reached almost 100%. Linkage to the TSC2 locus was demonstrated. Mutation analysis revealed a missense mutation in exon 23 of the TSC2 gene (2714G®A, 905R®Q).

This study should contribute to clarifying genotype-phenotype correlations in familial TSC2.

**Phenotypic consequences of mosaic MeCP2 high expression in cerebral cortical neurons: A quantitative comparison of normal and Rett brains.** *J.M. LaSalle<sup>1</sup>, J. Goldstine<sup>1</sup>, D. Balmer<sup>1</sup>, C.M. Greco<sup>2</sup>*. 1) Medical Microbiol & Immunology, Univ California Davis Sch Med, Davis, CA; 2) Medical Pathology, UCDCM, Sacramento, CA.

Rett syndrome (RTT) is an X-linked dominant neurodevelopmental disorder caused by mutations in *MECP2*, encoding the methyl-CpG-binding protein 2 (MeCP2). The role of MeCP2 in postnatal neuronal development is currently unknown. We have recently developed an approach for quantitating the level and distribution of wild-type and mutant MeCP2 *in situ* by immunofluorescence and laser scanning cytometry. Surprisingly, cellular heterogeneity in MeCP2 expression level was observed in normal brain with a subpopulation of cells exhibiting high expression (MeCP2<sup>hi</sup>) and the remainder exhibiting low expression (MeCP2<sup>lo</sup>). MeCP2 expression was significantly higher in CNS compared to non-CNS tissues of human and mouse by automated quantitation of MeCP2 on multiple tissue arrays. Quantitative localization of MeCP2 expression phenotypes in normal human brain showed a mosaic but distinct distribution pattern, with MeCP2<sup>hi</sup> neurons highest in layer IV of the cerebrum. Using combined fluorescent staining approaches for neurons (fluorescent Nissl dye), chromatin (propidium iodide), nucleoli (anti-nucleolin), and mRNA (oligo dT hybridization), quantitation of phenotypic differences between MeCP2<sup>lo</sup> and MeCP2<sup>hi</sup> neurons was determined in normal human cerebral sections. MeCP2<sup>hi</sup> neurons had significantly larger nuclei with more euchromatin, larger nucleoli, and more transcription when compared to MeCP2<sup>lo</sup> neurons. In contrast, no difference was observed in the level of histone acetylation or Nissl stain between the two populations. Using a C-terminal specific anti-MeCP2 to identify neurons expressing the truncated allele of *MECP2* in RTT cerebrum, mutant-expressing neurons were found to have the phenotypic characteristics of MeCP2<sup>lo</sup> neurons. Use of an N-terminal specific anti-MeCP2 showed normal ratios of MeCP2<sup>hi</sup> cells in RTT brains, demonstrating normal expression of mutant MeCP2. These results demonstrate that MeCP2 mutations in RTT are primarily manifested in phenotypically MeCP2<sup>hi</sup> cells and suggest that MeCP2 loss-of-function inhibits chromatin organization and activation of cerebral neurons.

**Abnormal processing of proteolipid protein pre-mRNA is associated with an unusual presentation of Pelizaeus-Merzbacher disease.** *G.M. Hobson<sup>1</sup>, Z. Huang<sup>2</sup>, A. McCullough<sup>3</sup>, H.G. Marks<sup>4</sup>, D. Stabley<sup>1</sup>, K. Sperle<sup>1</sup>, F. Cambi<sup>2</sup>.* 1) Dept Research, Alfred I duPont Hosp Children, Wilmington, DE; 2) Dept Neurology, Thomas Jefferson University School of Medicine, Philadelphia, PA; 3) Dept Biochemistry and Molecular Biology, Baylor College of Medicine, Houston, TX; 4) Dept Pediatrics and Neurology, University of Pennsylvania Medical School, Philadelphia, PA.

Mutations in the proteolipid protein gene (*PLP1*) are associated with X-linked disorders that span in clinical severity from the severe developmental phenotype of Pelizaeus-Merzbacher disease (PMD) to mild forms of pure hereditary spastic parapareses (HSP). Genetic determinants of the phenotypic variability remain unclear. Two proteins, PLP and DM20, are generated from the same primary transcript by alternative splicing of intron 3, which is regulated as part of oligodendrocyte differentiation. We identified a deletion of a novel G-rich element within intron 3. The proband was affected initially by a very mild phenotype, but he lost motor and cognitive milestones in the end of his first decade of life, a rapidly progressive course not commonly observed in PMD. Early MRI studies demonstrated normal appearance of white matter, suggesting relatively normal myelin deposition; however, subsequent MRI and MRS studies showed a significant degree of axonal loss and some myelin breakdown. The imaging findings correlate with the clinical course of his disease. Our molecular studies show that PLP-specific splicing is impaired in CG4 cells and primary rat oligodendrocytes transfected with a chimeric construct carrying the 19-nucleotide deletion. DM20 transcript is expressed normally, suggesting that the deletion results in drastic reduction of PLP transcript and protein. In cross-linking experiments in vitro, we detected binding of a protein factor to the 19-nucleotide sequence. We conclude: 1) regulatory elements in the 19-nucleotide sequence participate in selection of splicing and cell-specific expression of the PLP transcript, 2) alterations in RNA processing that result from the deletion lead to the selective loss of PLP, and 3) the drastic reduction in PLP may affect myelin stability and axon-glia interactions resulting in axonal loss.

**Phenotypical variability in loci of holoprosencephaly.** *S. Odent*<sup>1</sup>, *M. Blayau*<sup>2</sup>, *L. Lazaro*<sup>2,3</sup>, *A. De La Pintiere*<sup>2</sup>, *C. Aguilera*<sup>2</sup>, *L. Pasquier*<sup>1</sup>, *C. Dubourg*<sup>2</sup>, *V. David*<sup>2,3</sup>. 1) Genetique medicale, Hopital Pontchaillou, Rennes, France; 2) Genetique molculaire, Hopital Pontchaillou, Rennes, France; 3) UPR41 CNRS, Faculte de medecine, Rennes, France.

Holoprosencephaly (HPE ; 1/16.000 live births ; 1/250 conceptuses) is a common development defect affecting both the forebrain and the face. Clinical expressivity is variable, ranging from a single cerebral ventricle and cyclopia to clinically unaffected obligated carriers in familial HPE. The disease is genetically heterogeneous but additional environmental agents also contribute to the aetiology of HPE. This study includes 121 unrelated nonchromosomal HPE cases (75 typical HPE, 28 atypical cases, 18 polymalformative cases). We provide clinical data regarding the subgroup of typical HPE and report 18 novel heterozygous mutations (15% for all the cases, 22% for typical HPE), 10 in Sonic hedgehog gene (SHH), 4 in ZIC2, 3 in SIX3, and 1 in TGIF. Nine mutations were found in familial cases whereas 9 mutations were identified in apparently sporadic cases. Original phenotypes associated with a mutation have been observed : isolated cleft lip and palate, abnormalities in the pituitary gland and corpus callosum, colobomatous microphthalmia and brachymetacarpia, choanal stenosis, without HPE. This study confirms the extremely variable phenotypes in HPE families and the genetic heterogeneity of the disease.

**Compensating for CNS dysmyelination: females with a *PLP* duplication and sustained clinical improvement.** *K. Inoue*<sup>1</sup>, *H. Tanaka*<sup>2</sup>, *F. Scaglia*<sup>1</sup>, *A. Araki*<sup>2</sup>, *L.G. Shaffer*<sup>1</sup>, *J.R. Lupski*<sup>1</sup>. 1) Molec & Human Genetics, Baylor College Medicine, Houston, TX; 2) Pediatrics, Asahikawa Habilitation Center for Disabled Children, Asahikawa, Japan.

A submicroscopic duplication in Xq22 that contains the entire proteolipid protein gene (*PLP*) is the major cause of Pelizaeus-Merzbacher disease (PMD), a central nervous system (CNS) dysmyelinating disorder. Previous studies revealed that carrier females for the duplication are usually asymptomatic. In this study we describe two unrelated female patients who present with mild PMD or spastic paraplegia. In one patient, the clinical features, along with findings on cranial magnetic resonance imaging and brainstem auditory evoked potentials, have improved dramatically over a ten year period. The other patient, who presented with spastic diplegia and was initially diagnosed with cerebral palsy, has also had clinical improvement. Interphase fluorescent in situ hybridization (FISH) identified a *PLP* duplication in both patients. FISH analyses of the family members indicated that the duplication in both patients occurred as de novo events. Neither skewing of X inactivation in the peripheral lymphocytes nor *PLP* coding alterations were identified in either patient. These findings indicate that, in rare cases, females with a *PLP* duplication can manifest an early onset neurological phenotype. We hypothesize that the remarkable clinical improvement is due to myelin compensation by oligodendrocytes expressing one copy of *PLP* secondary to selection for a favorable X inactivation pattern. These findings indicate plasticity of oligodendrocytes in the formation of the CNS myelin and suggest a potential role for stem cell transplantation therapies.

**Expression map of the DYT3 critical region in Xq13.1.** *U. Muller<sup>1</sup>, S. Niemann<sup>1</sup>, J. Ramser<sup>2</sup>, H. Lehrach<sup>3</sup>, R. Sudbrak<sup>3</sup>, D. Nolte<sup>1</sup>.* 1) Inst Human Genetics, Justus-Liebig Univ, Giessen, Germany; 2) Medical Genetics, LMU Munic, Germany; 3) MPI Molecular Genetics, Berlin, Germany.

The X-linked dystonia parkinsonism syndrome (XDP) is a severe movement disorder characterized by dystonia and by parkinsonism in about 50% of cases. Due to the origin of all XDP cases from an ancestral founder, the disease locus, DYT3, could be assigned by analysis of allelic association to a small interval of approximately 300 kb in Xq13.1. This interval is flanked by markers DXS559 distally and by DXS6673E (3) proximally. In search of the disease gene we have constructed an expression map of the region. There are at least seven expressed genes. They are - from proximal to distal - DXS6673E, a gene of unknown function, NonO coding for p54nrb (a nuclear RNA binding protein), a gene coding for muscle-specific melusin (that interacts with integrin), CCG1 coding for TATA binding protein-associated factor TAFII250, ING IL, a putative tumor suppressor gene that is a member of the p33INGI gene family, OGT the gene for O-linked N-acetylglucosamine transferase, NAAR1 coding for a nuclear acidic amino acid repeat containing nuclear protein, and CRK-L2 that codes for a G-protein coupled receptor. One of these genes, NAAR1 (nuclear acidic amino acid repeat 1) has not been recognized before. NAAR1 codes for a polypeptide with an acidic repeat tract of 21 units of 8-10 amino acids that has not been found in any other known protein. Several NLSs suggest nuclear location of the protein. Expressed portions of all genes were analyzed for mutations in XDP patients. The absence of a mutation in expressed sequences of these genes suggests that XDP is caused by either a mutation in a regulatory region or by a structural rearrangement.

**Mutational analysis in early-onset parkinsonism (EOP) including gene dosage studies.** *K. Hedrich<sup>1,2</sup>, J. Harris<sup>3</sup>, M. Kann<sup>1,2</sup>, T. Lynch<sup>3</sup>, H.M. Santana<sup>3</sup>, E. Schwinger<sup>1</sup>, P.P. Pramstaller<sup>4</sup>, S.B. Bressman<sup>5</sup>, S. Fahn<sup>3</sup>, K. Marder<sup>3</sup>, C. Klein<sup>1,2</sup>.* 1) Department of Human Genetics, Medical University of Luebeck, Luebeck, Germany; 2) Department of Neurology, Medical University of Luebeck, Luebeck, Germany; 3) Department of Neurology, Columbia University, New York, NY, USA; 4) Department of Neurology, Regional General Hospital, Bolzano, Italy; 5) Department of Neurology, Albert Einstein College of Medicine, Bronx, NY, USA.

Autosomal recessive EOP is a progressive neurodegenerative disorder which is clinically similar to idiopathic Parkinson's disease but may be associated with additional neurological signs and usually starts before the age of 50 years. EOP has been associated with different mutations in the parkin gene, including exon deletions and duplications. Heterozygous exon deletions and duplications (gene dosage alterations) are difficult to detect by conventional screening methods. To test for gene dosage alterations, we developed a new method of quantitative duplex PCR using the fluorescence resonance energy transfer (FRET) technique on the LightCycler. We co-amplified beta globin as internal standard with each individual exon of parkin. In this study, 37 isolated patients with EOP (mean age of onset  $39.3 \pm 9.1$  yrs.) and 13 EOP patients (mean age of onset  $34.5 \pm 14.1$  yrs.) ascertained by positive family history were collected. Among these 50 patients, we detected 8 alterations of gene dosage, including heterozygous deletions of exons 1, 2, 3, and 3-4 and a heterozygous duplication of exon 5. In addition, 12 mutations (eight missense mutations, a silent single basepair substitution, and three small deletions) and known polymorphisms in exons 2, 4, 8, 10, and 11 were detected by SSCP and sequence analysis. In total, we identified 7 compound heterozygous mutation carriers (14%), 6 with heterozygous mutations (12%), and 37 with no detected mutation (74%) in the parkin gene. Taken together, we performed the first study systematically screening all 12 exons of parkin by real-time, kinetic quantification, an accurate method to detect heterozygous gene dosage alterations in parkin. Genetic studies of EOP must therefore include gene dosage alteration detection.

**Giant Axonal Neuropathy (GAN) caused by mutations in the Gigaxonin gene.** *G. Kuhlenbaumer<sup>1</sup>, P. Young<sup>1</sup>, C. Oberwittler<sup>2</sup>, B. Ringelstein<sup>1</sup>, F. Stogbauer<sup>1</sup>.* 1) Neurology, University of Muenster, Muenster, Westfalia, Germany; 2) Neurology, St. Vincenz Krankenhaus, Limburg, Germany.

Giant Axonal Neuropathy (GAN, MIM256850) is a severe autosomal recessively inherited neuropathy. The age of onset is usually below seven years. In most cases motor milestones are delayed. Later clumsiness of gait and progressive weakness becomes apparent. Tendon reflexes are usually absent and pyramidal signs are positive. Subsequently dysarthria, nystagmus, facial weakness and mental retardation develop. Patients have characteristic "frizzly" hair. Electrophysiological findings are typical for axonal neuropathies. Pathologic studies demonstrated that GAN is a disorder of intermediate filaments. Recently disease causing mutations were found in the gigaxonin gene on chromosome 16q24.1. It has 11 exons and encodes a protein of 597 amino acids. Gigaxonin belongs to the BTB/kelch repeat gene family and is ubiquitously expressed. Most BTB/kelch repeat proteins play a role in the formation of the cytoskeleton. We describe clinically and genetically a child with GAN and confirm for the first time that the disease is caused by mutation in the gigaxonin gene. The propositus is a 12 year old boy with grey, characteristically curled hair. He started to walk at 2 years. Somewhat later he developed progressive symmetrical weakness predominantly affecting the lower limbs, distal sensory impairment, ataxia and nystagmus. His school performance started to deteriorate in the last couple of years and since 1999 he is wheelchair bound. The electrophysiological examination showed signs of a severe axonal neuropathy and the EEG was slowed. DNA sequencing of the protein coding region of the gigaxonin gene revealed a stop mutation in exon 3 (C601T; Arg201Stop) on one allele and a missense mutation in exon 8 (T1268C; Ile423Thr) on the other allele. The mutation in exon 3 leads to truncation of the protein. The missense mutation is located in the kelch repeat region. Both mutations were not detected in 180 control chromosomes. The stop mutation in exon 3 was inherited from the father and the missense mutation in exon 8 from the mother.

**Mutations in the paraplegin gene (*SPG7*) in patients with sporadic or autosomal recessive spastic paraplegia are associated with a clinically distinct phenotype.** C. Mariotti<sup>1</sup>, S. Baratta<sup>1</sup>, G. Casari<sup>2</sup>, C. Milanese<sup>1</sup>, S. DiDonato<sup>1</sup>, C. Gellera<sup>1</sup>, L. Morandi<sup>1</sup>, L. Chiapparini<sup>1</sup>, F. Taroni<sup>1</sup>. 1) Divisione di Biochimica e Genetica, Istituto Neurologico C. Besta, Milan, Italy; 2) TIGEM, Milan-Neaples, Italy.

Hereditary spastic paraplegias (HSP) are a clinically and genetically heterogeneous group of neurodegenerative disorders characterized by progressive weakness and spasticity of the lower limbs. They are clinically classified into “pure” and “complicated” forms (Harding, 1981). To date, 8 loci for autosomal dominant HSP, 3 loci for X-linked HSP, and 4 loci (*SPG5*, *SPG7*, *SPG11*, and *SPG14*) for autosomal recessive HSP (AR-HSP) have been identified. Pathogenic mutations in the *SPG7* gene, which is composed of 17 coding exons and encodes a novel mitochondrial metalloprotease named paraplegin, have been thus far demonstrated in 3 families with AR-HSP (Casari, 1998). We have analyzed the coding sequence (17 exons) of the paraplegin gene in 18 unrelated index cases, including 12 isolated cases and 6 cases with an autosomal recessive pattern of inheritance. An additional group of 10 patients have been tested for mutations in exons 2, 3 and 11. Mutation screening was carried out by direct automated sequencing of paraplegin exons and flanking intron sequences. We have identified 1 frameshift, 1 nonsense and 2 missense mutations in 5 out of 28 patients (18%). In our *SPG7*-mutated patients, age at onset ranged from 25 to 55 years. Clinical presentation was characterized by weakness and spasticity of the lower limbs associated with cerebellar signs such as gait ataxia and dysarthria. Cerebellar involvement was also clearly demonstrated by MRI. Despite the mitochondrial localization of the defective protein, proton-resonance spectroscopy of the brain did not show any metabolic abnormality. In conclusion, (1) the data would indicate that the frequency of mutations in the paraplegin gene might be higher than previously observed; (2) paraplegin mutations appear to be predominantly associated with a “complicated” phenotype.

**Frequency of Spastin mutations in German pedigrees with hereditary spastic paraplegia.** *S. Klimpe<sup>1</sup>, A. Visbeck<sup>1</sup>, D. Boensch<sup>2</sup>, H.C. Hopf<sup>1</sup>, T. Deufel<sup>2</sup>.* 1) Dept. of Neurology, Mainz, Germany; 2) Dept. of Clinical Chemistry, Jena, Germany.

**Introduction:** The Hereditary Spastic Paraplegias (HSP) comprise a genetically heterogeneous group of neurodegenerative disorders characterised by progressive spastic gait disorder and lower limb hyperreflexia; fifteen genetic loci have been described so far, with the SPG4 locus on chromosome 2p21-22 covering 40-50% in autosomal dominant families. The SPG4 gene has been identified and encodes for spastin, an AAA protein of unknown function. Mutation analysis has revealed all types of mutations in SPG4 patients. **Aim:** We screened German HSP families for spastin mutations to obtain prevalence data in this patient population. **Patients and Methods:** 16 families with 142 family members were assessed, 13 presented an autosomal dominant and three an autosomal recessive mode of inheritance. In addition, five patients with autosomal dominant family history but no familial blood samples were included. Inclusion criteria were according to Harding. Whenever there was a likelihood of autosomal dominant inheritance, segregation analysis for SPG4 was performed using polymorphic markers D2S352, D2S2283, D2S2347, D2S375 and D2S2351. In cases with positive LOD scores ( $>.0$ ), this was followed by direct sequencing of the spastin gene; additional cDNA sequencing was possible in four families. **Results:** In families with pure autosomal dominant HSP co-segregation with SPG4 was established in 11 pedigrees with LOD scores ranging from 0,3 to 2,7; in two families SPG4 could be excluded. In two pedigrees with LOD scores  $>2,0$  we detected spastin mutations that were present in all affected and in clinically possibly affected family members; cDNA sequencing revealed one splice site mutation and one single base deletion (exon 6, 1004delC, PTC +24AA), and genomic sequencing lead to the identification of the respective mutations. The splice site mutation leads to the deletion of exon 8, the single base deletion should result in a truncated protein. **Conclusions:** We identified spastin mutations in two out of 16 German pedigrees with pure autosomal dominant HSP families with possible linkage to the SPG4 locus. Ongoing sequencing of single patients samples may reveal further mutations.

**Analysis of SMAD2 as a candidate gene for holoprosencephaly.** *A.K. Kantipong<sup>1</sup>, J.D. Karkera<sup>2</sup>, E. Roessler<sup>2</sup>, M. Muenke<sup>2</sup>.* 1) HHMI-NIH Scholar, MGB, NHGRI/NIH, Bethesda, MD; 2) MGB, NHGRI/NIH, Bethesda, MD.

Genetic defects in all components of the Nodal signaling pathway including its signaling factors, receptors, cofactors and transcription factors have all been associated with the establishment of left-right axis symmetry and/ or cyclopia. In particular, SMAD2, an intracellular mediator of Nodal signaling, has been implicated in the development of cyclopia and defective left-right axis patterning in murine knockout studies. Holoprosencephaly (HPE) is characterized by a defect in the midline of the embryonic forebrain due to failure of growth and / or segmentation of the anterior end of the neural tube and is phenotypically similar to cyclopia. To determine whether sequence variants in SMAD2 can be associated with HPE, mutation scanning using PCR-dHPLC was conducted in a panel of over 400 patients (83 familial, and 350 sporadic). We have identified a silent variant (GA; Serine) in exon 8 and a deletion of two thymidines in the 5' intronic region of exon 10 but no obvious disease causing mutations. These variants were not found in our panel of normal controls (~200 chromosomes) suggesting that these are novel sequence variants. These data does not suggest a shift in fundamental human biology compared with animal systems but might be explained by the fact that 95% of HPE cases die in utero. Thus, mutations in SMAD2 which may be present in HPE fetuses might not be represented in our live-born sample set.

**Mutation analysis of the CX26 gene in sporadic cases with moderate to profound hearing impairment.** *S. Kupka<sup>1</sup>, T. Toth<sup>2</sup>, S. Aberle<sup>3</sup>, N. Blin<sup>3</sup>, I. Sziklai<sup>2</sup>, HP. Zenner<sup>1</sup>, M. Pfister<sup>1</sup>.* 1) Otolaryngology, University of Tuebingen, Tuebingen, BW, Germany; 2) Otolaryngology, University of Debrecen, Hungary; 3) Molekulare Genetik, University of Tuebingen, Tuebingen, BW, Germany.

Non-syndromic neurosensory recessive deafness (NSRD) is one of the most common human sensory disorders. Mutations in the connexin 26 gene have been established as a major cause of inherited and sporadic non-syndromic deafness in different populations. The CX26 gene encodes the gap junction protein connexin 26 (beta-2, GJB2) whose expression was shown in several tissues and in the cochlea. The 30delG mutation is the most frequent mutation in the CX26 gene. It represents a deletion of a guanosine (G) in a sequence of six G extending from position 30 to 35 of the CX26 cDNA. The deletion creates a frameshift resulting in a premature stop codon and a non-functional intracellular domain in the protein. The 30delG mutation can be detected at the molecular level using PCR followed by BsiYI-digestion. We now screened 100 control individuals and 250 patients with non-syndromic sporadic deafness for this mutation to determine their distribution in the German and Hungarian populations. The frequency of the 30delG mutation in the German pool of sporadic cases was 0.11 whereas in controls it was 0.04. While studying 24 small-sized Hungarian families, this frequency was 0.38. DNA from individuals showing a heterozygous status for 30delG was sequenced. This study revealed several new patient-related mutations and new gene variants resulting in e.g. amino acid substitutions (A->G; basic to acidic; G->A; nonpolar to polar; A->C; acidic to nonpolar). Moreover, one deletion and one insertion was noted. In summary, more than 20 new allelic changes were detected and for most of them, patterns of inheritance were documented.

**Investigation of the role of *MECP2* in the genetics and molecular pathology of Rett Syndrome.** A.M. Hever<sup>1</sup>, A. McDonnell<sup>1</sup>, M.T. Gardiner<sup>1</sup>, M. Ennis<sup>1</sup>, C. Johnstone<sup>1</sup>, A.M. Kerr<sup>2</sup>, G.J.R. Brock<sup>1</sup>, M.E.S. Bailey<sup>1</sup>. 1) Div. of Molecular Genetics, I.B.L.S., Univ. of Glasgow, Glasgow, U.K; 2) Dept. of Psychol. Medicine, Univ. of Glasgow, Glasgow, U.K.

Rett Syndrome is a severe neurodevelopmental disorder, inherited in an X-linked, dominant fashion and now known to be caused by loss-of-function mutations in the methyl CpG binding protein 2 gene, *MECP2*, located in chr.Xq28. The molecular pathology of the disorder is still very unclear, partly because the precise role of MECP2, which binds methylated CpG dinucleotides, has not been elucidated - it may play roles in regulation of tissue-specific genes, imprinting and suppression of mobile elements, the so-called genome defence hypothesis. Several other phenotypes are now known to be caused by mutations in the same gene, while not all patients with classic Rett syndrome harbour mutations in *MECP2*. We have investigated the molecular genetics of Rett Syndrome in 30 patients with the classic form and in 70 patients with atypical Rett syndrome. We have used intronic primers to screen patient DNA by PCR for mobility variants within exons 1, 2, 3, and coding portions of exon 4 using dHPLC technology, and then for mutations by direct sequencing and cloning. We have found mutations in more than 80% of patients with classic Rett syndrome, including several novel mutations. We are also examining the long 3'-UTR region, using multiple sets of overlapping primers, in those patients in whom no mutations were detected elsewhere. We have also investigated whether MECP2 has preferred binding sites in the genome by constructing an unbiased library of methyl binding domain (MBD)-binding genomic fragments using an MECP2 MBD binding column. Clones from this library have been identified by hybridisation to various classes of probe specific for different genomic DNA classes, followed by confirmatory sequencing of representative clones. Preliminary results have indicated that Alu repeats may be overrepresented in the library. We have therefore begun to investigate whether varieties of mobile element are overexpressed in Rett syndrome patients to try to determine the first step in the pathophysiology of Rett syndrome.

**A novel mutation of the sodium channel SCN1A in the epilepsy syndrome GEFS+.** B.T. MacDonald<sup>1</sup>, A. Escayg<sup>1</sup>, J. Spanpanato<sup>2</sup>, E. Montalenti<sup>3</sup>, P. Benna<sup>3</sup>, A.L. Goldin<sup>2</sup>, M.H. Meisler<sup>1</sup>. 1) Department of Human Genetics, University of Michigan, Ann Arbor, Michigan, USA; 2) Department of Microbiology and Molecular Genetics, University of California, Irvine, California, USA; 3) Department of Neuroscience, University of Torino, Turin, Italy.

Mutations of the voltage-gated sodium channel SCN1A on chromosome 2q24 have been identified in two epilepsy syndromes, Generalized Epilepsy with Febrile Seizures Plus (GEFS+) (MIM#604233) (Escayg et al., *Nat. Genet.* 24:343-345,2000) and Severe Myoclonic Epilepsy of Infancy (Claes et al., *Am. J. Hum. Genet.* 68:1327-1332,2001). GEFS+ is an autosomal dominant disorder characterized by fever-induced (febrile) seizures that persist beyond 6 years of age and progress to a variety of afebrile seizures. We previously described the effects of two GEFS+ mutations on SCN1A activity (Spanpanato et al, *J. Neurosci*, in press). Here we report the identification of a novel SCN1A mutation in an Italian family with GEFS+. In affected individuals in this family, febrile seizures persist to 12 years of age and progress to general tonic-clonic seizures. One child exhibited febrile seizures, myoclonic-astatic epilepsy, learning difficulties and behavioral problems. The exons of SCN1A were amplified from genomic DNA and screened by conformation-sensitive gel electrophoresis. A novel missense mutation was identified in an evolutionarily-invariant residue of the C-terminal domain. Protein structure predictions suggest that this mutation would change the boundary of an alpha-helical domain. Preliminary functional studies in *Xenopus* oocytes detected a reduced rate of fast-inactivation of the mutant channel with no change in other fast-gated properties. At the cellular level, this mutation would increase the persistent sodium current and is predicted to generate neuronal hyperexcitability.

**Genetics studies of neuronal nicotinic acetylcholine receptors in patients with megacystis and intestinal pseudo-obstruction.** *E. Lev-Lehman, M. Lising, D. Bercovich, W. Xu, A.L. Beaudet.* Molecular & Human Genetics, Baylor College Medicine, Houston, TX.

We are conducting a mutational analysis in patients with the rare autosomal recessive disorder megacystis, microcolon, intestinal hypoperistalsis syndrome (MMIHS) and the related syndrome of chronic intestinal pseudo-obstruction (CIP). Both of these disorders are characterized by abdominal distension, intestinal hypoperistalsis, intolerance to enteral feeding and in MMIHS also megacystis and abnormal voiding pattern. The phenotypic findings in these patients resemble the phenotype observed in mice lacking the  $\alpha 3$  subunit of the neuronal nicotinic acetylcholine receptor (nAChR) and in part, the phenotype observed in mice lacking the  $\beta 4$  subunit of the nAChR. This led to the hypothesis that mutations in the  $\alpha 3$  and/or the  $\beta 4$  subunits of the neuronal nAChR genes (*CHRNA3* and *CHRNA4*, respectively) might cause MMIHS or the related syndrome of CIP. We are therefore conducting a mutational analysis in these genes in patients with MMIHS or CIP. Both genes are mapped on chromosome 15q24.2-q25.1 in a cluster with the *CHRNA5* gene. In one patient, we found a possible splice mutation in the *CHRNA3* gene IVS2-14A@G which might cause exon skipping. In the *CHRNA4* we found a missense mutation of uncertain significance (Arg136Gln) in another patient. In addition, we identified several unprocessed partial pseudogenes of the *CHRNA4* gene on chromosome 15. The presence of a cluster of homologous genes and pseudogenes raises the possibility of complex genomic rearrangements that may be difficult to decipher. At this time, none of the changes is proven to be pathological, and we are interested in continuing the studies with additional patients affected with MMIHS or CIP.

**Expression Profiling of Menkes Disease Brain.** *P.-C. Liu<sup>1</sup>, Y.-W. Chen<sup>2</sup>, E.P. Hoffman<sup>2</sup>, S.G. Kaler<sup>1</sup>*. 1) Natl Inst Neurologic Disorders & Stroke, NIH; 2) Resesearch Ctr for Genetic Medicine, Children's National Med Ctr, Washington, DC.

Menkes disease (MD) is an X-linked recessive neurodegenerative disorder caused by mutations in a copper transporting P-type ATPase that normally delivers copper to the central nervous system. The precise reasons underlying the neurodegeneration in affected individuals are poorly understood. We hypothesized that gene expression changes in brain from patients with lethal mutations would suggest pathophysiological cascades associated with copper deficiency in the developing brain. To test this hypothesis, oligonucleotide probes for approximately 12,000 human gene sequences arrayed on Affymetrix Human Genome U95 GeneChips were used for expression profiling of fluorescently labeled primary cRNAs from postmortem brain of two well characterized patients who died at 5 and 7 months of age, respectively, despite very early (*in utero* in one case) copper histidine treatment. In both patients, the brains were harvested within 6 hours postmortem and were stored at -80 degrees C. As control tissue, we obtained similar high quality brain specimens from a Brain and Tissue Bank (University of Maryland). The control specimens selected (#463, frontal cortex and cerebellum; #569 frontal cortex) were obtained from normal infants who died accidentally, and who matched our patients for age, gender and race. Data analysis (completed by Affymetrix Microarray Suite v4.0 and Silicon Genetics GeneSpring) showed 60 genes significantly up-regulated ( $p < 0.001$ ) and 330 genes down-regulated ( $p < 0.001$ ) in the MD brains compared to the normal controls. Many of the 330 down-regulated genes were involved in signaling pathways, synaptic function, mitochondrial function, protein modification and metabolism. The majority of known up-regulated genes were involved in compensatory responses, including growth factors, anti-apoptosis, immune response and stress response genes. These findings provide considerable insight regarding the pathogenetic basis of neurodegeneration in MD patients with poor response to very early treatment with subcutaneous copper histidine injections.

**Two antioxidant proteins (TSA and PAG) interact in vivo with *Drosophila Psn* and may be candidates for Alzheimers disease.** *M.F. Wangler<sup>1</sup>, L.T. Reiter<sup>1</sup>, J.-J. Wu<sup>2</sup>, E. Bier<sup>1</sup>.* 1) Biology, UCSD, La Jolla, CA; 2) Pediatrics and Molecular Biology, Washington University School of Medicine, St. Louis, MO.

Presenilin 1 (*PSEN1*) is a transmembrane protein which when mutated in humans can result in the most prevalent form of familial early-onset Alzheimer's disease (FAD). Studies have shown that FAD mutations in *PSEN1* can lead to over-production of a neurotoxic form of beta-amyloid found in senile plaques. Although the cellular function of *PSEN1* is largely unknown, *PSEN1* has been implicated in diverse cellular activities including activation of the Notch and Wnt developmental signaling pathways, calcium homeostasis, and apoptosis. Evidence suggests that presenilins play a role in antioxidant biology, although no direct interactions with antioxidant proteins have been reported. We identified protein-protein interactions between human *PSEN1* and two antioxidant proteins, TSA and PAG, through a yeast two-hybrid screen using *PSEN1* as bait. We tested for *in vivo* interactions between these proteins by misexpressing them in *Drosophila* with fly *Psn* using the GAL4-UAS transactivation system. When TSA and PAG are coexpressed with *Drosophila Psn* in the wing and brain of flies we observed synergistic effects demonstrating that these proteins function in concert *in vivo* as well as *in vitro*. TSA and PAG alone generate no phenotype when misexpressed individually. As others have shown, *Psn* misexpression gives a weakly penetrant phenotype that appears to compromise Notch signaling and results in apoptosis. When PAG and or TSA are coexpressed with *Psn*, we observe a strong enhancement of this phenotype indicating that these proteins function in a concerted fashion. We also analyzed expression of Notch target genes and found that coexpression of PAG, TSA, and *Psn* interferes with the Notch mediated activation of these genes. These studies were extended to neural tissue by using brain specific GAL4 drivers to analyze interactions in the brain. Our analyses suggest that TSA and PAG play an important role in regulating apoptosis and Notch signaling through its interaction with *Psn*. We suggest that human genes like TSA and PAG should be considered as candidate genes for yet undetermined FAD loci.

**Antemortem diagnosis of Alexander disease in a Japanese patient by molecular genetic analysis.** *N. Shiroma*<sup>1,2</sup>, *N. Kanazawa*<sup>1</sup>, *M. Izumi*<sup>2</sup>, *K. Sugai*<sup>2</sup>, *M. Fukumizu*<sup>2</sup>, *M. Sasaki*<sup>2</sup>, *S. Hanaoka*<sup>2</sup>, *M. Kaga*<sup>2</sup>, *S. Tsujino*<sup>1</sup>. 1) Inherited Metabolic Disease, National Inst Neuroscience, Kodaira, Tokyo, Tokyo, Japan; 2) Neuropediatrics, Musashi Hospital, National Center of Neurology and Psychiatry, Tokyo, Japan.

Alexander disease is a rare type of leukodystrophy characterized clinically by macrocephaly, psychomotor retardation, spasticity and seizures, and histopathologically by the presence of numerous Rosenthal fibers (RF), cytoplasmic inclusion bodies in astrocytes. Recently, mutations in the gene encoding glial fibrillary acidic protein (GFAP) were identified in patients with Alexander disease. We sequenced the GFAP gene of a Japanese girl who presented with typical symptoms of Alexander disease but in whom the diagnosis was not proven by histopathology. We identified a missense mutation, R239C, which is identical to the mutation previously reported to be most frequent. As was the case in previously-described patients, our patient was also heterozygous for the de novo mutation. Interestingly, in spite of the fact that this is a de novo mutation, R239C was found to be common in different ethnic groups, implying that the site is a "hot spot" for mutagenesis. Molecular genetic analysis now makes the antemortem diagnosis of Alexander disease possible.

**SPG4 (spastin) mutation screening in hereditary spastic paraparesis.** *C. Proukakis<sup>1,2</sup>, C. Comiskey<sup>1</sup>, E. Reid<sup>3</sup>, P. Wilkinson<sup>2</sup>, D. Rubinsztein<sup>3</sup>, M.A. Patton<sup>1</sup>, T.T. Warner<sup>2</sup>, A.H. Crosby<sup>1</sup>.* 1) Department of Medical Genetics, St George's Hospital Medical School, London SW17 0RE, UK; 2) Department of Clinical Neurosciences, Royal Free Campus, Royal Free and University College Medical School, London NW3 2PF, UK; 3) Department of Medical Genetics, Cambridge University, Cambridge CB2 2XY, UK.

Hereditary spastic paraparesis (HSP) is a clinically and genetically heterogeneous condition. Inheritance is commonly autosomal dominant (AD), although recessive and X-linked forms exist. It has been estimated that up to 40% of AD pedigrees show linkage to the SPG4 locus at 2p21-22 which encodes spastin, an AAA protein (ATPase associated with diverse cellular activities).

Over 60 SPG4 mutations have been reported to date, with most occurring only in one family. These are scattered across most of the gene's 17 exons and include missense, nonsense and splicing mutations as well as insertions and deletions. SPG4 mutations are not fully penetrant, there is marked intrafamilial variability and there is one report of a mutation in a sporadic case apparently acting as recessive. The above problems have made large-scale diagnostic testing problematic.

In order to determine the frequency of SPG4 mutations in a cohort of patients diagnosed as HSP, we have obtained genomic DNA from over 90 unrelated patients. Most of these had a family history, and in some cases were members of pedigrees displaying clear AD inheritance.

All 17 exons of SPG4 were amplified by PCR (exon 1 was amplified as 3 separate fragments) and subjected to single strand conformation polymorphism (SSCP) analysis. All samples with apparent band shifts were sequenced on an ABI377 automated sequencer. Confirmation by subcloning (using a TOPO cloning kit) and sequencing was undertaken where appropriate.

We have detected a number of spastin mutations amongst this large collection of patients. A comparison of spastin mutation frequency is offered between familial and apparently sporadic cases.

**Diagnosis of spinal muscular atrophy for deletions of SMN: is it possible?** *V. Sokolnik, R. Khmel, G. Tsukerman.*  
Institute for Hereditary Diseases, MINSK, Belarus.

We have performed SSCP analysis of the SMN gene exons 7,8 and electrophoretic study of the NAIP gene exons 5,13 in 37 Belarus families (38 probands, submitted with a presumptive clinical diagnosis of SMA, and 67 SMA-asymptomatic family members). The control consisted of 40 dried blood spots from newborns. Of 38 patients with SMA, 31 have deletion changes of SMNt gene. The NAIP gene exon 5 was deleted in severe affected patients (9 of 23 presumptive SMA type I cases). All patients, who lacked the NAIP gene exon 5, also had deletion mutations of SMNt. Deletions of SMNt exon 7 alone were in both severe affected patients and milder ones. We observed three unaffected parents deleted for exon 5 of NAIP gene. In one of these families SMA-unaffected mother and SMA type I patient showed loss of band corresponding to SMNt exon 7. In another two cases child with SMA type I exhibited a deletion of SMNt exons 7, 8 and NAIP gene exon 5. We believe that two SMA-asymptomatic parents had deletion of exons 7 and 8 in the centromeric gene (SMNc). In one of these families the proband was deleted for both exons 7 and 8 of SMNt, in another one - for SMNt exon 7 only. In addition, mutation changes, which looked like a deletion of centromeric exons 7 and 8, were found in one (boy) of two patients with clinical diagnosis of SMA type I. In this family the mother had identical SSCP patterns, except that PCR product of exon 7 showed also extra bands with altered mobility. The father and second child (girl) retained at least one copy of both genes. Finally, absence of bands corresponding to exon 7 and 8 of SMNc have been demonstrated in the father of a patient with diagnosis of SMA, which subsequently was changed on muscular dystrophy. Control newborns showed neither the deletion mutations in SMNt nor the absence of NAIP exon 5. Deletions in SMNc have been demonstrated by SSCP in 5 of 40 controls and were represented by the deletions of centromeric exon 7 bands or deletions of both centromeric exon 7 bands and centromeric exon 8 band. Deletion analysis of control group and revision of clinical features of SMA families now are in progress.

**Mutation analysis of ATP7B gene in Russian Wilsons Disease patients.** *M.I. Shadrina<sup>1</sup>, A.O. Davydova<sup>1</sup>, P.A. Slominsky<sup>1</sup>, S.A. Limborska<sup>1</sup>, A.V. Karabanov<sup>2</sup>, I.A. Ivanova-Smolencskaya<sup>2</sup>.* 1) Dept Human Genetics, Inst Molecular Genetics, Moscow, Russia; 2) Institute of Neurology, Russian Academy of Medical Science, Moscow, Russia.

Wilson disease (WD) is an autosomal recessive disorder characterised by toxic accumulation of copper in liver and subsequently in brain and other organs. The world-wide incidence of this disease is about 30 per million, with the gene frequency of 0.56% and carrier frequency of 1 per 90. The WD ATP7B was mapped to chromosome 13q14.3. This gene is expressed most abundantly in liver and encodes a copper-transporting P-type ATPase. A large number of mutations of ATP7B gene have been identified. This study aimed to detect disease-causing mutations of ATP7B gene in Russian population.. We analyzed 33 WD patients by SSCP analysis, sequencing and rapid detection method for the most frequent in Russia His1069Gln mutation. We found that one patient was homozygous and 11 patients were heterozygous for the His1069Gln mutation, which is the most common mutation. Also we detected two mutations in exon 8 of ATP7B gene, one of these was a novel missense mutation (Trp712Cys). This mutation destroys restriction site for Rsa I. The same site was destroyed by known mutation Tyr713Cys. In two patients Gly710Ser missense mutation was found. Overall frequency of exon 8 mutations in non-His1069Gln alleles is 5,7%.

**Two spastin isoforms are developmentally regulated in fetal and adult human brain.** *E. Pegoraro*<sup>1</sup>, *A.M. Molon*<sup>1</sup>, *A. Fassina*<sup>2</sup>, *P. Magalhaes*<sup>3</sup>, *C. Angelini*<sup>1</sup>. 1) Neurological/Psychiatric Sci, Univ Padova, Padova, Italy; 2) Oncological and Surgical Sciences, University of Padova, Italy; 3) Department of Biomedical Sciences, University of Padova, Italy.

Spastin is a newly described protein belonging to the AAA protein family (ATPase Associated with different cellular Activities). Homology with the 26S proteasome of *Saccharomyces cerevisiae* suggests that spastin may be involved in transcriptional regulation of DNA; its functional role in the central nervous system, however, remains largely unknown. Two isoforms of spastin are generated by alternative splicing of exon 4: full length spastin (FL-SPG4), that retains exon 4, and exon 4 alternatively spliced spastin (AS-SPG4) that lacks 32 amino acid residues in a region of the protein showing, through blast searches, homology to a microtubule associated protein (MAP2). We examined the expression pattern of the two isoforms in post-mortem fetal and adult human brains by quantitative multiplex fluorescent RT-PCR (QMF-RT/PCR) through co-amplification of cDNAs corresponding to survival motor neuron (SMN), and spastin gene (SPG4). In the fetal central nervous system including corpus callosum and spinal cord both the FL-SPG4 and the AS-SPG4 were highly expressed with a clear predominance of the FL-SPG4. In adult, FL-SPG4 mRNA was mainly expressed in the cerebral cortex and cerebellum, whereas AS-SPG4 mRNA was mainly expressed in the corpus callosum and spinal cord where FL-SPG4 was barely detectable. Down-regulation of SPG4 in the corpus callosum and spinal cord started during early postnatal stages. Therefore, splicing of exon 4 undergoes distinct temporal and spatial regulation in the brain. The role of the AS-SPG4 is still unknown, however the homology shown by FL-SPG4 with MAP2 is lost when exon 4 is skipped suggesting a possible role of spastin in microtubule assembly.

**GBX2: a candidate gene for midline cerebellar defects.** G. Zanni<sup>1,2</sup>, F. Savini<sup>3</sup>, FM. Santorelli<sup>1</sup>, G. Neri<sup>2</sup>, A. Giannotti<sup>1</sup>, E. Bertini<sup>1</sup>. 1) Molecular Medicine, Bambin Gesù Children's Hospital Rome, Italy; 2) Medical Genetics, Catholic University, Rome; 3) Medical Genetics, University La Sapienza, Rome, Italy.

Genes regulating early specification and development of the cerebellum are attractive candidates to be investigated in malformation syndromes characterized by midline cerebellar defects. Joubert syndrome (JS) is a rare autosomal recessive disorder characterized by agenesis/dysgenesis of the cerebellar vermis with accompanying brainstem malformations and other developmental defects including ocular, renal, hepatic and limb abnormalities. This condition is clinically and genetically heterogeneous. One locus was identified on chromosome 9q34 but so far no responsible gene was found. Dandy Walker Malformation (DWM) is characterized by vermis agenesis/hypoplasia and cystic dilation of the 4th ventricle and is an associated symptom in many malformation syndromes. GBX2 (gastrulation and brain specific 2) gene, is a vertebrate homeobox related to *Drosophila unplugged* gene, which plays an essential role in the establishment of the isthmus organizer (IsO), a source of positional information for the development of midbrain and anterior hindbrain structures, at the mes-metencephalic junction of the developing embryo. It has been postulated that early abnormalities at the mesencephalic side of the isthmus could contribute to the pathogenesis of midline cerebellar defects. GBX2 null mutant mouse lacks normal rostral hindbrain and presents IsO abnormalities, while in GBX2 hypomorphic mouse mutant, the cerebellar vermis fails to develop. We have analyzed the GBX2 gene in 14 patients with cerebellar vermis abnormalities, 5 of them fulfilling the diagnostic criteria for JS and 5 with syndromal DWM. PCR was carried out using intronic and exonic primers for the two exons of GBX2. Mutation analysis was performed by direct sequencing using Big Dye Terminator Cycle sequencing kit. No differences were noted in the coding sequence of GBX2 between normal and affected individuals. However, the implication of GBX2 (as of other IsO genes: FGF8, WNT1, PAX2, EN 1-2 previously tested in Joubert patients) in the pathogenesis of cerebellar defects cannot be definitively ruled out.

**Caspr1/Paranodin/Neurexin IV is most likely not a common disease-causing gene for inherited peripheral neuropathies.** *V. Timmerman<sup>1</sup>, K. Venken<sup>1</sup>, J. Meuleman<sup>1</sup>, J. Irobi<sup>1</sup>, C. Ceuterick<sup>2</sup>, R. Martini<sup>3</sup>, P. De Jonghe<sup>1,4</sup>.* 1) Flanders Interuniversity Institute for Biotechnology (VIB), Born-Bunge Foundation (BBS), University of Antwerp (UIA), Antwerpen, Belgium; 2) Born-Bunge Foundation (BBS), University of Antwerp (UIA), Antwerpen, Belgium; 3) Department of Neurology, Section of Developmental Neurobiology, University of Wurzburg, Wurzburg, Germany; 4) Division of Neurology, University Hospital Antwerpen (UZA), Antwerpen, Belgium.

Contactin associated protein 1 (Caspr1/Paranodin/Neurexin IV) is an axonal transmembrane molecule mainly localised at the paranodal junction. Since molecular alterations in septate-like junctions at the paranodes might have important consequences for the function of the nerve fiber, we considered that Caspr1 could be involved in the pathogenesis of inherited peripheral neuropathies. We screened a BAC library to isolate clones containing the complete coding region of Caspr1. Full genomic characterisation of human Caspr1 (1384 AA, ORF of 4155 nucleotides) resulted in the determination of 24 coding exons. Metaphase FISH was used to localise the Caspr1 gene on chromosome 17q21. Using DHPLC and direct DNA sequencing we found 7 different sequence variations in 63 unrelated patients afflicted with distinct inherited peripheral neuropathies. Four sequence variations (c.151C>A, c.1861C>A, c.2340C>A and c.3588G>A) resulted in silent mutations and 1 variation (c.1577G>A) resulted in the amino acid change R526Q. None of these heterozygous or homozygous (c.151C>A) mutations co-segregate with the disease phenotype in the corresponding families. Furthermore, two splice-site mutations were found at IVS7-5C>G(1045-5C>G) and IVS10+5C>T(1628+5C>T). Both splice-site mutations were not localised in the most conserved nucleotides of the splice-donor (GT) and splice-acceptor (AG) sites, and did also not co-segregate within the patients families. We therefore conclude that Caspr1 is most likely not involved in the molecular pathology of inherited peripheral neuropathies in our patient cohort.

**Mutation screening of SPTLC1 in patients with Hereditary sensory neuropathy type I .** *K. Verhoeven<sup>1</sup>, E. De Vriendt<sup>1</sup>, V. Van Gerwen<sup>1</sup>, M. Auer-Grumbach<sup>2</sup>, A. Pou-Serradell<sup>3</sup>, P. de Jonghe<sup>1,4</sup>, V. Timmerman<sup>1</sup>.* 1) Flanders Interuniversity institute for Biotechnology (VIB), Born-Bunge foundation (BBS), University of Antwerp, Antwerpen, Belgium; 2) Department of Neurology, Karl-Franzens University, Auenbruggerplatz 22, A-8036 Graz, Austria; 3) Department of Neurology, University of Barcelona, Barcelona, Spain; 4) Division of Neurology, University Hospital Antwerpen (UZA), Antwerpen, Belgium.

Hereditary Sensory Neuropathy type I (HSNI) is a dominantly inherited degenerative disorder of peripheral sensory neurons. Symptoms of HSNI start in the second to third decade with loss of pain sensation followed by distal muscle wasting and weakness. Loss of pain sensation leads to chronic skin ulcers, requiring amputation. HSNI was genetically linked to chromosome 9q22.1-q22.3. Mutations in the serine palmitoyltransferase, long chain base subunit 1 gene (SPTLC1) were identified as underlying HSNI. Using direct DNA sequencing we screened a panel of 19 unrelated patients afflicted with HSNI. In a small Belgian family, two twin sisters carried a missense mutation (c.387G>A) which resulted in a G387A amino acid substitution. Furthermore, one splice-site mutation was found at IVS8-6 A>G (781-6A>G) in a small Spanish family with two patients. Both mutations were not found in 50 control patients. Interestingly, up until now all known mutations in the SPTLC1 gene were found in exon 5 and 6, while we found two novel mutations located in exon 13 and in the splice acceptor site of exon 9.

**Altered recruitment of 26S proteasome subunits and chaperones into neuronal intranuclear inclusions in SCA3.**

*Th. Schmidt<sup>1</sup>, K.S. Lindenberg<sup>2</sup>, A. Krebs<sup>2</sup>, L. Schöls<sup>3</sup>, F. Laccone<sup>4</sup>, J. Herms<sup>5</sup>, O. Riess<sup>1</sup>, G.B. Landwehrmeyer<sup>2</sup>.* 1) Medical Genetics, University of Rostock, Rostock, Germany; 2) Department of Neurology, University of Ulm, Ulm, Germany; 3) Department of Neurology, St. Josef's Hospital, Ruhr-University Bochum, Bochum, Germany; 4) Institute of Human Genetics, University of Göttingen, Göttingen, Germany; 5) Department of Pathology, University of Göttingen, Göttingen, Germany.

Spinocerebellar Ataxia Type 3 (SCA3) is an autosomal dominantly inherited neurodegenerative disorder caused by the expansion of a polyglutamine tract in the ataxin-3 protein. A neuropathological hallmark of SCA3 are intracellular aggregates forming neuronal intranuclear inclusions (NII). To characterize cellular responses to nuclear aggregates in more detail, we analysed nuclear inclusions in human postmortem brain of patients affected by SCA3 and controls immunohistochemically using a panel of antibodies directed against chaperones and proteasome subunits. About 20% of the nuclear inclusions in pontine neurons stained positively for the chaperone Hsp90a, whereas no staining by antibodies to Hsp27, Hsp60, and Hsp/Hsc70 was observed. Most nuclear inclusions in SCA3 are ubiquitin-positive (75%) suggesting degradation by ubiquitin-dependent proteasome pathways. Surprisingly only a minority of the inclusions were immunopositive with antibodies directed against subunits of the 20S proteolytic core of proteasomes, whereas most inclusions were stained by antibodies directed against the 19S regulatory subunits thought to recognize, bind and unfold ubiquitinated proteins. In addition, most NII were immunoreactive with 11S subunits antibodies. A comparison with normal control brains indicates more intense cytoplasmatic staining and less intense nuclear signals in SCA3 neurons suggesting a redistribution of proteasomes. The high proportion of NII stained with proteasome subunits 11S and 19S stands in marked contrast to the small percentage of NII immunostained with the 20S antibodies used. These results suggest that most neurons containing NII recruit proteasome subunits to NII possible in an attempt to refold mutant ataxin-3 and to dissolve nuclear aggregates.

**Characterization of the interaction between neurofibromin and members of the syndecan family.** *M. Volta*<sup>1</sup>, *Y. Hsueh*<sup>2</sup>, *M. Sheng*<sup>3</sup>, *R.G. Roberts*<sup>1</sup>. 1) Div. of Med. & Mol. Genet., Guy's Hospital, London, UK; 2) Inst. of Mol. Biol. Academia Sinica, Taipei, Taiwan, China; 3) Howard Hughes Medical Inst. & Dept. of Neurobiology, Massachusetts General Hospital, Boston, Massachusetts, USA.

Neurofibromatosis type 1 (NF1) is a common dominantly inherited disorder with symptoms which can include life-threatening benign and malignant nervous system tumours, skeletal abnormalities and learning disabilities. Although the identification of a small central region (GTPase activating domain) of neurofibromin, which acts to down-regulate members of the Ras family of small GTPase, could partially explain the tumor development in NF1 patients, the more complex events, which lead to the expression of the other phenotypic traits of this disease are still unknown.

We have recently identified an interaction between two distinct regions of neurofibromin and members of syndecan protein family of heparan sulphate proteoglycans (HSPGs). As syndecans are implicated in a range of regulatory aspects of the interactions between cells and their environment they represent particularly interesting candidates for functional partners of neurofibromin.

We subsequently set out to characterize this interaction in more detail by introducing a series of point mutations into the cytoplasmic domain of syndecan-2 and tested them in yeast two-hybrid experiments. Surprisingly, most of these mutations affected the binding of the two regions of neurofibromin and that of CASK (another syndecan-binding protein) in an almost identical way. In an attempt to explain this, we assessed the effect of these mutations on the interaction of syndecan-2 with itself (a dimerization interaction). This yielded the same pattern of results as neurofibromin and CASK. We interpret this as suggesting that syndecan dimerization is a prerequisite for interaction with neurofibromin and CASK. We were also able to identify residues which mediates specific interaction with neurofibromin.

These findings imply that syndecan genes could represent modifier loci for NF1 phenotype.

**The detection of hot spot mutations in exon three of MECP2 gene in Rett syndrom patients of Slavic origin.** R. Rosipal<sup>1</sup>, J. Hadac<sup>2</sup>, J. Zeman<sup>1</sup>, N. Misovicova<sup>3</sup>, S. Nevsimalova<sup>4</sup>, P. Martasek<sup>1</sup>. 1) Department of Pediatrics, Charles University, Prague, Czech Republic; 2) Thomayer Hospital, Prague, Czech Republic; 3) Martin Hospital, Martin, Slovak Republic; 4) Department of Neurology, Charles University, Prague, Czech Republic.

Mutations in X-linked MECP2 gene cause Rett syndrome - an X-linked dominant neurodevelopmental disorder affecting 1 in 10,000 to 15,000 females worldwide (1). MECP2 gene encodes for methyl-CpG-binding protein 2, which plays an important role in the regulation of gene expression (2). The spectrum of mutations in MECP2 gene is now known from numerous countries and ethnic groups and steps are being taken to determine the genotype/phenotype relationship in order to better understand the disease process (3,4). A systemic study in the Slavic population was initiated from which we present the results of 25 girls from the Czech and Slovak republics with established clinical diagnoses of Rett syndrome. There are 5 prevalent mutations in the methyl-CpG binding protein 2, that result in Rett syndrome. Four of them are detectable by restriction analysis. In this study we present the results of the search for 4 such prevalent mutations in the gene for methyl-CpG binding protein 2. Restriction analysis of PCR products of the methyl-CpG binding protein 2 gene revealed the presence of these 4 mutations [473 C/T (T158M) in 3 patients, 502 C/T (R168X) in 2 patients, 808 C/T (R270X) in 1 patient, and 906 C/T (R306C) in 2 patients] in 8 unrelated patients with Rett syndrome. The results of restriction analysis were confirmed by direct sequencing. This study of Rett syndrome in the Slavic population shows that 4 of the hot spot mutations in exon 3 of MECP 2 gene are present in 32% of the patients and dictates, therefore, the strategy in molecular diagnosis of Rett syndrome in this ethnic group. 1. **Mutational analysis of Cx32, MPZ, PMP22 and NEFL genes in 32 Chinese families with Charcot-Marie-Tooth Disease.** *J. Xiao<sup>1,2</sup>, B. Tang<sup>1</sup>, J. Xia<sup>1</sup>, G. Xie<sup>1</sup>, W. Luo<sup>1</sup>.* 1) Dept Neurology, Xiangya Hospital, Hunan Medical University, Changsha, Hunan, China. 410008; 2) Dept Neurology, Neuroscience Ctr, Memphis, TN.

Objective: To study the molecular pathogenesis of Charcot-Marie-Tooth disease (CMT) in China. Methods: 81 patients of CMT from 32 families around China were studied both in clinic and genetics. Mutational analysis of Cx32, MPZ, PMP22 and NEFL genes were performed by PCR-RFLP, PCR-SSCP, PCR-DGGE and /or direct sequencing. Results: 8 (25%) of the CMT families had mutations in the Cx32, MPZ and PMP22 genes. Four point mutations were found in the second exon of the Cx32 gene. They are 188ACC®GCC (Thr®Ala) in a XD family, 15CGG®CAG (Arg®Gln) and 183CGC®CAC (Arg®His) in two XR families and 164CGG®CAG (Arg®Gln) in a sporadic patient. One point mutation was found in MPZ gene (124ACG®ATG Thr®Met) in a AD family. Three tandem CMT1A-REP repeat mutations of PMP22 gene were found in three AD families. However, There is no point mutation in these patients both in PMP22 and NEFL gene. Conclusion: The results showed that Chinese CMT patients share the same mutations in Cx32, MPZ and PMP22 genes in the world although there is a little difference in the mutation site and inheritance patterns. However, most of the families without mutations in these genes need further research.

**Assessment of Glypican 3 gene mutation in patients referred for overgrowth syndrome.** *V. Gaston<sup>1</sup>, Y. Le Bouc<sup>1</sup>, L. Burglen<sup>2</sup>, V. Soupre<sup>3</sup>, M.P. Vazquez<sup>3</sup>, C. Gicquel<sup>1</sup>.* 1) Lab. d'endocrinologie -INSERM U515, hopital Trousseau, AP-HP, Paris, France; 2) service de genetique medicale, hopital Trousseau, AP-HP, Paris, France; 3) service de chirurgie maxillo-faciale, hopital Trousseau, AP-HP, Paris, France.

Overgrowth syndromes (OGS), include the well-studied Beckwith-Wiedemann syndrome (BWS) and the Simpson-Golabi-Behmel syndrome (SGBS) which have overlapping phenotypes and are often difficult to distinguish on a clinical background. The most frequent, BWS results from variable mutations or epigenetic modifications of imprinted genes in the 11p15 chromosomal region. SGBS is an X-linked syndrome involving mutation in the glypican-3 gene (GPC3) which encodes a heparan sulfate proteoglycan. As there are a great phenotypic variability in SGBS with the possibility of mild forms, and an overlapping phenotype with BWS, the aim of this study was to evaluate the incidence of SGBS in patients referred for OGS. From 144 patients (including 8 familial cases) referred for OGS, fifty-nine (41 %) did not exhibit abnormality in the 11p15 region (abnormal demethylation of KvDMR1, 11p15 uniparental disomy, isolated hypermethylation of the H19 gene or germline CDKN1C mutation). Among them, the 31 male patients were screened for GPC3 gene mutation. The entire coding region of GPC3 including intron-exon boundaries was analyzed by PCR and SSCP and all PCR products with aberrant SSCP migration patterns were directly sequenced. Two patients showed a point mutation that predict a loss-of-function of the GPC3 protein: a frameshift CG231T mutation and a missense mutation, V479M, changing a conserved aminoacid in a sporadic case. One patient exhibited a deletion involving exons 7 and 8 of the GPC3 gene. Two other unrelated patients showed the same 4 bp microdeletion in the 3' UTR which was not detected in the control population (174 X chromosomes analyzed). Two missense mutations (Q521H and G606R) were also found in two other patients directly referred with a clinical diagnosis of SGBS. Although mutations in the GPC3 gene are uncommon in the overall population of OGS patients, GPC3 analysis is appropriate in male patients without abnormality in the 11p15 region and may contribute to the genetic counseling.

**Karyotypic abnormality in a child whose phenotype overlaps Beckwith-Wiedemann syndrome defines a new overgrowth syndrome locus in 18qter.** *F. Lirussi<sup>1</sup>, D. Sanlaville<sup>2</sup>, V. Gaston<sup>1</sup>, C. Houdayer<sup>1</sup>, V. Soupre<sup>1</sup>, R.*

*Couderc<sup>1</sup>, C. Gicquel<sup>1</sup>, M-P. Vazquez<sup>1</sup>, Y. Le Bouc<sup>1</sup>, M-F. Portnoi<sup>2</sup>, M. Bahuaui<sup>1</sup>.* 1) Biochimie et Biologie Moléculaire (F.L., C.H., R.C., M.B.), Endocrinologie et Biologie Moléculaire (V.G., C.G., Y.LB.), Chirurgie Maxillofaciale (V.S., M-P.V., M.B.), Hôpital Trousseau, Paris, France; 2) Cytogénétique, Hôpital Saint-Antoine, Paris, France.

Beckwith-Wiedemann syndrome (BWS) is a tumor-predisposing condition with cardinal features of exomphalos, macroglossia, and gigantism in the neonate. BWS has been related to genetic imbalance in complex 11p15.5-linked region, which contains several imprinted genes. Other genetic loci may be involved in overgrowth syndromes in overlap with BWS. In particular, deletion 18q22.1 was shown in an infant with findings of macroglossia, umbilical hernia, neonatal hypoglycemia, and postnatal overgrowth. We report on a boy, term-born by C-section in a state of apparent death, who had findings of neonatal hypoglycemia, bilateral inguinal hernia, and other severe developmental problems. His tongue became progressively enlarged, causing major prognathism and hindering feeding. Adenoidomegaly caused airway to obstruct. There was a complex de novo chromosomal unbalance resulting from the presence, in all lymphocytes analyzed, of an abnormal monocentric chromosome 18 with partial duplication of 18q, and from a mosaic (50%), also exclusively 18-derived, small monocentric marker without identifiable subtelomeric specific sequences by FISH. The marker and der(18) were both characterized using a whole-chromosome paint probe. FISH using probe TEL 18q (D18S1390) elicited a signal on the normal 18 only demonstrating the 18qter deletion on the der(18). Molecular analysis for *IGFII* ruled out uniparental disomy in both leucocyte and tongue (glossectomy-derived) DNAs, and showed normal, monoallelic (paternal), expression from tongue RNA. Methylation of *H19* was restricted to the paternal allele whereas *KCNQ1OT1/LIT1* was methylated on the maternal allele only. This observation supports the existence of a genetic locus in the distal end of chromosome 18 whose haplo-insufficiency could entail a phenotype in overlap with BWS without visible imbalance in the 11p15.5 region.

**Molecular mechanism of disease in Carney Complex patients with mutations in *PRKARIA*.** *L.S. Kirschner<sup>1</sup>, F. Sandrini<sup>1</sup>, S.M. Lenherr<sup>1</sup>, J.A. Carney<sup>2</sup>, C.A. Stratakis<sup>1</sup>.* 1) Unit on Genetics and Endocrinology, DEB, NICHD, Bethesda, MD; 2) Department of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN.

Carney Complex (CNC) is a multiple endocrine neoplasia syndrome characterized by tumors of the adrenal cortex, anterior pituitary, thyroid, and gonads. Non-endocrine manifestations of this disease include spotty skin pigmentation, myxomas, and pigmented schwannomas. Genetically, this autosomal dominant disease has been mapped to 2p16 and 17q22-24. We have identified 68 kindreds with CNC from the NIH and Mayo Clinic, and we have used this cohort to identify mutations of *PRKARIA* in families mapping to 17q. Mutations in this gene, which codes for the Type 1A regulatory subunit of the cAMP-dependent protein kinase (PKA), have been detected in 41.2% of our CNC kindreds (28/68).

At the molecular level, CNC-causing mutations in *PRKARIA* were spread throughout the coding region of the gene. The majority of these mutations (22/28) were nonsense or frameshift mutations, leading to a premature termination codon. There were 5 splice site mutations and one mutation which abolished the initiator ATG of the protein. Analysis of the *PRKARIA* protein from cell lines from CNC patients with mutations showed that the predicted truncated proteins are not produced within the cells. Similarly, mRNA levels for the truncating transcripts are markedly reduced compared to the wild-type. Analysis of this phenomenon has demonstrated that these mutant mRNAs are rapidly degraded in the cells through the mechanism of nonsense-mediated mRNA decay, thus leading to selective suppression of the mutant protein.

At the functional level, PKA activity in CNC tumor cells is hyperresponsive to cAMP, suggesting an increase in cAMP-mediated signalling in these cells. The same phenomenon is observable in EBV-transformed lymphocytes from patients with CNC, indicating these patients may have more global abnormalities in cAMP-dependent pathways. Similar findings are observed in CNC patients lacking *PRKARIA* mutations, suggesting that the second CNC gene is also involved in the PKA signalling pathway.

**Differential Gene Expression in Monocytes from Probands with Elevated Lipoprotein (a).** *C. Buechler<sup>1</sup>, H. Ullrich<sup>1</sup>, M. Ritter<sup>1</sup>, K.J. Lackner<sup>1</sup>, S.O. Friedrich<sup>1</sup>, G.M. Kostner<sup>2</sup>, G. Schmitz<sup>1</sup>.* 1) Clin Chem/Lab Med, Univ Regensburg, Regensburg, Germany; 2) Med Biochem, Univ Graz, Graz, Austria.

Elevated plasma Lp(a) and cardiac events show a modest but significant association in various clinical studies. However, the influence of high Lp(a) on the gene expression in blood monocytes as a major cell involved in atherogenesis is poorly described. To identify genes influenced by elevated serum Lp(a) we analysed the gene expression on a cDNA microarray comparing monocytes from a patient with isolated Lp(a) hyperlipidemia and coronary heart disease with monocytes from a healthy blood donor with low Lp(a). Using this approach numerous genes were found differentially expressed in patient versus control monocytes. Verification of these candidates by Northern blot analysis or semiquantitative PCR in monocytes from additional patients with Lp(a) hyperlipidemia and healthy blood donors with elevated Lp(a) confirmed a significant induction of PAI-2 mRNA in monocytes from male but not from female individuals with high Lp(a) indicating that this observation is gender specific. This led also to increased intracellular and secreted PAI-2 protein in monocytes from male probands with Lp(a) hyperlipidemia. PAI-1 and LAL mRNA was found suppressed only in the patients monocytes and not in healthy probands with high Lp(a) levels. Purified Lp(a) induced PAI-2 mRNA and protein and reduced PAI-1 and LAL expression in monocytes isolated from various controls. The finding that PAI-2 is elevated in monocytes from male patients with isolated Lp(a) hyperlipidemia and male healthy probands with high Lp(a) and that purified Lp(a) upregulates PAI-2 in control monocytes in-vitro indicate a direct, but gender specific effect of Lp(a) for the induction of PAI-2 expression.

**Homozygous familial hypercholesterolaemia: Multiple founder mutations underlie phenotypic variation in the South African population.** *M. Callis<sup>1</sup>, S. Jansen<sup>1</sup>, R. Thiart<sup>2</sup>, M.J. Kotze<sup>2</sup>*. 1) Department of Human Genetics, University of the Free State, Bloemfontein, Free State, South Africa; 2) MRC Cape Heart Group, Division of Human Genetics, University of Stellenbosch, Tygerberg, South Africa.

**Objective.** Predominance of three low density lipoprotein receptor (LDLR) gene mutations in South African Afrikaner patients with familial hypercholesterolaemia (FH) significantly enhances the diagnostic prospects of the disease in this population. The degree of genetic heterogeneity in Afrikaner FH homozygotes was studied in relation to the phenotypic expression of the disease, in order to determine whether additional mutations should be included for routine DNA diagnosis, and to assess whether mutation status may provide useful parameters of disease progression in homozygous FH.

**Methods.** Polymerase chain reaction (PCR)-based methods were used to screen FH homozygotes without (or with only one copy of) the three founder-related mutations, D154N, D206E and V408M, for disease-related LDLR gene mutations. Afrikaner FH homozygotes with these mutations known to cause a receptor-defective or -negative phenotype, were grouped according to genotype for comparative analysis.

**Results.** Mutations W66G, D200G (heterozygous state) and S285L (homozygous state) were identified in three of the four Afrikaner FH homozygotes subjected to mutation analysis. Significantly higher mean total- ( $P < 0.008$ ) and LDL-cholesterol ( $P < 0.015$ ) levels were demonstrated in 24 FH homozygotes with at least one copy of the receptor-negative mutation V408M, compared with 23 patients with receptor-defective LDLR gene mutations D154N and/or D206E.

**Conclusions.** Mutation analysis provides useful parameters on which to base predictions of clinical progression of FH. Inclusion of all relevant mutations in routine DNA screening would therefore facilitate an improved diagnostic service for FH in the genetically homogeneous Afrikaner population.

**Lamin C mutation associated with variable expression of dilated cardiomyopathy and conduction-system disease (D-CM) and limb girdle muscular dystrophy type 1B (LGMD1B) in four generations of a large kindred. S.**

*Dyack*<sup>1,2</sup>, *K. Collins*<sup>1</sup>, *P. Welch*<sup>2</sup>, *C. Riddell*<sup>3,4</sup>. 1) Division of Medical Genetics, IWK Health Centre, Halifax, NS, Canada; 2) Department of Pediatrics, IWK Health Centre, Halifax, NS, Canada; 3) Department of Laboratory Medicine, IWK Health Centre, Halifax, NS, Canada; 4) Department of Pathology, Dalhousie University, Halifax, NS, Canada.

LMNA mutations have been described in four distinct medical conditions including dilated cardiomyopathy with conduction-system defects (D-CM), autosomal dominant Emery-Dreifuss muscular dystrophy (EDMD-AD), limb girdle muscular dystrophy type 1B (LGMD1B), and familial partial lipodystrophy (FPLD). Lamin A and C are nuclear proteins that are encoded by the LMNA gene and differ from each other only through alternative splicing of exon 10. We report here a unique family with a novel mutation, R541S, in exon 10 of the lamin C coding region of LMNA. There is variable expression of D-CM and LGMD1B in affected family members. Three affected individuals had severe, progressive D-CM resulting in sudden cardiac death. A 13 year old male with severe D-CM is now the youngest reported child with a LMNA mutation to develop D-CM and to require a cardiac transplant. Two members presented with a myopathy, subsequently discovered to be LGMD1B, and had less severe D-CM. One affected individual with mild LGMD1B had delayed ambulation as a child. Several asymptomatic individuals have cardiac conduction defects. Many affecteds have muscle pain and most have had an elevated CPK. Also noted is a distinct physical phenotype in females with a decrease in adipose tissue of the extremities, but not associated with the biochemical features of insulin resistance as seen in FPLD. This family illustrates that a single LMNA mutation may lead to the expression of several distinct phenotypes and, in light of these findings, it is suggested that individuals with LMNA mutations should be investigated for features of all of the above named conditions. In particular, it should be recognized that alterations in the lamin C sequence can lead to the development of severe D-CM and children with these mutations may require a heart transplant at a young age.

**Functional analysis of lamin A/C mutations leading to dilated cardiomyopathy, Emery-Dreifuss muscular dystrophy and partial lipodystrophy.** *G.L. Brodsky*<sup>1,2</sup>, *A.C. Moss*<sup>2</sup>, *L. Mestroni*<sup>1,2</sup>, *M.R.G. Taylor*<sup>1,2</sup>. 1) Dept Cardiology/Medicine, Univ Colorado Health Sci Ctr, Denver, CO; 2) University of Colorado Cardiovascular Institute, Aurora, CO.

Lamin A/C gene mutations have been identified in four different human diseases including Emery Dreifuss muscular dystrophy (EDMD), limb-girdle muscular dystrophy (LGMD), dilated cardiomyopathy (DCM) and partial lipodystrophy (PLD). The lamin A/C gene encodes two proteins which are the primary components of the nuclear lamina; a proteinaceous meshwork lining the nucleoplasmic face of the inner nuclear membrane. Lamins have also been shown to form intranuclear filaments. The nuclear lamina has been implicated in nuclear structural integrity, chromatin organization, cell cycle regulation and transcriptional unit organization.

As a first step in elucidating the molecular pathway by which lamin A/C mutations lead to human disease, we have examined the expression and localization of disease causing mutant lamin A proteins in mammalian cell culture. Single nucleotide substitutions responsible for EDMD, DCM and PLD were introduced into a wild type lamin A cDNA and transfected into mouse F9 cells. The expression and sub-cellular localization of the mutant lamin A proteins were determined by indirect immunofluorescence deconvoluting confocal microscopy.

All of the mutant lamin A proteins examined were found to be expressed and localized to the cell nucleus. The mutant proteins responsible for EDMD and DCM produced a wild type pattern of distribution, localizing to the nuclear lamina as well as intranuclear filaments. In contrast, the mutant lamin A proteins responsible for PLD were found to be concentrated in disk-like or punctate structures at the nuclear periphery. No diffuse lamina staining or intranuclear filaments were observed.

This is the first demonstration of altered lamin A function resulting from disease causing mutations. Furthermore, these results support a model where expression of dominant negative lamin proteins is responsible for the observed disease phenotypes.

**Identification of two novel missense mutations in the *CSX/NKX2-5* gene encoding a cardiac specific transcription**

**factor.** *I. Gutierrez-Roelens*<sup>1</sup>, *Th. Sluysmans*<sup>2</sup>, *K. Devriendt*<sup>3</sup>, *M. Gewillig*<sup>4</sup>, *M. Vikkula*<sup>1</sup>. 1) Lab. of Human Molec. Genetics, Christian de Duve Institute, Brussels, Belgium; 2) Division of Pediatric Cardiology, Universite catholique de Louvain, Brussels, Belgium; 3) Center for Human Genetics, KUL, Leuven, Belgium; 4) Division of cardiology, KUL, Leuven, Belgium.

Non-syndromic cardiac septation defects are common, yet the responsible genetic changes remain uncharacterised. However mutations in the *CSX/NKX2-5* gene encoding a cardiac specific homeobox transcription factor have been reported to cause atrial septal defects (ASD) associated with atrioventricular (AV) conduction block. The *CSX/NKX2-5* gene is expressed in cardiac muscle during embryonic, fetal and adult life, and its *Drosophila* ortholog *tinman*, is essential for the formation of the dorsal vessel. Targeted homozygous disruption of *Nkx2-5* in mice causes lethality due to failure of heart looping. In man, ten mutations in the *CSX/NKX2-5* gene have been described in individuals with variable cardiac phenotypes. The majority has ASD and/or atrioventricular conduction defects. In addition, ventricular septal defects (VSD), tetralogy of Fallot (TOF), subvalvular aortic stenosis, ventricular hypertrophy, pulmonary atresia, mitral valve abnormalities and Ebsteins anomaly are observed. Along our studies on non-syndromic familial cardiopathies, we have collected two families with some members presenting ASD and AV-block. In both families we identified a novel *CSX/NKX2-5* mutation in the homeodomain. Variable expressivity in the phenotype was observed in one of the families. Importantly, mutation carriers do not necessarily present AV-block at young age. We have also screened the *CSX/NKX2-5* gene in sporadic and familial cases of diverse cardiopathies, to estimate mutation frequency. As mutations were not found in other than the 2 families with AV-block, *CSX/NKX2-5* seems to be a rare cause of cardiopathies without conduction defect. (vikkula@bchm.ucl.ac.be).

**Somatic second hit-hypothesis is true for glomuvenous malformations.** P. Brouillard<sup>1</sup>, L.M. Boon<sup>1,2</sup>, O. Enjolras<sup>3</sup>, M. Ghassibe<sup>1</sup>, J.B. Mulliken<sup>4</sup>, M. Vikkula<sup>1</sup>. 1) Lab. of Human Molec. Genetics, Christian de Duve Institute, Brussels, Belgium; 2) Center for Vascular Anomalies, Division of Plastic Surgery, Universite catholique de Louvain, Brussels, Belgium; 3) Consultation des Angiomes, Hopital Lariboisiere, Paris, France; 4) Vascular Anomalies Center, Childrens Hospital, Harvard Medical School, Boston, MA.

Glomuvenous malformations (GVMs), *localized* defects of vascular morphogenesis, are single or multiple bluish-purple lesions that occur mainly in skin. Histologically, the distended veins present smooth muscle-like "glomus cells" in the media. GVMs are usually dominantly inherited and, with the more common mucocutaneous venous malformations, they are among the most frequent lesions in centers that specialize in treatment of vascular anomalies (Vikkula et al., 1998). In other abstracts submitted to this meeting, we describe the criteria for clinical differential diagnosis between common VMs and GVMs (Boon et al.), as well as the identification of the causative gene, glomulin, for GVMs (Vikkula et al.). As 13 of the 14 identified mutations cause premature stop codons, GVMs are likely to be caused by loss-of-function of glomulin. This guided us to test the hypothesis that these *localized* inherited vascular lesions are due to local complete lack of glomulin function. This might be due to a somatic second hit, as was suggested for retinoblastoma by Knudson's double-hit hypothesis. Thus, we screened for somatic mutations in GVM lesions resected from families with a characterized inherited mutation. Here we report on the identification of a mutation that was different from the inherited genetic alteration, and that was not seen in genomic DNA extracted from blood. Thus, it is a *de novo* somatic mutation in DNA of a GVM lesion. These data demonstrate that GVMs are due to complete *localized* loss of glomulin function. (vikkula@bchm.ucl.ac.be).

**STRUCTURAL AND FUNCTIONAL DEFECTS OF DESMIN CAUSING CARDIAC AND SKELETAL MYOPATHY.** *A. Dagvadorj<sup>1</sup>, K-Y. Park<sup>1</sup>, V.J. Ferrans<sup>1</sup>, N. Sambuughin<sup>2</sup>, K. Sivakumar<sup>2</sup>, M.C. Dalakas<sup>1</sup>, L.G. Goldfarb<sup>1</sup>.* 1) NINDS, National Institutes of Health, Bethesda, MD; 2) Barrow Neurological Institute, Phoenix, AZ.

Desmin myopathy is characterized by amorphous accumulation of desmin and other myofibrillar proteins in the sarcoplasm of cardiac and skeletal muscle fibers. Desmin is a cytoskeletal protein in interconnecting myofibrils and attaching them to other cellular structures. We identified nine point mutations at the C-terminal part of the alpha-helical rod that is critically important for filament assembly. Six of the nine mutations introduce proline that is known to disrupt the intermediate filament network. In addition, two families had splice site mutations; in both, desmin gene was lacking exon 3 leading to an in-frame deletion of 32 amino acids and making desmin molecule non-functional. Most of the studied families (9 of 13) show autosomal dominant pattern of inheritance. Patients in one family had compound heterozygosity with amino acid-altering point mutations on both desmin alleles. Three our patients were sporadic; neither of their unaffected parents showed desmin mutations, thus confirming that the mutations have occurred de novo. To demonstrate the functional consequences of desmin mutations we expressed wild type and mutant cDNA in SW13 cells and studied them by immunocytochemistry. SW13 cells are of epithelial origin and normally do not express desmin or other intermediate filaments. Cells transfected with wild type cDNA produced functional desmin that was capable of forming an intermediate filament network. Mutant desmin was unable to build an intermediate filament network and instead aggregated into clumps of desmin-reactive material scattered throughout the cytoplasm. The presence of desmin mutations in patients with desmin-related cardiac and skeletal myopathy clustered at the highly conserved C-terminal end of the desmin rod domain that plays an important role in filament assembly, and functional analysis of these mutations demonstrating the inability of mutant desmin molecules to construct a filament network, strongly suggest that the mutations we have identified in the desmin gene are implicated in the phenotypes observed in the affected families.

**Automated mutation screening using dideoxy fingerprinting and capillary array electrophoresis.** *P.S. Andersen<sup>1</sup>, M. Johnson<sup>2</sup>, C. Brown<sup>2</sup>, M. Christiansen<sup>1</sup>, R. Frank-Hansen<sup>1</sup>, J. Vuust<sup>1</sup>, L.A. Larsen<sup>3</sup>.* 1) Dept. of Clinical Biochemistry, Statens Serum Institut, Copenhagen, Denmark; 2) Applied Biosystems, Foster City, CA; 3) Dept. of Medical Genetics, University of Copenhagen, Copenhagen, Denmark.

The rapid progress in the isolation of genes associated with human disease has resulted in an increasing demand for mutation screening methods. The molecular diagnosis of the long QT syndrome (LQTS) - a cardiac disorder characterized by prolongation of the QT<sub>c</sub> interval in the ECG, syncope and sudden death - requires mutation screening of all exons in at least five genes, encoding cardiac Na<sup>+</sup> and K<sup>+</sup> channel subunits.

A method for automated dideoxy fingerprinting (ddF) using capillary array electrophoresis (CAE) was developed and the efficiency of the method was tested by analyzing 24 DNA samples with mutations in one of the genes *KCNQ1* and *KCNH2*, which are involved in 50% of LQTS cases. One of these mutations, 362insQK in *KCNQ1*, is novel.

The sensitivity was 100% using a single electrophoresis temperature of 18 °C or 25 °C. However, analysis of the samples in both the sense and anti-sense direction were required for high sensitivity. Analysis in a single direction resulted in a decrease of the sensitivity to 74% and 70%, respectively.

The throughput of the ddF method, if performed with a 16 capillary CAE instrument is 288 samples per 7 hours if each sample is analyzed on both strands.

**Familial thoracic aortic aneurysms and dissections : genetic heterogeneity with a major locus mapping to 5q13-**

**14.** *D. Guo<sup>1</sup>, R. He<sup>1</sup>, S.N. Hasham<sup>1</sup>, S. Shete<sup>2</sup>, D.M. Milewicz<sup>1</sup>*. 1) Dept Internal Medicine, Univ Texas/Houston Med Sch, Houston, TX; 2) Dept of Epidemiology, M.D.Anderson Cancer Centre, Houston, TX.

Thoracic aortic aneurysms and dissections (TAAs) are the major disease process affecting the aorta. Previous study on 15 TAAs families mapped a major locus to 7.8cM critical interval on 5q13-14 with a maximum LOD score ( $Z_{max}$ ) of 4.74. An STS tagged sequence based BAC contig was assembled for the critical region on 5q. Dinucleotide repeats were identified in the sequenced BACs of the critical interval and used for fine genotyping. Fine mapping was carried out in family TAA013 that had an affected individual with double recombination over the critical interval. The results suggest that the critical interval containing the defective gene lie in an interval of 2cM. Eleven new families with TAAs were recruited that did not show linkage to FBN1, one of which showed linkage to 5q. With this, the maximum LOD score for marker D5S2029 has increased to 5.6. All of these families were genotyped with the microsatellite markers surrounding the candidate loci at 3p and 11q. By haplotype analysis, five of families did not show evidence of linkage to markers on 3p, 5q or 11q. This indicates that there is at least one more locus for familial TAAs disease.

**The genetics of long QT syndrome: Mutation detection in 100 families.** *M. Christiansen*<sup>1</sup>, *L.A. Larsen*<sup>2</sup>, *R.F. Hansen*<sup>1</sup>, *P.S. Andersen*<sup>1</sup>, *J. Vuust*<sup>1</sup>, *J.K. Kanters*<sup>3</sup>, *L. Tranebjaerg*<sup>4</sup>, *G. Wettrell*<sup>5</sup>. 1) Dept Clinical Biochemistry, Statens Serum Inst, Copenhagen, Denmark; 2) Institute of Medical Biochemistry and Genetics, University of Copenhagen, Denmark; 3) Dept Medical Physiology, University of Copenhagen, Denmark; 4) Dept of Medical Genetics, Tromsø University Hospital, Tromsø; Norway; 5) Dept of Pediatrics, University Hospital, Lund.

100 families with long QT syndrome (LQTS), a hereditary cardiac disease characterized by prolonged cardiac repolarization and syncopes, polymorphous ventricular tachycardia and sudden death, were examined for mutations in genes coding for cardiac ion channels using SSCP-HD. In *KCNQ1* 19 mutations were found in 23 families, and in *KCNH2* 23 mutations were found in 24 families, whereas no mutations were found in neither *KCNE1* nor *KCNE2*. Three novel mutations in *SCN5A*, IVS5DS, V411M, and V1251M, were found in three families. Nearly all mutations were private and 75% were missense mutations. As prolonged repolarisation can theoretically be caused by changes in the transient outward potassium current (I<sub>to</sub>) conducted by ion channels coded for by the genes *KCDN2* and *KCDN3*, we examined whether mutations in the latter gene could be found in 23 families with no other mutations identified. As no mutations were found we conclude that mutations affecting I<sub>to</sub>, as well as mutations affecting I<sub>Na</sub>, conducted by *SCN5A*, are at most a rare cause of LQTS. A large number of common and rare polymorphisms were identified in the LQTS associated genes and their significance in propensity for arrhythmias and drug-induced proarrhythmia should be examined in large epidemiological studies. Furthermore, we still need to identify the genetic substrate for the disease in the 50% of familial LQTS cases where we do not find mutations in the known LQTS-associated genes.

**Sarcoplasmic calcium channel mutations in inherited and acquired forms of human ventricular arrhythmias.** *P.J. Laitinen*<sup>1,2</sup>, *H. Fodstad*<sup>1,2</sup>, *H. Swan*<sup>1</sup>, *K. Paavonen*<sup>1,2</sup>, *K. Piippo*<sup>1,2</sup>, *M. Viitasalo*<sup>1</sup>, *L. Toivonen*<sup>1</sup>, *N. Rosembli*<sup>3</sup>, *A.R. Marks*<sup>3</sup>, *K. Kontula*<sup>1,2</sup>. 1) Department of Medicine, University of Helsinki, Helsinki, Finland; 2) Program of Molecular Medicine, Biomedicum Helsinki, Helsinki, Finland; 3) Center for Molecular Cardiology, Columbia University, New York, USA.

Familial polymorphic ventricular tachycardia (FPVT) is a highly malignant, autosomally dominantly inherited disorder. It manifests with bidirectional and polymorphic ventricular tachycardias in response to vigorous exercise. No structural abnormalities of the heart are observed. We recently identified that the gene underlying FPVT is the cardiac ryanodine receptor gene (RYR2) which encodes a sarcoplasmic calcium channel. Point mutations in the RYR2 gene were found in three of the four known Finnish FPVT families. In addition two amino acid polymorphisms were detected. As an extension to these initial studies, we aim at characterizing the specific effects of the recently identified mutations and polymorphisms. Our second aim is to find out whether these alterations could predispose to arrhythmic disorders other than FPVT. To this end, specific restriction fragment length polymorphism assays for each DNA alteration were set up. Functional studies will be conducted using in vitro mutagenesis and patch clamp technique. We have expanded our FPVT pedigrees, and DNA samples of several new individuals from each FPVT family were added to the study. At present, the number of affected and non-affected individuals in Finnish FPVT families are as follows: P2328S 22 and 35, Q4201R 3 and 22, V4653F 11 and 26, respectively. We are currently screening RYR2 polymorphisms and mutations in several well documented clinical cohorts consisting of patients with ventricular fibrillation due to ischemic heart disease and other cardiac disorders as well as individuals undergoing sudden death. The prevalence of the HERG ion channel polymorphism K897T, associated with phenotypic effects on the cardiac repolarization duration is also being determined in these patients. We hypothesize that common RYR2 and HERG polymorphisms may constitute genetic markers of liability to ventricular fibrillation and cardiac sudden death.

**Comprehensive mutational analysis of the Lamin A/C gene in familial and sporadic dilated cardiomyopathies.** *L. Mestroni*<sup>1</sup>, *M.R.G. Taylor*<sup>1</sup>, *M. Robinson*<sup>1</sup>, *G.L. Brodsky*<sup>1</sup>, *A. Moss*<sup>1</sup>, *J.L. Goodnight*<sup>1</sup>, *G. Sinagra*<sup>2</sup>, *A. Di Lenarda*<sup>2</sup>, *P. Fain*<sup>1</sup>. 1) Cardiovascular Institute, University of CO, Aurora, CO; 2) University Hospital, Trieste, Italy.

**Background:** Mutations in the lamin A/C gene (*LMNA*) have been described in patients with dilated cardiomyopathy (DCM). The overall spectrum, the frequency, and the genotype/phenotype correlation of *LMNA* mutations in this condition remain unknown. **Methods:** Fifty-two families of DCM index patients from different ethnic groups were screened for *LMNA* mutations: 43 familial DCM and 9 non-familial (sporadic). DNA from 76 affected family members was screened for mutations in *LMNA*. Denaturing high performance liquid chromatography (DHPLC) was utilized for mutation analysis. **Results:** Putative *LMNA* mutations were detected in four nuclear families: exon 1 (Arg89Leu), exon 6 (delT959 and Arg377His) and exon 11 (Ser573Leu), respectively. The delT959 mutation is predicted to lead to a frameshift and novel carboxy-terminal protein sequence. The exon 11 missense mutation was present in a sporadic case. The Arg89Leu and the Ser573Leu mutations produced a DCM phenotype, with complicating arrhythmia, but no muscle or conduction defects. In both families with exon 6 mutations, there was significant inter- and intra-familial phenotypic variability, ranging from complete absence to overt signs of muscular dystrophy (Emery-Dreifuss or limb-girdle muscular dystrophy). Four patients had elevated creatine kinases and the 2 probands had abnormal muscle biopsies. Cardiac involvement included conduction abnormalities (6 cases) and atrial and/or ventricular arrhythmia in all patients. The mutated residues are highly conserved across differing species, the mutations were not observed in more than 150 chromosomes, and, in the familial cases, cosegregated with the disease. In addition, a number of intronic and 4 exonic single nucleotide polymorphisms were identified. **Conclusions:** These results suggest that *LMNA* mutations can cause DCM in a relevant proportion of familial and non-familial cases. The results also illustrate the variability in skeletal muscle disease phenotype that characterizes *LMNA* mutations.

**Genetic risk for sudden cardiac death: ethical issues of molecular testing for hypertrophic cardiomyopathy.** V. Meiner<sup>1</sup>, M.Y. Flugelman<sup>2</sup>, A. Lorber<sup>3</sup>, D. Stern<sup>4</sup>, S. Shpitzen<sup>4</sup>, L. Ben-Avi<sup>4</sup>, A. Keren<sup>5</sup>, E. Leitersdorf<sup>4</sup>. 1) Dept of Human Genetics, Hadassah Univ Hosp, Jerusalem, Israel; 2) Dept of Cardiology, Lady Davis Carmel Medical Center, Haifa, Israel; 3) Dept of Pediatric Cardiology, Rambam Medical Center, Haifa, Israel; 4) Center for Research, Prevention, and Treatment of Atherosclerosis, Hadassah University Hospital, Jerusalem Israel; 5) The Heiden Department of Cardiology, Bikur Cholim Hospital, Jerusalem, Israel.

Hypertrophic cardiomyopathy (HCM) is an autosomal dominant disorder associated with a variable clinical course. Possible treatments include change in life style, implantation of a cardioverter defibrillator, and drug treatment. A considerable inter- and intra-familial diversity is emphasized by the fact that HCM may be clinically evident in all stages of life. Moreover, some patients remain asymptomatic throughout their lives, others develop severe symptoms of heart failure, and some die suddenly in the absence of antecedent symptoms. The impact of molecular genetics in the diagnosis of HCM is continuously increasing, leading to improved understanding of various aspects of its pathophysiology. Yet, important questions are raised concerning the practical significance of DNA testing in HCM. In order to assess the potential merit of molecular genetics in HCM, we studied nine Israeli families and reviewed our experience. DNA samples from individuals with either familial or sporadic HCM were analyzed and specific mutations in sarcomeric genes were characterized. The value of genetic counseling as an integral part of the treatment in HCM is emphasized. In one of the families, prenatal diagnosis through CVS was applied and resulted in termination of the pregnancy. The dilemma of whether to ground therapeutic considerations on molecular findings in an uncertain phenotype within family members is constantly raised. Unpredicted disease course with possible sudden death as a presenting symptom combined with desperate families seeking for an active treatment, in contrast to the uncertain significance of the mutation without clinical findings, raises ethical questions as to the current role of molecular genetics in HCM.

**Detection of Sequence Variations in the LDL-Receptor Gene Using Denaturing High Performance Liquid Chromatography.** *S. Morrow<sup>1</sup>, M. Robinson<sup>1</sup>, M. Volkova<sup>2</sup>, E.I. Schwartz<sup>2</sup>, M.A. Marino<sup>2</sup>.* 1) Applied Genomics & Molecular Genetics, Transgenomic, Inc., Omaha, NE; 2) Applied Genomics & Molecular Genetics, Transgenomic, Inc., Gaithersburg, MD.

The low-density lipoprotein (LDL)-receptor gene contains a high degree of allelic heterogeneity. A variety of mutations at this locus result in the development of familial hypercholesterolemia (FH), an autosomal dominant lipoprotein metabolism disorder characterized by high cholesterol levels in the blood and premature coronary arteriosclerosis. This study utilized denaturing high performance liquid chromatography (dHPLC) to detect sequence variations in a panel of 28 patient samples with a clinical diagnosis of FH. PCR amplicons were designed for LDL-receptor exons 1-3 and 5-18, as well as the 5-UTR. DHPLC analysis demonstrated that all 28 patients were positive for a putative sequence variant in at least one exon. The DNA sequence variants are presently being confirmed by direct sequencing of PCR products. The use of dHPLC analysis utilizing the WAVE® system proved to be a useful tool for detecting both well-characterized as well as unknown sequence variations in the LDL-receptor gene.

**The WAVE® nucleic acid fragment analysis system: A versatile analytical tool for mutation detection. M.**

*Hepburn<sup>1</sup>, H. Liyanage<sup>2</sup>, L. Furu<sup>3</sup>, S. Somolo<sup>3</sup>, C. Vaughn<sup>4</sup>, C. Basson<sup>4</sup>, W. Xin<sup>5</sup>, K. Sims<sup>5</sup>, J. Affourtit<sup>6</sup>, A. Seymour<sup>6</sup>.*

The WAVE® Nucleic Acid Fragment Analysis System is a fully automated DNA analysis system that integrates denaturing high performance liquid chromatography (dHPLC) with the WAVEMaker® DNA melting prediction software and the DNASep® column. The WAVE® is an analytical tool, which excels at screening for unknown sequence variations. A few of the many disorders for which the WAVE® dHPLC system has been instrumental in the identification of previously unknown sequence variants include Holt-Oram syndrome which is caused by mutations in the T-box transcription factor gene TBX5, Familial long QT syndrome, or LQTS, a polygenic disorder involving the KVLQT1, HERG, and SCN5A genes, as well as the gene involved in the development of Neurofibromatosis type 2 (NF2). The automated high-throughput capability, high sensitivity of detection compared to other methods, and ease of data analysis have made the WAVE® the method of choice for high throughput SNP screening and mutation detection projects.

**CFC1 as a candidate gene for congenital cardiovascular malformations.** *J.D. Karkera<sup>1</sup>, A.K. Kantipong<sup>2</sup>, E. Roessler<sup>1</sup>, R.N. Bamford<sup>1</sup>, J. dela Cruz<sup>1</sup>, J.A. Towbin<sup>3</sup>, P. Bowers<sup>4</sup>, R. Burdine<sup>5</sup>, A. Schier<sup>5</sup>, E. Goldmuntz<sup>6</sup>, M. Muenke<sup>1</sup>.* 1) Medical Genetics Br, NHGRI/NIH, Bethesda, MD; 2) HHMI-NIH Scholar, MGB, NHGR/NIH, Bethesda, MD; 3) Baylor College of Medicine, Houston, TX; 4) Yale University, New Haven, CT; 5) Skirball Institute of Biomolecular Medicine, NY; 6) The Children's Hospital of Philadelphia, PA.

In vertebrates, the organs of chest and abdomen have a specific non-random asymmetric arrangement with respect to the midline of the body called Left-Right (L-R) asymmetry. Several reports have suggested that some cardiac abnormalities might be attributable to mutations in developmental control genes responsible for L-R asymmetry. Recently, mutations in CFC1 (encoding the CRYPTIC protein) have been implicated as a cause of laterality defects and transposition of the great arteries (TGA) in humans. CFC1 is a member of the EGF-CFC gene family. Studies of murine CFC1 and the zebrafish homologue *oep* have suggested that these factors play a critical role in the establishment of L-R axis. In this study we have decided to screen CFC1 for mutations using PCR-dHPLC in our panel of 310 patients with a wide spectrum of cardiac anomalies: tetralogy of fallot, truncus arteriosus, interrupted aortic arch, and AV canal. We have identified several SNPs, and missense mutations. Functional complementation of zebrafish embryos defective in *oep* function are in progress to assess the effect of these variants.

**Novel mutations in three families with dilated cardiomyopathy and conduction system disease cluster in the rod domain of lamin A/C.** *P.M. Jakobs<sup>1</sup>, H.L. Keegan<sup>1</sup>, E.L. Hanson<sup>1</sup>, M. Litt<sup>2</sup>, R.E. Hershberger<sup>1</sup>.* 1) Department of Medicine, Oregon Health & Sciences University, Portland, OR 97201, USA; 2) Department of Molecular and Medical Genetics, Oregon Health & Sciences University, Portland, OR 97201, USA.

Mutations in inherited forms of dilated cardiomyopathy account for at least 35% of cases of idiopathic dilated cardiomyopathy. Several autosomal dominant inherited, familial dilated cardiomyopathy (FDC) disease genes  $\alpha$ -cardiac actin, desmin, d-sarcoglycan,  $\beta$ -myosin heavy chain, troponin T,  $\alpha$ -Tropomyosin and lamin A/C - have been identified. Lamin A/C are alternatively spliced nuclear envelope proteins encoded by the LMNA gene. Mutations in LMNA are responsible for various pathologies: Emery-Dreifuss muscular dystrophy (EDMD2), limb girdle muscular dystrophy type 1B (LGMD1B), Dunnigan type familial partial lipodystrophy (FPLD) and dilated cardiomyopathy with conduction defects (CMD1A). Detailed phenotypic reports and the identification of novel mutations in distinct areas of this intermediate filament protein could give additional insight into the function of lamin A/C. We identified novel LMNA mutations in the rod domain of lamin A/C by direct sequencing of LMNA exons, including the exon / intron junctions, in one affected individual from sixteen large families. Variants were confirmed by either allele specific oligohybridizations (ASOs) or restriction digests (RFLPs). A missense mutation (E203K) was identified in 14 affected individuals of family A. Disease presented as progressive conduction disease in the 4th and 5th decades of life. A nonsense mutation (R225X) in ten adult subjects of family B showed progressive conduction disease with an average of one decade earlier onset of ventricular arrhythmias, left ventricular enlargement and systolic dysfunction. In family C, a missense mutation (L215P) was identified in seven adult subjects with disease onset in the 4th and 5th decades. This data, together with previous reports, suggest that lamin A/C mutations may account for 10-20% of cases of FDC.

**Mutations in cardiac actin appear to be rare in dilated cardiomyopathies.** R. Zolty<sup>1</sup>, G. Passarino<sup>2</sup>, G.L. Brodsky<sup>1</sup>, M.R.G. Taylor<sup>3</sup>, A. Moss<sup>1</sup>, M.R. Bristow<sup>1</sup>, L. Cavalli-Sforza<sup>2</sup>, P.A. Underhill<sup>2</sup>, L. Mestroni<sup>1</sup>. 1) CU-Cardiovascular Institute, UCHSC at Fitzimons, Aurora, CO; 2) Department of Genetics, Stanford University, Palo Alto, CA; 3) University of Colorado Health Sciences Center, Denver, CO.

**Background:** Idiopathic dilated cardiomyopathy (DCM) is frequently inherited and genetically heterogeneous. Previous investigators have reported mutations in exons 5 (Arg312His) and 6 (Glu361Gly) of the cardiac actin gene (*ACTC*) in two families with DCM. **Methods:** We designed a study to evaluate the prevalence and characteristics of *ACTC* gene mutations in DCM. 65 DCM patients from different ethnic backgrounds were studied: 48 had familial DCM (from 32 unrelated families) and 17 had sporadic DCM. The controls were two patients with ischemic heart disease. Genomic DNA was extracted from blood or explanted heart tissue using standard procedures. PCR products were produced from all 6 exons of the *ACTC* gene, allowing the inclusion of the exon/intron boundaries. The G-to-A transversion in codon 312 (Arg312His) of exon 5 introduces a unique Bcl1/Nde1 restriction site. Mutation analysis of all 6 exons was performed using denaturing high performance liquid chromatography (DHPLC) and sequence analysis. In addition, Exon 5 amplicons were digested with Bcl1/Nde1. **Results:** The mutant restriction fragments were not detected in any of the exon 5 amplicons. The DHPLC evaluation uncovered a single nucleotide polymorphism, which was confirmed by sequence analysis to be in intron 5 (C-62T). No genetic variations could be found in the other exons. **Conclusions:** *ACTC* mutations were not associated with DCM in our large population of familial and sporadic DCM. *ACTC* mutations appear to be only rarely associated with DCM.

**Haploinsufficiency for one *COL3A1* allele of type III procollagen results in a phenotype similar to the vascular form of Ehlers-Danlos syndrome (EDS type IV).** *U. Schwarze*<sup>1</sup>, *W.I. Schievink*<sup>2</sup>, *E. Petty*<sup>3</sup>, *M.R. Jaff*<sup>4</sup>, *D. Babovic-Vuksanovic*<sup>5</sup>, *K.J. Cherry*<sup>5</sup>, *M. Pepin*<sup>1</sup>, *P.H. Byers*<sup>1</sup>. 1) University of Washington, Seattle, WA; 2) Cedars-Sinai Medical Center, Los Angeles, CA; 3) University of Michigan, Ann Arbor, MI; 4) The Heart and Vascular Institute, Morristown, NJ; 5) Mayo Clinic, Rochester, MN.

Mutations in the *COL3A1* gene that encodes the chains of type III procollagen result in the vascular form of the Ehlers-Danlos syndrome, if they alter the sequence in the triple helical domain. Although mutations in other fibrillar collagen genes that lead to allele instability or failure to incorporate pro- $\alpha$  chains into trimer and thus reduce the amount of the mature molecule produced result in clinically apparent phenotypes, no such mutations in the *COL3A1* gene have been identified. Further, mice heterozygous for *Col3a1* "null" alleles have no identified phenotype.

We have now found three frame-shift mutations (1832delAA, 413delC, and 555delT) that led to premature termination codons (PTC) in exons 27, 6 and 9, respectively, and to allele product instability. The mRNA from the mutant allele was transcribed efficiently but rapidly degraded, presumably by the mechanisms of nonsense-mediated decay. In a fourth patient we identified a point mutation in the final exon (exon 52) that resulted in a PTC (4294C $\rightarrow$ T; Arg1432Ter). In this last instance the mRNA was stable but led to synthesis of a truncated protein that was not incorporated into the mature type III procollagen molecule. In all probands the presenting feature was vascular aneurysm or rupture. Thus, in contrast to mutations in genes that encode the dominant protein of a tissue (e.g., *COL1A1* and *COL2A1*) in which "null" mutations result in milder phenotypes than those that alter protein sequence, the phenotypes produced by these mutations in the *COL3A1* gene overlap with those of the vascular form of EDS. This suggests that the major effect of many of these dominant mutations in the "minor" collagen genes may be expressed through protein deficiency rather than incorporation of structurally altered molecules into fibrils.

**A novel mutation in the *SDHD* gene in a family with inherited paragangliomas.** *L. Renard*<sup>1</sup>, *C. Godfraind*<sup>2</sup>, *L.M. Boon*<sup>3,4</sup>, *M. Vikkula*<sup>4</sup>. 1) Dept. of Radiotherapy, Cliniques univ. St Luc, Univ. catholique de Louvain, Brussels, Belgium; 2) Lab. of Neuropathology, Cliniques univ. St Luc, Univ. catholique de Louvain, Brussels, Belgium; 3) Div. of Plastic Surgery, Centre for Vascular Anomalies, Cliniques univ. St Luc, Univ. catholique de Louvain, Brussels, Belgium; 4) Lab. of Human Molecular Genetics, Christian de Duve Institute & Univ. catholique de Louvain, Brussels, Belgium.

Paragangliomas (OMIM# 168000), (carotid body tumours) are vascularized tumors of the head and neck. These tumors may be unilateral, although in families with inherited predisposition, they tend to be bilateral and multiple. It has been observed that paragangliomas are inherited almost exclusively via the paternal line; thus maternal imprinting occurs. This helped in finding linkage to *11q23-qter* (Heutink et al. 1992). Positional candidate gene analysis recently resulted in the identification of the mutated gene, *SDHD* that encodes the small subunit of cytochrome b in the succinate-ubiquinone oxidoreductase complex (*PGL1*) (Baysal et al. 2000). This enzyme complex is important for the tricarboxylic acid cycle and the aerobic respiratory chains in mitochondria. Thus, *SDHD* is likely to be critical for the oxygen-sensing system, and its loss may lead to chronic hypoxic stimulation of cellular proliferation that leads to tumorous growth. Interestingly, another *PGL* locus has been mapped more telomerically on 11q (*PGL2*), and a mutation in the *SDHC* gene (*PGL3*) was identified in a family with non-maternally imprinted inheritance of paragangliomas (Niemann, and Muller, 2000). We studied a family with three generations affected with paragangliomas. Generation skipping of the phenotype was noted once, when the disorder seemed to be inherited from the mother. Thus, the *SDHD* gene became the most likely candidate. In fact, we identified a novel splice site mutation that co-segregated with the phenotype. Interestingly, six non-affected carriers were observed, and all of them had inherited the mutant allele from their mother. The identification of carriers enables genetic counseling, an important aspect for these usually treatable vascular tumors. (vikkula@bchm.ucl.ac.be).

**A new phenotype of familial visceral inversus/ atrial fibrillation/ ASD caused by a novel 7bp deletion in the CSX/NKX2.5 gene.** *Y. Watanabe*<sup>1,2</sup>, *S. Yano*<sup>2,3</sup>, *T. Akagi*<sup>2</sup>, *M. Yoshino*<sup>2</sup>, *J.C. Murray*<sup>1</sup>. 1) Department of Pediatrics, University of Iowa, Iowa City, IA; 2) Department of Pediatrics and Child Health, Kurume University School of Medicine, Fukuoka, Japan; 3) Medical Genetics, Department of Pediatrics, Childrens Hospital Los Angeles, University of Southern California, Los Angeles, CA.

*CSX/NKX2.5* (Cardiac Specific Homeobox) is homologous to mouse gene *NKX2.5* and plays an important role in early cardiac development. Mutations in the *CSX/NKX2.5* have been reported in individuals with AV node conduction failure and/or different cardiac structural anomalies, especially atrial septal defect (ASD). We identified a novel 7-bp deletion in exon 1 at nucleotide +215 from the translation starting point of the *CSX/NKX2.5* gene in a familial case of ASD, resulting in a frameshift of downstream codons. The mutation cosegregated with ASD and/or atrial-ventricular conduction abnormality as an autosomal dominant in four members in two generations. The proband had visceral inversus, polysplenia with symmetrical liver and an ASD. The younger sister of the proband was a carrier of this mutation and was diagnosed with atrial fibrillation (Af) as the only phenotypic expression of the gene mutation. This is the first report in humans that may suggest that the *CSX* gene is involved in the regulation of Left-Right axis determination and that *CSX* gene mutations can cause Af. In a previous phenotype-genotype correlation study (Kawahara, H., et al., *Journal of Clinical Investigation*, 2000. 106(2): p. 299-308) it was suggested that loss of function caused AV conduction delay but that hypomorphic mutant proteins cause cardiac anatomical anomalies such as ASD, VSD and TOF. The family reported here has a mix of conduction and structural defect, suggesting a role for genetic, stochastic or environmental modifiers. Searches for additional mutations in similarly affected individuals will be important.

**Iron metabolism in genetically iron overloaded frataxin deficient mice.** *M. Santos, C. Miranda, M. Pandolfo.* Centre de Recherche, Centre Hospitalier de l'Universite de Montreal, Montreal, Quebec, Canada.

Friedreich's ataxia (FA) is the most common form of autosomal recessive spinocerebellar ataxia. The disease is caused by an expanded intronic GAA repeat, which results in deficiency of a mitochondrial protein called frataxin. Inactivation of the frataxin mouse gene leads to early embryonic lethality (1). In humans, there is always residual frataxin expression (10-30%) and total frataxin deficiency has never been observed. In mice heterozygous for frataxin deficiency ( $Fx^{+/-}$ ), frataxin levels are 50% diminished. Some evidence indicate that frataxin deficiency leads to mitochondrial iron accumulation and associated production of oxygen free radicals. To gain insight into the pathogenesis of FA and to explore the possibility that iron overload could precipitate FA in  $Fx^{+/-}$  mice, we have bred  $Fx^{+/-}$  mice with  $Hfe^{-/-}$  knockout mice (2), an animal model of Hereditary Hemochromatosis (HH). HH is a prevalent human disease caused by a mutation in HFE, which encodes a non-classical Major Histocompatibility Complex (MHC) class I protein involved in regulation of intestinal iron absorption.  $Hfe$  deficiency causes systemic iron overload. The generated  $Hfe^{-/-}Fx^{+/-}$  mutant mice have increased serum iron and transferrin saturation. Blood erythroid parameters are normal. Iron concentration, determined by atomic absorption spectrometry, was significantly increased in the livers, a feature confirmed histologically. Motor coordination, evaluated using the rotarod test, is indistinguishable from wild type and single-mutant mice. These study shows that reduction of frataxin levels to 50% does not cause FA even in the presence of significant systemic iron overload. Gene therapy attempts to increase frataxin levels up to 50% in FA patients may thus constitute a promising approach. (1) Cossee M, Puccio H, Gansmuller A, Koutnikova H, Dierich A, LeMeur M, Fischbeck K, Dolle P, Koenig M. Inactivation of the Friedreich ataxia mouse gene leads to early embryonic lethality without iron accumulation. *Hum Mol Genet* (2000) 9:1219. (2) Levy JE, Montross LK, Cohen DE, Fleming MD, Andrews NC. The C282Y mutation causing hereditary hemochromatosis does not produce a null allele. *Blood* (1999) 94:9.

**Heterozygous b epithelial sodium channel mice exhibit features of pseudohypoaldosteronism type I (PHA I).** *R.A. Williamson<sup>1</sup>, B. Yang<sup>1</sup>, X.R. Cao<sup>1</sup>, M.J. Welsh<sup>2</sup>, J.B. Stokes<sup>2</sup>.* 1) Dept OB/GYN, and; 2) Internal Med, Univ. of Iowa Coll. of Med, Iowa City, IA.

Epithelial sodium channels (ENaC), composed of three homologous subunits (a, b, g), are key mediators of Na<sup>+</sup> balance and BP regulation. Loss of function mutations in any of the subunits cause PHA I, a salt wasting autosomal recessive condition. Our group inactivated the b-subunit of ENaC which produced perinatal death 8-48 hours after birth in affected homozygotes (McDonald FJ et al. Proc Natl Acad Sci USA 96:1727, 1999). The salient finding was a markedly elevated serum K<sup>+</sup>. Associated features included significantly elevated serum aldosterone levels, a decreased serum Na<sup>+</sup>, increased urine Na<sup>+</sup> and decreased urine K<sup>+</sup> in b ENaC <sup>-/-</sup> pups. We have studied b ENaC <sup>+/-</sup> mice utilizing a protocol which assured the controls and heterozygotes would be genetically equivalent by breeding heterozygous 129 to C57/B16 strain mice. For these experiments the carotid artery was cannulated for BP measurements and blood draws, the jugular vein was catheterized for drug and saline infusion, and the bladder catheterized for urine sampling. A minimum of five mice (age 2-3 months) per group was studied. No significant differences between heterozygotes and <sup>+/+</sup> controls were documented in serum aldosterone levels, serum and urine Na<sup>+</sup> and K<sup>+</sup>, resting BP, BP response to infused NaCl and KCl, and BP response to increasing doses of infused angiotensin II. However, whereas serum Na<sup>+</sup> and urine Na<sup>+</sup> were not altered in response to a normal saline volume load (5% of body weight infused over 30 minutes) or K<sup>+</sup> load (0.13 mEq/ml of KCl in normal saline in a volume equal to 5% of body weight infused over 30 minutes), we documented a significant decrease in the rate and total amount of urine K<sup>+</sup> excretion, and a decreased rate of clearance of serum K<sup>+</sup> in heterozygotes administered these challenges. Thus, b ENaC heterozygotes replicate some of the findings associated with PHA I. This study suggests that provocative testing of these heterozygous knockout mice reveals an otherwise undetectable defect in K<sup>+</sup> secretion.

**Complete glucokinase deficiency is not a common cause of permanent neonatal diabetes in European cases of neonatal diabetes.** *A.L. Gloyn<sup>1</sup>, S. Ellard<sup>1</sup>, J.P.H. Shield<sup>2</sup>, I.K. Temple<sup>3</sup>, D.J.G. Mackay<sup>3</sup>, T. Barrett<sup>4</sup>, A.T. Hattersley<sup>1</sup>.*  
1) Centre for Molecular Genetics, University of Exeter; 2) Royal Hospital for Sick Children, Bristol; 3) Wessex Regional Genetics Service and Laboratory, Salisbury; 4) Birmingham Childrens Hospital, UK.

Neonatal diabetes mellitus (NDM) is a rare disorder with an estimated incidence of 1 in 400,000. It is defined as insulin requiring hyperglycaemia within the first month of life. NDM is heterogeneous and can be either transient (TNDM) if resolved within 18 months or permanent (PNDM). Recently, 2 cases were reported where PNDM was found to result from homozygous mutations in the glucokinase gene resulting in complete absence of the enzyme glucokinase, a key regulator of glucose metabolism in pancreatic beta - cells. Heterozygous mutations in glucokinase (GCK) cause maturity onset diabetes of the young (MODY 2) which result in stable mild fasting hyperglycaemia. We studied the GCK gene in 12 cases of PNDM from a European collection to determine whether complete glucokinase deficiency is a common cause of PNDM. The coding regions and the intron-exon boundaries of the GCK gene were amplified and sequenced on an ABI 377 DNA sequencer. Sequencing identified a common previously reported polymorphism in intron 9 (IVS9 +8 c>t) but no mutations were detected. From a published series in gestational diabetes the population frequency of carriers of GCK mutations is approximately 0.0009, so we would predict a population frequency of 1/1,200,000 for compound heterozygotes or homozygotes. This may be an underestimate if there are consanguineous MODY 2 families. In conclusion homozygous or compound heterozygous glucokinase mutations are not a common cause of PNDM despite the fact that theoretically they might be predicted to account for up to 40% of cases of NDM.

**Autosomal recessive colobomatous micro/anophthalmia in a consanguineous Irish traveller family - further genetic heterogeneity.** *S. Ennis*<sup>1,2</sup>, *M. Ni Chroinin*<sup>2</sup>, *P. Tormey*<sup>3</sup>, *A.J. Green*<sup>1,2</sup>. 1) National centre for Medical Genetics, Dublin 12, Ireland; 2) Dept. of Medical Genetics, University College Dublin, Dublin, Ireland; 3) Dept of Ophthalmology, Waterford Regional Hospital, Waterford, Ireland.

We describe 9 members of a consanguineous Irish traveller family, with severe visual impairment due to anophthalmia, microphthalmia or colobomatous microphthalmia. Two members have complete bilateral anophthalmia, five had unilateral anophthalmia and contralateral colobomatous microphthalmia, and two had microphthalmia. There was no history of chemical exposure, no other associated malformations, and chromosomal analysis in two affected individuals was normal. There is pseudodominant inheritance in one family, with an affected son born to an affected father in a consanguineous marriage. Only a small number of families with autosomal recessive colobomatous micro/anophthalmia have been described before. Several reports have been of families with a consistent expression of exclusively bilateral anophthalmia in homozygotes, in contrast to the family we describe with a more varied expression in homozygotes. This is the first description of this condition in the Irish traveller population, and represents a further disease allele for this population. A previously known 14q32 locus for autosomal recessive anophthalmia, the recently described CHX10 gene on chromosome 14, and the RX gene on chromosome 18 known to cause autosomal recessive anophthalmia, have been excluded in this family. The candidate gene VSX1 has been excluded, suggesting at least a fourth locus for this condition. Homozygosity mapping for autosomal recessive anophthalmia is currently under way.

**Novel dystrophin gene mutations and unusual DMD/BMD phenotypes.** *E. Estrella*<sup>1</sup>, *R. Curless*<sup>1</sup>, *B. Roa*<sup>2</sup>, *T. Prior*<sup>3</sup>, *J. Mendell*<sup>3</sup>, *L. Baumbach*<sup>1</sup>. 1) Div Genetics, Univ. of Miami, Miami, FL; 2) Baylor College of Medicine, Houston TX; 3) Ohio State Univ., Columbus, OH.

Since the discovery of the Duchenne Muscular Dystrophy (DMD) gene, hundreds of patients with suspected primary dystrophinopathy have been evaluated for mutations. Knowledge gained from these studies has led to general genotype: phenotype predictions, although these do not account for the clinical variability noted in these disorders. Detection of novel mutations may provide new insights into functional aspects of dystrophin and/or associations with unusual clinical features. We describe patients who fall into one of these categories. The first two patients are presumed new mutations based on family history. Patient 1, 11 1/2 year-old Caucasian male, was referred for a long history of undefined weakness and unsteadiness. He had moderate elevations in serum CK. He has no pseudohypertrophy, no significant weakness, a modified Gowers maneuver, and normal reflexes. His only clinical complaint is of pain/cramps after strenuous exercise. Mutation studies revealed a DMD deletion spanning exons 3-4. This deletion has been reported in three other Becker patients. Patient 2, 6 1/2 year old African-American male, whose most significant finding is marked developmental delay for all motor and cognitive milestones since infancy, which is not found in any other family members. He is noted to have minimal muscle involvement, mild calf pseudohypertrophy, no ambulatory problems, but markedly elevated serum CKs levels. DNA studies revealed a novel exon 10-12 duplication, in conjunction with a reported African-American exon 8/9 RFLP. This patient represents a new mutation which resulted in a gross DMD gene rearrangement. His phenotype is unusual for the marked level of mental impairment. Patients three-five are classical BMD patients who share a common exon 45-53 in-frame deletion. Western blot analysis of muscle dystrophin revealed a normal level of the truncated, mutant form. DMD/BMD deletions which produce quantitatively normal dystrophin levels should be further investigated. It is our hope that similar patient descriptions will lead to further understanding of these disorders.

***CBFA1* mutations and polymorphisms in two Mexican patients with cleidocranial dysplasia.** *N. Monroy, L.E. Machuca-Tzili, S. Kofman.* Genética, Hospital General México/Facultad Medicina UNAM. México, D.F.

Cleidocranial dysplasia (CCD) is an autosomal dominant skeletal disorder whose phenotypic characteristics embrace a wide spectrum from classical cases with endochondral ossification problems to mild ones presenting neonatal or supernumerary teeth as the unique manifestation. It has been demonstrated that haploinsufficiency of *CBFA1* (located on chromosome 6p21) causes CCD, and several patients with deletions, insertions, missense and nonsense mutations of this gene have been described. In order to identify mutations in *CBFA1*, we analyzed genomic DNA from two unrelated patients with the typical craniofacial features of CCD syndrome. The DNA fragments from exon 0 to exon 7 of *CBFA1* were amplified by PCR and directly automated sequenced. Our results showed two novel mutations and three polymorphisms not previously described. One case showed a (Gln-Leu) change in exon 1, inside the Q/A domain. The other patient presented a change in exon 7 at the stop codon. In theory, the latter produces the addition of 23 aminoacids before the following termination triplet. Our findings expand the list of *CBFA1* allelic variants in CCD. We also discuss the genotype-phenotype correlations in these individuals.

**Adipocyte specific transcripts that interact with Lamin A: Implications for partial lipodystrophy.** *D.J. Lloyd, S. Shackleton, R.C. Trembath.* Division of Medical Genetics, Department of Genetics, University of Leicester, Leicester, Leicestershire, United Kingdom.

The nuclear lamina is a meshwork-like structure within the inner nuclear membrane, mainly composed of nuclear lamins. Lamin A and C are alternative transcripts of the LMNA gene at 1q21. Heterozygous mutations in LMNA have recently been reported in several inherited disorders each associated with an inability to maintain a specific cell type; these include Emery-Dreifuss muscular dystrophy, Limb-Girdle muscular dystrophy type 1B, dilated cardiomyopathy 1a or Dunnigan-type familial partial lipodystrophy (FPLD). How different mutations in LMNA can cause these different phenotypes is of much interest. Here we present the results of a yeast-two hybrid screen using mouse lamin A as bait exposed to an adipocyte cDNA library. Three categories of positive interacting clones were identified; a set of mouse lamin A clones, and a set of Sterol-regulatory element binding protein (SREBP) clones, and a set of novel transcripts. In vitro binding assays, co-immunoprecipitation of, and two-hybrid analysis of the human homologues confirmed the specificity of these interactions. SREBP exists in three known isoforms and is associated with cholesterol biosynthesis, but has also been recognised as an adipocyte differentiation factor. The novel transcript has domain homology to a nuclear membrane association protein involved in development. We therefore propose the mutations in LMNA which are associated with the FPLD phenotype interfere with these interactions, resulting in a defect in adipocyte development or maintenance.

**Establishment of a nomenclature system for X-linked amelogenesis imperfecta.** *P.S. Hart<sup>1</sup>, T.C. Hart<sup>1</sup>, J.T. Wright<sup>2</sup>*. 1) Dept Human Genetics, Univ Pittsburgh, Pittsburgh, PA; 2) Dept Pediatric Dentistry, School of Dentistry, Univ of North Carolina, Chapel Hill, NC.

The Amelogenesis Imperfecta (AI) are a group of inherited conditions that affect the development of enamel. Depending on the type of AI, the enamel defects include abnormalities in the amount, structure and composition. The molecular basis of these conditions has only been identified for the X-linked form, which is due to mutations in the X chromosome amelogenin gene (AMELX). Mutational analyses of affected individuals has begun to permit identification of genotype-phenotype correlations. For example, mutations altering the C terminus 3' of amino acid 172 result in a hypoplastic phenotype in contrast to other mutations that result in mineralization type defects. Past nomenclature systems have differed depending upon whether numbering began with the mature peptide or the signal peptide, with most beginning with the mature peptide. In addition, alternative splicing occurs, complicating the nomenclature system. As more families are analyzed, there needs to be a clearly defined nomenclature system for numbering the nucleotide and amino acid sequences. Thus, we are proposing a standard nomenclature system based on internationally agreed upon guidelines (Antonarakis et al., Hum Mutat 1998;11:1-3) using designated reference sequences. For cDNA numbering, the A of the initiator ATG is taken as +1, using NM001142 as the reference sequence. For previous numbering systems based upon the mature peptide, this will add 16 amino acids to protein designations and 48 nt to cDNA designations. As no complete genomic AMELX sequence is in the NCBI database, the authors have submitted a sequence that contains the complete genomic AMELX sequence. This sequence will serve as the reference sequence for genomic numbering. The 11 known AMELX mutations will be listed with the old and new nomenclature systems. A mutational database for AI has been established at [www.genetics.pitt.edu/AI](http://www.genetics.pitt.edu/AI).

**Identifacation and analysis of mutations in the Wilson disease gene (ATP 7B) from Indian children . R. Prasad<sup>1</sup>, G. kaur<sup>2</sup>, B.R. Thapa<sup>3</sup>.** 1) Biochemistry, PGIMER, Chandigarh-160012, U.T., India; 2) Department of Physiology, Chandigarh Medical College, Chandigarh 160034 INDIA; 3) Pediatric Gastroenterology , Postgraduate Institute of Medical Education and Research, Chandigarh 160012 INDIA.

Wilson Disease (WD) is an autosomal recessive disorder characterized by toxic accumulation of copper in the liver and subsequently in the brain and other organs. On the basis of sequence homology to known genes, the WD gene (ATP 7B) appears to be a copper transporting P-type ATPase. After performing allele specific oligonucleotide (ASO) hybridization and single strand conformational polymorphism (SSCP) analysis, we have identified mutations in 10 patients . Four of these mutations are single nucleotide insertions. Three of them were present in channel forming region of exon13. Other insertion mutation was found in carboxyterminal region of exon21 . All three-insertion mutations manifested hepatological problems in early childhood .His 1070 Gln mutation was found in four patients. Ile1103 thr mutation was found in two children. Altogether, this study infers that insertion type of mutations lead to early hepatic manifestation.

**Genetic mapping of Chuvash Polycythemia: An autosomal recessive disorder of oxygen sensing.** *D.W. Stockton<sup>1</sup>, H. Chen<sup>1</sup>, S.O. Ang<sup>1</sup>, A.I. Sergeyeva<sup>2</sup>, V.R. Gordeuk<sup>3</sup>, L.A. Polyakova<sup>2</sup>, J.T. Prchal<sup>1</sup>.* 1) Baylor College of Medicine, Houston, TX; 2) Chuvash State University, Cheboksary, Chuvashia, Russian Federation; 3) Howard University, Washington, DC.

**Purpose:** Familial erythrocytosis (MIM #263400) or Chuvash polycythemia (CP) is a recessive disorder of increased red cell mass endemic to the mid-Volga River region of Russia. In addition to high hematocrits (60%-70%) the condition manifests cardiovascular disease at an early age and possibly increased risk for malignancy. CP patients exhibit both indicators of primary and secondary polycythemias. We hypothesize a founder effect mutation in the hypoxia sensing pathway may play a role in its pathogenesis. Hypoxia inducible factor 1a (HIF-1a), is a major regulator of hypoxia inducible genes. The locus for Familial Benign Polycythemia (FBP) in Chuvash families was previously reported in chromosome band 11q23. Combining these hypotheses a functional and genetic approach was undertaken to identify the causal gene. **Methods:** We reviewed the clinical phenotype and the response of erythroid precursors to EPO, measured HIF-1a expression in lymphocytes cultured with or without cobalt, and measured total iron binding capacity and serum concentrations of iron, ferritin, and circulating transferrin receptor (TfR). Six families were used for linkage analysis between the CP phenotype and the HIF-1a and reported FBP locus genomic regions. A genome screen was started to localize the responsible gene. **Results:** TfR levels were inappropriately increased. Normoxic HIF-1a protein and mRNA levels were elevated and after exposure to cobalt, HIF-1a mRNA levels did not change in CP cells while they increased 5-fold in controls. Linkage analysis between the CP phenotype and the HIF-1a and the reported FBP loci resulted in LOD scores less than -2 across the regions. Preliminary positive LOD scores have been identified. **Conclusions:** Chuvash polycythemia is an autosomal recessive erythrocytosis caused by abnormalities of oxygen sensing. A major regulator of hypoxic adaptation, HIF-1a and the previously reported locus were genetically excluded. Additional candidate genomic regions have been identified that require verification.

**Mutations of the P and MC1R genes produce OCA2 with red hair.** *R.M. Schmidt<sup>1</sup>, J.E. Pietsch<sup>1</sup>, J.P. Fryer<sup>1</sup>, C.G. Summers<sup>2</sup>, W.S. Oetting<sup>1</sup>, R.A. King<sup>1</sup>.* 1) Medicine/Inst of Human Genetics, University of Minnesota, Minneapolis, MN; 2) Ophthalmology, University of Minnesota.

**Background:** P gene mutations produce oculocutaneous albinism type 2 (OCA2), characterized by the presence of pigmented yellow/blond or brown hair throughout life. We have identified an individual with oculocutaneous albinism who has had bright red hair since birth; red hair was present in both maternal and paternal relatives. The skin was white and did not tan. Irides were blue, nystagmus and an alternative strabismus were present, and best corrected visual acuity was 20/60. We hypothesized that this phenotype was the result of mutations at two genes, one responsible for the albinism (P gene) and one responsible for the red hair (MC1R). **Methods:** Sequence analysis of the P and MC1R genes was performed with DNA from the proband and parents using direct automated infrared fluorescence sequencing. Sequence analysis included all coding exons and the intron:exon borders. **Results:** The proband was a compound heterozygote for two mutations of the P gene - N489D and W679C; both of these mutations have previously been identified in individuals with OCA2. In addition, the proband was heterozygous for the R160W variant of the MC1R gene; this polymorphism has been associated with red hair. **Conclusion:** The pigment phenotype of OCA2 is broad, and usually is thought to include yellow/blond to brown hair. We have now identified an individual with OCA2 who has red hair, associated with P gene mutations and an additional change in the MC1R gene. The phenotype results from changes in two genes that influence pigment formation. This is the first demonstration of a molecular mechanism for OCA associated with red hair. Furthermore, this type of OCA should be differentiated from OCA3 or rufous/red OCA that is associated with a different phenotype and gene.

**The MYHIIA syndrome: A novel spectrum of autosomal dominant macrothrombocytopenias.** *K.E. Heath<sup>1</sup>, A. Campos-Barros<sup>1,2</sup>, A. Toren<sup>3</sup>, G. Rozenfeld-Granot<sup>3</sup>, L.E. Carlson<sup>4</sup>, J. Savage<sup>5</sup>, J.C. Denison<sup>6</sup>, M.C. Gregory<sup>6</sup>, J.A. White<sup>7</sup>, D.F. Barker<sup>6</sup>, A. Greinacher<sup>4</sup>, C.J. Epstein<sup>8</sup>, M.J. Glucksman<sup>1</sup>, J.A. Martignetti<sup>1</sup>.* 1) Dept. of Human Genetics, Mount Sinai School of Medicine, New York, NY; 2) University Hospital Niño Jesus, Madrid, Spain; 3) The Chaim Sheba Medical Center, Tel-Hashomer, Israel; 4) Ernst-Moritz-Amdt University of Greifswald, Germany; 5) Austin and Repatriation Medical Center, University of Melbourne, Australia; 6) University of Utah School of Medicine, UT; 7) University of Minnesota, MN; 8) University of California, San Francisco, CA.

May-Hegglin anomaly (MHA), Fechtner (FTNS) and Sebastian (SBS) syndromes form a group of autosomal dominant disorders that share macrothrombocytopenia (MTCP) and leukocyte inclusions. FTNS has the additional features of nephritis, deafness and cataracts. Previously, we identified that mutations in the nonmuscle myosin heavy chain 9 gene (*MYH9*), encoding MYHIIA, resulted in all three disorders. We have now expanded our studies to examine the spectrum of mutations, genotype:phenotype relationships, and structure-function correlates in a large cohort of patients including individuals with two other related platelet syndromes: Epstein (EPS) and Alport-like with MTCP (APSM). We now demonstrate that EPS and APSM are also caused by *MYH9* mutations. In total, 8 different mutations were identified in 20 affected individuals (74%). The R702C and R702H mutations were only found in FTNS, EPS and APSM which all share MTCP, nephritis and deafness; suggesting that they represent variants of the same syndrome. Moreover, these results define a critical region of MYHIIA that seems to be critical in the pathogenesis of nephritis and deafness. The coiled-coil domain mutations, E1841K, D1424N and R1933X, were common to both MHA and FTNS. A common haplotype was shared by three E1841K carriers (1 MHA, 2 FTNS). This suggests both a common ancestor and a potential disease modifier gene. Altogether, our data suggest that these 5 syndromes define a broad phenotypic spectrum of disorders all caused by *MYH9* mutations. We therefore propose the MYHIIA syndrome to encompass these disorders. (E-mail: kheath@hgmp.mrc.ac.uk).

**Cellular localization of mRNA expression of Usher IIa gene in rodent retina.** *D. Huang, D. Pretto, C. Talmadge, G. Zhou, M. Zhou, J.R. Davis, J. Eudy, E. Uzvolgyi, J. Sumegi.* Pathology and Microbiology, Center for Human Molecular Genetics, University of Nebraska Medical Center, Omaha, NE, USA.

Usher Syndrome (USH) is a clinically and genetically heterogeneous autosomal recessive disorder comprising hearing and visual impairment. It has been subdivided into 3 clinical subtypes, Usher type I (USHI), type II (USHII), and type III (USHIII). At present, 10 distinct loci have been identified for the 3 clinical subtypes. Mutations in Usher IIa gene account for the most common clinical type of Usher syndrome, USHII, which has the phenotype of moderate to severe hearing impairment, normal vestibular function, and later onset of retinal degeneration. The goal of our research is to identify the cellular source of the Usher IIa mRNA in developing and adult rodent retina. We isolated the rat and the mouse homologues of Usher IIa gene. Digoxigenin labeled RNA was synthesized in vitro from the cloned cDNA fragments and used in situ hybridization. We found that Usher IIa mRNA expression appeared to be restricted to photoreceptor cell outer nuclear layer in adult rat and mouse retina. In developing rat retina, Usher IIa mRNA can be detected as early as embryonic day 17 in the developing neural layer of the retina. RT-PCR showed that Y79, a human photoreceptor specific cell line expresses the Usher IIa transcript while the rat retina pigment epithelial cell line, RPEJ does not. This data is consistent with the results obtained by in situ hybridization.

**Molecular characterization of the 22q13 deletion syndrome: comparison of over 50 cases.** *H.E. McDermid<sup>1</sup>, W.Y. Tse<sup>1</sup>, G.A. Stapleton<sup>2</sup>, L. Artifoni<sup>3</sup>, B. Dallapiccola<sup>4</sup>, H.L. Wilson<sup>1</sup>*. 1) Dept Biological Sciences, Univ Alberta, Edmonton, AB, Canada; 2) Greenwood Genetic Center, Greenville, SC; 3) Università di Padova, Padova, Italy; 4) CSS-Mendel Institute, University La Sapienza, Rome, Italy.

Patients with the 22q13 deletion syndrome show profound global developmental delay, absent/severely delayed expressive speech, hypotonia, normal to excessive growth and mild dysmorphic features (Phelan et al, 2001). A critical region for at least a subset of neurological abnormalities associated with this syndrome has been suggested based on a patient, NT (Flint et al, 1995). NT has a 130 kb terminal microdeletion and shows developmental delay and severe delay of expressive speech. In order to confirm this critical region, we have delineated the deletion size in over 50 additional 22q13 deletion syndrome patients using microsatellite analysis and fluorescence in situ hybridization. In all but one of the patients, the deletion was terminal. These deletions ranged from less than 1 Mb to approximately 11 Mb, however the major neurological features of developmental delay and delay of speech were present in all of these cases. This confirms that a major candidate gene for this syndrome maps to the most distal Mb of 22q, and adds support for our hypothesis that this candidate gene is SHANK3 (formerly PROSAP2), which codes for a structural protein of the post-synaptic density and which localizes to the 130 kb NT deletion.

A single patient has an interstitial deletion, which does not overlap with the 15 smallest terminal deletions, but may fall entirely within some of the largest deletions. This patient, who therefore has a different but overlapping syndrome, may be helpful in identifying other genes affecting only the larger deletion cases.

**Instability of normal sized FMR1 alleles in two generations: evidence for a modifier effect?** *D. Kennedy, T. Ashfield, J. Guo, C. Pereira, D. Ramadeen, R. Rezaie, J. Steer, J. Tzountzouris, D.J. Allingham-Hawkins.* Molecular Genetics, North York General Hosp, North York, ON., Canada.

Fragile X syndrome is caused by the expansion of an unstable trinucleotide repeat, CGGn, in the 5' untranslated region of the FMR1 gene located at Xq27.3. Affected individuals generally have CGG>200. Alleles in the normal range, CGG6-54, are generally considered to be stably transmitted while those in the premutation range, CGG52-200, tend to change in size upon transmission to offspring. We recently reported a group of developmentally delayed males who demonstrated apparent instability of FMR1 alleles in the normal range (Tzountzouris et al., 2000). This population of patients represents approximately 1% of the patients tested for Fragile X syndrome in our laboratory. Here we present a family in which both a developmentally delayed boy and his father demonstrate two FMR1 alleles in the normal range upon PCR analysis. Neither of the child's alleles corresponds to a paternal allele while the presence of one maternal allele can be demonstrated. Paternity testing is pending. The presence of Y chromosome material was demonstrated in both the father and child by PCR analysis of the amelogenin locus. Southern blot analysis on the child's FMR1 gene showed the presence of the 2.8 kb band only suggesting that an inactive X chromosome is not present. Karyotype analysis on the child revealed a normal 46,XY karyotype on all 30 cells analysed, ruling out the possibility of Klinefelter's syndrome or mosaic Klinefelter's syndrome. Karyotype and Southern blot analyses on the father are pending. This family is interesting because it is the first time that instability of normal FMR1 alleles is apparent in both a parent and child. There are a number of possible explanations: a cryptic chromosome rearrangement involving the Xq27.3 band, non-paternity or, most interestingly, a modifier gene on an autosome or the Y chromosome that is contributing to instability of the FMR1 repeat. Molecular and cytogenetic analyses are ongoing to help elucidate the mechanism of instability in this family.

**Novel Molecular Mechanism for Occipital Horn Syndrome.** *S.G. Kaler<sup>1</sup>, P.-C. Liu<sup>1</sup>, D.J. Wattendorf<sup>2</sup>, K.N. Rosenbaum<sup>3</sup>*. 1) Clinical Neurosciences Program, Natl Inst Neurologic Disorders & Stroke, NIH; 2) Med Genet Branch, NHGRI, NIH Bethesda, MD; 3) Dept. Medical Genetics, Children's National Med Ctr, Washington, DC.

Occipital horn syndrome (OHS) is a mild allelic variant of Menkes disease (MD), an X-linked disorder of copper transport. Whereas MD combines severe neurological problems with connective tissue abnormalities including skin laxity, bladder diverticula and vascular tortuosity, OHS patients have minimal neurological problems. The molecular basis of OHS typically involves splice junction mutations that either reduce proper mRNA splicing, or lead to mislocalization of the gene product. One example of a deletion in the 5' regulatory region has also been reported. Here we report the first example of a missense mutation associated with OHS, in a male who is also the youngest (13 months) patient with this phenotype described to date.

The proband had a normal birth and was well until 9 months of age when urinary obstruction due to bladder diverticula was noted. Additional clinical findings including cutis laxa and coarse hair led to consideration of OHS at 13 months of age. Blood copper (98 mg/dl) and ceruloplasmin (331 mg/L) were well within the normal ranges for age, however plasma neurochemical levels indicated deficiency of dopamine beta hydroxylase (DBH), a copper-dependent enzyme. Sequence analysis of the MD/OHS locus disclosed a novel missense mutation (G892D) in exon 13.

This is the first example of a missense mutation causing OHS. The presence of normal circulating copper levels (without copper therapy) and absence of significant neurological findings implies that this mutation does not impair copper exodus at the GI tract or blood-brain barrier. However, the abnormal neurochemical pattern and connective tissue findings are consistent with deficient activities of DBH and lysyl oxidase, cuproenzymes processed within the trans-Golgi apparatus. These cumulative findings suggest that G892D induces mislocalization of the Menkes/OHS gene product, an hypothesis testable by immunocytochemical or *in situ*PCR experiments using this patient's cells.

**Characterization of a Subclass of Patients with Ehlers-Danlos Syndrome Type VI that Appears Unrelated to a Decrease in One of the Lysyl Hydroxylase Isoforms.** *H.N. Yeowell<sup>1</sup>, L.C. Walker<sup>1</sup>, M. Willing<sup>2</sup>, J.C. Marini<sup>3</sup>, W.A. Cabral<sup>3</sup>, E. Kitamura<sup>4</sup>, M. Yamauchi<sup>4</sup>.* 1) Div of Dermatology, Duke Univ Medical Ctr, Durham, NC; 2) Dept of Pediatrics, Univ of Iowa, Iowa City, IA; 3) Heritable Disorders Branch, NICHD, Bethesda, MD; 4) Dental Research Center, Univ. of N. Carolina, Chapel Hill, NC.

Ehlers-Danlos syndrome (EDS) type VI is an autosomal recessive disorder in which patients are characterized clinically by kyphoscoliosis, hypermobile joints, and skin that is fragile and hyperextensible and, biochemically, by a deficiency of the enzyme lysyl hydroxylase 1 (LH1, PLOD1). LH1 hydroxylates specific lysine residues in the collagen molecule that are critical in determining the pathways of intermolecular crosslinks essential for the tensile strength of collagen. A subclass of EDS VI exists in which patients have certain clinical characteristics of EDS VI but their levels of LH activity are normal. To examine the biochemical basis for this subtype, we compared levels of the mRNAs for LH1 and the two other isoforms for LH, LH2 and LH3, with the pattern of crosslinking, and enzyme activity in fibroblasts from 10 patients. In contrast to the typical EDS VI patients, in which levels of LH1 mRNA and corresponding LH activity are <25% of control, LH1 mRNA levels in this subgroup of patients ranged between 87-150% of control which correlated with their normal LH activity. However, decreased levels of LH2 mRNA were observed in two patients (45 and 54% of control, respectively), and in the first patient, the low (45%) LH2 mRNA was accompanied by a sharper decrease (16% of control) in the mRNA for LH3. Another patient also had decreased levels of LH3 mRNA (35% of control). Studies on long-term cultures of fibroblasts did not show a correlation between levels of the collagen reducible crosslinks, dehydrodihydroxylysinonorleucine and dehydrohydroxylysinonorleucine, and levels of mRNA for the LH isoforms. This study suggests that, unless this group of patients represents a heterogeneous subset of this EDS VI variant or an unidentified LH isoform is involved, an alternative pathway other than lysine hydroxylation of collagen may be affected.

**Cryptic splicing at a non-consensus splice-donor-site in a patient with a new mutation in the plakophilin 1 gene.**

*M. van Geel*<sup>1</sup>, *M.A.M van Steensel*<sup>1</sup>, *P.C.M van de Kerkhof*<sup>1</sup>, *R. Happle*<sup>2</sup>, *P.M. Steijlen*<sup>1</sup>. 1) Department of Dermatology, University Medical Center Nijmegen, Nijmegen, The Netherlands; 2) Department of Dermatology, University Hospital Marburg, Marburg, Germany.

Plakophilin 1 (*PKP1*) is a structural component of the desmosomes, which are intercellular adhesion junctions primarily found in epithelial cells. Mutations in the *PKP1* gene result in skin fragility ectodermal dysplasia syndrome, an autosomal recessive disease affecting skin, nails and hair. We identified a new homozygous mutation in the exon 9 splice-donor-site of *PKP1* (IVS9+1 G>A) in a patient with a relatively mild phenotype of erosive skin lesions, palmoplantar hyperkeratosis and loose hair. Transcriptional analysis of *PKP1* from a skin biopsy demonstrates complete functional inactivation of the mutated splice-donor-site. Besides transcripts in which intron 9 is retained, we observe alternate spliced transcripts in which a cryptic splice-site within exon 9 is actively used. Interestingly, this cryptic splice-donor-site does not contain a consensus GT but instead uses a GC, which has not been reported before in man. In addition, this alternate splicing preserves the correct open reading frame, putatively removing only 15 amino acids from the mature PKP1 protein. The functional rescue of the major part of the PKP1 protein by the alternate pre-mRNA splicing may explain the mild phenotype observed in this particular patient compared to the previously described patients. This unique genotype may eventually give new insights in the functional interactions of the PKP1 protein with other proteins of the desmosome.

**FOXL2 Mutations in type I and type II Blepharophimosis/Ptosis and Epicanthus Inversus Syndrome (BPES).** *M. Uda*<sup>1</sup>, *L. Crisponi*<sup>2</sup>, *M. Deiana*<sup>1</sup>, *F. Chiappe*<sup>2</sup>, *G. Usala*<sup>1</sup>, *P. Amati*<sup>3</sup>, *D. Bonneau*<sup>3</sup>, *F. Faravelli*<sup>4</sup>, *J. Tolmie*<sup>5</sup>, *L. Bisceglia*<sup>6</sup>, *L. Zelante*<sup>6</sup>, *A. Iolascon*<sup>7</sup>, *P. Gasparini*<sup>6</sup>, *G. Cripioni*<sup>2</sup>, *A. Cao*<sup>1</sup>, *G. Pilia*<sup>1</sup>. 1) IRTAM, CNR, Cagliari, Cagliari, Italy; 2) University of Cagliari, Italy; 3) Service de Genetique Medicale, Poitiers, France; 4) Ospedale Galliera, Genova, Italy; 5) Yorkhill NHS Trust, Glasgow, UK; 6) IRCCS, Ospedale CSS, San Giovanni Rotondo, Italy; 7) University of Bari, Bari, Italy.

In Type I Blepharophimosis/Ptosis/Epicanthus inversus Syndrome (BPES) eyelid abnormalities are associated with Ovarian Failure leading to Female Infertility. Apparently, type II shows only the eyelid defects and affected female could transmit the disorder. We have recently cloned a novel, winged helix/forkhead transcription factor gene, FOXL2, that we found to be mutated in both types of BPES. We report here on a FOXL2 mutation screening we carried out on 35 BPES families. Nonsense and frameshift mutations were identified on all 13 type I BPES families we analyzed. In 6 type II BPES patients we observed apparently milder mutations: a 30 bp in-frame duplication (909\_939dup) present in 3 independent type II BPES families, 2 different missense mutations and a 3 basepair deletion of the last codon, leading to a protein one amino acid-shorter than normal. Also we detected FOXL2 mutation in 7 additional BPES patients whose clinical type could not be determined. We could not find mutations in 4 type II and in 5 BPES families of unknown type. Mutations outside the FOXL2 gene or mutations in another gene could be responsible for these cases. These results further support the notion that FOXL2 loss-of-function mutations are probably incompatible with any kind of female fertility. Milder mutations could allow a child-bearing activity in affected females, but these mutations could nonetheless affect ovarian function and female reproductive life-span in type II BPES. In one instance for example, the 909\_939dup was present in a 14 years old girl with overt Ovarian Failure whose affected mother also had a history of Premature Ovarian Failure. These data therefore suggest that all female BPES patients with FOXL2 mutations should be carefully evaluated for their ovarian function.

**Mouse containing a human chromosome 21 models Downs syndrome.** *M. Oshimura<sup>1</sup>, T. Shinohara<sup>1</sup>, K. Tomizuka<sup>2</sup>, S. Miyabara<sup>3</sup>, Y. Kazuki<sup>1</sup>, S. Ikegami<sup>4</sup>, K. Inokuchi<sup>4</sup>, I. Ishida<sup>2</sup>.* 1) Dept Molecular Cell Genetics, Tottori Univ Sch Life Sci, Yonago, Japan/CREST, JST, Japan; 2) Pharmaceutical Res Lab, KIRIN Brewery Co. Ltd, Takasaki, Japan; 3) Dept Pathology, Saga Medical School, Saga, Japan; 4) Mitsubishi Kasei Inst Life Sci, Machida, Japan.

Trisomy 21(TS21) results in a constellation of features known as Downs syndrome (DS). To investigate the gene dosage effects of an extra copy of human chromosome 21 (Chr 21) on various phenotypes, we used microcell-mediated chromosome transfer to create mouse embryonic stem (ES) cells containing Chr 21. ES cell lines retaining Chr 21 as an independent chromosome were used to produce chimeric mice with a substantial contribution from Chr 21-containing cells. Fluorescence *in situ* hybridization and PCR-based DNA analysis revealed that Chr 21 was substantially intact but had sustained a small deletion. The freely segregating Chr 21 was lost during development in some tissues. These chimeric mice showed a high correlation between retention of Chr 21 in the brain and impairment in learning or emotional behavior. Hypoplastic thymus and cardiac defects were observed in a considerable number of chimeric mouse fetuses with a high contribution of Chr 21. However, each chimeric mouse has a different pattern of trisomic and euploid cells, complicating analyses. Thus, we are developing mice that have Chr 21 and defined fragments translocated to a mouse chromosome, using the Cre-loxP chromosome engineering techniques.

**C7orf2 gene is interrupted within intronic region by a de novo reciprocal chromosomal translocation t (5, 7)(q11, q36) in a patient with preaxial polydactyly.** *T. Horikoshi*<sup>1,2</sup>, *N. Endo*<sup>2</sup>, *M. Shibata*<sup>3</sup>, *M. Suzuki*<sup>4</sup>, *E. Takahashi*<sup>4</sup>, *T. Shinka*<sup>5</sup>, *Y. Nakahori*<sup>5</sup>, *D. Ayusawa*<sup>6</sup>, *K. Nakabayashi*<sup>7</sup>, *S.W. Scherer*<sup>7</sup>, *S. Noji*<sup>2</sup>. 1) Department of Orthopedic Surgery, Niigata University, Niigata, Japan; 2) Department of Biological Science and Technology, Faculty of Engineering, University of Tokushima, Tokushima, Japan; 3) Division of Plastic & Reconstructive Surgery, School of Medicine, University of Niigata, Japan; 4) Otsuka GEN Research Institute, Otsuka Pharmaceutical Co., Ltd., Tokushima, Japan; 5) Department of Public Health, School of Medicine, University of Tokushima, Tokushima, Japan; 6) Kihara Institute for Biological Research, Graduate School of Integrated Science, Yokohama City University, Yokohama, Japan; 7) Department of Genetics, The Hospital for Sick Children, University of Toronto, Toronto, Canada.

Human preaxial polydactyly (PPD) is an autosomal dominant developmental disorder, and its locus has been mapped to chromosome 7q36. We performed fine mapping of the 7q36 breakpoint of a de novo reciprocal translocation t (5, 7)(q11, q36) in a patient with sporadic PPD. FISH analysis and genomic Southern blot showed that C7orf2 gene, which is located in the vicinity of SONIC HEDGEHOG (SHH), was directly interrupted by the translocation breakpoint within intronic region. C7orf2, which encodes a putative transmembrane protein, has recently been identified as causative gene for a rare autosomal recessive congenital malformation of the limb, acheiropodia. However, no mutation within the coding sequence of C7orf2 has been found in PPD families. Another candidate gene, SHH, has been known to cause preaxial polydactyly when it is misexpressed in the anterior limb bud. SHH encodes a signaling molecule, which is thought to determine antero-posterior axis of the limb. Taken together, we speculate the two possible underlying genetic mechanisms for the mutation. First, truncated C7orf2 gene product generated by translocation may function as a dominant active form. Second, a distant limb-specific regulatory element of SHH may exist within C7orf2 genic region. To clarify which is right, genetic studies using animals and further genomic survey in PPD families remain to be done.

**Analysis of *ROR1* gene in a patient with *dirdup(1)(p21p31)* and clinical signs of Robinow syndrome.** *J.F. Mazzeu*<sup>1</sup>, *Z. Mustacchi*<sup>2</sup>, *R.C.M. Pavanello*<sup>1</sup>, *A.M. Vianna-Morgante*<sup>1</sup>. 1) Department of Biology, Universidade de São Paulo, São Paulo, Brazil; 2) Department of Genetics, Universidade Paulista, São Paulo, Brazil.

Robinow syndrome is characterized by fetal facies, orodental abnormalities, mesomelic dwarfism, and hypoplastic genitalia. A dominant and a recessive form of this syndrome have been described and can be distinguished by the severe mesomelic dwarfism and multiple rib and vertebral anomalies present in the recessive type. The mutated gene responsible for the recessive form has been mapped to 9q22 and then identified as *ROR2* gene. The *ROR2* protein is 58% homologous to *ROR1* protein, and *ROR1* maps to chromosome 1p31. Patients with duplications involving 1p31 have clinical features that resemble those of the dominant form of Robinow syndrome. A deletion of this segment has been already reported in a patient with the diagnosis of Robinow syndrome. Herein we describe a girl with clinical signs of Robinow syndrome, who carries a partial duplication of the short arm of chromosome 1: 46,XX,*dirdup(1)(p21p31)* after G banding. The association of Robinow syndrome features and chromosome alterations involving the segment 1p31, where *ROR1* maps, led us to investigate this gene as a candidate for the dominant form of Robinow syndrome. To refine the breakpoint analysis we performed FISH of sequences mapped to 1p as well as microsatellite genotyping. The proximal breakpoint could be restricted to the segment between YACs 943\_f\_11 and 784\_b\_5 at 1p21 and 1p13, respectively. The distal breakpoint was found to be located between YACs 892\_h\_12 and 842\_b\_8 at 1p31, thus coinciding with the mapping site of the *ROR1* gene. The hybridization of the *ROR1* intragenic probe AI206250 (Incyte Genomics), after Southern blotting of genomic DNA *EcoR* 1 digests, revealed a fragment of 4,4kb in the patient, her parents and two normal controls. A less intense extra fragment of 7.3 kb was also present in the patient, pointing to the disruption of *ROR1* gene. These results suggest *ROR1* gene as a candidate for the dominant form of Robinow syndrome.

**Sorting nexin 3 (SNX3) is disrupted in a patient with a translocation t(6;13)(q21;q12) and Microcephaly, Microphthalmia, Ectrodactyly, Prognathism (MMEP) phenotype.** V.S. Vervoort<sup>1,2</sup>, D. Viljoen<sup>3</sup>, R. Smart<sup>3</sup>, G. Suthers<sup>4</sup>, B. Dupont<sup>1</sup>, A. Abbott<sup>2</sup>, C. Schwartz<sup>1,2</sup>. 1) Greenwood Genetic Center, Greenwood, South Carolina; 2) Genetics and Biochemistry, Clemson University, Clemson, SC; 3) Department of Human Genetics, SAIMR, Johannesburg, South Africa; 4) Women's & Children's Hospital, North Adelaide, Australia.

MMEP is a rare disorder characterized by microcephaly, microphthalmia, ectrodactyly and prognathism. A patient with MMEP and mental retardation was previously reported to carry a *de novo* reciprocal t(6;13)(q21;q12) translocation (Viljoen and Smart, 1993). In an attempt to identify the presumed causative gene, we mapped the translocation breakpoints using Fluorescent *in situ* Hybridization (FISH). Two overlapping genomic clones crossed the breakpoint on the der(6) chromosome, locating the breakpoint region between D6S1594 and D6S1250. This region contains the Sorting Nexin 3 (SNX3) gene. Southern analysis allowed us to characterize the der(6) breakpoint and determine that SNX3 was disrupted. Using inverse-PCR, we were able to amplify and sequence the der(6) breakpoint region. The sequence exhibited homology to a BAC clone that contained marker D13S250. This allowed us to amplify and sequence the der(13) breakpoint region and to determine that no additional rearrangement was present at either breakpoint, nor was another gene disrupted. Therefore, the translocation was balanced and SNX3 was determined to be a candidate gene for MMEP. However, mutation screening by SSCP and Southern analysis of a sporadic case with MMEP (Suthers and Morris, 1996) failed to detect any point mutations or deletions in the SNX3 coding sequence. Considering the possibility of positional effect, another candidate gene could map in the vicinity of the der(6) chromosome breakpoint. Alternatively, another locus not on chromosome 6 may cause MMEP in the second patient. Several rearrangements involving the 6q21 region have been associated with ectrodactyly and various somatic malformations, which may be allelic forms of the MMEP phenotype. Therefore, SNX3 or other genes in the same region could be candidates for mutation screening in sporadic cases with ectrodactyly.

**A 1.5 million base pair inversion polymorphism in families with Williams-Beuren syndrome.** *L.R. Osborne<sup>1</sup>, M. Li<sup>2</sup>, B. Pober<sup>3</sup>, D. Chitayat<sup>2</sup>, J. Bodurtha<sup>4</sup>, T. Costa<sup>5</sup>, T. Grebe<sup>6</sup>, S. Cox<sup>6</sup>, L.C. Tsui<sup>2</sup>, S.W. Scherer<sup>2</sup>.* 1) Dept Medicine, Univ Toronto, Toronto, ON, Canada; 2) Dept Genetics, Hospital for Sick Children, Toronto, ON, Canada; 3) Dept Genetics, Yale University School of Medicine, New Haven, CT; 4) Dept Human Genetics, Virginia Commonwealth University, Richmond, VA; 5) Dept Pediatrics, Atlantic Research Centre, Halifax, NS, Canada; 6) Genetics Program, University of Arizona, Phoenix AZ.

Williams-Beuren syndrome (WBS) is caused by hemizygous deletion of a 1.5 Mb interval encompassing more than 23 genes at 7q11.23. The mechanism underlying the deletion is unequal meiotic recombination mediated by highly homologous DNA flanking the commonly deleted region. These flanking duplicons contain transcribed genes and conserved pseudogenes and are comprised of blocks of near identical DNA (>95% identity) occurring in the same and also opposite orientations. We hypothesized that in addition to the deletions commonly seen in WBS, the duplicons may mediate other genomic rearrangements. Using interphase FISH we identified a genomic polymorphism in WBS families consisting of an inversion of the entire WBS region. The inversion was found hemizygously in 3 of 11 (27%) atypical patients whom exhibit a subset of the WBS phenotypic spectrum and do not carry the typical WBS microdeletion. Moreover, in 4 of 12 (33%) families examined with a deleted WBS proband, the inversion was observed exclusively on the disease-transmitting parental chromosome. One atypical individual with the inversion polymorphism and a t(6;7)(q27;q11.23) through the ELN gene enabled a detailed analysis of the WBS region with more than 20 FISH probes from within the deletion region and surrounding chromosomal segment, and showed that the inversion breakpoints lie within the duplicons. These results suggest this newly identified genomic variant can be associated directly with atypical forms of the disease, as well as predispose to primarily WBS-causing microdeletions, but also translocations and inversions. Our findings support the idea that genomic polymorphism might be an important contributor in other *de novo* chromosome rearrangements and disease previously thought to be stochastic in nature.

**Histone Hypoacetylation of Subtelomeric DNA Repeats (D4Z4) Whose Deletion Causes Fascioscapulohumeral Muscular Dystrophy.** *G. Jiang, F. Tsien, M. Ehrlich.* Human Genetics, Tulane Cancer Center, Tulane Medical School, New Orleans, LA.

Fascioscapulohumeral muscular dystrophy (FSHD) is an unusual autosomal dominant syndrome caused by the loss of some copies of a complex repeat (D4Z4) in the subtelomeric region of one chromosome 4 homologue. The number of copies of this 3.3-kb repeat at 4q35 arm is polymorphic. Unaffected individuals have 11 to about 95 copies on each 4q35 while > 90% of FSHD patients have <10 copies at one 4q35. Many investigators have proposed that normally this region is heterochromatic but that when the number of tandem copies of D4Z4 is <10, the region loses its condensed chromatin structure. This is hypothesized to induce inappropriate gene expression in the affected muscle cells. However, there have been no reports of the chromatin structure in this region. Because constitutive heterochromatin has hypoacetylated core histones, which lead to chromatin compaction, we are testing the acetylation of D4Z4 repeat chromatin using chromatin immunoprecipitation (ChIP) with an antibody for tetra-acetylated histone H4 followed by PCR with various amounts of immunoprecipitated sample for DNA amplification. We compared H4 acetylation of chromatin containing the glyceraldehyde-3-phosphate dehydrogenase (*GAPDH*) gene, D4Z4 repeats, or centromeric satellite a repeats by ChIP assays on a normal lymphoblastoid cell line. *GAPDH* served as a euchromatic standard and satellite a repeats as the heterochromatic standard. H4 acetylation was quantitated from the immunoprecipitated chromatin normalizing for the PCR efficiency. The relative amounts of H4 acetylation were 1.0, 0.01, and <0.01, for *GAPDH*, D4Z4, and satellite a, respectively, which is consistent with heterochromatinization of D4Z4. We will analyze chromatin containing D4Z4, satellite a, or various euchromatic genes for mono- and tetra-acetylation of histone H4 to determine if D4Z4 chromatin is normally hypoacetylated compared to bulk euchromatin, as is satellite a heterochromatin. We will also compare cells from FSHD patients and analogous cells from unaffected individuals to determine if the D4Z4 repeats from the deletion-containing 4q35 are abnormally hyperacetylated in FSHD cells. Supported by FSH Society Grant FSHS-MB-06.

**Presence of a double homeobox gene in the D4Z4 locus of a patient with FSHD despite a subtelomeric exchange between chromosomes 4q35 and 10q26.** *I. Leclercq<sup>1</sup>, C. Mattéotti<sup>1</sup>, G. Deneubourg<sup>1</sup>, S.M. Van der Maarel<sup>2</sup>, R.R. Frants<sup>2</sup>, G. Padberg<sup>3</sup>, F. Coppée<sup>1</sup>, A. Belayew<sup>1</sup>.* 1) Lab. Molecular Biology, University of Mons-Hainaut, Mons, Belgium; 2) MGC Dept Human Genetics, Leiden University Medical Center, Leiden, The Netherlands; 3) Dept Neurology, University of Nijmegen, Nijmegen, The Netherlands.

The 4q35 D4Z4 locus comprises 10-100 tandem copies of a 3.3 kb repeat associated with heterochromatin. Heterozygous deletions leaving 1-10 repeats in D4Z4 are linked to facioscapulohumeral muscular dystrophy (FSHD). We have identified an intronless gene encoding a protein with a double homeodomain (DUX4) in each of the two 3.3 kb repeats left in the altered D4Z4 locus of a patient with FSHD (Gabriëls et al, 1999, Gene 236: 25-32). *DUX4* was functional as shown by transfection experiments, and the encoded protein located to the nuclear envelope. We hypothesize that partial D4Z4 deletions seen in patients could destabilize heterochromatin, allowing expression in some cells of the *DUX4* gene present in the few 3.3 kb repeats left. The resulting protein would be toxic to muscles. The D4Z4 repeat array has a homologue on chromosome 10q26. An argument raised against our hypothesis is the occurrence of subtelomeric exchanges between chromosomes 4 and 10, which are sometimes observed in patients. These can replace some D4Z4 repeats by D10Z10 ones (Lemmers et al, 1998, Hum Mol Genet 7: 1207-1214). We analysed genomic DNA from a patient with FSHD who had only two 3.3 kb repeats in his affected 4q35 locus, both originating from chromosome 10. One 3.3 kb unit was subcloned and sequenced, showing the presence of a *DUX10* gene very similar to *DUX4*. In precisely comparing *DUX4* and *DUX10*, we found sequencing errors in the very GC rich *DUX4* 3' end: their correction yielded an ORF encoding an identical DUX4/10 double homeodomain protein. In conclusion, our hypothesis on the role of a *DUX* gene in FSHD is still valid. It would also predict a specific feature on chromosome 4 driving *DUX* expression, since short repeat arrays on chromosome 10 are not pathogenic. (Supported by AFM-France, FSH Society, and MDA).

**Molecular genetic study of three patients with the 22q11 deletion syndrome.** *F. Rahkhoodae<sup>1</sup>, B. Dion<sup>1</sup>, P. Kleinfinger<sup>2</sup>, A. Aurias<sup>2</sup>, S. Demczuk<sup>1</sup>.* 1) Research Institute , Montreal Children's Hospital , Montreal, Quebec, Canada; 2) Institut Curie Section Recherche, Paris, France.

Microdeletions of chromosome 22 are associated with many developmental defects with a broad spectrum of clinical features such as hypocalcemia, heart defect, cleft palate, facial dysmorphism, and mental retardation. Patients vary in the size of the missing chromosomal region, but most of them have a 3 million bp interstitial deletion. Others have very small deletions or other type of rearrangements and very few patients have a normal chromosomal set with no apparent rearrangements. Many efforts have been developed to delimit a critical region for this syndrome. From these studies, it appears that there are at least two critical regions, one in the proximal part of the deleted region and one in the distal part, from which a number of genes have been isolated.

Three patients with typical phenotype have been studied, and preliminary analysis by FISH and FIBER-FISH strongly indicate the presence of a deletion in the 22q11 region. Cell lines from each patient were established. In order to separate the maternal and paternal (or normal vs deleted) chromosomes, somatic cell hybrids were constructed. The hybrid cell lines were verified for the integrity of the 22q11 chromosomal region. Equally spaced primer pairs were chosen from the cosmid suspected to be deleted in each patient and PCR was performed to confirm the existence of the deletion. For two of the three patients, this experiment did not confirm the presence of the deletion. The last patient is being studied. Nonetheless, these patients are invaluable tools to study the molecular pathogenesis of this syndrome. Specific genes for which there is recent evidence for an involvement in the syndrome (TBX1, CRKL, UFD1L) will be examined for point mutations and rearrangements in these patients.

Finding the responsible gene or genes for the 22q11 deletion syndrome will have an impact in the accurate diagnosis of the disease and might open the door to prognostic predictions which will be especially useful in prenatal diagnosis situation.

**Heterozygous PITX2/RIEG1 gene deletion associated with GH deficiency in Rieger syndrome.** *P. Bitoun<sup>1</sup>, K. Machinis<sup>2</sup>, E. Semina<sup>3</sup>, M. Jesuran-Perelroizen<sup>4</sup>, M. Feingold<sup>5</sup>, S. Odent<sup>6</sup>, B. Le Marec<sup>6</sup>, F. Dastot<sup>2</sup>, J. Gaudelus<sup>1</sup>, J.C. Murray<sup>3</sup>, S. Amselem<sup>2</sup>, V. Cacheux<sup>2</sup>.* 1) Medical Genetics and Pediatrics, CHU Paris-Nord, Hopital Jean Verdier, 93143 Bondy, France; 2) Cytogenetics and Molecular Genetics, Hopital Henri Mondor, Creteil,; 3) Dept of Genetics and Biological Sciences, U of Iowa, Iowa City Ia; 4) 15 rue du rempart Saint-etienne, Toulouse; 5) National Birth Defects Center, Waltham Ma; 6) Medical Genetics, Hopital Pontchaillou, Rennes.

The gooseoid homeobox transcription factor gene PITX2/RIEG1 is involved with Rieger syndrome which associates Rieger ocular anomaly, umbilical defects and oligodontia. Pitx2 also plays a key role in left-right axis patterning of heart, gut and lungs. Approximately 44% of our 30 patients with Rieger syndrome were found to have mutations in the PITX2 gene at 4q25. None of the families with short stature and associated growth hormone deficiency were found to have mutations within the coding region or splice sites of the PITX2 gene. Purpose : Because PITX2 is strongly expressed in midline structures like dental primordia, umbilicus and early in the pituitary anlage in mice and because of its role in left-right axis patterning PITX2 deletion could be involved with the GH deficiency of the Rieger syndrome. Patients and Methods : Lymphocytes, fibroblast cell lines and DNA samples from Patients with Rieger syndrome or various forms of selected anterior segment anomalies associated with GH deficiency were tested for heterozygous PITX2 gene deletion. The 4 cosmid clones identified to clone the PITX2 gene were used as fluorescent probes for hybridisation to the patients chromosomes from lymphocyte or fibroblast cell lines using FISH techniques. DNA samples were also obtained to test for hemizygosity at the PITX2 locus using microsatellite markers. Results : We found a heterozygous PITX2 deletion spanning the entire gene in one of two families with Rieger syndrome and GH deficiency. Only DNA being obtained from the other families, deletion will be tested by genotyping microsatellite markers. Our data are consistent with a major role of the PITX2 gene in human pituitary development.

**A novel mutation in RDS/Peripherin gene causing butterfly-shaped pattern dystrophy and adult onset foveal macular dystrophy.** Z. Yang<sup>1</sup>, Z. Yu<sup>1</sup>, Y. Li<sup>1</sup>, S. Jacobson<sup>2</sup>, S. Thirumalaichary<sup>1</sup>, D. Zack<sup>3</sup>, K. Zhang<sup>1</sup>. 1) Cole Eye Inst, Cleveland Clinic Foundation, Cleveland, OH; 2) University of Pennsylvania, Philadelphia, PA; 3) Wilmer institute, John Hopkins School of Medicine, Baltimore, MD.

**Purpose:** Butterfly-shaped pattern dystrophy (BPD) and adult onset foveal macular dystrophy (AOFMD) are two similar forms of autosomal dominant macular dystrophy characterized by deposits in the retinal pigment epithelium. Patients with these diseases present with pigmentary macular lesions with reduced visual acuity in the fifth decade. Various mutations in the RDS/peripherin gene, which encodes a photoreceptor specific glycoprotein, have been associated with both conditions. We identified one BPD family and one AOFMD family and conducted clinical and genetic analyses. **Methods:** Ophthalmologic examination and fluorescein angiography were performed in members of these two families. Mutational screening was performed by direct sequencing of PCR-amplified DNA fragments corresponding to the three exons of the gene. **Results:** Of the 5 patients at risk for BPD and 13 patients at risk for AOFMD in two Caucasian kindreds, four and eight individuals demonstrated macular changes on ophthalmoscopic examination and fluorescein angiography characteristic of BPD and AOFMD respectively. The BPD phenotype in the first family is relatively consistent in all four patients. However, there is a marked variation in AOFMD phenotype in the second family, ranging from mild pigmentary changes in the fovea, to macular geographic atrophy or choroidal neovascularization. Sequencing analysis identified an A to G change at nucleotide 422 predicting a novel Tyr141Cys substitution in both families. This change occurred in a highly conserved Tyrosine residual and segregated with the disease phenotype in both families. This change did not occur in 200 control chromosomes. **Conclusion:** We identified a novel mutation in the RDS/peripherin gene in two independent families. This mutation appears to cause diverse clinical phenotypes, such as BPD or AOFMD. Characterization of full spectrum of mutations in the RDS/peripherin gene will provide useful diagnostic and prognostic information.

**Mutation screening and further analysis of *TBX1* in non-deleted patients with DiGeorge/Velocardiofacial syndrome (DGS/VCFS).** W. Gong<sup>1</sup>, S. Gottlieb<sup>1</sup>, J. Collins<sup>1</sup>, A. Blescia<sup>1</sup>, H. Dietz<sup>2</sup>, D.M. McDonald\_McGinn<sup>1</sup>, E.H. Zackai<sup>1</sup>, B.S. Emanuel<sup>1</sup>, D.A. Driscoll<sup>1</sup>, M.L. Budarf<sup>1</sup>. 1) Division of Human Genetics and Molecular Biology, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Howard Hughes Medical Institute, John Hopkins University School of Medicine, Baltimore.

Recent studies using murine models suggest that *TBX1* is a candidate gene for DGS/VCFS (Jerome and Papaioannou 2001, Lindsay et al., 2001, Merscher et al., 2001). *TBX1* is a member of T-box gene family and haploinsufficiency of T-box genes, *TBX3* and *TBX5* are associated with human genetic diseases. To better understand the role of *TBX1* in the etiology of DGS/VCFS, we performed mutation screening of *TBX1* in 40 patients with the diagnosis of DGS/VCFS but without a detectable 22q11 deletion. PCR was performed with genomic DNA from patients and normal controls. SSCP and/or CSGE were used to screen for mutations of *TBX1*. Heterozygous changes were confirmed by direct sequencing. We identified five rare variants, including one single base change (-39C/T), one 3-bp insertion and three deletions (del 8 bp, del 9 bp, del 15 bp) that were not observed in over 100 normal controls. Sequence analysis of the family members of these patients demonstrates that these rare variants were transmitted from an unaffected parent to proband. We are performing in vitro assays to determine whether the rare variants of *TBX1* are diseases-causally related to DGS/VCFS. Among the rare variants detected, four of the five rare variants are located in the last exon and the 8-bp deletion is predicted to cause a frame shift at amino acid 425. We have generated cDNA constructs containing the full-length wild-type *TBX1*, the 8-bp deletion variant *TBX1* and a partial *TBX1* cDNA sequence without the terminal exon. These constructs allow us to analyze the expression and subcellular localization of the normal and variant forms of *TBX1* protein in the HEK 293 cells and Cos7 cells by immunofluorescence and immunoblotting. The characterization of the normal and altered forms of *TBX1* proteins will help us to understand the function of *TBX1* protein.

***de novo* mutation in the *SIX6* homeobox gene in a patient with bilateral anophthalmia.** M.E. Gallardo<sup>1,2</sup>, A.S. Schneider<sup>3</sup>, M.A. Dwyer<sup>3</sup>, S. Rodríguez de Córdoba<sup>1,2</sup>. 1) Unidad de Patología Molecular, Fundación Jiménez Díaz, Madrid, Spain; 2) Dept Immunología, CIB (CSIC), Madrid, Spain; 3) Dept Genetics, Albert Einstein Medical Ctr, Philadelphia, PA.

*SIX6* is a recently characterized member of the *SIX/sine oculis* family of homeobox genes. *SIX6* is expressed in the developing and adult retina, in the optic nerve and in the hypothalamic and pituitary regions. *SIX6* maps to chromosome 14q22.3-q23 within a region that is deleted in three individuals with bilateral anophthalmia and pituitary anomalies. To determine the implication of *SIX6* in ophthalmological malformations we have screened 30 families from the Anophthalmia /Microphthalmia Registry at Albert Einstein Medical Center, Philadelphia for mutations in *SIX6*. We have identified a patient who carries a mutation (c.59C®T) in the heterozygous form in the 5 untranslated region of the *SIX6* gene. This is the first time that a mutation in *SIX6* has been observed. The patient is a 7 year old female with bilateral anophthalmia born to consanguineous parents. Her karyotype was normal. Growth and development are appropriate for age and she has no known anomalies. The mutation is not present in the parents. Correct segregation of the parental chromosomes in the patient was demonstrated using four polymorphic markers (D14S997, D14S1038, D14S1010 and D14S1007) in the *SIX6* region. Since c.59C®T is clearly a *de novo* mutation in *SIX6* in the anophthalmic patient, it would be expected that this mutation is responsible for the disorder. However, the functional consequences of the c.59C®T mutation are unknown. A number of experiments are being performed to determine whether the c.59C®T mutation results in abnormal expression of the *SIX6* gene.

**Physical and transcriptional map of the Hereditary Inclusion Body Myopathy (HIBM) locus on chromosome 9p12-p13.** *I. Eisenberg<sup>1</sup>, H. Hochner<sup>1</sup>, M. Shemesh<sup>1</sup>, T. Levi<sup>5</sup>, T. Potikha<sup>1</sup>, M. Barash<sup>1</sup>, G. Grabov<sup>1</sup>, M. Sadeh<sup>2</sup>, Z. Argov<sup>3</sup>, C.L. Jackson<sup>4</sup>, S. Mitrani-Rosenbaum<sup>1</sup>.* 1) Molecular Biology Unit, The Hebrew University-Hadassah Medical School, Jerusalem, Israel; 2) Department of Neurology, Wolfson Hospital, Holon, Israel; 3) Department of Neurology, The Hebrew University-Hadassah Medical School, Jerusalem, Israel; 4) Department of Pathology, Rhode Island Hospital and Brown University, Providence, Rhode Island, USA; 5) Department of Genetics, Harvard Medical School, Boston, Massachusetts, USA.

Hereditary Inclusion Body Myopathy (HIBM)(OMIM 600737) is a unique group of neuromuscular disorders characterized by adult-onset, slowly progressive distal and proximal muscle weakness and typical muscle pathology. Previously, we have mapped the gene causing the recessive form of HIBM to chromosome 9p1 and narrowed the interval to one single YAC clone of 1Mb in size. As a further step towards the identification of the HIBM gene, we have constructed a detailed physical and transcriptional map of this region. A high resolution BAC contig that includes the HIBM critical region, flanked by marker 327GT4 and D9S1859, was constructed. This contig allowed the precise localization of twenty five genes and ESTs to the proximal region of chromosome 9. The expression pattern of those mapped genes and ESTs was established by Northern blot analysis. In the process of refining the HIBM interval, thirteen new polymorphic markers were identified, of which 11 are CA-repeats, and 2 are single nucleotide polymorphisms. Certainly, this map provides an important integration of physical and transcriptional information corresponding to chromosome 9p12-p13, which is expected to facilitate the cloning and identification not only of the HIBM gene, but also other disease genes which map to this region.

**Association Between Angiotensin-Converting Enzyme and Alzheimer Disease in the Korean population.** *E.S.*

*Shin<sup>1</sup>, S.R. Yoon<sup>2</sup>, S.K. Choi<sup>2</sup>.* 1) Genetic Research Laboratory : NeoDin Medical Institute, Seoul, Korea; 2) Department of Molecular biology, University of Southern California, CA, USA.

Angiotensin-Converting Enzyme (ACE) has been reported to show activity in patient with neurologic disease. An insertion-deletion polymorphism in ACE has recently been linked to heart disease, cerebrovascular disease, and Alzheimer Disease (AD). Other findings demonstrated a significantly higher ACE activity in the hippocampus, frontal and temporal cortex and other cerebral regions in subjects with AD. It has been recently shown that the ACE D allele bearing subjects have an increased risk of cognitive impairment, independent of other common risk factors such as advanced age, female gender and presence of Apolipoprotein E (APO-E) \*4 allele. In order to verify the association of ACE gene with AD, as well as its association with APO-E genotype, we performed ACE genotyping in subjects with Late-Onset Alzheimer's disease (LOAD, n=62), 68 healthy age-matched controls and 472 healthy controls, who were previously characterized for APO-E genotype. After the principal component analysis, ACE D and Apo-E \*4 alleles disclosed the highest prevalence in the Alzheimer's disease group in Korea ( $P < 0.05$ ). We concluded that in the population studied here, the ACE D acts in association with the ApoE \*4 as a susceptibility gene for AD.

**The Fanconi Anemia Mutation Database:** <http://www.rockefeller.edu/fanconi/mutate/>. A.D. Auerbach<sup>1</sup>, K. Pujara<sup>1</sup>, S.D. Batish<sup>1</sup>, O. Levrin<sup>1</sup>, C.G. Mathew<sup>2</sup>. 1) Lab Human Gen & Hematology, Rockefeller Univ, New York, NY; 2) Div. Medical & Molecular Genetics, Guy's Hospital, London, UK.

Fanconi anemia (FA) is an autosomal recessive syndrome with diverse clinical features that is characterized by DNA crosslink hypersensitivity and cancer predisposition. Eight complementation groups and 6 unique genes have now been identified (FANCA: OMIM 227650; FANCB: 227660; FANCC: OMIM 227645; FANCD1: OMIM 605724; FANCD2: OMIM 227646; FANCE: OMIM 600901; FANCF: OMIM 603467; FANCG: OMIM 602956). Detailed information regarding all the variants (mutations and polymorphisms) identified in FA genes is maintained in the Fanconi Anemia Mutation Database (FAMd), a model locus specific database (LSDB) for the Mutation Database Initiative (MDI, [www.genomic.unimelb.edu.au/mdi/](http://www.genomic.unimelb.edu.au/mdi/)). The FAMd was established on the worldwide web (<http://www.rockefeller.edu/fanconi/mutate/>) in 1997 and was redesigned and updated in June, 2001. Its goal is to serve researchers in the field by providing a means for rapid republication and dissemination of mutation data. Passwords are currently required for access to the "private" section of the database containing unpublished mutations, and are provided to all individuals who agree to abide by a set of guidelines protecting the priority rights of the researchers who submit data prior to publication. The database is maintained in a Filemaker Pro Database (Claris Corporation) on a Power Macintosh Server. Nomenclature conforms to the guidelines specified by the Nomenclature Working Group of the MDI. A summary of the number of variants in the database for the 6 cloned genes is shown.

	FANCA	FANCC	FANCD2	FANCE	FANCF	FANCG	Total
Variants	201	24	5	3	6	36	275

By contributing data to the future Central Database of MDI, FAMd helps provide investigators and clinicians with universal free access to the assembled total knowledge of human gene variation.

**Human disease genes: Protein function and clinical phenotypes.** *G. Jimenez-Sanchez, B. Childs, D. Valle.* Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD.

Availability of whole genome sequence from humans and from several model organisms has accelerated the identification of genes responsible for human genetic disease. To search for correlations between the function of the protein products of these "disease genes" and features of the corresponding disease, we assembled a list of nearly 900 human disease genes. We compared the function of their protein products to characteristics of the disease phenotypes such as frequency, mode of inheritance, age of onset, and impact on life expectancy. Originally we analyzed enzymes, modulators of protein function, receptors, and transcription factors (*Nature* 409: 853, 2001) and have currently extended our study to include intracellular structural proteins and extracellular matrix components and by subdividing functional categories that appeared to be correlated with certain aspects of disease phenotype. For example, we found that genes encoding transcription factors (TF) are a major cause of genetic diseases with onset *in utero*: 36 of 61 (59%) TF genes responsible for genetic disease produce phenotypes *in utero*. Classification of TF in TRANSFAC categories (<http://transfac.gbf.de/TRANSFAC/>) showed that 56% of these 36 (20) are members of the helix-loop-helix (HLH) superclass, most of these (12) are in the homeodomain class. By contrast, only 30% of the 23 TF causing disease with onset between 1 and 50 years are in the HLH superclass including only 4 (17%) in the homeodomain class; 9 (39%) are in the Zn finger superclass including 6 (26%) nuclear receptors of the Cys4 Zn finger class. An analysis of the human genome revealed >2000 hypothetical TF genes, with C2H2 Zn finger the largest class among transcriptional activators (*Nature* 409:832, 2001). Only 3 of the 61 TF (5%) causing disease are in this class. Similar differences in age of onset are apparent in genes encoding enzymes, most of which have their onset in extrauterine life. As knowledge of disease genes grows, including those contributing to complex traits, more sophisticated analyses will be possible; their results will yield deeper understanding of disease and enhanced integration of medicine with biology.

**The human LDL receptor gene (LDLR) database: Molecular analysis of 625 mutations.** *L. Villeger<sup>1</sup>, M. Abi-Fadel<sup>1</sup>, S. Rochaud<sup>1</sup>, A. Robin<sup>1</sup>, J-P. Rabes<sup>1,2</sup>, C. Junien<sup>1,2</sup>, C. Beroud<sup>1</sup>, C. Boileau<sup>1,2</sup>, M. Varret<sup>1</sup>.* 1) INSERM U383, Hopital Necker-Enfants Malades, Paris, France; 2) Laboratoire central de biochimie et de genétique moléculaire, CHU Ambroise Paré, Boulogne, France.

To date, 711 mutations have been identified in the LDLR gene, encoding the low-density lipoprotein receptor, in subjects with Familial Hypercholesterolemia. Although genotype/structure-function correlations have been substantially investigated, genotype/phenotype correlations have not been explored. Thus, we have compiled a database containing standardized data for each LDLR mutation, and developed the software that provides sorting tools and allows optimized multicriteria research [<http://www.umd.necker.fr>]. The analysis of the 625 point mutations in the UMD-LDLR database gives the following information: [1] 58% of the mutations are missense, and 17% occur in CpG dinucleotides known to be mutational hot spots; [2] although widely distributed throughout the gene, there is an excess of mutations in exons 4 and 6 (ligand-binding repeats), 7 (EGF-like repeat), and 9 (EGF-precursor-like); [3] there is a deficit of mutations in exons 10 and 13 (EGF-precursor-like), 15 (O-linked-sugar), 16 (transmembrane), 17 and 18 (cytoplasmic); [4] 47% of the small deletions occur between repeated sequences and can be explained by the slipped-mispairing model described by Krawczak and Cooper; [5] 68% of the mutations in the ligand-binding domain affect conserved amino-acids involved in LDL binding; [6] the functional data available for 183 (29%) mutations indicate 38% of class 2B (transport defective) and 33% of class 1 mutations (null alleles); [7] finally, the investigation of genotype/phenotype correlations is difficult since the clinical data is usually incomplete in mutation reports. Direct access to the database through the web site should facilitate the input of high quality clinical information and should overcome this shortage.

**Identification of a novel GUCY2D mutation in an Iranian family with Leber Congenital Amaurosis.** *T. Rezaie<sup>1</sup>, M.H. Karimi-Nejad<sup>2</sup>, M. Meshkat<sup>3</sup>, S. Sohbati<sup>2</sup>, R. Karimi-Nejad<sup>2</sup>, H. Najmabadi<sup>2</sup>, M. Sarfarazi<sup>1</sup>.* 1) Molecular Ophthalmic Genetics, Univ of Connecticut Health Center, Farmington, CT; 2) Karimi-Nejad Pathology & Genetic Center, Tehran, Iran; 3) Department of Ophthalmology, Kerman University of Medical Sciences, Kerman, Iran.

Evaluation of congenital blindness in southeastern region of Iran identified an extended family with Leber Congenital Amaurosis (LCA) in the Lore Tribe of Sirjan, Kerman. Immediate relatives of 8 affected subjects interconnected through 11 different generations shown an autosomal recessive pattern of inheritance. Full clinical and ophthalmological examinations revealed infantile nystagmus, keratoconus, narrowing of retinal vessels, retinal degeneration, mild pigmentary retinopathy and electrophysiological investigations consistent with diagnosis of LCA. DNA samples from first-degree relatives in 5 distantly related branches were used for linkage evaluation to known LCA loci on chromosomes 1, 6, 14, 17 and 19. Only one locus on 17p13.1 was consistent with linkage in 19 subjects of only 4 branches. Inspection of the inherited haplotypes suggested that a mutation in the LCA1/GUCY2D but not the LCA4/AIPL1 is more likely to be involved. Therefore, this gene was amplified and fully sequenced in an affected subject. A homozygous missense mutation (ATC->AGC; I816S) within the exon 13 of GUCY2D was identified. Sequencing of a 328-bp PCR fragment containing this mutation in 19 subjects fully segregated in 6 affected, 8 gene carrier parents and 5 normal members, including 2 heterozygote gene carriers. SSCP screening of I816S did not identify this mutation in 184 normal control chromosomes (70 Iranian and 114 other Caucasians). I816S falls within a putative dimerization domain of the guanylate cyclases protein and it is fully conserved in mouse, rat and bovine. We also identified one wobble (CAC->CAT; H247H) and another polymorphism (CTC->CAC; L782H) in this gene. Identification of I816S mutation provides a rapid molecular diagnosis for over 150 other members of this family that were not included in our initial screening. The I816S is a novel mutation in GUCY2D gene and, this is the first mutation report in an Iranian LCA family.

**Mutation analysis of KIT gene in human piebaldism.** *K. Fukai, N. Oiso, A. Kato, N. Hosomi, T. Murakami, M. Ishii.*  
Dept Dermatology, Osaka City Univ Medical Sch, Osaka, Japan.

Piebaldism is an autosomal dominant disorder, characterized by congenital circumscribed depigmented macules most frequently on the forehead, abdomen, and knees. This disorder has been shown to occur due to germline mutations of the c-KIT gene, which is necessary for the development and the differentiation of dermal melanocytes during embryogenesis. We had the oppertunities to study the c-KIT gene in 17 families with human piebaldism: four from Japan, four from Italy, four from the USA, two from UK, two from Holand, and one form Columbia. Genomic DNAs were prepared from peripheral leukocytes, and all exons and flanking introns were PCR-amplified, and direct-sequenced. We were able to identify mutations in 7 families. Among these, three were frameshift mutations, 142delG, 2247-2250delAAGA, 1768-1769delAG, and three missense mutations, C136R, D792Y, and V620A, and one nonsense mutation, E346X. All mutations except C146R were novel and not reported in the literature. We are screening SCF (stem cell factor) gene for KIT-mutation-negative cases with piebaldism.

**Molecular evidence for a founder effect in South African Afrikaners with pseudoxanthoma elasticum.** *K.B. Beck<sup>1</sup>, O. Le Saux<sup>1</sup>, C. Sachsinger<sup>1</sup>, C. Treiber<sup>1</sup>, AS. Marais<sup>2</sup>, E. Johnson<sup>3</sup>, L. Bercovitch<sup>4</sup>, S.F Terry<sup>5</sup>, D.L. Viljoen<sup>6</sup>, C.D. Boyd<sup>1</sup>.* 1) Pacific Biomed Research Ctr, University of Hawaii, Honolulu, HI; 2) Department of Genetics University of Cape Town Medical School; 3) Barrow Neurological Institute, Phoenix, AZ; 4) Department of Dermatology, Brown Medical school, Providence, RI; 5) PXE International Inc., Sharon, MA; 6) South African Inst. for Med. Res., University of Witswatersrand, Johannesburg, South Africa.

Pseudoxanthoma elasticum (PXE) is a heritable disorder characterized by dermal, vascular and ocular lesions resulting from the mineralization of elastic fibers in these tissues. Recently, the first mutations responsible for the development of PXE have been identified. The observed prevalence of this disorder is approximately the same in all population groups studied with one exception among South African Afrikaners. Previous reports suggested founder effects as a possible explanation for a higher prevalence of PXE in Afrikaners, a Europeans-derived population that first settled in South Africa in the 17th century. To investigate this hypothesis, we have performed a mutational analysis of ABCC6 in 17 apparently unrelated Afrikaner families with PXE, in addition to 6 unrelated PXE families from South Africa of British and Indian descent. In the Afrikaner population, 6 different mutations were characterized. Three alleles were missense variants, 2 were nonsense and 1 was a single base pair insertion. One mutation, R1339C, has been found to occur at a frequency of 53; others were noted at lower frequencies ranging from 3 to 12%. Putative disease-causing mutations were identified in about 85% of the 34 chromosomes studied. A single R1339C was found in a heterozygous state in a control panel of 100 alleles derived from unaffected Afrikaner individuals. In the 6 families of different origins, the mutations detection rate was 75%. Four out-of-frame insertion or deletions, 2 nonsense mutations and 1 missense variant were identified. Haplotype analysis of the Afrikaner families revealed that the 3 most frequent mutations were identical-by-descent, indicating a founder origin of PXE in this population.

**PAX3 and MITF Mutations in Colombian Patients with Waardenburg Syndrome.** *N.Y. Gelvez<sup>1</sup>, M. Rodriguez<sup>1</sup>, M.C. Lattig<sup>1</sup>, J.C. Prieto<sup>1</sup>, T. Friedman<sup>2</sup>, R. Morell<sup>2</sup>, M.L. Tamayo<sup>1</sup>.* 1) Instituto Genetica Humana, Universidad Javeriana, Bogota, Colombia; 2) NIDCD, NIH, Bethesda, MA, USA.

During the past two years we performed a screening program for Waardenburg Syndrome (WS) in Colombia, finding a frequency of 5.3% of the syndrome among the deaf institutionalized population. We evaluated 93 families (120 affected individuals) with clinical characteristics of WS. Twenty-seven families (27/93) were classified as WS type 1 (29%), fifty-six (56/93) as WS type 2 (60.2%) and ten (10/93) as no-determinate WS type (10.8%). We performed SSCPs for PAX 3 (responsible for WS1) and MITF (responsible for WS2) in the total of 93 detected families. All affected families were tested for both genes. The general results of the molecular analysis were: For PAX 3 gene we found 19 families with any mutation (20.3%), and for MITF gene we found mutation in 15 families (16%). The detailed results by each gene, were: PAX3 gene mutations in exon 2: 12.9% (12/93); exon 4: 1.07% (1/93); exon 5: 1.07% (1/93); exon 6: 2.1% (2/93) and exon 7: 3.2,% (3/93). For the MITF gene, we found mutation in exon 1: 2.1% (2/93) and exon 9: 13.9% (13/93). Sequence analysis is in progress to confirm the type of mutation. Results by type of syndrome were more interesting. We discuss the use of the molecular study to define the diagnosis in WS patients with no-determinate clinical type. Our population has a bigger frequency for WS type 2 (60,2%) than WS type 1, opposite to previous reports. Although we have not yet analyzed the exons 9 and 10 for the PAX 3 gene, the heterogeneity of the syndrome is clear due to the fact that 75,2% of the total of our affected population did not present mutation in any of the known causing genes.

**Mal de Meleda (MDM) is caused by mutations in the SLURP-1 gene in patients from Palestine and the United Arab Emirates.** *K.M. Eckl<sup>1,2</sup>, H.P. Stevens<sup>3</sup>, G.G. Lestringant<sup>4</sup>, P.M. Frossard<sup>4</sup>, I.M. Leigh<sup>3</sup>, P. Nürnberg<sup>1</sup>, A. Reis<sup>5</sup>, H.C. Hennies<sup>1</sup>.* 1) Molecular Genetics and Gene Mapping Center, Max Delbrück Center, Berlin, Germany; 2) Faculty of Biology, Chemistry, and Pharmacy, Free University, Berlin, Germany; 3) Center for Cutaneous Research, St Bartholomew's and the Royal London School of Medicine, London, UK; 4) Tawam Hospital and Faculty of Medicine and Health Sciences, Al Ain, United Arab Emirates; 5) Human Genetics, Friedrich Alexander University, Erlangen, Germany.

Mal de Meleda (MDM), or keratosis palmoplantaris transgrediens of Siemens, was first reported on the island of Meleda, now Mljet, in Croatia. It is characterized by diffuse palmoplantar keratoderma (PPK) and transgressive keratosis with an onset in early infancy before one year of age. There is no associated involvement of other organs. A rather broad spectrum of clinical presentations with other optional and variable features is characteristic of MDM. Some patients show marked progression of most symptoms of the disease. A locus for MDM was found on chromosome 8q24-qter, and recently, mutations in the *ARS (component B)* gene were identified in patients with MDM. However, we have shown lately that a very similar phenotype of transgressive PPK is not linked to the interval on chromosome 8q in several families from the United Arab Emirates. Here we analyzed further families with transgressive PPK. In a large Palestinian pedigree with multiple consanguinity, patients were homozygous for a new mutation, 1764G>A, in *ARS (component B)*, which substitutes an arginine for a conserved glycine residue. Moreover, another new mutation, 578A>C, was seen in patients from an Emirati family, which alters the translation initiation codon. *ARS (component B)* encodes the secreted Ly-6/uPAR-related protein-1 (SLURP-1). SLURP-1 is a member of the Ly-6 protein superfamily and belongs to a subgroup that also contains various secreted cytotoxins. These findings show that the MDM type of transgressive PPK may be caused by SLURP-1 mutations also in other than Croatian patients. A founder effect is supposed in patients from Mljet, however, allelic heterogeneity was observed here for mutations in the SLURP-1 gene.

**A spectrum of ABCC6 mutations is responsible for pseudoxanthoma elasticum.** *O. Le Saux*<sup>1</sup>, *K. Beck*<sup>1</sup>, *C. Sachsinger*<sup>1</sup>, *C. Silvestri*<sup>1,2</sup>, *C. Treiber*<sup>1</sup>, *H. Gring*<sup>3</sup>, *E. Johnson*<sup>4</sup>, *A. De Paepe*<sup>5</sup>, *M. Pope*<sup>6</sup>, *I. Pasquali-Ronchetti*<sup>2</sup>, *L. Bercovitch*<sup>7</sup>, *S.F. Terry*<sup>8</sup>, *C. Boyd*<sup>1</sup>. 1) Pacific Biomed Research Ctr, University of Hawaii, Honolulu, HI; 2) Department of Biomedical Sciences, University of Modena, Modena, Italy; 3) Department of Genetics, Southwest Foundation for Biomedical Research, San Antonio, TX; 4) Barrow Neurological Institute, Phoenix, AZ; 5) Center for Medical Genetics, University Hospital, Universitair Ziekenhuis Gent; Belgium; 6) MRC Connective Tissue Genetics Group, Institute of Medical Genetics, University Hospital of Wales, Cardiff, UK; 7) Department of Dermatology, Brown Medical School, Providence, RI; 8) PXE International Inc., Sharon, MA.

To better understand the pathogenetics of pseudoxanthoma elasticum (PXE), we have performed a mutational analysis of ABCC6 in 122 unrelated PXE patients, the largest cohort of patients yet studied. Thirty-six mutations were characterized and 26 were novel variants. 21 alleles were missense variants, 6 were small insertion or deletions, 5 were nonsense, 2 were likely to result in aberrant mRNA splicing and 2 were large deletions involving ABCC6. The total number of ABCC6 mutations known to date is 43. Whilst most mutations appeared to be private variants, two disease-causing alleles occurred frequently in apparently unrelated individuals. R1141X was found at a frequency of 18.8% and was preponderant in European patients. ABCC6del23-29 occurred at a frequency of 12.9% and was prevalent in patients from the United States. These results suggested that R1141X and ABCC6del23-29 might have been derived regionally from founder alleles. Putative disease-causing mutations were identified in 64% of the 244 disease alleles studied. Our results suggest that the undetected mutant alleles could either be genomic rearrangements or mutations occurring in non-coding regions of the ABCC6 gene. The distribution of ABCC6 mutations revealed a cluster of disease-causing variants within exons encoding a large C-terminal cytoplasmic loop and in the C-terminal nucleotide-binding domain (NBD2). We discussed the structural and functional significance of this mutation pattern.

**Survival of male cases of incontinentia pigmenti carrying a lethal mutation can be explained by somatic mosaicism or a 47,XXY karyotype.** S.J. Kenwick<sup>1</sup>, A. Smahi<sup>2</sup>, S. Aradhya<sup>3</sup>, G. Shuttleworth<sup>4</sup>, S. Lyonnet<sup>2</sup>, C. Kashork<sup>3</sup>, H. Woffendin<sup>1</sup>, E. Mayer<sup>4</sup>, L. Greenhalgh<sup>5</sup>, T. Jakins<sup>1</sup>, M. Levy<sup>3</sup>, R. Lewis<sup>3</sup>, L. Shaffer<sup>3</sup>, A. Munnich<sup>2</sup>, D. Nelson<sup>3</sup>. 1) WTCMMD, Univ. Cambridge, Cambridge, U.K; 2) Hôpital Necker-enfants Malades, Paris, France; 3) Baylor College of Medicine, TX, USA; 4) Bristol Eye Hospital, U.K; 5) St Michael's Hospital, Bristol, U.K.

incontinentia pigmenti (IP) is an X-linked dominant disorder characterised by abnormalities of skin, teeth, hair and eyes, skewed X-inactivation and recurrent male miscarriages. IP results from mutations in the gene for NEMO with deletion of exons 4-10, mediated by tandem repeats, accounting for ~80% of new mutations. Males inheriting this mutation and other null mutations die *in utero*. Less deleterious mutations give rise to surviving males with ectodermal dysplasia and immunodeficiency and female carriers with variable or no IP. Males with abnormalities typical of IP (without immunodeficiency) are rare and have been found with a 47,XXY karyotype. However, 46,XY cases have also been reported. We describe three 46,XY and one 47,XXY male cases of IP who presented with all the hallmarks of IP (neonatal blistering, keratotic lesions, hyperpigmentation, dermal scarring and hypoplastic teeth). PCR and Southern blot analysis demonstrates that the 47,XXY male has inherited the common deletion from his IP-affected mother, and an additional X chromosome from his father. He has selectively eliminated cells expressing the mutated X resulting in skewed X-inactivation. The 46,XY cases also have both wild type and deleted copies of *NEMO* and are therefore mosaic. Furthermore, analysis of samples from a 9yr old IP boy shows that cells expressing the mutated X are selectively eliminated. Thus, the repeat-mediated recombination leading to the common deletion is not restricted to meiosis and most likely occurs via intrachromosomal exchange. Post-zygotic deletion may explain reports of anticipation in IP pedigrees. Finally, karyotypic abnormalities and post-zygotic mutation provide two mechanisms for survival of males carrying a *NEMO* mutation.

**Anhidrotic Ectodermal Dysplasia with Immunodeficiency not associated with NEMO mutations.** A. Smahi<sup>1</sup>, G. Courtois<sup>3</sup>, R. Doffinger<sup>2</sup>, J.L. Casanova<sup>2</sup>, A. Munnich<sup>1</sup>. 1) Unite de Recherches sur les Handicaps Genetiques de l'Enfant. INSERM U393, Hopital Necker, Paris, France; 2) Laboratoire de Genetique Humaine des Maladies Infectieuses, Faculte de Mdecine Necker-Enfants Malades, Paris, France; 3) URA CNRS 1773, Institut Pasteur, Paris, France.

Anhidrotic Ectodermal Dysplasia (EDA) is a rare developmental syndrome responsible for absent sweat glands, sparse scalp hair and rare conical teeth. Mutations in the Ectodermal Dysplasia 1 (ED1) and downless (dl) genes account for a form of X-linked recessive and autosomal recessive/dominant type of EDA respectively. On the other hand, EDA with Immunodeficiency is a X-linked recessive condition which associates ectodermal dysplasia with impaired response to various pathogens (EDA-ID). This syndrome has been recently ascribed to hypomorphic mutations in the NEMO gene, resulting in impaired NF-KB signaling. Here we describe two EDA-ID syndrome patients with no mutation of the NEMO gene. Patient 1, the son of a healthy mother, had mild EDA and was highly susceptible to infectious disease caused by micro-organisms including Gram positive Cocci, Gram negative bacilli and mycobacteria. Bone marrow transplantation was performed at the age of 2 years. The second patient, a girl with Ectrodactyly-ectodermal dysplasia with immunodeficiency, had random X-inactivation. The complete coding region of NEMO gene and the three non coding exons of 5' part were sequenced at the genomic level. No mutation was observed. Mutations in the regulatory regions of NEMO are unlikely as Western blot analysis of patient 1 fibroblasts showed a level of NEMO protein similar to controls fibroblasts. Since a defective IKBalpha degradation after TNFalpha and IL1 stimulation is observed in patient 1 fibroblast, impaired NF-KB activation is most likely. This study suggests that beside NEMO, other autosomal or X-linked recessive genes of the NF-KB cascade can cause EDA-ID in our patients.

**Identification of a Novel Splice Site PPOX Gene Mutation in an Ancient Variegate Porphyria Balearic Family.** *S. Puig<sup>1</sup>, C. Badenas<sup>2</sup>, L. Jimenez<sup>2</sup>, A. Toll<sup>1</sup>, C. Herrero<sup>1</sup>, M. Lecha<sup>1</sup>, M. Mila<sup>2</sup>.* 1) Dermatology Service, Hospital Clinic, Barcelona, Spain; 2) Genetics Service, Hospital Clinic, Barcelona, Spain.

Variegata porphyria (VP) is an autosomal dominant disorder with low penetrance characterised by acute neuro-visceral attacks and skin lesions that can occur separately. The molecular basis of the disorder is a partial deficiency of protoporphyrinogen oxidase encoded by the PPOX gene. This infrequent disease is relatively common in South Africa, where most patients share the same mutation and a common ancestor. Recently, it has been reported the PPOX gene molecular analysis of 108 unrelated VP patients from United Kingdom and France. This study demonstrates VP allelic heterogeneity outside South Africa, and shows that genotype is not a significant determinant of mode of presentation. We have biochemically analysed ninety-six members belonging to a VP family from Mallorca Isle, with 9 symptomatic patients. DNA samples from affected members were screened for mutations in PPOX gene by SSCP analysis. Abnormal pattern in exon 6 was sequenced and a T to A transversion was identified at the consensus splice site (IVS6+2T>A). This change should affect the correct splicing of exon 6 and be the causative mutation in this family. This mutation has not been previously reported, but another exon 6 splice site mutation of PPOX gene has been associated with VP.

**A Tandem Duplication within the Elastin Gene is Associated with Autosomal Dominant Cutis Laxa.** Z. Urban<sup>1</sup>, J. Gao<sup>2</sup>, F.M. Pope<sup>3</sup>, E.C. Davis<sup>2</sup>. 1) Pacific Biomedical Res Ctr, Univ Hawaii, Honolulu, HI; 2) Cell Biology, UT Southwestern Med Ctr, Dallas, TX; 3) Medical Genetics, Univ Hosp Wales, Cardiff, Wales.

Autosomal dominant cutis laxa (adCL) is characterized by redundant, inelastic skin, hernias and, in some cases, pulmonary emphysema and vascular tortuosity. We have used metabolic labeling and immunoprecipitation to analyze elastin gene (ELN) expression in skin fibroblasts from patients with adCL. In addition to the normal 70kD protein, an abnormal 120kD tropoelastin was detected in an adCL patient and her affected daughter. Northern blot analysis confirmed the existence of a correspondingly larger (5 kb instead of 3.5 kb) mRNA. 3'-RACE amplification and RT-PCR experiments indicated that the mutant transcript had the following structure: exons 1-33, 9-33, 9-10, intron 10. Further RT-PCR experiments demonstrated that the normal alternative splicing patterns of exons 23 and 32 were not affected by this duplication. Genomic PCR and DNA sequencing confirmed the duplication breakpoints to be between introns 33 and 8 and Southern-blot experiments demonstrated a tandem duplication at the ELN locus. While the exact pathomechanism of this mutation is not clear, the fact that fibroblasts secrete some of the abnormal tropoelastin suggests a dominant negative effect. Interestingly, a similar tandem duplication in fibrillin-1, another elastic fiber component, causes the tight skin (tsk) phenotype in mice, an apparent opposite of cutis laxa.

**The new mutation Q167K in PIT-1 gene leads to combined pituitary hormone deficiency in an Italian patient.** S. Malvagia, G.M. Poggi, E. Pasquini, M.A. Donati, I. Pela, A. Morrone, E. Zammarchi. Dep. of Paediatrics, Azienda Ospedaliera "A. Meyer" University of Florence, Italy.

Pit-1 gene encodes a transcription factor, important for the development and differentiation of the cells which produce growth hormone (GH), prolactin (Pr1) and thyroid-stimulating-hormone (TSH) in the anterior pituitary gland. Patients with the Pit-1 mutations show a combined pituitary hormone deficiency (CPHD). Eleven mutations have been reported in the Pit-1 gene, up to now. These genetic lesions can be inherited either in an autosomal dominant or an autosomal recessive mode. We report the first Italian patient, a girl, affected by CPHD. At neonatal screening the patient was found positive for congenital hypothyroidism (with low TSH levels). Substitutive therapy was started, but subsequent growth was very poor, while psychomotory development was substantially normal. At the age of 10 months she was hospitalised because of a hypotonic crisis. Clinical examination on admission showed prominent forehead, a depressed nasal bridge, antverted nostrils and a small facial skull. She showed growth retardation (below the 3rd percentile) and her bone age was delayed. EEG was normal. A remarkable nonketotic hypoinsulinemic hypoglycemia (36 mg/dl) was detected with normal cortisol but prolactin was not detectable; IGF-1 and IGFBP-3 were below the normal range. HGH stimulation tests (arginine, clonidine and GHRF) showed a total unresponsiveness. Substitutive hGH therapy (0,6 UI/day) was begun and subsequently the patient gained 2,5 cm/month. Mutation DNA analysis of all 6 exons and exon/intron boundaries in the patients Pit-1 gene identified the novel Q167K amino acid change at the heterozygous level. The highly conserved Q167 residue is located in the POU-specific domain. No mutation was detected in the other allele. DNA analysis in the probands parents did not identify this amino acid substitution, suggesting a de novo genetic lesion. A benign polymorphism for the Q167K amino acids substitution was excluded by restriction enzymatic analysis of 200 normal alleles. Based on these data it can be hypothesised that the Q167K mutation plays a dominant negative effect.

**Mutation in the IgII domain of FGFR2 causes the eponymous form of Pfeiffer syndrome.** *S-H. Kan<sup>1</sup>, N. Elanko<sup>1</sup>, S.R.F. Twigg<sup>1</sup>, L.R. Cornejo-Roldan<sup>2</sup>, M. Muenke<sup>2</sup>, A.O.M. Wilkie<sup>1</sup>*. 1) Institute of Molecular Medicine, John Radcliffe Hospital, Oxford, UK; 2) Medical Genetics Branch, NHGRI, Bethesda, MD.

In 1964 RA Pfeiffer described a three-generation family showing dominant inheritance of a new form of acrocephalosyndactyly, characterized by craniosynostosis with brachycephaly, broad, medially deviated thumbs and great toes, and variable cutaneous syndactyly. The eponymous label of Pfeiffer syndrome came into use once further patients with this spectrum of features were recognized. In 1994 it was demonstrated that some patients with Pfeiffer syndrome harbour a specific mutation in the fibroblast growth factor receptor 1 (*FGFR1*) gene; the following year, mutations in *FGFR2* were also identified. All *FGFR2* mutations described to date in Pfeiffer syndrome localize to the extracellular IgIII domain.

Investigation of Pfeiffer's original family by Schell *et al* (*Hum Mol Genet* 4:323-328; 1995) showed suggestive linkage to *FGFR2* but did not identify a causative mutation. We revisited this problem by undertaking mutation screening of the entire *FGFR2* gene using Wave DHPLC analysis. We identified substitutions of two adjacent nucleotides, 514G>T and 515C>T, predicting the amino acid substitution A172F, in all three affected members of the family who were available for testing. This substitution replaces a key alanine residue in the IgII domain that is involved in formation of the immunoglobulin fold and makes a receptor:receptor contact during dimerization.

This is the first mutation of the IgII domain to be described in any FGFR, suggesting that further scrutiny of this domain for mutations would be worthwhile. Evaluation of the clinical features described in the original report highlights the relative severity of the limb anomalies in this family.

**MOLECULAR ANALYSIS OF THE CBP GENE IN 65 PATIENTS WITH RUBINSTEIN-TAYBI**

**SYNDROME.** *D. Lacombe*<sup>1,2</sup>, *I. Coupry*<sup>2</sup>, *C. Roudaut*<sup>2</sup>, *M. Steff*<sup>2</sup>, *M.A. Delrue*<sup>1</sup>, *L. Taine*<sup>1</sup>, *B. Arveiler*<sup>1,2</sup>. 1) Dept Medical Genetics, Pellegrin Hospital, Bordeaux, France; 2) University Victor Segalen Bordeaux 2, Bordeaux, France.

Rubinstein-Taybi syndrome (RTS) is a well-known MCA/MR syndrome characterized by growth and mental deficiencies, typical facial dysmorphism, broad thumbs and halluces, various malformations, and an increased risk of neoplasia. RTS is caused by an autosomal dominant mutation, occurring as a submicroscopic deletion or a point mutation, and is due to haploinsufficiency of the CBP (CREB-Binding Protein) gene at chromosome 16p13.3. Gross chromosomal rearrangements and microdeletions detected by fluorescence in situ hybridization (FISH), truncating mutations revealed by the protein truncation test (PTT) and Western blot analysis account for only 20 % of RTS cases. We have developed new molecular tools to thoroughly analyse the CBP gene in a cohort of 65 RTS patients. These include cDNA probes to search for gross rearrangements by Southern blot analysis and to identify CBP mRNA of abnormal sizes on Northern blot, intragenic microsatellite markers to look for intragenic deletions, as well as a complete series of primers to PCR amplify each of the 31 exons of the gene for mutation search by direct sequencing. We have analysed 65 patients using the various techniques and identified 28 mutations : 3 gross rearrangements by Southern blot and/or microsatellite analysis, 1 truncated RNA by Northern blot and 24 point mutations resulting in either stop codons, aminoacid substitutions or abnormal splicing of the CBP RNA. Three additional patients were found to be deleted by FISH analysis. These results showed that a combination of the various techniques allowed to identify a CBP mutation in 47.7 % of RTS cases.

**Sporadic mutations in *TCOF1* arise both in maternal and paternal chromosomes and are not related to advanced parental age.** A. Splendore<sup>1</sup>, E.W. Jabs<sup>2</sup>, M.R. Passos-Bueno<sup>1</sup>. 1) Dept Biol, Univ de Sao Paulo, Sao Paulo, SP, Brazil; 2) Johns Hopkins University School of Medicine, MD, USA.

Sporadic cases of a number of autosomal dominant disorders, including Achondroplasia, Apert, Crouzon and Pfeiffer syndromes have been attributed to advanced paternal age. In all cases, new mutations in the *FGFR* genes that cause these syndromes have been shown to arise exclusively on the paternally-derived chromosome. It has been suggested that new mutations causing Treacher Collins syndrome may also occur preferentially on the germline of older men. Mutations in the *TCOF1* gene are spread throughout its coding region, but exons 23 and 24 are responsible for roughly 1/3 of all known pathogenic changes. To determine whether sporadic mutations in Treacher Collins syndrome occur preferentially on the paternal germline, we selected nine families that had a *de novo* pathogenic mutation either in exon 23 or 24. For all families, paternity was confirmed through five microsatellite markers. A known polymorphism in exon 23 (3938 C®T) was informative for 2 of 4 families with the pathogenic mutation in exon 23. Determination of which polymorphic allele was in *cis* with the mutation was achieved through observation of SSCP patterns and sequencing of PCR products. Through the screening of intron 24, we identified two novel changes (4209+350 C®G and 4209+439 C®A) that allowed us to discriminate paternal and maternal alleles in 4 of 5 families with a 5-bp deletion in exon 24 through ARMS amplification. Three pathogenic mutations - 2 in exon 23 and 1 in exon 24 - were located on the paternally-derived chromosome (mean age 29.5 yrs) and another 3 (all in exon 24) arose on the maternal germline (mean age 25.1 yrs), whereas the 3 remaining families were uninformative. In conclusion, new mutations in *TCOF1*, unlike those in the *FGFR* genes, do not arise preferentially in the paternal germline with no apparent increased age effect. It should be noted that all *FGFR* mutations tested to date were missense, whereas mutations tested in *TCOF1* are frameshift-causing insertions or deletions. This could indicate that these types of change arise through different mechanisms. FAPESP, HHMI, CNPq.

**NOVEL MUTATION IN THE EIF2AK3 GENE IN A CASE OF WOLCOTT-RALLISON SYNDROME. A.**

*Biason-Lauber, M. Lang-Muritano, E.J. Schoenle. Ped Endocrinology/Diabetology, Univ Children's Hosp, Zurich, Switzerland.*

The Wolcott-Rallison syndrome (WRS) is an autosomal recessive disorder characterized by permanent neonatal or early infancy insulin-dependent diabetes mellitus, epiphyseal dysplasia and growth retardation. Mutations in the EIF2AK3 gene have been found in 2 families affected by WRS. Eukaryotic Initiation Factor 2a-kinase 3 regulates protein synthesis during stress by phosphorylating the  $\alpha$  subunit of the eukaryotic initiation factor 2. A two months old girl, the only child of non-consanguineous parents, came to our attention because of severe hypertonic dehydration and diabetic ketoacidosis. She had two prolonged convulsive episodes prior to insulin treatment. The family history revealed that the mother suffers from a mild form of deafness, and that a motherly uncle is affected by type 2 diabetes. Diagnosis of type 1 diabetes was made and insulin treatment initiated. Antiislet cell autoantibodies (IAA, IA2, GAD) were negative and mitochondrial diabetes was excluded. The patient did not show any remission phase and metabolic control was mostly poor. Now, at 5.3 years of age, her average glycosylated hemoglobin is 8.7 % (normal values up to 6%). Her psychomotor development was normal until 2 yo, when she experienced atypical prolonged hypoglycemia with ataxia and hypotonia after an acute viral infection. The follow-up showed a retardation of psychomotor development (developmental age 2.7 years at age 5 years) and growth (height 3 SD, weight 1.6 SD). X-ray imaging identified signs of spondyloepiphyseal dysplasia in the whole skeleton. Mutation analysis of the EIF2AK3 gene was carried out via polymerase chain reaction amplification and direct sequencing of the gene. Based on the clinical data, a diagnosis of WRS was made. The patient carries a homozygous T to C exchange in exon 13 leading to the missense Ser 877 Pro mutation. Ser 877 is located in the catalytic domain and it is conserved among rat, mouse and human EIF2AK3 proteins. The mutation is not a polymorphism since it is absent in 50 normal controls (100 alleles). This is the third case of EIF2AK3 gene mutation related to WRS and confirms the crucial role of EIF2AK3 in pancreas islet and bone development in humans.

**AAAS mutations in patients with Allgrove Syndrome and sequence alterations of the same gene in a patient with iACTHR suggesting a new source or genetic heterogeneity for iACTHR.** C. Farmakidis, F. Sandrini, L.S. Kirschner, C.A. Stratakis. Unit on Genetics and Endocrinology, Developmental Endocrinology Branch, NICHD, Bethesda, MD.

Familial glucocorticoid deficiency due to corticotropin resistance consists of three distinct genetic syndromes, all inherited as autosomal recessive traits: mutations of the *MC2R* gene, isolated ACTH resistance (iACTHR) without *MC2R* mutations, and Allgrove or triple-A syndrome (AS). Our group collected families with iACTHR (N=5) and AS (N=7) to investigate the molecular basis of AS, and also to examine whether mutations of *AAAS* are associated with iACTHR. Sequencing analysis found no ACTHR receptor gene defects in any kindreds. Five of 7 AS families had *AAAS* mutations including a kindred with AS that was homozygous for a missense point mutation (43C>A, Gln15Lys) and showed a distinctly milder AS phenotype. While no mutations were found in the *AAAS* gene of iACTHR families, one iACTHR patient was found to be a heterozygote for a sequence change 503C>T in exon 5. cDNA analysis for this family showed an abnormal splice variant skipping exon 4 leading to a premature stop codon in the mother, also a carrier of the sequence change. In the case of the affected child's cDNA, while *B Actin* control primers yield PCR products, *AAAS* primers known to work do not yield full length cDNA amplicons for the gene, which suggests downregulated expression of the gene. Transfection experiments are on the way to distinguish if the exon 5 sequence change is a neutral sequence alteration or is instead a mutation that causes the post-transcriptional skipping of exon 4 and therefore contributes to the iACTHR phenotype. We conclude that *AAAS* was found mutated in families that we had previously mapped to 12q13. This gene was also found to have a coding sequence polymorphism/mutation in 1/5 of families with iACTHR indicating that there may be overlap in the genetic causes of the two syndromes, as well as genotype-phenotype correlation.

**Comparative analysis of 81 *NR0B1* mutations identified in adrenal hypoplasia congenita patients.** *J.K. Phelan, Y-H. Zhang, B-L. Huang, E.R.B. McCabe.* Pediatrics, UCLA School of Medicine and Mattel Children's Hospital at UCLA, Los Angeles, CA.

A wide variety of mutations in *NR0B1*, the gene encoding the nuclear receptor (NR) superfamily orphan member DAX1, are associated with X-linked adrenal hypoplasia congenita (AHC) and hypogonadotropic hypogonadism. In this study, we examined the types and distributions of all 71 published intragenic *NR0B1* mutations and an additional 10 novel mutations identified in our laboratory by sequencing amplified genomic DNA samples from patients with AHC. Of the 81 mutations, 42 (52%) were frameshifts and were distributed throughout the coding sequence. As many as 22 of these 42 frameshifts may have arisen by slipped mispairing errors of polymerases during DNA replication. Nonsense mutations, also distributed throughout the coding sequence, occurred in 22 of 81 mutations (27%). There are 18 codons in the genetic code, encoding 10 amino acids, which are susceptible to conversion into premature stop codons by single nucleotide substitutions. Among the nonsense susceptible codons in the *NR0B1* coding sequence mutations appeared to occur differentially: the most frequently mutated were TGG (tryptophan, 5/10 sites mutated) and TAC (tyrosine, 6/13 sites mutated). Missense alterations represented 15 of 81 mutations (18.5%). Of these, 14/15 occurred in the DAX1 carboxy terminal region similar to the ligand binding domain (LBD) of a typical NR. The exception to this distribution was the C200W mutation, which was found at the boundary of the DAX1 amino-terminus and the LBD. Of the 37 identified nonsense and frameshift mutations, none appear to have occurred by the deamination of methylcytosine at CpG dinucleotides. Lastly, two in-frame codon deletions were identified among the 81 mutations (2.5%), both in the LBD. In summary, protein truncating frameshift and nonsense mutations are distributed across the *NR0B1* coding sequence, while missense mutations and codon deletions are preferentially found in the LBD. Additionally, slipped mispairing errors during replication area a common cause of *NR0B1* mutations, while CpG methylcytosine deamination mutagenesis is rare.

**Gonadal Mosaicism in Pseudoachondroplasia: A Second Family with a COMP mutation of Asp518His. E.M.**

*Gutter*<sup>1</sup>, *A.C.M. Smith*<sup>1</sup>, *J.T. Hecht*<sup>2</sup>, *C.A. Francomano*<sup>3</sup>. 1) National Human Genome Research Institute, Bethesda, MD; 2) University of Texas Medical School, Houston, TX; 3) National Institute of Aging, Baltimore, MD.

Pseudoachondroplasia (PSACH, OMIM #177170) is a skeletal dysplasia caused by a mutation in the gene encoding cartilage oligomeric matrix protein (COMP). PSACH is characterized by short-limb dwarfism that becomes apparent in early childhood. More than 50 novel mutations have been identified in the conformationally sensitive type 3 calcium binding domains. While this condition is typically inherited in an autosomal dominant pattern, there are several reported cases of known or suspected somatic or gonadal mosaicism. At least three cases of gonadal mosaicism have been confirmed through mutational analysis. Two of these cases were due to mutations in exon 17B, the most common location of identified PSACH mutations, and the other was due to a mutation in exon 18A, G1577C, changing an aspartic acid to a histidine. We report a second unrelated family with the same mutation in exon 18A. Two sisters with typical findings of PSACH presented in early childhood and diagnosis was confirmed by mutational analysis using bi-directional sequencing (GeneDX, Inc., Rockville, MD). Neither parent in this family showed evidence of this mutation through restriction digest analysis in DNA obtained through peripheral blood. The possibility of germline mosaicism in one parent, while not confirmed, remains the most likely explanation for the recurrence of PSACH in this family. It is intriguing that the same mutation was found in two unrelated families, each with two affected daughters, due to gonadal mosaicism. Investigation of isolated or believed spontaneous cases of PSACH is warranted to assist in genetic risk assessment, as somatic or gonadal mosaicism has been identified in several cases.

**Analysis of CAG Repeats Expansion SCA7 in Patients with Usher Syndrome with Cerebellar Alterations. C.**

*Duran<sup>1</sup>, P. Gonzalez<sup>1</sup>, L. Fernandez<sup>1</sup>, J.C. Prieto<sup>1</sup>, S. Plaza<sup>1</sup>, M.L. Tamayo<sup>1,2</sup>.* 1) Instituto de Genetica Humana, Universidad Javeriana, Bogota, Colombia; 2) Fundacion Oftalmologica Nacional, Bogota, Colombia.

The association of retinal degeneration, deafness and cerebellar alterations is present in several diseases, two of them are Usher Syndrome and Spinocerebellar Ataxia type 7 (SCA7). Types of cerebellar abnormalities seen in both diseases are very similar. Usher syndrome (USH) is an AR disorder characterized by congenital sensorineural deafness, vestibular dysfunction, and progressive retinitis pigmentosa. A chronic neurodegenerative process has been suggested in USH. Ataxia and cerebellar abnormalities have also been reported. In Colombia we carried out a neurological evaluation and MRI analysis in USH patients. We observed abnormal gait in 88,9% of USH1, in 66,7% of USH2 patients, abnormal coordination in 33,4% of USH1, in 58,3% of USH2. MRI analysis showed cerebellar abnormalities in 50% of USH1 and 75% of USH2 patients. SCA7 is a progressive neurodegenerative disorder caused by CAG expansion, characterized by cerebellar ataxia (100%) with retinal degeneration (83%), optic atrophy (25%), ophthalmoplegia (53%) and deafness (24%). Brain imaging showed marked atrophy in the cerebellum, particularly in the vermis. We studied 13 USH individuals with cerebellar abnormalities, representing 5 kindreds. Of the 13 individuals 8 (61.5%) were USH1 and 5 (38.5 %) USH2. The MRI findings were atrophy of the cerebellar vermis, enlargement of the cisterna magna, prominence of the folias and enlargement of the superior cerebellar cistern. These patients do not show genetic anticipation. We investigated the normal size range of the SCA7 gene by genotyping of normal Colombian individuals. The range of the number of CAG repeats was 11-17. We analyzed the CAG expansions of SCA7 in USH affected individuals, and did not find SCA7 mutation in any patient. Although we did not find any CAG expansion SCA7 in our USH patients, we consider that taking into account the clinical and neuroradiological findings seen in USH, it is important to emphasize the need to make a differential diagnosis with SCA7, especially in USH sporadic cases, considering the genetic heterogeneity observed in both diseases.

**X- and Y-bearing sperm are not different in CAG repeat size at Huntington's locus , confirming that gender-dependence of expansion arises postzygotically.** *I.V. Kovtun<sup>1</sup>, G. Welch<sup>5</sup>, H.D. Guthrie<sup>5</sup>, K.L. Anderl<sup>4</sup>, R.B. Jenkins<sup>4</sup>, C.T. McMurray<sup>1,2,3</sup>.* 1) Department of Molecular Pharm, Mayo Clinic, Rochester, MN; 2) Biochemistry and Molecular Biology, Mayo Clinic, Rochester, MN; 3) Molecular Neuroscience Program, Mayo Clinic, Rochester, MN; 4) Medicine and Pathology, Mayo Clinic, Rochester, MN; 5) Germplasm and Gamete Physiology Laboratory, USDA, Beltsville, MD.

Huntington's Disease (HD) is a progressive neurodegenerative disorder in which the underlying mutation is a CAG expansion encoding a polyglutamine tract. It has been documented that alterations in length of the CAG repeat after transmission are distinctly dependent on the gender of the transmitting parent. Large changes in repeat number are always associated with paternal transmission in HD. However, by following transmission in HD transgenic mice that model intergenerational instability, we found that CAG repeat size of the mutant human gene is different in male and female progeny from identical fathers. Males predominantly expand the repeat while females predominantly contract the repeat. This has raised the issue of whether the gender dependence of expansion in HD is "imprinted" in the germ cells of the parent or arises from the differences in the postzygotic stages. To distinguish between the two possibilities, we evaluated whether CAG repeat size differed in the X- and Y-bearing sperm of the founding father. Sperm from founding fathers were separated into distinct X- and Y-bearing populations by FACS analysis and the CAG repeat size in each population was evaluated. The purity of sorted cells was confirmed by FISH. We found no difference in CAG repeat distribution among the two sorted populations. We conclude that the gender dependence of CAG expansion in HD mice occurs postzygotically in the early embryo. Since the gender of the embryo is determined by the presence of X,X or X,Y chromosomes, our data support a model in which X- and Y-encoded factors contribute to the expansion.

**Trinucleotide and pentanucleotide repeats in 202 unrelated families with spinocerebellar ataxia.** *I. Silveira<sup>1</sup>, I. Alonso<sup>1,2</sup>, C. Miranda<sup>1,2</sup>, L. Guimarães<sup>1,2</sup>, M.C. Moreira<sup>1,2</sup>, P. Mendonça<sup>1</sup>, A. Ferro<sup>1</sup>, J. Pinto-Basto<sup>1</sup>, J. Coelho<sup>1</sup>, F. Ferreirinha<sup>1,2</sup>, L. Jardim<sup>4</sup>, P. Coutinho<sup>3</sup>, J. Sequeiros<sup>1,2</sup>.* 1) UniGENe, IBMC - Univ Porto, Porto, Portugal; 2) Lab. Genética Médica, ICBAS- Univ Porto, Portugal; 3) Serviço de Neurologia, Hospital São Sebastião, Feira, Portugal; 4) Hospital de Clínicas de Porto Alegre, Brazil.

Eleven neurodegenerative disorders characterized by spinocerebellar ataxia (SCA) are known to be caused by trinucleotide repeat (TNR) or pentanucleotide repeat expansions. We have (1) assessed trinucleotide and pentanucleotide sizes at all known loci, (2) determined frequency distributions of normal alleles and (3) of expansions, and (4) looked at genotype-phenotype correlations, in a large group of Portuguese and Brazilian patients with SCA. No differences were found in frequency distributions of normal alleles in both groups; DRPLA, MJD1, SCA1, SCA8, TBP, and SCA6 were the most polymorphic loci. Patients from 110 unrelated families with SCA showed TNR expansions at one of the loci studied; dominantly transmitted cases had (CAG)<sub>n</sub> expansions at the MJD1 (63%), SCA2 (3%), DRPLA (2%), SCA6 (1%) or SCA7 (1%) loci, or (CTG)<sub>n</sub> expansions at the SCA8 (2%) gene, whereas (GAA)<sub>n</sub> expansions in the FRDA gene were found in 64% of families with recessive ataxia. Isolated patients also presented TNR expansions at the MJD1 (6%), SCA8 (6%) or FRDA (8%) genes; in addition, an expanded allele at the TATA-binding protein (TBP) gene, with 43 CAGs, was present in a patient with ataxia and mental deterioration. Associations between frequencies of SCA2 and SCA6, and the frequency of large ANs were found in Portuguese and Brazilians, respectively. Interestingly, no association between the frequency of DRPLA and the frequency of large ANs was found in the Portuguese group. In conclusion, our results show that (1) a significant number of isolated cases with ataxia is due to TNR expansions, (2) expanded DRPLA alleles in the Portuguese may have evolved from an ancestral haplotype, and (3) small (CAG)<sub>n</sub> expansions at the TBP gene may be implicated in ataxia with mental deterioration.

**Dynamic of inclusion formation and processing of huntingtin.** *Y. Trottier<sup>1</sup>, A. Lunkes<sup>1</sup>, K.S. Lindenberg<sup>2</sup>, D. Devys<sup>1</sup>, G.B. Landwehrmeyer<sup>2</sup>, J.L. Mandel<sup>1</sup>.* 1) IGBMC/ULP/CNRS/INSERM U184, Strasbourg, France; 2) Department of Neurology, University of Ulm, 89075 Ulm, Germany.

Cellular and animal model systems for Huntingtons Disease (HD) have demonstrated that formation of nuclear inclusions (NIs) and cytoplasmic inclusions (CIs) depends primarily on the number of Glns and the length of the huntingtin (htt) protein expressed. In cellular models in particular, NIs were mainly observed with very truncated versions of htt and only in a few instances with full length htt in a low frequency of cells. We have previously reported that a tetracycline inducible cell model expressing truncated versions of htt or full length htt is able to produce both CIs and NIs at a high frequency (Lunkes et al. HMG 1998). Using our cell model, we show that CIs and NIs form with different dynamics thereby reflecting a different make-up of NIs versus CIs. On immunofluorescence analysis with antibodies that recognize different htt epitopes, we observe that in both, our cell model and in HD brains, NIs and CIs are heterogenous and are composed of different forms of htt cleavage products. Disaggregation of the NIs formed in the cell model reveals a major breakdown product that is highly ubiquitinated. We have identified a domain of 10 aminoacid in which htt cleavage most likely occurs and we are currently performing mutagenesis to assess whether inhibiting the cleavage will prevent NI formation.

**Slowly progressive cerebral dysfunction with selective striatal neuronal inclusions in a rat model transgenic for the Huntington disease mutation.** *O. Riess<sup>1</sup>, I. Schmitt<sup>2</sup>, H.P. Nguyen<sup>3,9</sup>, C. Holzmann<sup>1</sup>, T. Schmidt<sup>1</sup>, T. Walther<sup>4</sup>, M. Bader<sup>4</sup>, R. Pabst<sup>3</sup>, P. Kobbe<sup>3</sup>, D. Stiller<sup>6</sup>, A. Kask<sup>6</sup>, A. Vaarmann<sup>7</sup>, S. Rathke-Hartlieb<sup>8</sup>, J.B. Schulz<sup>8</sup>, U. Grasshoff<sup>1</sup>, I. Bauer<sup>1</sup>, M. Paul<sup>4</sup>, B. Landwehrmeyer<sup>5</sup>, X.J. Li<sup>9</sup>, St. von Hoersten<sup>3</sup>.* 1) Dept Med Gen, Children's Hosp, Univ Rostock, Rostock, Germany; 2) Dept Neurol, Univ Bonn, Bonn, Germany; 3) Funct and Appl Anatomy, Hannover Med School, Germany; 4) Max-Delbrueck-Center, Berlin, Germany; 5) Dept Neurol, Univ Ulm, Ulm, Germany; 6) Non-invasive Imaging, Leibnitz Inst of Neurobiol, Magdeburg, Germany; 7) Dept Pharmacol, Univ Tartu, Estonia; 8) Dept Neurol, Univ Tuebingen, Germany; 9) Dept Genetics, Emory Univ, School Med, Atlanta, USA.

Huntington's disease (HD) is a slowly progressive neurodegenerative disorder clinically characterized by involuntary movements, cognitive alterations and emotional and behavioural disturbances of mid-life onset. The disease is caused by a CAG trinucleotide repeat expansion in a gene of unknown function. To create an animal model for HD which is more suitable for behavioural and MR/PET-studies than mice we generated transgenic rats carrying a truncated HD-gene fragment including 51 CAG repeats under the control of the native HD promoter. These rats develop signs of HD including nuclear inclusions, neuropil aggregates, and altered tryptophan metabolism in the striatum and showed striatal shrinkage in MRI scans. Furthermore, they exhibit a slow progressive neurological phenotype composed of emotional disturbance, cognitive impairments, and motor dysfunction. This is the first transgenic rat model of a neurodegenerative disorder of the central nervous system closely resembling a human disease.

**Length of the CAG repeat in the SCA1 gene, but not Apo E status, modifies age of onset in spinocerebellar ataxia type 2 (SCA2).** *S.M. Pulst<sup>1</sup>, N. Santos<sup>2</sup>, L. Velazquez<sup>2</sup>, K.P. Figueroa<sup>1</sup>*. 1) Med, Div Neurology, Cedars-Sinai Medical Ctr, Los Angeles, CA; 2) CIRAH, Holguin, Cuba.

Expansion of a polyglutamine (polyQ) tract is a common mutation in several genetic late-onset neurological diseases. Although there is a clear inverse correlation between age of onset (AO) and repeat length, a significant variation is observed in the AO for a given CAG repeat length. For example, 37 repeats in the SCA2 gene are associated with an AO ranging from 15 to 65 years of age. To identify genetic modifiers of AO in SCA2 we analyzed age of onset and SCA2 repeat length in 300 patients from Holguin, Cuba. As reported for other polyglutamine diseases CAG repeat length contributed <60% of variation in AO in Cuban SCA2 patients. For each repeat class we determined mean age of onset and standard deviation (SD). Patients with an AO greater than the mean+1SD (n=31) constituted the 'delayed' onset group, patients with an AO of mean-1 SD (n= 33) the 'premature' onset group. We compared the frequency of alleles for the following candidate genes: SCA1, 3, 6, 7, apoE, hSKCA3, RAI1. Allelic association was detected only for CAG repeats in the SCA1 gene. Statistical significance was confirmed both for a threshold model for repeats > 30 (chi square test; (p=0.001) and for a model assuming a continuous effect of CAG alleles (Wilcoxon rank test; p=0.005). We could not confirm RAI1 as an age of onset modifier in this population. These results provide evidence for a possible association between longer alleles in the SCA1 gene and age of onset of SCA2. It is important to note that ataxin-1 and ataxin-2 have a very similar cellular distribution including strong expression in Purkinje cells and CA3 neurons of the hippocampus thus providing a biologic rationale for the observed association. Ataxin-1 proteins with long normal alleles may contribute to overall cellular stress over long time periods, thus aggravating the cellular dysfunction caused by pathologically expanded SCA2 repeats. Due to relative genetic homogeneity and similar environmental exposure the ataxia population in Holguin may represent a unique population to study age of onset modifiers for neurodegenerative diseases.

**Autosomal dominant susceptibility to tuberculosis in a multi-case pedigree.** *S.J. Campbell<sup>1</sup>, G.S. Cooke<sup>1</sup>, D.A. Lammas<sup>2</sup>, R. Barretto<sup>2</sup>, A.V.S. Hill<sup>1</sup>.* 1) WTC for Human Genetics, University of Oxford, UK; 2) Medical Research Council Centre for Immune Regulation, University of Birmingham, UK.

Clinical tuberculosis (TB) in people of British origin is now fairly uncommon in the UK and most often seen in people who have travelled from endemic regions of the world or who have an immunodeficiency, such as being HIV positive. Here we present a unique three-generation family from the UK who have no defined risk factors, yet have suffered from recurrent episodes of clinical TB. The episodes of TB seen in this family span 19 years, have occurred more than once in four members and in total have affected eight members of the family. One member has also been affected by a severe episode of *Aspergillus* infection. In the lungs, the alveolar macrophage is the first line of defence against both *Mycobacterium tuberculosis* and *Aspergillus*. The co-occurrence of both infections in this family is highly suggestive of a specific immune defect, possibly affecting some aspect of macrophage function.

Analysis of the pedigree suggests genetic susceptibility governed by an autosomal dominant, single major gene. Therefore, with the prior hypothesis that there is a dominant susceptibility locus in this family, a genome wide screen was carried out to locate it. 343 microsatellite markers spanning 22 autosomes were typed, the average distance between any two informative markers being 10cM (maximum 25cM). Multipoint analysis with GenehunterPlus, gave a maximum LOD score of 2.43, strongly supporting the presence of a dominant major susceptibility gene in this family.

**A nonsense mutation in CRYBB1 underlies autosomal dominant cataract linked to human chromosome 22q. D.S.**

*Mackay*<sup>1</sup>, *W. Walker*<sup>1</sup>, *K.J. Lampi*<sup>2</sup>, *A. Shiels*<sup>1</sup>. 1) Department of Ophthalmology and Visual Sciences, Washington University School of Medicine, St Louis, MO 63110; 2) Department of Oral Molecular Biology, Oregon Health Sciences University, Portland, OR 97201.

Non-syndromic hereditary cataract is a clinically and genetically heterogeneous lens disorder that most often presents as an autosomal dominant sight-threatening trait in childhood. Here we identify a locus for an autosomal dominant form of pulverulent cataract that maps to the b-crystallin gene cluster on chromosome 22q. Linkage analysis gave tentatively positive two-point LOD scores at markers D22S1167 ( $Z=2.09$  @  $q=0$ ) and D22S1154 ( $Z=1.39$  @  $q=0$ ). Haplotyping indicated that the cataract gene lay in the ~1.4cM interval between markers D22S1167 and D22S1154, which flank the genes for bA4-crystallin (CRYBA4) and bB1-crystallin (CRYBB1). Sequencing failed to detect any nucleotide changes in CRYBA4, however a G→T transversion was found in exon six of CRYBB1. Allele-specific PCR analysis showed that the G→T change co-segregated with affected individuals in the pedigree but was not present in twenty-five normal unrelated individuals. This single nucleotide change was predicted to introduce a chain termination mutation at codon 220 that changed glycine to a translation stop codon (G220X). Expression of recombinant human bB1-crystallin showed that the truncated G220X mutant was significantly less soluble in bacteria than its wild type counterpart. This study has identified the first mutation in CRYBB1 associated with autosomal dominant cataract in humans.

**Autosomal dominant canine malignant hyperthermia is caused by a mutation in the gene encoding the skeletal muscle calcium release channel (*RYR1*).** *M.C. Roberts<sup>1</sup>, J.R. Mickelson<sup>1</sup>, E.E. Patterson<sup>2</sup>, T.E. Nelson<sup>3</sup>, P.J. Armstrong<sup>2</sup>, D. Brunson<sup>4</sup>, K. Hogan<sup>4</sup>.* 1) Veterinary PathoBiology, Univ Minnesota, St Paul, MN; 2) Small Animal Clinical Sciences, Univ Minnesota, St. Paul, MN; 3) Anesthesiology, Wake Forest Univ, Winston-Salem, NC; 4) Anesthesiology, Univ Wisconsin, Madison, WI.

Malignant Hyperthermia (MH) is an inherited muscle disorder, characterized by rhabdomyolysis, generalized skeletal muscle contracture, cardiac dysrhythmia, renal failure, and typically an elevated body temperature, that develops when susceptible patients are exposed to succinylcholine or volatile anesthetics. All swine and 50% of human MH is caused by a mutation in the skeletal muscle calcium release channel of the sarcoplasmic reticulum, also designated as the ryanodine receptor (*RYR1*). To determine the molecular basis for canine MH, a breeding colony was established with a male Labrador Retriever who survived a reaction to halothane. He was mated to three unaffected females to produce four litters, and backcrossed to an affected daughter to produce one litter. An affected son of his was mated to an unaffected female to produce one litter. All dogs were phenotyped with an in vitro contracture test (IVCT), and they were diagnosed as MH susceptible (MHS) or MH normal (MHN). There were 21 MHS and 18 MHN pups in the five outcross litters. In the backcross litter there were two MHS and one MHN, and five pups that did not survive past two months. Pedigree analysis revealed MHS in this colony to be transmitted as an autosomal dominant trait. *RYR1* has been mapped to canine chromosome 1 (CFA01), and eight CFA01 microsatellite markers were tested for linkage to MHS. The marker closest to *RYR1*, FH2294, is linked to MHS at a distance of 5 cM with a LOD score of 8.9. The *RYR1* cDNA was partially sequenced and a polymorphism was found at base pair 1640 that changes amino acid 547 from a valine to an alanine. This polymorphism segregates with the affected individuals, and has a LOD score of 12.29 at  $Q = 0.0$  with the MHS locus. The polymorphism changes a highly conserved amino acid, which supports its role as the causative MH mutation.

**A novel gene for autosomal dominant Stargardt-like macular dystrophy with homology to the SUR4 protein family involved in very long chain fatty acid synthesis.** *R.L. Ritter<sup>1</sup>, L.A. Donoso<sup>2</sup>, A.O. Edwards<sup>1</sup>*. 1) Dept Ophthalmology, Univ Texas Southwestern, Dallas, TX; 2) Wills Eye Hospital, Philadelphia, PA.

**Purpose:** To describe a novel gene causing a Stargardt-like phenotype in a dominant macular dystrophy family and the exclusion of all known genes within the disease locus.

**Methods:** Meiotic breakpoint mapping in a family of 2,314 individuals enabled refinement of the location of the disease gene. The genomic organization and expression profile of known and putative genes within the critical region were determined using bioinformatics, cDNA cloning, and RT-PCR. The coding sequence of genes expressed within the retina was scanned for mutations using DNA sequencing.

**Results:** The disease-causing gene (*STGD3*) was further localized to 562 kb on chromosome 6 between D6S460 and a new polymorphic marker centromeric to D6S1707. Of the 4 genes identified within this region, all were expressed in the retina or retinal pigment epithelium. The only coding DNA sequence variant identified in these 4 genes was a 5 bp deletion in exon 6 of *ELOVL4*. The deletion is predicted to lead to a truncated protein with a net loss of 44 amino acids including a dilysine endoplasmic reticulum retention motif. The *ELOVL4* gene is the fifth known example of a predicted human protein with homology to mammalian and yeast enzymes involved in the membrane bound fatty acid chain elongation system. The genomic organization of *ELOVL4* and primer sets for exon amplification are presented.

**Conclusions:** *ELOVL4* causes macular dystrophy in this large family distributed throughout North America and implicates fatty acid biosynthesis in the pathogenesis of macular degeneration. The PRC-based assay for the 5 bp deletion will facilitate more accurate genetic counseling and identification of other branches of the family.

**North American Indian Childhood cirrhosis (NAIC or CIRH1A): fine mapping and sequencing of candidate genes.** *P. Chagnon, G.A. Mitchell, A. Richter.* Service de Génétique Médicale, Hôpital Sainte-Justine, Montréal, Québec, Canada.

NAIC/CIRH1A (MIM 604901) is an early onset, familial cholestasis, frequent in the Ojibway-Cree population of the Abitibi region in north-western Quebec, Canada. Our clinical collaborators identified a total of 30 cases. The disease typically presents with transient neonatal jaundice in a child who is otherwise well, and progresses to biliary cirrhosis requiring hepatic transplantation in childhood or young adulthood. Clinical and physiological investigations have failed to discover the underlying cause of NAIC. We mapped the NAIC locus by homozygosity to chromosome 16q22 using DNA samples from 13 patients. High-density mapping identified a five-marker haplotype (D16S3067, D16S752, D16S2624, D16S3025 and D16S3106) spanning 4.9 cM that is shared by all affected individuals (Btard et al. *Am. J Hum Genet* 67:222-228,2000). Recently we recruited a new patient, his mother as well as 2 siblings of a previously sampled patient to the study and obtained DNA from archival tissue samples from 6 patients. In order to better delimit the NAIC gene critical region, we have recently genotyped 6 other markers (D16S421, D16S3085, D16S3095, D16S3066, D16S3115 and D16S3086) mapped to 16q22. The observed recombination events indicate that the NAIC region is located between D16S3085 and D16S3095. Data in the Human Genome Browser (<http://genome.ucsc.edu/>) currently estimates the physical distance between these two markers at 2,3 Mb. This region contains around 60 genes. In order to identify the NAIC gene we are proceeding with a sequence based approach that compares gene sequence obtained in patient DNA with that of heterozygote parents and unaffected controls. The complete coding regions and some flanking intronic sequence of twelve genes, most preferentially expressed in liver (CA7, CES2, SLC9A5, HSD11B2, ATP6DV, PSMB10, LCAT, CDH1, HAS3, TAT, DHODH and PRP16) have now been sequenced. In addition, we also sequenced representative ESTs from 10 Unigene clusters that are expressed in fetal liver. Although the causal mutation of NAIC remains to be identified, we found many neutral SNPs that are associated with the disease and confirm the microsatellite markers analysis.

**A Novel mutation in TM4SF2 causes MRX58.** *F.E. Abidi<sup>1</sup>, E. Holinski-Feder<sup>2</sup>, G. Turner<sup>3</sup>, F. Kooy<sup>4</sup>, H.A. Lubs<sup>5</sup>, R.E. Stevenson<sup>1</sup>, C.E. Schwartz<sup>1</sup>.* 1) JC Self Res Inst, Greenwood Genetics Ctr, Greenwood, SC; 2) Medizinisch Genetisches Zentrum, Bayerstrasse 53, D-80335, Munchen, Germany; 3) University of Newcastle, Hunter Genetics, Waratah, New South Wales, Australia; 4) Department of Medical Genetics, University of Antwerp, Antwerp, Belgium; 5) Department of Pediatrics/Genetic Division, University of Miami, School of Medicine, Miami, FL.

Approximately 210 XLMR conditions (136 MRXS and 74 MRX) have been mapped. To date, 34 genes have been cloned. Of these, 9 are MRX genes: FMR2, OPHN1, GDI1, PAK3, RSK2, IL1RAPL, ARHGEF6, TM4SF2 and MECP2. One of these genes, TM4SF2, maps to Xp11.4 and is a member of the transmembrane 4 superfamily. We have screened probands from 14 families (10 linked to Xp11.4 and 4 small families with no linkage data) for mutations in the TM4SF2 gene. We report a novel 2 bp deletion (564delGT) in MRX58, which segregates with MR in the family. This deletion causes a frame shift at amino acid 186 (FS186X) thereby resulting in stop codon six amino acids downstream. The deletion falls in the 2nd extracellular domain and results in a truncated protein missing the 4th transmembrane as well as the carboxy end of the gene. The phenotype observed in MRX58 consists of mild to moderate MR with no dysmorphic features and is not much different from the phenotype reported in a family with a truncating mutation removing a similar portion of the TM4SF2 (Zemni et al. 2000). This implies that loss of function of the TM4SF2 results in a phenotype comprised mainly of an impaired cognitive function. Furthermore, our finding also supports the hypothesis that many of the published XLMR conditions could be due to mutations in the same gene.

**In search of MFS2 gene, the second gene implicated in Marfan syndrome.** *C. Boileau<sup>1, 3</sup>, K. Dahan<sup>1</sup>, MC. Bouterin<sup>1</sup>, G. Jondeau<sup>2</sup>, O. Dubourg<sup>2</sup>, JP. Bourdarias<sup>2</sup>, C. Junien<sup>1, 3</sup>, G. Collod Beroud<sup>1, 3</sup>.* 1) INSERM U383, Hopital Necker Enfants Malades, Paris, France; 2) Service de cardiologie, Hopital Ambroise Pare, Boulogne, France; 3) Laboratoire central de Biochimie, d Hormonologie et de Genetique moleculaire, Hopital Ambroise Pare, Boulogne, France.

It is now well established that defects in the fibrillin gene located on chromosome 15 (FBN1) cause not only classic Marfan Syndrome (MFS), but also a large range of milder, overlapping phenotypes. MFS was the founding member of the "heritable disorders of connective tissue". Cardinal manifestations of this autosomal dominant syndrome involves the eye, skeleton, and cardiovascular systems. We have been investigating a large family of more than 200 subjects presenting with MFS. By excluding the FBN1 locus in this large French family we raised the issue of genetic heterogeneity in MFS and the implication of a second locus (MFS2). Linkage analyses, performed in this family with dispersed anonymous DNA markers, have localized MFS2 successively to a region of 9 cM then less than 7 cM between D3S1293 and D3S2335 which map at 3p24.2-p25. The analysis was enlarged to 20 new family members and 4 new dinucleotide and 4 tetranucleotide DNA markers were tested in the family. These data refined the genetic localization of MFS2 to an area of less than 1 cM between markers D3S1583 and D3S3700. This region has an estimated physical distance of less than 1,5 Mb. Combination of data from the different integrated maps shows less than 60 potential cDNA transcripts. We have constructed complete YAC and BAC contigs and the transcriptional map of the critical region and located 6 known genes that are not plausible candidates (RAR beta, THRB, RPL15, NR1D2, UbcH6, kappa-B-RAS) and 18 regional ESTs. Of these 18 ESTs, 7 represent unknown genes. We are currently searching for the complete sequence of corresponding genes by Race PCR.

**Homozygosity mapping in a Norwegian family of a new locus for autosomal recessive ataxia to 20q11-q13. L.**

*Tranebjaerg*<sup>1,2</sup>, *T.M. Teslovich*<sup>3</sup>, *M.M. Barmada*<sup>5</sup>, *T. Fagerheim*<sup>2</sup>, *M. Jones*<sup>4</sup>, *A. Dahl*<sup>6</sup>, *E.M. Gillanders*<sup>4</sup>, *J.M. Trent*<sup>4</sup>, *D.A. Stephan*<sup>3</sup>. 1) Dept Audiology, H:S Bispebjerg Hosp, DK-2400 Copenhagen, Denmark; 2) Dept Med Genet, Univ Hosp, N-9038 Tromsø, Norway; 3) Res Center Genet Med, Children's Nat Med Center, Washington, DC 20010; 4) Cancer Genet Branch, Nat Hum Genome Res Inst, NIH, MD 20892; 5) Dept Hum Genet, Univ Pittsburgh, PA 15261; 6) Dept Neurol, Univ Hosp, N-Oslo.

Autosomal recessive ataxia shows genetic heterogeneity with loci identified for 6p21-23, 8q13.1 (vit-E deficiency), 9q33.3 (Friedreich ataxia), 10q34, and 19p13.3.

A six-generation Norwegian inbred family with slowly progressive autosomal recessive ataxia (Kvistad PH, et al. *Acta Neurol Scand*, 1985; 71:295-302) has been re-investigated. Seven patients, aged 4-59, had delayed walking ability, and infantile ataxia with cerebellar atrophy on CT-scans, but otherwise normal electrophysiological examinations. Six patients, and 17 additional family members provided DNA for a genome-wide scan with 412 microsatellite markers at 10 cM spanning. Six additional markers from chromosome 20 were genotyped. Multipoint nonparametric (NPLall) analysis demonstrated significant linkage (p-value < 0.007) for markers in the 22 cM region between D20S112 and D20S119 (20q11-q13). Markers in the 4.7 cM region between D20S912 and D20S884 were homozygous in all affected individuals. The mapping of a new locus for ataxia extends previously reported genetic heterogeneity.

We thank Jeff Trent at Cancer Genetics Branch, NHGRI, NIH, for providing expert laboratory facilities for this study. *Kvistad PH, et al Acta Neurol Scand., 1985; 71:295-302.*

**CHILD syndrome: molecular and functional analysis.** *K.-H. Grzeschik<sup>1</sup>, A. Koenig<sup>2</sup>, D. Bornholdt<sup>1</sup>, H. Engel<sup>1</sup>, R. Happle<sup>2</sup>.* 1) Dept Human Genetics, Philipps Univ, Marburg, Germany; 2) Dept Dermatology, Philipps Univ, Marburg, Germany.

CHILD syndrome (Congenital Hemidysplasia with Ichthyosiform Nevus and Limb Defects, MIM 308050, an X-linked dominant, male-lethal trait characterized by an inflammatory nevus that usually shows striking lateralization with strict midline demarcation as well as ipsilateral hypoplasia of the body is caused by mutations in the gene NSDHL (NAD(P)H steroid dehydrogenase-like protein) encoding an enzyme functioning in the distal Kandutsch-Russell pathway for cholesterol biosynthesis. NSDHL maps to Xq28. Heterozygous nonsense or missense mutations, scattered over the coding region, were identified in 19 patients with CHILD syndrome. The severe developmental defects in CHILD syndrome may originate from teratogenic by-products of the cholesterol biosynthetic pathway or a disturbance of the synthesis of steroid hormones. The pattern of lateralization observed in most CHILD syndrome patients appears to be unique and difficult to explain. In fibroblasts from the affected side of different patients, X-chromosome inactivation is skewed in different proportions, however, on the non-affected side only the X with the intact NSDHL appears to be active. This pattern might reflect a defect of the mixing of differentially inactivated cells during gastrulation or, alternatively, asymmetric gene expression in and around the node which is responsible for left-right determination in vertebrates might result in lateralized selection against NSDHL-deficiency in a population of cells with X-chromosomes inactivated at random. Two murine X-linked dominant male-lethal traits, bare patches (Bpa) and striated (Str) had previously been associated with mutations in *Nsdhl*. The skin defect in these mice provides a model for the development of ichthyosis. However, the lack of lateralization of the skin defect in Bpa and Str questions the role of the mouse as a model for the study of left/right determination in early human development. CHILD syndrome heralds a gene that plays a pivotal role at an early stage of human development, when the formation of the primitive streak confers a bilateral symmetry on the embryonic disk.

**A defect in a novel Nek-family kinase causes cystic disease in the mouse and in zebrafish.** S. Liu<sup>1</sup>, W. Lu<sup>1</sup>, S. Kuida<sup>1</sup>, T. Obara-Ishihara<sup>2</sup>, I. Drummond<sup>2</sup>, D.R. Beier<sup>1</sup>. 1) Genetics Division, Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 2) Renal Division, Massachusetts General Hospital, Boston, MA, United States.

The murine autosomal recessive juvenile cystic kidney (*jck*) mutation results in progressive polycystic kidney disease (PKD). Using a positional cloning strategy, we identified a mutation in a novel gene that is a member of the the Nek (NIMA-related-kinase) protein family, which we call *Nek8*. The mutation results in a glycine-to-valine substitution in a highly conserved motif contained in the presumptive regulatory domain of the protein. To prove that a defect in the *Nek8* gene causes cystic disease, we performed a cross-species analysis taking advantage of the evidence that morpholino anti-sense oligos can be used to abrogate gene function in developing zebrafish. Treatment of embryos with an oligo corresponding to the 5' end of the zebrafish ortholog of *Nek8* resulted in the formation of pronephric cysts.

Immunohistochemical analysis of an HA-tagged *Nek8* construct transfected into COS cells demonstrates that the protein is localized in the cytoplasm. Transfection of either the *jck* mutant *Nek8* gene or a construct mutated in the kinase domain results in markedly enlarged and multinucleated cells. These enlarged cells demonstrate a striking loss of actin stress fibers. Mutant *jck* kidneys do not show multinucleation in vivo and immunohistochemical analysis does not show mislocalization of membrane proteins. However, EM analysis reveals that, prior to cyst formation, there is a dramatic expansion and disorganization of the basal labyrinth and the collecting duct epithelia appear to be lifting off the basement membrane. We suggest that a disruption in actin cytoskeletal assembly by the *jck* mutation affects cellular transport functions, which results in the development of cysts. Further, we suggest that a comparative analysis of gene function in different model systems represents a powerful means to annotate gene function.

**Characterisation of a novel gene on distal 11q as a potential candidate for Hypoplastic Left Heart Syndrome.**

*H.M. Phillips<sup>1</sup>, G. Renforth<sup>2</sup>, M. Jackson<sup>1</sup>, M. Clement-Jones<sup>1</sup>, L. Craven<sup>1</sup>, B. Havarani<sup>1</sup>, D.I. Wilson<sup>2</sup>.* 1) Institute of Human Genetics, University of Newcastle Upon Tyne, Newcastle Upon Tyne, England, UK; 2) Division of Human Genetics, Southampton University, Southampton, UK.

Hypoplastic Left Heart Syndrome (HLH) is a severe congenital heart defect, which affects approximately 1 in 5,000 live-born. It is characterised by underdevelopment of the left ventricle with severe atresia of the aortic valve and / or mitral valve. At present the cause of HLH is unknown but there is evidence for a genetic aetiology in a proportion of cases. HLH has been associated with 11q23-qter deletions, (Jacobsen Syndrome), which is characterised by cardiac defects (including HLH), trigonocephaly and thrombocytopenia. We have narrowed down the critical region for cardiac defects within 11q by investigating three patients with HLH, who had terminal deletions of 11q. Using FISH and microsatellite analysis, the breakpoints were mapped and defined an 8Mb region of haploinsufficiency on distal 11q. Within this critical region, genes and ESTs were assessed and one was chosen for further characterisation. Using RACE, full-length cDNA sequence was obtained. Sequence analysis showed that it was a member of a cell adhesion molecule gene family that was highly conserved between species. Northern blot analysis showed that the highest expression was in brain, skeletal muscle, heart, lung, kidney and placenta. More detailed expression analysis was performed using tissue in situ hybridisation on human embryonic tissue sections between Carnegie stages 13-21 (28-52 days post conception). Expression was highest in the neural tube, skeletal muscle and the aortopulmonary valves and atrioventricular cushions of the heart. We are currently investigating isolated and familial cases of HLH for mutations and deletions of this gene. Conclusion: we have significantly refined the critical region on chromosome 11q associated with HLH and identified a gene, the expression of which strongly implicates it as a candidate for this phenotype.

Program Nr: 2569 from the 2001 ASHG Annual Meeting

**Profound effects on neural development obtained by modulating ATRX dosage.** *D.J. Picketts, N.G. Bérubé, M. Jagla, C.A. Smeenk, Y. DeRepentigny, R. Kothary.* Molecular Medicine Program, Ottawa Health Research Inst, Ottawa, Ontario, Canada.

ATRX, a SWI/SNF-like protein, causes severe X-linked mental retardation (XLMR) and a wide range of developmental defects when mutated. Evidence from patient mutations indicate that that the major phenotypic features are sensitive to ATRX dosage. To examine the molecular basis of this dosage sensitivity we have overexpressed ATRX in transgenic mice and assessed its role in neural development. These mice display a variable phenotype including early embryonic lethality and malformation of the neuroepithelium that is suggestive of a defect in cell proliferation. This study demonstrates that ATRX dosage is crucial for cortical development and provides a basis for the XLMR observed in patients.

Program Nr: 2570 from the 2001 ASHG Annual Meeting

**A novel gene is disrupted by a Cornelia de Lange-associated translocation breakpoint at 3q26.3.** *E. Tonkin, M. Smith, P. Eichhorn, D.M. Hagan, S. Herrell, M. Lusher, M. Ireland, J. Burn, T. Strachan.* Institute of Human Genetics, University of Newcastle, Newcastle, UK.

Cornelia de Lange Syndrome (CDLS) is a developmental malformation syndrome characterised by mental handicap, growth retardation, distinctive facial features and limb reduction defects. Although most cases occur sporadically, estimated sib recurrence risks and transmission patterns in rare multicase pedigrees have suggested dominant inheritance. A CDLS locus, CDL1, has been postulated at 3q26.3-q27 based on phenotypic overlap with the duplication 3q syndrome whose critical region has been reported to be 3q26.2-q27, and by the identification of a classical CDLS patient with a balanced de novo t(3;17)(q26.3;q23.1) translocation. We have constructed YAC and BAC/PAC-based contigs for the CDL1 region of chromosome 3, defining the breakpoint. We have mapped a variety of genes in the breakpoint region, including a novel gene with a large transcription unit which is disrupted by the translocation. Northern hybridisation has revealed multiple hybridisation bands with prominent bands in kidney and placenta. The gene has multiple exons spanning more than 1 Mb and is predicted to produce multiple isoforms through alternative splicing/polyadenylation. On-going studies of the expression pattern during early development and mutation-screening will be reported.

**Three novel  $\beta$  thalassemia mutations and other prevalent mutations found in the Celtic (Irish and Scottish) populations.** *P.A. Bignell<sup>1</sup>, A. Jani<sup>2</sup>, C.A. Fisher<sup>1</sup>, S.M. Jobanputra<sup>3</sup>, M. van Mourik<sup>3</sup>, E.A. Chalmers<sup>3</sup>, N.P. Lucie<sup>4</sup>, J.M. Old<sup>1</sup>.* 1) Haemoglobinopathy Laboratory, Weatherall Institute of Molecular Medicine, Oxford, Oxon, UK; 2) Kennedy Galton Institute, Northwich Park, London, UK; 3) Dept of Haematology, Royal Hospital for Sick Children, Glasgow, UK; 4) Dept of Haematology, Western Infirmary, Glasgow, UK.

Thalassemia in Britain was thought to be present predominantly in the ethnic groups that have migrated into the country. However, both  $\alpha$  and  $\beta$  thalassemia has been found in the indigenous population. We have investigated the molecular basis of  $\beta$  thalassemia found in the Celtic population. Fourteen different families with no known foreign ancestry and presenting with typical  $\beta$  thalassemia trait were characterised. DNA was analysed for  $\beta$  thalassemia mutations using a combination of allele specific priming and direct sequencing of genomic DNA amplified by the polymerase chain reaction. Three mutations previously described on mainland Europe were identified. Two were Mediterranean mutations: codon 39 (C $\rightarrow$ T) was found in 9 families and IVS1-110 (G $\rightarrow$ A) in a single family. The third mutation, IVSII-850 (G $\rightarrow$ A), was also found in a single family and has been previously reported in a family of North European origin. Three novel mutations were identified. The mutations codon 131 (+A) and codon 131 (C $\rightarrow$ T) were found in two Scottish families and the mutation codon 125/126 (+A) was found in an Irish family. The prevalence of the two Mediterranean mutations could have resulted from population migration at the time of the Roman occupation of England, but as with the novel mutations, an independent origin of these mutations in the Scottish and Irish populations is possible. The  $\beta$  globin haplotypes associated with these mutations are being studied to investigate this further.

**SAETHRE-CHOTZEN SYNDROME: report on 4 Brazilian families without mutation on TWIST gene. S.R.D.**

*Nascimento*<sup>1,2</sup>, *M.P. Mello*<sup>2</sup>, *V.L.G.S. Lopes*<sup>1</sup>. 1) Medical Genetics Department, State University of Campinas, Campinas, So Paulo, Brazil; 2) 2. Centro de Biologia Molecular e Engenharia Genetica (CBMEG), Universidade Estadual de Campinas , Campinas, SP- Brasil.

Saethre-Chotzen syndrome (acrocephalosyndactyly type III) is an autosomal dominant craniosynostosis syndrome, with high penetrance and variability of expression. This syndrome is characterized by both premature fusion of the calvarial bones (craniosynostosis), facial asymmetry, hypertelorism, blepharoptosis, deviated nasal septum, low frontal hairline, small ear with prominent crura, brachydactyly, broad great toes, and partial cutaneous syndactyly. Mutations in Twist gene ( 7p21 ) have been reported in some patients affected by SCS. Four families with ACS III were screened for Twist mutations. The analysis was carried out by direct DNA sequencing of PCR amplified products for exon 1 in the proband of each family. No Twist mutations were found. This result suggested that this four SCS families may have mutations in other genes of the same developmental pathway. The FGFR2 and FGFR3 genes appears to be implicated in interactions with Twist. Additional screening of these sequences may identify other critical regions involved in the pathogenesis of Saethre-Chotzen syndrome in these families.

**Mutational analysis of DM domain genes in the region on 9p associated with 46,XY gonadal dysgenesis. C.**

*Caloustian*<sup>1</sup>, *C. Ottolenghi*<sup>2</sup>, *G. Berkovitz*<sup>3</sup>, *K. McElreavey*<sup>2</sup>. 1) Le Centre National de Genotypage, Evry, France; 2) Immunogenetique Humaine, Institut Pasteur, Paris France; 3) Division of Pediatric Endocrinology, University of Miami, Miami, Florida.

Mutations in the coding region of the mammalian master sex-determining gene, SRY, account for less than 20% of cases of 46,XY complete gonadal dysgenesis. A similar condition is associated with deletions of the distal short arm of chromosome 9, suggesting that mutations in a locus mapping to band 9p24.3 may be responsible for isolated male-to-female sex reversal in humans. The gene DMRT1, located immediately proximal to the centromeric boundary of the minimal deleted region (at less than 700 kb from the 9p telomere), appears as an interesting candidate because it contains a unique domain, termed DM, that is conserved in two genes involved in invertebrate sex differentiation. Mouse *Dmrt1* is required for testis differentiation. However, anomalies occur postnatally in the mouse knock-out model and previous extensive screens detected only a single potential mutation in a sex-reversed patient. This suggested that the human 9p-deletion phenotype may be a contiguous gene syndrome, possibly involving other DM-containing genes in the region. We sequenced the DMRT1 DM domain in 104 sex reversed patients and found several single nucleotide variants, including a potential de novo missense mutation in a female with 46,XY complete gonadal dysgenesis and in her cryptorchid brother. We also characterised and screened an additional DM domain gene, DMRT3, located 8 kb downstream of DMRT1, and an unrelated, anonymous gene located upstream of it. No mutations were detected in these genes. Although not conclusive, these results strengthen the hypothesis that DMRT1 may be directly involved in human sexual development.

**A novel insulin-like 3 (*INSL3*) gene mutation associated with human cryptorchidism.** P. Marin, A. Ferlin, A. Rossi, E. Moro, L. Bartoloni, C. Foresta. Dpt of Medical and Surgical Sciences, University of Padova, Italy.

Cryptorchidism (impaired testicular descent) occurs in 1-2% of full-term male newborns and it is associated with a high risk of infertility and testicular cancer. The outgrowth of gubernaculum and regression of the cranial suspensory ligament result in the descent of the testes into the scrotum. The aetiology of this disorder is for the most part unknown and genetically heterogeneous. Male mice *Ins13*<sup>-/-</sup> exhibit cryptorchidism due to alteration of gubernaculum development, suggesting *INSL3* as putative gene for such disease. The *INSL3* gene consists of two exons coding for a proprotein characterised by a signal peptide, a B chain, a C-peptide and an A chain. The signal and the C peptide are cleaved during the hormone maturation. We found two aminoacid substitutions in heterozygosis in a patient with cryptorchidism and infertility, the common polymorphism A60T in exon 1 and a novel C to T transition in exon 2, which changes Arg 102 in Cys (R102C). This change was found in one allele over 1146 in a population of ex-cryptorchid patients and controls. The mutated arginine belongs to a conserved stretch of positively charged aminoacids near the C peptide cleavage site. The change of the aminoacid sequence might abolish the processing of C peptide. The *INSL3* receptor links to the A chain N-ter, and, if the C peptide is not excised from the A chain, the hormone will not be able to properly stimulate its receptor. A and B chains are linked by two disulfide bonds, and an extra disulfide bond is present within two A chain cysteines. The presence of an additional Cys in proximity of the N-ter of A chain might interfere with the forming bonds. If the Cys in the mutated residue forms a disulfide bond with one of the other Cys there will be a lacking bond between the chains A and B or an altered A chain conformation. Moreover, even if the cleavage site between C peptide and the A chain is recognised, the cleaved C peptide, attached to the A chain because of the disulfide bond, will sterically disturb the link to the receptor. The low frequency of this base change and the physiochemical differences between R and C suggest that this is a deleterious mutation.

**A Familial Mutation in the Testis-Determining Gene SRY Shared by an XY Female and her Normal Father. B.K.**

*Jordan*<sup>1</sup>, *D. Frasier*<sup>2</sup>, *E. Vilain*<sup>1,2</sup>. 1) Department of Human Genetics, University of California at Los Angeles, Los Angeles, CA; 2) Department of Pediatrics, University of California at Los Angeles, Los Angeles, CA.

In humans, mutations in the testis-determining gene SRY result in XY sex reversal with pure gonadal dysgenesis (PGD). However, only about 25% of the cases of PGD can be explained by mutations within the SRY open reading frame, suggesting the existence of other sex-determining genes. Although SRY is known to bind and bend DNA, its target and mode of action remain elusive. Here we describe a novel mutation in SRY in codon 127, resulting in a Y to F substitution in the protein. This sequence variant was found not only in the XY female patient, but also in her father who is a phenotypically normal male. The substitution affects a highly conserved Tyr residue in the HMG box of SRY, in which a *de novo* mutation has been previously described which caused XY sex reversal with PGD. The fact that another missense mutation in this codon resulted in sex reversal suggests that our observed variant is not a polymorphism. The allelic variant of SRY transmitted in this family and shared by both a phenotypic female (proband) and a phenotypic male (proband's father) emphasizes the effects of modifier genes. In particular, it illustrates the importance of the interaction of specific alleles of polymorphic sex-determining genes on sexual development.

**The Epstein syndrome: a further renal disorder due to mutations in the nonmuscle myosin heavy chain 9 gene.**

*M. Seri*<sup>1</sup>, *M. Savino*<sup>2</sup>, *F. Di Bari*<sup>3</sup>, *D. Bordo*<sup>4</sup>, *R. Cusano*<sup>1</sup>, *B. Rocca*<sup>5</sup>, *R. Landolfi*<sup>5</sup>, *I. Epstein syndrome (EPTS) is an autosomal dominant disease characterized by nephritis, mild hearing loss, and thrombocytopenia with giant platelets. Renal and hearing abnormalities were indistinguishable from those seen in Fechtner syndrome (FTNS), an Alport-like variant. Macrothrombocytopenia is similar to that described not only in FTNS but also in May-Hegglin anomaly (MHA) and Sebastian syndrome (SBS), three disorders due to mutations in the nonmuscle heavy chain myosin IIA (MYH9). The clinical features of EPTS and the chromosomal localization of the respective gene in the same region as MYH9 suggested that this disorder could be allelic with the other giant platelet disorders. We identified MYH9 missense mutations in two familial cases of EPTS. In both families, an Arg702His substitution was found. An amino acid substitution at the same codon (Arg702Cys) has been previously identified in a FTNS patient. Notably, while the mutated thiol reactive group of Arg702Cys may lead to intermolecular disulfide bridges, with consequent formation of the inclusions typical of FTNS, the Arg702His mutation does not allow the protein to aggregate and give rise to Dohle-like bodies, which are indeed absent in EPTS. Finally, in a patient previously diagnosed as EPTS, we identified a de novo Asp1424His substitution identical to that reported in a FTNS patient. An accurate cytological reevaluation allows us to classify this patient. Thus, our results extend the allelic heterogeneity of MYH9 mutations and contribute to clarify the pathogenesis of several clinically distinct syndromes.

**Mutational analysis of the coding and non-coding regions of MECP2 gene, parental origin and X-inactivation studies, in a large cohort of Italian RTT subjects.** *L. Giunti, S. Guarducci, U. Ricci, I. Sani, M.L. Giovannucci Uzielli.* Genetics and Molecular Medicine University of Florence Department of Paediatrics (Italy).

Two years after the identification of the first mutations of MECP2 gene in RTT patients (Amir et al., 1999), many points remain unclear regarding the pathogenic mechanism of MECP2 gene and the apparent genetic heterogeneity of this disorder. Direct Mesp2 sequencing analysis reveals missense, nonsense and frameshift mutations only in a part of RTT subjects, both with classic and non-classic phenotypes. We have already screened a large cohort of RTT subjects, and found that 78% of them presented mutations (82/105). We had only one familial event (normal mother and affected daughter) and 80 isolated, unrelated, RTT affected girls. We have now in progress a deletion analysis of RTT subjects without apparent MECP2 mutation of the coding and non-coding regions, by using Fluorescence in Situ Hybridization. Parental origin of isolated MECP2 mutations by intronic polymorphisms analysis, and X-inactivation studies complete our scientific involvement in this disorder.

**Gene conversion events in adult-onset Spinal Muscular Atrophy.** *R. Mazzei<sup>1</sup>, F.L. Conforti<sup>1</sup>, A. Gambardella<sup>1,2</sup>, A. Magariello<sup>1</sup>, A. Patitucci<sup>1</sup>, A.L. Gabriele<sup>1</sup>, D. Pirritano<sup>2</sup>, A. Labate<sup>2</sup>, M. Muglia<sup>1</sup>, P. Valentino<sup>2</sup>, F. Bono<sup>2</sup>, M. Zappia<sup>2</sup>, A. Quattrone<sup>1,2</sup>.* 1) Institute of Experimental Medicine and Biotechnology National Research Council, Mangone, Cosenza, Italy; 2) Institute of Neurology, School of Medicine of Catanzaro, Italy.

**Objective:** The survival motor neuron (SMN) gene is involved in the pathogenesis of spinal muscular atrophy (SMA). We present the molecular analysis of three patients with adult onset SMA, who carried an apparent homozygous deletion of telomeric SMN (SMNt) exon 7 but not of exon 8. **Materials and Methods:** Patient 1 is a sporadic case, patients 2 and 3 are two brothers. SMN exon 7 and exon 8 were amplified and subsequently digested with DraI for exon 7 and DdeI for exon 8. We found homozygous deletion of the SMNt exon 7 but not of the exon 8 in our SMA patients. In order to amplify a 1,010 bp fragment, we used the primers R111 and 541C1120. The PCR products were further amplified with primers for exon 8, and the fragments obtained were digested with DdeI. **Results:** In all patients the SMNc exons 7 and 8 were present. To distinguish between deletion and a sequence conversion event of telomeric exon 7, we performed an amplification of the region surrounding exon 7 and 8. The resulting 1,010 bp fragments were subjected to nested PCR of exon 8. The subsequent analysis by DdeI digestion showed products for both telomeric and centromeric copies of exon 8. These findings indicate a gene conversion event as the site for primer R111 was retained at least in one of two alleles. **Discussion:** The results of our study have demonstrated that SMA patients with a milder type IV phenotype and an isolated deletion of exon 7 as detected by traditional methods carry a gene conversion event when deeply investigated. As far as we are aware, this is the first evidence of a conversion event in adult-onset SMA in which exon 7 of SMNt is converted to SMNc. **Conclusions:** Our results provide the first evidence that a conversion event may be also associated with adult-onset SMA phenotype, and further support the notion that a gene conversion event may be correlated with a milder SMA phenotype and a later onset of disease.

**A novel mutation in the NOTCH3 gene in an Italian family with CADASIL.** *A.M.F. Patitucci<sup>1</sup>, R. Mazzei<sup>1</sup>, F.L. Conforti<sup>1</sup>, A. Magariello<sup>1</sup>, N. De Stefano<sup>3</sup>, A.L. Gabriele<sup>1</sup>, A. Labate<sup>2</sup>, M. Zappia<sup>2</sup>, A. Gambardella<sup>1,2</sup>, M. Muglia<sup>1</sup>, A. Federico<sup>3</sup>, A. Quattrone<sup>1,2</sup>.* 1) Institute of Experimental Medicine and Biotechnology, National Research Council, Mangone, Cosenza, Italy; 2) Institute of Neurology, Department of Medical Sciences, University of Catanzaro, Catanzaro, Italy; 3) Department of Neurological Sciences, University of Siena, Siena, Italy.

Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) is an hereditary syndrome with adulthood onset, characterized by recurrent strokes. Mutations within the Notch3 gene have been identified as the underlying genetic defect associated with CADASIL. We identified two patients belonging to a large pedigree in whom clinical and laboratory findings were suggestive of CADASIL. We undertook mutation analysis of the Notch3 gene in the two patients. Furthermore, patients underwent to magnetic resonance spectroscopic imaging (MRSI). Sequence analysis of exon 6 showed a new missense mutation CGC>TGC in codon 332, resulting in the replacement of an arginine residue with a cysteine. The restriction enzyme MvnI recognizes the sequence CGCG, and the C>T transition causes the loss of an MvnI restriction site in the mutant PCR product. MvnI cleaves the wild type PCR product of 279 bp into 224 bp and 55 bp digestion fragments, but does not cleave the corresponding region of the Notch3 gene in CADASIL patients. We demonstrated the occurrence of this mutation in the affected subjects of the family, in none of the unaffected members of the family, and in none of the 200 control chromosomes examined. Here we describe a novel mutation occurring in exon 6, a location not previously recognised in CADASIL patients. Similar to previously reported mutational modifications in other exons of Notch3, this mutation is located at the 5' end of the gene and is characterised by the gain of a cysteine residue. It has been proposed that these modifications to the primary sequence affect the folding of Notch3 or induce inappropriate disulfide bonding between Notch3 and other cysteine-containing proteins.

**Isolation, characterisation and mutation analysis of a novel gene in the Noonan Syndrome critical region.** *K. Kalidas<sup>1</sup>, A.H. Crosby<sup>1</sup>, A.M. Ion<sup>1</sup>, H. Kremer<sup>2</sup>, I. Van der Burg<sup>2</sup>, H.G. Brunner<sup>2</sup>, K. Montgomery<sup>3</sup>, R. Goldberg<sup>4</sup>, R.S. Kucherlapati<sup>4</sup>, M.A. Patton<sup>1</sup>, S. Jeffery<sup>1</sup>. 1) Medical Genetics Unit, St George's Hospital Medical School, London, UK; 2) Department of Human Genetics, University Hospital Nijmegen, Nijmegen, Netherlands; 3) Molecular Genetics Department, Albert Einstein College of Medicine, Bronx, New York, USA; 4) Howard Hughes Medical Institute, Whitehead Institute and Department of Biology, Massachusetts Institute of Technology, Cambridge, Massachusetts, USA.*

Noonan syndrome is an autosomal dominant condition characterised by cranio-facial dysmorphism, congenital heart defects and short stature. We have previously mapped a gene for NS to chromosome 12q24.1. We have used RT-PCR, RACE and cDNA library screening to identify candidate genes for NS that map to this region. Here we describe the structure, chromosomal location and expression pattern of a novel gene. We extended the sequence of an EST (Accession ID:10948129) with 5' and 3' RACE. A cDNA library was screened with a probe generated from this sequence and a clone was identified. The 1.6 kb clone was sequenced and comparison to genomic sequence showed that the gene lacked introns and contained a 300bp ORF. The gene was mapped to PAC P784A12 and BACs B385N17 and B435A10. To determine the expression pattern of this gene a 1.2kb sequence was hybridised against a multiple human tissue mRNA blot. The gene is expressed at high levels in heart, lung and placenta. SSCP was used to evaluate this gene for disease specific mutations in a cohort of 20 NS patients. No variants were identified, confirming that this gene does not contribute to the development of Noonan syndrome.

**Mutation analysis of the MECP2 gene in Southern Italy.** *F.L. Conforti<sup>1</sup>, R. Mazzei<sup>1</sup>, A. Fiumara<sup>2</sup>, A. Magariello<sup>1</sup>, A. Patitucci<sup>1</sup>, A.L. Gabriele<sup>1</sup>, G. Barone<sup>2</sup>, R. Nistico<sup>3</sup>, L. Mangone<sup>3</sup>, M. Muglia<sup>1</sup>, L. Pavone<sup>2</sup>.* 1) Institute of Experimental Medicine and Biotechnology, National Research Council, Mangone, Cosenza, Italy; 2) Department of Paediatrics, University of Catania, Catania, Italy; 3) Institute of Neurology, Department of Medical Sciences, University of Catanzaro, Catanzaro, Italy.

Rett syndrome is a childhood neurodevelopmental disorder almost exclusively affecting females. A gene for Rett syndrome (MECP2) has been identified on the X chromosome in q28 that binds to single methylated CpG base pairs throughout the genome and silences other genes. MECP2 encodes the methyl-CpG-binding protein 2, an ubiquitous DNA-binding protein that is thought to act as a global transcriptional repressor. This gene consists of 4 exons encoding 486 aa and shows a highly conserved large 3'UTR region that has been suggested to have regulatory functions. We report a detailed analysis by direct sequencing, of the MECP2 gene in 39 patients from southern Italy with classical or atypical Rett syndrome. Mutations in MECP2 were found in 11 of 15 classical Rett patients (73.3%), in 2 of 6 (33.3%) cases with variant form, and in 1 of 18 Rett-like patients (5.6%). Two novel mutations, not found in 100 control chromosomes, were detected. The first mutation, P376S (1126 C>T), was identified in a patient with classical Rett syndrome and the second, S388P (1162 C>T), was found in a patient with atypical Rett phenotype. To determine the role of X Chromosome Inactivation (XCI) contribute in phenotypic variability in Rett patients, we also evaluated XCI in patients with MECP2 mutations using the AR methylation assay. Our data indicate that the random XCI is associated with most classical Rett patients. In conclusion, our study shows a heterogeneous spectrum of disease-causing MECP2 mutations in a high proportion (73.3%) of classical Rett patients, confirming MECP2 is the major locus involved in the pathogenesis of Rett syndrome.

**Gene mutation and expression in Ellis van Creveld Syndrome.** *M. Galdzicka<sup>1</sup>, J.A. Egeland<sup>2</sup>, M.G. Hirshman<sup>1,3</sup>, S. Patnala<sup>1</sup>, B.M. Martin<sup>3</sup>, W.J. Kleijer<sup>4</sup>, E.I. Ginns<sup>1</sup>.* 1) Brudnick Neuropsychiatric Research Institute, Department of Psychiatry, University of Massachusetts Medical School, Worcester, MA; 2) Amish Study, Department of Psychiatry, University of Miami School of Medicine, Miami, FL; 3) Clinical Neuroscience Branch, NIMH, NIH, Bethesda, MD; 4) Clinical Genetics, Erasmus University, Rotterdam, The Netherlands.

Ellis van Creveld syndrome (EvC) is an autosomal, recessively inherited skeletal disorder manifesting with dwarfism, polydactyly, ectodermal dysplasia, congenital heart disease, and occasionally renal failure. The gene for EvC syndrome, located on human chromosome 4p16.1, has been identified. We have investigated the differential expression of EVC gene in patients from the Netherlands and Old Order Amish from Pennsylvania. We found that some patients having the mutation in the splice acceptor site of intron 13 have either a) two transcripts, one having exon 13 extended by 115 bp and the other with exon 13 spliced out, or b) only one transcript having exon 13 extended by 115 bp. One of the Amish patients who does not have the mutation in the splicing site of exon 13 yields transcripts with additional exons that introduce stop codons in the middle of the protein or transcripts with no alternative splicing. Abnormal splicing of pre-mRNA observed in this Amish individual might be a mechanism responsible for the disease in the Dutch patients. We also examined the genomic DNA sequence for the occurrence of tissue specific transcripts and we identified a mutation that may be responsible for the tissue specific symptoms. However, the expected tissue-specific transcripts have not been observed in fibroblasts or lymphoblasts. Our results suggest that (1) alternative splicing of the EVC gene is tissue specific, and (2) that other factors such as differential expression and/or heterogeneity of alternative splicing may be responsible for a variety of clinical manifestations observed in EvC syndrome.

**Genotype phenotype correlations suggest a contiguous gene syndrome in retinoblastoma patients with germline 13q14 deletion.** *O. Baud*<sup>1</sup>, *F. Doz*<sup>2</sup>, *V. Cormier-Daire*<sup>1</sup>, *C. Turleau*<sup>1</sup>, *B. Bardoni*<sup>3</sup>, *A. Munnich*<sup>1</sup>, *S. Lyonnet*<sup>1</sup>, *A. Tullio-Pelet*<sup>1</sup>. 1) Department of Genetics, Necker Enfants Malades Hospital and INSERM U-393, Paris, FRANCE; 2) the Department of Paediatric Oncology, Institut Pierre et Marie Curie, Paris, FRANCE; 3) IGBMC INSERM U-184 Strasbourg, FRANCE.

Retinoblastoma is the most common malignant intra-ocular tumour of children in developed countries (1/20 000 live births). The retinoblastoma susceptibility gene RB1 located in band 13q14.2 encodes a nuclear phosphoprotein. While most RB1 gene mutations are point mutations, some retinoblastoma cases result from a cytogenetically detectable interstitial deletion encompassing the RB1 locus. The phenotype of such patients varies widely from isolated retinoblastoma to severe neurological impairment, occasionally associated with intra-uterine growth retardation and dysmorphic features suggesting the involvement of contiguous genes. We have studied the breakpoints and genotype/phenotype correlations of 13 patients with constitutional and cytogenetically detectable rearrangements of band 13q14. Chromosomal rearrangements included 11 de novo 13q14 interstitial deletions, and 2 de novo translocations involving chromosome 13q. Among deletions, 9/11 (82%) and 2/11 (18%) were of paternal and maternal origin respectively. In the four deleted patients with normal psychomotor outcome, the deletion spanned the D13S291 to D13S1268 interval (10cM). In contrast, patients with mental retardation presented deletions extending centromeric from locus D13S291 to locus D12S1297. Interestingly, the critical interval between these two markers (2.7 cM), includes the NUFIP1 locus, encoding a protein interacting with FMR1, which could be therefore regarded as a candidate gene for neuromotor abnormalities. Finally, the two patients displaying both neurological abnormalities and prenatal growth retardation harboured a larger deletion extending telomeric with respect to locus D13S176 (8cM). Thus, our data suggest that contiguous genes centromeric and telomeric with respect to RB1 should account for the neurological impairment and growth retardation in our patients.

**NONSENSE MEDIATED mRNA DECAY FOR hMRE11 MUTATIONS.** *L. Chessa<sup>1</sup>, M. Piane<sup>1</sup>, C. Savio<sup>1</sup>, C. Ciotta<sup>2</sup>, A. Muleti<sup>1</sup>, M. Bignami<sup>2</sup>, G. Giannini<sup>1</sup>, E. Ristori<sup>1</sup>, S. Palmeri<sup>3</sup>, A.M.R. Taylor<sup>4</sup>.* 1) II Faculty Medicine, Hosp S Andrea, Rome, Italy; 2) I.S.S., Roma, Italy; 3) Dept. Neurology, University of Siena, Italy; 4) CRC Institute for Cancer Studies, University of Birmingham, UK.

Brother and sister, born to unrelated healthy parents and now in their thirties, were referred some years ago to the Italian Registry for Ataxia Telangiectasia. They were diagnosed as Ataxia without Telangiectasia, due to the mild and slow-progressive neurological features and the absence of telangiectasias. At cellular level both show intermediate radiosensitivity between classical AT and controls. Lymphoblastoid cell lines were established and subsequently used for molecular studies. No mutations in ATM and NBS genes were found at molecular analysis, performed by means of SSCP, HD and direct sequencing. Western blottings for ATM, NBS and Mre11 proteins showed reduced amounts of the three proteins of the p95/Rad50/Mre11 complex. Sequencing of hMre11 gene allowed the identification of the maternal mutation 1612C>A in compound heterozygosity. The second mutation was not apparent at cDNA level, due to nonsense mediated mRNA decay. In fact, it was a truncating mutation (1714C>T) resulting in a stop codon. Interestingly enough, this second mutation was already found in an English family previously described (Stewart et al., 1999). The functional impact of these mutations on the p95/Rad50/Mre11 complex was analyzed by means of Irradiation Induced Foci. We successfully applied a new protocol to study foci on lymphoblastoid cell lines. The complete abrogation of foci formation after g-irradiation at 12 Gy was observed. Work partially granted by Italian Telethon (E.764), AIRC and COFIN (to L.C.) REFERENCES Stewart et al., 1999. The DNA Double-Strand Break Repair Gene hMre11 is mutated in individuals with an Ataxia Telangiectasia-like Disorder. *Cell* 99,577-587.

**Spectrum and distribution of *FOXL2* gene mutations and variants in BPES, POF and XX male patients: tentative genotype-phenotype correlation.**

*E. De Baere*<sup>1</sup>, *M. Dixon*<sup>2</sup>, *K. Small*<sup>3</sup>, *E. Jabs*<sup>4</sup>, *B. Leroy*<sup>1</sup>, *K. Devriendt*<sup>5</sup>, *Y. Gillerot*<sup>6</sup>, *G. Mutations in *FOXL2*, a forkhead transcription factor gene, have recently been shown to cause type I and II blepharophimosis-ptosis-epicanthus inversus syndrome (BPES). In BPES type I a complex eyelid malformation is associated with premature ovarian failure (POF), while in BPES type II the eyelid defect occurs as an isolated entity. We describe the identification of novel mutations in the *FOXL2* gene in BPES type I and II families, in sporadic BPES patients, and in BPES families where the type could not be established. In 67 percent of the patients studied, we identified a mutation in the *FOXL2* gene. We demonstrate that there is a genotype-phenotype correlation for both types of BPES by the finding that mutations predicted to result in a truncated protein both lacking or containing the forkhead domain lead to type I BPES. In contrast, duplications within or downstream of the forkhead domain, and a frameshift downstream of them, all predicted to result in an extended protein, cause type II BPES. In addition, a series of unrelated patients with isolated POF and XX males were screened for *FOXL2* mutations. Several changes were identified, of which the causality is further investigated. Our study provides further evidence that *FOXL2* haploinsufficiency may cause BPES type I and II by the effect of a null allele and a hypomorphic allele, respectively. Furthermore, we propose that in a fraction of the BPES patients the genetic defect does not reside within the coding region of the *FOXL2* gene and may be caused by a position effect.

**FGFRs and TWIST mutations in craniosynostosis patients.** *C. Carbonara*<sup>1</sup>, *M. Valenzise*<sup>2</sup>, *S. Bosso*<sup>3</sup>, *L. Sbaiz*<sup>3</sup>, *P. Peretta*<sup>4</sup>, *L. Genitori*<sup>4</sup>, *M. Silengo*<sup>2</sup>, *G. Restagno*<sup>3</sup>, *G.B. Ferrero*<sup>2</sup>. 1) Dept Neonatology, OIRM-S.ANNA, Torino, Italy; 2) Dept Pediatrics, Univ Torino; 3) Dept Clinical Pathology; 4) Dept Pediatric Neurosurgery, OIRM-S. Anna, Torino, Italy.

Mutations in three of the four fibroblast growth factor receptor genes (FGFRs) and in the transcription factor TWIST have been reported in several craniosynostosis syndromes. Here we report the results of a screening for FGFRs and TWIST mutations in 90 patients surgically treated for various form of craniosynostosis in our department. Clinically the patients could be classified as follows: Crouzon syndrome (8 cases), Saethre-Chotzen syndrome (7 cases), Pfeiffer syndrome (1 case), Apert syndrome (5 cases), isolated plagiocephaly (18 cases), isolated brachycephaly (8 cases), trigonocephaly (16 cases), scaphocephaly (6 cases) and unclassified forms (21 cases). As already described, we observed a higher percentage of mutations among syndromic patients (75%) compared to isolated cases (26%). No mutations have been detected in patients with trigonocephaly, scaphocephaly and unclassified forms. All FGFR2 mutations observed are known molecular defects and have been found in 6 of the 8 patients, in 1/1 Pfeiffer patient and in 5/5 Apert patients. The recently described FGFR3 Pro250Arg mutation has been observed in 3/7 Saethre-Chotzen, in 3/18 isolated plagiocephaly and in 2/8 isolated brachycephaly. Among the 8 patients carrying this peculiar mutation 5 were familiar and 3 sporadic. Mutations in the TWIST gene have been found in 2/7 Saethre-Chotzen and interestingly in 2 cases of isolated plagiocephaly and brachycephaly respectively. One of these five TWIST mutations have been already reported (R116H), the remaining being newly described. All of them are de novo mutations, involving functional domains of the gene. Due to the wide clinical spectrum of phenotypes associated with these mutations, and in particular with TWIST and FGFR3 Pro250Arg, molecular characterization of these conditions represents an important tool in genetic counselling, clinical classification and in the identification of additional candidate gene.

**Molecular Analysis of Concurrent Williams-Beuren Syndrome and Chronic Granulomatous Disease.** *J.M.*

*Gastier, L. Schulz, J. Frick, A.M. Sommer, G.D. Wenger.* Children's Hosp, Ohio State Univ, Columbus, OH.

Williams-Beuren Syndrome (WBS) and Chronic Granulomatous Disease (CGD) are distinct clinical entities that can be caused by abnormalities of loci in the 7q11.23 region. A patient was identified with both disorders. WBS is caused by a 2-3 Mb deletion of band 7q11.23. CGD is usually an X-linked disorder, but an autosomal recessive form is caused by mutations in the NCF1 gene at 7q11.23. To determine the etiology of WBS and CGD in this patient, molecular genetic analysis was performed on somatic cell hybrids (SCH) with the patient's chromosome 7 homologues separated. The inclusion of NCF1 in the common WBS deletion has remained controversial. Analysis of NCF1 is complicated by the presence of proximal (NCF1P1) and distal (NCF1P2) pseudogenes. Genotype analysis of SCH with D7S489 showed deletion of both D7S489B (proximal to NCF1) and D7S489A (distal to NCF1), suggesting that NCF1 is deleted on one chromosome of this patient. TaqI and PstI digestions were performed on amplicons from exons 3-4 of the NCF1 gene. The PCR primers also amplify the same region in the pseudogenes, but single base differences between the true and pseudogenes were distinguished by the restriction enzymes. Digestions of the product from a SCH with the deleted chromosome 7 confirmed the absence of the NCF1 gene and suggested that NCF1P1 is also deleted. The most commonly observed WBS deletion does not include either the D7S489A or NCF1P1 locus, suggesting that this patient may have a larger WBS deletion than normally observed. The most common mutation in NCF1 that leads to CGD is a two base pair (GT) deletion in exon 2, causing a frameshift. This deletion is present in both pseudogenes. In a normal individual, sequencing is not interpretable after the GT deletion due to a mixed population of gene and pseudogene amplicons. Sequence analysis of SCH and patient peripheral blood suggested the presence of the GT deletion in NCF1 on the nondeleted chromosome, as indicated by clean sequence through the region. CGD in this patient was determined to be caused by deletion of the NCF1 locus on the WBS deletion chromosome and the presence of a GT deletion in exon 2 of NCF1 on the other chromosome.

**New update of the FBN1 mutation database.** *G. Collod-Beroud*<sup>1</sup>, *S. Le Bourdeles*<sup>2</sup>, *I. Dehaupas*<sup>2</sup>, *S. Grey*<sup>2</sup>, *C. Junien*<sup>1, 2</sup>, *C. Beroud*<sup>1</sup>, *C. Boileau*<sup>1, 2</sup>. 1) INSERM U383, Hopital Necker-Enfants Malades, Paris, France; 2) Laboratoire Central de Biochimie, d Hormonologie et de Genetique moleculaire, Hopital Ambroise Pare, AP-HP, Boulogne, France.

A major goal of geneticists is to elucidate the molecular basis of human phenotypes. Approximately 5,000 phenotypes are currently known and the number of genes is estimated to be near 30,000. At present, gene-phenotype associations have been identified only between a few hundred genes and specific diseases. For some genes like FBN1, the gene coding fibrillin-1, the situation is more complex with the association of mutations with a large spectrum of conditions related to Marfan syndrome (MFS)(OMIM 154700). FBN1 has also been shown to harbor mutations in ectopia lentis, neonatal Marfan syndrome, Marfanoid skeletal syndrome, atypical Marfan syndrome without cardiac implication, Shprintzen-Goldberg syndrome, some cases of thoracic aortic aneurysms and probably Weill-Marchesani syndrome. All the mutations described in FBN1 are widely distributed throughout the gene with no apparent disease specific or structural/function relationship. To date, the only genotype/phenotype relationship is still limited to exons 24 to 32 in which most mutations causing neonatal Marfan syndrome are clustered. To facilitate the mutational analysis of FBN1 mutations and the identification of structure/function and phenotype/genotype relationships, we created, in 1995, a human FBN1 mutation database which gives access to a software package that provides specific routines that are optimized multicriteria research and sorting tools [NAR, 1998, vol26: 229-233; Hum Mutation 2000, 15: 86-94]. For each mutation, information is provided at gene, protein, and clinical levels. The database has been recently modified to follow the guidelines on mutation databases of the Hugo Mutation Database Initiative including the new nomenclature [Antonarakis et al., Hum Mutation 1998, 11: 1-3]. The current update shows more than 350 FBN1 (137 mutations in the last publication in 1998) and will soon be available on its Internet Web site. You can access the Marfan Site and Mdb at <http://www.umd.necker.fr/>

boileau or collod@necker.fr.

**Myotonic dystrophy in the North of Portugal: a significant but still overlooked problem.** *T. Coelho*<sup>1</sup>, *A. Tuna*<sup>2</sup>, *M. Freijo*<sup>2</sup>, *M.C. Palmares*<sup>3</sup>, *R. Santos*<sup>4</sup>, *M. Santos*<sup>5</sup>, *A. Sousa*<sup>6</sup>. 1) Neurophysiology, HGSA; 2) Neurology, HGSA; 3) Centro Genética Clínica; 4) Inst. Genética Médica Jacinto Magalhães; 5) Neuropediatria, Hospital Maria Pia; 6) Inst. Ciências Biológicas Abel Salazar, Porto, Portugal.

Myotonic dystrophy, one of the most frequent hereditary muscular disorders has never been systematically studied in Portugal. Complete molecular diagnosis became available only recently. Since 1991, 74 cases of myotonic dystrophy from --35 different families were diagnosed at one paediatric (Hospital Maria Pia) and one adult (Hospital Santo António) integrated neuromuscular outpatient clinics in Porto. Recently 32 families (69 patients, 37 female and 32 male) had molecular confirmation of the CTG expansion in chromosome 19. The size of this expansion was quantified in 36 patients. Clinical type, age-of-onset, family history and molecular studies were reappraised in these 69 patients. Age-at-onset was established in 57: congenital form presented in 10 patients (8 probands) and varied from 1 to 63 years in the non-congenital forms. Concerning parental transmission, 28 patients inherited the disease from their fathers and 29 from their mothers; 12 cases had unidentified transmitter. Mean age-of-onset was higher (23.3 years) in offspring of affected fathers than in offspring of affected mothers (13.8 years). Myotonic dystrophy is a relevant problem in the North of Portugal. Systematic molecular diagnosis of all patients will help in ascertainment of families and genetic counselling.

**Diagnostic testing for X-Linked Ocular Albinism (OA1) with an hierarchical mutation screening protocol.** *M.R. Hegde<sup>1</sup>, R.A. Lewis<sup>1,2</sup>, C.S. Richards<sup>1</sup>*. 1) Diagnostic Sequencing Laboratory, Department of Molecular and Human Genetics, Baylor College of Medicine, One Baylor Plaza, Houston, TX 77030; 2) Department of Ophthalmology, Baylor College of Medicine, One Baylor Plaza, Houston, TX 77030.

Albinism is a group of inherited conditions in which affected individuals have less than normal pigment in the eyes, skin, and hair compared to others of the same race and ethnic background. The prevalence of all types of albinism in the United States is estimated at 1 in 20,000, based on poor epidemiological data. X-linked Nettleship-Falls Ocular Albinism (XLOA or OA1) affects ~ 1/150,000 males in the general population. OA1 results in reduced visual acuity with nystagmus and a mild skin and hair phenotype and occurs mostly in XY males. Female carriers of XLOA/OA1 have normal visual acuity but usually show iris punctate transillumination and a classic mosaic pattern of retinal pigmentation. Studies of OA1 have shown linkage of a single gene to markers at Xp22.3-p22.2. About 48% of the reported mutations in the OA1 gene have been intragenic deletions and about 43% are point mutations. We have developed a hierarchical mutation screening strategy for diagnostic analysis for X-Linked Ocular Albinism with multiplex PCR to detect intragenic deletions, dHPLC (Denaturing High Performance Liquid Chromatography) to scan for mutations, and sequencing to confirm putative mutations in OA1 gene. Prenatal diagnosis can be provided to families after the mutation has been identified. Symptomatic males are tested with a multiplex PCR-based assay for all nine exons of the gene to detect intragenic deletions in the first tier of testing. The second tier of analysis involves the amplification of all exons individually and screening them for point mutations and small deletions/insertions with dHPLC. Variants identified by dHPLC are subsequently sequenced in both directions for mutation/polymorphism identification as defined by ACMG guidelines for interpretation of sequence variations. We have validated this procedure with positive controls that were identified in patients with SSCP. In this hierarchical strategy, these procedures have an analytical sensitivity of >99%.

***MECP2* mutations in atypical patients.** I. Meloni<sup>1</sup>, I. Longo<sup>1</sup>, M. Zappella<sup>2</sup>, A. Renieri<sup>1</sup>. 1) Department of Molecular Biology, Medical Genetics, University of Siena, Siena, Italy; 2) Child Neuropsychiatry, Policlinico Le Scotte, Siena, Italy.

Mutations in the *MECP2* gene cause the severe neurodevelopmental disorder called Rett syndrome. Here we report clinical and mutation analysis of 18 preserved speech variants (PSV). Ten of them, all showing a slow recovery of verbal and praxic abilities, evident autistic behavior and normal head circumference had a *MECP2* mutation (55%).

To test how broad the *MECP2* phenotypic spectrum is, we also screened nineteen girls with a clinical diagnosis of Autism, two of them having lost, along the years, the autistic features reaching a high degree of mental abilities. A pathogenic mutation was found only in the latter two cases (R133C and R453X). These results confirm previous clinical studies suggesting that the spectrum of the *MECP2*-associated phenotype is wide and includes girls with mental abilities considerably higher (I.Q. close to 50) than in classic Rett Syndrome.

Significantly, all mutations found in the atypical cases described above are either missense or late truncating mutations. In particular, we did not find the 4 early truncating hot spots, R168X, R255X, R270X, R294X. These results suggest that early truncating mutations lead always to a poor prognosis (classic Rett) while late truncating and missense mutations lead either to classic Rett or PSV or to girls with an I.Q. close to 50. We hypothesize that a missense or late truncating mutation is necessary but not sufficient to reach a high degree of mental ability, based on the presence of one (or more) modifier genes whose product may interact in an epistatic manner with MeCP2 protein.

**Breakpoint analysis of deletions in patients with Greig cephalopolysyndactyly.** *J.J. Johnston<sup>1</sup>, I.M. Olivos-Glander<sup>1</sup>, J.K. Blancato<sup>2</sup>, L.G. Biesecker<sup>1</sup>.* 1) NHGRI, NIH, Bethesda, MD; 2) Inst. of Mol. Hum. Gen., Georgetown Univ., Washington, D.C.

Greig cephalopolysyndactyly syndrome (GCPS) is due to haploinsufficiency of *GLI3*. The phenotype includes polydactyly, macrocephaly and/or hypertelorism, mental retardation (MR), hernias and dysgenesis of the corpus callosum. A range of genetic alterations affecting *GLI3* is responsible for GCPS including point mutations, frameshifts, and deletions. We have analyzed 28 families for deletions of 7p13. Ten of our families have deletions and we are working to identify the breakpoints to determine if a common mechanism underlies the deletions in GCPS. Furthermore, identifying the breakpoints will allow us to correlate clinical findings in our families with their complement of haploinsufficient genes. Initial analysis has shown developmental delay (DD) and MR to be more prevalent in deleted families (9/10) than in undeleted families (1/13) and we hypothesize that this is due to other genes in the region. STS analysis of hybrids with only the deleted chromosome 7 from each patient is being used to determine the extent of the deletions. We currently have hybrid clones from 4 patients and have determined the maximum deletion sizes, which range from 180 Kb to 12 Mb. Patient G-2, the only deleted individual that does not have DD or MR, has a deletion restricted to *GLI3*. The deletion breakpoints are within BACs AC005026 and AC005158. The deletion in patient G-11, diagnosed with DD, deletes *GLI3* and *INHBA* but no other known genes. The breakpoints are in BACs AC012596 and AC073181. Patients G-17 and G-21 have larger deletions including more than 30 genes. The telomeric breakpoint in G-17 lies in BAC AC005483 and the centromeric breakpoint lies between BACs AC004859 and AC069282. The telomeric breakpoint in G-21 is just telomeric to BAC AC005483 and the centromeric breakpoint lies between BACs AC011992 and AC004920. Results from FISH and STRP analysis show an additional 4 patients with deletions larger than *GLI3*. Importantly, all of these breakpoints are distinct. We conclude that *GLI3* deletions associated with GCPS have unique breakpoints and are not generated by stereotypical deletions.

**The Spectrum of Glucocerebrosidase Mutations among Korean Gaucher pts: its implications on clinical phenotype and genetic diversity.** *H.J. Kim<sup>1,2</sup>, C.A Yang<sup>2</sup>, S.J. Park<sup>2</sup>, M.J. Ha<sup>2</sup>, W.K. Kim<sup>3</sup>*. 1) Genetics Clinic, Ajou Univ. Hosp; 2) Medical Genetics Research lab, Ajou Univ. Sch. of Med; 3) Lab of Molecular biology, Ajou Univ. Sch. of Med.

Mutational analysis of glucocerebrosidase(GC) gene in 20 unrelated Korean Gaucher Disease pts(9 type1, 4 type2, 4 type3A, 3 type3B) identified 12 different mutations in 27 alleles by direct sequencing of PCR amplified genomic DNA. L444P mutation was found to be most prevalent (20%) in both non-neuronopathic(NNP) and neuronopathic (NP) phenotypes. Next common mutation, F213I was found in one allele of type 1 & 3 alleles of NP. R257Q, a rare mutation was also detected in both phenotypes for one each. G46E was detected only in NNP and G202R only in NP (3 alleles for each). Other 7 rare mutations were identified in only one allele for each mutation (R48W&V406V in type1 and N188S, V191G, F331L, G377S and D409H in NP). The lack of N307S mutation, known to be associated with a mild type1 phenotype and protective mutation from neuronopathic phenotype among Korean may explain the phenotypic characteristics of non-neuronopathic type1 being associated with early onset in childhood & severe phenotype and the preponderance of neuronopathic phenotype(>50%)among Korean GD pts. L444P, common mutation (about40%)among Non-jewish Caucasian and Japanese, is known to be associated with neuronopathic phenotype, and esp. homoalleles for L444P is most common in type 3 pts. However among 11 Korean neuronopathic pts. only 3 alleles (< 15%) and no homoalleles were detected. Instead, two homoalleles for rare mutations, G202R in type1 and F213I in a type3B ,were found. V191G, previously reported as a novel mutation of mild phenotype in type1 was detected in a heteroallele with R257Q in a type2 pt. The spectrum of 12 identified GC mutations among Korean is rather unique from those of Jewish & non-Jewish Caucasian, but similar to that of Japanese, yet the striking difference in L444P homoallelic frequency and other allelic heterogeneity exist between GD, especially neuronopathic form of Korean & Japanese, which can be explained in part with genetic diversity and cultural difference toward consanguinity mating.

**Increased diagnostic and prognostic sensitivity of spinal muscular atrophy (SMA) testing.** *M.D. Mailman<sup>1</sup>, J.W. Heinz<sup>1</sup>, B. Wirth<sup>2</sup>, A.H.M. Burghes<sup>3</sup>, T.W. Prior<sup>1</sup>.* 1) Dept Pathology, Ohio State Univ, Columbus, OH; 2) Institute of Human Genetics, Bonn, Germany; 3) Dept of Medical Biochemistry, Ohio State University, Columbus, OH.

Spinal muscular atrophy (SMA) is an autosomal recessive hereditary neuromuscular disease characterized by proximal muscle weakness due to the loss of a-motor neurons in the spinal cord. In very well characterized SMA cases, the survival motor neuron (SMN1) gene on chromosome 5q13 is homozygously deleted more than 95% of the time. The remaining patients have a neurodegenerative condition unassociated with chromosome 5q or are compound heterozygotes with an intragenic mutation and a deletion. To increase the sensitivity for detection of mutations in the SMN1 gene, we have developed an allele-specific fluorescent PCR panel that detects 7 of the most common intragenic mutations found in SMA patients. Identification of an intragenic mutation is followed by a dosage test to confirm compound heterozygosity. Results of a SMN2 gene dosage study comparing 52 type I versus 90 type II and III SMA patients indicated that patients with a more mild presentation have significantly more copies of the SMN2 gene than severe cases of the disease. We present data comparing ages at diagnosis with SMN2 copy number. Finally, we present results of five years of SMA carrier testing. Since we began offering the SMN1 dosage test in 1996, our laboratory has tested 399 family members for SMN1 deletion carrier status. The results of these carrier tests are consistent with SMA segregating with a carrier frequency of 3% and a combined new mutation or two-copy chromosome rate of 5%.a.

**Genotype/phenotype correlations in 202 Rett syndrome patients.** *L.M. Moses<sup>1</sup>, K.C. Hoffbuhr<sup>1</sup>, C. Scacheri<sup>1</sup>, L. Falke<sup>1</sup>, S. Budden<sup>2</sup>, A. Percy<sup>3</sup>, M. Philippart<sup>4</sup>, G. Bibat<sup>5</sup>, S. Naidu<sup>5</sup>, E.P. Hoffman<sup>1</sup>.* 1) Research Center for Genetic Medicine, Children's National Medical Center, Washington, DC; 2) Child Development and Rehabilitation Center, Oregon Health Sciences University, Portland, OR; 3) Pediatric Neurology, University of Alabama at Birmingham, Birmingham, AL; 4) Mental Retardation Research Center, UCLA, Los Angeles, CA; 5) Neurogenetics Unit, Kennedy Krieger Institute, Johns Hopkins University, Baltimore, MD.

Rett syndrome (RTT) is a neurodevelopmental disorder in girls caused by mutations in the methyl CpG binding protein 2 (*MeCP2*). We performed mutation analysis of the *MeCP2* gene in 202 individuals with variable clinical diagnoses. In this study, we identified a total of 37 different mutations, including 10 novel mutations. Those with a typical presentation of RTT showed a high percentage of *MeCP2* mutations (85%; 68/80). In contrast, only 25% (7/28) of individuals with a diagnosis of atypical RTT had mutations in the *MeCP2* gene. *MeCP2* mutations were not detected in 10 males with variable clinical presentation or 21 individuals with uncharacterized neurological disorders and no specific diagnoses. Clinical information was not available for 63 patients; 34 mutations were identified in these individuals (54%). Eight mutations (R106W, R133C, T158M, R168X, R255X, R270X, R294X, R306C) accounted for 72% (49/68) of all mutations in those with classical RTT and 57% (4/7) in those with atypical RTT. Of these 7 individuals, 3 showed frame-shift deletions in the C-terminal of *MeCP2*. We identified 2 novel rearrangements in the C-terminus of the *MeCP2*: the first involving two in-frame deletions (93bp and 18bp) and an 8bp out of frame insertion, and the second involving a 211bp out of frame deletion and a 111bp in-frame inversion. This study identified several novel polymorphisms in the *MeCP2* gene, including a 12 basepair in frame deletion that results in the loss of 4 amino acids in a non-conserved C-terminal region of the *MeCP2* gene.

**Screening of Pancreatic Secretory Trypsin Inhibitor (PSTI) mutations in chronic pancreatitis by DHPLC.** *C. Le Marechal<sup>1</sup>, O. Raguene<sup>2</sup>, I. Quere<sup>2</sup>, J. Chen<sup>1</sup>, C. Ferec<sup>1,2</sup>*. 1) EFS Bretagne, Brest, France; 2) CHU de BREST, France.

Over the past five years, genetic studies of patients with Chronic Pancreatitis (CP) have been led in order to find an etiology in idiopathic forms of CP. "Gain of function" missense mutations in the cationic trypsinogen gene have been increasingly identified as being associated with hereditary and/or sporadic pancreatitis. Based upon a candidate approach, presumably "loss-of-function", mutations in the pancreatic secretory trypsin inhibitor (PSTI) gene can be involved CP disease. A N34S missense mutation, was identified as being strongly associated with chronic pancreatitis in young patients. We extended to evaluate the PSTI gene in a large cohort of unrelated French subjects with CP by Denaturing High Performance Liquid Chromatography (DHPLC). The major new findings are as follows. Firstly, we confirmed that N34S carrier frequency in the < 20 years group is significantly higher than the 25~65 years group, suggesting an increased environmental contribution to the disease in the later group. Secondly, in addition to other known variants (e.g., c.-53C>T and c.-41G>A), five novel variants were identified (-2C>A, L12F, L14R in exon 1 ; IVS2+54C>T in exon 2 ; R65Q in exon 3). The L12F variant was found in three unrelated CP patients and none control. It thus can probably be considered as a disease associated nucleotide change. The R65Q variant was found in only one control and is probably a polymorphism. Others were discovered only once in CP patient, so their interpretation remain difficult. This study confirmed the potential of DHPLC to screen quickly and accurately a gene and could be used for scanning others candidate genes implicated in CP. These results help further resolve the elusive etiology of sporadic pancreatitis.

**A new family with a mutation in exon 2 of COL2A1 and Stickler syndrome without systemic manifestations.** *A.H. van der Hout<sup>1</sup>, E. Verlind<sup>1</sup>, H. Scheffer<sup>1</sup>, J.M.M. Hooymans<sup>2</sup>*. 1) Dept Clinical Genetics, University Hospital Groningen, Groningen, Netherlands; 2) Dept Ophthalmology, University Hospital Groningen, Groningen, Netherlands.

Stickler syndrome is an autosomal dominantly inherited connective tissue disorder with ocular, orofacial, auditory and articular manifestations. There are two types, based on different abnormalities in the vitreous gel. Type 1 families show a characteristic membranous anomaly in the vitreous gel. In these families mutations are found in the COL2A1 gene. In some families with the type 1 vitreous phenotype there are no systemic manifestations of the disease. Richards et al. (2000) found mutations in exon 2 of COL2A1 in 3/3 families with the type 1 vitreous phenotype and almost no systemic manifestations. This is consistent with the major form of type II procollagen in non-ocular tissues having exon 2 spliced out. All three mutations resulted in a premature stopcodon in exon 2. In our family linkage to COL2A1 was established several years ago. There are 25 affected individuals, all with the characteristic type 1 abnormal vitreous gel. No systemic signs of Stickler syndrome, such as joint hypermobility, high arched or cleft palate, abnormalities of the dentition or craniofacial skeleton, or hearing loss, are present. Sequencing of exon 2 of COL2A1 revealed an A to C mutation, changing codon 64 into a stopcodon. This mutation is different from the three described by Richards et al. Sequencing of exon 2 of COL2A1 can be a quick method to find a mutation in families with autosomal dominant vitreoretinal degeneration, even if the family is too small for linkage analysis. In counselling it is important to realise that individuals with an exon 2 COL2A1 mutation are at high risk of retinal detachment, but at a much lower risk of developing the other features of Stickler syndrome. Richards et al., *Br. J. Ophtalm.* (2000) 84, 364-371.

**Nested deletions in the murine region syntenic to the human Smith-Magenis syndrome.** *J. Yan*<sup>1</sup>, *S. Carattini-Rivera*<sup>1</sup>, *K. Walz*<sup>1</sup>, *A. Bradley*<sup>2</sup>, *J.R. Lupski*<sup>1</sup>. 1) Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX; 2) Sanger center, Cambridge, UK.

Smith-Magenis syndrome (SMS) is a microdeletion syndrome on chromosome 17p11.2. The main clinical manifestations include mental retardation, developmental delay, craniofacial anomalies, neurobehavioral abnormalities, and defects of heart and kidneys. The complex phenotype is thought to result from haploinsufficiency effects of contiguous genes that map in the critical interval. Because there are no small deletions in the patients that enable us to elucidate the gene or genes responsible for different phenotypes, we began to construct nested deletions in murine syntenic region to the human SMS common deletion. The murine syntenic region maps to the chromosome 11 32-34 CM interval. Many genes mapped to the human SMS region also have been mapped to the murine syntenic region. In order to make nested deletions, we first targeted *Cops3*, a gene at one end of the murine syntenic region, with one loxP and half of the *Hprt* gene. Another loxP site and another half of the *Hprt* gene were introduced using an engineered retrovirus. After recombination between two loxP sites by Cre recombinase, we obtained 39 deletion clones. Southern-blot analysis of the proviral junction fragments demonstrates that there are ten independent deletion events. FISH and inverse PCR(IPCR) have been carried out to identify the deletion end points. ES cells are now waiting injection. Our work will lead us to the gene or genes responsible for different phenotypes, and will eventually enable an understanding of the molecular basis for the SMS.

**Identification of novel CLCN1 and SCN4A mutations in a clinical spectrum of ion channelopathy patients.** *F.F. Wu*<sup>1,2</sup>, *J. Devaney*<sup>3</sup>, *T. Hodics*<sup>4</sup>, *Z. Korade-Mirnic*<sup>5</sup>, *E. Pegoraro*<sup>5</sup>, *J. Giron*<sup>2</sup>, *D. Escolar*<sup>2</sup>, *M. Marino*<sup>3</sup>, *E.P. Hoffman*<sup>2</sup>.  
1) Human Genetics, University of Pittsburgh, PA; 2) Children's National Medical Center, Washington, DC; 3) Transgenomic Inc, Gaithersburgh, MD; 4) George Washington University, Washington, DC; 5) Department of Molecular Genetics and Biochemistry, University of Pittsburgh, PA.

The muscular chloride and sodium channel disorders (channelopathies) represent a group of clinically overlapping and genetically heterogeneous diseases showing abnormal alterations in the excitability of the sarcolemma. The cardinal symptoms include non-dystrophic and non-progressive myotonia and periodic paralysis. Over the past decade, most efforts to elucidate the genetic causes and pathophysiologic features of myotonia and paralysis have been focused on the typical phenotypes, reducing the potential of identifying new mutations that may result in unusual phenotypes. In this study, we widened our clinical window to analyze a broad spectrum of myotonia and paralysis phenotypes. We used a cohort of patients referred from molecular diagnosis to be negative for common mutations of CLCN1 and SCN4A. We screened all exons of CLCN1 in 115 familial and sporadic myotonia patients and all exons of SCN4A in 56 periodic paralysis patients. SSCP and DHPLC were used for screening, followed by direct sequencing. We identified six novel CLCN1 mutations (five missense and one nonsense) and five new missense SCN4A mutations. While the former were shown to be distributed all over the chloride channel protein, the latter resided in unusual regions of the sodium channel protein (amino and carboxy termini), which could account for the atypical phenotypes. Our study not only identified significant number of novel CLCN1 and SCN4A mutations but also proved that the clinical variability and genetic heterogeneity of channelopathies is larger than commonly believed, and that there are broader and atypical myotonia and periodic paralysis yet to be characterized in which the causative mutations of the condition reside equally in the CLCN1 or SCN4A. These unexpected results open a new pathway to further characterization of the important group of channelopathies.

**The I148T *CFTR* mutation confers a variable phenotype and occurs on multiple haplotypes.** *E.M. Rohlf's*<sup>1</sup>, *Z. Zhou*<sup>2</sup>, *E.A. Sugarman*<sup>1</sup>, *R.A. Heim*<sup>1</sup>, *R.G. Pace*<sup>3</sup>, *M.R. Knowles*<sup>3</sup>, *L.M. Silverman*<sup>2</sup>, *B.A. Allitto*<sup>1</sup>. 1) Genzyme Genetics, Framingham, MA; 2) University of North Carolina, Dept Pathology & Laboratory Medicine; 3) University of North Carolina, Dept Medicine, Chapel Hill, NC.

The cystic fibrosis (CF) phenotype varies from mild to severe disease and is in part determined by the *CFTR* genotype of the individual. For example, the phenotypic effect of the R117H mutation is modified by the length of the polythymidine tract (5, 7 or 9 thymidines) found in intron 8. The I148T mutation has been characterized as "severe" due to its identification in pancreatic insufficient CF patients. However, we have evidence from carrier testing that the I148T mutation is associated with a variable phenotype. We identified 5 unaffected individuals (ages 21 to 56) with a DF508/I148T genotype who had been referred for carrier testing. The presence of both mutations on the same chromosome was ruled out by family studies in 2 individuals. Carrier testing of 42,784 individuals of varying ethnic backgrounds identified 1754 *CFTR* mutation carriers and I148T accounted for 6.4% of the mutations identified. Yet, this mutation accounts for only 0.06% of the mutations in individuals whose indication for testing was "known affected with CF" (n=9236 chromosomes). To determine if other changes in the *CFTR* gene were modifying the CF phenotype, we sequenced all *CFTR* exons and the intron 8 polythymidine tract from 5 reportedly unaffected individuals (genotypes I148T/I148T or DF508/I148T) and from 5 individuals with a known or suspected diagnosis of CF (genotypes DF508/I148T or N1303K/I148T). We have determined that the I148T mutation occurs on at least 2 haplotypes: 1) a 9T background which was identified in all 5 unaffected individuals and 1 affected individual 2) a 9T/3199del6 background which was identified in 4 of the 5 affected/suspected individuals. The 3199del6 sequence change was not identified in 386 non-CF chromosomes. We conclude that I148T occurs on at least 2 haplotypes and these haplotypes may differ between those individuals with and without symptoms of CF.

**Mutation analysis in the noncoding region of *ABCA4* (promoter region and genomic rearrangements) among STGD patients.** A.N. Yatsenko, N.F. Shroyer, R.A. Lewis, J.R. Lupski. Human Molecular Genetics, Baylor College Med, Houston, TX.

Stargardt disease (STGD1, OMIM#248200) is an autosomal recessive retinal dystrophy classically observed at an early age. The estimated frequency of STGD1 in the United States is between 1:8,000-10,000. The causative gene for STGD1 has been cloned in the chromosome region 1p21-1p13. This gene, *ABCR* (also known as *ABCA4*), contains 50 exons and encodes a photoreceptor-specific ATP-binding cassette transporter, which expresses specifically in the both cone and the rod photoreceptors. *ABCR* protein appears to function as an outwardly directed flippase for retinoids. Previous studies showed a range of different types of mutant *ABCR* alleles in STGD1 families. Recently, based on direct DNA sequencing of all *ABCR* exons, we have performed mutation screening for patients with late-onset STGD1 (Yatsenko et al. 2001) and STGD patients with AMD relatives (Shroyer N.F., personal data). We found mutations in 66% and 80% of disease chromosomes. Therefore we suggested that a potential cause for the remaining 34-20% STGD alleles are noncoding *ABCR* mutations or other gene(s) located in distinct chromosome regions. To investigate the disease cause in these patients we analyzed the promoter region, which spans ~3 kb located 5' to transcription start and includes exon 1. Based on published prediction for 0.8 kb 5' region and our computer analysis we predict several potential sites for transcription factors. We performed direct sequence of the ~3 kb region in STGD patients. We identified several potential mutation sites involved in transcription regulation. Direct sequencing of same region in control individuals is in progress. To further test these potential sites we will perform a functional reporter assay for them. These functional assays will be performed in retina-specific lines Y79 and WERI, which express several photoreceptor specific proteins. In addition to test the possibility of DNA rearrangement mutations in the same patients we performed Southern analysis with *ABCR* gene specific probes. Preliminary data showed few STGD patients with potential junction fragments in *ABCR* specific region. Further analysis will confirm or refute pathogenic role of these findings.

**Bloom's syndrome: Cellular BLM proteins from splice-site mutations.** *M.M. Sanz*<sup>1</sup>, *R.M. Pauli*<sup>2</sup>, *N.A. Ellis*<sup>3</sup>, *J. German*<sup>1</sup>. 1) Cornell University Medical College, New York, NY; 2) University of Wisconsin, Madison, WI; 3) Memorial Hospital, New York, NY.

Of the 64 distinct Bloom's syndrome (BS)-causing mutations we have characterized at the molecular level, 9 are altered splice sites. Cultured cells from a sub-set of these 9, affecting splice-donor sites in introns 2, 6, 7, and 18, were studied by immunofluorescence microscopy employing antibodies to BLMp and PMLp. Proliferating normal cells have abundant nuclear BLMp, distributed as diffuse granularity or concentrated in foci, some foci appearing as extremely fine "speckles" and a few as larger "dots," many of the dots co-localizing with PML nuclear bodies. In all four splice-site mutant cell lines, nuclear fluorescence is demonstrable by antiBLM in some but not all cells, the amounts (always very low) and distributions being distinctive in each of the four. The diffuse granularity seen in normal cells is greatly reduced or undetectable. BLM foci are produced in each splice-site mutant, but with respect to number, size, and degree of co-localization with PML nuclear bodies the mutant cells differ from normal, and also from each other. In 2 mutants, PML bodies are unusually numerous, large, and irregular in contour.

One mutation, IVS6+3A->G, well upstream of the recQ helicase-encoding regions of *BLM*, is of special interest because the affected young man, 112(NaSch) in the Bloom's Syndrome Registry, has a relatively normal phenotype (re height, testicular size, immunocompetence). He is a genetic compound whose second *BLM* mutation, A814T, is truncating. The abnormal but possibly functional BLM protein(s) that 112(NaSch)'s cells synthesize by some undefined splicing pattern now can be characterized extensively at the molecular level. We postulate that they (i) can carry out some of BLMp's normal functions, perhaps the control (suppression) of recombination in those cellular mechanisms concerned with body-size determination, immune function, and germ-cell maturation but, because his SCE rate is characteristically elevated, (ii) cannot control recombination during S-phase DNA synthesis in somatic cells.

**Erythrocyte Ankyrin Promoter Mutations Associated With Recessive Hereditary Spherocytosis Cause Significant Abnormalities in Ankyrin Expression.** *P.G. Gallagher<sup>1</sup>, D.E. Sabatino<sup>2</sup>, D.M. Nilson<sup>2</sup>, C. Wong<sup>1</sup>, A.P. Cline<sup>2</sup>, L.J. Garrett<sup>2</sup>, D.M. Bodine<sup>2</sup>.* 1) Dept Pediatrics, Yale Univ Sch Medicine, New Haven, CT; 2) Hematopoiesis Section, NHGRI, NIH, Bethesda, MD.

Ankyrin deficiency is the most common abnormality found in the erythrocyte membranes of patients with hereditary spherocytosis (HS). Several reports have identified sequence variations in the ankyrin gene promoter in individuals with recessively inherited, ankyrin-deficient spherocytosis. These variations have been proposed to decrease ankyrin synthesis, but there are no functional data to support this hypothesis. We analyzed the effects of two common ankyrin gene erythroid promoter mutations, -108T-C and -108T-C *in cis* with -153G-A, on ankyrin expression. No difference between wild type and mutant promoters was demonstrated in reporter gene transfection or gel shift assays *in vitro*. Transgenic mice with a wild type ankyrin promoter linked to a human <sup>A</sup>g-globin gene expressed g-globin in 100 percent of erythrocytes in a copy number-dependent, position-independent manner. Transgenic mice with the mutant -108 promoter demonstrated variegated g-globin expression, but showed copy number-dependent and position-independent expression similar to wild type. Severe effects in ankyrin expression were seen in mice with the linked -108/-153 mutations. Two lines did not express the transgene, indicating position-dependent expression, and 5 lines expressed significantly lower levels of <sup>A</sup>g-globin mRNA than wild type (0.006 percent vs. wild type 0.041 percent, *p* less than 0.0001). Three of 5 expressing lines showed variegated g-globin expression and there was no correlation between transgene copy number and RNA level, indicating copy number-independent expression. These data are the first demonstration of functional defects due to HS-related, ankyrin gene promoter mutations. These promoter mutations may represent a common pathogenetic mechanism of recessive hereditary spherocytosis in ankyrin-deficient patients.

**Genetic heterogeneity of autosomal dominant nonsyndromic macrothrombocytopenias.** *A. Savoia*<sup>1</sup>, *C.L. Balduini*<sup>2</sup>, *M. Savino*<sup>3</sup>, *P. Noris*<sup>2</sup>, *A. Bianco*<sup>1</sup>, *M. Del Vecchio*<sup>3</sup>, *S. Perotta*<sup>4</sup>, *M. Di Pumpo*<sup>2</sup>, *V. Poggi*<sup>5</sup>, *L. Zelante*<sup>3</sup>, *A. Iolascon*<sup>6</sup>. 1) Telethon Institute of Genetics and Medicine (TIGEM), Naples; 2) Department of Internal Medicine, University of Pavia, Pavia; 3) Medical Genetic Service, IRCCS Hospital CSS, San Giovanni Rotondo, Foggia; 4) Department of Pediatrics, II University of Naples, Naples; 5) Department of Pediatric Hematology, Azienda Santobono, Pausilipon, Naples; 6) Department of Biomedicine of Evolutive Age, University of Bari, Bari, Italy.

We have studied an autosomal dominant macrothrombocytopenia characterized by mild or no clinical symptoms, normal platelet functional activity, and normal megakaryocyte. Linkage analysis in two large families localized the gene on chromosome 17p, in an interval containing the GPIIb gene, which is altered in Bernard-Soulier syndrome (BSS). A heterozygous Ala156Val missense substitution (Bolzano variant) was identified in the two families and in another six pedigrees. BSS is an autosomal recessive disorder characterized by prolonged bleeding time, thrombocytopenia, and large platelets due to a defect of the platelet glycoprotein (GP) Ib/IX/V complex. GPIb/IX/V consists of four genes, GPIIb, GPIIb3, GPIIX, and GPV. BSS patients are homozygotes or compound heterozygotes for mutations in these genes. Consistent with a BSS heterozygous condition, the vWF receptor GPs were reduced in all patients with the Bolzano variant. Platelet membrane GP studies were performed on families characterized by macrothrombocytopenia without Ala156Val. The analysis distinguished two groups: 3 patients had the GPIb/IX/V complex normally distributed (true autosomal dominant macrothrombocytopenia) and 5 patients showed a reduction of GPs. We hypothesized that mutations in the BSS genes were responsible for the phenotype of the second group. Thus, the coding regions of the GPIb/IX/V complex genes were amplified. Sequencing analysis of the PCR product excluded the presence of mutations. These results suggest that there is at least another gene responsible for the BSS heterozygous phenotype. A positional cloning strategy based on linkage analysis and mutation screening in candidates is in progress.

**Identification of the gene for Oral-facial-digital type I syndrome (OFD1).** *B. Franco<sup>1</sup>, M.I. Ferrante<sup>1</sup>, G. Giovanna<sup>1</sup>, S. Feather<sup>2,3</sup>, A. Bulfone<sup>1</sup>, V. Wright<sup>2</sup>, A. Selicorni<sup>4</sup>, F. Scolari<sup>5</sup>, A. Woolf<sup>3</sup>, S. Odent<sup>6</sup>, B. Le Marec<sup>6</sup>, S. Malcom<sup>2</sup>, R. Winter<sup>2</sup>, A. Ballabio<sup>1</sup>.* 1) TIGEM, Telethon Inst Genet&Med, Naples, Italy; 2) Insitute of Child Health, Clinical and Molecular Genetics Unit, London UK; 3) Insitute of Child Health, Nephro-Urology Unit, London UK; 4) Clinica Pediatrica De Marchi, Milan, Italy; 5) Division of Nephrology, Spedali Civili and University of Brescia, Italy; 6) Department of Pediatrics and Genetics, University Hospital Pontchaillou, Rennes, France.

Oral-facial-digital syndromes (OFDS) are a heterogeneous group of developmental disorders of which at least nine different forms have been described. Oral-facial-digital type 1 syndrome (OFD1; MIM 311200) is transmitted as an X-linked dominant condition with lethality in males and is characterized by malformations of the face, oral cavity, and digits with a highly variable expressivity even within the same family. Malformation of the brain and polycystic kidneys are commonly associated with this disorder. The locus for OFD1 was mapped by linkage analysis to a 12 Mb interval flanked by markers DXS85 and DXS7105 in the Xp22 region. To identify the gene responsible for this syndrome we analyzed several transcripts mapping to the region and found mutations in OFD1 (formerly named Cxorf5/71-7a) encoding a protein containing coiled-coil  $\alpha$ -helical domains. Seven patients affected by OFD1 were analyzed including three familial and four sporadic cases. Analysis of the familial cases revealed a missense mutation, a 19-bp deletion and a single base pair deletion leading to a frameshift. In the sporadic cases we found a missense (de novo), a nonsense, a splice and a frameshift mutation. RNA in situ studies on mouse embryo tissue sections show that *Ofd1* is developmentally regulated and is expressed in all tissues affected in OFD1 syndrome. The involvement of OFD1 in oral-facial-digital type 1 syndrome demonstrates an important role of this gene in human development.

**Identification and mutation screening of candidate genes for X-linked cleft palate and ankyloglossia (CPX). C.**

*Braybrook<sup>1</sup>, K. Doudney<sup>1</sup>, A-C.B. Marçano<sup>2</sup>, A. Arnason<sup>3</sup>, A. Bjornsson<sup>4</sup>, M.A. Patton<sup>5</sup>, P.J. Goodfellow<sup>6</sup>, G.E. Moore<sup>1</sup>, P. Stanier<sup>1</sup>.* 1) Institute of Reproductive and Developmental Biology, Imperial College School of Medicine, Hammersmith Campus, Du Cane Road, London W12 ONN, UK; 2) Departamento de Genética, Hospital de Reabilitação de Anomalias Craniofaciais, Universidade de São Paulo, Bauru, São Paulo, Brazil, P.O. Box 1501, 1743-900; 3) The Bloodbank, 101 Reykjavik, Iceland; 4) Department of Plastic Surgery, The University Hospital, 101 Reykjavik, Iceland; 5) Medical Genetics Unit, St George's Hospital Medical School, Tooting, London SW17 ORE, UK; 6) Departments of Surgery, Genetics, and Obstetrics and Gynecology, Washington University School of Medicine, St. Louis, Missouri, USA.

Cleft palate has an incidence in humans of approximately 1/1500. It most commonly occurs sporadically and displays a multifactorial mode of inheritance. The complex interactions between environmental and genetic factors have made it difficult to identify the genetic defects responsible for clefting. However, several families from different ethnic origins have been reported in which cleft palate displays an X-linked, semi-dominant mode of inheritance. Ankyloglossia (tongue-tie) has also been reported in most of these families, and along with submucous cleft and bifid or absent uvula this has become an important diagnostic criteria for X-linked cleft palate (CPX, MIM 303400). Linkage data performed on five well characterised families localises the gene responsible for CPX to Xq21, between the markers *PGK1* and *DXS1217*. This genomic region has been examined for candidate genes by analysis of genomic sequence using gene prediction programmes or using the Human Genome Project (HGP) web site (<http://genome.cse.ucsc.edu/>). The current transcript map contains approximately 15 genes. The full genomic structure of candidate genes has been determined, to allow for mutation detection by direct DNA sequencing. Here we present the transcript map and sequence analysis of candidate genes in 6 CPX families.

**Naxos disease: Linkage analysis and evidence for genetic heterogeneity.** *K. Djabali<sup>1</sup>, A. Martinez-Mir<sup>1</sup>, L. Horev<sup>3</sup>, L. Klapholtz<sup>3</sup>, B. Glaser<sup>4</sup>, A. Zlotogorsky<sup>3</sup>, A.M. Christiano<sup>1,2</sup>.* 1) Department of Dermatology, Columbia University, New York, NY; 2) Department of Genetics and Development, Columbia University, New York, NY; 3) Department of Dermatology, Hadassah Medical Center, Jerusalem, Israel; 4) Department of Endocrinology, Hadassah Medical Center, Jerusalem, Israel.

Naxos disease is an autosomal recessive syndrome affecting the heart, skin and the hair. The heart disease, right ventricular dysplasia (ARVD), is severe and may result in arrhythmia and premature sudden death. The patients also present with nonepidermolytic keratoderma, mainly involving pressure areas in the palms and soles. Finally, the hair involvement is unique, and is characterized by woolly, curly, rough and light colored scalp hair and sparse eyebrows. A similar triad of symptoms has been previously described in patients from the Greek island of Naxos and from Ecuador, with combined epidermolytic palmoplantar keratoderma with woolly hair and dilated cardiomyopathy. Recently, mutations in the plakoglobin and desmoplakin genes have been identified as responsible for the disease in the Greek and Ecuadorean families, respectively. Here we report two new consanguineous families with Naxos disease from Israel. We first excluded a mutation in the desmoplakin and plakoglobin genes by sequence and cosegregation analysis, suggesting that at least one additional gene underlies Naxos disease in these families. On the basis of the role of both desmoplakin and plakoglobin in cell adhesion, we analyzed several other genes coding for components of the desmosomes or proteins involved in different aspects of cell adhesion. These included the genes coding for type I and type II keratins, on chromosomes 17 and 12, respectively, desmoyokin, on 11q13.1, the desmocollin/desmoglein cluster, on 18q12.1, plakophilin 1, on 1q32, plakophilin 2, on 12p13, and plakophilin 4, on 2q23-q31. None of these regions showed cosegregation with the disease trait or homozygosity in these inbred families. According to these results, we are currently performing a genome-wide search to identify the gene underlying the particular presentation of Naxos disease in the families studied.

**Novel mutations and polymorphism of CYP1B1 in Ecuadorian patients with congenital glaucoma.** *S.M. Curry*<sup>1</sup>, *A.G. Daou*<sup>1</sup>, *A. Molinari*<sup>2</sup>, *R.A. Lewis*<sup>1,3,4,5</sup>, *B.A. Bejjani*<sup>1</sup>. 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Hospital Metropolitano, Quito, Ecuador; 3) Ophthalmology, Baylor College of Medicine, Houston, TX; 4) Medicine, Baylor College of Medicine, Houston, TX; 5) Pediatrics, Baylor College of Medicine, Houston, TX.

Primary congenital glaucoma (PCG) is an autosomal recessive developmental anomaly of the anterior chamber that manifests in the perinatal or infantile period. It is the most common form of glaucoma in infancy. Mutations in the cytochrome P4501B1 gene (*CYP1B1*) have been shown to cause the disease in about 80 percent; of patients with PCG. More than seventeen different *CYP1B1* mutations have been reported in PCG families from the US, Turkey, Saudi Arabia, Canada, UK and Japan. There is anecdotal evidence that PCG is common in the Native American population of Ecuador. We studied fifteen such families from Ecuador by PCR amplification of the *CYP1B1* coding exons followed by sequencing of the PCR products. Individuals in whom no mutations were detected by PCR amplification and direct sequencing were studied by Southern blot analysis to investigate the possibility of large rearrangements not detectable by the PCR method. These studies identified a compound heterozygous mutation in an affected individual (G61E/4340delG) and a novel homozygous missense mutation in another affected individual (R390C). Furthermore, a novel silent nucleotide polymorphism at position 563 from the start site (C to A) was also found in a family in whom no PCG-associated mutations were detected. No mutations were found in 13 out of the 15 families studied. Southern blot analysis with 3 restriction enzymes on patients and normal controls did not identify any genomic rearrangements of *CYP1B1*. These results show that mutations in *CYP1B1* are a cause of PCG in a small percentage of patients in Ecuador and suggest that there is at least one additional locus yet to be identified. Finally, these studies show that there are individuals and families with unique or rare sequence polymorphisms in addition to the known common polymorphisms already described in *CYP1B1*.

**Identification, characterization and testing of candidate genes for the CDB2 form of autosomal dominant corneal dystrophy located on chromosome 10q23-25.** *S.J. Bowne<sup>1</sup>, X. Xu<sup>1</sup>, A.R. Carr<sup>2</sup>, S.P. Daiger<sup>2</sup>, R.W. Yee<sup>1</sup>.* 1) Ophthalmology & Visual Sciences, Univ. of Texas Health Science Center, Houston, TX; 2) Human Genetics Center, Univ. of Texas Health Science Center, Houston, TX.

Corneal dystrophy affects thousands of Americans and is characterized by irregular scarring of the epithelium, Bowman's membrane, or stroma. Irregular scarring of these layers of the cornea leads to progressive visual impairment, often associated with recurrent attacks of irritation, pain, and photophobia. To date, mutations in seven genes have been associated with corneal dystrophy, but the genes and mutations associated with 5 additional corneal dystrophy loci remain to be identified. One uncloned loci, CDB2, has been mapped to chromosome 10q23-q25 using a large American family. In order to elucidate the gene and mutation associated with this disease, we created a gene map of the minimal disease region on chromosome 10 using information contained in both the public and private human genome databases. This map contains over 100 candidate genes and EST clusters. These genes and EST clusters were prioritized as candidates for disease based upon positive expression in the cornea, biological relevance to disease, and the availability of overlapping genomic sequence. To date, three genes, glutathione-S-transferase-like mRNA (GSTTLp28), stearoyl-coA desaturase (SCD), and actin-related protein 1 (ACTR1A) have been characterized and tested. The genomic structure of each gene was determined and then one affected and one unaffected member of the CDB2 family were tested for the presence of disease-causing mutations by automated PCR product sequencing. No variants were detected in any of the coding regions or flanking intron/exon junctions. One A to T substitution was detected in the 3'UTR region of GSTTLp28. This substitution changed the consensus polyadenylation signal from AATAAA to AATAAT. Subsequent analysis of this variant determined that this A to T substitution occurs at polymorphic levels in the population, and is therefore not a likely cause of disease. Additional research is currently underway to characterize and test additional candidate genes for CDB2.

**The elongation of very long chain fatty acids (ELOVL4) gene is not associated with sporadic cases of Stargardt Disease.** *D. DUCROQ<sup>1</sup>, J.-M. ROZET<sup>1</sup>, E. SOUIED<sup>1</sup>, S. GERBER<sup>1</sup>, I. PERRAULT<sup>1</sup>, S. HANEIN<sup>1</sup>, F. BARBET<sup>1</sup>, I. GHAZI<sup>2</sup>, J.-L. DUFIER<sup>2</sup>, A. MUNNICH<sup>1</sup>, K. ZHANG<sup>3</sup>, J. KAPLAN<sup>1</sup>.* 1) Laboratoire de Recherches sur les Handicaps Genetiques de l'Enfant, INSERM U393, Hopital des Enfants Malades, Paris Cedex 15, France; 2) Service d'Ophthalmologie, Hopital Necker, Paris, France; 3) Cole Eye Institute, Cleveland Clinic Foundation, Cleveland, OH 44195.

Stargardt disease has been originally described as an autosomal recessive macular degeneration. It is characterized by a broad clinical heterogeneity contrasting with a surprising genetic homogeneity (a single gene, ABCA4, on 1p22) with clear-cut genotype-phenotype correlations. Nevertheless, some cases of patients have been reported to be affected with a Stargardt-like phenotype inherited as an autosomal dominant trait. One locus has been previously mapped to chromosome 13q34 and recently identified: the elongation of very long chain fatty acids gene (ELOVL4). On the other hand, 80% of patients affected with Stargardt disease are sporadic cases in our series (151 / 188). Surprisingly, in about 50% of these patients, the ABCA4 screening failed to identify any mutation. Therefore we screened the ELOVL4 gene in these sporadic cases of Stargardt. The six exons of the ELOVL4 gene and their intronic flanking regions were analyzed in 77 sporadic cases of STGD by single strand confirmation polymorphism (SSCP) and automatic direct sequencing using specific primers. Only two infrequent intronic polymorphisms were found in two unrelated patients (IVS3-18 C/T, and IVS5+45 delT), respectively. No mutation was found in any of the 6 exons for all patients, excluding ELOVL4 as STGD-causing gene in our series.

**Transcript map of the critical region for keratolytic winter erythema (KWE) on chromosome 8p22-p23 between D8S550 and D8S1759.** S. Appel<sup>1</sup>, K. Reichwald<sup>2</sup>, A. Bergheim<sup>3</sup>, M. Filter<sup>4</sup>, E. Ogilvie<sup>3</sup>, S. Arndt<sup>3</sup>, W. Zimmermann<sup>2</sup>, A. Simmons<sup>5</sup>, M. Lovett<sup>5</sup>, W. Hide<sup>6</sup>, A. Reis<sup>7</sup>, A. Rosenthal<sup>2</sup>, M. Ramsay<sup>3</sup>, H.C. Hennies<sup>1</sup>. 1) Molecular Genetics and Gene Mapping Center, Max Delbrück Center Berlin, Germany; 2) Genome Sequencing Center, Institute of Molecular Biotechnology, Jena, Germany; 3) Human Genetics, The South African Institute for Medical Research, Johannesburg, South Africa; 4) Bioinformatics, Max Delbrück Center Berlin, Germany; 5) Human Genetics, Washington University, St. Louis, USA; 6) South African National Bioinformatics Institute, University of the Western Cape, Bellville, South Africa; 7) Human Genetics, Friedrich Alexander University, Erlangen, Germany.

Keratolytic winter erythema (KWE) is an autosomal dominant skin disorder characterized by erythema, hyperkeratosis, and peeling of the skin of the palms and soles especially during winter. The KWE locus has been mapped to human chromosome 8p22-p23. This region has also been associated with frequent loss of heterozygosity (LOH) in different types of cancer. To identify positional candidate genes for KWE, a BAC contig between D8S550 and D8S1695 was constructed and sequenced. It was extended to D8S1759 by a partially sequenced BAC clone identified by database searches. In the 634,404 bp contig 13 new polymorphic microsatellite loci and 46 single nucleotide and insertion/deletion polymorphisms were identified. Twelve transcripts were found between D8S550 and D8S1759 by exon trapping, cDNA selection, and sequence analyses. They were localized on the genomic sequence, their exon/intron structure was determined, and their expression analyzed. Only one of the transcripts corresponds to a known gene, encoding B-lymphocyte specific tyrosine kinase, *BLK*. A putative novel myotubularin-related protein gene (*MTMR8*), a potential human homologue of the mouse *Amac1* gene, and two transcripts showing similarities to the mouse L-threonine 3-dehydrogenase gene and the human *SEC* oncogene, respectively, were found. The remaining seven transcripts did not show significant similarities to known genes. This identification of novel genes and polymorphisms in the region will facilitate the further analysis of disease loci that map to chromosome 8p22-p23.

**Mutation screening of SF2 and HPRP3P in patients with autosomal dominant Retinitis pigmentosa. C.F.**

*Chakarova<sup>1</sup>, E. Vithana<sup>1</sup>, N. Ebenezer<sup>1</sup>, M. Papaioannou<sup>1</sup>, A.C. Bird<sup>2</sup>, S.S. Bhattacharya<sup>1</sup>.* 1) Molecular Genetics, Institute of Ophthalmology, University College London, London, UK; 2) Moorfields Eye Hospital, London, UK.

Autosomal dominant Retinitis pigmentosa (adRP) is an inherited progressive retinal degeneration characterised by night blindness and constricted visual fields. adRP primarily affects the rod photoreceptor cell function and the pigment epithelial layer of the retina. adRP is genetically heterogeneous and mutations have been found in two known genes, rhodopsin and peripherin/Rds. Genetic linkage studies have identified several loci for adRP on chromosomes 1q, 7p, 7q, 8q, 17p, 17q and 19q. The basis of our study is screening of candidate genes for adRP on chromosome 1q and 17q. Two candidate genes were investigated the essential pre-mRNA splicing factor (SF2) which influences 5splice site selection and U4/U6 associated splicing factor (HPRP3P). The preliminary linkage analysis on a large Dutch and South African family has localized the region of RP17 in an interval of 7.7 cM on 17q22. The critical interval for RP18 has been narrowed down to 2 cM on 1q21 in a large Danish and English family. SF2 and HPRP3 were selected as appropriate candidate genes for adRP on the bases of their function, expression pattern and gene localization. Two affected and unaffected members of RP17 and RP18 adRP families were subjected to mutation screening by DHPLC system. Four exonic SF2 and fifteen exonic HPRP3P were screened by automatic direct sequencing. RT-PCR was done to show the expression pattern of both genes. GeneBridge4 Radiation Hybrid Mapping Panel was used to find out the approximate localization of SF2 and HPRP3P related to markers with the highest lod score. Both SF2 and HPRP3P are expressed in retina and have wide expression profile. To date one polymorphism each has been identified in both SF2 and HPRP3P. Mutation screening has yet not revealed any mutation in the coding sequence of SF2 and HPRP3P but 5promotor and 3 UTR still remain to be investigated.

**Mutation screening of caveolin-3 and myotilin in autosomal dominant Limb Girdle Muscular Dystrophy and other dominant myopathies.** *R.D. Dancel<sup>1</sup>, J.M. Stajich<sup>1</sup>, J.M. Vance<sup>1</sup>, M.A. Pricak-Vance<sup>1</sup>, P.C. Gaskell<sup>1</sup>, J.M. Gilchrist<sup>2</sup>, R.W. Tim<sup>3</sup>, M.C. Speer<sup>1</sup>, M.A. Hauser<sup>1</sup>.* 1) Section of Medical Genetics, Department of Medicine, Duke University Medical Center, Durham, NC; 2) Rhode Island Hospital, Providence, RI; 3) Raleigh Neurology Associates, Raleigh, NC.

Limb-girdle muscular dystrophy (LGMD) is a genetically heterogeneous condition with both autosomal dominant and autosomal recessive forms and extensive heterogeneity demonstrated within each of the two forms. In the autosomal dominant form of LGMD, loci have been identified on chromosomes 5 (myotilin), 3 (caveolin-3), 1, and 6. To date, only one family has been identified as having a mutation in myotilin. Thus, we undertook a screen of myotilin and caveolin-3 in 32 autosomal dominant LGMD families. We also investigated patients affected with other autosomal dominant myopathies including individuals affected with non-chromosome 4 linked facioscapulohumeral muscular dystrophy, scapuloperoneal muscular dystrophy, and other non-specific dominant myopathies. Each of the 9 coding exons in the myotilin gene and 2 coding exons in the caveolin-3 gene was PCR amplified from genomic DNA in pools of 5 unrelated individuals. The PCR products were analyzed by denaturing high performance liquid chromatography using the Transgenomic WAVE DHPLC system. Several different temperatures were tested for each PCR amplicon to optimize mutation detection sensitivity. Any pools displaying altered retention time were separated and the constituent samples were reanalyzed individually. All observed changes were confirmed by sequencing both strands using the Beckman CEQ2000 capillary electrophoresis sequencer. A single polymorphism, present in both affected and control individuals, was detected in the caveolin-3 gene. To date, no caveolin-3 or myotilin mutations have been detected, excluding mutations in these genes as a common underlying cause of disease in these families.

**Novel mutations in the GDAP1 gene are responsible for Charcot-Marie-Tooth disease type 4A.** *R.V. Baxter, K. Ben Othmane, J.M. Rochelle, J.E. Stajich, J.E. Stenger, M.A. Pericak-Vance, J.M. Vance.* Center for Human Genetics, Duke University Medical Center, Durham, NC.

The Charcot-Marie-Tooth (CMT) phenotype is the most common inherited peripheral neuropathy. The autosomal recessive demyelinating form of CMT, CMT4, was previously sub-divided based on pathological findings, a division that was upheld by later linkage studies. We have previously shown linkage of CMT4A to chromosome 8q21 with four consanguineous families. The minimal candidate region (MCR) was narrowed using haplotype analysis to approximately 300Kb. Screening of candidate genes lying within the region for expression in peripheral nerve demonstrated one candidate, GDAP1, to be highly expressed in this tissue. GDAP1 has been shown to be highly expressed at the Neuro2a differentiated stage, and is expressed in mouse brain at gradually increasing levels over the course of development, peaking at the adult stage (Liu et al, 1999). After analysis of the sequence data for all six GDAP1 exons, the 92<sup>nd</sup> base pair of Exon 1 showed a homozygous G>A change in affected members of two families. This single base-pair change causes a Trp31STOP mutation, which would effectively truncate the protein. A second mutation in Exon 5, shows a C>G change at the 2<sup>nd</sup> base pair in affected family members, which would cause a Ser194STOP mutation, also cutting short the resultant protein. Mutation studies are underway for the fourth family. How the lack of GDAP1 leads to CMT4A remains to be understood, but further study should continue to provide insight into the normal mechanisms of peripheral nerve biology.

**Autoimmune Lymphoproliferative Syndrome (ALPS) Due to Fas-ligand Mutations.** *L. Bi<sup>1</sup>, L. Zheng<sup>1</sup>, J.K. Dale<sup>1</sup>, T.P. Atkinson<sup>3</sup>, J.M. Puck<sup>2</sup>, M.J. Lenardo<sup>1</sup>, S.E. Straus<sup>1</sup>.* 1) LCI & LI/NIAID/NIH, Bethesda, MD; 2) Genet Mol Biol Branch/NHGRI/NIH, Bethesda, MD; 3) Dept Peds/UAB, Birmingham, AL.

ALPS is a disorder of lymphocyte homeostasis due to mutations in gene products that regulate apoptosis. ALPS is classified as Type Ia when there are mutations in APT1 encoding Fas (TNFRSF6); Type II ALPS involves mutations in Caspase-10; in Type III no genetic defects have been found. ALPS Type Ib, with mutations in Fas-ligand (FasL, TNFSF6), has been postulated to exist. We sequenced the coding region for FasL in 32 patients with features suggestive of ALPS and normal Fas. Unique single nucleotide mutations were found in each of 2 unrelated patients but not in 100 chromosomes of normals. The first patient is a 10 yo boy with typical features of ALPS: generalized adenopathy and splenomegaly, idiopathic thrombocytopenic purpura (ITP) and elevated CD4<sup>+</sup>CD8<sup>-</sup> T cells. A heterozygous A530G mutation of FasL cDNA leads to a change of Arg to Gly at peptide site 156, predicted by molecular modeling of a soluble Fas ligand fragment to be part of an external loop of the protein. Cytotoxicity of his PBMCs for Fas positive (Jurkat) cells was reduced compared with PBMCs from normals. The second patient is an 8 yo girl with a history of ITP but no adenopathy or splenomegaly. Sequencing of her FasL showed a heterozygous A320G mutation of cDNA leading a conservative change of Met to Val at peptide site 86 in the predicted transmembrane domain of FasL. To correlate these two mutations with our clinical findings, cDNAs encoding wild type (WT) FasL, both patient variants, and the humanized mouse gld FasL mutant, were cloned into an expression vector, transfected into 293-T cells, and used to kill Jurkat cells. The cells expressing WT and the girls FasL killed Jurkat cells efficiently; gld expressing cells had very low kill activity and cells expressing the boys FasL showed reduced kill activity. Dominant interference studies involving co-transfection of mutant and WT FasL are in progress to elucidate the mechanism of action of these mutations. The cumulative data indicate that only the boy has ALPS Type Ib, and he is the first patient reported to have this diagnosis.

**Dominant vitreoretinal degeneration without systemic manifestations: Stop codon mutation in exon 2 of the COL2A1 gene in a new large family.** A.O. Edwards<sup>1</sup>, R.L. Ritter III<sup>1</sup>, L.A. Donoso<sup>2</sup>. 1) Dept Ophthalmology, Univ Texas SW Medical Ctr, Dallas, TX; 2) Wills Eye Hospital, Philadelphia, PA.

**Objective:** To identify the gene responsible for an autosomal dominant vitreoretinal degeneration occurring in a large family without associated systemic manifestations.

**Methods:** Participating family members were evaluated clinically over a 30 year period. Genetic linkage, genotyping, mutation screening, and an extensive genealogical investigation were performed.

**Results:** We identified a single large family, over 2,000 total family members, with vitreoretinal degeneration spanning 12 generations. We clinically evaluated 165 study participants (95 clinically affected and 70 unaffected). The earliest clinical findings in affected individuals included an optically empty vitreous and posterior perivascular cystic degeneration resembling radial lattice. Later findings included vitreous band formation, multiple retinal tears and detachments predominately along the posterior and peripheral vessels. A cytosine to adenosine (C/A) transition was identified at position 4363 within exon 2 of the *COL2A1* gene, leading to the creation of a stop codon at position 86 (Cys86Stop).

**Conclusions:** A large family with vitreoretinal degeneration without significant associated systemic findings was described. The disease causing mutation was identified as a novel C/A transition in exon 2 creating a stop codon in the *COL2A1* gene. Clinical relevance: This highly specific genotype-phenotype relationship illustrates the importance of vitreoretinal examination in identifying the affected offspring of patients with this disorder. The identification of the disease causing mutation in this family allows for presymptomatic genetic testing to identify family members needing early examination and consideration for prophylactic therapy.

**A mutation in the SLC11A3 gene is associated with autosomal dominant hemochromatosis.** *O.T. Njajou, N. Vaessen, M. Joosse, B. Berghuis, J. van Dongen, M. Breuning, P.L. Snijders, W.P. Rutten, L. Sandkuijl, B.A. Oostra, C.M. van Duijn, P. Heutink.* Genetic-Epidemiology Unit: Departments of Epidemiology & Biostatistics, and Clinical genetics Erasmus University Medical Center, Rotterdam, The Netherlands.

Hereditary Hemochromatosis (HH) is a very common iron disorder in caucasians usually inherited as a recessive trait. The disease is characterized by increased absorption and progressive storage of iron in body tissues resulting in multi-organ damage and widespread pathology including diabetes, cardio-vascular diseases, stroke and cancer. Several genes involved in iron metabolism have been implicated in the pathology of hemochromatosis. Mutations in the HLA-H/HFE gene on chromosome 6p, the transferrin receptor gene (TFR-2) on chromosome 7q have been identified and juvenile hemochromatosis maps to chromosome 1q. However not all HH patients carry these mutations. Also, families with dominant or pseudo-dominant mode of inheritance have been reported. This suggests that other genes are involved in the pathology of hemochromatosis. A very large Dutch family with hemochromatosis has been described in which the disease segregates as a dominant trait that did not map to any known locus. We performed a systematic genome scan for linkage in this family and mapped the disease gene to chromosome 2q. In the critical region, the Solute Carrier family 11 member A3 (SLC11A3) gene also called ferroportin1 has been localized. Subsequent mutation analysis of SLC11A3 identified a single base change in all patients but not in healthy individuals from the family or the general population. This A to C transversion at position 734 (A734C) located in a transmembrane domain of the protein leads to a substitution of asparagine by histidine (N144H) resulting in change of polarity and is predicted to result in excessive SLC11A3 mediated iron transport. We describe for the first time an heterozygous mutation that can explain autosomal dominant hemochromatosis.

**Multiple cutaneous leiomyoma and uterine fibroids: Confirmation and refinement of the *MCUL1* locus. A.**

*Martinez-Mir*<sup>1</sup>, *D. Gordon*<sup>3</sup>, *L. Horev*<sup>4</sup>, *J. Ott*<sup>3</sup>, *A. Zlotogorski*<sup>4</sup>, *A.M. Christiano*<sup>1,2</sup>. 1) Department of Dermatology, Columbia University, New York, NY; 2) Department of Genetics and Development, Columbia University, New York, NY; 3) Laboratory of Statistical Genetics, Rockefeller University, New York, New York; 4) Department of Dermatology, Hadassah University Medical Center, Jerusalem, Israel.

Uterine leiomyomas are common benign tumors of smooth muscle origin. Although it is a leading cause of hysterectomy, little is known about the molecular mechanisms underlying these tumors. Genetic predisposition, steroid hormone concentrations, and environmental factors have been suggested to play a role in the pathogenesis of these tumors (Stewart, 2001). The association of uterine leiomyomas (myomas or fibroids) with cutaneous leiomyomas in an autosomal dominant syndrome called multiple cutaneous leiomyoma (MCL [MIM 150800]) facilitates the study of the genetic causes underlying these tumors.

Very recently, the locus responsible for MCL has been mapped to a ~14 cM region on chromosome 1q42.3-43 (Alam et al, 2001). Moreover, the same locus has been identified in a separate study as the susceptibility locus for a hereditary cancer syndrome including renal cell cancer, as well as uterine and cutaneous leiomyoma (Launonen et al, 2001). Here, we report the clinical and genetic findings in an extended Israeli pedigree with MCL. We describe the clinical features of MCL in a new large family, with emphasis on the particular timing and specific pattern in the appearance of the skin lesions. The genetic analysis of the family has allowed us to narrow the location of the *MCUL1* locus to a region of 4-7 cM on chromosome 1.

**The mutations in the untranslated *RMRP* gene that result in cartilage-hair hypoplasia, a pleiotropic human disease.** *I.I. Kaitila*<sup>1, 2, 3</sup>, *M. Ridanpää*<sup>1, 2, 3</sup>. 1) Clinical Genetics Unit, Helsinki Univ Central Hosp,; 2) Department of Medical Genetics, Univ Helsinki,; 3) Folkhälsan Institute of Genetics, Helsinki, Finland.

We have recently demonstrated that mutations in *RMRP* gene are the cause of cartilage-hair hypoplasia (CHH), an autosomal recessive multiorgan condition (Ridanpää et al., Cell, 2001, 204:197 - ). The primary transcript of the gene consists of 267 nucleotides, only, and it encodes the RNA component of an endoribonuclease RNase MRP that acts in cleavage of RNA in mitochondrial DNA synthesis and nucleolar cleaving of pre-rRNA. Other functions probably exist. The clinical manifestations of CHH consist of short stature due to metaphyseal chondrodysplasia, hair hypoplasia, defective erythropoiesis presenting with refractive anemia, defective cell-mediated, and often, humoral immunity, defective spermatogenesis, variable Hirschsprung disease, and risk of malignancies. CHH is common among the Amish in the USA and the Finns, and rare in other populations. In order to understand the pathogenetic mechanisms in CHH we screened 91 Finnish and 36 non-Finnish CHH patients for *RMRP* mutations. We found that 84 per cent of the Finnish patients were homozygous for nt70A->G substitution, and 13 per cent were compound heterozygotes with nt70A->G/nt262G->T. The nt70A->G was also observed in 25 chromosomes out of the 36 patients from other populations. In particular, nt 70A->G homozygotes were found in Canada, England, Turkey, USA, and the Netherlands whereas compound heterozygotes with variable allelic mutations in Australia, Brazil, Canada, England, Germany, and USA. Thus, nt70A->G is probably an ancient mutation. Other types of mutations were substitutions, insertions, duplications and deletions located either upstream of the coding sequence or in the transcribed region of the gene. The allele carrying an insertion or deletion in the region upstream of the coding sequence probably does not express. - The mutation screening can be offered as a diagnostic test in a suspected case of CHH. *RMRP* is the first untranslated gene the product of which has functions in the nucleolar and mitochondrial RNA biochemistry.

**Transcriptome analysis of the *rd1* mouse.** *T. Leveillard*<sup>1</sup>, *C. Lavedan*<sup>2</sup>, *S. Mohand-Säid*<sup>1</sup>, *M. Dressman*<sup>2</sup>, *A. Dölemeyer*<sup>3</sup>, *G. Lambrou*<sup>3</sup>, *J. Sahel*<sup>1</sup>. 1) INSERM/ULP/HUS EMI 99-18, Strasbourg France; 2) Pharmacogenetics, Novartis, Gaithersburg, MD; 3) Novartis Ophthalmics, Basel, Switzerland.

In the *rd1* mouse, an animal model of Rod-Cone dystrophy, the loss of rod photoreceptors results from a mutation in the rod b-Phosphodiesterase gene. This leads to cone degeneration by deprivation of Rod-dependant Cone Surviving Factors. Reintroducing these factors to prevent vision loss is a valuable therapeutic approach of Retinitis Pigmentosa (RP). To identify genes whose expression is lost, we have performed gene expression analysis of neural retina following rod degeneration using Affymetrix microarray technology. Among the ~9,800 genes studied, 1,229 had a difference in expression of at least three fold between *rd1* and wild type samples. The expression of 640 genes was reduced in the absence of rods and 589 genes had an elevated expression in the *rd1* mouse neural retina at five weeks compared to wild type. The apparent lower expression of certain genes in *rd1* could be a direct consequence of the loss of rod cells or indirectly of other cells dependent on rods. The kinetics of expression of these genes during rod degeneration was studied using RT PCR. Their human orthologues are candidate genes that may be mutated in RP. Genes with higher expression in *rd1* are induced by the degeneration of rod cells; they are upregulated by the cones of the outer retina and/or other cells of the inner retina. We classified the 1,229 genes with differential expression according to their known function. The percentage of Transcription Factor and Signal Transduction genes did not significantly vary between the *rd1* and wild type samples, reflecting the complexity of signaling involved in rod maintenance or in the response to rod degeneration. The majority of up-regulated genes were classified as Chaperone, Apoptosis, Cell Adhesion and Redox control genes and might reflect stress signaling in response to rod degeneration. Gene expression profile analysis of rod degeneration in a mouse model of RP provides a new way to identify genes and pathways implicated in retinal function, and neuro-protective molecules with therapeutic potential.éé.

**The Polynucleotide Kinase 3-Phosphatase Gene is not Responsible for Autosomal Recessive Charcot-Marie-Tooth Disease type 2 in Chromosome 19q13.3.** A. Leal<sup>1,2</sup>, B. Morera<sup>3</sup>, G. Del Valle<sup>4</sup>, D. Heuss<sup>5</sup>, C. Kayser<sup>5</sup>, M. Berghoff<sup>5</sup>, B. Neundoerfer<sup>5</sup>, R. Barrantes<sup>2</sup>, A. Reis<sup>1</sup>, B. Rautenstrauss<sup>1</sup>. 1) Institute of Human Genetics, University of Erlangen-Nuremberg, Erlangen, Germany; 2) Institute of Health Research (INISA) and School of Biology, University of Costa Rica, San Jose, Costa Rica; 3) Unitat de Biologia Evolutiva, Universitat Pompeu Fabra, Barcelona, Spain; 4) Department of Neurology, San Juan de Dios Hospital, San Jose, Costa Rica; 5) Department of Neurology, University of Erlangen-Nuremberg, Erlangen, Germany.

Charcot-Marie-Tooth disease (CMT), a group of hereditary motor-sensory neuropathies, is a clinically and genetically heterogeneous disorder of the peripheral nervous system. Recently, we found linkage in a Costa Rican family with autosomal recessive CMT type 2 (ARCMT2B) in chromosome 19q13.3. The critical interval was defined between markers D19S902 and D19S907 (5.5 cM). Clinically, the age at onset of chronic symmetric sensory-motor polyneuropathy was 28 to 42 years (mean 33,8) in this family, and the electrophysiologic data clearly reflect an axonal degenerative process. After localizing the gene, contigs of the region were reconstructed *in silico*, and using several programs (i.e. NIX program) 72 unigene-clusters were identified in the critical region. The genomic sequence of the interval was compared automatically (HUSAR package, DZKF) against 15,000 sequences from five peripheral nerve cDNA libraries (CGAP, NCI). The Polynucleotide kinase 3-phosphatase gene (*PNKP*) was found being present in the critical interval and expressed in peripheral nerve. PNKP is a DNA-specific kinase, and it is predictive of a function in DNA repair. Intronic primers for testing this gene were designed based in the exon-intron structure, obtained comparing the cDNA sequence (AF120499) against the genome sequence (AC021163), and was checked for any alternative splicing reported until know (Alternative Splice Finder program). Finally, this positional and expressional candidate gene was analyzed by direct sequencing, however, no mutation was found in patients with ARCM2B in the Costa Rican family.

**Analysis of candidate genes for Hereditary Neuralgic Amyotrophy (HNA).** *J.R. Meuleman, G.D.J. Watts, K.C. O'Briant, P.F. Chance.* Department of Pediatrics, University of Washington, Box356320, Seattle, WA 98195.

Hereditary Neuralgic Amyotrophy (HNA) is an autosomal dominant disorder characterized by sudden, painful episodes of brachial plexus neuropathy. Linkage analysis defined a locus on chromosome 17q25, which was recently narrowed down to a 1 Mb interval. Furthermore, 4 positional candidate genes had been excluded recently. Here we present the analysis of 6 known positional candidate genes (the *ET* transcripts, *KIAA1067*, *KIAA0585*, *LAK4P*, *PRPSAP1* and *SYNGR2*) and one novel positional candidate gene homologous to the *MGAT5* gene. The genes were studied in affected and control individuals from 6 — 9 HNA families, which were previously linked to the 17q25 HNA locus. We performed mutation analysis by sequencing the coding regions at cDNA or genomic DNA. No nucleotide changes were detected in the *ET* transcripts, *KIAA1067*, *KIAA0585*, *LAK4P*, *PRPSAP1* and *SYNGR2*. The last gene we analyzed was deduced from the hypothetical protein DKFZp761J107 using RT—PCR, Genscan predictions and the apparent homology with the *MGAT5* gene. We determined the genomic structure of 18 exons by alignment with the genomic sequences of RP11—87G24. Mutation analysis showed 5 silent base changes (1203G>C, 1338C>T, 1476C>T, 2022C>T and 2316C>T) and 2 base changes causing an amino acid substitution (208G>A and 661G>A leading to I70V and G221R respectively). However, none of these coding SNPs could be linked with the HNA phenotype since they were present in both affected and unaffected, married-in individuals. Furthermore, the exclusion was confirmed by the recent refinement of the HNA linkage interval. Hereby we excluded all known positional candidate genes.

**A missense mutation of human Gephyrin (*GPHN*) is associated with Hyperekplexia and transcript isoform analysis re-defines the genomic structure of *GPHN*.** M.I. Rees<sup>1</sup>, K. Baer<sup>1</sup>, H. Ward<sup>1</sup>, S.L. Coleman<sup>2</sup>, I.L. Evans<sup>3</sup>, J. Miller<sup>1</sup>, H. Waldvogel<sup>4</sup>, R.L.M. Faulk<sup>4</sup>, M.J. Owen<sup>2</sup>, R.G. Snell<sup>1</sup>. 1) Department of Molecular Medicine, University of Auckland Medical School, Auckland, New Zealand; 2) Department of Psychological Medicine, University of Wales College of Medicine, Cardiff, U.K; 3) University of Birmingham Medical School, Birmingham, U.K; 4) Department of Anatomy, University of Auckland Medical School, Auckland, New Zealand.

Gephyrin (*GPHN*) is an organisational protein that clusters and localises the inhibitory glycine (GlyR) and GABAA receptors to the microtubular matrix of the neuronal postsynaptic membrane. Mice that are deficient in gephyrin develop a hereditary molybdenum cofactor deficiency and a neurological phenotype that mimics startle disease (hyperekplexia). We have previously confirmed genetic heterogeneity for hyperekplexia by demonstrating mutations in the  $\alpha 1$ -subunit (*GLRA1*) and  $\beta$ -subunit (*GLRB*) of the GlyRs. However, the exclusion of *GLRA1* and *GLRB* mutations in a proportion of our sporadic sample of patients, indicates the presence of additional genetic determinants and candidate gene analysis of *GPHN* was undertaken. Following the *in silico* determination of the genomic structure of *GPHN* from chromosome 14 BACS, mutation analysis of all 27 *GPHN* exons in hyperekplexia patients revealed several polymorphisms, and most significantly, a missense mutation (A28T) in exon 1 that causes an amino acid substitution (Asn10Tyr). This change disturbs a myristylation consensus region at the N-terminus of *GPHN* and we speculate that this affects binding of gephyrin to the postsynaptic plasma membrane and compromises the gephyrin scaffold. Preliminary data from neuronal and non-neuronal human RNA isoforms confirm the presence of 27 *GPHN* exons (5 alternatively spliced), whereas the existence of 29 exons (7 alternatively spliced) in rat tissues raises the possibility of additional uncharacterised isoforms. This work will provide a basis for mapping gephyrin isoform distribution in human brain.

**Mutation and deletion analysis of the Van der Woude syndrome locus at chromosome 1q32-q41.** *B.C. Schutte<sup>1,2</sup>, Y. Watanabe<sup>1</sup>, B.C. Bjork<sup>2</sup>, E.L. Howard<sup>3</sup>, S.A. Hoper<sup>1</sup>, M.I. Malik<sup>1</sup>, M.M. Fang<sup>1</sup>, P.I. Hemerson<sup>1</sup>, M.J. Dixon<sup>3</sup>, J.C. Murray<sup>1,2</sup>.* 1) Dept Pediatrics, Univ Iowa, Iowa City, IA; 2) Genetics PhD Program, Univ Iowa, Iowa City, IA; 3) Univ Manchester, Manchester, UK.

Van der Woude syndrome (VWS) is an autosomal dominant orofacial clefting disorder (OMIM #119300). Characteristics of VWS include lower lip pits, cleft lip with and without cleft palate, isolated cleft palate, hypodontia and normal intelligence. The VWS locus maps to a 1.6 cM region between markers D1S491 and D1S205 on chromosome 1q32-q41. The finished sequence for this region is available, and we have identified 41 genes within and adjacent to the 363 kb critical region. Using SSCP, we screened 137 exons that contain an open reading frame for mutations in 90 probands. We identified 25 mutations, but none were etiologic for VWS. Previously, we observed that deletion of the VWS critical region was etiologic in two families. Many deletions would not be detected by SSCP analysis, so we also performed an allele loss assay to screen for new VWS-causing deletions. We genotyped 30 VWS triads with 22 single nucleotide polymorphisms (SNPs) from the SNP consortium (<http://snp.cshl.org>). The average heterozygosity for these SNPs was 40% and 43% in CEPH control and VWS populations, respectively. We did not observe an allele loss with any of the SNPs in any of the 30 families tested. However, we observed a large region of monozygosity in a single pedigree (family 1470) that is consistent with the presence of a deletion. This region contains seven markers, including the STRP D1S3753 which is located in the middle of the monozygous region and has 85% heterozygosity. Based on the combined heterozygosities of the seven markers, there is a 1.7% probability that the observed monozygosity is a random event. Southern analysis was performed using a probe inside the monozygous region (5 kb proximal to D1S3753) and a control probe from a different chromosome. No differences were seen between the proband and control samples. We conclude that the region proximal to D1S3753 is not deleted in family 1470, and more generally, that deletions larger than 20 kb do not significantly contribute to VWS etiology.

**Candidate gene screening of periaxin and its interactors in Charcot-Marie-Tooth neuropathy.** *H. Takashima*<sup>1</sup>, *C.F. Boerkoel*<sup>1</sup>, *D.L. Sherman*<sup>3</sup>, *P.J. Brophy*<sup>3</sup>, *J.R. Lupski*<sup>1,2</sup>. 1) Mole Human Gen/TX Med Ctr, Baylor Col Medicine, Houston, TX; 2) Department of Pediatrics, Texas Childrens Hospital, Houston, TX; 3) Department of Preclinical Veterinary Sciences, University of Edinburgh, Edinburgh, UK.

Charcot-Marie-Tooth neuropathy (CMT), one of the most common inherited neurologic diseases, is clinically and genetically heterogeneous. At least 15 genetic loci and 9 genes have been associated with CMT and related neuropathies; however, we have ascertained 168 CMT families without an identified gene mutation. Therefore this observation suggests that mutations in other genes must also cause CMT. We hypothesized that mutations in Periaxin (PRX), or proteins interacting with Periaxin, might cause demyelinating neuropathy because PRX<sup>-/-</sup> mice develop a severe demyelinating neuropathy. We performed denaturing high-performance liquid chromatography (DHPLC) and DNA sequencing analysis to screen for mutations of these genes in 168 families without mutations involving PMP22, MPZ, GJB1, EGR2 and MTMR2. We identified three Dejerine-Sottas neuropathy (DSN) patients with recessive PRX mutations; two had compound heterozygous nonsense and frameshift mutations and one had a homozygous frameshift mutation. Sequence alterations of proteins interacting with Periaxin have also been identified and the association of these alterations with disease is being evaluated.

**LAMA2 mutation thought to be molecular basis of congenital muscular dystrophy in the merosin-deficient *dy2j* mouse is found to be splicing variant present in normal mice.** *D.M. Pillers, J. Pang.* Dept Pediatrics and Molecular & Medical Genetics, Oregon Health Sci Univ, Portland, OR.

Laminin is a trimeric extracellular glycoprotein that is a component of the extracellular matrix. It plays an important role in cell adhesion and migration, in addition to signaling through transmembrane molecules such as integrin and dystroglycan. Laminin-2, also known as merosin, is critical in skeletal muscle development and function. Mutations in laminin-a2 are associated with human congenital muscular dystrophy (CMD) and with muscular dystrophy in the mouse models *dy* and *dy2j*. A G to A splice donor mutation at exon 2 in *dy2j* was defined by Xu et al. (1994) as the site of the mutation resulting in the muscular dystrophy phenotype based upon the creation of a group of aberrant laminin-a2 transcripts. In one, exon 2 is skipped but the reading frame is retained. In others, a stop codon is predicted to result in a truncated protein. We performed RT-PCR analysis of the alternatively spliced products for laminin-a2 and found that the spliced-in fragment described by Xu et al. is present in both normal C57Bl/6J mice and the muscular dystrophy mouse model *dy2j* suggesting that the mutation may actually be a polymorphism. Furthermore, we found that the truncated products predicted by Xu et al. could be translated into near full-length proteins, lacking only domain VI of the laminin-a2 subunit which contains the binding sites for heparin and cell surface receptors. We also found that the skipping pattern of exon 2 resulted in skipping the entire exon 2 while retaining the reading frame, as opposed to skipping part of exon 2 and the entire exon 3 as suggested by Xu et al. Thus, we propose that the splicing-in variant is expressed in normal mouse and likely has a specific function. In addition, we propose that the alternative splice pattern occurs independent of the G to A polymorphism and is the result of a novel regulatory mechanism.

**SOD -A multigenic disorder?** *K.S. Woods, D. McNay, J.P.G. Turton, M.T. Dattani.* Biochem/Endoc/Metabolism Unit, Institute of Child Health, London, England.

Development of the anterior pituitary gland is a multigenic process regulated by complex signalling pathways which determine expression and interaction of a number of transcriptional factors. Fate map analysis reveals that the anterior neural ridge will give rise to the anterior pituitary and olfactory lobe whereas adjacent regions of the neural plate give rise to the hypothalamus, posterior pituitary, optic vesicles and ventral forebrain. We have previously described the association between septo-optic dysplasia (SOD), a human disease characterised by midline forebrain abnormalities, pituitary dysplasia and optic nerve hypoplasia, and mutations in the homeobox gene *HESX1*<sup>(1)</sup>. However mutations in this gene account for only a small number of cases of SOD (8/570). We have now screened a large cohort (n=205) of SOD patients with variable phenotypes for a number of candidate genes implicated in forebrain and pituitary development

The genes selected for this on going study (*EMX2, PAX6, SIX3, and SIX6*) were chosen on the basis of developmental expression pattern, information from mouse studies, and previous association with genetic disorders affecting similar tissue types. Whilst to date no definitive mutations have been documented, a number of polymorphisms, both exonic and intronic, have been identified.

Two intragenic polymorphisms have previously been described in *SIX6*<sup>(2)</sup>, one of which is within the homeobox of this gene. This polymorphism appeared to be present at a high frequency within our cohort of patients and further characterisation within a control population using pyrosequencing technology confirmed a similar prevalence.

Although these polymorphisms are present in control populations, they may well lead to a change in protein function e.g. an N125S polymorphism within *HESX1* (MT Dattani;personal communication). Interactions with other proteins and/or the environment may therefore be crucial factors in the manifestation of a phenotype.

<sup>1</sup>(Dattani *et al.* 1998) <sup>2</sup>(Gallardo *et al.* 1999).

**Towards the identification of at least 12 genes in Leber congenital amaurosis.** *I. PERRAULT<sup>1</sup>, S. GERBER<sup>1</sup>, S. HANEIN<sup>1</sup>, J.-M. ROZET<sup>1</sup>, D. DUCROQ<sup>1</sup>, F. BARBET<sup>1</sup>, I. GHAZI<sup>2</sup>, J.-L. DUFIER<sup>2</sup>, A. MUNNICH<sup>1</sup>, J. KAPLAN<sup>1</sup>.* 1) Laboratoire de Recherches sur les Handicaps Genetiques de l'Enfant, INSERM U393, Hopital des Enfants Malades, PARIS Cedex 15, FRANCE; 2) Service d'Ophtalmologie, Hopital Necker, PARIS, FRANCE.

Leber congenital amaurosis (LCA) is an autosomal recessive condition responsible for congenital blindness or greatly impaired vision since the first months of life. A subtle clinical variability has long been reported but largely ignored. Conversely, the genetic heterogeneity of this condition no more needs to be demonstrated, as since 1996, six different genes have been identified. All together, these six genes account for about 45% of all cases. These genes are unequally responsible for the disease in our series of 145 LCA patients: the retinal-specific guanylate cyclase (retGC1) gene in 22%, the retinal pigment epithelium 65 KDa (RPE65) gene in 5.5 %, the cone-rod homeobox containing gene (CRX) in 1.4%, the Aryl Hydrocarbon-interacting protein-like (AIPL1) gene in 5.5%, the retinitis pigmentosa GTPase regulator-interacting protein (RPGRIP1) gene in 5.5% and the crumb homolog (CRB1) gene in 5%. All six genes are involved in very different physiopathologic pathways. Genotype-phenotype correlations clearly demonstrate that the most severe phenotype is related to retGC1 mutations which constantly lead to a dramatic stationary cone-rod dystrophy since birth. Conversely, the milder phenotype is related to RPE65 mutations which are responsible for a very early but progressive rod-cone dystrophy, consistent with a poor visual fonction in the first years of life. The four other gene mutations account for a profound visual impairment which severity varies between the two extreme ends represented by retGC1 and RPE65, respectively. Genome-wide searches for other LCA genes failed to map another major locus comparable to retGC1. Therefore it is very likely that numerous genes remain to be identified so that to account for the remaining 55% patients. Consequently, we speculate that at least six additional LCA genes should be identified, each of them accounting for a small proportion of patients.

**Dominant X linked RP are constantly accounted for by truncating mutations in the ORF 15 exon of the RPGR gene.** *J.-M. ROZET<sup>1</sup>, I. PERRAULT<sup>1</sup>, N. GIGAREL<sup>1</sup>, E. SOUIED<sup>1</sup>, I. GHAZI<sup>2</sup>, S. GERBER<sup>1</sup>, J.-L. DUFIER<sup>2</sup>, A. MUNNICH<sup>1</sup>, J. KAPLAN<sup>1</sup>.* 1) Unite de Recherches sur les Handicaps Genetiques de l'Enfant, INSERM U393, Hopital des Enfants Malades, Paris, Cedex 15, FRANCE; 2) Service d'Ophtalmologie, Hopital Necker, Paris, FRANCE.

Retinitis pigmentosa (RP) is a group of progressive hereditary disorders of the retina in which various modes of inheritance have been described. In 1997, we reported on X-linked RP in nine families with constant and severe expression in carrier females. However, the phenotype was milder and delayed in females compared to hemizygous males. This form of X-linked RP could be regarded therefore as partially dominant (DXLRP). The disease gene has been mapped to chromosome Xp21 in the genetic interval encompassing the RP3 locus ( $Z_{max} = 13.71$ ). At this time, direct sequence analysis of the retinitis pigmentosa GTPase regulator (RPGR) gene, which accounts for RP3, failed to detect any mutation in our families. Very interestingly, in 2000, an additional RPGR exon (ORF15 exon) has been identified and reported to be a hot spot for mutations in recessive X-linked RP. Subsequently we undertook the screening of this novel exon in the nine original DXLRP families as well as in 11 additional cases. Fifty-five percent of these 20 families were found to harbour a truncating mutation in the ORF15 exon of RPGR gene. Interestingly, in two of these families, the mutation was identified in two asymptomatic potential carriers. This finding confirms the incomplete penetrance of the gene and improves genetic counselling in families affected with DXLRP.

**Identification of Novel Retina and Cochlea Specific Genes in the Critical Region for Usher Syndrome Type III.**

*G. Zhou*<sup>1</sup>, *R.R. Fields*<sup>2</sup>, *D. Huang*<sup>1</sup>, *J. Davis*<sup>1</sup>, *M. Zhou*<sup>1</sup>, *M.D. Weston*<sup>2</sup>, *W.J. Kimberling*<sup>2</sup>, *J. Sumegi*<sup>1</sup>. 1) Dept Pathology & Microbiology, center for human molecular genetics, Univ Nebraska Medical Ctr, Omaha, NE; 2) Department of Genetics, Boys Town National Research Hospital, Omaha, NE.

Usher syndrome type 3 (USH3; MIM 276902) is an autosomal recessive disorder associated with progressive hearing loss, variable vestibular responses and adolescent onset retinitis pigmentosa (RP). A locus for USH3 was originally mapped to a 5 cM region on chromosome 3q25, and has recently been refined to a 250-kb genomic fragment between markers 107G19CA7 and D3S3625 by a group in Finland (Tarja J et al; Genomics 63, 409-416, 2000). Using a positional candidate approach, cDNA library screening, RACE and cloning in silico, we identified two USH3 candidate genes USH3Ca and USH3Cb in the USH3 critical region. Both genes are expressed in retina and inner ear. The size of transcripts of both genes is approximately 10-11 kilobases. USH3Ca mRNA has 3 exons and a large open reading frame (ORF) encoding a predicted protein of 2365 amino acids. This predicted protein has multiple immunoglobulin like domains and high homology to adlican (AAF86402), a novel protein expressed in human arthritic tissues. The USH3Cb mRNA has 39 exons and an ORF of 6438 nucleotides. Predicted USH3Cb protein has high homology to human thyroid hormone receptor-associated protein (NP\_005111) and *Drosophila m.* protein kohtalo (AAG48320). The characterization of USH3 candidate genes provides the basis for mutational screening of USH3 families to identify the gene mutated in Usher Syndrome type III.

**Clinical and genetic heterogeneity in connexin disorders of the skin.** *G. Richard*<sup>1</sup>, *A. Krol*<sup>2</sup>, *F. Rouan*<sup>1</sup>, *N. Brown*<sup>1</sup>, *J.J. DiGiovanna*<sup>3</sup>, *S.J. Bale*<sup>4</sup>, *J. Uitto*<sup>1</sup>. 1) Dermatology & Cutaneous Biol, Thomas Jefferson Univ, Philadelphia, PA; 2) Division of Dermatology and Cutaneous Sciences, University of Alberta, Edmonton, Canada; 3) Department of Dermatology, Brown University, Providence, RI/NCI, NIH; 4) NIAMS, NIH, Bethesda, MD/GeneDx, Rockville, MD.

Dominant mutations in at least 4 connexin genes expressed in ectodermal tissues may impair hearing, epidermal differentiation, or both. Erythrokeratoderma variabilis (EKV) is an inherited disorder of the skin caused by mutations in *GJB3* (Cx31) or, as recently suggested (Macari et al., Am J Hum Genet 2000), in *GJB4* (Cx30.3). In a large series of 23 unrelated EKV families, 12 were found to carry heterozygous missense mutations in *GJB3* including 4 novel mutations (G12S, G45E, S26T and L209F). In addition, 5 EKV families harbored pathogenic mutations in *GJB4* affecting a conserved residue in the N-terminus (G12D) or the transmembrane domains of Cx30.3 (T85P, F137L and F189Y). While these defects in Cx31 and Cx30.3 produce a common EKV phenotype with subtle differences in erythema and hyperkeratosis, dominant mutations in the Cx26 gene have a pleiotropic effect, causing either hearing impairment alone or associated with distinct forms of palmoplantar keratoderma (PPK). We identified a family segregating a novel *GJB2* mutation (N54K) substituting a highly conserved asparagine in the first extracellular loop of Cx26. Besides deafness and PPK, this mutation resulted in development of prominent knuckle pads and leukonychia, a disorder diagnosed as Bart-Pumphrey syndrome. Our observations extend the phenotypic spectrum of Cx26 mutations to include also nail abnormalities. The striking clinical overlap between defects in Cx26, Cx31, Cx30.3 and Cx30 emphasizes the importance of gap junctions for the normal development and function of ectodermal tissues.

**Chromosomal duplication at the *IRIDI* locus on 6p25 associated with wide variability of the glaucoma phenotype.**

V. Raymond<sup>1</sup>, S. Dubois<sup>1</sup>, M.A. Rodrigue<sup>1</sup>, F. Couture<sup>1</sup>, J.L. Anctil<sup>2</sup>, G. Côté<sup>2</sup>, M. Amyot<sup>3</sup>, P. Blondeau<sup>4</sup>, E. Bergeron<sup>5</sup>, M. Walter<sup>6</sup>, J. Morissette<sup>1</sup>. 1) Molecular Endocrinology, Laval University Hospital (CHUL) Research Center, Québec, QC, Canada; 2) Ophthalmology, St-Sacrement Hosp, Québec, QC; 3) Maisonneuve-Rosemont Hosp, Montréal, QC; 4) Sherbrooke Univ, Sherbrooke, QC; 5) St-Hyacinthe Hosp, QC; 6) Ophthalmology/Medical Genetics, Univ. of Alberta, Edmonton, AL, Canada.

Mutations in *FOXC1*, a forkhead/winged-helix transcription factor located at the *IRIDI* locus on 6p25, cause defects of the anterior chamber of the eye associated with developmental glaucoma. We observed a large French-Canadian family: pedigree BV-001, in which 30 patients showed wide phenotypic variability, ranging from asymptomatic anomalies of the eye to primary open-angle glaucoma (POAG). The disorder was linked to the *IRIDI* locus; however, no mutations were identified in the coding region of *FOXC1*. To characterize the genetic defect, a high resolution physical map was constructed between D6S1600 and D6S344 using 89 BACs/PACs and "in silico" mapping. Our contig spanned 500 kb and encompassed two other candidate genes: *FOXQ1* (previously known as *HFH1*) and *FOXF2*, also harboring forkhead/winged domains. No coding mutations were detected in either genes. Two novel SNPs positioned the disease interval centromeric to *FOXQ1*. Four microsatellites: 668J24-GT, AFMb034ya5, UT7184 (D6S967) and 118B18-CA47, showed a three allele system in branches of the pedigree. Segregation analysis of these markers identified the presence of a small 6p25 duplication in affected persons carrying the disease haplotype. The minimal duplicated region spanned from 668J24-GT to 118B18-CA47, about 12 kb telomeric to *FOXC1*, and encompassed *FOXF2*. Our data suggest that duplication events at 6p25 may be associated with mild ocular abnormalities as well as with wide variability of the glaucoma phenotype, including typical POAG. This duplication event may increase dosage of *FOXC1* and/or *FOXF2* and/or alter the transcriptional activity of these two genes by unrecognized positional effects.

**Mutation analysis of two candidate genes in the paroxysmal dystonic choreoathetosis locus on chromosome 2q.** *D. Tokarz, D. Thomas, S.R. Rainier, J.K. Fink.* Department of Neurology, University of Michigan, Ann Arbor, MI.

Paroxysmal dystonic choreoathetosis (PDC) is a movement disorder characterized by involuntary movements affecting the extremities, trunk and face. Episodes last from minutes to hours and are generally brought on by stress or ingestion of alcohol or caffeine. The disorder was linked to 2q (Fink et al. *Am. J of Hum Genet.* 59:140-145, 1996 and Fouad et al. *Am. J. Hum. Genet.* 59:135-139, 1996) and the locus was reduced to a 2.7 cM locus by the work of a number of laboratories including Hofele et al. *Neurology* 49:1252-1257, 1997, and Jarman et al. *Neurology* 48:A996, 1997. Since many other movement disorders are caused by mutations in ion channel genes, ion channel genes are considered to be primary candidates for PDC. There are two ion channel genes in the reduced PDC locus, AE3 (solute carrier family 4, member 3) and ASIC4 (a putative acid sensing channel). These ion channel genes have already been examined by our laboratory and others. There are no disease specific mutations in the coding regions or splice junctions of these genes. We have examined two other candidate genes in this locus, SLC11A1 and flj13021. SLC11A1 is a proton coupled divalent metal ion transporter, also known as NRAMP1 for its function as a natural resistance-associated macrophage protein. We sequenced the 14 exons of this gene as well as the splice junctions from 3 affected and one unaffected individual from our PDC pedigree. No disease specific mutations or polymorphisms were identified. The second gene flj13021 is 82% homologous to rat phospholipase C delta 4 gene at the nucleotide level and 63% and 51% homologous with rat and bovine phospholipase C, respectively, at the protein level. Since phospholipases are important in intracellular signaling pathways, flj13021 was considered a possible candidate for PDC. Flj13021 has 14 exons which were sequenced along with the splice junctions from 4 affected members of our PDC pedigree. Although several polymorphisms were found, no disease specific mutations were identified. There are a number of other genes in the locus which are important in cell signaling. Mutation analysis of these PDC candidate genes is underway.

**Exclusion of interleukin-17 (cytotoxic T-lymphocyte-associated serine esterase 8) as a candidate for autosomal recessive polycystic kidney disease.** *L.C. Wilkins<sup>1</sup>, W.S. Davidson<sup>1</sup>, P.S. Parfrey<sup>2</sup>, J.S. Green<sup>2</sup>, E. Dicks<sup>2</sup>.* 1) Molecular Biology and Biochemistry, Simon Fraser University, Burnaby, BC, Canada; 2) Faculty of Medicine, Memorial University of Newfoundland, St. John's, Nfld., Canada.

Autosomal recessive polycystic kidney disease (ARPKD) is one of the most common hereditary diseases in children affecting the kidneys and biliary tract. The locus, PKHD1, has been mapped to chromosome 6p21.1-p12. Using a combination of microsatellite and SNP markers, we have been able to reduce the critical region to approximately 580 Kbp whose sequence has been determined as part of the Human Genome Project (NT\_019428). Only two genes, MCM3 (minichromosome maintenance deficiency) and interleukin-17 (cytotoxic T-lymphocyte-associated serine esterase 8) and a suspected pseudogene, carnitine/acylcarnitine translocase, have been identified in this region. MCM3 has previously been excluded as a candidate for PKHD1. Primers were designed that amplify the exons and exon-intron boundaries of the interleukin-17 gene. We used these to determine the corresponding sequences in a large multiplex Newfoundland family in which there are five affected individuals in two branches, one of which is known to be consanguineous. No variation from the published sequence was detected except for a known SNP in the 3' untranslated region of the gene. Thus, it would appear that interleukin-17 can be excluded as a candidate for PKHD1. We are currently examining the structure of the suspected pseudogene in this family and investigating the possibility that an as yet undetected gene exists in this segment of the genome. (Supported by funds from the Kidney Foundation of Canada and the Canadian Institutes of Health Research.).

**Abnormal Expression of Immune Function Genes in B Cell Lines from ICF Syndrome Patients with Known Mutations in DNA Methyltransferase 3B Alleles.** *M. Ehrlich*<sup>1</sup>, *G. Jiang*<sup>1</sup>, *F. Tsien*<sup>1</sup>, *K. Buchanan*<sup>2</sup>, *W. Vicker*<sup>2</sup>, *D. Misek*<sup>3</sup>, *R. Kuick*<sup>3</sup>, *S. Hanash*<sup>3</sup>. 1) Dept. Human Genetics, SL31, Tulane Medical Sch., New Orleans, LA; 2) Dept. Microbiol. Immunol., Tulane Medical Sch., New Orleans, LA; 3) Dept. Ped. Hematol. Oncol., Univ. Mich., Ann Arbor, MI.

ICF (immunodeficiency, centromeric region instability, facial anomalies) is a recessive disease caused by mutations in the DNA methyltransferase 3B gene (*DNMT3B*). Patients invariably have immunodeficiency, chromosome 1 and 16 pericentromeric anomalies in mitogen-stimulated lymphocytes, and a small decrease in genomic 5-methylcytosine levels. Serum immunoglobulin (Ig) levels and numbers of B cells and T cells in blood samples are highly variable among ICF patients but the typical finding is low serum Ig coupled with normal B and T cell numbers in peripheral blood. Polyclonal B lymphoblastoid cell lines (LCLs) from five ICF patients with diverse mutations in their *DNMT3B* alleles were compared with analogous normal LCLs by microarray analysis of expression of about 6000 genes and by flow cytometry for detection of surface immunoglobulins. Four of the five ICF LCLs were highly positive for cell surface IgM (sIgM<sup>+</sup>) and moderately sIgD<sup>+</sup>, and all were sIgG<sup>-</sup> and sIgA<sup>-</sup>. In contrast, most of the normal LCLs had a large fraction of sIgG<sup>+</sup> or sIgA<sup>+</sup> cells and a very small fraction of sIgD<sup>+</sup> or sIgM<sup>+</sup> cells. Furthermore, all the ICF LCLs had high levels of IgM and IgD heavy chain RNAs but very low levels of IgG3, IgA1, and IgA2 heavy chain RNAs compared to the control LCLs. Among the genes that were dysregulated specifically in the ICF LCLs, as revealed by microarray analysis, were nine whose functional properties can help explain the particular patterns of immunodeficiency seen in ICF patients. These genes are involved in lymphocyte activation, migration, or survival and are being analyzed to determine how *DNMT3B* mutations lead to the increased RNA levels for some of them and decreased levels for others. (Supported by PHS Gt. CA81506.).

***p63* mutations are not a major cause of non-syndromic SHFM.** X.J. de Mollerat<sup>1,2</sup>, D. Everman<sup>1</sup>, K. Clarkson<sup>1</sup>, C. Rogers<sup>1</sup>, A. Aylsworth<sup>3</sup>, J. Graham<sup>4</sup>, R.E. Stevenson<sup>1</sup>, C.E. Schwartz<sup>1,2</sup>. 1) Greenwood Genetic Center, South Carolina; 2) Department of Genetics and Biochemistry, Clemson University, South Carolina; 3) Departments of Pediatrics and Genetics, University of North Carolina, Chapel Hill; 4) Cedars Sinai Medical Center, UCLA, California.

EEC syndrome is an autosomal dominant disorder characterized by ectodermal dysplasia, ectrodactyly and cleft lip/palate. Recently, missense mutations in the DNA-binding domain of the *p63* gene on chromosome 3q27 have been associated with both EEC syndrome and non-syndromic split hand/foot malformation (SHFM). We have screened 25 SHFM and 7 EEC patients for mutations in *p63*. Among the SHFM patients, 12 had isolated SHFM and 11 had SHFM associated with long bone deficiency (SHFLD). The other 2 patients had syndromic SHFM, including one with nystagmus (Karsch Neugebauer syndrome) and one with seizures and mental retardation. All of the EEC patients displayed 2 or more characteristic features of EEC syndrome. Two of these patients also had a coloboma and another had seizures, mental retardation and blindness. SSCP analysis of *p63* detected no mutations in the DNA binding domain (exons 5-10) in the 25 SHFM patients. In 20 of these patients, additional SSCP analysis of exons 1-4 and 11-14 was performed and did not demonstrate any mutations. In the EEC patients, 4 missense mutations within the DNA binding domain were detected, including two novel mutations. Two of the EEC patients, neither of whom have clefting of the lip and/or palate, had a missense mutation affecting the G at position 755, G755T and G755A, leading to R204Q and R204P substitutions respectively. The other 2 patients, both of whom have clefting of the lip and/or palate, had a mutation affecting the G at position 1055, G1055A and G1055C, leading to R304Q and R304P substitutions respectively. These observations support a major causative role for *p63* in EEC syndrome but not in non-syndromic SHFM. In addition, the mutations identified in our EEC patients suggest a correlation between the position of the mutation within the DNA binding domain of *p63* and the presence/absence of cleft lip/palate.

**Molecular studies of preaxial polydactyly in three North American families and a novel mouse mutant.** A.V. Hing<sup>1</sup>, S. Cook<sup>2</sup>, M.B. Dobbs<sup>3</sup>, N. Syed<sup>1</sup>, M. Davisson<sup>2</sup>. 1) Div Gen/Dev, Univ Washington, Seattle, WA; 2) The Jackson Laboratory, Bar Harbor, ME; 3) Dept Orthopaedic Surg, Wash Univ, St. Louis, MO.

Preaxial polydactyly (PPD) with triphalangeal thumb is an autosomal dominant trait linked to human chromosome 7q36. Although PPD has been mapped to a region of 500 kb on chromosome 7q36, the molecular basis remains unknown. Linkage studies have expanded the phenotype to include complex polysyndactyly, tibial hemimelia, and sternal defects. Three mouse mutants, (*hemimelic extra-toes*, *luxate*, and *sasquatch*), have been mapped to the region of mouse Chromosome 5 that is homologous to the human chromosome 7q36 PPD locus. The phenotype in the mouse mutants is strikingly similar to the human counterpart including preaxial polydactyly, triphalangeal first digit, and tibial hemimelia. We describe a new mouse mutant, *preaxial polydactyly with hemimelia*, with preaxial polydactyly of all four limbs and tibial hemimelia. This mutant arose spontaneously in a C57BL/10 congenic called B10.PL-H2<sup>u</sup>(73NS)/Sn. Both homozygotes and heterozygotes are affected equally and both sexes appear to be viable and fertile. Linkage studies performed at The Jackson Laboratory demonstrated flanking markers of *D5Mit124* and *D5Mit229* at 13 cM and 18 cM from mouse Chromosome 5 centromere, respectively. There were no recombinants in 100 meioses with the marker *D5Mit387*, 15cM from the centromere, placing *preaxial polydactyly with hemimelia* close to *hemimelic extra-toes*. Three families with PPD linked to chromosome 7q36 are available for mutation studies. These include a family from Illinois segregating triphalangeal thumb with variably duplicated thumbs/great toes and two pedigrees from Iowa, one with isolated bilateral triphalangeal thumb. Genomic sequence for both the human and mouse PPD loci in the form of finished/unfinished sequence can be accessed from Genbank. We have identified regions of mouse/human sequence homology, aligned known human and mouse orthologous transcripts [*HLX9(Hlxb9)*, *c7orf2(Lmbr1)*, *FKSG33(Lmbr2)*, and *HFBck28 (D5Kng1)*], and characterized novel transcripts from the PPD region. We describe mutation analysis of candidate transcripts in both human pedigrees and mouse mutant.

**Mutations in the Cartilage Derived Morphogenetic Protein-1, in kindred affected with Grebe Type severe short limb dwarfism and DuPan Syndrome.** *M.F. Ul Haque<sup>1</sup>, W. Ahmad<sup>2</sup>, S.H.E Zaidi<sup>1</sup>, S. Haque<sup>2</sup>, A. Wahab<sup>2</sup>, A.C. Azim<sup>3</sup>, A.S. Teebi<sup>1</sup>, M. Ahmad<sup>2</sup>, D.H. Cohn<sup>4</sup>, T. Siddique<sup>3</sup>, L.C. Tsui<sup>1</sup>.* 1) Dept Genetics, Hosp Sick Childre, Toronto, ON, Canada; 2) Quaid-i-Azam Univ, Islamabad, Pakistan; 3) Northwestern Univ Med Sch, Chicago, IL; 4) Cedars-Sinai Med Cent, Los Angeles, CA.

Autosomal recessive inheritance was observed in two large inbred families from Pakistan exhibiting the clinical features resembling the Grebe type severe short limb dwarfism (13 affected) and fibular hypoplasia and complex brachydactyly similar to DuPan Syndrome (9 affected). While carrier parents did not exhibit any apparent skeletal abnormalities, affected individuals show reductions and absence of bones in the limbs, and appendicular bone dysmorphogenesis with unaffected axial bones in all affected individuals. Cartilage derived morphogenetic protein-1 (CDMP-1) has been reported to regulate limb patterning and distal bone growth. CDMP-1 is a member of the transforming growth factor- $\beta$  superfamily of secreted signaling molecules that regulate gene expression through interactions with the bone morphogenetic protein receptors and smad proteins. We examined the genomic DNA from affected and unaffected subjects of the two families for possible mutations in the CDMP-1 gene. In the family exhibiting Grebe type phenotype, an insertion of C at nucleotide 297 of the coding sequence was discovered. This insertion produced a shift in the reading frame at amino acid 99 causing truncation of the polypeptide at six amino acids downstream. This is expected to result in complete loss of its signaling function due to the absence of secreted active domain of CDMP-1. In the second family that we have previously reported, exhibited the clinical features of Du Pan syndrome, a missense Leu441Pro substitution was found in the mature domain of the CDMP-1 gene. This mutation may alter the activity of CDMP-1 protein and interfere with its downstream signaling. These changes were not found in the 41 control subjects of Pakistani origin. Our finding confirms that CDMP-1 regulates limb bones growth during development and further suggests that its absence does not interfere with other developmental processes.

**Alpha-B crystallin gene (CRYAB) mutation causes dominant congenital posterior polar cataract in man.** *P.J. Francis<sup>1</sup>, V. Berry<sup>1</sup>, M.A. Reddy<sup>1</sup>, D. Collyer<sup>1</sup>, E. Vithana<sup>1</sup>, I. MacKay<sup>3</sup>, G. Dawson<sup>3</sup>, A.H. Carey<sup>3</sup>, A. Moore<sup>1,2</sup>, R.A. Quinlan<sup>4</sup>, S.S. Bhattacharya<sup>1</sup>.* 1) Molec Genetics, Inst Ophthalmology, London, England; 2) Moorfields Eye Hospital, London, England; 3) Oxagen Limited, 91 Milton Park, Abingdon, Oxon, OX14 4RY, UK;; 4) Department of Cell Biology, University of Durham, Durham, UK.

Congenital cataract is the commonest treatable cause of childhood blindness in USA and Europe with a prevalence of 1-6 cases per 10,000 births. Inherited cataracts accounts for up to half of all congenital cataract and the commonest mode of inheritance is autosomal dominant (ADCC). To obtain further insight into the genetic aetiology of congenital cataract we performed linkage analysis on a four-generation family of English descent with autosomal dominant posterior polar cataract. Twelve affected and ten unaffected members of the family underwent a full ophthalmological examination, after ethical approval was granted. The opacity which, was bilateral in all cases, consisted of a single well-defined plaque confined to the posterior pole of the lens and varied from 0.5-3 mm in diameter. We identified a new ADCC locus on chromosome 11q21.2-q22.3. This locus (CPP2) was mapped to a 16cM region flanked by microsatellite markers D11S4176 and D11S908 encompassing the candidate gene CRYAB, which encodes aB crystallin. Sequence analysis of the CRYAB gene revealed a deletion mutation (450delA) in exon3 that co-segregated with disease in the family. The mutation causes a frameshift in codon 150 and produces an aberrant protein consisting of 184 residues. The mutation was not found in a panel of 100 normal unrelated individuals thus excluding the possibility that it was a rare polymorphism.

**Linkage analysis, physical mapping and candidate gene analysis of the Amish microcephaly (MCPHA) locus of 17q25.** *M.J. Rosenberg<sup>1</sup>, I. Makalowska<sup>1</sup>, G. Amish microcephaly (MCPHA) is a distinct syndrome with severe congenital microcephaly, increased urinary excretion of the TCA cycle intermediate,  $\alpha$ -ketoglutarate, and premature death. The disorder is inherited in an autosomal recessive pattern and has only been observed in Old Order Amish families who have ancestors in Lancaster County, PA. Using a genealogy database and automated pedigree software, we constructed a pedigree connecting 21 sibships with an affected child to a common ancestor. A whole genome scan, fine mapping, and haplotype analysis localized the MCPHA gene to a 3 cM or 2 Mb region on 17q25. Six consecutive standard markers from D17S1301 to D17S801 are consistent with linkage and have two-point LOD scores above 10.0 using equal allele frequencies. A physical map of this region was constructed that contains 79 genomic clones of which 21 have sequence data in GenBank. The sequenced BACs have been assembled into three contigs. We have analyzed the contigs using the Santa Cruz Working Draft website and BLAST searches and found 27 characterized genes and 56 additional clusters of full-length transcripts or spliced ESTs. We have connected the three contigs derivable from the public sequence data into a single contig by STS mapping and are currently sequencing three BACs to obtain sequence information for the two gaps. We are analyzing the entire region using gene prediction software to look for additional candidate genes. We hypothesize that this disorder is due to a mutation in a gene involved in  $\alpha$ -ketoglutarate metabolism with secondary microcephaly, a mutation in a pleiotropic gene that affects brain development and the TCA cycle, or a recessive contiguous gene syndrome.

**Genetic Analysis of Two Pedigrees with Charcot-Marie-Tooth Neuropathy Type 1C.** *V.A. Street<sup>1</sup>, J.D. Goldy<sup>2</sup>, A.S. Golden<sup>1</sup>, B.L. Tempel<sup>1</sup>, T.D. Bird<sup>3</sup>, P.F. Chance<sup>2</sup>.* 1) Bloedel Hearing Ctr, Univ Washington, Seattle, WA; 2) Pediatrics, Division of Genetics and Development, University of Washington School of Medicine, Seattle, WA; 3) Neurology, University of Washington School of Medicine and Veterans Administration Medical Center, Seattle, WA.

Charcot-Marie-Tooth (CMT) neuropathy is the most common inherited peripheral nervous system disorder affecting approximately 1 in 2000 individuals and characterized by degenerative changes in motor and sensory nerves. The hallmark of CMT Type I (CMT1) is reduced nerve conduction velocities (NCVs) (<40 meters/sec) and nerve biopsies that demonstrate hypertrophic demyelination. The present study includes two large five-generation CMT1C pedigrees (K1550 and K1551). Affected members have clinical findings and reduced NCVs consistent with CMT1. Male-to-male transmission is present confirming autosomal dominant inheritance. Previous linkage analysis with markers from the CMT1A region on chromosome 17p11-12 and CMT1B region on chromosome 1p21 excluded linkage. Furthermore, the DNA duplication commonly associated with CMT1A is not present. Sequence analysis for five genes known to play critical roles in the development of demyelinating neuropathies, the peripheral myelin protein (PMP-22), the myelin protein zero (MPZ), and the early growth response 1 and 2 genes (EGR1 and 2) also known as Krox-24 and Krox-20, and PERP, disclosed no abnormalities, confirming further genetic heterogeneity in CMT1 and indicating that the mutant gene in these CMT1C pedigrees represents a novel unmapped form of CMT1. To assign a chromosomal address, we are performing a 10 cM genome scan on both pedigrees. No linkage has been detected on chromosomes 5, 6, 14, and 19-22 for pedigree K1550, nor on chromosomes 19-22 for pedigree K1551.

**A recessive contiguous gene deletion of chromosome 2p16 associated with cystinuria and a mitochondrial disease.**

*R. Parvari*<sup>1</sup>, *I. Brodyanski*<sup>2</sup>, *O. Elpeleg*<sup>3</sup>, *S. Moses*<sup>2</sup>, *D. Landau*<sup>2</sup>, *E. HersHKovitz*<sup>2</sup>. 1) Microbiol/Immunol/Fac Hlth Sci, Ben Gurion Univ, Beer-Sheva, Israel; 2) Department of Pediatrics, Soroka Medical Center and the Faculty of Health Sciences, Ben Gurion University of the Negev, Beer Sheva; 3) Metabolic Disease Unit, Shaare Zedek Medical Center, Jerusalem, Israel.

Deletions ranging from a 100Kb to a megabase, which are too small to be detected under the microscope, may still involve dozens of genes, thus causing microdeletion syndromes. The vast majority of these syndromes are caused by haploinsufficiency of one or several genes and are transmitted as dominant traits. We identified seven patients originating from an extended family who presented with a unique syndrome, inherited in a recessive mode, characterized by cystinuria, neonatal seizures, hypotonia, lactic acidemia, severe somatic and developmental delay and facial dysmorphism. Reduced activity of all the respiratory chain enzymatic complexes which are mitochondrial encoded was found in the muscle biopsies of the patients examined. The molecular basis of this disorder is a homozygous deletion of 179,311 bp on chromosome 2p16, which includes the type I cystinuria gene SLC3A1, the protein phosphatase 2C beta gene, an unidentified gene (KIAA 0436) and several ESTs. The extent of the deletion suggests that this unique syndrome is related to the complete absence of all these genes products, one of which may be essential for the synthesis of mitochondrial-encoded proteins.

***FOXC2* truncating mutation in distichiasis lymphedema and cleft palate (DLC).** *M. Bahuau*<sup>1,2</sup>, *V. Soupre*<sup>2</sup>, *R. Couderc*<sup>1</sup>, *M-P. Vazquez*<sup>2</sup>, *C. Houdayer*<sup>1</sup>. 1) Biochimie et Biologie Moléculaire, Hôpital Trousseau, Paris, France; 2) Chirurgie Maxilo-Faciale, Plastique et Stomatologie, Hôpital Trousseau, Paris, France.

We have previously reported a family showing autosomal dominant segregation of upper- and lower-eyelid distichiasis (double row of eyelashes) in seven affected relatives over three generations, in addition to below-knee lymphedema of pubertal onset (lymphoedema praecox) in three of them. Two children had cleft palate/velum in addition to distichiasis, and without the previously reported association to the Pierre Robin anomalad. Other ophthalmologic anomalies included divergent strabismus and early-onset myopia. This family was found to be thoroughly linked to D16S3074 and thereby proposed to be allelic to distichiasis-lymphedema syndrome (DL, MIM 153400) in 16q24.3, although pterygium colli, congenital heart disease, or facial dysmorphism were not features here. Since *FOXC2/FKLH14* mutations were found to underlie DL and diverse hereditary lymphedema conditions, this gene was thoroughly scanned by sequence analysis. An out-of-frame deletion (914-921del) was identified and found to segregate with the disease, further highlighting the phenotypic heterogeneity of lymphedema conditions linked to *FOXC2* truncating mutations. Whether such heterogeneity is related to genotype-phenotype correlation, a hypothesis not primarily supported by the apparent loss-of-function mechanism of the mutations, or governed by modifying genes, remains to be determined.

**Phenotypic heterogeneity in lymphedema-distichiasis with *FOXC2* mutations.** *T.W. Glover<sup>1</sup>, R.P. Erickson<sup>2</sup>, S.L. Dagenais<sup>1</sup>, M.T. McDonald<sup>3</sup>, M.S. Caulder<sup>1</sup>, B.P. Brooks<sup>4</sup>, M.W. Glynn<sup>1</sup>.* 1) Department of Human Genetics, University of Michigan, Ann Arbor, MI; 2) Department of Pediatrics, University of Arizona, Tucson, AZ; 3) Department of Pediatrics, Duke University, Durham, NC; 4) Department of Ophthalmology, University of Michigan, Ann Arbor, MI.

Hereditary lymphedema-distichiasis is an autosomal dominant disorder that classically presents as lymphedema of the limbs, with variable age of onset, and aberrant growth of eyelashes along the lid margins and from the Meibomian glands (distichiasis). Other reported complications include cardiac defects, cleft palate, photophobia, hydrops and extradural cysts. Recently, we reported that truncating mutations in the forkhead transcription family member *FOXC2* resulted in lymphedema-distichiasis in two families. We now describe an additional eight families with lymphedema-distichiasis, including the original family reported by Falls and Kertesz in 1964. Through sequence analysis, we identified truncating mutations in all families studied. These included 3 nonsense, 3 insertion, 1 deletion, and 1 insertion-deletion mutation. Distichiasis was the most common clinical feature, followed by age-dependent lymphedema. Distichiasis alone was found in one small pedigree ascertained for this disorder. There is large variation in expression of associated secondary features with tetralogy of Fallot and cleft palate each seen in about 10% of cases. Our results are consistent with the interpretation that haploinsufficiency for *FOXC2* is responsible for the phenotype in all cases. There is no apparent genotype-phenotype correlation. The factors that determine phenotypic heterogeneity are at present unclear, but are important for characterization of the molecular mechanisms underlying lymphedema-distichiasis and for informative genetic counseling.

**In vitro expression studies of 11 mutations identified in the GLB1 gene of GM1- gangliosidosis patients. A.**

*Caciotti<sup>1</sup>, E. Zammarchi<sup>1</sup>, T. Bardelli<sup>1</sup>, S. Bisanzi<sup>1</sup>, M.A. Donati<sup>1</sup>, A. D'Azzo<sup>2</sup>, A. Morrone<sup>1</sup>.* 1) Dep. of Paediatrics, University of Florence, Florence, Italy; 2) Dept. of Genetics, St. Jude Childrens Research Hospital, Memphis, USA.

The deficiency of acid b-galactosidase results in two lysosomal storage disorders: GM1 gangliosidosis (infantile, juvenile and adult forms) and Morquio B. GLB1 gene encodes for two proteins: GLB1 and EBP. We have previously identified 11 aminoacid substitutions in 8 GM1 gangliosidosis patient. The S54N, R59H, R59C, G579D, Y591C and the new P263L were detected in 4 patients affected by the infantile form, the R201H and C230Y were found in the 2 juvenile patients and the T329A, R442Q and R521C were detected in 2 adult patients. Only the R201H mutation was previously expressed in vitro. In order to determine the impact of each mutation on the biochemical properties of the normal enzyme we carried out expression studies in COS-1 cells. GLB1 enzymatic assays showed that the mutations: S54N, R59H, R59C, P263L, Y591C, G579D, C230Y and T329A rendered b-galactosidase enzymatically inactive. The R201H, detected in compound heterozygosity in the 2 juvenile patients, and the R442Q, identified in one adult patient, resulted in residual activity of the mutant enzymes, accounting for the mild clinical phenotype of the patients. Expression of the R201H mutant resulted in a level of GLB1 activity higher than that of the R442Q variant. This finding can be due to differences in affinity of the two mutant proteins towards the synthetic substrate. The R521C genetic lesion, previously reported as a polymorphism, was detected at homozygous state in one adult patient. Expression study, showing an enzymatic activity of 51% of normal values, suggested a possible effect of the R521C on the GLB1 activity. Except for the R201H and the C230Y, all the mutations studied can affect both GLB1 and EBP. Each mutation could interfere with the processing of the precursors, the transport of mutant GLB1 to the lysosome, the capacity of b-galactosidase to assemble with PPCA and neuraminidase and/or the kinetic properties and activity of the mutant enzymes. The financial support of Telethon-Italy and MPS-Italy are gratefully acknowledged.

**Screening of NCL genes in French patients with ceroid lipofuscinoses..** *C. Caillaud*<sup>1,2</sup>, *J.P. Puech*<sup>1,2</sup>, *J. Manicom*<sup>1,2</sup>, *L. Poenaru*<sup>1,2</sup>. 1) Dept Genetique, CHU Cochin, Paris, France; 2) INSERM U129, CHU Cochin, Paris, France.

Neuronal ceroid lipofuscinoses (NCL) are inherited neurodegenerative disorders characterized by the accumulation of autofluorescent lipopigments in various tissues. Four main NCL forms are distinguished according to clinical and morphological features : infantile (INCL), late infantile (LINCL), juvenile (JNCL) and adult (ANCL), but numerous atypical forms have also been described. Recent advances in the molecular genetics of NCL has allowed to delineate at least eight loci (from CLN1 to CLN8) as responsible for these different forms, two of them encoding soluble enzymes : palmitoyl-protein thioesterase (PPT) for CLN2 and tripeptidyl-peptidase I (TPP-I) for CLN1. In LINCL, the most common clinical form in France, the CLN2 locus was frequently involved, as demonstrated by the presence of a tripeptidyl-peptidase I deficiency in the majority of patients. Complete sequencing of the CLN2 exons showed the predominance of two previously reported mutations (Arg208Stop and 3556 G>C), accounting for 28 and 34 % of the alleles, respectively. Novel private mutations were also characterized, such as deletions (6082-6092del), splice (4635 A>G), nonsense (Trp548Stop, Gln509Stop, Glu394Stop) or missense (Arg339Trp, Ser153Pro, Ser456Pro) mutations. Some LINCL patients had no TPP-I deficiency and are likely candidate for the CLN6 or CLN7 loci. A palmitoyl-protein thioesterase (PPT) deficiency was found in three classical INCL patients with age of onset between 7 and 20 months and in one patient with an early juvenile form. Four previously reported CLN1 mutations were characterized in these patients : Lys55Stop, 774-775insA, Arg151Stop, Val181Met. Two novel mutations were also described : Gln142Stop and Tyr109Cys, which one was found in the patient presenting the early juvenile form. Among patients with classical juvenile forms, only 3 alleles were found to carry the common 1.0 kb deletion. Further studies will define if other mutations of the CLN3 locus are responsible for these late-onset forms or if various other genes are involved in these patients. Delineation of the NCL loci will allow to offer a reliable genetic counselling to couples at-risk for these diseases.

**Fabry disease: identification of ten novel mutations.** *K. Azibi<sup>1,2</sup>, C. Caillaud<sup>1,2</sup>, J. Manicom<sup>1</sup>, J.P. Puech<sup>1</sup>, A. Kahn<sup>2</sup>, L. Poenaru<sup>1,2</sup>.* 1) Genetique, Faculte de Medecine Cochin, Paris, France; 2) INSERM U-129, CHU Cochin, Paris, France.

Fabry disease is an X-linked glycosphingolipid storage disease caused by a deficiency of the lysosomal enzyme alpha-galactosidase A (GLA). This deficiency leads to the accumulation of uncleaved glycosphingolipids in the lysosomes of vascular endothelial and smooth muscle cells and also in plasma. Patients studied have typical clinical manifestations of Fabry disease, including angiokeratoma, abdominal pain, corneal opacities, paresthesias in the extremities and renal failure. All of them exhibited an alpha-galactosidase deficiency, with a GLA residual activity comprised between 0.8 and 4 nmol/h/mg protein. To clarify the molecular mechanism causing the enzyme defect and to facilitate a rapid detection of Fabry hemizygotes and carriers, the seven GLA exons, including intron-exon junctions were PCR-amplified and directly sequenced. 14 mutations were characterized in this group of patients, among which four have been previously reported. Ten novel mutations were identified, including two nonsense mutations (W245X and W262X), three missense mutations (A156N, Q279H, S297C), a small nucleotide insertion (insG10678) and four small deletions (1235del15, 7316delA, 7337delG, 10666 delATCA) resulting in premature stop codon. These mutations were found in 18 Fabry patients and further helped the heterozygosity detection in carrier females. These results demonstrate the molecular heterogeneity of Fabry disease. The study also permit to explore possible genotype / phenotype correlations in patients with previously described mutations. Finally, the origin of mutational events in different families will be precised by the haplotype determination for some mutations, using microsatellite polymorphisms in the alpha-galactosidase A gene.

**Identification of novel mutations in the cystinosin gene (CTNS) in patients with cystinosis.** *M. Kiehntopf<sup>1</sup>, H.G. Koch<sup>2</sup>, T. Coskun<sup>3</sup>, S. Ozen<sup>3</sup>, T. Deufel<sup>1</sup>, E. Harms<sup>2</sup>.* 1) Institut fuer Klinische Chemie, Friedrich-Schiller Universitaet Jena, Jena, Germany; 2) Klinik und Poliklinik fuer Kinderheilkunde, Universitaetsklinikum Muenster, Muenster, Germany; 3) Department of Pediatrics, Faculty of Medicine, Hacettepe University, Ankara, Turkey.

Cystinosis is an autosomal recessive lysosomal storage disorder caused by mutations in the Cystinosin (CTNS) gene; CTNS consists of 12 exons and encodes a 55 kDa lysosomal transmembrane protein. To date, 46 different CTNS mutations have been described in the most common form of cystinosis, the classical, infantile nephropatic phenotype; non-classical, benign, intermediate or the late-onset form of the disease have been associated with, so far, nine distinct CTNS mutations. In a population of European cystinosis patients we have analyzed the CTNS gene by sequencing of exons 3 to 12. We have identified six novel CTNS mutations, including one deletion involving exon 3 (400delGGT) resulting in disruption of the 5'-splice site in intron 3, and two insertions in exon 6 (632insA) and exon 7 (684insCACTT) leading to a frame shift with a premature stop at codon 124 and 119, respectively. Moreover, we have identified three novel nucleotide substitution in exon 11 (1262G>T), exon 7 (790A>G) and exon 10 (1118 T>C) leading to an amino-acid change at codon 308 (G>V) in the predicted transmembrane domain TM6, at codon 151 (R>G) and at codon 260 (I>T), respectively.

**Novel mutations and haplotype analysis in a-mannosidosis.** *H.M.F. Riise Stensland*<sup>1, 2</sup>, *H. Klenow*<sup>2</sup>, *D. Malm*<sup>3</sup>, *O.K. Tollersrud*<sup>4</sup>, *O. Nilssen*<sup>2</sup>. 1) Department of Human Genetics, Gonda #6309, UCLA, Los Angeles, CA, USA; 2) Department of Medical Genetics, University Hospital of Tromsø, Tromsø, Norway; 3) Department of Internal Medicine, University Hospital of Tromsø, Tromsø, Norway; 4) Department of Medical Biochemistry, University of Tromsø, Tromsø, Norway.

Lysosomal a-mannosidase (LAMAN, EC 3.2.1.24) is an exoglycosidase involved in the ordered degradation of N-linked oligosaccharides. Lack of LAMAN activity leads to the lysosomal storage disorder a-mannosidosis (MIM 248500), an autosomal recessive disorder described in man, cattle, cats and guinea pigs. Affected individuals accumulate partially degraded oligosaccharides in the lysosomes, and typical symptoms in man are mental retardation, hearing loss, recurrent infections and various skeletal changes. We have earlier reported 23 disease causing mutations in the LAMAN gene of 42 unrelated a-mannosidosis patients. Here we have analyzed additional 43 unrelated patients by screening for known mutations and by sequencing of the 24 LAMAN exons as well as the exon-intron borders. Thirty-three novel mutations; 9 missense, 8 nonsense, 5 splice site and 11 small insertions/deletions, were identified. In total, the 56 mutations were detected on 159 of the 170 alleles (93.5%). Most of the mutations were private or occurred in 2-3 families, except for one missense mutation, R750W, that was detected in patients from 12 different countries, and present on 55 unrelated alleles (32.3%). Haplotype analysis using 4 intragenic SNPs revealed that the 750W allele existed on 3 different haplotypes. The majority of the alleles where the phase could be determined (36 of 40, 90%) shared the same haplotype, indicating that the 750W mutation probably spread by migration and founder effect. The 2 other associated haplotypes could have emerged from the ancestral haplotype by single recombinatorial events or, alternatively, resulted from recurrent mutational events.

**Towards identification of the mental retardation genes associated with balanced chromosome translocations.** *P.S. Edwards<sup>1</sup>, K.E. Miller<sup>1</sup>, M. Beachem<sup>1</sup>, S. Ladd<sup>1</sup>, F. Romero-Pastrana<sup>1</sup>, R.J. Schroer<sup>1</sup>, K. Clarkson<sup>1</sup>, L. Seaver<sup>1</sup>, R. Saul<sup>1</sup>, R.C. Rogers<sup>1</sup>, G.S. Pai<sup>2</sup>, C.E. Schwartz<sup>1</sup>, B.R. DuPont<sup>1</sup>, R.E. Stevenson<sup>1</sup>, A.K. Srivastava<sup>1</sup>.* 1) J C Self Res Inst of Hum Genet, Greenwood Genetic Ctr, Greenwood SC; 2) Dept of Pediatrics, Med Univ of South Carolina, Charleston, SC.

Mental retardation (MR) is a common condition affecting about 2-3% of the human population. Among various causative factors, a substantial portion of the genetic component of MR is due to mutations in specific genes. Subtelomeric deletions account for approximately 6% of idiopathic MR. Several syndromic and non-syndromic MR genes (predominantly X-linked) have been cloned, and in many cases MR-associated balanced chromosome translocations have been instrumental in the MR gene identification. Mapping and cloning of autosomal MR gene remains difficult due to the lack of large families and the phenotypic variability among small families precludes the pooling of families for linkage analysis. We have identified fifteen patients with balanced translocations and MR. Clinically most of the patients have profound MR and in many cases, additional abnormalities have also been noted. Cytogenetic characterization and preliminary molecular analysis of the translocation breakpoints in seven MR patients with autosome; autosome translocation, and in two female MR patients with X; autosome translocation, have delineated several potential chromosomal regions for autosomal and X-linked MR. FISH analysis using genomic clones to map the translocation breakpoints has further narrowed the critical MR regions to less than 3 Mb in the first seven cases analyzed. A BAC clone spanning the Xq24 breakpoint in one female patient has been identified and is being characterized for the candidate MR gene. In a second patient the Xp21.2 breakpoint was found to disrupt the DMD gene. A cryptic deletion at a 6q22 breakpoint has been found in one patient. Identification and characterization of the candidate MR genes associated with these translocation should provide a major advance in understanding brain function critical for development of intellectual and learning abilities as well as facilitating objective diagnosis in a portion of the MR populations.

**Maternally-transmitted MECP2 gene deletion in a 4-year-old boy with cognitive impairment and developmental delay.** *A. Bottani<sup>1</sup>, A. Dayer<sup>1</sup>, D. Cruzado<sup>2</sup>, C.-A. Haenggeli<sup>2</sup>, S.E. Antonarakis<sup>1</sup>, M.A. Morris<sup>1</sup>.* 1) Div Medical Genetics, Dept Gynecology/Obstetrics, Geneva Univ Hosp, Geneva, Switzerland; 2) Neuropediatric Unit, Dept Pediatrics, Geneva Univ Hosp, Geneva, Switzerland.

Mutations of MECP2, the X-linked gene responsible for Rett syndrome in girls, have also been recently implicated in males presenting with variable clinical pictures, ranging in severity from lethal infantile encephalopathies to non-specific mental retardation in adult patients.

We report a mentally-handicapped 4-year-old boy and his unaffected transmitting mother, both having a 44 bp truncating deletion (1158del44) in exon 4 of MECP2, resulting in a frameshift and premature truncation (386fs388X) of the MECP2 protein.

The proband was born at term after a pregnancy marked by diminished fetal movements and growth retardation. Birth weight and head circumference were below the 10th centile, while length was at the 10th centile. The baby was placid and showed axial hypotonia. Milestones were delayed: sitting at 10 months, standing with help at 15 months, first words at 20 months. Independent walking has never been achieved. Facial phenotype showed low-set anteverted ears and a prominent frontal upswing ("cowlick") of hair. Motor regression was noted at the age of 46 months, the child being unable to crawl or stand anymore. Seizures (up to 20 episodes/day) characterized by tonic upper limb movements, eye revulsion and loss of contact were observed. EEG showed diffuse paroxysmal abnormalities. Neurological examination at 4 years revealed microcephaly, involuntary stereotypic hand movements and frequent hand-to-mouth movements, intentional tremor, permanent head nodding, intermittent convergent strabismus and multidirectional nystagmus, bruxism, absent speech, spasticity of the inferior limbs with hyperreflexia and a bilateral Babinski sign.

MECP2 mutations must now be considered in the diagnostic work-up of males with unexplained mental retardation and/or neurological regression.

**X linked recessive syndrome with severe mental retardation, spastic dystonia, seizures, and migraine.** *K.L. Gardner<sup>1</sup>, N. Pulipaka<sup>1</sup>, T. Wieser<sup>1,2</sup>, M. Barmada<sup>1</sup>, R. Hendrickson<sup>1</sup>, E. McPherson<sup>3</sup>, N. Bohnen<sup>1</sup>.* 1) Neurology, Human Genetics Univ Pittsburgh, Pittsburgh, PA; 2) Neurology Martin-Luther University of Halle, Germany; 3) Genetics, Magee Women's Hospital, Pittsburgh, PA.

Several X-linked MR syndromes (MRXS) with different extrapyramidal features have been described, including MR with Parkinsonism, psychosis, macroorchidism at Xq28; Parkinsonism, seizures, megalencephaly at Xq27.3-q28; dystonic hand movements at Xp22; and dystonia, optic atrophy, deafness at Xq22. Clinical evaluation included Stanford Binet testing, neurologic exams, videos. Blood for DNA extraction / cell lines was collected from 45 members. Twenty-five fluorescent labeled markers spanning ChrX were genotyped and two-point, multipoint linkage, affected relative allele sharing performed using VITESSE 1.1 and ALLEGRO with Sall scoring function. We examined 37/45 available family members from 4 generations including 5/13 affected males with severe MR, spastic-dystonia, dysarthria, history of seizures (2), headaches (3), later onset loss of ambulation with contractures, mild scoliosis (1), normal stature, near normal life span. The most severely affected patient has macrocephaly but proband has microcephaly and macroorchidism without definite dysmorphic features. Five obligate carriers have variable cognitive impairment with dementia noted by sixth decade. Migraine was prominent in females (16/18) without aura (7) and with aura (11) including hemiparesis (3 branches) but not characterized for MR males. Proband had normal karyotype, metabolic and SCA screen, with MRI showing mild cerebellar atrophy. Scores for MR-dystonia peaked at Xq28, DXS8061 with multipoint LOD 1.67, theta 0 and NPL 5.9 using 65% penetrance, 0% phenocopy, allele freq .0001. Highest scores for migraine peaked more proximally at DXS1001, Xq24 showing 2-point LOD 1.12, theta 0, co-dominant model with penetrance 75-90%, .01% phenocopy, and 20% allele freq. This may represent a new MR syndrome with distinctive extrapyramidal features and suggestion of linkage at Xq28. High prevalence of migraine in this family may be partly due to pleiotropy and variable expression of the MRXS gene plus additional X linked or autosomal contributions.

**Mutation analysis of EXT1 and EXT2 genes in two patients with hereditary multiple exostoses and mental retardation.** *H. Li, T. Yamagata, M. Mori, M.Y. Momoi.* Department of Pediatrics, Jichi Medical School, Minamikawachi, Tochigi, Japan.

Hereditary multiple exostoses (EXT) is an autosomal dominant bone disorder that affects endochondral proliferation. EXT1 and EXT2 genes are responsible for EXT. EXT1 and EXT2 form a complex that catalyzes the synthesis of heparan sulfate. Mental retardation is reported in patients with EXT and tricho-rhino-phalangeal syndrome (TRPS) as a contiguous gene deletion syndrome of EXT1 and TRPS1. The gene responsible for mental retardation has not been identified. Here we report two patients with severe EXT and mental retardation without TRPS. We screened the gene mutation of EXT1 and EXT2 and detected two base deletions in EXT1 in both patients. Both patients have mental retardation with pervasive developmental disorder. Their fathers also have EXT with normal intelligence. The patients EXT is more severe with early onset and many tumors than their fathers. Their mothers were unaffected. We detected the mutations of EXT1 and EXT2 genes using DHPLC and direct sequencing analysis in both patients. Patient I had a 1742delTGT-G in the exon 9 of EXT1 gene. Patient II had a 2093delTT in the exon 11 of EXT1 gene. These two deletions were both inherited from their fathers and caused frame-shift and early termination of EXT1. EXT1 gene shows ubiquitous expression pattern including the brain. Here we propose that EXT1 is responsible for mental retardation and pervasive developmental disorder probably relating to the difference of the penetrance between the generation and the type of mutation, like tuberous sclerosis and neurofibromatosis. EXT1 may play an important role in cognitive function in the brain as well as tumorigenesis in the bony tissue.

**Complex Glycerol Kinase Deficiency: Defining the Deletional Breakpoints in the Original Patient Described with this Contiguous Gene Syndrome.** *K.K. Niakan<sup>1</sup>, Y.-H. Zhang<sup>2</sup>, B.-L. Huang<sup>2</sup>, E.R.B. McCabe<sup>2</sup>*. 1) Departments of Human Genetics and; 2) Pediatrics, UCLA, Los Angeles, CA.

We have previously reported a patient (CM) with Duchenne muscular dystrophy (DMD), glycerol kinase deficiency and adrenal hypoplasia congenita (Guggenheim et al, *Ann Neurol* 7:441, 1980). Subsequently we showed a less than 2Mb deletion in this patient (McCabe et al, *Am J Hum Genet* 51:1277, 1992). Southern analysis of genomic DNA from CM, using DMD probes, revealed that the deletion in the patient resided in a region within 1kb of the 3' end of the DMD mRNA (McCabe et al, *J Clin Invest*, 83:95, 1988). The goal of this investigation was to sequence the DNA breakpoints in CM and attempt to determine events responsible for the deletion in this Xp22-p21 region. The approach we used to define the breakpoint in CM involved obtaining the genomic DNA sequence for the breakpoint regions from the public and private databases in order to create PCR primers, which we used to walk from intact DNA toward each breakpoint in the patient. We have narrowed the region of the breakpoints to within approximately 300 base pairs on either side. The telomeric breakpoint is in intron 6 of a gene, interleukin-1 receptor accessory protein-like-1 (IL1RAPL1), which when mutated is associated with X-linked mental retardation (Carrie et al, *Nat Genet* 23:25, 1999). The centromeric breakpoint is in intron 71 of DMD. The deletion breakpoints observed in CM are very similar to those described by Jin et al (*Euro J Hum Genet* 8:87, 2000): telomeric in IL1RAPL1 intron 7 and centromeric in DMD intron 78. The involvement of IL1RAPL1 in these patients provides an explanation of their mental retardation. In addition, the similarities between their breakpoints suggest that there may be structural features in these regions that predispose to instability. Defining the exact nature of patient breakpoints will be important to not only elucidate the specific events involved in this particular human contiguous gene syndrome, but also to understand the mechanisms responsible more broadly for genomic instability.

**High frequency of *MECP2* mutations MR males: implications for routine DNA diagnostics.** *H.G. Yntema, T. Kleefstra, A.R. Oudakker, A. Jacobs, B.A. de Vries, E. Sijdermans, H.G. Brunner, B.C.J. Hamel, H. van Bokhoven.* Dept Human Genetics 417, Univ Medical Centre Nijmegen, Nijmegen, Netherlands.

Recently it was discovered that mutations in the methyl-CpG binding protein 2 (*MECP2*) gene are not always lethal in males. *MECP2* mutations have been found in males with a phenotype varying from severe mental retardation with, RETT-like, progressive neurological symptoms to mild nonspecific mental retardation. A recent French pilot study showed that the frequency of mutations in *MECP2* in mentally retarded males is comparable to the frequency of the CGG expansion in the *FMR1* gene. We have extended this study by screening the *MECP2* gene in a cohort of 500 male patients and 100 female patients who were negative for the expansions across the *FRAXA* CGG repeat. Our results confirm a mutation frequency of almost 2% in the Dutch population. To rule out the possibility of private polymorphisms, family members of the patients and a control population are being tested. The patients with a causal mutation will be clinically re-examined, to detect a possible phenotypic pattern. The results from this study will be presented. The high frequency of *MECP2* mutations in the Fragile-X negative population favours the implication of this gene in a routine diagnostic setting. This will greatly enhance the possibilities for diagnosis and counseling in MRX.

**Candidate genes for X-linked mental retardation and X-linked congenital ataxia on chromosome Xp11.22-**

**Xq13.3.** *K. POIRIER*<sup>1</sup>, *R. ZEMNI*<sup>1</sup>, *J.P. FRYNS*<sup>2</sup>, *H. VAN BOCKHOVEN*<sup>3</sup>, *H.H. ROPERS*<sup>4</sup>, *C. MORAINÉ*<sup>5</sup>, *E. BERTINI*<sup>6</sup>, *C. BELDJORD*<sup>1</sup>, *J. CHELLY*<sup>1</sup>, *T. BIENVENU*<sup>1</sup>. 1) INSERM U129, ICGM, CHU Cochin, Paris, France; 2) Center for Human Genetics, Department of Clinical Genetics, Leuven, Belgium; 3) Department of Human Genetics, University Hospital, Nijmegen, The Netherlands; 4) Max Planck Institut für Molekulare Genetik, Berlin-Dahlem, Germany; 5) Service de Genetique, CHU Bretonneau, Tours, France; 6) Department of Neurosciences, Bambino Gesù Children's Hospital, Rome, Italy.

Different disease entities such as X-linked mental retardation (XLMR) and congenital ataxia (XCA) have been mapped to the Xp11.22-Xq13.3 region. To identify the transcribed DNA sequences mapped within this large region, we searched the public databases. 53 known genes and 24 mRNAs or ESTs have been mapped within this 26 Mb region. We analysed the expression of 54 transcripts by RT-PCR on total RNA extracted from normal human fetal brain and lymphocytes. 45 genes were expressed in the brain of which either 7 showed no expression in lymphocytes. 5 further genes were only expressed in lymphocytes and 4 potential genes were not expressed in tissue. To date, in order to isolate genes involved in XLMR and XCA, the complete genomic organization of 3 candidate genes (KIAA0189, EPLG2 and AK001475) were defined by the computational analysis of cDNA and genomic DNA sequences. KIAA0189 was classified in the RhoGAP gene family; EPLG2 is a member of the Eph receptor family; and AK001475 was classified in the GTPase gene family. We analysed the coding sequence of these 3 candidate genes in 28 unrelated patients with XLMR (n=25) or XCA (n=3). DHPLC analysis was carried out using the Transgenomic system. The screening of KIAA0189 revealed three exonic polymorphisms R327Q, G425R and S529S. Analysis of the coding region of EPLG2 revealed the presence, in one of the patients with MR, of a missense mutation located in exon 4, V189A. This sequence variation was not found in more than ninety control X chromosomes. Other than an intronic polymorphism 1038+20C->T, no mutations were identified in AK001475. Further genes isolated from this region will also be evaluated for mutations in XLMR or XCA patients.

**Mutations Found in PKD1 by DHPLC Analysis.** *P.R. Fain<sup>1</sup>, W.J. Kimberling<sup>1</sup>, G. Stetler<sup>1</sup>, C. Roberts<sup>1</sup>, A. Johnson<sup>1</sup>, G. Wu<sup>2</sup>, S. Morrow<sup>2</sup>, M.L. Robinson<sup>2</sup>.* 1) Barbara Davis Ctr Childhd Diab, Univ Colorado Health Sci Ctr, Denver, CO; 2) Applied Genomics and Molecular Genetics, Transgenomic, Inc., Omaha, NE.

Autosomal dominant polycystic kidney disease (ADPKD) is one of the most common hereditary diseases in man and is responsible for about 8-10% of all end-stage renal disease. The majority (85%) of cases are due to mutations in the PKD1 gene on chromosome 16p13.3. The PKD1 gene, which was isolated in 1994, spans about 52 kb of genomic DNA and consists of 46 exons that code for a 14 kb transcript. The predicted polycystin-1 protein has 4,302 amino acid residues. PKD1 mutation screening and studies of genotype/phenotype correlations have been impeded by the complex structure of the gene, much of which (~70%) is replicated at least 3 times in regions centromeric to the PKD1 gene.

We have designed and optimized 60 amplicons for the 46 exons of the PKD1 gene for DHPLC analysis. We are presently screening a population of 700 patients, and preliminary results indicate the presence of nucleotide changes.

**Coupled Analysis of DHPLC and Single-Base Extension to Localize and Genotype Mutations in the HFE Gene.**

*M.A. Marino<sup>1</sup>, P.E. McAndrew<sup>1</sup>, A. Sharma<sup>1</sup>, C. Woolcock<sup>1</sup>, J.M. Devaney<sup>2</sup>.* 1) Applied Genomics & Molecular Genetics, Transgenomic Inc, Gaithersburg, MD; 2) Research Center for Genetic Medicine, Children's National Medical Center, Washington, DC.

A powerful analytical method combining the ability to discover and genotype mutations linked to Hereditary Hemochromatosis (HH) was developed for the HFE gene. HH is a common autosomal recessive disease that affects ~1 in 300 persons of Northern European descent, with an estimated carrier frequency of 1 in 10. Excessive iron deposition in major body organs due to the loss of regulation of dietary iron absorption can lead to liver cirrhosis, diabetes mellitus, cardiomyopathy, endocrine dysfunctions, and arthropathy. Early diagnosis of this disorder is critical, since simple phlebotomy treatments to remove iron-rich red blood cells can result in a normal life expectancy for HH patients.

We developed denaturing-HPLC (DHPLC) methods to scan HFE exons 2, 4 and 5 for mutations. Samples that showed a heteroduplex pattern were analyzed using a multiplexed single-base extension (SBE) genotyping assay. This rapid and accurate method is capable of genotyping the following six missense mutations in the HFE gene: H63D, S65C, G93R, I105T, C282Y, and R330M. SBE primers were designed to anneal adjacent to the base pair of interest. A thermostable DNA polymerase was used to specifically extend the 3' end of the SBE primer with the 2'-3' dideoxynucleotide (ddNTP) that is the Watson-Crick complement of the target base to be genotyped. The SBE products were analyzed using ion-pair reversed-phase HPLC (IP-RP HPLC) on the Transgenomic Wave® Nucleic Acid Fragment Analysis System with the DNASep® column. IP-RP HPLC is able to reproducibly separate oligonucleotides which differ only at their 3' base position, with the 3' base elution order of C-G-A-T at a column temperature of 70°C. This approach combines the efficiency of DHPLC mutation scanning with the specificity of the SBE assay and can be readily adapted for a variety of applications in molecular diagnostics and SNP studies.

**Evaluation of real-time quantitative PCR for carrier detection of dystrophin gene rearrangements.** *S. Tuffery-Giraud, C. Saquet, S. Chambert, M. Claustres.* Lab Genetique Moleculaire, CHU Montpellier, France.

Large deletions and duplications in the dystrophin gene are detected in about two third of patients with Duchenne (DMD) or Becker (BMD) muscular dystrophy. This enables accurate carrier detection and prenatal diagnosis in those families. Diagnosis of heterozygous deletions is mainly based on haplotype analysis, involving detection of loss of heterozygosity for microsatellite alleles or other polymorphic markers, whereas Southern blot is the method currently used to assess gene dosage for duplications. To meet the need for an easy-to-perform, rapid direct diagnosis of BMD/DMD carrier status, we report the development of a method based on measurement of gene copy number. Gene copy number analysis by real-time quantitative PCR can be targeted directly to a selected sub region of the gene of interest, and does not depend on the availability of informative flanking markers or parental DNA. Also, it involves no radioisotopes and requires no post-PCR handling. Heterozygosity for duplication increases the gene dose from two to three, whereas heterozygosity for a deletion reduces the gene dose from two to one. The amplification was performed in the Light-Cycler<sup>TM</sup> PCR system using the LightCycler FastStart DNA master SYBR Green I kit. In order to demonstrate the accuracy and reliability of the method for genetic testing, we analyzed 15 patients and relatives females with previously identified deletions or duplications including either exon 11 or 44. Fifteen normal samples were also tested as controls. All samples were run in triplicate. In order to correct for differences in the amount of input genomic DNA, the method involves amplification of a reference locus with known copy number and the use of a common standard DNA for amplification of the test and reference loci. The presence or absence of the genomic deletion or duplication was unambiguously diagnosed in all individuals. Hence, our initial data demonstrated the effectiveness of this approach, which could be extended to the analysis of multiple dystrophin exons in a cost- effective manner. Support: the Association Franaise contre les Myopathies (AFM).

***GNAS1* loss-of-methylation defect in a PHP-Ib kindred with linkage discordance to the chromosomal region**

**20q13.3.** *M. Bastepe*<sup>1</sup>, *D. Feig*<sup>2</sup>, *H. Jüppner*<sup>1,3</sup>. 1) Department of Medicine, Massachusetts General Hospital, Harvard Medical School, Boston, MA; 2) Endocrinology and Metabolism, Mount Sinai Hospital, Toronto, Ontario, Canada; 3) MassGeneral Hospital for Children, Massachusetts General Hospital, Boston, MA.

Pseudohypoparathyroidism type-Ib (PHP-Ib), a disorder characterized by isolated PTH resistance in the kidney, links to a region on 20q13.3 that includes a part of the imprinted *GNAS1* locus. The autosomal dominant form of PHP-Ib becomes clinically apparent only after maternal transmission of the mutated allele, and is associated with a loss of methylation at *GNAS1* exon A/B. Current evidence thus suggests that the genetic defect causing PHP-Ib resides within close proximity of *GNAS1*, presumably disrupting a cis-acting element that regulates imprinting of this locus. We investigated a novel PHP-Ib kindred in whom a loss of methylation at exon A/B was demonstrated for the two affected individuals, but not the unaffected family members. These findings were similar to those previously reported for several sporadic and familial cases of PHP-Ib. However, analysis of markers spanning the PHP-Ib locus on 20q13.3 (~9 cM) revealed that the haplotype shared by the two affected sisters was also present in an unaffected sibling and an unaffected daughter/niece. Considering autosomal dominant inheritance, these data indicate linkage discordance between the genetic defect responsible for the PTH-resistance in this kindred and the 20q13.3 region, thus providing evidence for locus heterogeneity for PHP-Ib. Sharing of only one parental haplotype by the affected individuals of this kindred excludes this chromosomal region also as a positional candidate for an autosomal recessive disorder. The loss of methylation at exon A/B observed in the affected individuals from this kindred, however, suggests a common pathway for the molecular mechanisms leading to the genetically distinct forms of PHP-Ib. Identification of the genetic mutation underlying the methylation defect in the kindred described above, and the actual mode of inheritance for this form of PHP-Ib will require further investigation and additional families with similar findings.

**Assembly and iron binding activity of human frataxin.** P. Cavadini, H. O'Neill, J. Adamec, G. Isaya. Departments of Pediatric and Adolescent Medicine and Biochemistry and Molecular Biology, Mayo Clinic and Foundation, Rochester, MN.

Frataxin deficiency is the primary cause of Friedreich ataxia (FRDA), an autosomal recessive degenerative disease (Campuzano et al. 1996). Frataxin is a conserved mitochondrial protein that plays a critical role in cellular iron homeostasis. Increased oxidative damage and mitochondrial iron accumulation are associated with frataxin defects in yeast, mouse, and human cells (Babcock et al. 1997; Puccio et al. 2001; Wong et al. 1999) but the underlying biochemical defect is unknown. We have shown that ferrous iron stimulates self-assembly of yeast frataxin (Yfh1p) into regular multimers that store as many as 3,000 atoms of iron in soluble form (Adamec et al. 2000) and that this enables Yfh1p to stimulate heme synthesis and to prevent iron-induced Fenton chemistry *in vitro* (Adamec et al. submitted). Because human frataxin can maintain mitochondrial iron homeostasis in yeast (Cavadini et al. 2000), we have hypothesized that the yeast and human proteins share a similar mechanism of action. When expressed in *E. coli*, the mature form of human frataxin (residues 56-210) can be isolated as monomer as well as a high MW form (>600,000). Dynamic light scattering has shown that the high MW form has a hydrodynamic radius of  $14 \pm 2$  nm, and electron microscopy has revealed a spherical shape. This species is stable at 4°C but readily disassociates into monomer upon treatment with 0.25% SDS. As isolated from bacterial cells, the high MW form contains low levels of iron (<1 Fe/subunit) that can be increased to at least 10 Fe/subunit upon incubation with ferrous ammonium sulfate *in vivo*. The iron-loaded multimer can be separated on non-denaturing polyacrylamide gels and detected by protein or iron staining. These results suggest that, similar to Yfh1p, human frataxin is an iron-storage protein. The iron binding activity of frataxin may prevent iron-induced oxidative damage and mitochondrial iron accumulation *in vivo*.

**Exclusion of two COX assembly genes in cytochrome c oxidase deficiency: SCO2 and COX10.** *S. LEBON, I. VALNOT, A. ROTIG, P. RUSTIN, A. MUNNICH.* INSERM U393, Hopital Necker, Paris, France.

Isolated cytochrome c oxidase (COX) is a frequent cause of respiratory chain defects in human and results in a variety of clinical manifestations including Leigh syndrome, cardiomyopathy, hepatic failure and encephalopathy. This clinical heterogeneity presumably stems from the large number of nuclear genes involved in the expression of the 13 COX subunit polypeptides and their subsequent maturation and assembly into the functional complex. In an attempt to better understand putative phenotype/genotype relationships, we screened 59 patients with isolated complex IV defects for mutations in two COX assembly genes previously shown to be involved in COX deficiency: SCO2 and COX10. SCO2 is involved in mitochondrial copper transport and/or insertion and mutations of this gene have been reported in several unrelated patients with cardioencephalomyopathy (Papadopoulou et al 1999, Nat Genet, 23, 333-7). On the other hand, COX10 encodes a heme A:farnesyl transferase and is mutated in COX-deficient patients presenting with proximal tubulopathy and encephalopathy (Valnot et al, 2000 Hum Mol Genet 9:1245-9). The coding sequences of the COX10 and SCO2 genes were tested by Denaturing High Performance Liquid Chromatography (DHPLC). Abnormal fragments were then directly sequenced. No mutations in SCO2 were identified in any patient (including those with cardioencephalomyopathy). Similarly, no mutations in COX10 could be detected either, confirming the very low incidence of COX10 mutations in patients with complex IV defects. Finally, we also studied COX11, COX15 and COX17 in few of these patients, but failed to identify any abnormality. This study brings support to the remarkable genetic heterogeneity of COX deficiencies in human.

**Using *Drosophila melanogaster* as a tool for analyzing human disease etiology.** E. Bier, L. Reiter. Cell and Developmental Biology, UCSD, La Jolla, CA.

We conducted an analysis of human disease gene homologues in *Drosophila melanogaster* with the goal of identifying genes amenable to study using *Drosophila* molecular genetics. Based on our analysis, which resulted in the identification of 714 human disease gene counterparts (see [Homophila](#)), we initiated studies into several human disease genes including those causing primary congenital glaucoma (PCG), Angelman syndrome (AS), and two antioxidant genes potentially involved in Alzheimer's disease (AD). We also began collaborations with human geneticists for each of these projects to integrate our studies into a gene discovery and analysis loop addressing the unanswered questions about various disease etiologies. The objective of our PCG study is to identify potential candidate genes in *Drosophila* corresponding to a suppressor locus on chromosome 8p that ameliorates the effects of *CYP1B1* mutations in some individuals. We generated a series of mutant alleles in a fly homolog of *CYP1B1* (*cyp18a*) which result in fluid flow problems reminiscent of those involved in PCG and are screening for second site suppressors of these mutations. Through a collaboration with Dr. B. Bejjani we will determine if any of these genes correspond to the suppressor locus he has mapped to human chromosome 8p by sequencing the human homologs of these genes in his patient pool. In AS the gene affected encodes an E3 ligase that targets certain proteins in the brain for degradation. To identify E3 ligase targets we will screen for suppressors of semi-lethal loss-of-function mutations in the *Drosophila* gene (*das*). In collaboration with Dr. A. Beaudet's group we will determine whether human or murine counterparts of these putative target proteins are present in elevated levels in a UBE3A<sup>-</sup> background. Finally, we will determine if the two antioxidant proteins we identified map to AD candidate loci through a collaboration with Dr. C. Van Broekhoven. Through these experimental approaches, we hope to validate *Drosophila* as a powerful model system for answering questions about disease gene function and set a precedent for establishing collaborations between clinical geneticists and researchers utilizing model organisms.

**A search for targets mediating Angelman syndrome pathogenesis using *Drosophila melanogaster*.** M. Bowers<sup>1</sup>, L.T. Reiter<sup>1</sup>, Y.-H. Jiang<sup>2</sup>, A.L. Beaudet<sup>2</sup>, E. Bier<sup>1</sup>. 1) Biology, UCSD, La Jolla, CA; 2) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

The human *UBE3A* gene encodes an E3 type ubiquitin ligase, E6-AP, whose function is to mark specific protein targets for ubiquitin-mediated degradation. *UBE3A* is expressed biallelically in most human tissues, but is genetically imprinted in the brain of humans and mice where only the maternal allele is expressed in the hippocampal and cerebellar neurons. Loss of function mutations in the maternal gene, paternal uniparental disomy, and imprinting mutations that prevent expression of both alleles result in Angelman syndrome (AS). Since it is thought that an overabundance of the proteins targeted by functional E6-AP is the cause of the neurological defects observed in AS patients, identification of these target proteins could lead to therapeutic strategies. Using the [Homophila](#) database, we identified a *Drosophila* homologue of *UBE3A*, which we named the *Drosophila* Angelman syndrome (*d-as*) gene. Utilizing an existing strain containing a *p*-element inserted into the 5'-UTR of *d-as*, we generated both lethal and semi-lethal alleles of *d-as*. The *p*-element line used also contains 14 copies of the yeast upstream activator sequence (UAS) which we used to misexpress *d-as* in various patterns via GAL4 expressing fly lines. Misexpression of *d-as* using the wing specific driver MS1096 results in the formation of ectopic wing veins and blisters indicative of a signaling pathway disruption. We also cloned the *d-as* cDNA and identified two spliceforms of the gene. The shorter transcript uses a cryptic splice site in exon V fused to exon I resulting in a much shorter protein product that is 71% similar to human *UBE3A*. In order to identify the protein targets of *d-as*, a genetic screen for second site suppressors of the *d-as* phenotype has been initiated. Once the *d-as* protein targets have been isolated in *Drosophila*, we will search for the corresponding proteins in mice and humans and assay their abundance in the brains of knock-out mice lacking *Ube3a*.

**The Jackson toxic milk mouse: a model for copper loading.** V. Coronado, M. Nanji, D.W. Cox. Department of Medical Genetics, University of Alberta, Edmonton, Alberta, Canada.

Copper is an essential trace element required for the function of several eukaryotic enzymes. However, when present in excess, copper becomes toxic, catalyzing the production of highly reactive oxygen species (ROS). Recently, ROS-induced oxidative stress has been implicated in a variety of neurological disorders, including Alzheimer disease (AD). Copper has been shown to accumulate in AD-affected brains and induce amyloid aggregation. Copper toxicity has been primarily studied in Wilson disease (WD), an autosomal recessive disorder in which ATP7B, a copper transporting ATPase expressed predominantly in the liver, is defective. Disruption of the copper transporting pathway results in decreased biliary excretion of copper and reduced incorporation of copper into ceruloplasmin. Consequently, copper accumulates in the liver, brain, and kidney, ultimately leading to liver cirrhosis and/or neurological damage frequently associated with kidney malfunction. Animal models of copper loading disorders are important in understanding these diseases and testing new potential therapies. The original toxic milk (*tx*) mouse, a WD model, has a Met1356Val substitution in the eighth transmembrane segment of Atp7b. In 1987, a new autosomal recessive mutation (*tx<sup>J</sup>*) arose in the C3H/HeJ mouse line (Jackson Laboratory) and has been maintained on the C3HeB/FeJ background, which is now a readily available *tx* strain. Like *tx/tx* mutants, homozygous *tx<sup>J</sup>* mice develop cirrhosis, and infant mice are pale colored, copper deficient, and display early mortality. The *tx<sup>J</sup>* mutation has been shown to be allelic with the original mutation, but the specific mutation has not been identified. We have cloned and sequenced the *tx<sup>J</sup>* Atp7b gene and conclude that the causative mutation is a Gly712Asp substitution in the second transmembrane segment of the deduced protein. This mutation creates a novel restriction site allowing for quick identification of normal and affected mice. Knowledge of this mutation will facilitate the use of this strain in studies of metabolic disorders and neurological diseases, in which copper accumulation plays an active role in pathology.

**An Animal Model of Mild Spinal Muscular Atrophy (SMA).** *U.R. Monani*<sup>1</sup>, *M. Pastore*<sup>2</sup>, *T. Gavrilina*<sup>1</sup>, *C. Andreassi*<sup>1</sup>, *A.H.M. Burghes*<sup>1,2</sup>. 1) Dept of Neurology, Ohio State Univ, Columbus, OH 43210; 2) Department of Molecular and Cellular Biochemistry, Ohio State Univ., Columbus OH 43210.

Spinal muscular atrophy (SMA), a neurodegenerative disorder, is the most common genetic cause of childhood death. It is caused by mutations in the *SMN1* gene and occurs in severe (type I), intermediate (type II) and mild (type III) forms. We have recently developed a mouse model of SMA. As in humans, mice lacking mouse *Smn* but carrying one or two copies of the human *SMN2* gene develop severe SMA and die by 8 days of age. What is more, *SMN2* can modify phenotypic severity and mice with 8 copies of the gene have a normal life-span and display no disease phenotype. Mice with 16 copies of *SMN2* are also normal indicating that over-expression of this protein is not deleterious. To generate a mouse with mild SMA, we have created a transgene with a missense mutation in exon 1 of the *SMN1* gene derived from a human patient. The transgene under the control of the SMN promoter was introduced onto the 1 or 2 copy *SMN2*; *Smn*<sup>-/-</sup> background. Preliminary results indicate that the *SMN2*; *Smn*<sup>-/-</sup> mice carrying the transgene display a typical type III SMA phenotype. They are smaller, display abnormal muscle and motor neuron pathology reminiscent of type III patients and are significantly weaker than their normal littermates. Further, although they develop normally, the mice die between 6 months of age and a year. These mice will be an important tool in testing drugs for the treatment of SMA, for which we and others have developed high-throughput screens.

**Functional conservation of the regulatory cascade for CFTR-mediated chloride secretion.** *J.E. Mickle<sup>1</sup>, K.J. Karnaky, Jr.<sup>2</sup>, G.R. Cutting<sup>1</sup>*. 1) Inst Genet Med, Johns Hopkins Univ Sch Med, Baltimore, MD; 2) Dept Cell Biol/Anatomy, Med Univ of South Carolina, Charleston, SC.

Cystic fibrosis (CF) is a life-limiting pulmonary disease that develops from abnormal ion transport. The gene responsible for CF encodes a protein, CFTR, that functions as an epithelial chloride channel and as a regulator of separate ion channels. The regulatory cascade of CFTR activation initiates when extracellular agonists bind b-adrenergic receptors; accordingly, proteins along the activation pathway are potential modifiers of the CF phenotype. However, the study of human CFTR in its native environment is hampered by low-level expression in relatively inaccessible tissues. Thus, a model system where native protein is highly expressed and readily available for functional analyses would be extremely beneficial. CFTR is abundantly expressed in chloride cells of killifish gill and opercular epithelium. The latter tissue is exceptional in that it is a naturally occurring polarized monolayer of epithelium suitable for functional genomic studies. To assess conservation of the CFTR regulatory pathway in killifish, opercular epithelium from seawater-adapted fish was mounted in Ussing chambers. After transepithelial voltage reached a stable value, the membrane was voltage-clamped and short circuit current (Isc) was recorded. No effect was observed upon the addition of 10mM isoproterenol, a b-adrenergic agonist, to the apical surface (Isc before:  $40.01 \pm 24.31$  SEM mAmp/cm<sup>2</sup>; Isc after:  $40.49 \pm 24.23$  mAmp/cm<sup>2</sup>,  $p = 0.42$ ,  $n = 3$ ). However, chloride transport was significantly increased by application of isoproterenol to the basolateral membrane (Isc before:  $37.16 \pm 10.88$  mAmp/cm<sup>2</sup>; Isc after:  $82.68 \pm 14.05$  mAmp/cm<sup>2</sup>,  $p = 0.004$ ,  $n = 7$ ). The response was inhibited by DPC and NBBP but not by DIDS. The functional measurements are consistent with molecular identification of CFTR in chloride cells; these measurements demonstrate that the regulatory cascade for CFTR activation is conserved in opercular epithelium. Thus, killifish provide a functional model similar to human epithelia that can be used to identify genes involved in the CFTR regulatory cascade using comparative genomic approaches.

**Characterization of the mouse orthologue of the human spastin gene to generate genetically engineered mouse models for autosomal dominant hereditary spastic paraplegia type 4 (SPG4).** *J. Schickel*<sup>1</sup>, *D. Boensch*<sup>1</sup>, *S. Klimpe*<sup>2</sup>, *R. Sudbrak*<sup>3</sup>, *G.E. Homanics*<sup>4</sup>, *T. Deufel*<sup>1</sup>. 1) Institut fuer Klinische Chemie und Laboratoriumsdiagnostik, FSU Jena, Jena, Germany; 2) Neurologische Universitaetsklinik, Mainz, Germany; 3) MPI fuer Molekulare Genetik, Berlin, Germany; 4) Department of Anesthesiology and Critical Care Medicine, University of Pittsburgh, Pittsburgh, USA.

Autosomal dominant hereditary spastic paraplegia (AD-HSP) is a genetically heterogeneous neurodegenerative disease characterised primarily by hyperreflexia and progressive spasticity of the lower limbs. The SPG4 locus at 2p21-p22 has been shown to account for approximately 40-50% of all AD-HSP families. The SPG4 gene was recently identified; it is ubiquitously expressed in adult and fetal tissues and encodes for spastin, an 616-amino-acid ATPase of unknown function belonging to AAA protein family. We have identified two novel SPG4 mutations in German AD-HSP families. A deletion of the first nucleotide of exon 9 leading to a premature stop codon is predicted to generate a truncated protein of 393 amino acids, and a large genomic deletion resulting in the loss of exons 13-16; patients carrying those mutations differ in their electrophysiological findings. With the aim to elucidate the function of the spastin gene and its role in the pathogenesis of spastic disorder, we have set out to generate genetically engineered mouse models carrying these two mutations defining distinct human disease phenotypes. As a first step we analysed the genomic organization of the mouse orthologue of SPG4 using screened BAC- and PAC-clones. The mouse gene consists of 17 exons spanning at least 35 kb of genomic DNA; subclones from the corresponding BACs/PACs were generated and provide the basis for the construction of targeting vectors to manipulate mouse embryonic stem cells and produce genetically altered mice.

**A mouse model for Smith-Magenis Syndrome.** *K. Walz, S. Carattini-Rivera, H. Vogel, R. Paylor, A. Bradley, J.R. Lupski.* Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX.

Smith-Magenis Syndrome (SMS), associated with del(17)p11.2, is characterized by a genomic deletion of 4Mb. This deletion is believed to be the outcome of homologous recombination between flanking repeat gene clusters. The complex phenotypic features of SMS patients and the size of the deletion suggest that the haploinsufficiency of one or more genes in the commonly deleted region contribute to this disorder. Clinical features in humans include mental retardation, short stature, minor craniofacial anomalies, microcornea, developmental defects of the heart and kidneys, Smith-Magenis Syndrome (SMS), associated with del(17) and neurobehavioral abnormalities. The goal of this project is to generate a mouse model for SMS in order to define the gene or group of genes responsible for SMS phenotype. Human chromosome 17p11.2 is syntenic to the 32-34 cM region of murine chromosome 11. Utilizing chromosomal engineering we deleted a region on mouse chromosome 11 that spans the syntenic region for the human commonly deleted interval. Mice heterozygous for the deletion in a 129SvEvBrd/C57BL/6 background were obtained at a mendelian rate. However, no homozygous mutant mice were recovered. Analysis of heterozygous mice indicated that some of the human clinical features are present in the model we generated. Craniofacial abnormalities were observed in the mutant mice with full penetrance. 20 percent of the mutant mice analyzed presented seizures, a percentage similar to the observed for human patients. No anatomical or histological anomalies were detected in a limited set of mutant mice analyzed (n of 6). Nevertheless, as the proportion of heart or kidney defects in the human SMS population is approximately 30 percent, more animals need to be studied. Behavioral studies are being done and analysis of the data is in progress.

**Transgenic expression of CECR1 results in developmental abnormalities similar to features of cat eye syndrome.**

*M.A. Riazi, M. Buchwald.* Genetic & Genomic Bio/Res Inst, Hosp for Sick Children, Toronto, ON., Ontario, Canada.

CECR1 is a novel putative growth factor/adenosine deaminase that maps within the critical region for cat eye syndrome encompassing approximately 2 Mb of DNA on chromosome 22q11. Common features of cat eye syndrome includes coloboma, preauricular pits and tags, heart (anomalous pulmonary venous defect, tetralogy of Fallot), and kidney (hypoplastic, absent) defects. CECR1 is expressed in a number of organs including heart and kidney and therefore is a candidate for features of cat eye syndrome. We have produced transgenic mice expressing CECR1 under the control of either a promoter with ubiquitous expression (beta-actin promoter) or a heart-specific promoter (alpha-myosin heavy chain promoter). Three beta-actin and three alpha-myosin heavy chain (MHC) lines with various integration sites and transgene copy numbers were analyzed in detail. The expression of CECR1 in the transgenic lines was confirmed with RT-PCR. The actin-CECR1 transgenic lines express CECR1 in most organs including the heart, kidney, and liver while the expression of CECR1 is mainly restricted to the heart in the MHC-CECR1 transgenic lines. A number of mice from each line were analyzed for phenotypic abnormalities. A high rate of embryonic and neonatal lethality was observed in two of the MHC-CECR1 lines. The transgenic mice produced with both constructs demonstrated cardiac hypertrophy. The hypertrophy was mostly due to the enlargement of the atria and right ventricle (both increased in weight by ~20%) as examined in 1-month old mice. In addition to the heart defects, the kidneys of the actin-CECR1 transgenics were hypoplastic or underdeveloped in two lines. Other abnormalities such as divided or cystic kidneys were occasionally observed in one line. Further study on the expression level of CECR1 in the transgenic mice as well as the specific cardiovascular defects in these mice is in progress. (Supported by the Lombard Insurance Chair in Pediatric Research and the Hospital for Sick Children Foundation).

**Triplet Duplication in  $\alpha 1(I)$  collagen chain of proband with lethal osteogenesis imperfecta shifts register of alpha chains in helix and alters incorporation of mutant trimers into fibrils and ECM.** W.A. Cabral<sup>1</sup>, M. Merts<sup>2</sup>, S. Leikin<sup>2</sup>, J.C. Marini<sup>1</sup>. 1) Section on Connective Tissue Disorders, HDB/NICHD/NIH, Bethesda, MD; 2) LPSB, NICHD/NIH, Bethesda, MD.

The helical region of type I collagen alpha chains consists of uninterrupted repeats of the amino acid triplet Gly-X-Y. The Gly-X-Y triplet defines the "register" of the alpha chains in collagen heterotrimer. We investigated the effect of shifting the interchain alignment of the collagen helix by a single Gly-X-Y triplet on collagen assembly, stability and incorporation into fibrils and matrix. These studies utilized a collagen mutation occurring in lethal type II OI. The proband has a triplet duplication in COL1A1 exon 44 cDNA and gDNA subclones. The normal allele encodes three Gly-Ala-Hyp triplets at aa 868-876, while the mutant allele encodes four. The register shift delays helix formation, causing overmodification of all CNBr peptides. Pericellular processing of secreted procollagen demonstrated more rapid appearance of pC- and mature collagen than control. In matrix deposited by proband cultured fibroblasts, overmodified chains were abundant in the immaturely cross-linked fraction but constituted a minor fraction of maturely cross-linked collagen. Trimers purified from cell culture exhibited markedly different behavior depending on whether they had two (+/+), one (+/-) or no (-/-) mutant  $\alpha 1$  chains. Differential scanning calorimetry revealed that +/+ molecules denature in sequential steps, 6°, 5° and 4°C below the T<sub>m</sub> of wild type protein; +/- molecules denature in a single step, 2°C below wild type. The three species appeared to be secreted in a 1:2:1 ratio consistent with random chain association. *In vitro* fibrillogenesis of this mixture produced fibers containing no +/+ molecules and a smaller +/- to -/- ratio than in the starting mixture. The rate and extent of fiber formation were comparable to wild type only at 4X higher protein concentration. Furthermore, turnover of +/- molecules was comparable to normal helices in ECM deposited by proband fibroblast cultures. The profound effects of shifting the collagen triplet register correlate with the severe clinical outcome.

Program Nr: 2672 from the 2001 ASHG Annual Meeting

**Molecular Basis of Mild form of Sickle cell -Beta Thalassemia syndrome in two Bahraini girls.** *S.S. Al Arrayed, N. Jassim.* Genetic Dept, Salmaniya Medical Ctr, Manama, Bahrain.

Two unrelated asymptomatic Bahrain female students were presented ,through a student screening project for hemoglobinopathies.with an atypical profile of HPLC of the whole blood .HPLC showed lower levels of HbA (20.8 and 21%).sickle Hb levels at 60.2and 62.4%.respectively.HbA2 levels at 8.9and7.3%.and elevated level of fetal hemoglobin at 7.9 and 6.8%.Both student were asymptomatic with normal clinical phenotype and without anemia.with HB of 12.7and 13.1% respectively.Molecular investigation by DGGE and RFLP studies revealed them to be compound heterozygotes for the sickle cell mutation (Bcd6A-T),and a B thal mutation nt-88(C-A)which is a mild B+ thalassemia mutation.Haplotype analysis indicates that sickle cell mutation is of the Saudi-Indian haplotype,while nt-88(C-A)mutation is associated with haplotype IX .Mapping of the alpha globin genes revealed both of the students as homozygotes for the rightward deletion(-a3.7/-a3.7).As a conclusion,these molecular investigation may explain unequivocally several of the bizzare clinical condions created by the presence of both sickle cell gene ,Beta thalassemia gene and alpha thalassemia gene in the same individual which is a common occurance in our region.

**Reduced hippocampal GABA<sub>A</sub> receptors and increased kainic acid seizure susceptibility in the fragile X mouse.**

*C.S. Dobkin, X. Ding, W.T. Brown, A. El Idrissi.* Dept Human Genetics, NYS Inst Basic Research, Staten Island, NY.

The Fragile X mental retardation syndrome often includes childhood seizures and electroencephalogram irregularities. Recent reports show that the Fragile X knockout (Fmr1 ko) mouse model for this disorder has increased susceptibility to audiogenic seizures. We find that these Fmr1 ko mice are also more sensitive to kainic acid (KA)-induced limbic seizures and show a striking increase in seizure-induced cell death in the CA3 subfield of the hippocampus. In vitro studies of cerebellar granule cells indicated that Fmr1 ko neurons are insensitive to inhibition by gamma-amino butyric acid (GABA). Immunohistochemical analysis of GABA<sub>A</sub> receptors in situ showed that these post-synaptic receptors were virtually eliminated from the Fmr1 ko mouse hippocampal formation. Hippocampal neurons normally express high levels of the Fmr1 gene product, FmrP, and GABA<sub>A</sub> receptor expression was partially rescued by introduction of a human FMR1 transgene. Taken together, these results indicate that the reduction of hippocampal GABA<sub>A</sub> receptors was due to the absence of FmrP in the Fmr1 ko mouse brain. Since expression of GABA<sub>A</sub> receptors depends in part on extracellular cues, the identity of the cell autonomously affected by the lack of FmrP is not yet clear. Nevertheless, reduced GABA<sub>A</sub> receptor expression in the hippocampal formation and the resulting loss of inhibition would explain the increased susceptibility to KA seizures and CA3 cell death in the Fmr1 ko mouse. GABA<sub>A</sub> receptor reduction was not apparent in the cerebellum or other brain areas, but it may be related to the increased audiogenic seizure susceptibility and altered startle response observed by others in the Fmr1 ko mouse. Decreased GABA inhibition may also contribute to the susceptibility to childhood seizures as well as some of the cognitive features in the Fragile X Syndrome.

**Procollagen from an OI proband with  $\alpha 1(I)$  exon 41 skipping has impaired binding of  $\alpha 1(I)$  C-telopeptide and confirms importance of this region for fibril assembly.** *J.C. Marini<sup>1</sup>, W.A. Cabral<sup>1</sup>, A. Fertala<sup>2</sup>, L.K. Green<sup>1</sup>, J. Korkko<sup>2</sup>, A. Forlino<sup>1</sup>.* 1) HDB/NICHD/NIH, Bethesda, MD; 2) Ctr for Gene Therapy, MCP Hahnemann University, Phila, PA.

Previous *in vitro* data on type I collagen self-assembly into fibrils suggested that the aa 776-797 region of  $\alpha 1(I)$  is crucial for fibril formation because it serves as the recognition site for the telopeptide of a docking collagen monomer. We used a natural collagen mutation with a deletion of aa 766-801 to confirm the importance of this region for collagen fibril formation. The proband is heterozygous for a COL1A1 IVS 41 A<sup>+4</sup>® C substitution. The intronic mutation causes splicing out of exon 41, confirmed by sequencing of normal and shorter RT-PCR products. The abnormal transcript is translated; structurally abnormal alpha chains are demonstrated in the cell layer of proband fibroblasts by SDS-Urea-PAGE. The proportion of mutant chains in the secreted procollagen was determined by digestion with MMP-1 to be 10%. Mutant chains are resistant to MMP-1 digestion because exon 41 also contains the vertebral collagenase cleavage site. The proportion of mutant protein was supported by quantitative RT-PCR on RNA from proband dermal fibroblasts and clonal cell lines, showing the mutant cDNA was about 15% of total  $\alpha 1(I)$  cDNA. Secreted proband collagen was used for analysis of kinetics of binding of  $\alpha 1C$ -telopeptide using an optical biosensor. Telopeptide had slower association and faster dissociation from proband than from normal collagen. Purified proband pC-collagen was used to study fibril formation. The presence of the mutant molecules decreases the rate of fibril formation. The fibrils formed in the presence of 10-15% mutant chain have an altered morphology, with increased length. These results suggest that trimers containing the mutant chain are incorporated into fibrils and that the absence of the telopeptide binding site from even a small portion of the monomers interferes with fibril growth. The severe type III OI phenotype of the proband may result from a combination of abnormal fibril morphology and longer persistence of mutant molecules in tissue, due to the lack of the MMP-1 cleavage site.

**Analysis of RNase MRP (RMRP) function in cartilage hair hypoplasia (CHH).** *P. Hermanns<sup>1</sup>, A. Bertuch<sup>1</sup>, A. Mian<sup>1</sup>, B. Zabel<sup>2</sup>, C. Bacino<sup>1</sup>, V. Lundblad<sup>1</sup>, B. Lee<sup>1</sup>.* 1) Dept Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Children's Hospital of the University of Mainz, Germany.

Cartilage hair hypoplasia is an autosomal recessive disorder characterized by short stature, sparse hair, defective cellular immunity, and predisposition to several cancers. The critical region was mapped to 9p13 and recently, Ridanp et al. (2001) have shown that most CHH patients have mutations in the RNase MRP (RMRP) gene with one major Finnish allele in their population. RMRP is a ribonucleoprotein which functions as an endonuclease and is involved in processing of pre-rRNA in the nucleolus, cleavage of mitochondrial RNA, and priming of mitochondrial DNA replication. In a cohort of 15 patients we found mutations in both alleles in 13 patients. Two patients had no mutations in the RMRP gene. Of these, 21 mutations have not been previously identified. The mutations include insertions in the promoter, missense substitutions of evolutionarily conserved as well as divergent bases. The transcribed part of the RMRP gene is highly conserved among different species (mouse, rat, cow, human, xenopus, *A. thaliana*, *S. cerevisiae*). However, the only mutation, which is conserved between human and yeast is the main Finish mutation (70AG). This mutation has been reported to cause no reduction of RMRP level in patients or alteration of protein-RMRP binding. The RMRP complex still forms (Ridanp et al., 2001). To understand the function of RMRP mutations we have generated yeast targeted for the orthologous RMRP gene termed nuclear mitochondrial endonuclease 1 (NME1. The NME1 mutation causes cell lethality by tetrad analysis and current studies are aimed at rescuing the lethality with the human RMRP gene expressed from the endogenous promoter as well from a yeast ADH promoter. Human mutations will be introduced to ascertain their effects on cell viability, growth rate, growth phenotype at different temperatures, alteration in nutritional requirements, and changes in RNA and chromosomal stability including the ratio of 5.8SS and 5.8SL RNA. Together these studies will provide insight into the pathogenesis of the pleiotropic effects observed in CHH.

**Post mortem molecular genetic investigation of multiple hamartomas in a female TSC patient with pulmonary lymphangiomyomatosis.** *K. Mayer<sup>1</sup>, A. Dimmler<sup>2</sup>, A. Schaenzer<sup>2</sup>, H.D. Rott<sup>1</sup>.* 1) Institute of Human Genetics, Erlangen, Germany; 2) Institute of Pathology, Erlangen, Germany.

We report on the post mortem examination of a 41 year old female TSC patient who deceased from pulmonary lymphangiomyomatosis. Cerebral TSC manifestations were multiple cortical tubers with multiple astrocytic and multinuclear giant cells as well as a subependymal nodule with central calcification and statement of glial fibrillary acidic protein (GFAP). Renal involvement included four bigger renal angiomyolipomas up to 8x7 cm in size with central necrosis and multiple smaller tumours within the renal cortex. Cause of death was a chronic right heart insufficiency originated by pulmonary lymphangiomyomatosis. Native samples from multiple brain and kidney hamartomas as well as from normal tissue were obtained for molecular genetic analyses. In order to identify the combination of both inactivating TSC mutations in different lesions we started with LOH screening in both TSC genes using microsatellite markers analyzed with Genotyper 2.5 on an ABI 310 sequencer and single nucleotide polymorphisms analyzed with DHPLC which offers the possibility of a quantitative determination of allele ratios in tumour versus normal tissue. We continued with exon screening applying DHPLC and direct sequencing if no LOH was detected. Fibroblast cultures obtained from pericard and hamstring were screened to confirm the patients germline mutation. The results of this study will offer the opportunity to give insights to the molecular pathogenesis of individual hamartomas in the same patient according to the two hit tumour suppressor inactivation model.

**Peripheral nervous system involvement in laminin alpha2 chain-null mutant ( $dy^{3K}/dy^{3K}$ ) mice.** *M. Nakagawa*<sup>1,3</sup>, *Y. Miyagoe-Suzuki*<sup>2</sup>, *K. Ikezoe*<sup>3</sup>, *Y. Miyata*<sup>4</sup>, *I. Nonaka*<sup>3</sup>, *K. Harii*<sup>5</sup>, *S. Takeda*<sup>2</sup>. 1) Plastic and Reconstructive Surgery, Saitama Medical School, Saitama, Japan; 2) Molecular Therapy, National Institute of Neuroscience, National Center of Neurology and Psychiatry, Tokyo, Japan; 3) Ultrastructural Research, National Institute of Neuroscience, National Center of Neurology and Psychiatry, Tokyo, Japan; 4) Pharmacology, Nippon Medical School, Tokyo, Japan; 5) Plastic, Reconstructive and Aesthetic Surgery, Graduate School of Medicine, University of Tokyo, Tokyo, Japan.

The laminin alpha2 chain is major component of basal lamina in both skeletal muscle and the peripheral nervous system. The laminin alpha2 chain deficiency causes merosin-deficient congenital muscular dystrophy, which affects not only skeletal muscle, but also the peripheral nervous system. It has been reported that the formation of basal lamina is required for myelination in the peripheral nervous system. In fact, the spinal root of dystrophic mice ( $dy/dy$  mice), whose laminin alpha2 chain expression is greatly reduced, shows lack of basal lamina and amyelination. To investigate the role of laminin alpha2 chain and basal lamina in vivo, we examined the peripheral nervous system of  $dy^{3K}/dy^{3K}$  mice, which are null mutants of laminin alpha2 chain. The results indicate the presence of myelination although Schwann cells lacked basal lamina in spinal root of  $dy^{3K}/dy^{3K}$  mice, suggesting that basal lamina is not an absolute requirement for myelination in vivo. Immunohistochemically, the expression of laminin alpha4 chain was increased and laminin alpha5 chain was preserved in endoneurium of the spinal root. Laminin alpha4 and alpha5 chains may play the critical role in myelination instead of laminin alpha2 chain in  $dy^{3K}/dy^{3K}$  mice. In addition, the motor conduction velocity of the sciatic nerve was significantly reduced. This reduction in conduction velocity may be due to small axon diameter, thin myelin sheath and patchy disruption of the basal lamina of the node of Ranvier in  $dy^{3K}/dy^{3K}$  mice.

**The Townes-Brocks syndrome gene SALL1 is a transcriptional repressor and interacts with UBC9 and SUMO-1.**  
*J. Kohlhase, L. Rieger, S.K. Bohlander, C. Netzer.* Institute for Human Genetics, University of Goettingen, Goettingen, Germany.

The SALL1 gene encodes a putative zinc finger transcription factor (1324 aa) which is mutated in Townes-Brocks syndrome. This syndrome is inherited as an autosomal dominant trait and is characterized by imperforate anus, preaxial polydactyly, and dysplastic ears. Little is known about the cellular function of SALL1. To investigate its possible role as a transcription factor we performed reporter gene assays expressing portions of SALL1 fused to the GAL4 DNA binding domain transiently in mammalian cells. These experiments revealed that the central 1000 aa of SALL1 strongly repress the expression of a luciferase reporter gene controlled by the thymidine kinase promoter and GAL4 DNA binding sites. Trichostatin A, an inhibitor of histone deacetylases, was not able to relieve this repression suggesting that SALL1-mediated repression does not lead to the recruitment of mSin3A, N-CoR or histone deacetylases. We also employed the yeast two-hybrid system to identify protein interaction partners of SALL1. One of these interacting proteins is UBC9 which is known to mediate the covalent modification of other proteins by SUMO-1. The SALL1/UBC9 interaction was confirmed in vitro by a GST pulldown experiment. We could also demonstrate interaction between SALL1 and SUMO-1 in the yeast system indicating that SALL1 is modified by sumoylation. Sumoylation is known to target proteins to certain subnuclear compartments. Expression of a GFP-SALL1 fusion protein in NIH3T3 cells showed indeed localization of GFP-SALL1 in distinct nuclear speckles.

**The CCM1 gene product KRIT1 interacts with the integrin binding protein ICAP-1.** *J.S. Zawistowski<sup>1</sup>, I.G. Serebriiskii<sup>2</sup>, M.F. Lee<sup>1</sup>, E.A. Golemis<sup>2</sup>, D.A. Marchuk<sup>1</sup>.* 1) Department of Genetics, Duke University Medical Center, Durham, NC; 2) Division of Basic Science, Fox Chase Cancer Center, Philadelphia, PA.

Cerebral Cavernous Malformations (CCM) are vascular anomalies of the brain consisting of grossly enlarged capillary-like vessels with no intervening neural tissue. Individuals affected with CCM most often present with the symptoms of seizures, intracerebral hemorrhage leading to stroke and focal neurological deficits. Our lab and others have identified the CCM1 disease gene as *Krit1*, a protein initially identified based on a yeast two-hybrid interaction with the Ras-family GTPase RAP1A. As the function of the KRIT1 protein and its role in CCM1 pathogenesis remain unknown, we performed yeast two-hybrid screens to identify additional protein binding partners. Utilizing the Dual Bait two-hybrid system (Serebriiskii et al. 1999 *J. Biol. Chem.* 274(24):17080), we used the N-terminal 276 amino acid residues of KRIT1 as bait, a region lacking similarity to any known protein upon database searches. Much of this region has been recently identified as additional upstream coding sequence not originally reported as part of the *Krit1* coding region (Sahoo et al. 2001 *Genomics* 71(1):123). From parallel screens of human fetal brain and HeLa cDNA libraries, we obtained multiple independent isolates of human ICAP-1 (integrin cytoplasmic domain-associated protein-1) as interacting clones. The specificity of the N-terminal KRIT1/ICAP-1 interaction within the context of the yeast two-hybrid system was verified by retransformation assays performed in parallel with a non-specific bait. The  $\alpha$  isoform of ICAP-1 is a serine/threonine-rich phosphoprotein which binds the cytoplasmic tail of  $\beta_1$  integrins. In addition, its phosphorylation status is regulated during cell-matrix interactions, suggestive of the protein playing an important role in integrin-mediated cell adhesion. The interaction between ICAP-1 and KRIT1, and the presence of a FERM domain in the latter, suggest that KRIT1 may be involved in the bidirectional signaling between integrin molecules and the cytoskeleton. Furthermore, these data suggest that CCM1 pathogenesis might involve cell adhesion processes via integrin signaling.

**Impaired *IMPT1* expression in kidney stone disease demonstrated by reverse transcription-polymerase chain reaction *in situ* hybridization.** A. Sahota<sup>1</sup>, E.G. Tzortzaki<sup>1</sup>, M. Yang<sup>1</sup>, D. Glass<sup>1</sup>, J. Barrera-Oro<sup>1</sup>, L. Deng<sup>1</sup>, A.P. Evan<sup>2</sup>, S. Bledsoe<sup>2</sup>, P.J. Stambrook<sup>3</sup>, J.A. Tischfield<sup>1</sup>. 1) Dept. Genetics, Rutgers Univ., Piscataway, NJ; 2) Dept. Anatomy and Cell Biology, Indiana Univ. Sch. Med., Indianapolis, IN; 3) Dept. Cell Biology, Neurobiology, and Anatomy, Univ. Cincinnati Coll. Med., Cincinnati, OH.

The mRNA for imprinted multimembrane-spanning polyspecific transporter-like gene 1 (*IMPT1*) is highly expressed in organs with metabolite transport functions, including the kidney. In a knockout mouse model for adenine phosphoribosyltransferase (APRT) deficiency and 2,8-dihydroxyadenine (DHA) nephrolithiasis, we previously observed a decrease in *IMPT1* mRNA expression in the kidney, suggesting that this may be responsible, at least in part, for the impaired renal function in these mice. To assess the functional significance of this observation, we identified the cell types expressing *IMPT1* mRNA in paraffin-embedded mouse kidney sections. *IMPT1* mRNA was not detected using *in situ* hybridization (ISH), but we observed intense nuclear staining in the cortex, medulla, and glomeruli from wild-type mice using an improved RT-PCR ISH procedure. We used only six PCR cycles, and uniform heat distribution over the slides, in order to minimize tissue damage and/or PCR product diffusion during amplification. *IMPT1* expression was significantly decreased in all three regions in kidney sections from APRT-deficient male mice, and this was confirmed by solution RT-PCR. APRT-deficient female mice are less severely affected by DHA lithiasis than their male counterparts, and we observed only a modest reduction in *IMPT1* expression in these mice. *IMPT1* expression in *Aprt* heterozygotes was comparable to that in wild-type mice, suggesting imprinting of one of the parental alleles. These findings suggest that one consequence of renal deposition of DHA in APRT deficiency is impaired *IMPT1* mRNA expression and this may have adverse effects on glomerular and tubular transport functions. RT-PCR ISH can be used to localize the site of expression of transcripts that may not be detectable using standard ISH procedures. Supported by NIH grants DK38185, ES05652, and ES06096.

**DNA rearrangements at the D4Z4 locus in South African facioscapulohumeral muscular dystrophy families.** A. van der Merwe<sup>1</sup>, C-M. Schutte<sup>1</sup>, S.M. van der Maarel<sup>2</sup>, M. Alessandrini<sup>1</sup>, E. Honey<sup>1</sup>, R.R. Frants<sup>2</sup>, A. Olckers<sup>1</sup>. 1) University of Pretoria, South Africa; 2) Leiden University Medical Centre, The Netherlands.

Facioscapulohumeral muscular dystrophy (FSHD) is an autosomal dominant, late-onset degenerative neuromuscular disorder. Disease onset occurs generally within the first or second decade of life. The phenotypical expression varies in the age of onset and clinical severity. FSHD is characterised at onset by the progressive weakness and atrophy of the facial and shoulder girdle muscles. Linkage was established to the sub-telomeric region of chromosome 4q35. This sub-telomeric region contains a polymorphic repeat array locus (D4Z4) consisting of 3.3 kb repeats. An integral number of repeats are deleted in affected individuals. Integrated haplotypes were constructed for 177 individuals from five extended South African FSHD families. Southern Blot analysis was performed to determine DNA rearrangements in 162 individuals from this selected group of families. Deletion fragments were observed in all families investigated. A BlnI resistant deletion fragment of 24 kb segregated with the postulated FSHD-haplotype in families F10, F30 and F40. The FSHD-haplotype in all three families was identical, with the entire nine-allele haplotype segregating in one sub-family of F10 (F15) and in family F30. Six alleles of this haplotype co-segregated with the FSHD phenotype in F13 (sub-family of F10) and three alleles co-segregated in F40. It was previously reported that an identical six allele FSHD-haplotype segregated in families F20 and F60. The deletion fragments segregating in these families were also of identical size. To date, only two FSHD haplotypes have been observed in the South African population - each co-segregating with a deletion fragment of a specific size.

**The Dystrophin-Associated Complex in *Drosophila* and Lamprey.** *M.J. Greener*<sup>1</sup>, *G. Tear*<sup>2</sup>, *R.G. Roberts*<sup>1</sup>. 1) Div. of Med. & Mol. Genet., Guy's Hospital, London, UK; 2) MRC Centre for Developmental Neurobiology, Guy's Hospital, London, UK.

Mutations in the genes for dystrophin, and other members of the dystrophin-associated complex (DAC) result in phenotypically related forms of muscular dystrophy. Work in mammals is somewhat complicated by the diversity of proteins which contribute to the DAC in different tissues and subcellular localizations (3 dystrophin-like proteins, 2 dystrobrevins, 5 syntrophins, 5 sarcoglycans).

We have found that the model invertebrate *Drosophila melanogaster* has a substantially simpler repertoire of orthologous proteins (1 dystrophin, 1 dystrobrevin, 2 syntrophins, 3 sarcoglycans). In an attempt to assess whether fruitfly dystrophin performs a single ancestral role or functionally encompasses the fundamental activities of all three human dystrophin-like proteins (dystrophin, utrophin, DRP2), we have performed in-situ hybridization and stage-specific expression analysis. These suggest both a neuronal and muscular function, consistent with a "union set" of vertebrate dystrophin roles.

To provide an evolutionary "snapshot" of a situation intermediate between invertebrates and mammals, we examined the agnathon fish, lamprey. Amplification of reverse transcripts using degenerate oligonucleotides revealed the presence of two dystrophin-like sequences. Phylogenetic analysis suggests that one of these is a common orthologue of dystrophin and utrophin, while the other is more DRP2-like. This is consistent with the 2R hypothesis, whereby much of the chordate genome was duplicated in two events, one before and one after the divergence of lampreys.

This work will help to complete our picture of the DAC as a biological entity which has diversified with the growing complexity of the host organism, and will help to broaden our understanding of the etiology of muscular dystrophy.

**Temporal expression profiling in a progressive disease, Duchenne muscular dystrophy.** *Y.-W. Chen<sup>1</sup>, M. Bakay<sup>1</sup>, R. Borup<sup>1</sup>, S. Toppo<sup>2</sup>, G. Valle<sup>2</sup>, G. Lanfranchi<sup>2</sup>, E.P. Hoffman<sup>1</sup>.* 1) Center for Genetic Medicine, Children's National Medical Center, Washington, DC; 2) CRIBI Biotechnology Center, University of Padua, Padua, Italy.

Duchenne muscular dystrophy (DMD) is a progressive muscular disorder caused by mutations in the dystrophin gene. Although the primary biochemical defect is known, the downstream biochemical changes leading to later patient weakness and death are not understood. To identify differentially expressed genes involved in the progression of the disease, we report expression profiling of pre-symptomatic, early-stage and mid- to end-stage DMD muscles by using custom made Affymetrix MuscleChip containing approximately 1000 full-length genes and 2000 muscle ESTs. Among the total 4,654 probe sets on the MuscleChip, expression of 3688 (80%) genes was detected by the MuscleChip at least once out of 46 chips in this study. We found a large number of significant gene expression changes in fetal muscles (193 up- and 8 down-regulated genes) years before the onset of symptoms. By applying both correlation and K-means analysis, 48 genes were identified up-regulated during the progression of the DMD while down-regulated in the age-matched control individuals. One hundred and fifty seven genes were down-regulated during disease progression while up-regulated in control individuals. Among the down-regulated genes, 55% of the known genes were mitochondrial and metabolic genes. Genes involved in regulation of oxidative stress, protein metabolism were also identified. The major up-regulated genes are genes involved in fibrosis and extracellular matrix remodeling, muscle fiber structure, protein synthesis and degradation. Interestingly, expression levels of many genes that we previously reported misregulated by comparing pooled 5-9-year-old DMD vs. control (ex.  $\alpha$ -cardiac actin and chondroitin sulfate proteoglycan versican) showed correlation to the progression of the disease. By comparing the pre-symptomatic, early- and mid- to late-stage DMD profiles, we set the stage for progression-specific therapeutic targets for this common and lethal inherited disease.

**Deficiency of a-dystrobrevin and b2-syntrophin defines a new form of inherited myopathy.** *K.N. North<sup>1</sup>, K.J. Jones<sup>1</sup>, A. Compton<sup>1</sup>, M.M. Mills<sup>1</sup>, N. Yang<sup>1</sup>, D. Mowat<sup>2</sup>, M. Peters<sup>4</sup>, L.M. Kunkel<sup>3</sup>, S.C. Froehner<sup>4</sup>.* 1) Institute for Neuromuscular Research, Childrens Hospital at Westmead, Sydney, Australia; 2) Sydney Children's Hospital, Australia; 3) Children's Hospital, Boston, MA; 4) University of Washington, Seattle, WA.

The syntrophins and dystrobrevins are members of the dystrophin-associated-protein complex expressed at the sarcolemmal membrane and at the neuromuscular junction (NMJ). They are excellent candidate genes for human muscle disease based on their reduced expression in primary dystrophinopathy. In addition, both a1-syntrophin and a-dystrobrevin knockout mice demonstrate muscle pathology. We have characterized the expression of the syntrophins and a-dystrobrevin in normal human muscle and in biopsies from 162 patients with myopathies of unknown etiology. All patient biopsies had normal staining with antibodies to dystrophin, the sarcoglycans, sarcospan, caveolin, laminin-a2, a- and b1-syntrophin. Deficiency of a-dystrobrevin, in some cases accompanied by loss of b2-syntrophin, was found in 16/162 (10%) patients. All 16 patients presented with congenital-onset hypotonia and weakness. Two major clinical patterns emerged: patients with deficiency of b2-syntrophin and a-dystrobrevin presented in the newborn period with severe skeletal and respiratory muscle weakness and died in the first year of life. CK was normal. One infant from a consanguineous family had a sibling and first cousin with the same clinical picture and identical immunocytochemical profile, suggestive of AR inheritance. The remaining cases were sporadic. Two patients with deficiency of a-dystrobrevin alone had congenital muscular dystrophy and complete external ophthalmoplegia. One of these demonstrated clinical improvement on acetylcholinesterase inhibitors, suggesting that NMJ dysfunction was contributing to his clinical picture. We have sequenced a-dystrobrevin and b2-syntrophin but have not identified any mutations. This suggests that disease-causing mutations occur outside the coding region of these genes or in a gene encoding another component of the syntrophin-dystrobrevin subcomplex. We are currently screening other dystrobrevin binding proteins.

**Pathological and genetic analysis of the *degenerating muscle (dmu)* mouse: a new allele of *Scn8a*.** R. Kothary<sup>1,2,3</sup>, P.D. Côté<sup>1,2</sup>, M. Pool<sup>1,2,3</sup>, S. Girard<sup>3</sup>, S.M. Vidal<sup>3</sup>, Y. De Repentigny<sup>1,2</sup>. 1) Ottawa Health Research Institute, Ottawa, ON, Canada; 2) University of Ottawa Center for Neuromuscular Disease; 3) University of Ottawa, Ottawa, ON, Canada.

Mouse mutants suffering from muscle defects have served as valuable models in the identification of genes implicated in human neuromuscular disorders as well as in the elucidation of the pathogenesis of muscle disease. Here, we describe a novel spontaneous autosomal recessive mutation in the mouse that is characterized by skeletal and cardiac muscle degeneration. We have named this mutant *degenerating muscle (dmu)*. At birth, mutant mice are indistinguishable from their normal littermates. Thereafter, the disease progresses rapidly and a phenotype is first observed at approximately 11 days after birth; the *dmu* mice are weak and have great difficulty in moving. The principal cause of the lack of mobility is muscle atrophy and wasting in the hindquarters. Affected mice die at or around the time of weaning of unknown causes. Histopathological observations and ultrastructural analysis revealed muscle degeneration in both skeletal and cardiac muscle, but no abnormalities in sciatic nerves. Using linkage analysis, we have mapped the *dmu* locus to the distal portion of mouse chromosome 15 in a region syntenic to human chromosome 12q13. Interestingly, scapuloperoneal muscular dystrophy (SPMD) in humans has been linked to this region. SPMD patients with associated cardiomyopathy have also been described in the past. Initial analysis of candidate genes on mouse chromosome 15 reveal that although intact transcripts for *Scn8a* are present in *dmu* mice, their levels are dramatically reduced. Furthermore, genetic complementation experiments between *dmu* and *med* (mutation in *Scn8a*) mice reveal that they are allelic, although their phenotypes are not entirely identical. Our results suggest that at least a portion of the *dmu* phenotype is caused by a down-regulation of *Scn8a*, the gene encoding the sodium channel 8a subunit.

**Syncoilin Expression in Neuromuscular Disorders.** *E.V. Howman<sup>1</sup>, E. Poon<sup>1</sup>, S.E. Newey<sup>1</sup>, S. Torelli<sup>2</sup>, S. Brown<sup>2</sup>, D. Hilton-Jones<sup>3</sup>, W. Squier<sup>3</sup>, F. Muntoni<sup>2</sup>, K.E. Davies<sup>1</sup>.* 1) MRC Functional Genetics Unit, Department of Human Anatomy and Genetics, Oxford University, Oxford, United Kingdom; 2) The Dubowitz Neuromuscular Centre, Department of Paediatrics, ICSM, London, United Kingdom; 3) Department of Neurobiology, Radcliffe Infirmary, Oxford, United Kingdom.

We recently identified a new member of the dystrophin-associated protein complex, syncoilin, through its interaction with  $\alpha$ -dystrobrevin in skeletal muscle (Newey et al, 2001). Syncoilin is found at the sarcolemma and the neuromuscular junction, where it colocalizes with  $\alpha$ -dystrobrevin, and is also found at the Z-lines of skeletal muscle. Syncoilin is proposed to be a member of the intermediate filament superfamily based on sequence analysis. Based on the cellular localization, we hypothesize that syncoilin may form a link between the dystrophin-associated protein complex and the intermediate filament network found at the sarcomere. We have shown that syncoilin is upregulated in pathological conditions suggesting that it may have a role in maintaining the integrity of muscle fibres through the stabilization of the intermediate filament network. The critical role of intermediate filaments in muscle has been highlighted by the identification of mutations in the genes for several intermediate filaments in various myopathies associated with aberrant intermediate filament organisation. In this study we have assessed syncoilin expression in a range of neuromuscular disorders including Duchenne muscular dystrophy, Becker muscular dystrophy, congenital muscular dystrophy, spinal muscular atrophy and desmin-related myopathies. The aim was to a) develop an understanding of the role syncoilin plays in the stabilization of the muscle fibre and b) to screen patients with a myopathy of unknown causation because a dysfunction or absence of syncoilin may result in the disruption of the intermediate filament network leading to muscle necrosis. The results of these case studies will be presented. Newey et al. (2001). Syncoilin, a novel member of the intermediate filament superfamily that interacts with  $\alpha$ -dystrobrevin in skeletal muscle. *J. Biol. Chem.* 276, 6645-6655.

**A novel RYR1 mutation Q474H identified in a Japanese family with malignant hyperthermia and central core disease.** *K. Ogata*<sup>1,2</sup>, *J. Goto*<sup>1,2</sup>, *S-Y. Jeong*<sup>1,2</sup>, *Y. Takahashi*<sup>1,2</sup>, *J. Shimizu*<sup>1</sup>, *M. Yoshimura*<sup>1</sup>, *H. Kikuchi*<sup>3</sup>, *Y. Ichihara*<sup>3</sup>, *I. Malignant hyperthermia (MH) in humans is an autosomal dominant skeletal muscle disorder characterized by hypercatabolic reactions induced by anesthetic agents, with symptoms of sustained uncontrolled skeletal muscle calcium regulation resulting in life-threatening organ and systemic failure. Central core disease (CCD) is an autosomal dominant congenital myopathy characterized by hypotonia and muscle weakness with the 'central core' microscopical change in muscle fibers. Genetic investigations revealed that missense mutations in the ryanodine receptor 1 gene (*RYR1*) can cause both MH susceptibility (MHS) and/or CCD. MHS with RYR1 mutation is named MHS1. Here we report a novel missense mutation of RYR1 mutation in a Japanese family with MH and CCD.

Four affected members of this family showed mild muscle weakness and elevated serum creatine kinase levels. One member had an episode of MH while under general anesthesia. CT images demonstrated diffuse mild fatty changes in skeletal muscles of two affected members. Biopsied muscle from the proband of this family showed mild myopathic changes with type 1 predominancy and cores in muscle fibers. Functional tests with saponized muscle fibers demonstrated increase in calcium-induced calcium release rate. Direct sequencing and denaturing high-performance liquid chromatography analysis with the genomic PCR product from three affected and two unaffected members of this family revealed Q474H missense mutation in RYR1. All affected patients were heterozygous for the mutation. Sixty unrelated subjects, taken as controls did not demonstrate a similar mutation. This novel mutation is located in one of the main region for pathogenic mutation, the so-called foot region of RYR1. Our result is supportive of the hypothesis that this region is essential for the regulation of calcium release from sarcoplasmic reticulum through RYR1.

**Hereditary rippling muscle disease is caused by caveolin-3 mutations.** C. Kubisch<sup>1</sup>, R. Betz<sup>1</sup>, B. Schoser<sup>2</sup>, D. Kasper<sup>2</sup>, K. Ricker<sup>3</sup>, A. Rippling muscle disease (RMD; MIM 600332) is an autosomal dominant disorder characterized by mechanically-triggered, electrically silent contractions of the skeletal muscle. The genetic cause of this non-dystrophic muscle disease is unknown. By genome-wide linkage analysis we found evidence for linkage in three unrelated German RMD families on human chromosome 3p25. Testing of the positional candidate gene *caveolin-3* (*CAV3*) identified missense mutations in those three and additional two RMD-families including the original Norwegian RMD family first described in 1975. Some of these mutations have already been described in limb-girdle muscular dystrophy type 1C (LGMD1C) or idiopathic elevation of serum creatine kinase. All mutations lead to a reduced cav3 surface expression in muscle biopsies or stably transfected C2C12 myotubes, while the localization of a variety of calcium transport proteins of the skeletal muscle and sarcolemmal neuronal nitric oxide synthase (nNOS) was unaltered. Interestingly, NO-production in response to cytokine stimulation was 30-40% higher in cells transfected with mutant cav3 than in controls. In summary, the mislocalization of cav3 and the associated increased inducibility of nNOS may contribute to the mechanically induced muscle contractions in RMD. Moreover, the allelism between dystrophic LGMD1C and non-dystrophic RMD suggests that hereditary caveolinopathies may represent a valuable model to identify factors which determine whether a muscle disease shows a non-dystrophic or a dystrophic course.

The sarcomere is the unit of skeletal and cardiac muscle contraction. In the past few years, there has been major efforts in the attempt to elucidate the role of skeletal and cardiac muscle proteins. Mutations in several sarcomeric proteins such as actin, nebulin, alpha-tropomyosin 3, TPM-2 and Troponin T1 have been found to cause nemaline myopathy, while mutations in the genes for telethonin and myotilin, autosomal recessive LGMD-2G and autosomal dominant LGMD-1A, respectively. The number of known protein components of the sarcomere is rising, and new proteins, such as ZASP, FATZ (myozenin or Calsarcin), and Ankrd2, have recently been identified. We have been analyzing the status of proteins from the sarcomere in a large cohort of patients affected by the several forms of dystrophies and myopathies in the Brazilian population. To date, mutations in the nebulin gene have been identified in one family and a deficiency of the C-terminal domain of nebulin was observed in a second NM patient. Screening for myotilin deficiency in 20 candidate patients showed normal results, while deficiency of telethonin/T-cap was detected in 4 out of 153 LGMD families. Normal expression of the newly described ZASP, FATZ and Ankrd2 sarcomeric proteins was observed by immunohistochemical analyses, in studied 20 muscle biopsies from patients with clinical and histopathological characteristics of MD, previously excluded for the other known muscle protein deficiencies (dystrophin, the 4 sarcoglycans, calpain, dysferlin). The study of sarcomeric proteins is important for understanding the physiopathology of neuromuscular diseases and to establish genotype/phenotype correlation at the protein level. Financial support: CEPID-FAPESP, PRONEX, CNPq, ABDIM.

**Genotype-phenotype correlation in nemaline myopathy.** *M.M. Ryan<sup>1</sup>, C. Schnell<sup>2</sup>, C.D. Strickland<sup>1</sup>, L.K. Shield<sup>3</sup>, G. Morgan<sup>4</sup>, S.T. Iannaccone<sup>2</sup>, N.G. Laing<sup>5</sup>, K.N. North<sup>6</sup>, A.H. Beggs<sup>1</sup>.* 1) Neurology and Genetics, Children's Hospital, Boston, MA; 2) Neurology, Texas Scottish Rite Hospital, Dallas, TX; 3) Neurology, Royal Children's Hospital, Victoria, Australia; 4) Genetics, Sydney Children's Hospital, Sydney, Australia; 5) Australian Neuromuscular Research Inst., Nedlands, Australia; 6) Neurogenetics, Children's Hospital at Westmead, Sydney, Australia.

Nemaline myopathy (NM) is a clinically heterogenous disorder defined by the presence of rods or nemaline bodies in muscle fibres. Disease-causing mutations have been identified in 5 genes, all encoding components of the muscle thin filament. We have characterized the clinical, pathological and genetic features of 118 cases of NM. Inheritance was autosomal recessive in 26 patients from 16 kindreds and autosomal dominant in 27 patients from 22 kindreds. 65 cases were sporadic. There was marked intrafamilial phenotypic heterogeneity within both autosomal dominant and recessive kindreds. Disease severity was not predictive of mode of inheritance. 16/59 patients tested had mutations in the skeletal muscle  $\alpha$ -actin gene (*ACTA1*). Clinical presentation and course varied widely in these cases. One patient with severe neonatal weakness was a compound heterozygote for two *ACTA1* mutations. 12 patients were sporadic cases with new dominant mutations in *ACTA1*. Three of 35 patients tested had mutations in  $\alpha$ -tropomyosin<sub>SLOW</sub> (*TPM3*).

On light microscopy, rod number and localisation did not correlate with disease severity or mode of inheritance. Simultaneous biopsies of different muscles revealed variable disease expression. Serial biopsies showed progressive fibre size variation, fibrosis and an increase in the number of rods over time. Fibre hypertrophy was associated with a milder phenotype. Considerable pathologic heterogeneity was seen where multiple family members were biopsied. Tropomyosin NM was characterised by marked variation in fibre size and preferential rod formation in type 1 fibres. Glycogen accumulation was prominent in actin NM, and the degree of sarcomeric disruption on electron microscopy correlated with disease severity.

**Gene expression in nemaline myopathy skeletal muscle.** *D. Sanoudou<sup>1</sup>, J.N. Haslett<sup>1</sup>, S. Greenberg<sup>2</sup>, H.G.W. Lidov<sup>1</sup>, I.S. Kohane<sup>2</sup>, L.M. Kunkel<sup>1</sup>, A.H. Beggs<sup>1</sup>.* 1) Genetics Div., Childrens Hosp, Boston, MA; 2) Bioinformatics Program, Children's Hospital, Boston, MA.

The nemaline myopathies (NM) are a clinically and genetically heterogeneous group of disorders characterized by nemaline rods and primary skeletal muscle weakness that is usually congenital. They vary from rapidly fatal in the neonatal period to relatively nonprogressive and compatible with normal life span and activity. Five different NM genes (ACTA1, NEB, TPM2, TPM3, TNNT1) have been identified, however, the molecular consequences of these mutations are unknown. Using Affymetrix oligonucleotide microarrays we have analyzed the expression patterns of over 12,000 genes in the skeletal muscles of 12 NM patients. The datasets obtained were compared to a baseline of 10 normal skeletal muscle specimens and datasets from other congenital myopathies and dystrophies. Conventional fold-difference comparisons, as well as automated classification and clustering techniques were used to identify genes with significant differences in their expression patterns between NM and normal samples. Of the 100 genes with the strongest hybridization signals, 28 were ribosomal, and 23 were muscle specific. 41 ribosomal genes were significantly overexpressed compared to all normal muscle samples. This feature was unique for NM patients, and was not seen in DMD or other diseases we studied. This provides evidence to suggest that protein turnover may be increased, despite the non-degenerative appearance of NM muscle. A number of genes encoding sarcomeric proteins were also overexpressed (troponin T1, troponin C,  $\alpha$ -actin, filamin, nebulin and myomesin). All of these genes showed normal expression in the other muscle diseases studied. Overall, the gene expression patterns in NM patients exhibit a distinct clustering pattern, reflecting uniqueness in the molecular pathophysiology of this disorder. Some of the changes identified are expected to be disease- and/or gene-specific while others will reflect non-specific responses of myopathic muscle. Knowledge of these alterations will shed light on both the unique functions of NM genes as well as on more general aspects of skeletal muscle pathophysiology.

**Novel Dysferlin Mutations in Brazilian LGMD2B Patients.** *F. Paula<sup>1</sup>, M. Vainzof<sup>1</sup>, E.S. Moreira<sup>1</sup>, M.R. Passos-Bueno<sup>1</sup>, K. Bushby<sup>2</sup>, R. Bashir<sup>2</sup>, M. Zatz<sup>1</sup>.* 1) Ctr Study Human Genome, Univ de São Paulo, São Paulo, SP, Brazil; 2) Dept of Biochemistry and Genetics, Newcastle Upon Tyne, Newcastle Univ, UK.

The limb girdle muscular dystrophy 2B (LGMD2B) and Miyoshi myopathy (MM) are caused by allelic mutations in the dysferlin gene. Only few pathogenic changes have been reported to date. In order to establish a genotype-phenotype correlation we are analyzing the distribution of dysferlin mutations in patients from 18 LGMD2B and MM Brazilian families, classified by linkage analysis (10) or dysferlin deficiency (8).

Through SSCP, dHPLC and sequencing of abnormal fragments we identified to date 5 different mutations in 7 unrelated families: 2 missense changes in heterozygosity (the L189V in 2 families and D396H in one, exons 6 and 13 respectively), one stop codon in exon 28 (W999X) in 2 families (one homozygous and another in heterozygous state) and 2 frameshift mutations in the last 2 families: 3522-3523delTC (in one allele) and 3446-3453insCAGTGCTT (a duplication of 8pb in homozygosity state), both in exon 29. Dysferlin protein analyzed in muscle from all of these families showed absence of this protein. No hot spot for mutations was identified.

All these patients related weakness first in the distal muscles of the lower limbs and involvement in upper limbs on average 10 years later, but with a variable course even in patients belonging to the same family. All showed slow progression and on average, the phenotype in patients with nonsense mutations was not more severe than among those with missense mutations. In one of the families with the W999X mutation, the parents (deceased in their sixties) who were first degree cousins, were both affected. They had 10 children, also with a variable course. The intrafamilial variability, despite the high degree of consanguinity in this unusual family gives further support to the existence of modifying factors modulating the severity of the phenotype. Supported by FAPESP/CEPID, CNPq, PRONEX and IAEA.

**Expression profiling in facioscapulohumeral muscular dystrophy (FSHD) indicates a defect in myogenic differentiation.** *S. Winokur<sup>1</sup>, J. Martin<sup>1</sup>, Y-W. Chen<sup>2</sup>, J. Ehmsen<sup>1</sup>, K. Flanigan<sup>3</sup>.* 1) Dept Biological Chemistry, Univ California, Irvine, CA; 2) Children's National Medical Center, Washington, D.C; 3) Eccles Institute of Genetics, University of Utah, Salt Lake City, UT.

Facioscapulohumeral muscular dystrophy (FSHD) is an autosomal dominant neuromuscular disorder resulting from integral deletions of a 3.3 kb tandem repeat (D4Z4) in the subtelomeric region of chromosome 4q. Although the specific genes affected by this deletion have not been identified, a regional disruption of chromatin structure affecting local gene expression is thought underlie the pathophysiology. The global gene expression profiling of mature muscle tissue in FSHD presented here elucidates aberrant cellular processes previously concealed by this unusual molecular mechanism. FSHD expression profiles were compared to those generated from normal muscle and other types of muscular dystrophies (DMD, aSGD, JDM) in order to determine FSHD specific changes. In addition, matched biopsies (affected and unaffected muscle) from patients with FSHD served to monitor expression changes during the progression of the disease and to reduce non-specific changes resulting from individual variability. Among 15 genes upregulated in an FSHD specific and highly significant manner were several involved in cellular differentiation and proliferation. These include muscle LIM protein (MLP), delta homolog (DLK1) and the mitotic inhibitor huWEE1. As MLP and DLK were not increased further in the affected to unaffected FSHD muscle, these may represent a primary change in FSHD rather than an effect of progressing dystrophy. Increased MLP and DLK expression was confirmed by both real time RT-PCR and a second GeneChip format. The majority of FSHD-specific genes with reduced expression reflect a diminished capacity to buffer oxidative stress. These FSHD specific downregulated genes include SNAPC1 (HHCPA78 homolog) and nuclear factor of kappa light polypeptide gene alpha (NFKB1A). Enhanced vulnerability to oxidative stress is a characteristic previously demonstrated in cultured FSHD undifferentiated myoblasts. We propose a model linking aberrant myogenic differentiation and oxidative stress to subtelomeric shortening in FSHD.

**Developmental and overexpression studies of CASK in skeletal muscle.** *J.L. Siders<sup>1</sup>, T.A. Hainsey<sup>1</sup>, S. Murnaghan<sup>2</sup>, J.B. Wilson<sup>2</sup>, J.A. Rafael<sup>1</sup>.* 1) Department of Molecular and Cellular Biochemistry, College of Medicine, The Ohio State University, Columbus, OH; 2) I.B.L.S. Division of Molecular Genetics, University of Glasgow, 54 Dumbarton Rd., Glasgow, U.K.

The role of PDZ domain-containing proteins in skeletal muscle has yet to be clearly defined. We have previously shown that CASK and Dlg, two PDZ domain-containing proteins, are present in skeletal muscle and specifically at the post-synaptic membrane of the neuromuscular junction. CASK and Dlg belong to the membrane associated guanylate kinase family of proteins and are known to cluster channels and receptors at central nervous system synapses. These PDZ domain-containing proteins are therefore likely to play a significant role at the skeletal muscle neuromuscular junction and in neuromuscular diseases. We have conducted studies using the C2C12 mouse myogenic cell line to further characterize the role of these proteins in skeletal muscle. These studies demonstrate that CASK is expressed in a developmental specific manner. CASK localizes to the nucleus in cultured myoblasts, then is transported out to the cytoplasm as cells differentiate and fuse into multinucleated myofibers. As these fibers mature CASK protein expression greatly increases. Dlg shows only a slight increase in expression as myofibers mature. Interestingly, neither of these proteins cluster in response to agrin-induced acetylcholine receptor clustering suggesting a novel mechanism of localization of CASK and Dlg to the neuromuscular junction. This myogenic culture system will be used for transfection experiments to determine critical protein interaction domains of CASK. Transgenic mouse lines overexpressing full length CASK around the entire skeletal muscle membrane have been generated. Analysis of these mice and comparisons with mice overexpressing a PDZ domain truncated version of CASK will further elucidate the role of these proteins in vivo in skeletal muscle and in neuromuscular diseases.

**Two novel mutations in the glycine decarboxylase (P-protein) gene in patients with nonketotic hyperglycinemia (NKH).** *D.A. Applegarth*<sup>1,2,3</sup>, *J.R. Toone*<sup>1,3</sup>, *M.B. Coulter-Mackie*<sup>1,2</sup>. 1) Department of Pediatrics, University of British Columbia, Vancouver, British Columbia, Canada; 2) Department of Pathology and Laboratory Medicine, University of British Columbia, Vancouver, British Columbia, Canada; 3) Biochemical Diseases Laboratory, B.C.'s Children's Hospital, 4480 Oak Street, Vancouver, British Columbia, V6H 3V4, Canada.

A defect in the P-protein gene causes NKH in more than 80% of patients. The molecular study of this gene has been hampered by the presence of a processed full-length pseudo-gene and few mutations have been identified. Two recurring mutations have been reported: S564I in Finnish patients and R515S (now found in 8 unrelated cases).

We have characterised the region of exons 6 and 7 and intervening sequence (GenBank AF288639) which represents >10% of the coding region of the P-protein gene and contains sequences of the gene conserved from human to *E.coli*. Using 1 PCR product and 1 sequencing primer, we have tested 10 patients shown to have a P- or H-protein defect by liver glycine exchange assay. Three had already been identified as heterozygous for R515S.

We found 3 positive alleles: one patient was homozygous for P329T, a conserved amino acid in a conserved region of the gene in exon 7; a second patient was heterozygous for A283P in exon 6. A283P is not completely conserved but a PCR/SacI restriction digest assay showed that it was absent in 100 normal alleles. The introduction of a proline residue is expected to disrupt secondary protein structure.

Many NKH patients investigated in Japan (Kure et al (1999) *Am J Hum Gen* 65 (4), abstract 2406) have been shown to have rare or private mutations. Identifying regions of clusters of mutations will aid in a customised approach for sequencing DNA of patients who do not have a recurrent mutation.

This work was supported by a grant from the Garrod Association of Canada.

**Detection of Mutations in the Dystrophin Gene Via Automated DHPLC Screening and Direct Sequencing.** *R.R.*

Kunkel*<sup>1,3,4</sup>. 1) Division of Genetics, Children's Hospital, Boston, MA; 2) Department of Human and Clinical Genetics, Leiden University Medical Center, Leiden, Netherlands; 3) Department of Genetics, Harvard Medical School, Boston, MA; 4) Howard Hughes Medical Institute, Children's Hospital, Harvard Medical School, Boston, Massachusetts, USA.

Duchenne Muscular Dystrophy (DMD) is a genetic disorder which manifests itself in one of every 1600 to 2000 live births. One in 3200 to 4000 will be severely disabled boys and one in 3200 to 4000 will be carrier females with reproductive complications and potential late-onset cardiac complications. Approximately 65% of mutations causing this disease are large deletions or duplications, most of which are found by the existing set of multiplex PCR primers. The other 35% have remained undetected in most patients. The purpose of this project was to develop an efficient and inexpensive process for detecting mutations large and small. We have obtained sequence upstream and downstream of each exon as well as the 5' and 3' UTRs from the NIH human genome database and have designed primers to include 30 to 100 bases on either side of each exon. These primers were designed to produce a single clean band on agarose gel, to create DNA fragments with melting characteristics appropriate for DHPLC analysis using the WAVE from Transgenomic Inc. for DNA variation screening, and finally to sequence well on automated DNA sequencers. We have tested eight patients --selected from medical records as clearly having DMD but no large mutation-- using these new primers in conjunction with the WAVE and PE-ABI 373 sequencer. We have detected six disease-causing mutations. The remaining two patients have been completely sequenced. Several polymorphisms have been detected in each, most of which are known to be non disease-causing. Further investigation is required to determine the cause of DMD in these two patients.

**Identification of non-pathogenic mutations by a new statistical approach. Analysis of CFTR gene mutations in a random population.** *F. Belpinati*<sup>1</sup>, *S. It may be difficult to determine the role of not obviously pathogenic mutations in causing disease, in particular when a high number of mutations is known. We have proposed a straightforward method to classify non pathogenic mutations. Given  $q$  as the global frequency of all the alleles causing a disease, any allele with a frequency certainly higher than  $q$  minus the cumulative frequency of the already known disease causing mutations cannot be the cause of that disease. This principle was applied to the analysis of CFTR gene mutations as cause of CF. In the first part of the work, the CFTR gene (coding and proximal non coding region) of 191 DNA samples from random individuals from Italy, France and Spain was investigated. A total of 46 mutations was detected: 3 were known to be CF-causing and 13 were classified as non CF-causing alleles (Hum Genet 2000;106:172). We here present the second part of the work. The analysis of the 30 mutations not yet classified was extended by DGGE and restriction testing to other 1265 individuals (2530 genes) from Italy, France, and the Czech Republic. This is sufficient to classify mutations with a frequency of at least 0.01. A total of 41 mutations, 11 of which were found during the second step, was detected: 8 mutations (R75Q, 1716G/A, G576A, R668C, 3041-71G/C, 4404C/T, 3030G/A, 1001+11C/T) were classified as non CF-causing, 2 were not described mutations (A1009T, 3813A/G), 3 mutations were known to be CF-causing. In conclusion, on a total of 57 mutations identified in the two steps of the work: 21 mutations (37%) were classified as non CF-causing on the basis of their frequency, 6 were known to be CF-causing and 6 new mutations were first described.

**MEFV and TNFRSF1A gene mutations in patients suffering from AA amyloidosis.** *C. Dode<sup>1</sup>, C. Pecheux<sup>1</sup>, D. Cattan<sup>2</sup>, B. Hazenberg<sup>3</sup>, B. Moulin<sup>4</sup>, A. Barthelemy<sup>5</sup>, M-C. Gubler<sup>6</sup>, M. Delpech<sup>1</sup>, G. Grateau<sup>7</sup>.* 1) EMI 00-05, INSERM, Paris, France; 2) Service d'hépatogastroentérologie, Centre hospitalier, Villeneuve-St Georges, France; 3) Rheumatology Department, Academic Medical Hospital, Groningen, The Netherlands; 4) Service de néphrologie et d'hémodialyse, Hôpital civil Strasbourg, France; 5) Service de néphropédiatrie, Hôpital Necker, Paris, France; 6) INSERM Unité 423, Hôpital Necker Paris, France; 7) Service de médecine interne, Hôtel-Dieu, Paris, France.

Mutation analysis in MEFV and TNFRSF1A genes was carried out in 40 patients suffering from AA amyloidosis associated with recurrent inflammatory attacks. MEFV mutations were only found in patients belonging to FMF at risk ethnic origins (34 patients) such as Sephardic Jews, Turks, Armenians, Arabs from the Maghreb. 22/34 patients displayed an homozygous MEFV mutation (19 M694V/M694V, 2 M694I/M694I, 1 M680I/M680I). 2/34 patients had a single mutations (M694V/M694V) and 10/34 had no mutation. Among patients with a single one or without mutation, we searched for mutations in TNFRSF1A gene. Five novel mutations were found: C55S, C70Y, R92Q, C96Y in Caucasian patients and the Y20H mutation was found in a Sephardic patient. In this series, FMF was the main cause of AA amyloidosis in Sephardic Jewish and Turkish populations. In the Maghrebian patients, AA amyloidosis was due to MEFV mutations in only 5/14 cases suggesting another cause for renal AA amyloidosis. In two cases, this cause seemed to be due to an autosomal recessive disease of unknown origin. Our results showed that TRAPS is not always found in Caucasian populations but also in patients belonging to at-risk FMF ethnies such as Sephardic Jews. The molecular diagnosis is very important because the therapeutic behaviors are different for these two diseases.

**An APC allele harbouring both Y159X and E1317Q in a large family with attenuated familial adenomatous polyposis.** *N. Al-Tassan<sup>1</sup>, J. Maynard<sup>1</sup>, N. Fleming<sup>1</sup>, D.R. Davies<sup>2</sup>, J.R. Sampson<sup>1</sup>, J.P. Cheadle<sup>1</sup>.* 1) Institute of Medical Genetics, University of Wales College of Medicine, Cardiff, UK; 2) Dept. of Medicine, University Hospital of Wales, Cardiff, UK.

It has been proposed that seemingly benign missense variants in the APC gene show association with colorectal adenoma and carcinoma. The variant, E1317Q, has been found to be over represented in the constitutional DNA of patients with multiple colorectal adenomas and carcinoma and has been identified as a somatic change in sporadic colorectal cancer. We have investigated a large family (17 members with multiple adenomas and / or carcinoma) with an attenuated FAP (AFAP) phenotype. Sequence analysis of the APC coding region identified the missense variant E1317Q in all affected family members, but also the earlier exon 4 nonsense mutation Y159X. This early truncating mutation has been previously reported in another AFAP family. We suggest that the Y159X mutation is likely to be the cause of colorectal adenoma and carcinoma predisposition in the present family, although a contributory affect of the E1317Q allele through low level alternate splicing cannot be formally excluded at present.

**Identification of a putative mosaic *MECP2* mutation in an atypical Rett syndrome patient by denaturing high performance liquid chromatography.** *K.R. Bowles<sup>1</sup>, I.M. Buysse<sup>1</sup>, K.T. Hoon<sup>1</sup>, M.T. Bashford<sup>1</sup>, P. Arn<sup>2</sup>, B.B. Roa<sup>1</sup>.* 1) Baylor DNA Diagnostic Laboratory, Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Division of Genetics, Nemours Children's Clinic, Jacksonville, FL.

Rett syndrome is an X-linked dominant neurodevelopmental disorder wherein affected females appear normal at birth, followed by deterioration of higher brain function, loss of motor and language skills, acquired microcephaly, ataxia, seizures, and autistic behavior beginning at 6-18 months of age. The Rett syndrome gene *MECP2* encodes methyl-CpG-binding protein 2. Clinical diagnostic testing for *MECP2* mutations is performed in our laboratory using denaturing high performance liquid chromatography (DHPLC) and automated DNA sequence analysis. We studied an atypical Rett syndrome patient who presented at 2 years of age, but retained purposeful hand movements, is not microcephalic, and has a normal MRI. Analysis of patient DNA by DHPLC showed a consistently abnormal chromatogram indicative of a sequence variant; however, DNA sequencing of the corresponding PCR product indicated a wild-type sequence. The specific PCR product was subsequently fraction-collected off the DHPLC column, and individual fractions were used as templates for PCR and sequence analysis. Sequencing of fractions that coincided with the variant DHPLC peak identified a single base change, 1093 G-T, predicting a nonsense mutation, E365X. The low-level mutation in this patient was further confirmed by Pyrosequencing, an automated primer extension-based assay, which estimated an allele ratio of 82:18 (normal:mutant). Similar results were obtained with DNA samples from patient peripheral blood lymphocytes, buccal cells, and cultured fibroblasts. Analysis of maternal DNA did not identify the E365X nonsense mutation, suggesting a *de novo* *MECP2* mutation in the patient. In conclusion, a putative mosaic *MECP2* nonsense mutation was identified by three different methods in a patient with atypical Rett syndrome. Under optimized conditions, DHPLC analysis may provide greater sensitivity than DNA sequence analysis for the detection of certain low-abundance mutations.

**Gene mutations in the succinate dehydrogenase subunit SDHB cause susceptibility to familial pheochromocytoma and to familial paraganglioma.** *D. Astuti<sup>1</sup>, F. Latif<sup>1</sup>, N. Morgan<sup>1</sup>, T. Martinsson<sup>2</sup>, A. Dallol<sup>1</sup>, P. Dahia<sup>3</sup>, F. Douglas<sup>4</sup>, E. George<sup>5</sup>, F. Sköldbberg<sup>6</sup>, E. Husebye<sup>6</sup>, C. Eng<sup>7</sup>, E.R. Maher<sup>1</sup>.* 1) Section of Medical and Molecular Genetics, University of Birmingham, Birmingham B15 2TT, UK; 2) Department of Clinical Genetics, Gothenburg University, Gothenburg, Sweden; 3) Department of Cancer Biology, Dana-Farber Cancer Institute, Boston, MA 02115, USA; 4) Northern Regional Genetics Service, Royal Victoria Infirmary, Newcastle upon Tyne NE2, UK; 5) Department of Medicine, Kings Lynn Hospital, Norfolk, UK; 6) Dept. of Medical Sciences, Uppsala University, Sweden; 7) Clinical Cancer Genetics and Human Cancer Genetics Programs, Comprehensive Cancer Center, and the Division of Human Genetics, The Ohio State University, Columbus, OH 43210, USA.

Pheochromocytoma susceptibility may be associated with germline mutations in the VHL and NF1 tumour suppressor genes and the RET proto-oncogene. However, the genetic basis for most cases of nonsyndromic familial pheochromocytoma is unknown. Recently pheochromocytoma susceptibility was associated with germline SDHD gene mutations which were originally described in hereditary paraganglioma. The SDHD and SDHC gene products anchor the two other components of the mitochondrial complex II (SDHA and SDHB), which form the catalytic core, to the mitochondrial inner membrane. Although mutations in SDHD and SDHC may cause hereditary paraganglioma, germline mutations in SDHA are associated with juvenile encephalopathy and the phenotype of SDHB mutations had not been defined. To investigate the genetic causes of pheochromocytoma we analysed the SDHB and SDHC genes in familial and sporadic cases. Inactivating SDHB mutations were detected in 2/5 kindreds with familial pheochromocytoma, 2/3 kindreds with pheochromocytoma and paraganglioma susceptibility and 1/24 cases of sporadic pheochromocytoma. These findings suggest that germline SDHB mutations are an important cause of pheochromocytoma susceptibility. As SDHB maps to 1p36, a region deleted in many tumor types we have proceeded to analyse sporadic neuroblastomas, lung tumours and renal carcinomas for somatic SDHB mutations.

**MAPH detection of deletions/duplications in Duchenne/Becker Muscular Dystrophy: an alternative to quantitative Southern blotting.** *M.H. Breuning, S. White, M. Kalf, M. Villerius, E. Bakker, G.-J.B. van Ommen, J.T. den Dunnen.* Center for Human and Clinical Genetics, LUMC, Leiden, Netherlands.

Currently most genetic diagnostic protocols are PCR-based and do not readily yield quantitative data. As a consequence, potential deletions and duplications of the regions analyzed go undetected unless specific methods are applied. Southern blotting is most commonly used, but is time consuming and laborious. Recently an alternative method was published, called Multiplex Amplifiable Probe Hybridization (MAPH). In this technique a series of short DNA fragments are cloned in such a way that all can be PCR-amplified using one pair of primers. The probes are hybridized to genomic DNA immobilized on nylon filters, and after stringent washing the probes are recovered off the filters and PCR-amplified in a quantitative manner. We have applied this technique to the diagnosis of Duchenne/Becker Muscular Dystrophy (DMD/BMD), diseases caused by mutations in the dystrophin gene. This gene is the largest known, covering 2.4 Mb, containing 79 exons. In approximately 65 % of cases the mutation is a deletion or duplication of one or more exons. Frame-shift mutations cause the lethal DMD, whereas maintenance of the reading frame leads to the less severe BMD. For this reason it is important to assess the boundaries of rearrangements, a potentially arduous task. A technique allowing simultaneous analysis of all exons would greatly simplify this procedure. We cloned all 79 exons into the same vector and divided the PCR products into 2 pools. Following hybridization the secondary PCR was performed using a fluorescently labeled primer, allowing the products to be analyzed on a 96 capillary sequencer. This allows parallel analysis of 96 samples in ~48 hours. The number of copies of each exon could be determined by comparing the appropriate peaks between controls and patients. Using this technique we were able to detect exon deletions and duplications missed using current methods. Further probe sets are being developed to cover other areas of interest such as breast cancer and deletion syndromes. The possibility of analyzing many more regions simultaneously using microarrays is being investigated.

**ND gene: Mutations found in two Portuguese families.** *H.F.R. Caria<sup>1</sup>, M. Vitorino<sup>1</sup>, A. Mena<sup>1</sup>, I. Galhardo<sup>2</sup>, M. Simao<sup>2</sup>, O. Dias<sup>2</sup>, M. Andrea<sup>2</sup>, C. Correia<sup>1</sup>, G. Fialho<sup>1</sup>.* 1) Center of Genetics and Molecular Biology, University of Lisbon, Portugal; 2) Center of CORL, University of Lisbon, Portugal.

Norrie disease (ND, McKusick n 31060) is a rare and a severe X-linked form of congenital blindness accompanied by mental retardation and deafness in at least one third of the patients. The blindness is bilateral and caused by a vascularized mass behind each lens due to a maldeveloped retina (pseudoglioma). The ND gene spans 28 kb of genomic DNA comprised in three exons where the coding portion includes the half part of the exon 2 and the first part of exon 3. The ND gene encodes a 133 aminoacids protein, which function is not well known, although homologies with known proteins and molecular modelling data suggest a role in the regulation of cell interaction or differentiation processes. In the present work two unrelated portuguese families with Norrie disease were analysed. In one family the screening of the entire coding region allowed the identification of a IVS2-1G>C mutation in all the affected males. For the same region, the other family exhibits a single base pair transversion (G>C) at nt828, apparently not related to the disease. The mutations were detected by sequencing analysis and confirmed by restriction analysis. DNA analysis was also used to determine the carrier status of females.

**Mutations in the COL4A4 and COL4A3 Genes Cause Familial Benign Hematuria.** *C. Badenas<sup>1</sup>, B. Tazon<sup>1</sup>, L. Heidet<sup>3</sup>, C. Arrondel<sup>3</sup>, M. Mila<sup>1</sup>, C. Antignac<sup>3</sup>, A. Darnell<sup>2</sup>, R. Torra<sup>2</sup>.* 1) Genetics, Hospital Clinic, Barcelona, Barcelona, Spain; 2) Nefrologia, Hospital Clinic, Barcelona, Barcelona, Spain; 3) Nephrology Department. INSERM U423, Universit Ren Descartes, Hpital Necker-Enfants Malades, Paris, France.

Familial benign hematuria is a common autosomal dominant disorder characterised by the presence of persistent or recurrent hematuria. The clinical and pathological features of this syndrome resemble those of early Alport syndrome and for this reason a common molecular defect has been proposed. The COL4A3/4 genes seem to be involved in both autosomal Alport syndrome and familial benign hematuria. We have performed linkage analysis for the COL4A3/4 loci and searched for mutations within these genes in 11 biopsy proven FBH families. The linkage studies demonstrated that six out of 11 families were linked to the COL4A3/4 locus, and one was not linked. However this family included three affected women who could be carriers of an X-linked Alport syndrome. Four families were too small to perform linkage analysis, but in two of them linkage to the COL4A3/4 was possible. The mutational studies disclosed two new mutations in the COL4A3 gene (G985V, G1015E) and four new mutations in the COL4A4 gene (3222insA, IVS23-1G>C, 31del11, G960R) It is the first time that mutations within the COL4A3 gene are described in families with FBH. The present study clearly demonstrates the involvement of the COL4A4 and COL4A3 genes in the pathogenesis of FBH.

**High frequency of autosomal recessive forms of Chronic Granulomatous Disease in Tunisian patients.** R. EL Kares, M.R. Barbouche, S. Abdelhak, K. Dellagi. Laboratoire d'Immunologie, Institut Pasteur de Tunis, Tunisia.

Chronic granulomatous disease (CGD) is a group of inherited disorders of host immune system caused by genetic defects in any of the four components of phagocyte NADPH oxidase, namely gp91-, p22-, p47-, and p67-phox. This deficiency leads to a profound impairment of microbicidal functions of the phagocytic system. The most common form as far reported is X-linked and is due to defects in the *CYBB* gene that encodes for gp91-phox. The remaining cases are inherited in an autosomal recessive mode, through mutations in the genes for p22- (*CYBA*), p47- (*NCF-1*) or p67-phox (*NCF-2*). Mutations in the gp91-, p22- and p67-phox are highly heterogeneous. In contrast a single defect corresponding to a GT deletion (DGT) in exon 2 of *NCF-1* gene accounts for the vast majority of p47-phox deficiency cases. In the present study a total of 13 CGD patients (7 males and 6 females) have been investigated. The diagnosis of CGD was confirmed on the basis of the absence of nitroblue tetrazolium (NBT) reduction by the patient neutrophils. Most of these patients (75%) are born to consanguineous parents. In this context of high consanguinity the strategy used to identify genes involved is homozygosity mapping using microsatellites markers within the region of *CYBA*, *NCF-1* and *NCF-2* genes mapped respectively to 16q24, 7q11.23 and 1q25. Linkage to chromosome 16, 7 and 1 has been found for 4, 5 and 1 patients respectively. Three patients show no homozygosity with any of the autosomal loci. Since these patients are males, X-linked gene mutation could not be ruled out. The study of mutations within the corresponding genes were investigated by RT-PCR amplification and direct sequencing. Along with recurrent mutations that have been identified in other studies such as the recurrent (DGT) deletion, we report a novel mutation in the *CYBA* gene corresponding to a deletion of 7 base-pairs in exon 5 designated as 295 del 7. Our results show the higher frequency of linkage to autosomal recessive genes in Tunisian patients affected with CGD compared to data from USA, Europe and Japan. This is probably the consequence of the higher rate of consanguinity in our population.

**GSD type II: Description of four novel mutations causing acid  $\alpha$ -glucosidase deficiency.** *D. Bali, A.J. McVie-Wylie, M. Lowery, E. Faulkner, D. Lamson, Y.T. Chen.* Div. of Medical Genetics, DUMC, Durham, NC, 27710.

Glycogen storage disease type II (GSD II, Pompe disease) is a lysosomal storage disease resulting from deficiency of the enzyme acid  $\alpha$ -glucosidase (GAA). Clinically, Pompe disease encompasses a range of phenotypes from a severe, fatal infantile form characterized by cardiomyopathy and skeletal muscle weakness to a slowly progressive adult presentation limited to skeletal muscle. Over 50 mutations causing GSD-II have been described; here we reported four novel mutations in two Caucasian patients with the severe infantile presentation of the disease and less than 1% normal GAA activity. Patient one is a compound heterozygote with a maternally inherited 2bp frameshift deletion in exon 4 (721-722 delTT) and a paternally inherited nonsense mutation (C1687T, Gln563Ter) introducing a stop codon in exon 12. Western blot analysis indicates that this patient does not make detectable protein and cDNA analysis was impossible due to a lack of amplifiable material. Therefore, it is probable that both of these mutations result in unstable mRNA production and consequently no protein production. Patient two is also a compound heterozygote with a paternally inherited mutation in the intron 9 splice acceptor site resulting in the deletion of exon 10 (IVS9(-1G>C)). Since part of the catalytic site of GAA is present within exon 10, we assume that exon 10 skipping would result in a non-functional protein. The maternally inherited mutation in this patient results in a missense change in the protein within exon 12 (T1655C, Leu552Pro). We believe that this alteration will affect the activity of the protein and this hypothesis is being tested by in vitro mutation analysis. Interestingly, only the precursor, not the mature form of the enzyme can be detected by Western blot analysis in this case, confirming our suspicion that a splicing mutation and a missense mutation are the probable cause of enzyme deficiency. In addition, we have not detected either of these changes in a population of 100 normal alleles ruling out the possibility of polymorphism. Our results further confirm the extensive genetic heterogeneity in the Caucasian patients affected with the infantile Pompe disease.

**Enhancing the sensitivity of mutation detection in tuberous sclerosis TSC1 and TSC2 genes by DHPLC, Primer Extension and Quantitative PCR analysis.** A. Allavena<sup>2</sup>, S. Padovan<sup>1,2</sup>, L. Longa<sup>2</sup>, A. Brusco<sup>2</sup>, C. Michielotto<sup>2</sup>, C. Cagnoli<sup>2</sup>, B. Ferrando<sup>2</sup>, M. Barberis<sup>2</sup>, N. Migone<sup>1,2</sup>. 1) CNR-CIOS, Torino; 2) Dept. of Genetics, Biology and Biochemistry, Torino University, Italy.

In a diagnostic setting, it is commonly observed that 20-30% of TSC patients does not reveal any mutation in either TSC gene following a single-step mutation screening. Low-level mosaicism, gene deletion, and cryptic mutation causing aberrant splicing or mono-allelic expression could partly account for these findings. In order to assess the relative contribution of the latter phenomena, we tested by DHPLC 199 TSC probands (75% sporadic, 25% familial): 156 probands (78%) showed pathogenic TSC mutations and 43 were mut-negative. Our multi-step strategy on DHPLC-neg cases is based on: a) Southern blot analysis, b) comparison of DHPLC and primer extension (PE) profiles at polymorphic sites with "reference heterozygotes" showing a 1:1 allelic ratio, c) quantitative fluorescent PCR to reveal mosaic or non-mosaic full gene deletions, wherever DHPLC and PE are inapplicable due to lack of heterozygosity and, d) PE adjacent to heterozygous sites on cDNA vs. DNA templates to detect unbalanced allelic expression. Our preliminary results are summarized as follows: Southern blot analysis allowed us to identify 20 partial/full gene deletions virtually undetectable by DHPLC. Two large TSC2 gene deletions were revealed by quantitative PCR only. PE on cDNA vs. DNA templates appeared precious in detecting two cases of unbalanced allelic expression. Overall, using this strategy, large rearrangements or cryptic mutations could be assigned in 24 of 43 apparently DHPLC-neg probands, enhancing the sensitivity of mutation detection (90%). So far only 1/2 of our mut-neg patients have been fully investigated by PE, PTT or quantitative PCR; it is likely that additional mutations will be identified in this subset, suggesting that the involvement of novel TSC loci should be confined to a minority of TSC probands. Work supported by Telethon, Italy (project E.730 ) and by "Assoc. E. & E. Rulfo per la Genetica Medica". M. Barberis is recipient of a fellowship from "Assoc. Italiana Sclerosi Tuberosa".

**Point mutations in the dystrophin gene: a super hot spot of mutation at a CpG dinucleotide and a difference in the pattern of microdeletions.** *C.H. Buzin<sup>1</sup>, J. Yan<sup>1</sup>, J. Feng<sup>1</sup>, J.R. Mendell<sup>2</sup>, S.S. Sommer<sup>1</sup>*. 1) Molecular Genetics, City of Hope Medical Center, Duarte, CA; 2) Ohio State University Medical Center, Columbus, OH.

About 35% of patients with Duchenne muscular dystrophy have point mutations in the dystrophin gene, one of the largest known genes that spans nearly 2.4 Mb of genomic DNA, contains 79 exons, and encodes a 14 kb transcript. Comprehensive mutation scanning was performed with DOVAM-S, a partially automated method that detects virtually all mutations. In this study, genomic DNA from 141 patients with DMD, ascertained both clinically and by muscle biopsy, was scanned in all coding exons, associated intronic splice regions, and promoter sequences. Although prior screening had excluded most patients with large deletion and duplication mutations, eight of the patients were found to have a large deletion. Of the remaining 133 patients, 98 (74%) had truncating point mutations, including nonsense, small deletions or insertions, and splice mutations. Of the 98 causative point mutations, 94 were independent as determined by haplotype analysis. No causative missense mutations were found, although many missense polymorphisms were discovered, all of which were seen also as second site changes in patients in which a truncating mutation was found. For frameshift and nonsense mutations (86 independent mutations), a mutation target could be determined within the coding region. One super hot spot mutation, a transition at CpG in exon 59 (arg2905ter), was detected in six patients, all with different haplotypes. When the point mutation types are normalized for their target, the relative rates of microdeletions/insertions, transitions and transversions at and not at CpG were similar to the factor IX gene. However, the size distribution of microdeletions was significantly different in DMD and factor IX.

**A Missense Mutation at Codon 846 in CRB-1 Gene Causes RP12 in a Pakistani Family.** *M. Ismail, A. Abid, A. Hameed, K. Anwar, S.Q. Mehdi, S. Khaliq.* Dr. A. Q. Khan Research Laboratories, Biomedical & Genetic Engineering Division, 24 Mauve Area, G-9/1, Islamabad, Pakistan.

Retinitis pigmentosa is clinically and genetically a group of inherited ocular diseases that involve progressive degeneration of photoreceptors resulting in the release of pigment by degenerating cells in the retinal pigment epithelium (RPE). It manifests initially as night blindness, followed by progressive loss of vision. RP12 is a severe and rare form of autosomal recessive RP characterised by a typical preservation of the para-arteriolar retinal pigment epithelium (PPRPE). Dysfunction of CRB-1 (human homolog of *Drosophila* cell-polarity gene 'crumbs') has been characterized as the cause for RP12. Several mutations have been reported in CRB-1 in a panel of unrelated RP12 patients including a homozygous AluY insertion. It has been suggested that it is an extracellular protein and probably plays a central role in localising the phototransduction complex to the apical membrane. A large Pakistani family was ascertained, showing typical autosomal recessive PPRPE phenotype. Linkage analysis of this family mapped the disease locus on chromosome 1q31-q32.1. Screening of the CRB-1 gene showed a homozygous G-A transition in exon 7 at nucleotide 2536 in all patients. Since the mode of inheritance was autosomal recessive, none of the parents (carrier) was homozygous for the mutation. The G-A transition results in the substitution of arginine for glycine at codon 846. This change has not been reported previously and could be the probable cause of RP in this family.

**The role of hPMS1 and hPMS2 in predisposing to colorectal cancer.** *T. LIU<sup>1</sup>, S. Kuismanen<sup>2</sup>, A. Percesepe<sup>3</sup>, ML. Bisgaard<sup>4</sup>, M. Pedroni<sup>3</sup>, P. Benatti<sup>3</sup>, M. Ponz de Leon<sup>3</sup>, P. Peltomki<sup>5</sup>, A. Lindblom<sup>1</sup>.* 1) Department of Molecular Medicine, Karolinska Institute, S171 76 Stockholm, Sweden; 2) Department of Medical Genetics, Haartman Institute, University of Helsinki, 00290 Haartmaninkatu, Helsinki; 3) Deptment of Internal Medicine, University of Modena, Viua del Pozzo, 71, 41100 Modena, Italy; 4) .Danish polyposis Register, Hvidover University Hospital, DK2100 Copenhagen, Denmark; 5) Human Cancer Genetics, Comprehensive Cancer Center, Ohio State University, 43210 Columbus Ohio, U.S.A.

Hereditary nonpolyposis colorectal cancer (HNPCC) is due to deficiency of mismatch repair. Inactivation of DNA mismatch repair underlies the genesis of microsatellite instability (MSI) in colorectal cancer. Germline mutations in three DNA mismatch repair genes, hMSH2, hMLH1, and hMSH6, have been found to segregate in HNPCC and HNPCClike families. The two DNA mismatch repair genes hPMS1 and hPMS2 have also been suggested to predispose to HNPCC. In this study 84 HNPCC and HNPCClike kindreds without a mutation in the other three known DNA mismatch repair genes, were screened for germline mutations in the hPMS1 or hPMS2 gene. No clear-cut pathogenic mutation was identified. Since the hPMS1 and hPMS2 genes were first reported in two HNPCC patients, germline mutations in hPMS2 have been demonstrated primarily in patients with Turcots syndrome. However, no mutation in any of the two genes has so far been found to segregate in HNPCC families. Until there is better evidence for an increased colorectal cancer risk associated to germline mutations in these genes, a conservative interpretation of the role of mutations in these genes is advised.

**FISH analysis and mutation screening of the Enhancer Of Zeste homolog 2 (EZH2) gene : a candidate gene for Coffin-Siris syndrome.** *A. Lossi<sup>1</sup>, M. Rahmoun<sup>1</sup>, D. Depetris<sup>1</sup>, M.G. Mattéi<sup>1</sup>, J. Bodurtha<sup>2</sup>, E. Lammer<sup>3</sup>, L. Villard<sup>1</sup>.* 1) Inserm U491. Faculté de Médecine La Timone. 27, Bd. Jean Moulin. 13385 Marseille Cedex 5. France; 2) Virginia Commonwealth University, Richmond VA 23298; 3) Genetics Center, Oakland Childrens Hospital, Oakland CA 94709.

Coffin-Siris syndrome (MIM #135900) is characterized by mental retardation, nail and phalanx abnormalities, and distinctive facial features. Most cases are sporadic, although a few familial cases have been described. The transmission mode is still debated. Two chromosomal rearrangements were described in patients with Coffin-Siris syndrome, both involving the 7q32-q34 region. These findings are compatible with a gene responsible for CSS located on chromosome 7. A specific interaction was reported between the XNP/ATR-X gene, responsible for ATR-X syndrome (MIM #301040) and the protein encoded by the enhancer of zeste homolog 2 gene (EZH2). EZH2 is located in 7q34. Given the presence of mental retardation and somewhat similar facial dysmorphism in both CSS and ATR-X patients, we questioned whether EZH2 could be involved in the etiology of CSS. In a first step, we used a genomic clone containing the EZH2 gene (clone RP5-1151\_m\_5) in FISH experiments to detect a potential chromosomal anomaly at this locus. Seven patients with a classical form of CSS were selected for this analysis. No deletion or other rearrangement were detected using the patients lymphoblasts for FISH experiments. We next screened the EZH2 gene for mutations in the seven patients. No disease-causing mutations were identified although a common polymorphism was detected. Taken together, these data probably rule out EZH2 as being the gene involved in Coffin-Siris syndrome.

**Hemochromatosis: Use of pyrosequencing for rapid detection of the most frequent mutations.** *P. Hilbert, A. Tricot, L. Van Maldergem, Y. Gillerot.* Inst.de Pathologie et de Genetique, Loverval, Belgium.

Hemochromatosis is a common autosomal recessive disorder of the iron metabolism. Different mutations of the HFE gene and recently of the TFR2 gene have been described associated with the disease. More than 80 % of the affected patients are homozygotes for the 845G --> A (C282Y) mutation of the HFE gene. However, depending on the population, 10-20 % of hereditary hemochromatosis may be due either to other HFE genotypes, particularly the compound heterozygous state for C282Y and the 187 C --> G (H63D) mutation, or to mutations of new other genes. Our aim was to develop a rapid and non expensive assay allowing us to rapidly screen our patients for the new mutations described in this disease. This method needed to be suitable to screen new patients as well as our collection of clinically affected patients previously tested negative for the C282Y and H63D mutations. We chose pyrosequencing to developed assays for the detection of mutations H63D, S65C, E168X, W169X and C282Y of the HFE gene as well as mutation Y250X of TFR2 gene. This new method allows rapid detection of SNPs . It is a sequencing-by-synthesis method in which a cascade of enzymatic reactions yields detectable light, which is proportional to incorporated nucleotides. One feature of typing SNPs with pyrosequencing is that each allelic variant will give a unique sequence compared to the two other variants. These variants can easily be distinguished by a pattern recognition software. The software displays the allelic alternatives and allows for direct comparison with the pyrosequencing raw data.

**Identification of a de novo mutation (P35S) for symphalangism in NOG gene.** *M. Mangino*<sup>1</sup>, *E. Flex*<sup>1</sup>, *M.C. Digilio*<sup>2</sup>, *A. Giannotti*<sup>2</sup>, *B. Dallapiccola*<sup>1,3</sup>. 1) C.S.S. Mendel, Rome, Italy; 2) Medical Genetics and Cardiology Bambino Gesù Hospital, Rome, Italy; 3) Dept. of Experimental Medicine and Pathology, University "La Sapienza" Rome, Italy.

Symphalangism (SYM1 [OMIM 185800]) is an autosomal dominant disorder characterized by early onset and progressive ankylosis of the proximal interphalangeal joints and conductive hearing loss. In 1999 Gong identified 5 dominant noggin gene mutations in unrelated families segregating proximal symphalangism and a de novo mutation in a patient with unaffected parents. The same authors also described a dominant NOG mutation in a family with multiple synostoses syndrome (SYNS1 [OMIM 186500]), demonstrating that SYM1 and SYNS1 are allelic disorders. We analysed an Italian family in which father and son had bilateral symphalangism of fingers 2-5 and toes 3-4, short first metacarpals, hypoplasia of distal phalanges of hands, and mild conductive hearing loss. The father had also thoracolumbar scoliosis. Facial appearance was unremarkable in both patients. We identified in our patient a de novo mutation (P35S) in the noggin gene. A different mutation in the same codon has been previously described by Gong et al. (P35R). Comparison between different noggin gene orthologs shows that codon 35 is conserved. Therefore this amino acid residue may play an important role in noggin gene function and is a mutation hot spot.

**Mutational analysis and phenotype-genotype correlation of the NOD2 gene in Crohn disease.** *S. Lesage<sup>1</sup>, H. Zouali<sup>1</sup>, J.P. Czard<sup>2</sup>, J. Belaiche<sup>3</sup>, S. Almer<sup>4</sup>, C. Tysk<sup>5</sup>, C.A. O'Morain<sup>6</sup>, M. Gassul<sup>7</sup>, R. Modigliani<sup>8</sup>, J.F. Colombel<sup>9</sup>, F. Merlin<sup>1</sup>, M. Chamaillard<sup>1</sup>, G. Thomas<sup>1</sup>, J.P. Hugot<sup>1</sup>.* 1) Fondation Jean Dausset, Paris, France; 2) Hopital Robert Debr, Paris, France; 3) Lige, Belgium; 4) Linkping, Sweden; 5) rebro, Sweden; 6) Dublin, Ireland; 7) Barcelona, Spain; 8) Hopital Saint Louis, Paris, France; 9) Hopital Calmette, Lille, France.

**Background** : Crohn's disease (CD) (MIM 266600) and ulcerative colitis (UC) (MIM 191390) are multifactorial diseases. Recently, the NOD2 gene was reported to be involved in CD susceptibility (Hugot et al, 2001; Ogura et al, 2001). **Aim** : to provide a detailed mutation analysis of the NOD2 gene in Inflammatory Bowel Disease (IBD) and genotype-phenotype correlation studies. **Patients and Methods** : Unrelated participants included 467 CD, 159 UC and 103 healthy controls. A complete questionnaire with detailed phenotype was obtained for all patients. The coding sequence of the NOD2 gene was entirely analysed by direct sequencing or using a Denaturated High Performance Liquid Chromatography (dHPLC) screening. ANOVA analyses and Chi square tests were used. **Results** : In addition to the 3 main variants (R765W, G881R, 980fs981X) known to be associated with CD, 65 additional variants were observed. These variants were significantly more frequent in CD than in UC and controls ( $p < 0,01$ ). They were found unfrequent in the exons encoding for the CARD domains. Considering only the potentially functional variations(s), 30% and 18% of CD patients had a single and double dose mutation, respectively. Genotype-phenotype correlation analyses argue for a stronger association of NOD2 to diseases with early onset (17 vs 20 years,  $p < 0,05$ ), ileo-caecal involvement ( $P < 0,001$ ) and complication by stenosis ( $P < 0,001$ ). **Conclusion** : Beside the 3 main variants of NOD2, several additional mutations are expected to play a role in CD predisposition. NOD2 mutations are more frequent in case of regional enteritis as described by Crohn in 1932.

**Complete-type X-linked Congenital Night Blindness (CSNB1): Novel NYX (Nyctalopin) mutations cause selective dysfunction of the ON-bipolar cell.** *K.T. Hirianna<sup>1</sup>, N. Khan<sup>1</sup>, E.L. Bingham<sup>1</sup>, P.A. Sieving<sup>1,2</sup>.* 1) Ophthalmology and Visual Sciences, Kellogg Eye Center, University of Michigan, Ann Arbor, MI; 2) National Eye Institute, NIH, Bethesda, MD.

CSNB1 is a recessive hereditary retinal disorder characterized by impaired visual sensitivity in very dim lighting. Associated ocular symptoms include myopia and nystagmus. The electroretinogram (ERG) shows a unique pattern of normal a-wave from rod and cone photoreceptors but a severely reduced b-wave from post synaptic retinal cells. Mutations in the NYX gene, that codes for nyctalopin and located at Xp11.23, have recently been identified in CSNB1 patients. We analyzed three "complete-type CSNB" families and identified two novel NYX gene mutations. One in exon 3 (803G→C) causes a missense change (R268P) affecting the Lucine Rich Repeat (LRR) 9 motif of the NYX protein. The second family has a two nucleotide change (710T→A;711C→A) that causes a missense change (L237Q) in LRR8 motif. The third Family has the same deletion of 24 nucleotides (85-108 del 24 nt.) in exon 3 that was previously reported for seven other CSNB1 families. We used sine-wave flicker ERG methods to attempt to localize the functional deficit in the neural pathways in the inner retina. We compared results in CSNB1 to ERG changes in monkey after applying glutamate analogs to the retina. We found that using DL-2-amino-4-phosphobutyric acid (APB) to block the sign-inverting synapse of cone photoreceptors on to the depolarizing (ON-) bipolar cells in monkey completely mimicked the human CSNB1 deficit, whereas using cis-2,3-piperidinedicarboxylic acid (PDA), an OFF-pathway blocker, gave quite dissimilar results. The APB treated monkey eyes show the unique loss of the normal flicker amplitude dip and the phase deflection near 12 Hz, as is also found in CSNB1 patients. These results for the first time localize the cone pathway dysfunction to the depolarizing bipolar cells of the ON-pathway of CSNB1 patients and exclude involvement of the hyperpolarizing (OFF-) bipolar cells. These results confirm the hypothesis developed earlier that retinal ON-pathway signaling is defective in complete-type CSNB.

**Refined Mapping of the Lanceolate Hair (*lah*) Gene.** A. Kljuic<sup>1</sup>, V.M. Aita<sup>1</sup>, A.A. Panteleyev<sup>1</sup>, J.P. Sundberg<sup>2</sup>, X. Montagutelli<sup>3</sup>, A.M. Christiano<sup>1</sup>. 1) Columbia University, Departments of Genetics & Development and Dermatology, New York, New York; 2) The Jackson Laboratory, Bar Harbor, Maine; 3) Institut Pasteur, Paris, France.

Lanceolate hair (*lah*) is an autosomal recessive mouse mutation characterized by generalized atrichia associated with the breakage of abnormal hair shafts. These hair shafts contain focal degeneration at their breakpoints with pronounced enlargement at the apex that resembles a lance head. The hairs are short and sparse and histological examination of anagen-stage follicles revealed abnormal cornification of the hair matrix. Initial genetic linkage and segregation analysis mapped the *lah* gene within a 5 cM region on mouse chromosome 18. We have further narrowed the interval by genotyping additional microsatellite markers within the region. The *lah* mutation arose in the PAS strain and has been backcrossed for 12 generations onto BALB/cByJ background. Thus, the markers were scored for retention of PAS specific alleles and critical recombination events were identified by the presence of BALB/cByJ alleles. The new critical interval is delineated by markers D18Mit21 and D18Mit223. Thus far, several genes involved in intracellular structures map to this region including laminin- $\alpha$ 3 and six desmosomal cadherin genes. We are currently screening potential candidate genes by Northern blot analysis and direct sequencing of cDNA templates.

**Molecular characterization of the LDL receptor gene in patients with familial hipercolesterolemia. M.T.**

*Inocencio<sup>1</sup>, W.A. Silva-Jr<sup>1,2</sup>, M.C.R. Costa<sup>1</sup>, J.K.S. Hotta<sup>3</sup>, J.E. Santos<sup>3</sup>, M.A. Zago<sup>1,4</sup>.* 1) Lab Biol Molecular, Centro de Terapia Celular - Hemocentro Ribeirao Preto, Sao Paulo, Brazil; 2) Universidade Federal do Para - Nucleo Santarem; 3) Laboratorio de Nutricao do Hospital das Clinicas de Ribeirao Preto - SP; 4) Faculdade de Medicina de Ribeirao Preto - USP.

Familial Hypercholesterolemia (FH) is a common dominant autosomal disease which affects 1 in 500 individuals in most Western populations. It is characterized by high LDL (low density lipoprotein) plasma levels and is caused by a defect in the gene encoding the LDL receptor. In the human genome, the LDL receptor gene is located at the chromosome 19, being organized in 18 exons and it spans a region of about 60 kb. Gene analysis of the LDL receptor in patients with FH allowed the identification of more than 150 different mutations including insertions, deletions, and frameshift or nonsense mutations, distributed throughout the gene. Exon 4 (encodes the ligand-binding domain) keeps the majority of reported mutations. In this study, we have analyzed 66 patients with FH using two experimental methods (PCR amplification followed by automated sequencing in an ABI377™ sequencer). Thus far, we have investigated the first thirteen exons of the LDL receptor gene and we have detected four different point mutations, two of them synonymous and two non-synonymous. In the exon 4, there were identified the mutations G551A and C530T, that cause the aminoacid substitutions C163Y and S156L, respectively. The first mutation was identified in a patient and the second in another two unrelated patients. The two synonymous mutations identified were: T1773C (in the exon 12) and C1959T (in the exon 13). The parcial results presented here show that the experimental approach is appropriated for the molecular characterization of HF. Supported by: FAPESP & FUNDHERP.

**Design and development of a high-throughput test for Connexin 26 associated deafness using primer extension and mass spectrometric analysis.** *P. Merritt, H. Khoja, M.J. McGinniss.* Molecular Biology, Sequenom, Inc, San Diego, CA.

The incidence of congenital hearing loss is approximately 1 per 2,000 infants. Mutations in the GJB2 gene (chromosomal locus 13q11-q12) encoding the gap-junction protein connexin 26 (Cx26) are the most common known cause of severe to profound deafness that is inherited in an autosomal recessive fashion (DFNB1). One mutation in the GJB2 gene (35delG) accounts for approximately two-thirds of all Cx26 mutations in DFNB1 patients. We have developed an assay using Sequenom's patented MassARRAY<sup>TM</sup> system that relies on matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF-MS) for automated genotyping and analysis. This assay is designed to genotype the two most common disease-associated mutations (35delG and 167delT) in a 5 ul biplex PCR and primer extension reaction optimized for 384-well format. We used this assay for genotyping 96 DNA samples, including 3 positive controls (35delG / 35delG, 35delG / 167delT and 35delG / wt) and 8 negative controls. 93 out of 96 samples were genotyped with 100% accuracy, and overall 96.8% assay success. Two samples were genotyped with low probability and one sample failed either due to failure of the extend reaction or it was not spotted on the mass spectrometric chip. No other unknown peaks were seen in this initial study. No carriers of the 35delG mutation were detected in this set of normal control samples. Direct measurement of primer extension products with mass spectrometry is a highly accurate, cost-effective and efficient method to detect common genetic forms of deafness such as Connexin 26. This MALDI-TOF MS method can now be further optimized and validated for clinical diagnostic testing in a high throughput setting.

**Molecular characterization of juvenile glaucoma.** *E. Heon*<sup>1, 2, 3</sup>, *A.L. Vincent*<sup>1, 2</sup>, *G. Billingsley*<sup>1, 2</sup>, *Y. Buys*<sup>1, 3</sup>, *G. Trope*<sup>1, 3</sup>, *M. Priston*<sup>1</sup>, *D. Williams-Lyn*<sup>1</sup>, *J. Sutherland*<sup>2</sup>, *A.V. Levin*<sup>2</sup>. 1) Ophthalmology, Vision Sci, Univ Toronto, Toronto, ON., Ontario, Canada; 2) Department of Ophthalmology, The Hospital for Sick Children, Toronto, On., Canada; 3) Department of Ophthalmology, The Toronto Western Hospital, Toronto, On., Canada.

Juvenile glaucoma (JOAG) refers to open angle glaucoma that is manifest between the age of 5 and 40 years of age. Glaucoma is genetically heterogeneous with at least three glaucoma genes identified. Although some cases of JOAG share a common genetic background with cases of adult-onset glaucoma, the natural history of JOAG is thought to be different. To better understand the basis of JOAG we did mutational analysis of three glaucoma related genes (MYOC, CYP1B1 and PITX2) in 65 cases affected with JOAG. The search for mutations was done using a combination of single strand conformation polymorphism (SSCP) and direct sequencing. Mutations were identified in 11% of JOAG cases. Mutations of MYOC were identified in 7 cases that included an individual with pigment dispersion syndrome and another family with cases of mixed glaucoma. Mutations in CYP1B1 were identified in three cases that did not have features suggestive of congenital glaucoma. No disease causing mutations was identified in PITX2. The phenotype-genotype correlations will be discussed. This work supports the important role of MYOC in JOAG but further demonstrates the variability in the expression of this gene. We report the association of MYOC mutations with mixed glaucoma and Pigment dispersion syndrome for the first time. This association of CYP1B1 with a non-congenital eye disorder, supports its role beyond congenital glaucoma and a potential role as a glaucoma-modifier gene.

**A PCR strategy for screening of  $\alpha$ -thalassemia mutations in Singapore.** *H.Y. Law<sup>1</sup>, G.P. Tan<sup>2</sup>, I. Ng<sup>1,2</sup>.* 1) Pediatrics, KK Women's and Children's Hosp, Singapore, Singapore; 2) National Thalassaemia Registry.

$\alpha$ -thalassemia is the most common genetic disease in Singapore, estimated to afflict 3-4% of the population which consists of Chinese (76.8%), Malay (13.9%), Indian (1.4%) and others (1.4%). A PCR strategy was established for the screening of various mutations that were identified in a systematic screen of  $\alpha$ -thalassaemia mutations in microcytic anemic patients attending the National Thalassaemia Registry, Pediatric outpatient and prenatal diagnosis clinics. The strategy consists of using 2 sets of multiplex PCRs for the detection of deletional mutations, and a Reverse Dot Blot (RDB) analysis for the detection of 5 point mutations: Hb Constant Spring(CS), Hb Pakae(PK) (Cd142T/C), Hb Quong Sze (QS) (Cd125CTG/CCG), Cd30(-GAG) and Cd59(GGC/GAC). All samples were first screened for 3 types of 2-gene deletion: South East Asian (SEA), Thai and Fil deletions. HbH samples and samples which gave negative results were also analysed by a multiplex PCR which detects 3.7kb and 4.2kb single gene deletions. Samples negative for both PCRs were then subjected to further RDB analysis for point mutations. Using this strategy, a total of 1292 unrelated individuals were screened and 1355 alleles analysed. While each ethnic group had it's characteristic frequency distribution of various mutations, the overall result showed that the SEA 2-gene deletion was the most common mutation(77.1%), followed by 3.7kb(14.9%) and 4.2kb(3.2%) single gene deletions, Thai 2-gene deletion(1.4%), HbCS(1.3%), HbQS(0.5%), Fil 2-gene deletion(0.3%) and HbPK, Cd30 and Cd59(0.1% each). Of the 11 alleles (0.8%) which were negative to all tests, 3 were found to have other point mutations by sequencing and 8 remained unidentified. In conclusion, 97% of the mutations were detected by 2 multiplex PCRs, and a futher 2% can be detected by RDB to achieve a 99% detection rate. This screening strategy is thus both efficient and effective in mutation identification which is important for the prevention and control of the disease.

**Congenital myasthenic syndrome due to a novel mutation in the acetylcholine receptor  $\epsilon$  subunit gene. V.**

*Neocleous<sup>1</sup>, A. Papadimitriou<sup>2</sup>, R. Divari<sup>2</sup>, E. Zamba<sup>3</sup>, T. Kyriakides<sup>3</sup>, K. Christodoulou<sup>1</sup>.* 1) Molecular Genetics Department D, The Cyprus Institute of Neurology and Genetics, Nicosia, Cyprus; 2) Department of Neurology, The Red Cross Hospital, Athens, Greece; 3) Department of Neurology, The Cyprus Institute of Neurology and Genetics, Nicosia, Cyprus.

Congenital myasthenic syndromes (CMS) are genetically heterogeneous disorders caused by presynaptic, synaptic or postsynaptic defects. Previously described kinships with CMS showed a marked deficiency of acetylcholine receptors (AChR) at the neuromuscular junctions. We hereby, present our genetic findings in a 33-year-old woman from Greece with a classic CMS phenotype. Mutation screening revealed a novel 20 base pair homozygous deletion at position 4084 of the acetylcholine receptor epsilon subunit intron 11. Deleterious epsilon AChR mutations usually result in AChR deficiency. This novel mutation is currently under further investigation.

**Identification of a 40 kb deletion in 3q23 causing the Blepharophimosis, Ptosis and Epicanthus inversus**

**Syndrome (BPES).** *K. Lagerstedt*<sup>1</sup>, *G. Annerén*<sup>1</sup>, *S. Jagell*<sup>2</sup>, *L. Crisponi*<sup>3</sup>, *G. Pilia*<sup>3</sup>, *M-L. Bondeson*<sup>1</sup>. 1) Dept of Genetics and Pathology, Rudbeck Laboratory, Uppsala, Sweden; 2) Dept of Pediatrics, Gavle County Hosptial, Gavle, Sweden; 3) Istituto Regionale sulle Talassemie ed Anemie Mediterranee CNR, Dipartimento di Scienze Biomediche e Biotecnologie, Universita' degli studi di Cagliari, Cagliari, Italy.

The blepharophimosis, ptosis, epicanthus and inversus syndrome, BPES, is an autosomal dominant disorder affecting the craniofacial development. In type I, BPES is associated with female infertility while type II presents with the eyelid defects only. Recently, it was demonstrated that both types are associated with mutations in the FOXL2 gene located at 3q23. The FOXL2 gene encodes a putative winged helix/forkhead transcription factor where truncated proteins result in BPES type I and larger proteins in type II. Here, we report on the identification of a de novo deletion at 3q23 in a patient affected by BPES, mental retardation, microcephaly, fair skin and low set ears suggestive of a contiguous gene syndrome. We have analyzed the interval defining the deletion by using highly polymorphic markers and the fluorescent in situ hybridisation (FISH) technique. FISH analysis with twelve cosmids or PACs from around the FOXL2 gene showed haploinsufficiency for sequences corresponding to one of the cosmids analysed. From fiber-FISH analysis the size of the deletion was estimated to 40 kb. Cosmids and PACs located within the BPES critical region were mapped relative to the FOXL2 and the novel C3orf5 gene by STS content mapping. The deleted region was assigned to the C3orf5 gene that is located approximately 180 kb telomeric of the FOXL2 gene. No mutations were identified in the FOXL2 gene. The 40 kb deletion represents the smallest interstitial deletion reported so far associated with BPES, microcephaly and mental retardation. Our data suggest that the intragenic deletion in C3orf5 associated with BPES, microcephaly, mental retardation, ear dysmorphism and fair skin may exert position effect on expression of one or several genes in the BPES region.

**Characterization of two splice mutations provides conclusive evidence of the identification of the gene responsible for Bardet-Biedl syndrome type 4.** *K. Mykytyn<sup>1</sup>, A. Wright<sup>2</sup>, R. Riise<sup>3</sup>, E. Stone<sup>4</sup>, V. Sheffield<sup>1</sup>*. 1) Dept of Pediatrics, Howard Hughes Medical Institute, University of Iowa, Iowa City, IA; 2) MRC Human Genetics Unit, Western General Hospital, Edinburgh, Scotland; 3) Dept of Ophthalmology, Central Hospital, Hedmark, Hamar, Norway; 4) Dept of Ophthalmology, University of Iowa, Iowa City, IA.

Bardet-Biedl syndrome (BBS) is a heterogeneous autosomal recessive disorder characterized by obesity, pigmentary retinopathy, polydactyly, renal malformations, mental retardation, and hypogenitalism. The disorder is also associated with diabetes mellitus, hypertension and congenital heart disease. There are six distinct BBS loci. Although BBS is rare in most populations, there is considerable interest in identifying the genes causing BBS because components of the phenotype are common. Recently, we reported the positional cloning and identification of mutations in BBS patients in a novel gene designated *BBS4*. These homozygous mutations consisted of a missense mutation, an in-frame deletion predicting the loss of 48 amino acids, and two different splice site mutations. One splice mutation was a G>C transversion at the +1 position of the splice donor site in exon 4. The other was an A>C transversion at the -2 position of the splice acceptor site of exon 7. Although these mutations would be expected to result in abnormal splicing, we decided to confirm this by exploring the effect of the mutations on RNA processing. RNA from patient cell lines was isolated and used to synthesize cDNA for PCR analysis of the *BBS4* transcript. Sequencing of these PCR products demonstrated that the splice donor site mutation causes the skipping of exon 4 or exons 4 and 5, both of which are frameshift deletions. Sequencing of the transcript from the patient with the splice acceptor site mutation demonstrated aberrant splicing at a site five base pairs upstream of the original site, thereby introducing an insertion of five base pairs. The identification of the gene responsible for BBS4 will allow for the exploration of its function and the examination of potential interactions of the BBS4 protein with other BBS proteins and additional targets.

**Reevaluation of a genetic model for the development of exostosis in Hereditary Multiple Exostosis.** *J.T. Hecht<sup>1,3</sup>, C.R. Hall<sup>1</sup>, W.G. Cole<sup>2</sup>, R. Haynes<sup>3</sup>*. 1) Dept Pediatrics, Univ Texas Medical Sch, Houston, TX; 2) Department of Surgery, Hospital for Sick Children, Toronto, Canada; 3) Shriners Hospital-Houston, Houston, TX.

Mutations in the *EXT1* and *EXT2* genes cause Hereditary Multiple Exostosis (HME), a syndrome characterized by bony exostoses that develop juxtaposed to the growth plate. We and others have previously suggested that a two hit mutational model applies to the development of exostosis where a germline mutation coupled with a somatic mutation results in the loss of *EXT1* or *EXT2* function and subsequent aberrant chondrocyte proliferation and exostosis formation. We report the direct sequencing and LOH analyses of DNA from twelve HME exostoses from ten HME families, four solitary exostoses from individuals without HME, one Langer Gideon and one Trevor syndrome patient, and corresponding constitutional DNAs. All HME germline mutations were identified in both the exostosis and constitutional DNA samples. These mutations (85%) include two point mutations and three small deletions in the *EXT1* gene and one point mutation, one small deletion, and one small insertion in the *EXT2* gene. In addition, the two remaining (15%) HME exostosis samples were found by LOH and parental studies to have germline deletions of the *EXT1* or *EXT2* gene. Of the four solitary exostoses, only two were found to harbor mutations in the *EXT1* gene, which were not present in the constitutional DNA. Only a chromosome 8 deletion was identified in the constitutional and exostosis DNAs of the Langer Gideon patient, while no mutations were found in the Trevor patient. Of the eighteen exostoses screened, we find only one solitary case in which two somatic mutations, a deletion and LOH of the *EXT1* gene, is present. This provides limited support for the two hit hypothesis involving the *EXT1* and *EXT2* genes as a common mechanism for the development of exostosis. Alternative models based on the functional significance of the EXT proteins in heparan sulfate biosynthesis are suggested.

**A novel molecular diagnostic test for SHOX deficiency using mutation detection and SNP-based detection of whole gene deletions by DHPLC reveals new mutations.** *P. Marttila<sup>1</sup>, J. Ross<sup>2</sup>, A. Zinn<sup>3</sup>, S. Blakely<sup>1</sup>, J. Sernberger<sup>1</sup>, M. Stene<sup>1</sup>.* 1) Esoterix Endocrinology, Calabasas Hills, CA; 2) Department of Pediatrics, Thomas Jefferson University, Philadelphia, PA; 3) McDermott Ctr Human Growth/Dev, University of Texas SW Medical School, Dallas, TX.

The SHOX (Short Stature Homeobox) gene defect causes Leri-Weill Dyschondrosteosis (LWD), impaired growth in some non-growth hormone deficient children, and short stature and skeletal features of Turner syndrome. LWD is a pseudoautosomal dominant disorder characterized by mesomelic dysplasia, short stature, and Madelung deformity. Most SHOX defects (70%) are whole gene deletions, the rest being point mutations.

We developed a highly sensitive and specific molecular diagnostic test for SHOX deficiency, named SHOX-DNA-Dx™. It detects both point mutations and whole gene deletions using heteroduplex analysis by DHPLC. Whole gene deletions are identified utilizing intragenic SNP's within the SHOX gene. SNP's were discovered by designing PCR amplicons throughout the SHOX gene and testing them for SNP content using DHPLC. The most informative SNP's were selected by screening 52 normal controls. Eight PCR amplicons were selected for SHOX-DNA-Dx. They include 2-5 SNP's or other polymorphisms per PCR amplicon. Heterozygosity in each PCR amplicon is high, varying from 33-88%. SHOX-DNA-Dx™ was validated by analyzing normal control samples, as well as subjects with short stature who were previously screened using FISH, and comparing the results.

We studied 12 unrelated LWD probands, and found whole gene deletions in seven, point mutations in four, and a partial deletion in one of the probands. This is the first time that partial deletion of SHOX has been reported. Three point mutations are new, previously unknown, and they all cosegregate with the LWD phenotype. In conclusion, SHOX-DNA-Dx™ is a highly sensitive and specific test for SHOX deficiency due to whole gene deletions, known or previously unknown point mutations in the SHOX gene.

**New Polymorphic Short Tandem Repeat for Diagnosis of the CMT1A Duplication and HNPP Deletion.** *K.S. Lee<sup>1</sup>, E.S. Park<sup>2</sup>, I.S. Seo<sup>1</sup>, B. Oh<sup>1</sup>, S.C. Jung<sup>1</sup>, J.S. Lee<sup>1,2,3</sup>.* 1) Biomedical Science, Nat'l Institute of Health, Seoul, Korea; 2) Brain Korea 21 for Biomedical Science, Yonsei University, Seoul, Korea; 3) Department of Pediatrics, Yonsei University College of Medicine, Seoul, 120-752, Korea.

Alterations in gene copy number may lead to under or over expression of these genes, resulting in the observed disease phenotype. Two well-documented diseases known to be caused by gene copy number alterations are the Charcot-Marie-Tooth type 1A (CMT1A) and hereditary neuropathy with liability to pressure palsies (HNPP). CMT1A and HNPP are associated with dominantly inherited 1.5 Mb duplication or deletion at chromosome 17p11.2-p12, encompassing the peripheral myelin protein (PMP22) gene. Although several methods including southern blot, pulse-field gel electrophoresis, fluorescence in situ hybridization, real-time fluorescent PCR are useful to detect the DNA duplication or deletion, but they require labor-intensive or costly machines. Microsatellite marker typing is widely used for molecular diagnosis because of its convenience. In this study, we have developed a new microsatellite marker to improve the diagnosis of CMT1A/HNPP in Korean. The polymorphic short tandem repeat marker, (CA)<sub>n</sub> repeats, is located at about 3 Kb upstream region of PMP22 gene and shows more effective results than other markers in Korean CMT1A/HNPP patients. This microsatellite marker combined with other markers can be used for clinical application and for molecular diagnosis preferentially.

**Mutations of mitochondrial tRNA<sup>Leu</sup> and tRNA<sup>Lys</sup> gene in Korean patients with mitochondrial myopathy<sup>LeuLys</sup>.** *J-I. Kim<sup>1</sup>, K-S. Lee<sup>2</sup>, S-J. Jin<sup>2</sup>, S-K. Koo<sup>2</sup>, B. Oh<sup>2</sup>, S-C. Jung<sup>2</sup>, H-K. Lee<sup>3</sup>, J-S. Lee<sup>1,2,4</sup>.* 1) Brain Korea 21 Project for Medical Science, Yonsei University, Seoul, Korea; 2) Division of Genetic Disease, National Institute of Health, Seoul, Korea; 3) Department of Internal Medicine, Seoul National University School of Medicine, Seoul, Korea; 4) Department of Pediatrics, Yonsei University College of Medicine, Seoul, Korea.

Mitochondrial myopathies are associated with mutations in the mitochondrial or nuclear genome affecting mitochondrial function and frequently shown in mitochondrial diseases, such as mitochondrial encephalomyopathy, lactic acidosis and stroke-like episodes (MELAS), myoclonic epilepsy with ragged red fibers (MERRF), lebers hereditary optic neuropathy (LHON). Using PCR-direct sequencing analysis, we have investigated mitochondrial tRNA<sup>Leu</sup> gene for MELAS, tRNA<sup>Lys</sup> gene for MERRF and nucleotide 3460, 11778, 14484, 15257 mutations for LHON, which are known as major mutation sites in each case. In 7 of 66 cases, we identified four mutations at nucleotide A3243G, T3271C in tRNA<sup>Leu</sup>, A8344G in tRNA<sup>Lys</sup>, and G3460A. Two novel single nucleotide polymorphisms (SNPs) were also detected at nucleotide C3206T, C8431T. The low detection rate of the mutation in tested patients suggests that other neurologic diseases should be distinguished from MELAS and MERRF clinically. In addition, DNA analysis could be the choice of diagnostic method prior to muscle biopsy for mitochondrial myopathies.

**Mutation load in the mouse is age and tissue specific but not obviously related to rates of cell proliferation.** *K.A. Hill, A. Halangoda, P.W. Heinmoeller, C. Chitaphan, J. Wang, S.S. Sommer.* Molecular Genetics, City of Hope Ntl Med Ctr, Duarte, CA.

It is of interest to examine mutation load (mutation frequency, pattern and spectrum) with tissue type and age and identify mutational markers for aging and disease. The Big Blue® assay was used to measure mutation load in whole fetus (13.5 dpc) and eight tissues in post-natal mice at 10 days and 3, 10, 14, 17, 22, 25 and 30 months of age. There are three periods of mutagenesis: increasing mutagenesis during development, a plateau phase from early to mid-adulthood and a tissue specific increase in old age. Tissues that divide rapidly, moderately or not at all have quantitatively similar time courses of mutation from 10 d to 30 mo. Mutation load is unchanged from 3 to 30 mo in neurons and sperm, non-dividing and rapidly dividing tissues, respectively. The nondividing tissues, heart and adipose have increases in mutation load in old age, similar to the moderately dividing tissues, liver and kidney. Additional interesting findings include the following. 1) There is a single core mutation pattern in all tissues that is unaltered even when mutation frequencies change more than five fold. 2) Tandem GG to TT mutations occur in liver and adipose tissue and show increases with age and certain hotspots in liver. 3) Doublet mutations are enhanced over that expected for two independent events. 4) The distance between doublet mutations fits an exponential distribution consistent with their occurrence in the same cell cycle. The constancy of mutation load in sperm suggests that no advanced paternal age effect on mutation load will be found in mice; compatible with the absence of an advanced paternal age effect observed in the human factor IX gene (Hum Gen 105:629). It is significant to consider the difference in hypotheses related to mutational mechanisms for a three-step, tissue-specific profile of mutation load with age versus a constant linear increase in mutation load with age. Different life stages may have different mutagen exposures and different responses to antimutagens. These data provide a useful reference for future study of endogenous and exogenous mutagenesis.

**Krit1 mutations are responsible for the majority of inherited CCMs: a molecular genetic study of 38 families.** *D. Verlaan*<sup>1</sup>, *W.J. Davenport*<sup>1</sup>, *H. Stefan*<sup>3</sup>, *A.M. Siegel*<sup>2</sup>, *G.A. Rouleau*<sup>1</sup>. 1) Center for Research in Neurosciences, Dept. of Neurology, McGill University, Montreal, Quebec, Canada; 2) Epilepsy Program, Dept. of Neurology, University Hospital Zurich, Switzerland; 3) Kopfklinikum, University of Erlangen-Nurnberg, Germany.

Cerebral cavernous malformation (CCM) is a cerebral vascular lesion that can cause hemorrhagic strokes or seizures (MIM 116860). CCMs may arise sporadically or be dominantly inherited. Currently, three loci have been mapped, CCM1 (7q21-22), CCM2 (7p13-15) and CCM3 (3q25.2-27), accounting for 40%, 20% and 40% respectively of families affected with the disorder. The Krit1 gene has been identified as the gene causing CCM1. Recently, the presence of four additional upstream coding exons of the Krit1 gene has been predicted. In order to confirm the existence of these exons and determine the relative frequency with which Krit1 mutations cause CCM, we screened the gene for mutation by SSCP in 38 families participating in the International Familial Cerebral Angioma Study (IFCAS). We have found two new mutations in these novel upstream exons confirming the role of these exons in the disorder as well as six additional mutations in the previously known exons. Results indicate that approximately 50% of our CCM families tested have a mutation in this gene, indicating that the percentage of CCM caused by Krit1 mutations may be higher than previously thought.

**A G>T Substitution 7 bp downstream from the *CPT2* gene polyadenylation site associated with carnitine palmitoyltransferase II deficiency.** *G.D. Vladutiu<sup>1</sup>, D.R. Smail<sup>1</sup>, L. Gambino<sup>1</sup>, M.J. Bennett<sup>2</sup>*. 1) Dept Pediatrics, SUNY Buffalo, Buffalo, NY; 2) Dept Pathology & Pediatrics, Univ of Texas Southwestern Medical Center, Dallas, TX.

The polyadenylation region of nearly all eukaryotic pre-mRNAs contains important primary (AAUAAA and GU-rich sequences) and secondary structures (stem-loop) necessary for the binding of polyadenylation factors such as CPSF and CstF. These proteins are important for proper 3' end cleavage and addition of the poly(A) tail. Mutations in genomic DNA encoding the polyadenylation region can adversely affect gene expression by altering the structure of the pre-mRNA, and its ability to be bound by such proteins. A patient with myopathic CPT II deficiency (8% of normal activity in fibroblasts) was screened for the 6 most common mutations in the *CPT2* gene and found to be heterozygous for the S113L mutation. DNA sequencing of all 5 exons, 650 bases of flanking intronic sequence, 890 bases of the promoter region and 130 bases beyond the polyadenylation site identified a novel base pair substitution (PAS+7 G>T) 7 nucleotides downstream of the polyadenylation site. PAS+7 G>T was not found in 50 individuals from the general population, nor in 43 patients with varying degrees of CPT II deficiency. A third polymorphism, PAS+11 T>C (general population: T=0.62; C=0.38) for which the study patient was TT, exists 4 bp downstream from the new mutation. In preliminary studies, the frequency of the T allele was increased (T=0.85) in individuals with significant CPT II deficiency. Both PAS+7 G>T and PAS+11 T>C occur within the GU-rich sequence, yet PAS+7 G>T appears to be more disruptive to the predicted stem-loop target of the CstF protein than the polymorphism. Based on our findings, it may be hypothesized that PAS+7 G>T is a pathogenic mutation that impairs polyadenylation by altering the secondary structure of pre-mRNA. This is the first report of a mutation outside the *CPT2* gene coding region that appears to be causative for CPT II deficiency demonstrating the need for thorough screening of the entire gene region in suspected cases.

**Keratin-9 gene mutation in a family with Epidermolytic Palmoplantar Keratoderma.** *L. Peleg<sup>1</sup>, B. Goldman<sup>2</sup>, M. Karpati<sup>1</sup>, B. Amichai<sup>1</sup>*. 1) The Danek Gertner Institute of Human Genetic, Sheba Medical Ctr, Tel Hashomer, Israel; 2) Department of Dermatology, Huzot Clinic, Kupat Holim, Ashkelon, Israel.

Voerners Epidermolytic palmoplantar keratoderma (EPPK) is one form of a heterogeneous group of dermatoses, most frequently inherited in an autosomal dominant manner. The gene associated with EPPK was mapped to 17q11-23, to the type 1 (acidic) keratin gene cluster. In 1993 the cDNA of Keratin 9 (KRT9) was cloned and sequenced and the resulting polypeptide was found to be expressed in the epidermis of palms and soles. Most of the mutations with a clear association to EPPK have been located within residues 156-171 of the KRT9 polypeptide. We studied four affected and two non-affected individuals of three generations of an Ashkenazi Jewish family from Russia, suffering from EPPK. In addition DNA samples of two non-related healthy controls were also analyzed. An A to G substitution at position 545 was identified by sequencing a 200 bp fragment (bp 497-697), generating an amino acid substitution of asparagine in position 160 to serine. Since this mutation does not alter the recognition site of any known restriction enzyme, its presence was confirmed by sequencing all the studied DNA samples. The mutation was restricted to the four affected individuals' DNA and was not found in the four healthy individuals. As this mutation was already reported in an Austrian-Alpine family with EPPK, an analysis of the polymorphic CA repeat region in intron 4 of the gene was undertaken. In the Austrian family the disease was associated with an allele containing 21 repeats. In the present family (six members) four alleles were revealed: 17, 20, 22 and 23 CA repeats. The mutation 545A to G was associated with the allele containing 20 repeats. These results suggested that different ancestors introduced the mutation in the 2 families.

**Identification of ABCC6 pseudogenes on human chromosome 16p: Implications for mutation detection in pseudoxanthoma elasticum.** *L. Pulkkinen, A. Nakano, F. Ringpfeil, J. Uitto.* Dept Dermatology and Cutaneous Biology, Thomas Jefferson Univ, Philadelphia, PA.

Pseudoxanthoma elasticum (PXE), a heritable disorder affecting the skin, eyes and the cardiovascular system, has been recently linked to mutations in the ABCC6 gene on chromosome 16p13.1. The original mutation detection strategy employed by us consisted of amplification of each exon of the ABCC6 gene with primer pairs placed on the flanking introns, followed by heteroduplex scanning and direct nucleotide sequencing. However, this approach suggested the presence of multiple copies of the 5'-region of the gene when total genomic DNA was used as template. In this study, we have identified two pseudogenes containing sequences highly homologous to the ABCC6 5'-end. First, by the use of allele specific PCR, two BAC-clones containing a putative pseudogene of ABCC6, designated as ABCC6-y1, were isolated from the human BAC-library. Sequence analysis of ABCC6-y1 revealed it to be a truncated copy of ABCC6 which contains upstream region as well as exon 1-intron 9 segment of the gene. Secondly, homology search of a high-throughput sequence (htgs) database revealed the presence of another truncated copy of ABCC6, designated as ABCC6-y2, which was shown to harbor upstream sequences as well as a segment spanning exon 1 through intron 4 of ABCC6. In addition to several nucleotide differences in the flanking introns and the upstream region, both pseudogenes contain several nucleotide changes in the exonic sequences, including stop codon mutations, which complicated mutation analysis in patients with PXE. Nucleotide differences in flanking introns between these two pseudogenes and ABCC6 allowed us to design allele specific primers which eliminate the amplification of both pseudogene sequences by PCR, providing reliable amplification of ABCC6-specific sequences only. The use of allele specific PCR has revealed thus far two pathogenetic 5'-end PXE mutations, 179del9 and T364R in exons 2 and 9, respectively, as well as several polymorphisms within the upstream region and exons 1-9 of ABCC6.

**Patients definitively diagnosed with TSC yield a higher mutation detection rate.** A.J. Tucker<sup>1</sup>, H. Northrup<sup>1</sup>, C.J. Ohl<sup>1</sup>, E.S. Roach<sup>2,3</sup>, S.P. Sparagana<sup>2,3</sup>, M.R. Delgado<sup>2,3</sup>, L.L. Batchelor<sup>2</sup>, K.S. Au<sup>1</sup>. 1) The University of Texas-Houston Medical School, Houston, TX; 2) Texas Scottish Rite Hospital for Children, Dallas, TX; 3) The University of Texas Southwestern Medical School, Dallas, TX.

Tuberous sclerosis complex (TSC) is an autosomal dominant human disease characterized by hamartomas and hamartias in multiple tissue organs. A mutation in either the TSC1 or TSC2 gene is causative for this condition. Diagnostic criteria have been developed to aid physicians in diagnosis, utilizing a classification of *Definite*, *Probable* or *Possible* diagnoses. Familiarity with these criteria may vary with physician expertise or background. Previous attempts to develop clinical DNA testing protocols have utilized mutation-screening methods with detection rates ranging from 58% (heteroduplex analysis) to 68% (DHPLC). This study employed a new protocol of direct sequencing of PCR products from all TSC1 and TSC2 coding exons. A group of 49 patients have been sequenced to date, including 10 that had screened negative by SSCA. The remaining 39 patients included 20 with documented *Definite* diagnoses referred by the TSC clinic at Texas Scottish Rite Hospital (TSRH) and 19 (15 *Definite* and 4 *Possible* or non-specific criteria) with undocumented diagnoses referred by various sources. Upon sequencing 52 of the 62 most frequently mutated coding exons, three likely disease-causing mutations were identified among the 10 patients previously studied, indicating a likely increased sensitivity of direct sequencing. In the 20 TSRH patients, 17 likely disease-causing mutations were identified, resulting in a detection rate of 85% in this group. In contrast, likely disease-causing mutations were found in 11 (9 *Definite*, 2 *Possible*) of the 19 remaining patients, with a detection rate of 57.9%, significantly lower than that for the TSRH group ( $p < 0.001$ ). The detection rate in patients with undocumented *Definite* diagnoses was 60%, again significantly lower than that of TSRH cases ( $p < 0.01$ ). These findings suggest the consistent application of clinical diagnostic criteria by those trained in TSC diagnosis will yield a more definitive diagnosis, therefore yielding a higher rate of mutation detection.

**Biplex Invader® assays for simple, accurate detection of factor V Leiden and other thrombosis risk factors.** *E.B. Rasmussen<sup>1</sup>, D.E. Burris<sup>1</sup>, E.K. Dorn<sup>1</sup>, S.S. Wigdal<sup>1</sup>, D. Arco<sup>1</sup>, P. Agarwal<sup>1</sup>, R. Selzer<sup>2</sup>, K. Hogan<sup>2</sup>, B. Neri<sup>1</sup>, R. Kwiatkowski<sup>1</sup>. 1) Third Wave Technologies, Inc., Madison, WI; 2) Department of Anesthesiology, University of Wisconsin - Madison, Madison, WI.*

The factor V Leiden mutation is one of several genetic variations linked to an increased risk of deep vein thrombosis (DVT). Some polymorphisms, such as those affecting the factor V and factor II genes, disrupt the normal functioning of the coagulation cascade by acting directly on key players within that biochemical pathway. Other polymorphisms act through ancillary pathways, such as mutations within the methylenetetrahydrofolate reductase (MTHFR) gene. Such mutations can lead to elevated levels of plasma homocysteine or hyperhomocysteinemia, a secondary risk factor for DVT. Accurate diagnosis of these and other risk factors is essential for the proper management of patients at a heightened risk for thrombotic or embolic complications.

Using our proprietary Invader technology, we have produced analyte specific reagents for use in the genetic detection of a number of thrombotic and cardiac risk factors, including polymorphisms in factor V [Leiden (G1691A)], factor II [G20210A], MTHFR [C677T and A1298C], Gp IIIa [PLA1/2 (T1565C)], and Apolipoprotein E [E2, E3, and E4 Isoforms], with still others under development. Assays using these reagents are simple, requiring only a single post set-up addition, and fast, producing a result directly from genomic DNA in just over four hours without the need for target amplification by PCR. Detection is straightforward; the reaction is isothermal and homogeneous, and the biplex format allows for the assessment of both wild-type and mutant alleles in a single reaction well. Assays are run in a standard 96-well microtiter format and the results are read directly by any fluorescence plate reader capable of detecting two spectrally-distinct fluorophors.

In this study, we demonstrate the application of Invader reagents to the biplex detection of these thrombotic and cardiac risk factors across a panel of human subjects.

***MECP2* gene analysis in Japanese patients with classical and variant Rett syndromes and with Rett-like features.**

Y. Yamada<sup>1</sup>, K. Miura<sup>2</sup>, T. Kumagai<sup>2</sup>, T. Ohki<sup>2</sup>, C. Hayakawa<sup>2</sup>, S. Miyazaki<sup>3</sup>, A. Matsumoto<sup>3</sup>, N. Nomura<sup>1</sup>, S. Sonta<sup>1</sup>, T. Yamanaka<sup>2</sup>, N. Wakamatsu<sup>1</sup>. 1) Dept Genetics Inst Dev Res; 2) Central Hosp; 3) Resid Fac Mentl Phisic Disabil, Aichi Human Service Ctr, Kasugai, Aichi, Japan.

The Rett syndrome (RTT, MIM 312750), an X-linked dominant neurodevelopmental disorder, is caused by mutations in the methyl-CpG-binding protein 2 gene (*MECP2*). We have analyzed the gene in 37 Japanese patients divided into classical RTT (14 cases), variant RTT (13 cases), and mentally retarded patients with Rett-like features (10 cases). Mutations in *MECP2* were identified in most of the patients with classical and variant RTT (25 of 27 cases). Six reportedly common mutations including 3 missense mutations (R133C, T158M, and R306C) and 3 nonsense mutations (R255X, R270X, and R294X) were detected in 17 cases. Rare single nucleotide substitutions, Y141X, D156E and P225R, were also each identified in one patient, respectively. In addition, one insertion mutation (1189insA resulting in 397fs404X) and four deletion mutations, including one double deletion (451delG resulting in 151fs159X, 100del4 resulting in 34fs124X, 1124del53 resulting in 376fs386X, and 881del289 plus 1187del8 resulting in an insertion of 6 different amino acids instead of deleted 105 amino acids) were newly identified. In the 10 mentally retarded patients with Rett-like features, however, no mutations were detected in the coding region of *MECP2*. The finding of *MECP2* mutations in 92.5 % of patients with RTT indicates that RTT fulfilling the diagnostic criteria are due to genetic alteration. Although no significant genotype-phenotype correlations were apparent, some tendencies were observed regarding symptoms like microcephaly and an inability to walk. First, the patients without microcephaly were limited to those with missense mutations or a deletion at CTR. Second, in most of the patients who able to walk, the mutations were found downstream from TRD of *MECP2*, except in 3 cases with MBD missense mutations.

**A novel Q378X mutation exists in *ABCC6* and its pseudogene - Implications for mutation analysis in pseudoxanthoma elasticum (PXE).** B. Struk<sup>1, 7</sup>, A. Lumsden<sup>2</sup>, L. Cai<sup>1</sup>, U.P. Guenther<sup>7</sup>, S.A. Neldner<sup>1</sup>, S. Zäch<sup>3</sup>, R. Ramesar<sup>4</sup>, D. Hohl<sup>3</sup>, D.F. Callen<sup>2</sup>, K.H. Neldner<sup>5</sup>, R.I. PXE is an inherited disorder of the elastic tissue with progressive calcification of elastic fibers in skin, eye, and the cardiovascular system. Recently, mutations in the *ABCC6* gene were identified as cause of PXE. We had previously identified the starting point of a large genomic segmental duplication within the PXE locus in the cytogenetic interval defined by the *Cy19* and *Cy185* somatic cell hybrid breakpoints on chromosome 16p13.1. We more precisely mapped this duplication to include exons 1 to 9 of *ABCC6*. Sequence and RFLP analysis for exon 9 in all members from the PXE families and in 192 controls revealed either a homozygous or heterozygous state for the Q378X (C1132T) nonsense mutation in all individuals, suggesting that one or several copies of an *ABCC6* pseudogene (*yABCC6*) lie within this duplication. At least one copy contains exon 1 to 9 and maps to *Cy163*, but not to *Cy11*. This copy and/or an additional copy of *yABCC6* within *Cy19-Cy183* carry the Q378X mutation that masks its correct identification as being causative in PXE. Long range PCR of exon 9 from sequence outside the genomic replication circumvents interference from the *yABCC6* DNA sequences and demonstrates that the Q378X mutation in the *ABCC6* gene is associated with PXE in some families.

These findings lead us to propose that gene conversion from *yABCC6* to *ABCC6* plays a functional role in mutations causing PXE.

**Relevance of exon 15 mutations in PKD1 disease.** *R.A. Perrichot<sup>1,2</sup>, A. Grall<sup>1</sup>, B. Mercier<sup>1</sup>, A. Carre<sup>1</sup>, I. Quere<sup>1</sup>, J. Cledes<sup>2</sup>, C. Ferec<sup>1</sup>.* 1) Genetic Laboratory, ETSBO-CHU, Brest, France; 2) Nephrology department, CHU la Cavale Blanche, Brest - France.

PKD1, the major gene involved in the transmission of autosomal dominant polycystic kidney disease is actually subjected to intensive molecular analysis all around the world considering the frequency of the disease and the number of patients requiring renal replacement therapy. The molecular analysis of PKD1 is especially not easy undertaking since two thirds of the gene is repeated a number of times on the proximal part of the short arm of chromosome 16, however the identification of locus-specific primers that can selectively amplify PKD1 but not its homologues has enabled the analysis of the 5' region of the gene. Both our group and others have contributed to the identification of more than 150 mutations in this gene, nevertheless the mutation detection rate remains disappointingly low in each group. Using a step of long-range amplification of exons 11-15 from genomic DNA of French ADPKD patients, we performed a DGGE screening for mutations in this PKD1 region. We identified about 20 DNA variants including 11 novel mutations and several polymorphisms. If we take into account these results, to our knowledge 167 mutations have been reported in PKD1 gene up to now; among them 44 (26.34%) are located in exon 15. This rate will be probably higher in a few years when all groups working in this field will achieve their mutation screening. Unfortunately one could not exclude a bias in this analysis, linked to the large size of this exon; however this region of the gene seems to be functionally important binding the PKD domains (previously named immuno-globulin like domains) supposed to play an important role in cell-cell and cell-matrix interactions as suggested recently in vitro. The loss of intercellular interactions due to a mutated protein can be an important step in cystogenesis process actually not yet understood. The occurring of mutation in this region were recently associated with more severe phenotype, however before considering the relationship between PKD1 genotype and phenotype we must extend our mutation screening to the whole coding sequence.

**Evaluation of PCR enzyme related parameters affecting Denaturing High Performance Liquid Chromatography.**

*J. Walter<sup>1</sup>, H. Lamb<sup>1</sup>, C. Griffiths<sup>1</sup>, K. Hecker<sup>2</sup>, M. Robinson<sup>3</sup>, P. Krause<sup>1</sup>, M. Daniels<sup>1</sup>, D. Gjerde<sup>2</sup>, P. Taylor<sup>2</sup>.* 1) Applied Genomics and Molecular Genetics, Transgenomic, Ltd., Crewe, Cheshire, UK; 2) Transgenomic, Inc., San Jose, CA; 3) Transgenomic, Inc., Omaha, NE.

Denaturing High Performance Liquid Chromatography (DHPLC) has gained significant popularity as a method for identifying mutations. Routinely, PCR from genomic DNA samples followed by heteroduplex formation in the presence of a mutation enables resolution of homoduplex and heteroduplex species using Ion Paired Reverse Phase HPLC and the DNASep® Cartridge technology (Transgenomic Inc, CA). A variety of PCR enzymes have been used in conjunction with the DHPLC application to successfully locate both unknown mutations and develop diagnostic genotyping applications. The same principle enabling the discovery of sequence changes in DNA using the DNASep® Cartridge technology and the WAVE® Nucleic Acid Fragment Analysis System allows analysis of the differing PCR enzyme related parameters affecting the quality of DHPLC results. Primarily, the application specific PCR enzyme misincorporation rate can be compared between enzymes since individual misincorporation events throughout the PCR amplification process will be present during subsequent DHPLC sample analysis. The misincorporation events appear as a random low-level heteroduplex peak, which can be comparatively quantified. Secondly, the high throughput nature for DHPLC related applications (SNP mapping and diagnostic genotyping for example) requires a high level of reproducibility, which can be enhanced by PCR component compatibility. One of the major contributors to sample to sample variability lies in the compatibility of PCR buffer constituents in relation to the DNASep® matrix. These two main factors affecting DHPLC related methodologies are examined here for a variety of routinely used PCR enzyme preparations.

**SNP identification, linkage disequilibrium (LD), and maternal origin of mutations within the TSC2 gene.** *P.S.*

*Roberts<sup>1</sup>, J. Chung<sup>1</sup>, S. Jozwiak<sup>4</sup>, S.L. Dabora<sup>1</sup>, A. Nieto<sup>1</sup>, R. Perez<sup>1</sup>, D. Franz<sup>3</sup>, E. Thiele<sup>2</sup>, D.J. Kwiatkowski<sup>1</sup>.* 1) Medicine, Brigham & Women's Hospital, Boston, MA; 2) Neurology, Children's Hospital, Boston, MA; 3) Neurology, Children's Hospital, Cincinnati, OH; 4) Neurology, Children's Hospital, Warsaw, Poland.

Inactivating mutations in the TSC2 gene, consisting of 41 coding exons in 40 kb on 16p13, cause the hamartoma syndrome tuberous sclerosis. We have identified over 250 mutations in the TSC2 gene (e.g. AJHG 2001, 68:64-80). During this analysis we also identified 10 SNPs that occur within exons or close to exon boundaries at minor allele frequencies of > 5%. The last six of these SNPs (minor allele freq. 9-27%) and the microsatellite marker kg8 occur within a region of 600 bp that contains exons 40 and 41; exons 38 and 39 are also nearby. The other four SNPs are found 23-33 kb from this cluster. We genotyped the 6 SNPs and kg8 in a set of 39 Caucasian and 1 African parent-child trios, and determined haplotypes by Mendelian segregation, with cloning as needed. 26 unique haplotypes were determined in the 160 chromosomes of the parents, with the most common haplotypes accounting for 53%, 11%, 6%, and 5% of chromosomes. 12 of 15 pairwise comparisons among the 6 SNPs showed strong LD with  $D' > 0.8$ ; the other 3 had  $D' 0.54-0.68$ . Exons 38-40 are relative hotspots for mutation in TSC2, and we have identified 30 families with small mutations in this region, and 9 families with large genomic deletions that include this region. The haplotypes on which these mutations occurred was determined by cloning and sequencing, and family studies. The distribution of 38 mutation-bearing haplotypes was similar to that of the trio parents, indicating that there was no haplotype that predisposed to mutation in this region of TSC2. When possible we performed family analysis in sporadic cases to determine the parent of origin of mutation. In 7 cases (5 sm mtns, 2 deletions) the mother was the parent of origin, while in 2 cases (both sm mtns) the father was the parent of origin. Thus, mutations in TSC2 are predominantly of maternal origin, in contrast to most other genetic disease.

**Haplotype analysis of tyrosinase gene in OCA1.** *J.E. Pietsch<sup>1</sup>, S. Shriram<sup>1</sup>, J.P. Fryer<sup>1</sup>, R.A. King<sup>1,2</sup>, W.S. Oetting<sup>1,2</sup>.*  
1) Department of Medicine, University of Minnesota, Minneapolis, MN; 2) Institute of Human Genetics, University of Minnesota, Minneapolis, MN.

**Background:** Mutations of the tyrosinase gene produce oculocutaneous albinism type 1 (OCA1). Most affected individuals are compound heterozygotes with different maternal and paternal mutations, and the majority of the identified mutations have been sequence changes in the coding region or adjacent introns. Some individuals with OCA1 have only one of the two mutations identified, however, suggesting another type mutation responsible for loss of function of this allele. We hypothesize that regulatory regions of this gene beyond those currently characterized may be responsible for this loss of function, and therefore have extended our analysis of the 5 promoter region of this gene.

**Methods:** 4000 bp of the 5 promoter region of the tyrosinase gene was sequenced in DNA from 11 individuals with OCA1 who had 1 of 2 mutations identified. Specific parts of this region were then sequenced in DNA from an additional 6 families containing a child with OCA1. **Results:** Four single nucleotide polymorphic (SNP) changes were identified: -3879 (g ® a), -3748 (a ® c), -3421 (g ® a), and 3046 (g ® a). A polymorphic LINE insertion was also identified at 2093. Extended haplotypes were constructed with the 4 new SNPs, the insertion, and the known polymorphisms at 301 (c®t), -199 (c ® a), codon 192 (C ® A), codon 402 (G ® A) and the Taq I site in intron 1. One extended haplotype was found in 6/9 individuals with OCA1 and only 1 of 2 identified mutations. In all cases, the haplotype represented the allele without the mutation. The haplotype was not found in the parent who carried the mutation nor in individuals with both mutations identified. **Conclusion:** We have identified a haplotype of the tyrosinase gene in OCA1 that has no pathologic sequence change in the coding region but is associated with the loss of pigmentation. The mutation(s) responsible for inactivation of this allele appears to be in disequilibrium with this haplotype but has not been identified.

**Usher Syndrome type I mutations in MYO7a and Harmonin.** *M.D. Weston, L.M. Astuto, C.A. Carney, W.J. Kimberling.* Dept Genetics, Boys Town National Res Hosp, Omaha, NE.

Usher syndrome type I (USH1) is a genetically heterogeneous autosomal recessive disease of congenital profound hearing loss, vestibular areflexia and retinitis pigmentosa. Six genetic subtypes (USH1A-F) and 3 genes have been discovered to cause the disease. The most prevalent genetic subtype, USH1B, is caused by mutations in MYO7A. The causative genes for USH1C, USH1D and USH1F have been shown to be the harminin, CDH23 and PCDH15. As these and other genes involved in Usher Syndrome are discovered, an accurate molecular diagnosis of the causative gene defect will be an important variable in evaluating the benefit of existing and new treatment options for slowing and/or arresting retinal deterioration. The accuracy of genetic counseling of recurrence risk estimation will also be increased as the distribution and frequencies of mutations is more accurately estimated ethnically and geographically. Towards this end, clinical cases of USH1 have been screened for mutations in 3 of the known genes. Based on tests of genetic heterogeneity using linkage data, 70% of Usher I cases were compatible with linkage to 11q with the majority of the rest showing 10q linkage, the location for both USH1D (CDH23) and USH1F (PCDH15). From an original cohort of 152 clinical cases of Usher type I, mutation screening in MYO7a diagnosed ~40% (67/152) of these cases. Results of CDH23 and Harmonin mutation screening to date have diagnosed an additional ~9% (13/152) and ~4% (6/152), respectively, from this same cohort. The previously published MYO7a missense mutations R1602Q and Y1719C, are questionable in producing the Usher phenotype, based on cis linkage to other more highly conserved missense mutations and/or their presence in control populations.

**Possible involvement of interleukin 10 receptor alpha (IL10RA) in Familial Enteropathy with Villous Edema.**

*M.J. Somerville<sup>1</sup>, A.Y. Ng<sup>1</sup>, M. Hicks<sup>1</sup>, S.M. Haase<sup>1</sup>, T. Johnson<sup>1</sup>, J.S. Bamforth<sup>1</sup>, H.F. Pabst<sup>2</sup>, M.A. Walter<sup>1</sup>, K.A. Sprysak<sup>1</sup>, B.G. Elyas<sup>1</sup>, L.M. Vicen-Wyhony<sup>1</sup>.* 1) Dept Medical Genetics, Univ Alberta, Edmonton, AB, Canada; 2) Pediatrics, University of Alberta, Edmonton, AB, Canada.

Familial Enteropathy with Villous Edema and immunoglobulin G2 deficiency (FEVE; MIM 600351), is an autosomal dominant disorder that typically manifests in childhood as a recurrent acute, life-threatening secretory diarrhea associated with distinctive jejunal histologic changes and IgG2 subclass deficiency. Symptoms typically begin abruptly with anorexia and vomiting, and rapidly progress to massive secretory diarrhea and shock with profound neutropenia and hypoproteinemia, including hypoalbuminemia and hypogammaglobulinemia. We previously reported the results of a genome-wide screen for the FEVE locus, in which a 12.5cM region on chromosome 11q23 was identified with a LOD score of 6.2. Subsequent work using a higher density marker array has reduced the critical interval to about 9 cM. Several candidate genes map to this region and we have initiated sequencing in parallel with ongoing linkage analysis.

The CD3-delta subunit, which maps to the FEVE region, has been previously reported to be associated with intestinal malabsorption. Sequencing of this gene in affected FEVE family members revealed a C->G transversion, but this base change in intron 4 (IVS4+60) is not predicted to affect exon splicing.

Interleukin 10 down-regulates the inflammatory response, and protects against the lethality of intra-abdominal infection and sepsis. Interleukin 10 receptor alpha maps to the FEVE critical region. Sequencing of this gene revealed an A->G transition in exon 2 resulting in a Serine to Glycine missense substitution (S101G). This mutation segregates with the condition in this family, and has not been found in any unrelated controls. The mouse protein sequence contains a glutamine at this position, with extensive proximal sequence homology. This mutation is currently unclassified, but work is ongoing to determine whether IL10RA may play a direct role in FEVE.

**Genotype frequencies of C282Y and H63D alleles in the Hemochromatosis (HFE) gene from 16,822 patient samples submitted to a reference laboratory for HFE genotyping.** *W. Sun, A. Buller, N. Huynh, S. Huang, M. Vu, L. Avila, C. Chen, B. Bower, S. York, T. Entwistle, C. Strom.* Molec Gen Dept, Nichols Inst, Quest Diagnostics Inc, San Juan Capistrano, CA.

Hereditary hemochromatosis (HH) is one of the most common autosomal recessive genetic diseases in the US affecting between 1:200 - 1:500 people. Two missense mutations (C282Y and H63D) in the HFE gene have been associated with HH. This study investigated genotype frequencies of these mutations in samples sent to a reference laboratory for HFE genotyping. It is assumed these patients have symptoms of iron overload and / or positive family histories of HH. These data are important for quality assurance monitoring of HH testing and for clinicians to be aware of the percentage of such patients who will actually have HFE mutations.

Quest Diagnostics / Nichols Institute has been performing HH genotyping since 12/99. Since that time 16,839 specimens were submitted and 16,822 (>99.8%) were successfully genotyped. We compared our data to those of a recent study (Steinberg et al, JAMA 285:2216-2222) reporting the frequency of these alleles in an unselected US population cohort of 5,171 individuals. Our population had a 53 fold increase in the frequency of homozygous C282Y (14% vs 0.26%), with more modest elevations (3.6 fold and 1.8 fold) in the frequency of compound heterozygotes for C282Y / H63D (7.1% vs 1.97%) and homozygotes for H63D (3.5% vs 1.89%).

Several studies have demonstrated the prevalence of C282Y homozygotes in patients with HH. These data provide further evidence that the C282Y mutation is an important contributor to HH. The minimal enrichment of patients with H63D mutations in the patient population sheds further questions on whether this allele is a significant contributor to iron overload syndromes despite the published observation of a significantly increased risk of HH in homozygotes for H63D.

**Screening a human male infertility candidate gene, *BOULE*, to identify sequence variants in infertile men.** *E.Y. Xu<sup>1</sup>, D. Lee<sup>1</sup>, P. Turek<sup>2</sup>, R.A. Reijo Pera<sup>1</sup>.* 1) OBGYN and Reproductive Science, Univ. of California-San Francisco, San Francisco, CA; 2) Dept. of Urology, University of California-San Francisco.

**Objectives:** Genetic male infertility has begun to explain a significant fraction of male infertility, despite our knowledge of only few identified genes. One way to improve our understanding of genetic causes of infertility is to identify candidate fertility genes and then to screen for gene mutations in a population of infertile patients. We have identified a candidate gene, *BOULE*, that is specifically expressed in human testes. Our goal is to try to study the function of this gene by screening for single nucleotide polymorphisms (SNPs) and mutations in this gene in a population of infertile patients. **Design:** Analysis of the coding region of *BOULE* gene by DNA sequencing and DHPLC analysis in a population of azoospermic and oligospermic men. **Methods:** DNA from a bank of infertile men (n=100 patients) was assessed for the integrity of *BOULE* gene. Primers were designed that surround and amplify each exon of the candidate gene by PCR. The PCR product for each exon was then used for detection of SNP or mutations by two techniques: DHPLC and sequence analysis. **Results:** There are total of 11 exons in this gene that encompass a 70kb genomic region. Initial screening for SNPs or mutations in exon 3 of this candidate male fertility gene in 50 infertile men has revealed 3 SNP sites in 2 azoospermic patients and 1 oligospermic patient. A systematic survey of all exons in more infertile patients and compared to a cohort of fertile patients is in progress. **Conclusions:** Identification of several SNPs in *BOULE* gene from a population of infertile men is encouraging, however, to make any link between those SNPs and male fertility, we need to compare these alterations to those found in normal fertile men and to examine RNA and protein expression of this candidate gene in the patients harboring those sequence variants.

**Characterization of FOXL2 mutations in patients affected with Blepharophimosis syndrome (BPES).** *V. Yellore<sup>1</sup>, N. Udar<sup>1</sup>, M. Chalukya<sup>1</sup>, S. Yelchits<sup>1</sup>, R. Silva-Garcia<sup>1</sup>, K. Dipples<sup>1</sup>, C. von Kap-herr<sup>2</sup>, M.J. Pettenati<sup>2</sup>, E. McCabe<sup>1</sup>, K. Small<sup>1</sup>.* 1) Department of Ophthalmology, Jules Stein Eye Inst and Department of Pediatrics, University of California, Los Angeles, CA; 2) . Department of Pediatrics, Section on Medical Genetics, Bowman Gray School of Medicine of Wake Forest University Medical Center, Winston-Salem, North Carolina 27157, USA.

Blepharophimosis syndrome (BPES) is a rare autosomal dominant disorder localized on human chromosome 3q23. This disorder is characterized by blepharophimosis (shortening of the palpebral fissures), ptosis, epicanthus inversus and telecanthus. In type I and type II BPES differ in the previous one being associated with female ovarian failures. Due to the defect in the palpebral fissure the patients tend to tilt their head backwards in order to see. There is also a high rate of sporadic mutations. The gene for this disease was cloned recently. The gene responsible for this disease is winged/forkhead transcription factor FOXL2. The level of proline and alanine are high in this protein. We have carried out mutation analysis on 30 individuals affected with this disease. We have identified mutations in 50% of these individuals. These mutations range for missense mutation to small deletion and duplication in the polyalanine and polyproline track. In patients with large deletions we have additional features like cardiac defects and mental retardations associated with the disease. Unidentified deletions and mutations in regulatory elements of the gene might account for some of the remaining patients.

**Genotype-phenotype correlations in methylmalonyl-CoA mutase deficiency.** *C. Cavicchi, A. Morrone, T. Bardelli, S. Funghini, M.A. Donati, G.M. Poggi, E. Pasquini, E. Zammarchi.* Dep. of Paediatrics, University of Florence, A.O. "A. Meyer", Florence, Italy.

Methylmalonyl-CoA mutase (MCM) deficiency is an autosomal recessive inborn error of metabolism, leading to methylmalonic aciduria (MMA). Biochemical cell studies delineate two phenotypic variants:  $\text{mut}^0$  with no detectable enzymatic activity and  $\text{mut}^-$  with a residual mutase activity. Clinical manifestations vary from benign persistent MMA to severe neonatal forms. The MCM enzyme comprises different functional domains: N-terminal domain involved in dimerization of two monomers, (b/a)<sub>8</sub> barrel domain with the CoA-binding site, C-terminal (b/a)<sub>5</sub> domain with the cobalamin-binding site. Three novel amino acid substitutions R108H, G215S and C560Y and a new small deletion c1758delA were identified in the MCM gene (MUT) of three Italian patients affected by neonatal severe form of  $\text{Mut}^0$  MMA. Both the R108H and G215S involve highly conserved residues of the barrel domain. The R108 is localised in the first b-strand of the barrel which lines the access channel for CoA ester substrates to the MCM active site. It can be hypothesized that the C560Y mutation, located in the linker region between barrel and C-terminal domain, alters the structural stability of MCM protein. The c1758delA leads to an early stop codon that destroys the B12 binding domain. The severe alteration of structure and/or function of MCM enzyme, caused by the above-mentioned mutations, demonstrates the deleterious nature of these defects, that can be correlated with the severe clinical phenotype. One patient with a mild form of neonatal  $\text{Mut}^0$  MMA was compound heterozygous for the new in frame deletion c1038-1040delTCT and for the G215S mutation. The c1038-1040delTCT results in deletion of a barely conserved leucine residue (346delL). Since the G215S was identified at homozygous level in one of the patients with severe MMA the c1038-1040delTCT can be correlated with the mild clinical phenotype. In addition two new (K212K and A499T) and two known (H532R, V671I) polymorphisms were identified. The financial support of Cometa-Italy is gratefully acknowledged.

**FGFR3 mutations associated with acanthosis nigricans increase keratinocyte survival via PI3-K/Akt signaling.**

*G.A. Bellus, J. Janik, D.P. Kelly.* Dept Dermatology, B-153, Univ Colorado Health Sci Ctr, Denver, CO.

Acanthosis nigricans (AN) is a non-malignant hyperproliferative skin disorder that is often associated with metabolic states characterized by increased activity of growth factor signaling pathways (e.g. hyperinsulinemia or neoplasia). AN also occurs in patients who carry unique, activating FGFR3 mutations associated with the Crouzono-dermato-skeletal (A391E) and SADDAN (K650M) syndromes. Previously, we reported evidence that keratinocytes from patients with FGFR3 A391E or K650M mutations, in comparison to control keratinocytes, express increased amounts of the anti-apoptotic protein bcl-2 and are resistant to several different triggers that induce apoptosis. Based on this data we hypothesized that AN may result from prolonged survival of keratinocytes in the epidermis due to activation of signaling pathways that disrupt the normal process of differentiation and programmed cell death. In patients without FGFR3 mutations, AN is often associated with inappropriate activation of IGF-1 or EGF receptors by circulating growth factors. These receptors affect many signaling molecules including activation of PI3-K. PI3-K activation leads to phosphorylation of Akt which, in turn activates several different cellular survival signals. Using quantitative Western blots, we determined that, under growth factor deprived conditions, keratinocytes with FGFR3 A391E or K650M mutations have 3 to 7 times higher levels of phosphorylated Akt than control keratinocytes. Levels of the PI3-K inhibitor PTEN were not significantly different among mutant and control keratinocytes. Furthermore, treatment of FGFR3 A391E and K650M keratinocytes with the PI3-K inhibitors wortmannin or LY294002 restored levels of apoptosis caused by uv irradiation, cisplatin or beauvaricin to that of control keratinocytes. This data supports our hypothesis that AN results from increased survival of keratinocytes in the epidermal compartment and that activation of PI3-K/Akt by mutant FGFR3 receptors may play an important role in the pathogenesis of AN in Crouzono-dermato-skeletal syndrome and SADDAN syndrome.

**Molecular analysis and prenatal screening in spinal muscular atrophy in Singapore.** *P.S. Lai<sup>1</sup>, M.H. Liew<sup>1</sup>, S. Abbs<sup>2</sup>, S. Tay<sup>1</sup>, W.C. Yee<sup>3</sup>, A. Biswas<sup>4</sup>, S.C. Ng<sup>4</sup>, P.S. Low<sup>1</sup>.* 1) Dept Pediatrics, National Univ Singapore, Singapore, Singapore; 2) Genetics Centre, Guy's and St Thomas' Hospital Trust, London, UK; 3) National Neuroscience Institute, Singapore; 4) Dept Obstetrics & Gynaecology, Nat Univ Hospital, Singapore.

Spinal muscular atrophy (SMA) is an autosomal recessive disorder characterized by progressive anterior horn cell degeneration. There are three phenotypes based on clinical severity and onset age. All three types map to chromosome 5q13 and nearly 95% of patients display deletion of the SMN1 gene. The involvement of NAIP gene and possible modifier genes like H4F5 have also been implicated in some patients. We report a study on 31 SMA children of Asian ethnicity. 87% of patients show deletion of exon 7 of the telomeric SMN gene (SMNI), 74.2% showed deletion in exon 8, and 6.5 % showed NAIP gene deletion. Among the subtypes, homozygous deletion of exon 7 of SMNI was detected in 77.8%, 100% and 66.7% of type I, II and III patients respectively, homozygous deletion of exon 8 of SMNI was detected in 66.7%, 81.3% and 66.7% in the respective subtypes while NAIP was observed in 22.2% of type I patients only. This unusual pattern of homozygous deletion may be due to a different molecular basis for SMA in our population, such as presence of point mutations, conversion events and hybrid SMN gene. No SMNI or NAIP homozygous gene deletions have ever been found in our normal population, and it is clear that for affected patients, SMNI gene deletions would be diagnostic for SMA. We have also carried out prenatal diagnosis on a fetus conceived by intrauterine artificial insemination from an anonymous sperm donor. The family had a previous child also conceived by artificial insemination using sperms from the azoospermic father's brother who presented clinically with SMA type II. SMNI exons 7 and 8 were deleted in the affected child. Prenatal testing of the fetus demonstrated absence of the SMNI gene deletions. However, we were unable to determine in this particular analysis, if the fetus is a carrier. Nonetheless, since at least one SMNI gene copy is intact, this child should not be affected.

**Laminin is required to produce membrane instability in muscular dystrophy mediated by sarcoglycan loss.** *E.M. McNally*<sup>1</sup>, *K. Lavidos*<sup>2</sup>, *M. Hadhazy*<sup>1</sup>, *A.A. Hack*<sup>2</sup>. 1) Department of Medicine, The University of Chicago, Chicago, IL; 2) Department of Molecular Genetics Cell Biology, The University of Chicago, Chicago, IL.

The sarcoglycans, a group of transmembrane proteins in muscle and heart, are part of the dystrophin glycoprotein complex (DGC). Mutations in sarcoglycan genes cause cardiomyopathy and muscular dystrophy in humans and in mice by producing instability of the remaining sarcoglycans while leaving dystrophin intact. In contrast, mutations in dystrophin cause a reduction in not only the sarcoglycans, but also in additional DGC proteins such as the syntrophins and dystrobrevins. We used a genetic analysis to evaluate whether sarcoglycan is sufficient to mediate membrane instability and by generating mice lacking both dystrophin (*mdx*) and g-sarcoglycan. Mice lacking both g-sarcoglycan and dystrophin (*gdx*) had an identical phenotype to mice lacking only g-sarcoglycan with a similar degree of central nucleation and serum creatine kinase elevation. This demonstrates that sarcoglycan loss is sufficient to produce alterations in membrane permeability and the dystrophic process. In parallel experiments, we evaluated the role of the extracellular matrix protein laminin in the dystrophic process by producing mice mutant for both g-sarcoglycan and laminin-a2. Laminin-a2 is the major site of attachment to the extracellular matrix for the DGC. Mice mutant for both g-sarcoglycan and laminin-a2, (*gdy*), surprisingly displayed a severe dystrophic process yet had little evidence for disruption of membrane integrity. Little to no Evans Blue Dye uptake was seen and serum creatine kinase was only minimally elevated in (*gdy*) mice. These genetic analyses demonstrate that sarcoglycan loss is sufficient to produce the dystrophic process, and that laminin is required for disruption of membrane integrity and increased membrane permeability that is seen when sarcoglycan is absent.

**X-linked adrenoleukodystrophy associated with 10 novel ABCD1 gene mutations in 23 Portuguese families.** C.P. Guimaraes<sup>1,2</sup>, M. Lemos<sup>1,3</sup>, J.E. Azevedo<sup>1,2</sup>, M.C. Sá Miranda<sup>1,3</sup>. 1) Genetic Neurobiology, IBMC-UP, Oporto, Portugal; 2) ICBAS-UP, Oporto, Portugal; 3) Enzymology Department, IGMJM; Oporto, Portugal.

X-linked adrenoleukodystrophy (X-ALD) is a severe neurodegenerative disease. It has been associated with mutations in the ABCD1 gene, which encodes a peroxisomal half ATP-binding transporter (ALDP).

In order to characterize the molecular lesions underlying the biochemical defect, the mutational spectrum of the X-ALD Portuguese families was determined.

A RT-PCR based mutation screening was the preferred methodology. All the amplified products covering the entire coding region were analyzed by CSGE and only the altered fragments were sequenced. The results obtained show that the association of RT-PCR with CSGE analysis is highly efficient, since 100% of mutations are detected at the CSGE step. Using this strategy we have identified 14 missense, two nonsense mutations, three small deletions (two of them resulting in frameshift) and three splicing defects (of which two also allow the production of normal mRNA molecules). Additionally, two polymorphisms were found. The identification of 10 new mutations and 1 new polymorphism adds to the large number of genetic alterations already described as being associated with X-ALD.

Immunoblotting studies were also performed in patient's fibroblasts. Normal levels of ALDP were found in three patients and decreased in all the others affected with missense mutations. In the two splicing cases where we observed the presence of non-mutated ALDP, the levels of this protein were quantified. In patients with either nonsense, frameshift mutations or with a double mutated gene (with two missense) ALDP was not detectable.

The molecular analysis of X-ALD gene still remains of extreme importance in the pre-natal diagnosis, carrier detection and in the early identification of at risk males. The characterization of mutations in X-ALD would also be important for the elucidation of X-ALD pathogenic mechanism.

**The contribution of genotypes at the SAA1 locus to amyloidosis and disease severity in patients with Familial Mediterranean fever.** *R. Gershoni-Baruch*<sup>1,3</sup>, *R. Brik*<sup>2,3</sup>, *M. Shinawi*<sup>1</sup>, *T. Paperna*<sup>1</sup>, *A. Livneh*<sup>4</sup>. 1) Institute of Human Genetics, Rambam Medical Center, Haifa, Israel; 2) Pediatric Rheumatology Service, Rambam Medical Center; 3) The Bruce Rappaport Faculty of Medicine, Technion-Israel Institute of Technology, Haifa, Israel; 4) Heller Institute, Tel-Hashomer, Israel.

Familial Mediterranean fever is an autosomal recessive disease characterized by recurring attacks of fever and serositis. Amyloidosis, leading to renal failure, is the most severe manifestation. Mutations in the pyrin/marenostrin (MEFV) gene have been identified in the majority of patients. The wide clinical variability of the disease has been partly attributed to MEFV allelic heterogeneity with the M694V mutation and particularly the M694V/M694V genotype being associated with a severe phenotype and amyloidosis. Since patients with identical mutations vary in their clinical manifestations especially as regards the development of amyloidosis, a role for additional genetic and/or environmental modifiers has been proposed. Recently, polymorphisms at the SAA1 (serum amyloid A1) locus, or rather the SAA1a/a genotype, were found to influence susceptibility to renal amyloidosis. In this study we evaluated the contribution of genotypes at both the MEFV and the SAA1 loci to disease severity and amyloidosis. DNA samples from 220 FMF patients (42 of them with amyloidosis) in whom two mutant FMF alleles have been identified, were further analyzed for genotypes at the SAA1 locus. Disease severity was calculated according to Tel-Hashomer severity score. Of the 42 patients with amyloidosis 33 (78%) were M694V homozygotes, while the rest were compound heterozygotes for either the M694V or the complex V726A-148Q allele. Fourteen of them (33%) had the SAA1a/a genotype in comparison to only 17/178 (10%) of the pt's without amyloidosis. No correlation was found between disease severity and the presence of the SAA1a/a genotype. The results of this study agree with the observation that the SAA1 locus plays a key role in conferring genetic susceptibility to amyloidosis. Otherwise, polymorphisms at the SAA1 locus were not found to be associated with disease severity.

**Targeted disruption of the Diamond-Blackfan anemia homologue *Rps19* in mice.** *H. Matsson*<sup>1</sup>, *D. Drapchinskai*<sup>1</sup>, *E. Davey*<sup>1</sup>, *E. Forsberg*<sup>2</sup>, *P. Leveen*<sup>3</sup>, *S. Karlsson*<sup>3</sup>, *N. Dahl*<sup>1</sup>. 1) Genetics and Pathology, The Rudbeck Laboratory, Uppsala University, Sweden; 2) Medical Biochemistry and Microbiology, BMC, Uppsala, Sweden; 3) Gene Therapy Center, WNC, University of Lund, Sweden.

Diamond-Blackfan anemia (DBA) is a rare bone marrow failure syndrome characterized by specific decrease or absence of erythroid precursors. Additional anomalies are present in 20-30% of cases including short stature, limb malformations and heart defects. Patients present with a variable expression of the disease and the overall mortality rate is approximately 30%. The disease may be inherited as a dominant trait but most cases are sporadic. The molecular mechanisms behind DBA are unknown. However, the gene encoding ribosomal protein S19, *RPS19*, is mutated in 25% of patients. The *RPS19* gene consists of six exons of which five encode a 16-kDa protein located in the small ribosomal subunit. Diamond-Blackfan anemia is the first proven example of a disease caused by mutations in a gene encoding a ribosomal protein, suggesting an extra-ribosomal role of the S19 protein. Evidence for additional functions of ribosomal proteins have previously been gathered from studies of *D. melanogaster* and *C. elegans* models. In human, a homodimer of *RPS19* is believed to act as a chemotactic factor involved in removal of apoptotic cells. A mouse model with one *Rps19* allele deleted for exon 1-5 was created in order to gain new insight into the functions of the ribosomal protein S19. We show that mice with targeted disruption of one *Rps19* allele are viable. Male mice are sterile and associated with a reduced testicular volume whereas female mice show reduced fertility. Reduced fertility is not reported in patients with DBA and our findings suggest an extra-ribosomal function for *Rps19* in mouse gonadal development.

**MEFV mutant alleles sustain a differential role in the clinical profile of familial Mediterranean fever. M.**

*Shinawi<sup>1</sup>, R. Brik<sup>2,3</sup>, T. Papperna<sup>1</sup>, A. Livneh<sup>4</sup>, R. Gershoni-Baruch<sup>1,2</sup>.* 1) Dept of Medical Genetics, Rambam Medical Center, Haifa, Israel; 2) Pediatric Rheumatology Service, Rambam Medical Center; 3) Bruce Rappoport Faculty of Medicine, Technion-Israel Institute of Technology; 4) Heller Institute, Sheba Medical Center, Tel-Hashomer.

Familial Mediterranean fever (FMF) is an autosomal recessive disease characterized by recurring attacks of fever and serositis. Amyloidosis, leading to renal failure, is the most severe manifestation. Five sequence alterations (M694V, V726A, M680I, M694I and E148Q) in the MEFV gene account for the majority of FMF chromosome. The wide clinical variability of the disease has been attributed, in part, to MEFV allelic heterogeneity. Homozygotes for the M694V mutation have a more severe form of the disease and more frequently demonstrate articular and renal manifestations. Mutations E148Q and V726A have reduced penetrance. The clinical features, associated with the M680I and the complex V726A-E148Q allele, are not well defined. The aim of this study is to further characterize the phenotypic profile associated with the major MEFV mutations, particularly M680I, M694I and the complex V726A-E148Q alleles, predominant in our FMF patients of Arab origin. We investigated 230 FMF patients (135 Jewish and 95 Arabs) in whom both FMF alleles have been identified and found that different mutations and genotypes are distinguished by a differential clinical profile and penetrance. Homozygotes for mutations at the 694 locus (M694I and M694V) are frequently severely affected. Homozygotes for the complex V726A-E148Q allele are at least as severely affected and often endure renal amyloidosis. The complex V726A-E148Q and the M694V alleles are associated with the most severe form of the disease. Compound heterozygotes for the complex V726A-E148Q allele in combination with either the E148Q, the V726A or the M680I allele are more severely affected than compound heterozygotes for the M694V allele with either of these alleles. The morbidity associated with the complex V726A-E148Q allele by far outweighs that associated with the V726A allele, bearing evidence to the fact that the E148Q mutation is not a benign polymorphism.

**Genetic Polymorphism of Aldehyde dehydrogenase in Chinese: Sex, Age, Geography, Culture and Genotypes of ALDH2.** *H-R. Luo, Y-P. Zhang.* Lab Cellular & Molec Evol, Kunming Inst Zoology, Kunming, Yunnan 650223, People's Republic of China.

The genetic polymorphisms of the aldehyde dehydrogenase-2 (ALDH2) locus have been considered a potential explanation for individual differences in drinking behavior and those individuals with the defected, atypical ALDH2<sup>2</sup> alleles are alcohol flushers because of the acetaldehyde can't be metabolized in time. In order to understand the relation between the age, sex, geography and the genotypes of ALDH2, we have invested the ALDH2 genotypes in total six hundred and thirty-eight unrelated healthy Chinese samples from 7 Chinese geographic populations with different sex and age in current assay. The frequency for the atypical ALDH2<sup>2</sup> allele in the total samples was 17.71%. The frequencies of the ALDH2<sup>1</sup>/ALDH2<sup>1</sup>, ALDH2<sup>1</sup>/ALDH2<sup>2</sup> and ALDH2<sup>2</sup>/ALDH2<sup>2</sup> genotypes in the 638 subjects were 68.65% (438/638), 27.27% (174/638) and 4.08% (26/638), respectively. The frequencies of the individuals with the atypical ALDH2<sup>2</sup> allele was ranged from 22.00% (Wuhan Han) to 54.35% (Guangdong Han) in different Chinese geographic groups, which was similar to that of other reported Asian populations (28%-56%). The individuals from Guangdong Han population had significantly higher frequencies of the atypical ALDH2<sup>2</sup> alleles (30.98%) than the other geographic populations had (12.00%-20.00%)( $p < 0.01$ ), which suggested that there were some differences in the atypical allele frequency in different geographic populations. The different sex and age had little effect on the frequencies of ALDH2<sup>2</sup> allele ( $p > 0.05$ ). The low alcohol consumption in Chinese women could be explained by culture, but not genotypes of ALDH2. The probable reason for the no difference between the three age groups (Infant, Young and Old) was that the individuals with the atypical alleles could discount the alcohol intake, and consequently the defected alleles did not affect the survival of the individuals. This was the first report about age-related ALDH2 genotypes, so the results of this assay could provide some information for the further studies of ALDH2 genotypes.

**Association between c-erbB-2 codon 655 polymorphism and NF1.** *L. Fishbein, S.A.M. Thomson, B. Eady, M.R. Wallace.* Molecular Genetics and Pediatric Genetics, Univ. of Florida, Gainesville, FL.

Neurofibromatosis 1 (NF1) is an autosomal dominant disorder characterized by overgrowth of neural crest derived tissues, such as neurofibromas. There is variable expressivity and it is thought that other genes likely modify NF1 phenotype. The proto-oncogene c-erbB-2 (or HER2/neu) encodes a tyrosine kinase receptor. A member of the epidermal growth factor receptor family, c-erbB-2 is thought to control cellular functions such as cell proliferation. After dimerization with other erbB family members and activation, c-erbB-2 transmits a signal downstream to cytoplasmic targets, including the MAPK pathway, also downstream of NF1. ErbB proteins have roles in neural crest proliferation and/or have been implicated in neurofibroma development. The c-erbB-2 gene is frequently amplified or over-expressed in breast cancer and a number of adenocarcinomas. Animal models of neurofibromas have a specific activating c-erbB-2 mutation, although no human tumors have been reported with this mutation. An Ile/Val polymorphism exists at codon 655 in the transmembrane domain near the mutation. It is not known if this polymorphism results in different tyrosine kinase activities. However, there is an association of the Val allele with an increased risk for breast cancer. The role that the c-erbB-2 gene product plays in cell proliferation, as well as the critical function of the transmembrane domain in the receptor activation, make this polymorphism a strong candidate for a modifier gene for NF1. As an initial analysis, we examined the association between the c-erbB-2 codon 655 alleles and NF1. Our study has found that the Val allele was less prevalent ( $p=0.009$ ) among NF1 patients ( $n=184$ ) than among our control populations ( $n=274$  combined). In fact, the number of NF1 patients with a homozygous Val/Val genotype is significantly lower ( $p=0.044$ ) than that found in our control populations. Despite this, the number of heterozygous Ile/Val and Ile/Ile genotypes is not significantly different in the NF1 population. This may suggest that there is a selective mortality associated with the combination of an NF1 mutation and a c-erbB-2 homozygous Val/Val genotype.

**Homologous sequences between *CHST5* and *CHST6*, which occur gene conversion and cause macular corneal dystrophy type II.** *T. Akama*<sup>1</sup>, *A. Tanigami*<sup>2</sup>, *M.N. Fukuda*<sup>1</sup>. 1) Glycobiology Program, The Burnham Inst, La Jolla, CA; 2) Otsuka GEN Research Institute, Tokushima, Japan.

*CHST6* (carbohydrate sulfotransferase 6) is located next to *CHST5* with the same orientation on Chr.16q22. These two genes are highly homologous to each other not only in the coding region but also in the upstream and downstream sequences, suggesting that *CHST5* and *CHST6* were created by gene duplication during evolution<sup>1</sup>. This hypothesis is supported by the fact that mouse genome has only one orthologue (*Chst5*) corresponding to *CHST5* and *CHST6*<sup>2</sup>. Unequal cross-over and gene conversion between *CHST6* and *CHST5* cause a lack of enzymatic activity of corneal GlcNAc 6-O sulfotransferase, encoded by *CHST6*, in corneal cells and result in a recessive hereditary eye disease, macular corneal dystrophy (MCD). By sequencing of a BAC clone that contains *CHST5* and *CHST6*, and by collecting sequences from human genome database, we assembled a large contig covering *CHST5* and *CHST6*. We also identified junction sequences of a gene conversion found on *CHST6* of MCD patient's genome. A 3 kbp converted region was located on 4.2 kbp upstream of *CHST6* exon 1 and each of both flanking sequences of the donor (*CHST5*) and acceptor (*CHST6*) were highly homologous (more than 90 %) to each other. Chi-like sequences were also found in the flanking sequences of the converted region. The upstream region of *CHST6*, which is lost in MCD type II, may contain corneal epithelium-specific enhancer because MCD type II patient lacks *CHST6* expression in the corneal epithelium but not in the other tissues such as cartilage.

**Regulation of expression of the *JAGGED1* gene responsible for Alagille syndrome.** *M. Meunier-Rotival<sup>1</sup>, L. Luron<sup>1</sup>, C. Crosnier<sup>1</sup>, N. Raynaud<sup>1</sup>, C. Driancourt<sup>1</sup>, J. Boyer<sup>1</sup>, M. Hadchouel<sup>1,2</sup>.* 1) Genetique et maladies du foie de l'enfant, INSERM U347, Kremlin-Bicetre, France; 2) Service Hepatologie pediatrique, Hopital de Bicetre, France.

Heterozygous mutations in *JAGGED1*, encoding a ligand for Notch receptors, cause Alagille syndrome (MIM 118450), a polymalformative disorder affecting mainly the liver, heart, skeleton, eye and face. Minor features involving kidney, arteries, ear, and limb have also been described. Haploinsufficiency could be invoked due to cytogenetically visible deletions in 20p12, or mutations in the very 5'-translated part of the gene. The sites of *JAGGED1* transcription during human development are correlated with tissues affected by the major and minor features of the syndrome. The Notch signaling pathway is known to be very sensitive to gene dosage. To gain insight into the regulation of *JAGGED1* expression, we performed transient transfections with the Dual Luciferase Reporter Assay system in Cos cells. Five overlapping fragments corresponding to the 5'-flanking sequence (ranging from -239 to -2760 bp) were tested. A high luciferase activity was detected with the fragment spanning 500 bp upstream of the mRNA start, suggesting the presence of positive regulatory elements. Computational analyses indicated various binding sites for transcription factors such as Sp1, AP1, AP2, and GATA, in this region. These factors mostly correspond to ubiquitous factors (except for GATA), and could be involved in the basic activity of the promoter. Given that *JAGGED1* is mainly expressed in the cardiovascular system, experiments with other cell lines including endothelial cells will be performed to test the tissue-specificity of *JAGGED1* expression. meunier@infobiogen.fr.

**Genetic mechanisms of puberty-onset amelioration of hemophilia B Leyden: animal models, and critical roles of ASE and growth hormone.** A. S. Kurachi, J. Huo, A. Ameri, H. Atoda, K. Kurachi. Human Genetics, University of Michigan Medical School, Ann Arbor, MI.

Hemophilia B Leyden is characterized by its unique puberty onset amelioration of bleeding. This phenotype is caused by specific single-nucleotide mutations clustered in a small region (LSR) of the 5' UTR of human factor IX (hFIX) gene. Recently we determined the age-regulatory mechanisms of the hFIX gene, identifying two critical genetic elements ASE and AIE, which are essential for age-dependent stable and increasing expression patterns of the gene, respectively (Science 1999;285:739-743). These findings enabled us to construct transgenic mouse models, robustly recapitulating the Leyden phenotype. Both male and female transgenic mice carrying -802(-20A)FIXm1, a mutant hFIX minigene which contains ASE and a Leyden mutation at nt -20 (T to A change), but not animals carrying a hFIX Leyden minigene, -416(-20A)FIXm1 which lacks ASE, fully recapitulated the unique Leyden characteristics (puberty-onset induction of hFIX gene expression). Hypophysectomy and growth hormone (GH) supplementation performed with these transgenic animals showed that the GH signal transduction pathway, but not that of androgen, is directly responsible for the amelioration, supporting that both male and female animals can have the hFIX Leyden phenotype. Animal models of other Leyden mutations (nt +13) as well as a null-amelioration mutation at nt -26 (Brandenburg phenotype) were also successfully constructed. Together, these observations indicate that the mechanisms of puberty-onset amelioration of hemophilia B Leyden involve a unique set of gene expression switches occurring through the puberty period. After years of elusiveness, the basic genetic mechanisms of hemophilia B Leyden have finally been established. Such mechanisms are also being implicated in subsequent age-associated regulation not only of the hFIX gene but also many other genes.

**Phenotypic and genetic heterogeneity of unexplained neonatal/early infantile respiratory distress in Reunion**

**Island : SP-B deficiency and alveolar proteinosis.** *M. Tredano*<sup>1</sup>, *M. Griese*<sup>2</sup>, *J. de Blic*<sup>1</sup>, *F. Capron*<sup>1</sup>, *E. Mallet*<sup>3</sup>, *C. Houdayer*<sup>1</sup>, *J-L. Alessandri*<sup>3</sup>, *D. Feldmann*<sup>1</sup>, *R. Couderc*<sup>1</sup>, *J. Elion*<sup>1</sup>, *M. Bahuaud*<sup>1</sup>. 1) Biochimie et Biologie Moléculaire (M.T., C.H., D.F., R.C., M.B.), Hôpital Trousseau ; Pneumologie et Allergologie Pédiatriques (J.B.), Hôpital des Enfants-Malades, Paris ; Anatomie et Cytologie Pathologiques (F.C.), Hôpital Bécclère, Clamart, France; 2) Dr. von Haunerschen Kinderspital, München, FRG; 3) Néonatalogie (E.M.), Hôpital Sud Réunion ; Pédiatrie (J-L.A.), Hôpital Félix-Guyon, Ile de La Réunion, France.

Two main discrete entities with primary/unexplained hereditary or acquired lung disease leading to respiratory distress (RD) are characterized by storage of periodic acid Schiff-positive material within the alveoli : i, SP-B deficiency, with an essentially proteinaceous storage and rapid fatal outcome in the neonate, linked to *SFTPB* gene (MIM 1786640); ii, alveolar proteinosis (AP), clinically heterogeneous (age at onset/severity), with storage of a mixed, protein/lipid material. Akin to SP-B deficiency, primitive congenital/severe infantile AP is regarded as Mendelian autosomal recessive. Unexplained RD is unusually common in the white settler sub-population of Reunion Island, suggesting founder effect. However, no deleterious mutation or disease locus has been identified. We report a consanguineous male Caucasian infant from Reunion Island who had RD in his neonate and died at age 1 month. There was no immunodetectable SP-B in postmortem lung tissue. DNA analysis unveiled a novel homozygous mutation in *SFTPB* exon 2 (496delG). This mutation, or any other *SFTPB* lesion, was not found in the DNAs of nine patients with early infantile AP diagnosed by lung ultrastructural study, or two patients with neonatal RD, all from Reunion Island. In addition, some of these patients stained positive for SP-B in their bronchoalveolar lavage (BAL) fluid and the ones diagnosed with AP are maintained by repeated therapeutic BAL. Altogether, these results highlight the phenotypic and genetic heterogeneity of neonatal RD in Reunion Island, only a fraction of which could be linked to *SFTPB*.

**Analysis of mannose binding lectin (MBL) haplotypes in a large cohort of cystic fibrosis patients.** *J.S. Zielenski<sup>1</sup>, L. Pereira<sup>2</sup>, L. Culpi<sup>2</sup>, S. Raskin<sup>2</sup>, L.C. Tsui<sup>1</sup>*. 1) Department of Genetics, Hospital for Sick Children, Toronto, ON., Ontario, Canada; 2) Department of Genetics, Universidade Federal do Parana, Parana, Brazil.

Cystic fibrosis (CF) is an autosomal, recessive disease caused by mutations in the cystic fibrosis transmembrane regulator (CFTR) gene. The considerable phenotypic variability of CF is attributed to CFTR genotype as well as secondary genetic and environmental factors. The mannose binding lectin (MBL), a collectin that is important for innate immunity to infection, has been found in previous studies to have an effect on CF pulmonary disease, including infection status, the age-adjusted, percent predicted forced expiratory volume in one second (%predFEV1) and forced vital capacity (FVC). Several MBL variants have been associated with low levels of MBL protein in serum and, therefore, a compromised efficiency of the innate response. We have analyzed the haplotypes of the sequence variations of the gene at nucleotide position -221 and codons 52, 54 and 57 among 480 CF patients, with respect to a series of clinical parameters, including age of onset of *Pseudomonas aeruginosa* (Pa) and *Burkholderia cepacia* (Bc) infection, the infection status for Pa, Bc, *Haemophilus influenza*, *Staphylococcus aureus* and *Klebsiella* species (particularly at ages of 6, 12 and 24 months), as well as and FEV1 FVC. The result showed that the low MBL secretion haplotypes were significantly associated with earlier age of Pa infection ( $P < 0.05$ ). Also, a trend was detected between the low secretion haplotypes and poor pulmonary function as measured by infection status, pulmonary function and survival. There was no significant difference between patients homozygous for most common CFTR mutation, deltaF508, and other severe CFTR genotypes. Therefore, MBL may be considered as a modifier gene for CF pulmonary disease.

**The effect of cellular and viral splicing factors on the level of normal CFTR RNA.** *M. Nissim-Rafinia, B. Kerem.*  
Dept Genetics, Hebrew Univ, Jerusalem, Israel.

Variable levels of aberrantly spliced CFTR transcripts, carrying splicing mutations, were shown to correlate with variable CF severity. We suggested that the mechanism underlying this variability involve splicing factors known to regulate alternative splicing. We focus on two mutations causing alternative splicing of the CFTR RNA: the 3849+10kb C®T which can lead to cryptic exon inclusion and the IVS8-5T (5T) which can lead to exon 9 skipping. We constructed minigenes containing these mutations and studied the effect of splicing factors on the splicing pattern of these minigenes. Overexpression of the cellular factors ASF/SF2 and hnRNP A1, and the viral factor E4-ORF6 promoted exon skipping of RNA transcribed from the minigenes. Thus, in the 5T minigene, it led to a substantial decrease in the level of correctly spliced RNA, while in the 3849+10kb C®T minigene it led to the generation of correctly spliced RNA that was not found without this overexpression. The viral factor, E4-ORF3 led to the antagonistic effect, thus led to a substantial increase of the correct transcripts from the 5T minigene.

We further studied the modulation effect of the splicing factors on native CFTR alleles carrying the 3849+10kb C®T mutation. For this we established a nasal epithelial cell line, 091398k, from a nasal polyp of a CF patient carrying the mutation. 21% of the transcripts in 091398k cells are aberrantly spliced. Overexpression of the SR proteins ASF/SF2, SC35 and SRp20, hnRNP A1 and E4-ORF6 into these cells promoted exon skipping, and led to a decrease in the level of aberrantly spliced transcripts. The most significant effect was achieved with ASF/SF2, which led to almost a complete abolishment of the aberrantly spliced transcripts. The viral factor E4-ORF3 and the non-essential cellular factor Htra2-b1 promoted exon inclusion and led to a significant increase in the level of aberrantly spliced transcripts (up to 80%). Thus, cellular and viral splicing factors might play an important role in the mechanism underlying phenotypic variability in CF and other genetic diseases, caused by splicing mutations.

**Constraint on intron size as a mutational mechanism in Rothmund-Thomson Syndrome.** *S.E. Plon<sup>1</sup>, L.L. Wang<sup>1</sup>, A. Gannavarapu<sup>1</sup>, K.C. Worley<sup>2</sup>*. 1) Dept Pediatrics, Baylor Col Medicine, Houston, TX; 2) Human Genome Sequencing Center, Baylor Col Medicine, Houston, TX.

Rothmund-Thomson Syndrome(RTS) is an autosomal recessive disorder characterized by poikiloderma, skeletal anomalies, cataracts and predisposition to osteosarcoma. *RECQL4* mutations have been reported in four kindreds. We are sequencing the entire *RECQL4* gene in a cohort of 34 RTS probands. The unusual *RECQL4* gene structure contains 21 exons in six kb of DNA, with 13 introns less than 100 bp in length. One RTS proband (FCP102) with severe rash and OS from a consanguineous Mexican family is homozygous for an 11 bp deletion in intron 8 (g2746del11), which was not found in 100 control subjects including 33 Hispanics. The deleted sequence, which is flanked by an 8 bp direct repeat, includes no consensus splice or branch sites but reduces the intron size to 66 bp. We hypothesized that this deletion creates an intron of insufficient size to splice correctly. RT-PCR of lymphoblast and fibroblast RNA from FCP102 revealed only abnormal splice products that retain intron 8, resulting in a frameshift and premature stop. We subcloned genomic DNA between exons 5 and 10 from control and FCP102 into a mammalian expression vector. RT-PCR of cytoplasmic RNA from transfected NIH3T3 cells showed that the deleted intron is not spliced. Thus, this intronic deletion disrupts the *RECQL4* gene. To prove this results from a constraint on intron size, site directed mutagenesis was used to replace the deletion with 11 unrelated bases. Transfection of this construct demonstrated that the replaced intron is correctly spliced. We identified a second RTS proband with a 24 bp deletion in intron 13 (g3712del24) resulting in a 54 bp intron. RT-PCR also showed abnormal RNA products consistent with exon skipping. Deletions in small introns will be missed by most exon-by-exon mutation scanning or sequence protocols. Analysis of mRNA sequences mapped to the human genome sequence reveals approximately 17% of genes with at least one intron less than 100 bp. Thus, complete mutational analysis should include assaying small introns for deletions.

**Characterization of the splicing mutation in *IKBKAP* that causes Familial Dysautonomia.** *S.A. Slaugenhaupt<sup>1</sup>, M. Leyne<sup>1</sup>, J. Mull<sup>1</sup>, S.P. Gill<sup>1</sup>, M.P. Cuajungco<sup>1</sup>, J.F. Gusella<sup>1</sup>, N. Dormand<sup>2</sup>, R. Reed<sup>2</sup>.* 1) Harvard Inst Human Genetics, Mass General Hosp, Boston, MA; 2) Dept of Cell Biology, Harvard Medical School, Boston, MA.

Recently we reported that two mutations in the gene *IKBKAP* cause Familial Dysautonomia (FD). FD is an autosomal recessive disorder present in 1 in 3,600 live births in the Ashkenazi Jewish population. *IKBKAP*, which is homologous to yeast Elp1 and believed to play a role in transcriptional elongation, harbors two mutations that are responsible for FD. The major mutation accounts for >99.5% of all disease chromosomes and is located at base pair 6 of intron 20. The result of this mutation is an apparent decrease in splicing efficiency that results in variable skipping of exon 20. Interestingly, despite the fact that FD is a recessive disease, normal mRNA and protein are still expressed in all patient cells suggesting that this mutation weakens but does not completely inactivate the splice donor site. The second mutation is a missense (R696P) in exon 19 that has been seen in only four FD patients that are heterozygous for the major splicing mutation. New assays designed to detect only the wild-type or mutant message show that lymphoblasts and fibroblasts express primarily wild-type mRNA, while FD brain expresses primarily mutant. We are currently examining the expression of *IKBKAP* in a variety of FD tissues. In addition, we are studying the effect of various culture conditions to determine if we can influence the splicing ability of FD cells. In order to investigate the role of the major mutation in defective splicing and to determine at which step the splicing process is hindered, we have also created a minigene construct containing exons 20 and 21 and 180 bp's of flanking intron 20 sequence. This model will enable us to determine the exact effect of the FD mutation, and provide a system to study the effect of various splicing factors on the mutant splicing pattern. Since all patients show wild type message and apparently normal protein, the prevention of exon 20 skipping by upregulating normal *IKBKAP* mRNA represents an exciting potential target for future therapy of FD.

**Predicted expression of *PLP1* splicing mutations in Pelizaeus-Merzbacher disease.** *S.R. Svojanovsky*<sup>1</sup>, *G.M. Hobson*<sup>2</sup>, *K. Sperle*<sup>2</sup>, *E.A. Sijtermans*<sup>3</sup>, *J.Y. Garbern*<sup>4</sup>, *P.K. Rogan*<sup>1</sup>. 1) Children's Mercy Hospital, Kansas City, MO; 2) A.I. duPont Hospital for Children, Wilmington, DE; 3) Univ Med Ctr, Nijmegen, Netherlands; 4) Wayne State Univ Sch Med, Detroit, MI.

Mutations in the *PLP1* gene cause dysmyelinating phenotypes in Pelizaeus-Merzbacher disease. The DM20 splice form of this gene, which utilizes an alternative donor site in exon 3, can partially compensate for *PLP1* in patients with mutations in the latter half of this exon. We examined the severity of splicing mutations that affect expression of the *PLP1* and/or DM20 transcripts. *PLP1* variants suspected or documented to alter splicing (n=28) were evaluated by individual information ( $R_i$ ) analysis (Hum. Mut. 12:152,1998) and compared with available mRNA expression data. Reduced binding affinity to the natural splice site, i.e. decreasing but not abolishing normal *PLP1* mRNA, was predicted by information analysis for IVS2+6T>C [-2.6 x], G453T [-9.8 X], G453C [-16 X], IVS3+4A>G [-5.7 X], A620G [-2 X], and IVS6+3G>T [-17 X]. Leaky expression of *PLP1* mRNA was found in IVS3+4A>G, but not for G453T or IVS6+3G>T, which are predicted to reduce mRNA levels to a greater extent, possibly below the detection limit. *PLP1* splicing was predicted to be inactivated [at least  $\sim 100$  X] for IVS3+2T>C, IVS5-1G>A, IVS6+1G>A, and IVS6+2T>C, which was confirmed for IVS3+2T>C. Cryptic splicing and inactivation of the natural site was predicted and confirmed for IVS2-2A>G, IVS3-2A>G, IVS3-1G>T, IVS5+2T>C, but not for IVS5+2T>G, where the activated cryptic site in IVS5+2T>C may not be used. T116K strengthens the DM20 splice site 4-fold to 7.4 bits and eliminates use of the weaker, 6.8 bit exon 3 donor. The following variants were not expected to alter *PLP1* or DM20 mRNA: T2C, G3A, G3del, A168G, C384G, C409G, A441T, IVS3+28-+46del, IVS4+28C>G; normal splicing has been verified for G3del and IVS4+28C>G. The observed *PLP1* and DM20 splicing patterns corresponded to predictions of information theory-based splice site analyses in nearly all instances studied.

**The Molecular Basis of Glycogen Storage Disease Type 1a: Structural and Functional Analysis of Mutations in Glucose-6-Phosphatase.** *J.J. Shieh, M. Terzioglu, C.J. Pan, L.Y. Chen, H. Hirawa, J.Y. Chou.* HDB/NICHD, National Institutes of Health, Bethesda, MD.

Glycogen storage disease type 1a (GSD-1a) is caused by the deficiency in glucose-6-phosphatase (G6Pase), a nine-helical endoplasmic reticulum transmembrane protein required for maintenance of glucose homeostasis. To date, 75 G6Pase mutations have been identified in GSD-1a patients, including 48 mutations result in single amino acid substitution. However, only 19 such mutations have been functionally characterized. Here, we report the results of structural and functional studies of all 48 missense and the delF327 mutations. While 31 missense and delF327 mutation abolish G6Pase activity, 18 missense mutations retained the activity ranging from 0.7 to 24% of wild-type enzyme. Immunoblot analysis shows that a large number of those mutants support the synthesis of lower amounts of G6Pase protein than that of the wild-type construct. This suggests the structural requirement for an active G6Pase is very rigid and disruption of the structural integrity of the enzyme destabilizes the protein. This mutational information also explains why the islet-specific G6Pase catalytic subunit-related protein is devoid of enzyme activity. Taken together, we have generated a data-base of G6Pase mutation that cause GSD-1a and elucidated the structural requirements for the stability and enzymatic activity of G6Pase.

**Distribution of Usherin in humans and its effects on reproduction in people with Usher Syndrome Type II.** *N.A. Pearsall<sup>1</sup>, G. Bhattacharya<sup>1</sup>, D. Cosgrove<sup>1</sup>, J.L. Wisecarver<sup>2</sup>, W.J. Kimberling<sup>1</sup>*. 1) Genetics Department, Boys Town National Research Hospital, Omaha, NE; 2) Pathology Department, University of Nebraska Medical Center, Omaha, NE.

Usher Syndrome is an autosomal recessive disease that results in varying degrees of hearing loss and retinitis pigmentosa. Three types of Usher Syndrome (I, II, and III) have been identified clinically and are distinguished by severity and progression of hearing loss along with the presence or absence of vestibular dysfunction. Usher Syndrome type II is the most common of the three types and has been localized to three different chromosomes 1q41, 3p, and 5q, corresponding to Usher type 2A, 2B, and 2C respectively. Usherin is a basement membrane protein encoded by the USH2A gene. Expression of usherin has been localized to the basement membranes of several tissues but it is not ubiquitous.

Immunohistochemistry detected usherin in the following human tissues: retina, small and large intestine, pancreas, bladder, prostate, thyroid, esophagus, thymus, salivary glands, placenta, ovary, oviduct, and fallopian tube. Usherin was not detected in many other tissues such as heart, lung, liver, kidney, and brain. This distribution is consistent with the usherin distribution seen in the mouse. Immunoperoxidase staining of the placenta or salivary glands may provide an effective and minimally invasive way to diagnose a person with Usher IIa.

The presence of usherin in the reproductive tissues prompted the investigation of reproductive patterns among those with Usher II. Evaluation of pregnancy and birth rates of those with Usher II demonstrates no statistical difference from those not affected with Usher II. Similar data is being collected to determine if people with Usher I have comparable reproductive patterns. Although normal usherin expression is essential for proper development and function of both the inner ear and retina, it does not seem necessary for reproduction in people with Usher II. Nevertheless, evolutionary conservation of expression in tissues unaffected in USH2A raises interesting issues regarding the source of evolutionary pressures.

**PFGE analysis of 4qter-10qter interchromosomal exchanges in Italian families with Facioscapulohumeral muscular dystrophy (FSHD).** *L. Felicetti*<sup>1,2</sup>, *G. Galluzzi*<sup>1,2</sup>, *L. Colantoni*<sup>1,2</sup>, *M. Rossi*<sup>1,2</sup>, *B. Merico*<sup>2</sup>, *F. Mangiola*<sup>1</sup>, *P. Tonali*<sup>2</sup>, *E. Ricci*<sup>2</sup>. 1) Ctr Neuromuscular Diseases, UILDM, Rome, Italy; 2) Institute of Neurology, Catholic University, Rome, Italy.

In 95% of FSHD patients, molecular diagnosis is based on the detection by probe p13E-11 of EcoRI, BlnI-resistant fragments of 10 to 35 kb, shorter than those found in normal individuals (35-300 kb). The size reduction is due to a deletion of a variable number of KpnI repeats at 4q35 region. 4q-10q interchromosomal exchanges occur both in normal and FSHD subjects, resulting in the reshuffling of 4q-type BlnI-resistant and 10q-type BlnI-sensitive repeats from one chromosome to the other. We analyzed the segregation of BlnI-resistant and BlnI-sensitive alleles in 55 FSHD Italian families for a total of 230 individuals (116 affected, 70 unaffected and 44 spouses). DNA extraction and subsequent restriction steps with EcoRI, BlnI and Tru9I were performed directly in agarose blocks. After separation by Pulsed Field Gel Electrophoresis (PFGE), the alleles were identified with p13E-11 and KpnI cloned sequences as probes. We observed different types of exchanges: total 4q to 10q transfers resulting in trisomy and tetrasomy; partial 10q to 4q transfers leading to monosomy and nullisomy; complex rearrangements such as multiple translocations, even in subjects with p13E-11 standard allele configuration. In addition, we detected two patients carrying 10q-4q translocations involving the short fragments associated with FSHD. Among 8 sporadic cases carrying a de novo p13E-11 small fragment (BlnI-resistant), we found four patients, with no evidence of somatic mosaicism, with one or both parents showing various types of rearrangements (trisomy, monosomy, etc.). The remaining four were somatic mosaics, all carrying 4q-10q translocations. Our results show the high frequency of 4qter-10qter interchromosomal exchanges in FSHD families and confirm that the instability of subtelomeric regions can play a role in the molecular mechanism of the disease. Telethon Italy grant n.1296.

**Frequency analysis of SCA10 ATTCT repeat expansions among ataxia patients.** *P. Fang<sup>1</sup>, W. Jin<sup>1</sup>, T. Matsuura<sup>2</sup>, T. Ashizawa<sup>2</sup>, B.B. Roa<sup>1</sup>.* 1) Baylor DNA Diagnostic Laboratory, Molecular and Human Genetics; 2) Department of Neurology, Baylor College of Medicine, Houston, TX.

Autosomal dominant cerebellar ataxias are a heterogeneous group of neurodegenerative disorders with overlapping clinical findings. The specific diagnosis for spinocerebellar ataxia often relies on DNA analysis of various SCA genes containing unstable repeat expansion mutations (CAG repeats for SCA1, 2, 3, 6, 7 and DRPLA, CTG repeats for SCA8). SCA type 10 is associated with very large expansions of a pentanucleotide repeat (ATTCT) in the novel SCA10 gene at 22q13-qter. A normal range of 10-22 repeats was reported for this highly polymorphic repeat (heterozygosity ~80%). SCA10 patients were previously reported to have expansions ranging from ~800 to ~4500 ATTCT repeats. To date, SCA10 expansion mutations have been documented exclusively in affected individuals of Mexican ancestry. To determine the frequency of the SCA10 ATTCT expansion mutation in a cohort of ataxia patients, we analyzed a total of 314 DNA samples from symptomatic individuals who were previously referred for clinical testing to the Baylor DNA Diagnostic Laboratory. Patients who had tested negative for SCA1, SCA2, SCA3, SCA6 or SCA7 expansion mutations were subsequently analyzed for SCA10. All DNA samples were initially tested by PCR analysis across the ATTCT repeat region. A total of 250 ataxia patients were identified to have two normal alleles, and 64 patients showed one normal allele (consistent with normal heterozygosity estimates, H=80%). These 64 patient samples were further tested by Southern analysis to assess the presence of SCA10 ATTCT expansion mutations. Southern analysis identified one ataxia patient who was positive for an SCA10 expansion of ~420 ATTCT repeats. This allele represents the smallest SCA10 expansion identified in an ataxia patient to date, and appears to define the lower limit of the SCA10 mutation range. The observed SCA10 expansion frequency of ~0.3% (1/314 patients) suggests a limited contribution of SCA10 to the overall ataxia patient caseload in the United States. Furthermore, these data underscore the need for further studies on genotype-phenotype correlations for SCA10.

**Analysis Molecular In Patients With Friedreichs Ataxia In Colombian Individuals.** *M. Gomez<sup>1</sup>, C. Duran<sup>1</sup>, O. Pedraza<sup>3</sup>, E. Espinosa<sup>4</sup>, P. Vega<sup>5</sup>, M. Penaranda<sup>4</sup>, J. Prieto<sup>1,2</sup>.* 1) Instituto de Genetica Humana, Universidad Javeriana, Bogota, Bogota, Colombia; 2) Hospital La Victoria, Dpto de Gentica, Bogot, Colombia; 3) Hospital San Ignacio,Dpto Neurologia, Bogota, Colombia; 4) Hospital Militar Central, Bogota, Colombia; 5) Hospital la Samaritana, Bogota, Colombia.

Friedreichs Ataxia (FRDA), an autosomal recessive neurodegenerative disorder, is the most common hereditary ataxia. FRDA is associated with the expansion of a GAA trinucleotide repeat in the first intron of the X25 gene. We studied 24 patients with FRDA according to the essential diagnostic criteria. 17 Patients had typical FRDA and 7 had FARR. The patients showed a range in the age of onset from 3-22 years. All patients had gait, limb ataxia, dysarthria and Babinsky sign, sensory axonal polyneuropathy (62.5%), Absent tendon reflexes in the legs (75%), Nystagmus (50%), Pes cavus (37.5%) and scoliosis (50%). The GAA repeats range in the normal colombian individuals was 0-26 repeats. Expand GAA repeats were found on both alleles of the frataxin gene in 20 patients. One patient was heterozygous for the expansion mutation and was known or expected carrier of a point mutation on the other allele. In the 20 patients who were homozygous for the GAA expansion, the repeats numbers ranged from 206 to 951. The mean numbers of GAA repeats on the smaller and the larger alleles were 650 and 709 respectively. We determined the correlations between the size of the smaller expansions and both age at onset and several of disease. An inverse relation was found between the size the smaller GAA expansion and age at onset and direct relation was found between the size the smaller GAA expansion and several of disease. We investigated the single nucleotide polymorphism FAD1 in patients, indicate a strong association of the rare allele B to the FRDA chromosomes. We consider a single founder effect mutation associated with FAD1B. We demonstrated that the spectrum of FRDA is broader in the Colombian population. Direct molecular diagnosis through determination of the size of the GAA expansion should become an essential tool in clinical practice and genetic counseling for patients with recessive or sporadic cerebellar ataxias.

**ATTCT repeat instability in spinocerebellar ataxia type 10 (SCA10).** *T. Matsuura*<sup>1</sup>, *P. Fang*<sup>2</sup>, *A. Rasmussen*<sup>3</sup>, *R.P. Grewal*<sup>4</sup>, *M.E. Alonso*<sup>3</sup>, *B.B. Roa*<sup>2</sup>, *T. Ashizawa*<sup>1</sup>. 1) Neurology, Baylor College of Medicine, Houston, TX; 2) Baylor DNA Diagnostic Laboratory, Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 3) Department of Neurogenetics, Instituto Nacional de Neurologia y Neurocirugia, Mexico City, Mexico; 4) New Jersey Neuroscience Institute, JFK Medical Center, Edison, NJ.

Spinocerebellar ataxia type 10 (SCA10) is an autosomal dominant progressive disorder characterized by ataxia, seizures and anticipation. The mutation of SCA10 is an unstable and massive expansion of an ATTCT pentanucleotide repeat (800~4500 repeats) in intron 9 of the novel gene *SCA10*. Previous studies have shown that intergenerational changes of the expanded alleles were highly variable. To understand the mechanisms underlying the variable transmission, we investigated ATTCT repeat expansions pattern through parent-of-origin transmission, somatic and germline instability, and size variability with aging. Our study showed a wide range of both allele expansion and contraction when the mutation is transmitted through the male germ line. The mean value of the repeat variation was +280 (+/-1540) repeats observed in 15 cases of paternal transmission, in contrast to an average increase of +60 (+/-120) repeats seen in 8 cases of maternal transmission ( $p<0.02$ ). Our studies also found evidence of somatic instability. In 3 out of 4 patients studied, allele contractions were observed in lymphoblastoid cells (-140 to -780 repeats) but not in blood or buccal samples. Consistent with the repeat instability observed with male transmission, analysis of sperm in two male patients showed variable expansions and contractions of the ATTCT expanded repeats (+520 to -1840 repeats). Lastly, analysis of SCA10 repeat expansion stability over time showed that the size of the expanded allele in one patient's blood lymphocytes increased by 400 repeats over a two year period. We conclude that: (1) paternal transmission is highly unstable in contrast to maternal transmission, (2) there is both somatic and germline mosaicism of the ATTCT repeat, and (3) the SCA10 repeat expansions may undergo variation with aging.

**Cloning and characterization of a CAG/CTG trinucleotide repeat expansion associated with a disorder similar to Huntington's disease.** *S.E. Holmes<sup>1</sup>, E. O'Hearn<sup>1</sup>, A. Rosenblatt<sup>1</sup>, C. Callahan<sup>1</sup>, H. Hwang<sup>1</sup>, R. Ingersoll-Ashworth<sup>1</sup>, G. Stevanin<sup>2</sup>, A. Brice<sup>2</sup>, A. Fleischer<sup>1</sup>, N. Potter<sup>3</sup>, C.A. Ross<sup>1</sup>, R.L. Margolis<sup>1</sup>.* 1) Johns Hopkins University, Baltimore, MD, USA; 2) Hôpital de la Salpêtrière, Paris, France; 3) University of Tennessee, Knoxville, TN, USA.

We recently reported a pedigree in which an autosomal dominant disorder similar to Huntington's disease (termed Huntington's disease-like 2, HDL2) segregates with an uncharacterized CAG/CTG expansion. Affected individuals tested negative for all known repeat expansions. We have now cloned the HDL2 repeat and flanking regions, and developed a PCR assay of repeat length. Unexpanded alleles in patients and controls contain repeats that range in length from 7 to 26 triplets. All affected individuals in the pedigree also have an expanded repeat of 51-57 triplets. We have now found HDL2 expansions of 44-50 triplets in three additional unrelated probands with unexplained HD-like phenotypes. The repeat, in the CTG orientation, occurs in a variably spliced exon of a brain-specific gene encoding a protein that is involved in calcium flux. Despite our previous finding of intranuclear inclusions stained by an antibody known to detect long stretches of polyglutamine (1C2) in the one available HDL2 brain, we have thus far not found evidence of a gene with the repeat in the CAG orientation. The reasons for this discrepancy remain unclear; an exon containing the repeat in the CAG orientation may have escaped detection, or 1C2 may stain material in the intranuclear inclusions other than long stretches of polyglutamine. Overall, our results suggest that the HDL2 expansion may cause selective death of striatal neurons, perhaps by a pathogenic process distinct from that of HD and other neurodegenerative disorders.

Program Nr: 2772

**Decrease of proteasome activity is age dependent and promotes nuclear accumulation of polyglutamine proteins.**

*X. Li<sup>1</sup>, F. Cao<sup>1</sup>, H. Li<sup>1</sup>, P. Shelbourne<sup>2</sup>, S-H. Li<sup>1</sup>.* 1) Dept Genetics, Emory University, Atlanta, GA; 2) Division of Molecular Genetics, University of Glasgow, Scotland, UK.

Expanded polyglutamine tracts cause proteins to accumulate and aggregate in the nucleus, a pathological feature common to eight glutamine repeat disorders that show late-onset neurodegeneration. In Huntingtons disease (HD) mice, the disease protein huntingtin accumulates and aggregates in the nuclei of striatal neurons as the animals age. This age-dependent nuclear phenotype precedes neurodegeneration, suggesting that an age-related alteration in cellular function contributes to the pathogenesis of HD. Since the proteasome degrades misfolded and aggregated proteins, we studied the relationship between proteasome activity and the nuclear accumulation of mutant huntingtin. Striatal neurons of aged HD mice had lower proteasome activity and more intranuclear huntingtin accumulation. Similarly, primary striatal neurons cultured for a longer time had less proteasome activity and, when transfected with mutant huntingtin, more intranuclear mutant huntingtin. Moreover, inhibition of proteasome activity increases the nuclear accumulation of mutant huntingtin in stably transfected HEK 293 cells, leading to decreased cell viability specific to the mutant huntingtin. Proteasome inhibition also increases the nuclear accumulation of the DRPLA protein, another polyglutamine disease protein. We propose that an age-dependent decrease in proteasome function may contribute to the late-onset nuclear accumulation of polyglutamine proteins.

**SCA8 Expansion in the Spanish Population Including one Homozygous Patient.** *M. Mila<sup>1</sup>, B. Tazon<sup>1</sup>, E. Muñoz<sup>2</sup>, D. Jimenez<sup>1</sup>, C. Badenas<sup>1</sup>.* 1) Serv Genetica, Hosp Clinico, Barcelona, Catalonia, Spain; 2) Serv Neurologia, Hosp Clinico, Barcelona, Catalonia, Spain.

Controversial data have been reported about SCA8 since its description in 1999. The most accepted hypothesis is that CTA/CTG combined repeat expansion in the SCA8 locus causes SCA8. It is inherited as a dominant trait with reduced penetrance. The aim of the present study was to investigate the mutation incidence in the Spanish population and its possible pathogenic role. 512 chromosomes from the Spanish population, belonging to controls (298) and ataxic patients (214). DNA was extracted from blood samples by standard methods. Amplification of the CTA/CTG 3untranslated region was achieved by PCR using primers SCA8-F4 and SCA8-R3 and conditions previously described. Neurological reevaluation was done in individuals carrying expanded alleles. We have detected 5 expanded unrelated alleles corresponding to 3 affected patients and 1 healthy individual. SCA8 represents a 4.4% of total dominant spinocerebellar ataxias studied in the Spanish population. One of these patients was homozygous for the expansion. He is a 25-year-old man with clinical picture of progressive ataxia and dysarthria that began at age 12. On neurological examination he showed ataxia, slight dysarthria and nystagmus to the extreme lateral gaze. Cranial MRI showed global atrophy of cerebellum but the brainstem was spared. Family history showed the presence of ataxia in his grandfather and father. His mother is healthy at age 52 and molecular study of SCA8, reveals one allele that could be considered as premutated. She has no ataxia antecedents in her family. The healthy individual carrying an expanded allele corresponds to a control. Our results are in agreement with CTA/CTG expansion in the SCA8 locus as responsible for the SCA8 ataxia showing reduced penetrance. Homozygous status advancing age at onset supports this idea.

**Friedreich ataxia and frataxin levels.** *C. Miranda*<sup>1,2</sup>, *M. Santos*<sup>1,2</sup>, *K. Ohshima*<sup>1</sup>, *J. Smith*<sup>3</sup>, *M. Koenig*<sup>4</sup>, *J. Kaplan*<sup>3</sup>, *M. Pandolfo*<sup>1</sup>. 1) CHUM-Notre Dame Hosp, Montreal, Quebec, Canada; 2) UnIGENE, IBMC, Porto, Portugal; 3) Dept of Pathology, Univ. Utah, Salt Lake City, UT; 4) IGBMC/INSERM, Illkirch, France.

Friedreich ataxia (FRDA) is the most common autosomal recessive ataxia. The majority of patients are homozygous for a (GAA)<sub>n</sub> expansion in intron 1 of the frataxin gene. The size of this expansion ranges from 100 to more than 1000 triplets, resulting in decreased levels of frataxin expression (4 to 29% of non affected individuals). Frataxin is a highly conserved mitochondrial protein that is thought to prevent toxic iron accumulation in mitochondria. In the frataxin knockout mouse absence of frataxin expression causes embryonic lethality a few days after implantation (E6), showing that at least a residual amount of frataxin has to be present for the embryo to be able to survive the embryonic period. Heterozygous knockout mice show a normal embryonic development, and do not develop any symptoms of the disease. With the aim to generate a *frda* mouse model that would express levels of frataxin close to the range observed in FRDA patients, we have generated a *frda* knock-in mouse by insertion of a 230GAA repeat expansion in intron 1 in the murine *frda* gene. The repeat is stably transmitted and does not show somatic instability. Homozygous *frda* knock-in mice show a mild reduction of expression of frataxin when compared with wild type mice. To further decrease the level of frataxin expression, we crossed heterozygous knock-in mice with heterozygous knockout mice to give double heterozygotes that show levels of expression of frataxin close to 25% of levels found in wild type mice. These animals are phenotypically normal at 12 months of age, in particular do not show reduced motor coordination at the rotarod test, suggesting that this level of frataxin is sufficient for normal mitochondrial iron homeostasis. Pathological and biochemical studies are in progress. We are also currently studying whether these mice respond normally to iron loading.

**A Mouse Model for Spinal and Bulbar Muscular Atrophy.** *C.J. O'Brien, E. Chevalier-Larson, S. Jenkins, D.E. Merry.* Biochemistry and Molecular Pha, Thomas Jefferson University, Philadelphia, PA.

Spinal and Bulbar Muscular Atrophy is an adult onset, slowly progressive motor neuropathy caused by an expansion of a polyglutamine tract within the androgen receptor (AR) protein. We have created an animal model of SBMA, using transgenic mice that bear the full-length mutant or normal AR cDNA driven by the prion protein (PrP) promoter. Preliminary characterization of transgenic mice revealed signs of neurologic disease. These signs include reduced activity and limb clasping, which was notably progressive, beginning with isolated hindlimb clasping at two months and progressing to forelimb clasping, then to a full body clasp by 8 months. This behavior was not observed in non-transgenic littermates, nor in any normal repeat transgenic mice. Also, clasping was seen in male transgenic mice as young as two months, but only observed in the mildest form in female mice of the same line beginning at 8 months of age. The PrP-AR112-27 transgenic line revealed clasping at 12 months of age, and an increased rate of early death. Another founder had progressive hindlimb gait abnormalities at 3 months of age. F1 mice from this founder are under study. Immunohistochemical analysis of brain and spinal cord from six month old transgenic PrP-AR112-34 animals revealed nuclear staining in most neurons of the brain and spinal cord. Also, intranuclear inclusions were identified in neurons of transgenic cerebral cortex and spinal cord with the N-terminal antibody AR(N-20) and with antibody AR318. Aggregates were not detected with antibody AR (C-19), indicating that inclusions detected in these transgenic mice resemble those of Kennedy's disease nervous tissue in the absence of C-terminal epitopes. The presence of selected epitopes in neuronal inclusions provides a system with which to investigate the role of AR proteolysis in the onset and progression of Kennedy's disease. The male-specific neurologic phenotypes observed in at least one line of transgenic mice likely result from the same pathogenic mechanism as in Kennedys disease and provides us with an appropriate model to test the effects of various AR ligands on phenotype onset and progression.

**A survey of *TWIST* for mutations in craniosynostosis reveals a variable length polyglycine tract in asymptomatic individuals.** A.O.M. Wilkie<sup>1,4</sup>, N. Elanko<sup>1</sup>, J.S. Sibbring<sup>2</sup>, K.A. Metcalfe<sup>2</sup>, J. Clayton-Smith<sup>2</sup>, I.K. Temple<sup>3</sup>, S.A. Wall<sup>4</sup>, D. Donnai<sup>2</sup>. 1) Weatherall Institute of Molecular Medicine, John Radcliffe Hospital, Oxford, UK; 2) Regional Genetic Service, St Mary's Hospital, Manchester, UK; 3) Wessex Clinical Genetics Service, The Princess Anne Hospital, Southampton, UK; 4) Oxford Craniofacial Unit, Radcliffe Infirmary, Oxford, UK.

The human *TWIST* gene encodes a 202 amino acid transcription factor characterized by a highly conserved basic-helix-loop-helix motif in the C-terminal half, and a less conserved N-terminal half that has binding activity towards the histone acetyltransferase p300. Between these domains is a repeat region of unknown function that encodes the glycine-rich sequence (Gly)<sub>5</sub>Ala(Gly)<sub>5</sub>. Heterozygous mutations of *TWIST* were previously described in the Saethre-Chotzen craniosynostosis syndrome.

During a search for *TWIST* mutations in patients with craniosynostosis, we identified, in addition to ten novel and one previously described *bona fide* intragenic mutations and one complete gene deletion, 13 individuals from 7 independently ascertained families with rearrangements of the glycine-rich region. These involved either deletion of 18 nucleotides (259\_276del18) or insertion of 3 (259\_260ins3), 15 (274\_275ins15) or 21 (276\_277ins21) nucleotides. These rearrangements converted the G<sub>5</sub>AG<sub>5</sub> sequence to G<sub>5</sub>, G<sub>6</sub>AG<sub>5</sub>, G<sub>5</sub>AG<sub>4</sub>AG<sub>5</sub>, and G<sub>5</sub>AG<sub>6</sub>AG<sub>5</sub>, respectively. None was consistently associated with clinical disease and we conclude that they are at most weakly pathogenic.

Less is known about the pathophysiology of variation in polyglycine repeats, compared to polyglutamine or polyalanine repeats. In the case of *TWIST* protein, the glycine stretch may serve as a flexible linker between the functional domains, and as such may be subject to reduced evolutionary constraint.

**A Sensitive Balance of Ataxin-2 Activity is Required for Proper Actin-Cytoskeletal Structure and Tissue Viability in *Drosophila*.** *T.F. Satterfield, L.J. Pallanck.* .

Spinocerebellar Ataxia Type 2 (SCA2) is a member of a class of neurodegenerative diseases caused by the expansion of an endogenous glutamine repeat in the coding sequence of the corresponding gene. The normal cellular function of the *SCA2* gene product, ataxin-2, and the mechanism by which polyglutamine expansion of any of the genes in this class of disorders causes neurodegeneration remain unknown. To assess the possible contribution of altered ataxin-2 function to *SCA2* pathology we have used a genetic approach to study a *Drosophila* ortholog of the *SCA2* gene (termed *datx2*). Mutations that reduce *datx2* activity, or transgenic overexpression of *datx2* results primarily in lethality with survivors typically displaying locomotor defects and tissue degeneration. Subcellular examination of tissues affected by altered *datx2* gene dosage reveals defects in actin filament organization and the appearance of polymerized actin aggregates. Together, these results demonstrate that *datx2* participates in actin filament formation, and that a sensitive balance of *datx2* activity is required for viability. These findings, when coupled with the observation that loss of cytoskeletal-dependent neuronal structure defines an early event in *SCA2* pathogenesis, support a mechanism of *SCA2* pathology involving actin cytoskeletal defects resulting from alteration of ataxin-2 activity.

**Mutations in *CRBI* are a major risk factor for the development of Coats-like exudative vasculopathy in retinitis pigmentosa, and are the cause of 13% of Leber congenital amaurosis.** A.I. den Hollander<sup>1</sup>, J.R. Heckenlively<sup>2</sup>, L.I. van den Born<sup>3</sup>, Y.J.M. de Kok<sup>1</sup>, S.D. van der Velde-Visser<sup>1</sup>, U. Kellner<sup>4</sup>, B. Jurklies<sup>5</sup>, M.J. van Schooneveld<sup>6</sup>, K. Rohrschneider<sup>7</sup>, B. Wissinger<sup>8</sup>, J.R.M. Cruysberg<sup>9</sup>, A.F. Deutman<sup>9</sup>, H.G. Brunner<sup>1</sup>, E. Apfelstedt-Sylla<sup>8</sup>, C.B. Hoyng<sup>9</sup>, F.P.M. Cremers<sup>1</sup>. 1) Dept. of Human Genetics, University Medical Centre Nijmegen, Nijmegen, Netherlands; 2) Dept. of Ophthalmology, University of California, Los Angeles, CA; 3) The Rotterdam Eye Hospital, Rotterdam, Netherlands; 4) Dept. of Ophthalmology, University Clinic Benjamin Franklin, Berlin, Germany; 5) Universitäts-Augenklinik, Essen, Germany; 6) Dept. of Ophthalmology, University Medical Centre Utrecht, Utrecht, Netherlands; 7) Universitäts-Augenklinik, Heidelberg, Germany; 8) Universitäts-Augenklinik, Tübingen, Germany; 9) Dept. of Ophthalmology, University Medical Centre Nijmegen, Nijmegen, Netherlands.

Previously we described mutations in the crumbs homologue 1 *CRBI* gene in a severe form of retinitis pigmentosa (RP12), which is characterized by a preserved para-arteriolar retinal pigment epithelium. To determine whether *CRBI* mutations are a common cause of retinal dystrophies, a mutation screen was performed in 97 patients with RP and 52 patients with Leber congenital amaurosis (LCA).

In the RP group, mutations were detected in a patient who had developed a Coats-like exudative vasculopathy, a relatively rare complication of RP that may progress to partial or total retinal detachment. Screening of 8 more patients who had developed this complication revealed mutations in 4 of them. Given that 4 out of 5 patients had developed the complication in one eye and that not all siblings with RP have the complication, *CRBI* mutations should be considered an important risk factor for the Coats-like reaction, although its development may require additional genetic or environmental factors.

Mutations were also detected in 7 (13%) of 52 LCA patients. In three patients we identified null mutations on both *CRBI* alleles, which suggests that LCA is the most severe phenotype that can be associated with mutations in *CRBI*.

**CDH23 mutational and clinical analyses: a continuum of genotype/phenotype relationships in a cohort of 94**

**Usher Id and DFNB12 patients.** *L.M. Astuto<sup>1</sup>, R.R. Fields<sup>1</sup>, J.W. Askew<sup>1</sup>, J.M Bork<sup>2</sup>, R.J. Morell<sup>2</sup>, H. Kremer<sup>3</sup>, P. van Hauwe<sup>3</sup>, W.J. Kimberling<sup>1</sup>.* 1) Gene Marker Laboratory, Boystown National Research Hospital, Omaha, NE USA; 2) Laboratory of Molecular Genetics, National Institute on Deafness and Other Communication Disorders, NIH, Rockville, MD, USA; 3) Department of Otorhinolaryngology, University Hospital, Nijmegen, the Netherlands.

Usher syndrome, the most common type of hereditary deaf-blindness, represents a heterogeneous group of autosomal recessive disorders characterized by sensorineural hearing impairment, progressive retinal degeneration and in some cases vestibular areflexia. Usher type Id (OMIM 601067), the fourth of six Usher I genetic localizations, was first mapped to 10q21-22 (Wayne et al. 1996), a region that overlaps DFNB12, a non-syndromic deafness localization (Chaib et al. 1996). Mutations in CDH23, a cell adhesion protein with multiple cadherin-like domains, are responsible for both syndromic (Usher Id) and non-syndromic (DFNB12) deafness (Bork et al. 2001). Specific CDH23 mutational defects were identified distinguishing these two phenotypes as only milder missense mutations were detected in DFNB12 families and nonsense and frameshift mutations were identified in Usher Id families. In this study, all 69 exons of CDH23 were amplified in 94 genetically independent and ethnically diverse Usher I and non-syndromic deafness probands. Mutation detection was assessed by heteroduplex analysis and direct sequencing. Our results have consistently verified and expanded the mutational specific observations of mild and severe mutations in DFNB12 and Usher Id families as previously reported. In addition, a thorough and extensive clinical evaluation of the CDH23 mutant families has revealed typical Usher I cases, as well as atypical and complex Usher I phenotypes manifesting variable hearing and vestibular involvement, a late to mild onset of retinitis pigmentosa and subnormal ERG retinal findings not entirely consistent with a non-syndromic deafness phenotype. These findings warrant a critical clinical evaluation of the phenotypic variation and type of mutation involved for accurate diagnosis of non-syndromic or syndromic hearing loss.

**Duplication as well as haploinsufficiency of the forkhead/winged-helix transcription factor FOXC1 cause human anterior segment dysgenesis.** *F. Mirzayans*<sup>1</sup>, *R. Saleem*<sup>1</sup>, *D.B. Gould*<sup>1</sup>, *J. Marshall*<sup>1</sup>, *O. Lehmann*<sup>2</sup>, *T. Jordan*<sup>2,3</sup>, *V.*

*Raymond*<sup>4</sup>, *A.J. Mears*<sup>5</sup>, *M.A. Walter*<sup>1</sup>. 1) Ophthalmology & Medical Genetics, Univ Alberta, Edmonton, Alberta, Canada; 2) Dept. of Molecular Genetics, Institute of Ophthalmology, Bath st. London, England; 3) Eye Institute, Southampton General Hospital, Southampton, England; 4) CHUL Research Center and Universite Laval, Quebec City, Quebec, Canada; 5) Kellogg Eye Center, Ann Arbor, MI,USA.

The human FOXC1 gene, a member of forkhead winged-helix family of transcription factors mapping to chromosome 6p25 has been previously implicated in the development of anterior segment of the eye. To date 16 different mutations of the FOXC1 have been detected in individuals with anterior segment dysgenesis and glaucoma (Mears et al., 98; Nishimura et al., 2001), including two frameshift and two nonsense mutations consistent with a haploinsufficiency model underlying FOXC1-associated ocular defects. However, mutational analysis of FOXC1 has not revealed any disease-associated alterations in two of our large families originally linked to 6p25. Analyses involving newly derived polymorphic markers have limited the critical region to 300 kb of genomic sequence. In addition to FOXC1, two other forkhead genes FOXF2 and FOXQ1 map within this critical interval at 6p25. Direct sequencing analyses detected polymorphisms in both the FOXF2 and FOXQ1 genes, but failed to detect any disease-causing alterations in our families. In the light of recent evidence pointing to duplications of the 6p25 region also associated with ocular defects (Lehmann et al., 2000; Nishimura et al., 2001), we reexamined our linkage data and noticed a subtle difference in intensity in the alleles segregating with the disease in these two families in markers clustering around FOXC1 and FOXF2 genes. Preliminary FISH and Southern blot analyses are consistent with the possibility of a small duplication of the region including FOXC1, in affected members of these two kindreds. These findings strongly suggest that FOXC1 normally functions within a very narrow threshold window, and that perturbations resulting in either too little or too much FOXC1 activity result in similar anterior segment defects.

**Mutations in the *Drosophila* homolog of the gene for primary congenital glaucoma cause fluid flow and neurological defects.** *L.T. Reiter*<sup>1</sup>, *M. McElroy*<sup>1</sup>, *B.B. Bejjani*<sup>2</sup>, *E. Bier*<sup>1</sup>. 1) Dept. Biology, UCSD, La Jolla, CA; 2) Baylor College of Medicine, Houston, TX.

Mutations in the human cytochrome P450 *CYP1B1* are known to result in primary congenital glaucoma (PCG). One of the characteristics of this disorder is a developmental defect resulting in an obstruction of fluid flow through the trabecular meshwork, increased intraocular pressure and optic nerve damage. *cyp18a* is the C-P450 gene in *Drosophila melanogaster* that is most similar to human *CYP1B1*. Misexpression of *cyp18a* in the wing results in a significant narrowing of the wing margin and ectopic wing vein material. Ubiquitous misexpression of *cyp18a* can cause lethality and wing malformations at several timepoints during pupal development. Mutation of the *cyp18a* gene on the X chromosome by *p*-element insertions at two different locations resulted in two distinct sets of phenotypes. Class I alleles are semi-lethal in males (1:100), have wing hinge defects, and appear to have a neurological defect which affects coordination and walking, while class II alleles are viable but exhibit fluid flow defects manifested as deflated wings and bloated abdomens filled with hemolymph. We screened a collection of 1300 *p*-element insertions for dominant suppressors of the class I *cyp18a* mutant phenotype and have thus far identified at least 16 genes which, when disrupted in the heterozygous state, can at least partially rescue the male semi-lethality. Three of these genes are known to be involved in cell adhesion: *vkg*, *Ten-m* and *dally*. We also identified a gene called *ttv* which is very similar to a tumor suppressor gene located on human chromosome 8p (the region in humans to which a suppressor of *CYP1B1* mutations is linked). We are currently investigating the role of apoptosis in the generation of the class II fluid flow defect and the semi-lethality. Preliminary results suggest that *cyp18a* is involved in the regulation of a small molecule which may direct apoptosis in the hinge and veins of the wing. These results raise the possibility that human *CYP1B1* may modify or produce a similar small molecule which is responsible for inducing normal apoptosis in the trabecular meshwork of the eye.

**A mutation in the RX homeobox gene in 2 individuals with different ophthalmological manifestations.** A.S. Schneider<sup>1</sup>, M.A. Dwyer<sup>1</sup>, V. Voronina<sup>2,5</sup>, C. O'Kernick<sup>2,5</sup>, P. Mathers<sup>2,3,4,5</sup>. 1) Dept Genetics, Albert Einstein Medical Ctr, Philadelphia, PA; 2) Dept Biochemistry, West Virginia University School of Medicine, Morgantown, WV; 3) Dept Otolaryngology, West Virginia University School of Medicine, Morgantown, WV; 4) Dept Ophthalmology, West Virginia University School of Medicine, Morgantown, WV; 5) Sensory Neuroscience Research Center, West Virginia University School of Medicine, Morgantown, WV.

The anophthalmia/microphthalmia (A/M) registry at Albert Einstein Medical Center, has been collecting data on individuals with A/M for 7 years and in the past 2 years has offered gene screening to registry participants. Testing involves mutational screening of several eye development genes. We have identified two patients from this screen who carry a mutation of the RX homeobox gene. Patient 1 is a 3 10/12 year old male with unilateral Persistent Hyperplastic Primary Vitreous (PHPV) and microphthalmia of the left eye. The right eye is completely normal. He has no other anomalies and his development is appropriate for age. Patient 2 is an 8 year old female with left anophthalmia, right microphthalmia with supranasal coloboma of iris, chorioretinal coloboma and hypoplastic optic nerve, global developmental delay and an ASD. Some autistic features have been noted.

Both individuals are heterozygous for a C-to-T mutation at position 147 of the RX homeobox gene. This mutation introduces a premature termination codon into helix 1 of the homeodomain, presumably preventing the protein binding activity of the native protein. Sequence analysis of the RX coding region in both affected individuals failed to identify a second mutation, though genetic evidence from a third family suggests that a single copy of the Q147X mutation is not sufficient by itself to cause abnormal eye development. DNA testing of the parents for both patients suggests that these mutations arose spontaneously. We are continuing efforts to identify the site of a potential second mutation in the RX gene. Together with data from a mouse Rx-gene deletion model, these data implicate the RX gene as crucial for the proper formation of the mammalian eye.

**Familial vestibulocerebellar disorder maps to chromosome 13q31-q33: a new nystagmus locus.** *N.K. Ragge<sup>1</sup>, C. Hartley<sup>2</sup>, A.M. Dearlove<sup>2</sup>, J. Walker<sup>3</sup>, I. Russell-Eggitt<sup>3</sup>, C.M. Harris<sup>4</sup>.* 1) St Thomas' Hospital, London, England; 2) Medical Research Council Human Genome Mapping Project Resource Centre, Cambridge; 3) Dept of Ophthalmology, Great Ormond St Hospital for Children, London; 4) Institute of Neuroscience, Plymouth University.

Pathological nystagmus (involuntary oscillation of the eyes) usually occurs in three settings: 1) onset at birth or in the first few months associated with ocular disease (sensory defect nystagmus); 2) a similar early onset with no detectable underlying pathology (congenital idiopathic nystagmus); and 3) acquired (onset after 6 months) associated with a neurological disorders (neurological nystagmus). We present a unique 4-generation family with dominantly inherited nystagmus that develops in the first year of life. The family was initially published several years ago (OMIM 193003), but the pedigree has enlarged since this time. We have performed a whole genome search and localized the disorder to chromosome 13q31-q33. Haplotype construction and analysis of recombination events narrowed the region to a 13.8 cM region between markers D13S1300 and D13S158. Potential candidate genes in this region include SOX21, TYRP2 and ZIC2. Identification of the gene may hold the key to understanding pathways for early eye movement development.

**Aryl-hydrocarbon receptor interacting protein-like 1 (AIPL1): a possible function in photoreceptor-specific regulation of apoptosis.** *M.M. Sohocki<sup>1</sup>, S.P. Daiger<sup>1</sup>, D.T. Akey<sup>1</sup>, X. Zhu<sup>2</sup>, C. Craft<sup>2</sup>*. 1) Hum Genet Ctr, Univ TX Health Sci Ctr, Houston, TX; 2) USC Keck School of Med, Doheny Eye Inst, Los Angeles, CA.

*AIPL1* was the fourth gene to be associated with Leber congenital amaurosis (LCA), and the AIPL1 protein contains functional motifs commonly identified in chaperone proteins. In order to determine potential targets for this predicted activity of AIPL1, a yeast-two hybrid (Y2H) approach was used.

Screening of a bovine retinal cDNA library identified two potential Aipl1-interacting proteins, aven and Nub1, three and two times, respectively. These interactions are undergoing further confirmation using co-immunoprecipitation, immunolocalization, and GST pull-down using both the bovine and human proteins.

Both Aven and NUB1 are recently identified proteins that are likely involved in regulation of apoptosis within the retina. Aven is a cell death regulator that interferes with the ability of Apaf-1 to self-associate, suggesting that it impairs the Apaf-1-mediation of the caspases. NUB1 inhibits expression of NEDD8, a protein involved in G1/S progression of the cell cycle. Apoptosis and the cell cycle are closely tied together, and re-expression of cell cycle markers has been linked to certain types of neuronal cell death. As the photoreceptor cell is committed to permanent cessation of cell division, it is thought that forced reentry of the photoreceptor into the cell cycle after this commitment causes cell death.

If confirmed, AIPL1 will be the first photoreceptor-specific regulator of apoptosis to be identified, and will likely be an integral gene and protein in the development of treatments for inherited retinal degenerations. These treatments might involve therapies for multiple forms of inherited blindness, because in all forms of human retinal degeneration studied, photoreceptors eventually degenerate by the apoptotic pathway, and in at least some forms of inherited retinopathy, photoreceptor degeneration may be prevented or slowed by treatment with agents that interfere with apoptosis.

**Fine mapping of the Cerulean Cataract Type 1 gene locus on 17q24-q25.** *B.W. Rigatti<sup>1</sup>, F.Y. Demirci<sup>1,2</sup>, R.E. Ferrell<sup>2</sup>, M.B. Gorin<sup>1,2</sup>.* 1) Dept. of Ophthalmology, University of Pittsburgh SOM, Pittsburgh, PA; 2) Dept. of Human Genetics, University of Pittsburgh GSPH, Pittsburgh, PA.

Cerulean cataracts represent one of many forms of autosomal dominant, early onset hereditary cataracts and are characterized by the appearance of tiny blue or white opacities, predominantly in the peripheral layers of the lens. There are two loci reported for this distinctive phenotype: cerulean cataract type 1 on 17q24-q25 and cerulean cataract type 2 on 22q11.2-q12.2. Type 2 has been shown to be caused by mutation in the beta-B2-crystallin gene. The type 1 locus is flanked by microsatellite markers D17S802 and D17S836 and no causative gene has been identified. The family originally mapped to 17q24-q25 contains individuals with 6 recombinations within the flanking markers, but further localization has been hampered by the lack of informative markers. To narrow the interval, we have used GenBank and other genomic databases to generate a preliminary BAC contig. Various ESTs, STSs and SNPs have been identified within this region using both the Human Genome Project and Celera databases. Sixteen SNPs spanning our critical region have been analyzed by first testing within two distinct branches of the family that include the key recombinant individuals, screening with nucleotide sequencing, and then followed by more extensive screening of the entire family with denaturing HPLC (Transgenomic Wave). Twelve out of the sixteen SNPs were polymorphic in some of the family members. Eleven SNPs are informative and have narrowed the critical region containing this locus so that we can evaluate a more limited set of candidate genes for mutations. To date, we have screened two genes and no mutations have been identified. The screening of the remaining genes in the critical region is underway.

**Molecular Basis for Reduced Penetrance in Primary Congenital Glaucoma.** *I. Stoilov<sup>1</sup>, I. Jansson<sup>2</sup>, J.B.*

*Schenkman<sup>2</sup>, M. Sarfarazi<sup>1</sup>.* 1) Molecular Ophthalmic Genetics Laboratory, Department of Surgery; 2) Department of Pharmacology, UConn Health Center, Farmington, CT.

The severe primary congenital form of glaucoma (PCG) is familial in 10-40% of index cases. In majority of the reported families, PCG is inherited as autosomal recessive trait. However, in some cases the number of affected sibs is lower than expected thus indicating the possibility of reduced penetrance for this phenotype. Such possibility has recently been supported by the molecular analysis of PCG, the CYP1B1 gene in the Saudi Arabian population. Here we report our progress in the characterization of two CYP1B1 mutations: G61E and R469W, which have been associated with reduced penetrance of the PCG phenotype. G61E is located within the hinge region of CYP1B1 that permits flexibility between the membrane-spanning domain and the cytoplasmic portion of the molecule while R469W is located in the heme-binding region. We created these two mutations in CYP1B1 cDNA by site-directed mutagenesis and expressed them in *E. coli*. Three recombinant hemoproteins CYP1B1, G61E and R469W were then compared with respect to their stability and metabolic activity. Highest stability occurred in R469W, which only exhibited 37% decline in the amount of cytochrome P450 by 48 hrs. The CYP1B1 itself lost 50% over the same period while G61E lost 55% of the hemoprotein spectrum by 5 hrs and 70% by 24 hrs. Compared to the CYP1B1, the 4-hydroxylase activity against 17-beta-estradiol was reduced by 70% and 80% for G61E and R469W respectively. The 2-hydroxylase activity was decreased 65% for R469W but only 20% for G61E. Our data suggest that both mutant forms associated with reduced penetrance have residual metabolic activity against 17-beta-estradiol. The significance of this observation is in the fact that the expression of CYP1B1 could be upregulated several folds by chemicals such as dioxin acting via the aryl hydrocarbon receptor (AhR). Therefore, environmental exposure causing AhR driven over-expression of these mutant forms during the critical stages of development may provide sufficient CYP1B1 activity for the normal eye development. Supported by: NIH (EY-11095; ES03154) and The Glaucoma Foundation.

**Genotype-phenotype correlations in a series of 26 Rett Syndrome patients with MECP2 mutations.** A. Moncla<sup>1</sup>, A. Kpebe<sup>2</sup>, B. Chabrol<sup>3</sup>, J. Mancini<sup>3</sup>, N. Philip<sup>1</sup>, L. Villard<sup>2</sup>. 1) Dept de Génétique Médicale, Hopital d'Enfants de la Timone, Marseille, France; 2) Inserm U491, Fac de Médecine de La Timone, Marseille, France; 3) Dpt de Neuropédiatrie, Hopital d'Enfants de La Timone, Marseille, France.

Rett Syndrome (RTT, MIM 312750) is a severe neurological disorder affecting exclusively females. Its prevalence is about 1 in 15,000 live born females. Rett patients stop developing at about 1 year of age, and have a series of clinical signs indicative of a neurodevelopmental abnormality : arrest of brain development, regression of acquisitions, and behavioural troubles (stereotypic hand movement, autism). Most cases are sporadic (99.5%), although a few families have been reported. Mutations in the human methyl-CpG binding protein 2 (MECP2) gene located in Xq28 were identified in 70 to 80% of sporadic Rett syndrome case. We have screened the coding region of the MeCP2 gene in 43 female patients with clinical signs evocative of Rett syndrome. We found 26 mutations (60%) affecting different regions of the MeCP2 protein : R106G, R106W (3 cases), P127L, P152R, T158M (3 cases), R168X (4 cases), R255X (4 cases), R270X (4 cases), R306C, 883delC, 1156del43, 1157del32, 1196del71+inv(1197-1238). Since several mutations affecting the same residue were found in different patients and since a detailed clinical description was available for each, we were able to compare the location and type of the mutation with the clinical signs. The X-chromosome inactivation status was also analysed in each case to determine if favourable skewing could lead to a milder phenotype.

**A Complete Gene Catalogue of Human Xp11.4 harboring Disease Loci for Diabetes Mellitus Type I, Mental Retardation and Retinal Disturbances.** *J. Ramser*<sup>1</sup>, *G. Wen*<sup>2</sup>, *Y. Demirci*<sup>3</sup>, *I. Martinez-Garay*<sup>4</sup>, *S. Engert*<sup>1</sup>, *C. Pusch*<sup>5</sup>, *K. Badenhoop*<sup>6</sup>, *M. Gorin*<sup>3</sup>, *M. Platzer*<sup>2</sup>, *A. Meindl*<sup>1</sup>. 1) Dept. of Medical Genetics, Ludwig-Maximilians-University, Munich, Germany; 2) Dept. of Genome Analysis, Institute for Molecular Biotechnology, Jena, Germany; 3) Dept. of Ophthalmology and Human Genetics, Pittsburgh, USA; 4) Dept. of Genetics, University of Valencia, Valencia, Spain; 5) Molekulargenetisches Labor, Universitaets-Augenklinik, Tuebingen, Germany; 6) Dept. of Medicine I, University of Frankfurt, Frankfurt, Germany.

Different disease entities like two syndromic forms of mental retardation, diabetes mellitus type I and two eye diseases have been mapped to the short arm of the X-chromosome including the Xp11.4 region. In order to isolate genes, involved in these conditions, we have constructed a complete BAC/PAC-contig for the Xp11.4 region between markers DXS8025 and DXS228 encompassing about 3.0 Mb. For the proximal part of this region, between DXS993 and DXS228, a complete transcription map was established. Six distinct genes were found in this 1.5 Mb large interval, four of them were screened for mutations in patients with the complete form of congenital stationary night blindness (CSNB1). A novel gene termed NYX was found to be mutated in CSNB1 families (Pusch et al., Nature Genetics 2000). NYX is widely and low expressed and codes for a 481 amino acid protein. In order to identify candidate genes for X-linked cone dystrophy (COD1) we are now analysing the 1.5 Mb large distal part of the contig (DXS8025-DXS993). Sequence analysis using different software packages, which combine gene prediction programs, the masking of repeats and homology searches against different DNA and protein databases has resulted in the identification of three genes so far. They are currently screened for mutations in COD1 families. Genes isolated from this region will also, together with genes from the adjacent fully characterized Xp21.1 region, be evaluated for variants in patients suffering from diabetes mellitus type I. Finally, all genes from the Xp11.4 region and from the proximally located regions Xp11.3 and Xp11.23, can be screened for mutations in Prieto- and Renpenning syndrome, respectively.

**Prenatal Diagnosis of Beta-thalassemia in Iranian population, results of ten years study.** *F. Sahebjam<sup>1</sup>, R. Karimi-Nejad<sup>1</sup>, S. Teimourian<sup>1</sup>, S. Sahebjam<sup>1</sup>, H. Najmabadi<sup>2</sup>.* 1) Karimi-Nejad Pathology and Genetic Center, Tehran, Tehran, Iran; 2) Genetics Research Center, University of Welfare Sciences, Tehran, Tehran, Iran.

Beta-thalassemia is the most common genetic disorder in Iran. It is estimated that at least 25,000 affected patients and 2 million carriers live in Iran. Therefore prenatal diagnosis is at present a primary goal for prevention. As a first center, 10 years ago we started mutation screening and prenatal diagnosis of beta -thalassemia in Iranian families. During 10-year period we have made prenatal diagnosis for 414 cases ( 211 amnion samples and 204 CVS samples). We used a 24 primers-based panel for diagnosing the mutations of the parents and samples. Using this panel along with RFLP we were able to provide a reliable prenatal diagnosis for over 95% of pregnancies. Out of these 414 cases, 76 (18.35%) were Normal, 188 (45.41%) cases were heterozygotes for a single beta-thalassemia mutation, and 116 (28.1%) cases were either homozygotes or compound heterozygotes. In 30 samples (7.4%) we could not detect the mutations. Our data showed a very close Mendelian distribution as expected for a Mendelian type mode of inheritance. The frequency of detected mutations also will be discussed.

**Penatal Diagnosis Of X-Linked Ichthyosis By Very Low Levels Of Maternal Serum Unconjugated**

**Oestriol(MSuE3)As Measured By The Triple Test.** *G. Bach<sup>1</sup>, S. Feinstein<sup>1</sup>, R. Bargal<sup>1</sup>, V. Suri<sup>1</sup>, I. Yonah<sup>2</sup>, O.*

*Bonne<sup>2</sup>, M. Zeigler<sup>1</sup>, Z. Ben-Neriah<sup>1</sup>.* 1) Dept Human Genetics, Hadassah Medical Organization, Jerusalem, Israel; 2) Dept Psychiatry, Hadassah Medical Organization, Jerusalem.

Since the advent of the triple test which includes the determination of unconjugated oestriol found in maternal serum (MSuE3) as a parameter for the identification of high risk pregnancies for Down Syndrome, there has been an increase in the number of detected fetuses affected with the dermatological disorder X-linked Ichthyosis (XLI). XLI is associated with very low levels of MSuE3. XLI is caused by a deficiency of the enzyme steroid sulfatase (STS). Since 85-90% of XLI males have a complete deletion of the STS gene and in ~ 5% of males the deletion of the STS gene is seen as part of a contiguous gene syndrome (CGS) giving rise to a complex phenotype, a problem arises in genetic counselling in families without prior history of the disease. To improve genetic counselling in these cases we have performed molecular studies on 21 unrelated XLI males and 20 XLI male fetuses found by very low MSuE3, 8 of whom were from families with prior history of XLI. The importance of the molecular test results and prenatal genetic counselling in these cases will be discussed. Key words: X- Linked Ichthyosis (XLI), Maternal serum unconjugated oestriol (MSuE3), Steroid sulfatase (STS), Contiguous gene syndrome (CGS).

**Clinical significance of prenatally detected Dandy-Walker malformation and variant.** *R.L. Olson<sup>1</sup>, L.H. Seaver<sup>1</sup>, R.C. Rogers<sup>1</sup>, P.C. Greig<sup>2</sup>, E.H. Dellinger<sup>2</sup>, S.J. Chapman<sup>2</sup>, R.E. Stevenson<sup>1</sup>.* 1) Greenwood Genetic Center, Greenwood, SC; 2) Greenville Hospital System, Greenville, SC.

Dandy-Walker malformation (DWM) is described as a posterior fossa cyst, cerebellar vermis defect, hydrocephalus of variable degree, and elevation of the torcula and tentorium. Dandy-Walker variant (DWV) is a less severe malformation described as isolated atresia of the cerebellar foramina, enlarged cisterna magna, or cysts that do not communicate with the fourth ventricle.

The prognosis and clinical significance of prenatally diagnosed DWM and DWV are controversial. Prognosis is heavily dependent on associated malformations and karyotype, but is not uniformly fatal [Kolble et al. 2000, Ecker et al. 2000]. We report 20 cases of prenatally diagnosed DWM (n=16) and DWV (n=4) from 1994 to 2000. For each case the prenatal ultrasound was compared with the available postnatal studies, autopsy findings, or clinical examinations. A review of the findings shows 12/20 patients are living today, but 5 patients have diagnosed MCA syndromes. The 8 patients who died had serious anomalies in addition to DWM. 4/17 who had chromosome analyses had cytogenetic abnormalities. Non-CNS anomalies were found in 11/20 patients. 3/20 had different or additional CNS defects identified. When comparing the prenatal and postnatal diagnosis, 5/13 patients were found to have normal or normal variant postnatal scans.

The findings in these patients suggest DWM is difficult to accurately diagnose prenatally. When diagnosed correctly there is a significant morbidity associated with DWM. If DWM is associated with non-CNS findings there is increased morbidity and mortality. Even apparent isolated DWM may prove to have additional defects. Since 5/13 patients had normal postnatal scans, caution should be used in prenatal counseling. Amniocentesis should be offered in all cases of prenatally diagnosed DWM. A careful postnatal genetic evaluation should be performed.

**No evidence for involvement of PPARG in neural tube defect families.** *D.G. Siegel<sup>1</sup>, E.C. Melvin<sup>1</sup>, H. Cukier<sup>1</sup>, T.M. George<sup>1</sup>, J.F. Mackey<sup>1</sup>, G. Worley<sup>1</sup>, J.S. Nye<sup>2</sup>, M.C. Speer<sup>1</sup> and NTD Collaborative Group.* 1) Center for Human Genetics, Duke University Medical Center, Durham, NC; 2) Northwestern University Medical Center, Chicago, IL.

An increase in the frequency of twins has been suggested in probands with neural tube defects (NTDs) and in close relatives of NTD probands. Reports as to whether the increase involves monozygotic or dizygotic (DZ) twinning are inconsistent. Recently, Busjahn et al. (Nat Genet 26: 398) reported that the gene encoding peroxisome activated receptor (PPARG) may be involved in the etiology of DZ twins. We hypothesized that if there is a similar mechanism influencing DZ twinning and NTDs, we would see differences in allele frequencies in NTD families when compared to controls. We looked at allele frequencies for PPARG in NTD cases, mothers of NTD cases, and fathers of NTD cases in 145 American Caucasian NTD families in which the proband had lumbosacral myelomeningocele. Each group was in Hardy-Weinberg equilibrium. There were no differences in allele frequencies between any of these groups and a series of unrelated controls, nor was there evidence for linkage disequilibrium within these families following testing via the pedigree disequilibrium test. However, when the parental allele frequencies were compared to those reported by Busjahn et al., we found a significant difference ( $p = 0.01$ ) between these groups. In our series of NTD families (N=750), we find that the rate of twinning among NTD probands and close relatives of NTD probands (e.g., siblings, parents, aunts/uncles) is not significantly higher than the general population frequency. These data suggest that the mechanism involved in DZ twinning associated with PPARG is different from the causation of lumbosacral NTDs in these American Caucasian families.

**Cardiac malformations in the first trimester fetuses with increased nuchal translucency.** *I.V. Novikova, G.L. Tsukerman, S.A. Shreder, O.V. Pribushenya, L.A. Savenko, N.A. Venchikova, L.M. Lishtvan, G.A. Krapiva, S.I. Kovalev, I.A. Kirillova.* Institute for Hereditary Diseases, MINSK, Belarus.

Pathological examination of the heart and great arteries was performed in 65 fetuses with increased nuchal translucency >3 mm. after surgical termination of pregnancy at 10-13 weeks of gestation. Cardiac defects (CD) were detected in 80.0% of all cases, in 78.8% of aneuploid fetuses and in 83.3% of fetuses with normal karyotype.

Karyotype	Total # of fetuses	# of fetuses with CD
Aneuploidy, including:	47	37
Trisomy 13	6	4
Trisomy 18	10	9
Trisomy 21	12	6
Other trisomies	2	1
Monosomy X	17	17
Normal karyotype	18	15
Total	65	52

These findings suggest that measurement of nuchal translucency thickness is effective for screening for cardiac abnormalities in fetuses with normal karyotype in addition to its role in detection of chromosomal disorders.

**Nature of a disease: Congenital deficiency of alpha fetoprotein.** *R. Sharony<sup>1</sup>, A. Amiel<sup>1</sup>, N. Bouaron<sup>1</sup>, D. Kidron<sup>2</sup>, D. Itzhaky<sup>3</sup>, M. Fejgin<sup>1</sup>.* 1) The Genetic Institute; 2) The Pathology Institute; 3) Immunology Laboratory, Sapir Medical Center-Meir Hospital, Kfar Saba, Israel.

The role of alpha-fetoprotein (AFP) is unknown for the most part. Several functions of AFP during fetal life have been suggested: regulation of osmotic pressure, mediation of the immune system and growth control. In this report we describe two cases of congenital absence of AFP that were identified by the current methods of detection. The pathological examination results, including an immunohistochemical stain, which refine the levels of AFP detected by the biochemical studies, are enclosed. In order to exclude chromosomal anomalies in the placentae, we performed complete genomic hybridization analysis on both placentae. The test did not reveal any abnormalities of the first placenta. However, the second placenta showed monosomy 16, which was confirmed by FISH. It has been reported that tissue-specific expression of the AFP gene is strongly stimulated by an enhancer present 3.3 to 4.9 kb upstream of the transcription initiation site mapped to 16q22.3-q23.1. An overview of the molecular biology of AFP production is set forth. An explanation is suggested for the lack of symptoms in a newborn of undetected levels of AFP and the mechanism by which this condition might occur. This may shed light on the mechanism by which this rare condition is generated and the lack of any symptoms in affected newborns.

**Testing Normality Of Fetal Dna Concentration In Maternal Plasma At 10-11 Completed Weeks' Gestation: Preliminary Approach To Integrated Screening For Aneuploidies.** P. Carinci<sup>1</sup>, E. Caramelli<sup>1</sup>, M. Concu<sup>1</sup>, N. Rizzo<sup>2</sup>, A. Farina<sup>1,2</sup> and Fondazione CARISBO" and "Progetto Giovani Ricercatori". 1) Dept Histology & Embryology, Univ Bologna, Bologna, Italy; 2) Department of Obstetrics & Gynecology, University of Bologna, Italy.

Extracellular foetal DNA has been detected recently in the plasma of pregnant women, and it could represent a further approach in non-invasive prenatal diagnosis. Aim of this paper was to evaluate the distribution of the values of foetal DNA in maternal plasma expressed as g/equiv of a population of normal pregnancies. Data were collected from 40 women who underwent a CVS. Samples were collected at 10-12 completed gestation weeks' determined by ultrasound scan. The blood samples, 5 ml, were processed within 24h of sampling. For analysis, DNA was extracted from 1 ml plasma (QiaAmp). The DNA extraction was carried out by female staff, to minimize the possibility of contamination. The DNA preparation were eluted in 200 ml elution buffer of which 10 ml was used as a template for the PCR reaction. To determine the amount of male foetal DNA the Y chromosome SRY locus was used. A standard protocol for Real time PCR was used. Descriptive statistics was performed by means of routine analysis. In order to tests for deviations from normal distribution, the Kolmogorov-Smirnov test (KS) was used. The KS statistic quantifies the discrepancy between the distribution of data and an ideal Gaussian distribution. The Dallal and Wilkinson approximation to Lilliefors' method was used. Maternal age was not taken into account in this paper as a possible confoundent on foetal DNA values, since our population was unbalanced. In fact 85% of the women were  $\geq 35$  years at delivery. Our results showed a normal distribution of fetal DNA at 10-12 week' gestation after natural logarithmic transformation. Mean value of foetal DNA was 71 g/equiv. This analysis can be considered a preliminary step for a possible integrated screening able to combine more variables to detect abnormal pregnancies and to improve sensitivity for genetic diseases at the first trimester.

**EVOLUTION OF THE DETECTION RATE OF CONGENITAL HEART DISEASES BY ROUTINE FETAL ULTRASONOGRAPHIC EXAMINATION.** *Y. Alembik, M.P. ROTH, B. DOTT, C. STOLL.* Service de Gntique Mdicale, Hpital de Hautepierre, Strasbourg, France.

The objectives of this study were to compare the detection rate of congenital heart diseases (CHD) by routine fetal ultrasonographic examination (US) from 1979 to 1999 in a well defined population. The material for this study came from our register of congenital anomalies which registered 13,500 births per year including livebirths, stillbirths and termination of pregnancy (TOP). Three US examinations, one for search of congenital anomalies and 2 for biometric purposes were performed routinely. CHD were classified as isolated or associated when at least one other major extra cardiac malformation was present. The studies periods were 1979 - 1988 (131,760 births), 1990 1993 (92,021 births) and 1994 1999 (80,076 births). For these 3 periods the overall detection rate (DR) was 9.2%, 13.7% and 19.9% respectively. The DR for isolated cases was 4.5%, 10.2% and 11.4% respectively. The DR for multiply malformed with CHD was 30.5%, 33.0% and 40.2% respectively. The DR for hypoplastic left heart was 38.7%, 46.1% and 64.3%, respectively, for tetralogy of Fallot 21.4%, 22.6% and 48.5%, respectively, for ventricular septal defect 4.3%, 6.6% and 19.8% and for atrial septal defect 5.8%, 8.8% and 7.2%. For all CHD, TOP was 2.6%, 6.4% and 12.3% respectively and for the CHD diagnosed prenatally TOP was 28.6%, 46.7% and 62.0%, respectively the results are in accordance with the other studies of routine prenatal diagnosis of CHD. However with the extended fetal ultrasonographic examination proposed by some authors the DR is much higher than in this study. In conclusion this study shows that there is an improvement in the prenatal detection rate of CHD over time but this increase is only slight, and higher for isolated cases than for multiply malformed with CHD. These results stress the need to obtain a definitive clear, four chamber view and a view of the inflow and outflow tracks of the fetal heart and to train sonographers in order to improve prenatal detection of CHD.

**PRENATAL DIAGNOSIS OF DYSMORPHIC SYNDROMES BY ROUTINE FETAL ULTRASONOGRAPHIC EXAMINATION ACROSS EUROPE.** *C. Stoll, M. Clementi.* Service de Gntique Mdicale, Hpital de Hautepierre, STRASBOURG, FRANCE.

The objectives of this study was to evaluate the prenatal diagnosis of dysmorphic syndromes by fetal ultrasonographic examination. Data from 20 registries of congenital malformations in 12 European countries were included in the study. 479 out of 2454 cases with congenital heart diseases were recognized syndromes including 375 chromosomal anomalies and 104 non chromosomal syndromes : 28 deletions 22q11 (44,4% were prenatally detected), 17 heterotaxy sequences (64,7% were prenatally detected), 15 VATER association (46,6% were prenatally diagnosed), and 44 others. 192 out of 1130 cases with renal anomalies were recognized syndromes, 161 out of them (83,3%) were diagnosed prenatally including 107 chromosomal aberrations and 64 non chromosomal syndromes (15 VATER, 13 Meckel Gruber, and 36 others). 54 out of the 250 cases with limb reduction deficiencies were recognized syndromes, including 16 chromosomal syndromes and 38 non chromosomal syndromes (7 amniotic bands, 6 VATER, and 25 others) ; 20 of them were diagnosed prenatally (37,0%) including 9 chromosomal syndromes. 57 out of 243 cases of abdominal wall defects were recognizable syndromes, 48 with omphalocele (27 chromosomal, 5 OEIS, and 9 others) and 9 with gastroschisis (4 limb body wall complexe, 2 megacystis-microcolon, 2 chromosomal aberrations and 1 OEIS), 48 out of them were diagnosed prenatally (82,5%). 64 out of 349 cases with intestinal anomalies were recognized syndromes, 34 were diagnosed prenatally (53.1%). There were 549 cleft lip and palate (CL(P)) and 197 cleft palate (CP) including 74 chromosomal aberrations and 73 recognised syndromes including 23 Pierre Robin. Prenatal diagnosis was done in 51 CL(P) (53.1%) and 7 CP (13.7%). Out of 290 cases with spina bifida, 18 were recognized syndromes, 17 of them were diagnosed prenatally. All 11 syndromic encephaloceles were diagnosed prenatally. In conclusion this study showed that around 50% of the recognized syndromes can be detected prenatally by the anomaly scan. However the detection rate varied with the type of syndromes and with the policy of prenatal screening between countries.

**Cornelia de Lange syndrome - Prenatal manifestations: Report of four cases.** *K.L. Chong<sup>1</sup>, M. Nowaczyk<sup>2</sup>, A. Pai<sup>1</sup>, P. Mohide<sup>2</sup>, D. Chitayat<sup>1</sup>.* 1) Prenatal Diagnosis and Medical Genetics Program, Mount Sinai Hospital, Toronto, Ontario, Canada; 2) Department of Genetics, McMaster University, Hamilton, Ontario, Canada.

Cornelia de Lange (CdL) or Brachmann-de Lange syndrome is a complex disorder of unknown etiology usually characterized by severe mental retardation, prenatal and postnatal growth retardation, microcephaly, small stature, limb deformities and characteristic facial features. Most cases of CdL syndrome are sporadic; however, rare familial cases and association with duplications of chromosome 3q have been reported. We present here four cases of CdL syndrome detected prenatally and confirmed by autopsy/ postnatal examination to illustrate the salient features of this syndrome on detailed ultrasonographic evaluation. All cases had unilateral or bilateral upper limb abnormalities ranging from absent fingers to single phalanx to absent hand or forearms. Intrauterine growth retardation was not consistently present prenatally. The remaining fetal anatomy was usually normal but other anatomical findings were present in 1 case. All karyotypes were normal. All cases presented had characteristic facial features of CdL syndrome including high arched eyebrows, synophrys and micrognathia, which confirmed the diagnosis postnatally. Although the differential diagnosis for limb abnormalities is broad and should consider several syndromes including TAR, Holt-Oram, EEC, Roberts syndrome, and Fanconi anemia, these cases highlight the importance of postnatal examination in confirming the diagnosis of CdL syndrome when a fetus presents with phocomelia or limb/hand abnormalities.

**Prenatal diagnosis of Pallister-Killian syndrome in a fetus with increased nuchal translucency.** *K. Bakou<sup>1</sup>, P. Kaminopetros<sup>2</sup>, C. Sarri<sup>3</sup>, M.B. Petersen<sup>1,3</sup>, V. Velissariou<sup>1</sup>*. 1) Cytogenetics Laboratory, MITERA Matern. Surg. Center, Marousi, Greece; 2) Dept. Fetal Medicine, MITERA Matern. Surg. Center, Marousi, Greece; 3) Dept. Genetics, Inst. Child Health, Athens, Greece.

The case of a fetus with Pallister-Killian syndrome (tetrasomy 12p) is presented during prenatal diagnosis in the first trimester of pregnancy. Chorionic villus sampling (CVS) was performed during the 12th week of gestation because of increased nuchal translucency (3.1 mm), left diaphragmatic hernia, polydactyly and clinodactyly which were detected during routine ultrasound investigation. In the direct preparation, chromosome analysis showed a normal female karyotype 46,XX in a total of 17 cells. In the culture, an extra metacentric marker chromosome of unknown origin was detected in 19% of cells. G-banding was suggestive of an isochromosome i(12p). In order to distinguish between a case of true mosaicism or Confined Placental Mosaicism (CPM), amniocentesis was performed. The same marker chromosome was detected in 86% of the amniocytes. FISH analysis with a whole chromosome 12 paint probe confirmed that the marker was indeed an isochromosome i(12p) and that the fetus suffered from the Pallister-Killian syndrome. The parents elected termination of the pregnancy. The presence of the i(12p) chromosome was confirmed in skin fibroblasts of the aborted fetus.

**PRENATAL DIAGNOSIS AND FAMILIAL APPROACH OF A  $t(1;18)(q21.3;q11.2)$ .** *R. Baez-Reyes, G. Razo-Aguilera, R. Garcia-Cavazos.* Departamento de Genetica, Instituto Nacional de Perinatologia. MEXICO.

The balanced reciprocal translocation can produce disbalanced gametes that precipitate the loss of gestation or products with congenital defects, otherwise can block gametogenesis depending on the involved chromosome and the sex of the carrier. A case of couple that went to Prenatal Diagnosis consult is reported, a 32th-week pregnancy from last menstruation date, whose previous son had hidrocephaly and not specified structural defects. A high-resolution ultrasound is made reporting dilatation of posterior fossa, congenital cardiopathy, abnormal position of both hands and hydramnios. Cytogenetic amniocentesis is made, obtaining a chromosomic complement:  $47,XY,der(1)t(1;18)(q21.3;q11.2)+der(18)t(1;18)$  by GTG and FISH. Then, cytogenetic study is made to the parents, finding that the mother is carrier of the balanced reciprocal translocation, with chromosomic complement  $46;XX,t(1;18)(q21.3;q11.2)$ . A male newborn is obtained, who presents early neonatal death. Correlation phenotype-kariotype is made and the cytogenetic study is completed to 27 members of the family in order to give real genetic advice.

**Monochorionic twins with discordant sex in a triplet pregnancy.** *J. Claus*<sup>1</sup>, *R.A. Quintero*<sup>2</sup>, *B.G. Kousseff*<sup>1</sup>. 1) USF Regional Genetics Program, Tampa, FL; 2) Florida Institute for Fetal Diagnosis and Therapy, St. Joseph's Women's Hospital, Tampa, FL.

We report an IVF (with two-embryo transfer) triplet pregnancy in a 30-year old primigravida with sex discordant monochorionic diamniotic twins and fetal demise of triplet A. On targeted sonogram triplet B showed hydrops and evidence of a micropenis. Aspiration of the cystic hygroma for chromosome analysis and to provide space for the ligation of the umbilical cord was done. Endoscopy confirmed the presence of abnormal genitalia, suggestive of micropenis. The umbilical cord ligation was performed to prevent adverse effects of the spontaneous demise of triplet B on the health of triplet C. The karyotype was 45,X. Amniocentesis of triplet C showed 46, XY. Triplet C developed hydrops and a month later was miscarried at gestation 22 weeks. A pathology report described monochorionic triamniotic triplet placentation. DNA testing for zygoty was not performed. Sex discordance has been reported in twelve articles. Of these, two (Gonsoulin et al., *Prenat Diagn* 10: 25-8; Schmid et al., *Prenat Diagn* 1990 20:999-1003) were based on prenatal diagnosis. It is likely that the discordance was either due to postzygotic nondisjunction or anaphase lag, before or during twinning. This report emphasizes the fact that suspected monozygoty does not exclude karyotyping both sacs when anomalies are noted.

**Pragmatic implications (few normal embryos) of preimplantation genetic diagnosis (PGD) for chromosomal rearrangements.** *N.R. Agan<sup>1,2</sup>, S. Torsky<sup>1</sup>, P. Cisneros<sup>1</sup>, S.A. Carson<sup>1</sup>, J. Buster<sup>1</sup>, L. Swaim<sup>3</sup>, J.L. Simpson<sup>1,2</sup>, F.Z. Bischoff<sup>1</sup>.* 1) Departments of OB/GYN; 2) Molecular/Human Genetics, Baylor College of Medicine, Houston, TX; 3) Houston Women's Care Associates, Houston, TX.

Individuals with chromosome rearrangements are at an increased risk for abortions and children with birth defects. The 10-15% empiric risk of liveborn unbalanced segregants (adjacent; 3:1) can be addressed by PGD. However, the efficiency of PGD depends on how many normal/balanced embryos are present. **OBJECTIVE:** To determine the proportion of normal/balanced embryos in two couples with chromosomal rearrangements. **METHODS:** In couple A, the husband carries a balanced translocation [46,XY,t(5;13)(p10;q10)]; in couple B the wife a derivative chromosome [46,X,der(X)t(X;Y)(p22.13;q11.2)]. Single biopsied blastomeres from fertilized embryos were subjected to FISH analysis. **RESULTS:** Frequency of normal embryos is far less than the 85-90% expected at CVS/amniocentesis. **CONCLUSION:** In PGD for rearrangements, relatively few normal embryos are found. Programs must be prepared to screen many embryos; the number of embryos screened may be more than usually needed for routine IVF.

	Couple A-Cycle 1	Couple A-Cycle 2	Couple B-Cycle 1
# embryos biopsied	24	19	16
# abnormal embryos	17	15	11
# uninformative	4	1	0
# normal embryos	3 (12.5%)	3 (15.7%)	5 (31.25%)
Pregnancy	No	Pending	Yes

**Mosaic Trisomy 16: High Percentage of Trisomic Cells in Amniotic Fluid Followed By Favorable Outcome.** *K. Morris<sup>1</sup>, J.R.R. Batanian<sup>2</sup>, D.K. Grange<sup>1</sup>, D. Hoyt<sup>1</sup>.* 1) Pediatrics, St. Louis University, St Louis, MO; 2) Pediatrics and Pathology, St. Louis University.

Numerous cases of prenatally diagnosed mosaic trisomy 16 have been reported. Outcomes have been highly variable and few reports include information about health and development beyond the newborn period. We report a patient with mosaic trisomy 16 with a high percentage of trisomic cells in amniotic fluid, in whom the outcome has been good. Amniocentesis was done at 16 weeks gestation because a triple screen was positive for Down syndrome. Amniotic fluid chromosomes revealed 39 of 42 cells (93%) with a 47,XX,+16 karyotype. The pregnancy was marked by intrauterine growth retardation and premature delivery at 32 weeks. Blood chromosome analysis at birth showed 20/20 cells with a 46,XX karyotype while placental chromosome analysis showed 20/20 cells with a 47,XX,+16 karyotype. Skin biopsy showed 2/50 cells with a 47,XX,+16 karyotype. Maternal disomy 16 has been ruled out by blood studies. No serious medical problems have yet been identified in the child. She is being followed by cardiology for mild aortic valve stenosis, with a possible bicuspid aortic valve. Neonatal renal and brain ultrasounds were normal. Ophthalmologic abnormalities include cloudy corneas which cleared spontaneously, mild microphthalmia and "setting sun" sign. Bilateral inguinal hernias were repaired at 5 months. Dysmorphology exam after birth showed only a lowset, slightly dysplastic ear and slightly curved fourth toes. Repeat exam at 6 months of age showed plagiocephaly, prominent forehead and hemangiomas on the glabella and upper eyelids, but was otherwise normal. At 9 months chronological age, weight and head circumference were within normal limits for corrected age (25th and 50th%), while height was less than 5%. At 10 months (8 months corrected age), Denver assessment showed development in the 9-10 month range for all areas tested. Gross motor development was in the 10-11 month range. This case demonstrates that a favorable outcome in terms of health and development can occur even with a high percentage of trisomic cells in amniotic fluid, and with a low level of mosaicism postnatally.

**Quantification of all fetal nucleated cells in maternal blood of aneuploid pregnancies using FISH and PRINS techniques.** *K. Krabchi, M. Bronsard, J. Masse, J-C. Forest, R. Drouin.* Dept Med Biol, Laval Univ and Hosp St Francois d'Assise, CHUQ, Quebec, Qc, Canada.

Recently, we have demonstrated that it is possible to quantify the total number of all fetal nucleated cells per unit volume of maternal blood obtained between 18th and 22nd weeks gestation in normal pregnancies (Krabchi K. et al., Clin. Genet. 2001, in press). This number fluctuated between 2 to 6 fetal cells per mL of maternal blood. The purpose of our study is to quantify, using the same approach, the total number of fetal nucleated cells in maternal blood of pregnant women bearing an aneuploid conceptus. In order to achieve maximum recovery of fetal cells, we used a simple and rapid harvesting method without any enrichment procedures, followed by either Fluorescent In Situ Hybridization technique (FISH) or PRimed In Situ (PRINS) labeling technique. Both techniques have been performed on blood specimens provided by eleven healthy pregnant women carrying an aneuploid fetus with the following karyotypes (the number of cases with this karyotype): 47,XY,+21(6); 47,XY,+18(1); 47,XXX(2); 47,XYY(1) and 69,XXX(1). Detection of fetal cells was carried out using specific sex chromosome probes directly coupled to fluorochromes for FISH ( CEP-X a-Satellite, CEP-Y Satellite III, LSI-21, CEP-18 a-Satellite, Vysis Inc.) or specific oligonucleotide primers for chromosomes X, Y, 21, 18, 7 and 8, followed by Taq DNA polymerase extension for PRINS reaction. The PRINS technique appears to be an interesting alternative to FISH and could be a useful tool for non-invasive prenatal cytogenetic analysis. Identification and quantification of fetal cells were performed by manual fluorescent microscopy screening. Between 11 to 26 fetal cells per mL were identified. These numbers are around 5-fold higher than the number of fetal cells observed in normal pregnancies. Thus, we demonstrate that it is possible, under optimized conditions, to reliably and reproducibly identify fetal cells in maternal blood, particularly when the fetus is aneuploid. In fact, in agreement with other studies, our results show that fetal cells in maternal circulation appear in much higher number in aneuploid pregnancies.

**Development of a new rapid test for Down's syndrome using real-time quantitative PCR.** *W. Holzgreve<sup>1</sup>, B. Zimmermann<sup>1</sup>, F. Wenzel<sup>2</sup>, S. Hahn<sup>1</sup>.* 1) Dept OB/GYN, Univ Basel, Basel, Switzerland; 2) Dep. Human Genetics, University Children's Hospital, Basel, Switzerland.

A significant proportion of clinical genetics is involved with the analysis of gross chromosomal anomalies. In prenatal diagnosis a major concern are aneuploidies, of which Down's syndrome is the most important in live births. The detection of these gross changes is still time consuming despite modern technologies such as FISH or quantitative fluorescent PCR. For this purpose we have developed a novel alternative using real time quantitative PCR using genetic loci in the Down's region of chromosome 21 and a control locus on chromosome 12. Simultaneous assessment of ratio of these two loci by multiplex real time PCR has shown that this technique can be used for the reliable and rapid distinction of trisomy 21 from karyotypically normal tissue. This technology can readily be extended to examine the most common fetal aneuploidies (13, 18, X and Y) or instances of chromosomal loss or gain. Furthermore, since it permits the rapid automatic analysis of numerous samples it is very well suited for high-throughput diagnostic settings.

**Prenatally diagnosed complex chromosome 4 rearrangement: A counseling dilemma.** *A.K. Yenamandra<sup>1</sup>, L. Mehta<sup>2</sup>, L. Hentze<sup>1</sup>, A. Shanmugham<sup>2</sup>, A. Ahmed<sup>3</sup>, P. Koduru<sup>1</sup>*. 1) Cell Genetics Lab, Dept. of Pathology; 2) Div. of Medical Genetics, Dept. of Pediatrics, North Shore University Hosp. Manhasset, NY; 3) Dept. Pathology, Univ. South Florida, Tampa, FL.

A 44 year old woman was referred for amniocentesis. She had a 4 year old healthy son and a history of two previous spontaneous abortions. Fetal karyotype was designated 46,XX,inv(4)(p15.2p16)(p12q21)(q33q35). Parental chromosomes were normal. FISH with coatosome 4 probe completely painted both homologues of chromosome 4. FISH with the Wolf-Hirschhorn region probe was normal in the fetus and the parents. Detailed fetal ultrasound and echocardiogram at 19 weeks gestation were normal. Parents were counseled that in a single de novo inversion involving two breakpoints, risks for abnormalities are approximately 7% (Warburton, 1991). The risk per additional breakpoint could be extrapolated to be 3.5% (Cotter, 1996), however this is arbitrary and in complex chromosome rearrangements (CCR) with several breakpoints information is scarce. Postnatal ascertainment of CCR's is biased towards high risks for mental retardation and physical defects. Based on the above, the risk of abnormality in this fetus was considered to be around 21%, given the six breakpoints. A normal fetal ultrasound and echocardiogram could indicate a lower risk. Despite the normal sonograms, the apparently balanced appearance of the rearrangement and normal FISH studies, the risk in this case was perceived as significant. The parents opted to terminate the pregnancy. Fetal examination could not be obtained. Multiple rearrangements within the same chromosome are rare, only one case of a double inversion of chromosome 5 presenting with cri-du-chat syndrome features could be ascertained. This case presented a counseling dilemma given the rarity of the abnormality and lack of information on prenatally diagnosed complex chromosome rearrangements.

**Advantage of utilization of whole genome amplification coupled comparative genomic hybridization in reproductive pathology.** *T.A. Loukianova<sup>1</sup>, S.S. Tang<sup>1</sup>, E. Rajcan-Separovic<sup>1,2</sup>, S. Ma<sup>3</sup>, D.K Kalousek<sup>1,2</sup>.* 1) Department of Pathology , University of British Columbia, Vancouver B.C; 2) Department of Pathology, Children's and Women's Health Centre, Vancouver, B.C; 3) Department of Gynecology, Vancouver General Hospital, Vancouver B.C.

Comparative genome hybridization (CGH) is a perfect tool for the recognition of aneuploidies that are common findings in reproductive pathology. However, the diagnostic ability of CGH is restricted by the amount of DNA required to perform CGH analysis. Maternal contamination also presents a problem for CGH analyses of reproductive tissues, originating from a pregnancy loss. Implementation of degenerate oligonucleotide-primed PCR(DOP-PCR) to supplement CGH technique expands the role of CGH in reproductive genetics. Utilizing DNA extracted from a small amount of tissue, even from a single cell represents, in addition, a sensitive diagnostic tool for detection of mosaicism in heterogeneous tissues. Our experience combining DOP-PCR with CGH comprises the analyses of 80 specimens including abortive tissues, gonadal tissues and tumors. All of them were successfully performed according to the published protocol by Kuukasjarvi et al. 1997. The template of DNA used for whole genome amplification ranged from 12pg (one cell extraction) to 200 ng. The amount of amplified DNA obtained was between 200-3000ng and allowed us to perform both CGH and SRY- specific PCR for sex confirmation. Cytogenetic findings include both whole as well as segmental chromosomal losses and gains. When possible, CGH results were verified with conventional cytogenetics. Our results highlight the advantage of the utilization of DOP-PCR coupled CGH in reproductive pathology.

**Improved MACS/CD71 fetal cell detection with rapid processing of maternal blood.** *J.L. Simpson<sup>1,2</sup>, D.A. Marquez-Do<sup>1</sup>, D.X. Dang<sup>1</sup>, C. Horne<sup>3</sup>, D.E. Lewis<sup>3</sup>, F.Z. Bischoff<sup>d</sup>*. 1) Depts of OB/GYN; 2) Molecular/Human Genetics; 3) Immunology, Baylor College of Medicine, Houston Texas.

Increasingly investigators are pursuing strategies for isolation and analysis of fetal cells in maternal blood as a method of noninvasive prenatal diagnosis. Given the low number of circulating fetal cells at any given time during pregnancy, optimizing methods for enrichment is necessary to maximize yield of these rare cells. **OBJECTIVE:** To determine whether the time at which sample processing is begun affects fetal cell detection. **METHODS:** Blood samples were obtained from women (n=25; ranging from 10.1 to 20.7 weeks gestation) prior to invasive prenatal genetic diagnostic procedure. Samples were blinded, divided into two aliquots, and processed within 2 or 16-18 hours later. Processing involved separation using discontinuous double gradient Percoll followed by MACS enrichment of CD71<sup>+</sup> cells. Recovered cells were analyzed by FISH for X and Y chromosomes. **RESULTS:** Frequency of fetal (XY) cells detected among the split specimens is summarized in the table below. Results were no influenced by gestational age.

Fetal Sex	Process within 2 hrs	Process within 16-18 hrs
Male	5/15 (33%)	2/15 (13%)
Female	1/10 (10%)	1/10 (10%)

**CONCLUSIONS:** A greater than two-fold increase in the detection of XY-cells observed in split samples processed within 2 hrs suggests that fetal CD71<sup>+</sup> cells may be less stable than maternal cells. Alternatively, these cells may be too low in number and variable among cases. Hence, an alternative marker (eg gamma globin) may be required for samples processed at a later time.

**Poor outcome in Down syndrome fetuses with cardiac anomalies or growth retardation.** *I.M.E. Frohn-Mulder<sup>1</sup>, M. Wessels<sup>2,3</sup>, F. Los<sup>2</sup>, P. Willems<sup>2</sup>, M. Niermeijer<sup>2</sup>, J. Wladimiroff<sup>2,3</sup>.* 1) Pediatric Cardiology, Sophia Children's Hospital, Rotterdam, The Netherlands; 2) Department of Clinical Genetics, Erasmus University, Rotterdam, The Netherlands; 3) Department of Obstetrics and Gynecology, Univ Hospital Dijkzigt, Rotterdam, The Netherlands.

In some cases of fetal Down syndrome an ultrasound scan performed in the second or third trimester of gestation shows fetal abnormalities leading to a cytogenetic diagnosis. Genetic counseling in these pregnancies is difficult as the prognosis of this particular group of Down syndrome fetuses is not well known. To determine the outcome of these pregnancies, we studied 55 women with sonographically suspected fetal anomalies, polyhydramnios or growth retardation due to trisomy 21 in the fetus. A detailed scan was performed to determine the nature of the anomalies and possible associated malformations. Cardiac malformations were diagnosed pre- and postnatally in 29 out of these 55 Down fetuses (53 %), with complete or incomplete atrioventricular septal defects and ventricular septal defects being the most frequent anomalies. The most frequent non-cardiac findings were a relative short femur (45 %) and a small-for-gestational age (SGA) fetus (27 %). Termination of pregnancy was carried out in 25 out of 55 pregnancies (45 %). Of the 30 continuing pregnancies, 10 ended with intrauterine death whereas the remaining 20 pregnancies resulted in the delivery of a live-born infant at a mean gestational age of 37 weeks. The prognosis of these live-born Down infants was poor with a 1-year survival of only 60 %. Combining intrauterine death and death in the first year of life indicated that the overall survival rate was only 40 %. Fatal outcome was noted in 68 % (13/19) of the cases in the presence of congenital heart disease, 83 % (10/12) in SGA fetuses, 86 % (6/7) in combined congenital heart disease and SGA, but only in 17 % (1/6) in the absence of congenital heart disease and SGA. This study indicates that Down syndrome fetuses diagnosed in the second or third trimester have a poor outcome when they present with congenital heart disease and/or SGA. This is important in the genetic counseling of such pregnancies.

**Success rate for culture of fetal postmortem tissue is dependent on the method of pregnancy termination.** *E.J.T. Winsor<sup>1</sup>, R. Windrim<sup>2</sup>, G. Ryan<sup>2</sup>, G. Seaward<sup>2</sup>, D. Chitayat<sup>2</sup>, H. Akoury<sup>2</sup>.* 1) Pathology and Laboratory Medicine; 2) Obstetrics and Gynecology, Mount Sinai Hospital and University of Toronto, Toronto, Canada.

For pregnancies terminated because of fetal abnormalities, cell culture for chromosome analysis or molecular studies is extremely important in order to provide genetic counselling. Assessment of success rates for culture of fetal post mortem tissue is usually complicated by differences in tissue type, mixture of specimens from spontaneous demise and induced abortion and transport conditions. As part of a randomized controlled trial to evaluate methods of second trimester termination of pregnancy, fetal umbilical cord specimens were cultured from three patient groups: (1) intra-amniotic injection of prostaglandin F<sub>2a</sub> ; (2) vaginal misoprostol and (3) oral misoprostol. In this study umbilical cord specimens were uniformly collected in transport media and details of time of delivery and method of pregnancy termination were collected.

	IAPG (Group 1)	VM (Group 2)	OM (Group 3)	Total
Successful	37 (54.4%)	66 (90.4%)	39 (83.0%)	142
Failed	31 (45.6%)	7 (9.6%)	8 (17.0%)	46

There was a significantly higher success rate for culture in the vaginal and oral misoprostol routes when compared with the intra-amniotic injection of prostaglandin. Options for obtaining tissue for genetic testing should be discussed with the patient prior to pregnancy termination.

**Contribution of congenital anomalies to gestational wastage: a prospective study in a Brazilian University**

**Hospital.** *D.P. Cavalcanti*<sup>1,2</sup>, *A.R. Aguirre*<sup>2</sup>, *M.A. Pessoto*<sup>3</sup>, *M.F. Mello*<sup>4</sup>. 1) Dept Genetica Medica FCM, UNICAMP, Campinas, Sao Paulo, Brazil, MD, PhD; 2) Programa Genetica Perinatal; 3) Serv Neonatologia, MD; 4) Dept Anatomia Patologica, MD.

We design a prospective descriptive investigation at the Women's Hospital (Caism), to determine the precise contribution of congenital anomalies to gestational wastage. The study included fetus dying before delivery as well as that occurring in the early neonatal period. During 19 months (Sept/1999 to April/2001) we examined all perinatal deaths occurring in the obstetrical center of the Hospital. The study of the births followed a protocol including genetic-clinical examination, x-rays, clinical photographs, autopsy, and a cytogenetic study when necessary. In the referred period, we observed 5,757 births with an overall incidence of birth defects of 7.7%. From a total of 228 perinatal deaths (PD), 80 (35%) fetuses were malformed. The causes of gestational wastage were classified as maternal (85 - 37%), fetal (104 - 45%), or unknown (39 - 17%). Among PD from fetal causes, 24 (23%) cases were twins. The remaining cases were all malformed fetuses distributed as follows: 35 (44%) isolated defects, 15 (19%) fetuses with multiple anomalies, and 30 (37%) syndromic fetuses. In the isolated group, congenital malformations of the CNS (22) followed by urogenital (12) were the most frequent anomalies. Among syndromic cases, we found 15 chromosomal anomalies, 6 LBW/ADAM complex, 3 skeletal dysplasias, 3 lethal multiple pterygium syndrome and 1 Beckwith-Wiedemann syndrome. When the fetuses were subdivided in two groups, early gestational wastage (below 500g) and stillbirth / early neonatal deaths (500g or heavier), we observed among fetuses with a known cause of the death that fetal causes are more frequent in the later. The previously cited anomalies were found in both subgroups. With regard to all the known causes of death in the whole group, we observed that secondary prevention is possible in more than half of the deaths with maternal origin. Among deaths from congenital anomalies of the fetus, prevention by genetic counseling is possible in 81% of the cases. Financial Support FAPESP 98/16006-6.

**Amniotic fluid AFP values associated with fetal omphalocele.** *S. Diment, J. Roberson.* Department of Medical Genetics, Henry Ford Hospital, Detroit, MI.

The incidence of omphalocele has been reported as between 1 in 4,000 to 1 in 7,000 births. Approximately 50% of cases of omphalocele have other birth defects. 12-30% have chromosome abnormalities. Omphalocele is one of the ventral wall defects associated with elevated levels of maternal serum alpha-fetoprotein (MSAFP) and amniotic fluid alpha-fetoprotein (AFAFP). The median MSAFP for omphalocele in one series was 4.1 MOM with a range of 0.5-29.8 MOM. However, the median and range of AFAFP MOM for omphalocele has not been previously reported.

Between January 1987 - April 2001, the Henry Ford Hospital AFP Program received 30,812 amniotic fluid AFP samples. Of these, 41 were identified as confirmed cases of omphalocele. The AFAFP in these samples was between 0.23 and 71.08 MOM with a median of 2.46 MOM. (In gastroschisis the published median AFAFP MOM is 15.3). In our patients, 16 of 41 (39%) had a chromosome abnormality. Eleven had trisomy 18, three had trisomy 13, one had triploidy and one had an unbalanced translocation resulting in a duplication of chromosome 3q. The median AFAFP MOM in the chromosomally abnormal group was 4.13 compared to a MOM of 2.13 in those with normal chromosomes. Only 1 of 25 (4%) with normal karyotype had a positive acetylcholinesterase (ACHE) while 9 of 16 (56%) with an abnormal karyotype did. However, 3 of 16 (19%) of the chromosomally abnormal fetuses had an associated open spina bifida defect. In the 3 with omphalocele, open spina bifida and abnormal karyotype the median AFAFP MOM was 7.27 while in the 13 chromosomally abnormal fetuses without an open spina bifida defect the median MOM was 3.99. It is of interest that the medical literature indicates that fetuses with a chromosome abnormality tend to have smaller omphaloceles although in our series, AFAFP was higher in the chromosomally abnormal group.

**Maternal serum alpha-fetoprotein levels in pregnancies with fetal cleft lip and palate.** *S. Deering*<sup>1</sup>, *J. Bienstock*<sup>2</sup>, *K. Blakemore*<sup>2</sup>, *N. Hueppchen*<sup>1</sup>. 1) OB/GYN, National Naval Medical Center, Bethesda, MD; 2) OB/GYN, The Johns Hopkins University School of Medicine, Baltimore, MD.

**OBJECTIVE:** Elevated maternal serum alpha-fetoprotein (MSAFP) levels have been well-described in the literature in pregnancies complicated by midline ventral wall defects, such as gastroschisis or omphaloceles. There are a few case reports of patients with cleft lip/palate associated with elevated MSAFP values, but no large series. The objective of this study was to determine if MSAFP levels are elevated in pregnancies complicated by fetal cleft lip/palate. **STUDY DESIGN:** We conducted a review of the records from the previous decade of patients in our ultrasound database at the National Naval Medical Center as well as the records of patients followed in the cleft lip/palate clinic at the Walter Reed Army Medical Center. Additional data from similar patients were obtained from The Johns Hopkins Hospital database. For this study, we defined an elevated MSAFP level as greater than 2.5 multiples of the median (M.o.M.). **RESULTS:** We identified a total of 107 patients with pregnancies complicated by cleft lip/palate. Maternal alpha-fetoprotein levels were available for twenty of these patients. The mean MSAFP was 1.105 M.o.M. with a range of 0.415-1.981 M.o.M. **CONCLUSIONS:** Isolated fetal cleft lip/palate defects do not appear to be associated with an increase in maternal alpha-fetoprotein levels. Unlike other midline defects, which are known to cause an elevated MSAFP, the increased exposure of the nasopharyngeal tissue in cleft lip and palate patients does not appear to have the same effect.

**Complete absence of bile and pancreatic ducts in a newborn: a new entity of congenital anomaly in hepato-pancreatic development.** *K. Nakamura<sup>1</sup>, H. Mitsubuchi<sup>1</sup>, H. Miyayama<sup>2</sup>, J. Ishimatsu<sup>2</sup>, T. Yamamoto<sup>3</sup>, F. Endo<sup>1</sup>.* 1) Department of Pediatrics, Kumamoto University School of Medicine, Kumamoto, Japan; 2) Kumamoto City Hospital, Kumamoto, Japan; 3) Division of Molecular Pathology, Graduate School of Medical Science, Kumamoto University School of Medicine, Kumamoto, Japan.

Liver and pancreatic buds appear from the foregut at about 4 weeks of gestation in the human embryo. Each bud differentiates into tissue which consists of hepatocytes and bile duct epithelial cells in the liver and exocrine and endocrine cells and pancreatic duct epithelial cells in the pancreas. During the differentiation, each tissue requires a developmental process directed by intracellular signaling stimulated by extracellular factors such as cell to cell contact, extra cellular matrix and cytokines. Loss of one of these processes can lead to defects or to malfunctions of the organ and fetal death can occur. Here we examined a newborn infant who had no bile and pancreatic ducts. The girl had hydrops after 29 weeks of gestation and died shortly after birth. One of her siblings previously died with hydrops at about 6 months of gestation and there were 2 more miscarriages of unknown causes. The familial history suggested that there was a genetic cause of hydrops. The liver had an abnormally round shape and the pancreas was not present in the normal position. Although the number of islets was markedly reduced, there was an ectopic small pancreas with normally developed islets. Histological analysis revealed complete absence of extra and intra hepatic bile and pancreatic ducts. Liver and pancreas was infiltrated with white blood cells and tissue destruction was extensive. Immunostaining of these tissues showed albumin and alpha feto protein production but no positive bile duct marker staining such as CK19 in the liver. Insulin and glucagon staining in the remaining islets was positive. These clinical features have not been reported in the literature. These investigations suggest an existence of a gene linked to the development of both bile duct and pancreatic ducts.

**Folate, homocysteine, and vitamin B<sub>12</sub> in serum of mothers of children with nonsyndromic orofacial clefts. T.**

*Mosby<sup>1</sup>, P. Calda<sup>2</sup>, J. Hyanek<sup>3</sup>, M. Tolarova<sup>1</sup>*. 1) Cleft Prevention Prg, UOP Sch of Dentistry, San Francisco, CA; 2) Dpt of OBGYN, 1st Sch of Med, Charles Univ Prague, Czech Republic; 3) Hospital Na Homolce, Prague, Czech Republic.

There is a conclusive evidence that folic acid (FA) administered periconceptionally decreases risk for NTD. Periconceptional supplementation with FA has also been demonstrated to decrease a risk of nonsyndromic cleft lip and palate (NSCL/P) recurrences. If there is an insufficient level of folate available to cells, DNA synthesis and DNA methylation are decreased and homocysteine accumulates in blood of a mother and in amniotic fluid surrounding a fetus.

The purpose of this study was to compare serum levels of folate, B<sub>12</sub> and total homocysteine in mothers of children with NSCL/P and in control mothers.

**MATERIAL AND METHODS:** A case control design was used in this pilot study. In 22 case mothers and in 29 control mothers, detailed interviews focused on dietary and lifestyle patterns were conducted. Blood was drawn for analysis of serum total homocysteine, vitamin B<sub>12</sub> and folate.

**RESULTS:** In the sample of case mothers, the mean values were: total homocysteine - 11.6±4.9 mmol/l; vitamin B<sub>12</sub> - 291.3±127.3 pmol/l; folate - 15.6±5.4 nmol/l. In the sample of control mothers, the mean values were: total homocysteine 9.8±2.5 mmol/l; vitamin B<sub>12</sub>- 300.1±109.2 pmol/l; folate - 20.85.6 nmol/l. Thus, a highly significant difference was observed between case mothers and control mothers for serum folate level (P=0.0008), a moderate significance for total homocysteine (P=0.048), and no significance for vitamin B<sub>12</sub> (P=0.4).

**CONCLUSIONS:** Our preliminary data support a view that insufficient folate metabolism played a significant role in causing clefts in offspring of case mothers. This is corroborated by no dramatical differences in dietary patterns and nutritional values between cases and controls. We are aware that more precise evaluation of a possible role of hyperhomocysteinemia in etiology of clefts needs to be done by using an oral methionine loading test.

**The utility of magnetic resonance imaging (MRI) as an adjunct in the prenatal diagnosis of congenital anomalies.**

*R.J. Lin<sup>1</sup>, R.A. Barth<sup>1</sup>, C.J.R. Curry<sup>2</sup>.* 1) Division of Medical Genetics, Departments of Pediatrics/Radiology, Stanford University School of Medicine, H-315, Stanford, CA; 2) Genetic Medicine, Valley Children's Hospital/UCSF, 9300 Valley Children's Place, Madera, CA.

Ultrasonography remains the imaging method of choice for the prenatal assessment of fetal anomalies due to its low cost, availability, safety and real-time capability. However, in some patients, clear images are not obtainable due to maternal obesity, fetal head engagement, oligohydramnios or other technical factors. Heretofore, the quality of conventional MRI was hindered by artifacts arising from the motion of the fetus. Recent technical advances in ultrafast MRI have enabled excellent resolution for fetal imaging by minimizing image degradation caused by fetal motion without the need for maternal or fetal sedation or paralysis. Compared with US, fast MRI has superior cerebral tissue contrast, operator independence, multiplanar imaging capacities and a larger field of view. Fast MRI is especially beneficial when evaluating fetal CNS abnormalities, particularly in detecting disorders of neuronal migration, evaluating the corpus callosum and posterior fossa, and in the evaluation of intrathoracic or intraabdominal anomalies. As with US, MRI does not expose patients to ionizing radiation, and there is no evidence that short-term exposure to electromagnetic fields harms the developing fetus.

We have recently performed ultrafast MR imaging on 7 pregnant patients referred for suspected fetal liver disease, familial microcephaly or ventriculomegaly. The results added invaluable clinical information that aided in genetic counseling and pregnancy management. Data from these cases and others from the literature further support the utility of fetal MRI as an adjunct to prenatal diagnosis in select cases.

**Limb-body wall complex in triplet pregnancy after IVF and CVS.** A.L. Shanske<sup>1</sup>, S. Pande<sup>2</sup>, K. Aref<sup>2</sup>, C. Vega-Rich<sup>2</sup>, S. Reznik<sup>3</sup>, I.E. Timor-Tritsch<sup>4</sup>. 1) Ctr. for Congenital Disorders; 2) Div. of Neonatology, and; 3) Dept. of Pathology, Children's Hospital at Montefiore, Albert Einstein College of Medicine, Bronx, NY; 4) Dept. of Obstetrics, New York University School of Medicine, New York, NY.

The limb-body wall complex (LBWC) is a rare sporadic defect usually defined by the presence of at least two of three characteristics: limb defects, anterior body wall defects, exencephaly or encephalocele with or without facial clefts. The incidence of major malformations after IVF and embryo transfer is similar to that of the general population. Though clusters of limb defects have been reported after CVS, recent series have shown no difference from the background population. We have identified the LBWC in a triplet following IVF, embryo transfer and CVS.

A male infant weighing 1320 gm was delivered to a 38 year old mother after a 30 5/7 weeks triplet gestation by section. The mother required a hysterectomy because of placenta accreta. The pregnancy was established by implanting 4 frozen embryos. Three chorionic sacs with embryos were visualized at the time a CVS was carried out at 10 5/7 weeks. CVS was performed first on triplet A transvaginally and then on B transvaginally and transabdominally. No evidence of any fetal malformations were noted in the triplets and A and B were later noted to have normal karyotypes. A follow-up ultrasound at 12 4/7 weeks revealed in triplet B a non-membrane covered protrusion of small bowel to the right of the cord insertion.

Triplets A and C were normal. The newborn examination of B revealed an abdominal wall defect consisting of cloacal exstrophy with an omphalocele. The umbilical cord was 15 cm long, the left lower extremity was phocomelic with the foot attached directly to the thigh and there was a covered lumbosacral meningomyelocele. The infant expired the next day during the repair of the neural tube defect.

Limb defects have been reported with CVS and there has been a single report of LBWC after IVF. The pathogenesis of LBWC is controversial and probably heterogeneous. Vascular or membranous disruption is thought to play a role. It is possible that direct trauma to uterine vessels or fetal membranes contributed to the defects observed in our patient.

**The outcome and management of isolated prenatally diagnosed unilateral multicystic kidney.** *G. Aubertin<sup>1</sup>, S. Cripps<sup>2</sup>, G. Coleman<sup>2</sup>, D. Shaw<sup>3</sup>, L.T. Arbour<sup>1</sup>*. 1) Medical Genetics, UBC, Vancouver, BC, Canada; 2) Division of Urology, UBC, Vancouver, BC, Canada; 3) Division of Maternal Fetal Medicine, UBC, Vancouver, BC, Canada.

Unilateral multicystic kidney (UMCK) occurs in approximately 1 in 2500 live-births. With routine prenatal diagnosis, most will be detected prenatally. To delineate the natural history, clinical outcome and appropriate management of prenatally diagnosed isolated UMCK, we report our experience of 73 cases. Methods: All cases of prenatally detected isolated UMCK presenting at the BC Childrens and Womens Health Centre, from July 1987 to July 1998 were reviewed. A total of 73 cases met criteria for eligibility. Subsequently diagnosed birth defects, chromosome abnormalities, pregnancy complications, and family histories were reviewed. In addition, pediatric medical and surgical outcomes were available for 54 cases. Results: Of those with known post-natal outcomes, renal /genital-urinary tract abnormalities were diagnosed subsequently in 33%. Non-renal abnormalities were present in 16% of which congenital heart defects were most frequent (7%). One chromosome abnormality, a trisomy 21, was present among 32 cases (3%) where karyotypes were known. Amniotic fluid volume abnormalities were present in 11 cases but not predictive of the presence of birth defects with the exception of one case where polyhydramnios was associated with VATER Association. A family history of structural renal anomalies was reported in 20% of those with known histories. There were 14 partial or complete involutions (25%), including 2 complete prenatal involutions of the cystic kidneys. No long-term associated morbidity such as hypertension or malignancy was present in our cohort, however, our follow-up was limited to 11 years. Conclusion: Based on our study and corroborating literature, amniocentesis and fetal echocardiograms should be offered as part of prenatal care when a seemingly isolated UMCK is detected on routine prenatal ultrasound. A third trimester follow-up ultrasound, as well as careful assessment and follow-up of the newborn are indicated.

**The DNA-analysis in families with some neuromuscular diseases in Moldova, postnatal and prenatal diagnosis.** V. Sacara. National Centre of Medical Genetics, S R I C & M H C, Chisinau, Moldova.

The dystrophinopathies, Duchenne and Becker muscular dystrophy (D/BMD), have traditionally been considered two different diseases. It's became clear that these diseases represent different phenotypes resulting from different mutations in a single gene. Hereditary motor and sensory neuropathies (Chariot-Marie-Tooth Disease - CMTD). The most common cause of the disease is a duplication of 17p11.2-p.12. Spinal muscular atrophy (SMA)- clinical impression has been borne out by the mapping of all forms of spinal muscular atrophy to one small region of chromosome 5. In 99% of patients who had this disorder, a mutation was found in a gene called survival motor neuron (SMN). 81 families with increased risk of DMD, 15 families with SMA and 2 families with CMTD passed clinico-neurological, biochemical, muscle-ultrasonography investigations and molecular study. 64 out of 85 DMD patients (76%) were proved to be carriers of dystrophin deletion. 70.3% of deletions occupied the distal part of the gene. No obvious deletions were detected in 21 DMD patients and corresponding families were used for RFLP-analysis (pERT87-8/TaqI, pERT87-15/BamH and 16intron/TaqI polymorphism). RFLP-analysis was also applied to the deletion group which requested carrier detection. 41% of families referred for carrier detection were found to be informative for RFLP-analysis. In 2 cases performed preclinical B/DMD diagnosis. Molecular analysis was efficiently applied to 11 fetuses in MDD/B families. In 11 out of 15 SMA families have been established deletion of 7 exon and in 4 cases- deletion of 8 exon of SMN gene. In 4 cases we performed prenatal diagnosis SMA. The accuracy of PD in 2 fetuses informative for a deletion should be considered close to 100%. Molecular analysis was efficiently applied to 2 SMTD patients and was established duplications of 17p11.2-p12. Thus, thanking the conspicuous progress in molecular analysis of the different gene, possibility for higher efficiency of PD in D/BMD, SMA and SMTD families is quite evident. Deletion detection and carrier testing is a decisive step in elaborating a reliable strategy of prenatal diagnosis in families at high risk of DMD, SMA and SMTD.

**Monozygotic twinning rate after artificial reproduction technology.** *C.A. Derom<sup>1</sup>, R.M. Derom<sup>2</sup>, R.F. Vlietinck<sup>1</sup>*. 1) CME, Genetic Epidemiology, Leuven, Belgium; 2) Association for Scientific Research in Multiple Births, Belgium.

While more and more authors have no doubt that the monozygotic twinning frequency is increased in association with artificial reproduction technology (ART), many questions about this unexpected phenomenon remain unanswered. The magnitude of the increase varies substantially according to the nature of the samples studied and the type of ART (ovarian stimulation alone, IVF and related procedures, timing of the transfer etc.). Most of the studies in the literature rely on hospital-based data and on chorionicity rather than on zygosity. This latter may underestimate the incidence of zygotic splitting, as one third of pairs are dichorionic in spontaneous monozygotic twin pregnancies.

This study reports on the monozygotic twinning rate after different assisted reproductive treatment modalities and different drugs to induce the ovulation in a population-based registry of multiples with known zygosity and chorionicity. Since 1964 the East Flanders Prospective Twin Survey collects data on all the multiples born in the province of East-Flanders, Belgium. Between 1976 and 2000 1346 twin pairs and 127 triplet sets were born after ART. Basic perinatal data, placentation and zygosity were recorded at birth. Of the 1346 twin pairs 93% are dizygotic, 4.5% monozygotic and 2.5% dichorionic with unknown zygosity. Of the 127 triplet sets, 86% are trizygotic, 10% dizygotic, 1% monozygotic and 3% trichorionic with unknown zygosity.

Within the twin sample the ratio of monozygotic versus dizygotic twins differs substantially according to the drug used to induce the ovulation and the type of ART. When clomiphene alone was used as treatment this ratio is 11% as to compare to 3% when no clomiphene was used ( $p < 0.001$ ). After induction of ovulation without IVF this ratio is 7% as to compare to 3% after IVF ( $p < 0.001$ ). The same trends are seen within the triplet sample.

If confirmed by other studies, clomiphene could be the first identified drug influencing the monozygotic twinning rate in humans.

**Variations in termination rates in pregnancies diagnosed with Klinefelter syndrome: Data from a cross**

**European study.** *I. Nippert<sup>1</sup>, B. Eiben<sup>2</sup>, P. Miny<sup>3</sup>, T. Marteau<sup>4</sup>, C. Mansfield<sup>4</sup>, M. Reid<sup>5</sup>, M. van Diem<sup>6</sup>, S. Garcia Minaur<sup>7</sup>, D. Kirwan<sup>8</sup>, S. Walkinshaw<sup>8</sup>, C. Verschuuren-Bemelmans<sup>6</sup>, C. de Vigan<sup>9</sup>.* 1) UKM, Muenster, Germany; 2) Inst f Klin Genetik NR, Germany; 3) Univ-Kinderspital beider Basel, Switzerland; 4) Guy's, King's & St Thomas' Schools of Medicine, London, UK; 5) Univ of Glasgow, UK; 6) Rijksuniv Groningen, NL; 7) Hospital de Cruces, Barakaldo, Spain; 8) Women's Hospital, Liverpool, UK; 9) EUROCAT Paris, France.

Introduction: Klinefelter syndrome (KS) occurs appr in 1 per 800 male live births. About 10%-20% are identified by prenatal diagnosis (PD). Most of these cases are detected incidentally when PD has been performed because of an increased risk for Down syndrome. Because KS is likely to be unfamiliar, information given about KS may be of crucial importance for parents' decisions about whether or not to continue with the pregnancy. Methods: A systematic review of the case notes of all KS diagnosed up to 24 weeks of gestation in 8 European regions in 5 European countries was conducted. The variables documented included maternal age, parity, gestational age at diagnosis, speciality of health professional providing information before and after PD. Results: Details of 111 pregnancies and their outcome were obtained. 44.1% pregnancies were terminated. Across the 8 European regions termination rates varied between 76.9% and 0%. Using multivariable logistic regression analysis, the only significant predictor of continuation of the pregnancy was the speciality of the health professionals conducting post diagnosis counseling: the affected pregnancy was more likely to continue when post diagnosis counseling involved only a genetics specialist (RR 2.42 (95% CI 1.14-5.92)). Discussion: There is an association between whether or not a pregnancy affected by an unfamiliar fetal anomaly is terminated and the professional background of the health professional providing counseling. The causal nature of this association remains to be determined. Health professionals in charge of organizing and delivering information services in prenatal testing should be aware that the way information is provided may impact parents' decisions. Introduction  
Methods Results Discussion.

**Bickers-Adams phenotype caused by disruptive brain damage.** *F. Enza-Razavi<sup>1</sup>, P. Saugier-Veber<sup>2</sup>, J. Martinovic<sup>1</sup>, C. Carves<sup>2</sup>, M.C. Aubry<sup>3</sup>, J.M. Jouannic<sup>3</sup>, Y. Dumez<sup>3</sup>, M. Vekemans<sup>1</sup>, T. Frebourg<sup>2</sup>.* 1) Département de Génétique et Service d'Histo-Embryologie et de Cytogénétique, Hôpital Necker Enfants-Malades, Paris, France; 2) Service de Génétique, CHU de Rouen et INSERM EMI 9906, IFRMP, Faculté de Médecine et de Pharmacie, 76183 Rouen, France; 3) Maternité, Hôpital Necker Enfants-Malades, Paris, France.

Bickers-Adams syndrome, now referred as Hydrocephalus with Stenosis of the Aqueduct of Sylvius (HSAS), is characterized by a broad spectrum of clinical and neurological abnormalities with inter- and intrafamilial variability i.e. mental retardation, hydrocephalus, lower limb spasticity and adductus thumbs. Neuropathological findings are conclusive in HSAS and consist of narrowing of the aqueduct of Sylvius and hypoplasia/aplasia of pyramids (responsible for the spasticity), occasionally associated to agenesis of the corpus callosum (which may explain mental retardation). HSAS was mapped to Xq28 and, to date, more than 75 different mutations in the *L1CAM* gene, which encodes a neural adhesion molecule, have been described. Here we present a sporadic case of hydrocephalus with adductus thumbs, detected by ultrasounds in a male fetus of 33 weeks' gestation. Neuropathological examination, after pregnancy termination, revealed a post-hemorrhagic triventricular dilatation with aqueduct of Sylvius obliteration, associated to severe hypoxic-ischemic brain damage with capsula interna and corticospinal tracts atrophy. Screening of the entire coding region of the *L1CAM* gene, using enzymatic cleavage and direct sequencing, revealed no mutation. We concluded therefore that the Bickers-Adams phenotype may result from disruptive hypoxic-ischemic lesions, mimicking the presentation of HSAS related to *L1CAM* mutations.

**Prenatal screening for aneuploidy using maternal blood spots on filter paper in the first and second trimester.**

*S.B. Melancon<sup>1</sup>, S. Demczuk<sup>1</sup>, S. Mercier<sup>1</sup>, S. Khalife<sup>1</sup>, L. Chiu<sup>1</sup>, M. Pelletier<sup>1</sup>, P. Miron<sup>1</sup>, D.A. Krantz<sup>2</sup>, T.W. Hallahan<sup>2</sup>, J.N. Macri<sup>2</sup>, M. BenKhalifa<sup>1</sup>.* 1) Procrea Genetic Services, Mount-Royal, PQ, Canada; 2) NTD Laboratories, Huntington Station, NY, USA.

Prenatal Down syndrome (DS) and open neural tube defects (ONTD) screening using multiple maternal serum markers is now well established in the second trimester (T2) of pregnancy. Enough data have become available to consider moving maternal screening into the first trimester (T1) combined with an ultrasound (US) measurement of the fetal nuchal translucency (NT). In collaboration with NTD Laboratories, Procrea began offering to women in Eastern Canada, T1 and T2 maternal screening for DS and ONTD using dried blood spots on filter paper in 1999. NT measurements were selectively offered in T1 and US dating in T2. From 10 3/7 to 13 6/7 weeks, PAPP-A and free b-hCG levels were coupled with fetal NT when available. Between 14 and 22 weeks, AFP and free b-hCG were assessed. Following positive screening results, couples were given the choice to follow up in a private or public clinical genetic setting. Between April 1999 and May 2001, 10181 pregnancies were monitored; 9169 had T1 (90%) and 1012 had T2. NT data were provided with 93% of T1 samples. In 47% of T2 samples, US dating was available. 25% of women were 35 years or older. There were 13 confirmed cases of DS, 12 in T1 and 1 in T2. In T1, 8/12 (67%) were at risk by blood markers alone, 6/10 (60%) by NT alone and 8/10 (80%) by combined blood/NT results. In the T2 case of DS, blood markers were negative. Using combined blood/NT data in T1, 14 other confirmed aneuploidies were found to be at risk; trisomy 18 in 3, trisomy 13 in 1, Turner syndrome in 4, triploidy in 6 and rare chromosomal anomalies in 3 more. 2 cases of ONTD were found at US in T1. One trisomy 18 and one ONTD were detected in T2. Our results agree with recent T1 screening data and support the case for Canadian women of all ages, including those over 35, to be offered combined T1 screening for DS in view of the significant number of other aneuploidies that will be detected as well.

**A Tale of Two Tails: Prenatal Diagnosis of Two Pseudotails.** *A. Toi<sup>1</sup>, H.M. Bedford<sup>2</sup>, B. Lo<sup>2</sup>, D. Chitayat<sup>1,2</sup>*. 1) Mount Sinai Hospital, Toronto, ON, Canada; 2) Division of Clinical & Metabolic Genetics, Hospital for Sick Children, Toronto, ON, Canada.

Human tails are rare malformations which may be divided into 2 categories: true tails and pseudotails. The term true tail should be restricted to the vestigial remnant of the embryonic tail. They may be composed of various tissues including adipose, connective, muscle, nerves and blood vessels. Pseudotails may be the end result of a variety of mechanisms and may occur anywhere along the spine. These may contain teratomatous elements including adipose tissue or cartilage. In both cases, spina bifida is the most commonly associated anomaly. Due to overlap of features, distinguishing a true tail from a pseudotail may be difficult.

We report 2 prenatally diagnosed fetuses with pseudotails. The first case was detected at 20 weeks gestation as a spinal appendage at the level of S3. Adjacent skin thickening with fatty echos in the spinal canal were seen in serial ultrasounds. A 3 cm finger-like appendage in the lumbar spinal region was confirmed at delivery. Neurologic examination was normal. No other anomalies were present. MRI of the spine confirmed a lipomyeloschisis, syringomyelia and a low-lying cord tethered to the fatty mass. The second case was detected at 19 weeks as a spinal projection at the level of S4. At delivery, a 5 cm curly tail-like appendage was confirmed in the L5 region originating from a base of thickened subcutaneous tissue. Stimulation of the appendage resulted in a further reflex curling. Neurologic examination was normal aside from an asymmetric anal reflex. MRI of the spine demonstrated an open dorsal sacral canal with extension of the fatty mass within the spinal canal, syringomyelia and a low-lying cord tethered to the mass. Unilateral duplication of the collecting system was seen on renal ultrasound. In both cases, good fetal movements were present and MS-AFP levels were in the normal range. Tails should be included in the differential diagnosis of prenatally detected spinal appendages and particular attention focused on the identification of an underlying spinal dysraphism. Families should be counselled about the potential for neurologic deficits.

**Prenatal detection and perinatal management of a giant cervical teratoma.** *L. Cartier, S. Khalife, V. Desilets, L. Beaumier, H. Flageole, J-M. Laberge.* McGill University Health Centre, Montreal, PQ., Canada.

A routine ultrasound at 18wks. revealed a left, multiloculated, cervical cystic mass. The differential diagnosis included; cystic hygroma, cystic teratoma, thyroglossal duct cyst, branchial cleft cyst, and hemangioma. Upon referral to our Fetal Diagnosis and Treatment Group, the patient met with the genetics team, a perinatologist, and a pediatric surgeon to discuss possible etiologies, testing indicated, prognosis, and pregnancy management options. The fetal karyotype result was 46, XX and a fetal echocardiogram was normal. Follow-up ultrasound findings were highly suggestive of a cervical teratoma measuring initially 35 x 42 x 43mm (32cc). Prenatal aspiration and amnioreduction were required on multiple occasions, removing from 300 to 800cc of cystic fluid and from 500 to 3,000cc of amniotic fluid at each sitting. An MRI was performed at 30wks. to evaluate the fetal airway. At 32.5 wks., with the mass measuring 17cm x 10cm x 7.5cm, cyst aspiration was performed (300cc), followed by the EXIT procedure to deliver the baby. The mass was resected, and pathology confirmed a teratoma. Its final weight was 1.1kg. and that of the baby 1.6kg. Postoperatively she has suffered from a left vocal cord palsy and gastroesophageal reflux necessitating a fundoplication. Discharged home at 3 months of age, she is doing well. The successful outcome is directly related to the quality of care given prenatally and postnatally to both mother and child. The couple was kept well-informed throughout, and was well supported by strict follow-up. The importance of referral to a multidisciplinary team of geneticists/ genetic counsellors, ultrasonographers, pediatric surgeons and neonatologists involved in fetal diagnosis and treatment, when a fetal malformation is diagnosed, cannot be overemphasized.

**Anhydramnios managed by serial amnioinfusions subsequent to failure of previously functional fetal vesico-amniotic shunt resulting in longterm perinatal survival.** *C. Kovac, B. Pierce, B.C. Calhoun, P. Nielsen, B. Joyner, R.F. Hume.* Madigan Army Med Ctr, Tacoma, WA.

Fetal obstructive uropathy with complete obstruction can lead to progressive oligohydramnios, fetal deformation, pulmonary hypoplasia, and renal dysplasia. Reported interventions include vesico-amniotic shunt placement in fetuses that meet eligibility criteria. Unfortunately, the clinical spectrum include cases which may challenge the medical-ethical decision making process.

Three recent cases involved late presentation of anhydramnios and cystic renal dysplasia. One case presented at 24 weeks with endstage polycystic kidney disease. A second case presented later with megacystis, and bilateral endstage renal dysplasia. Fetal karyotype obtained at bladder tap revealed 46 XY. The third case presented with severe oligohydramnios at 21 weeks gestation. After evaluation of fetal renal function with serial vesicocenteses, normal karyotype, and fetal therapy ethics board review, a vesico-amniotic shunt was placed. Amniotic fluid appeared stable for 7 days, after which the shunt appeared to migrate into the fetal bladder. In an attempt to prevent further pulmonary hypoplasia the remainder of the pregnancy was managed with serial (5) amnioinfusions between 22-28 weeks gestation. The patient subsequently developed chorioamnionitis and delivered a viable 1538 gm male infant at 29 weeks gestation. He initially required mechanical ventilation, but was extubated to room air at 12 hours of life. VCUG confirmed PUV and high grade bilateral vesicoureteral reflux. The infant went home at 12 weeks of age, with severe renal insufficiency, now requiring dialysis. Infant status remains guarded while awaiting renal transplant.

Antepartum amnioinfusion has traditionally been limited to evaluate fetuses with severe oligo/anhydramnios. Therapeutic amnioinfusion may prevent pulmonary hypoplasia and contractures. However, the risks are significant, including infection and preterm birth, and should be weighed against any potential benefit of this palliative treatment.

**Fluorescence In Situ Hybridization in uncultured amniotic fluid cells.** *V. Catala, E. Cuatrecasas, J. Colomer, M. Crespo, E. Dachs, T. Escabias, A. Seres-Santamaria.* Prenatal Genetics, Barcelona, Spainà.

Fluorescence in situ hybridization (FISH) is a technique than allows the evaluation of chromosome copy number in interphase cells. This characteristic gives FISH a great potential for the study of amniotic fluid samples for prenatal diagnosis. The major indications for prenatal diagnosis, such as advance maternal age, fetal malformation detected through ultrasonography, increased risk of trisomy estimated by maternal serum screening, or maternal anxiety require a rapid and accurate result. The classical cytogenetic analysis of amniotic fluid cells is, actually, the best technique to detect numerical and structural chromosome aberrations after cell culture, but the study is not completed in less than a week. FISH in uncultured amniotic fluid cells permits the detection of the most common aneuploidies in 24 hours after amniocentesis. We present a prospective study of 3047 uncultured AF samples by FISH, using commercial (ONCOR and Vysis) probes specific for 13, 18, 21, X and Y human chromosomes. FISH studies in amniotic fluid cells were performed in our laboratory since 1993 as an adjunctive of conventional cytogenetic studies. The characteristics of the probes (labelling, type of probe) have changed during the study. The best results were obtained using AneuVysion Assay (Vysis). Parallel cultures from each sample were grown and a standard cytogenetic result was informed at the end of the study. Sex chromosome aneuploidy was 0.7%. A total of 2% autosomal trisomies were observed Other authors have previously reported the use of FISH on uncultured amniotic fluid cells. Our results support than FISH is a feasible method to assess the most common aneuploidies. Actually FISH has to be considered, as an adjunctive method to classical karyotyping, however FISH allows an accurate result in less than 24h, and a rapid detection of aneuploidies is very important in prenatal diagnosis.

**Increased active GSTM1 (+/+; +/-) genotypes in endometriosis.** *D.A. Marquez-DO<sup>1</sup>, D.X. Dang<sup>1</sup>, M. Heard<sup>1</sup>, S.A. Carson<sup>1</sup>, J. Buster<sup>1</sup>, J.L. Simpson<sup>1,2</sup>, F.Z. Bischoff<sup>1</sup>.* 1) Depts of OB/GYN; 2) Molecular/Human Genetics, Baylor College of Medicine, Houston, TX.

Endometriosis affects 10-15% of premenopausal women. Although polygenic/ multifactorial inheritance is accepted, the underlying gene(s) and mechanism remain unknown. Given that environmental factors may be involved and given that the disease displays characteristics of malignancy, we are evaluating the role of polymorphic drug metabolizing enzymes in the pathogenesis of endometriosis. We postulate an association between the slow/rapid-acetylation NAT2 genotypes and/or the active/null GSTM1 genotypes among women with endometriosis. **METHODS:** Blood DNA from women surgically and histologically confirmed not to have endometriotic implants (n=37) or to have endometriosis was used for PCR amplification of the NAT2 (n=111) and GSTM1 (n=62) loci. For NAT2, restriction digestion was used to detect the wildtype (W) and mutant (M) alleles enabling classification into slow (M/M)- or rapid (W/W, W/M)-acetylation. For GSTM1, allele-specific PCR was used to distinguish active (+/- or +/+) from null (-/-) genotypes. **RESULTS:** See Table.

	NAT2/Slow	NAT2/Rapid	GSTM1 active	GSTM1 null
Endometriosis	45 (40%)	66 (60%)	49 (79%)	13 (21%)
Controls	15 (40%)	22 (60%)	16 (44%)	20 (56%)

**CONCLUSIONS:** We found an association between endometriosis and the GSTM1 active genotypes. The GSTM1 protein, which functions as a phase II foreign compound metabolizing enzyme, is believed to be important in the detoxification of the oxidative stress produced during the repair of the ovarian epithelium. We hypothesize that the active form may be involved in endometriosis through interactions with other cellular components which affect the expression of causative genes or protein binding.

**Prenatal diagnosis of Trisomy 12 Mosaicism: A Case Report and review of the literature.** *D.B. Schowalter, C. Zaleski.* Dept Medical Genetic Services, Marshfield Clinic, Marshfield, WI.

Mosaicism for trisomy 12 was ascertained prenatally through amniocentesis for maternal age. The small amount of published information surrounding trisomy 12 mosaicism makes prenatal counseling difficult. A 35-year-old Gravida I, Para 0 woman was referred for genetic counseling after amniocentesis results at 17 weeks gestation showed the presence of two cell lines. Sixteen colonies showed trisomy-12 and 10 colonies showed a normal female karyotype. These were all derived from three independent cultures. Level II ultrasound examinations performed at 19 and 27 weeks gestation revealed no structural abnormalities. Detailed pedigree was unremarkable other than a maternal cousin with Down Syndrome. This child's mother had a miscarriage and a stillbirth. At birth, there were no significant problems. Birth weight was at the 90th percentile, birth length over the 90th percentile, and head circumference was 75th percentile. Initial exam was unremarkable with the exception of a mongolian spot. Evaluation of the child by a clinical geneticist at 3 months was remarkable for slight posterior rotation of the ears, presacral dimple (base clearly seen), and the mongolian spot previously noted. Follow-up analysis of peripheral blood chromosome analysis was normal. One hundred cells were fully analyzed or scored for the presence of trisomy 12, and no trisomy cells were found in the study. The parents did not wish to pursue skin fibroblast chromosomes. We review the literature regarding prenatal mosaic trisomy 12, and outline the psycho-social issues the family dealt with throughout the pregnancy.

**Elevation of maternal serum hCG in the HIV+ women - implications for prenatal screening and placental**

**immunology.** *S. Klugman*<sup>1</sup>, *S. Carter*<sup>1</sup>, *B. Espinosa*<sup>2</sup>, *M. Crane*<sup>2</sup>, *C. Salafia*<sup>3</sup>, *S.J. Gross*<sup>1</sup>. 1) Obstetrics and Gynecology, Montefiore Med Ctr, Bronx, NY; 2) Bronx Lebanon Hosp, Bronx, NY; 3) Columbia U School of Public Health.

Ninety percent of women with human immune deficiency (HIV) infection are of reproductive age (NIH May 2001). Maternal multiple marker testing is now used routinely to screen for fetal NTDs and Down Syndrome. In a pilot study, we reviewed serum testing of HIV+ women who registered for care by the time of serum screening, and reported reduced mean human chorionic gonadotropin (hCG) in HIV+ women (Gross et al., ASHG #876;1997). The aims of this study were to validate our initial results and to identify underlying factors that may explain associations between maternal serum screening and HIV disease. Method: We reviewed the charts of pregnant HIV+ patients who had second trimester screening from 1994-2001. 44 of these patients had serum screening performed in the same laboratory. IRB approval for chart review of race, ethnicity, past reproductive history, viral load, CD4 count, concurrent illnesses, and serum screening results. Non-normal data was logtransformed prior to regression analysis with  $p < 0.05$  considered significant. Results: Both the mean hCG and mean AFP are increased (contrary to our pilot results). hCG levels were far more variable than the other markers. hCG MOM  $1.27 \pm 1.00$  (.44-5.2), AFP MOM  $1.52 \pm .8$  (.67-4.5). Increasing hCG MOM was highly correlated with decreasing CD4 count ( $p = 0.009$ ). Multivariate regression of effects of AFP and hCG on CD4 count showed only increasing hCG was independently associated with decreasing CD4 count ( $p = 0.02$ ,  $r = .44$ ). A non significant trend was found for increased hCG MOM with increasing viral load ( $p = 0.113$ ). Conclusion: Mean maternal serum MOM's for hCG and AFP are elevated in HIV+ women. HCG elevation is independently related to the patient's immune competence (as reflected by the CD4 count) and may result in an increased false positive rate for Down Syndrome risk assessment in this group. Furthermore, these findings may lead to further research and a better understanding of placental immune response and function in this setting.

**Prenatal Diagnosis in X-Linked Lymphoproliferative Disease.** *L. Li<sup>1</sup>, M. Morra<sup>2</sup>, C. Terhors<sup>2</sup>, J. Church<sup>1</sup>, J. Geng<sup>3</sup>, J. Zheng<sup>3</sup>, L. Cowan<sup>1</sup>.* 1) Dept. of Pediatrics, Childrens Hospital Los Angeles; 2) Div. of Immunology, Beth Israel Deaconess Med. Ctr., Harvard Medical School; 3) University Childrens Genetics Laboratory, ProGene Inc.

The discovery of genomic sequences and gene functions in human beings has brought about an enormous desire from the public for the application of basic scientific research in clinical medicine. Clinical molecular genetics laboratories have been taken to task to transform research achievement into clinical use, whereas quality controls in diagnosis are monitored by standard procedures and regulated by the College of American Pathologists (CAP). A recently cloned human gene, SAP (SLAM-associated protein), which plays an important role in regulating T/B-cell function against Epstein-barr virus (EBV) infection, was found defective in X-linked lymphoproliferative (XLP) disease. In the case reported here, the XLP mutation was detected in the proband by a research laboratory, and carrier testing and prenatal diagnosis were performed under the request of clinicians and family members at the University Children Genetics Laboratory, affiliated with Childrens Hospital Los Angeles. Using standard molecular techniques, the clinical genetic laboratory confirmed the carrier status of the mother and prenatal diagnosis on cultured amniocytes revealed that the male fetus inherited the XLP mutation. After consulting medical professionals and genetic counselors, the family decided to continue the pregnancy. A Follow-up study after the delivery confirmed that the babyboy has the same genotype in the XLP gene as his affected brother. The newborn baby was started on intravenous immunoglobulin infusions and anti-viral medicine at early stage, while bone marrow transplantation from an HLA-matched sister is planned to prevent EBV-related and unrelated complications. In conclusion, clinical genetic tests may not only predict the genotype of a fetus, but also help families and physicians to be prepared for early preventive treatment for affected patients with inherited disorders.

**Microchimerism for Y-chromosome bearing cells in nulligravid females presenting with pediatric autoimmune disease.** *R.N. Slotnick<sup>1</sup>, K. Atkins<sup>3</sup>, J. Leung<sup>1</sup>, A. Warren<sup>3</sup>, L. Blanchfield<sup>3</sup>, M.W. Stacey<sup>2</sup>, C. Gabriel<sup>1</sup>, C. Osgood<sup>2,3</sup>.* 1) Dept OB/GYN, Div Prenatal Diag, Eastern Virginia Medical Sch, Norfolk, VA; 2) Dept of Pediatrics, Eastern Virginia Medical School, Norfolk, VA; 3) Dept of Biological Sciences, Old Dominion University, Norfolk, VA.

Y-chromosome microchimerism within females has been suggested as a potential predictor, and possibly etiologically related to the development of autoimmune disease in women. Post-partum populations have been shown to carry low levels of fetal male cells, and in some cases microchimerism is detectable decades after delivery of a male infant. Autoimmune diseases have a higher prevalence in women as compared to men, including both rheumatologic and non-rheumatologic disorders. Female to male ratios of greater than 5:1 have been reported for systemic lupus erythmatosis (SLE) and scleroderma, while rheumatoid arthritis (RA) is at least three-times more common in females. Microchimeric cells have been identified in autoimmune disease lesions, lending credibility to the proposal that such cells may contribute to subsequent development of graft-versus-host disease in microchimeric females. Relatively little is known about the incidence or source of microchimeric cells in nulligravid females. We examined blood samples from 20 subjects, 10 diagnosed with SLE, 7 with RA and 3 with dermatomyositis. PCR primers from two regions on the Y-chromosome were used to detect qualitative presence of Y-bearing cells in DNA prepared from blood samples. In total, of 20 subjects, 70% showed detectable Y-chromosome DNA, while 30% did not. From 10 SLE patients, only one had a history of prior pregnancy, yet 80% of these patients were microchimeric. Of 7 nulligravid RA females, 57% were positive for Y-chromosome DNA. Two of three patients with dermatomyositis were positive for Y-chromosome DNA. Appropriate negative and positive controls behaved as expected. In summary, our results lend support to the proposal that nulligravid females with autoimmune disease are likely to carry chimeric male cells, and that such cells may contribute to disease development in those females.

**Second trimester screening for Down syndrome preferentially identifies affected pregnancies that are complicated by fetal hydrops.** *P.A. Benn<sup>1</sup>, J.F.X. Egan<sup>2</sup>, C.J. Ingardia<sup>3</sup>.* 1) Div Hum Genet, Dept Pediatrics, UCONN Health Ctr, Farmington, CT; 2) Div of MFM, Dept Ob/Gyn, UCONN Health Center, Farmington, CT; 3) Div of MFM, Dept Ob/Gyn, Hartford Hosp, Hartford, CT.

Low concentrations of second trimester maternal serum alpha-fetoprotein (MSAFP) and unconjugated estriol (uE3) together with high human chorionic gonadotropin (hCG) and inhibin-A (INH-A) are generally found in pregnancies complicated by Down syndrome (DS), hydropic Turner syndrome, or other non-immune hydrops. We compared the concentrations of these analytes in a group of 7 DS pregnancies with hydrops fetalis (generalized edema) and a control group of 85 DS pregnancies without hydrops. All cases were ascertained through positive maternal serum screening tests.

MS-AFP concentrations in the hydropic DS pregnancies (median 0.38, range 0.2-0.74 MoM) were significantly lower than those in the non-hydropic cases (median 0.82, range 0.37-1.86 MoM) (Mann Whitney test,  $P < 0.01$ ). Similarly, uE3 values were lower in hydropic (median 0.33, range 0.21-0.78 MoM) versus non-hydropic cases (median 0.63, range 0.16-1.16 MoM) ( $P < 0.01$ ). hCG levels were higher in the hydropic DS (median 4.07, range 3.28-10.36 MoM), relative to the non-hydropic pregnancies (median 2.51, range 0.76-6.86 MoM) ( $P < 0.01$ ). No significant difference was noted in INH-A concentrations for a sub-set of 5 hydropic cases (median 3.84 range 1.84-6.51 MoM) relative to that found in 42 non-hydropic cases (median 2.75, range 0.53-15.21 MoM). DS risks associated with these results were significantly higher for the hydropic cases ( $P < 0.01$ ) with all 7 hydropic cases having second trimester risks greater than 1:10.

These observations further strengthen the association between abnormal second trimester analyte values and disturbed fluid homeostasis. Increased nuchal thickness in DS fetuses probably represents a mild manifestation of fluid imbalance. A correlation may therefore exist between second trimester serum markers and ultrasound measurements of the nuchal fold.

**Pregnancy outcomes with undetectable uE3 on multiple marker screening.** *S. Dhandha, L. Fraer, W.A. Hogge.*  
Dept Genetics, Magee Hosp, Univ Pittsburgh, Pittsburgh, PA.

**Intro:** Undetectable unconjugated estriol (uE3) on multiple marker screen (MMS) has been associated with steroid sulfatase (STS) deficiency, fetal death, and IUGR. Our objective is to examine outcomes in pregnancies with undetectable uE3 on MMS, and to determine which MMS results are most likely to be associated with STS deficiency. **Methods:** We screened 70,018 patients between May 3, 1993 and April 30, 2001. Of these patients, 65 had undetectable uE3. We reviewed pregnancy outcomes in these cases, and correlated them with MMS results. **Results:** Of the 65 patients with undetectable uE3, 8 patients had an otherwise normal MMS. The 6 patients who were tested for the STS deletion were all carriers. Of the remaining 2 pregnancies, one was a pregnancy loss and one was a male at birth. 23 patients had an elevated AFP as well as an increased risk for trisomy 18 on MMS. An additional 4 pregnancies had only an increased AFP. All 27 resulted in pregnancy loss. 30 pregnancies had an increased risk for Down Syndrome and/or trisomy 18 on MMS. The 8 patients tested for the STS deletion were all carriers. Of the remaining cases, 4 had 46,XY karyotype. One patient declined amnio and STS testing, but had a family history of ichthyosis, and delivered a normal male. 14 of these pregnancies resulted in fetal losses, and 3 were lost to follow up. Excluding the losses, there were 6 pregnancies with an increased risk for Down Syndrome on MMS. All had an elevated hCG with a normal AFP. The 3 patients in this group tested for the STS deletion were all carriers. In contrast, there were 5 known surviving pregnancies among the patients who were screen positive for trisomy 18. All 5 had a low hCG and normal AFP on MMS. Four of these patients were tested and found to be carriers of the STS deletion. **Conclusion:** Patients with undetectable uE3 and normal MMS are all carriers of the STS deletion. Undetectable uE3 in association with elevated AFP is a marker of impending fetal demise. Patients with undetectable uE3 and an elevated hCG (increased risk for Down Syndrome) as well as those with undetectable uE3 and low hCG (increased risk for trisomy 18) should be offered STS testing.

**Outcomes in morbidly obese pregnant women.** *R. Dhanireddy, K. Yanamandra, T.F. Thurmon, D.D. Jefferson, C.S. Hill, D. Napper, J.A. Bocchini Jr.* Pediatrics, LSU Medical School, Shreveport, LA.

Our Pediatric Prenatal laboratory has been screening pregnant women from Northwest Louisiana for Neural tube defects (NTD) and Chromosomal Defects (CD) using triple screening (MSAFP, MShCG, and MSuE3) for the past several years. We routinely adjust MSAFP values for maternal weight, race and Insulin Dependent Diabetes Mellitus (IDDM) to improve the screening for NTD. After adjusting MShCG and MSuE3 values for maternal weight along with MSAFP and maternal age, prenatal CD risks are obtained. The reason for the maternal weight adjustment is to correct the analyte dilution from small or heavier mothers, so that precise prenatal risks are obtained. There have been several reports regarding the relationship of maternal overweight and susceptibility to birth defects including NTD. Thus we set out to investigate our prenatal screening by studying the delivery outcomes for any congenital anomalies. While analyzing the outcome data for NTD and CD for maternal weights in excess of 300lbs (300lbs-415lbs) and eliminating the possible confounding problems, we have not found any congenital anomalies. However, we have found that a statistically significant proportion of them have been delivered by Ceasarean section, 47% vs 20% in total population (OR 3.6, 95%CI 2.0-6.3). On stratification of the data by ethnicity, we found that both African-American and the Caucasian population are at higher risk. It is highly advisable to have genetic and obstetric counseling with these patients to apprise them of possible obtetric complications and the need for constant monitoring of their pregnancies. Data and statistics including the composition of outcomes will be presented.

**Activin A levels in pregnancies affected with neural tube defects.** *G. Lambert-Messerlian*<sup>1</sup>, *P. Florio*<sup>2</sup>, *F. Petraglia*<sup>2</sup>, *F. Severi*<sup>2</sup>, *J. Canick*<sup>1</sup>. 1) Pathology and Laboratory Med, Women & Infants Hosp, Providence, RI; 2) Obstetrics and Gynecology, University of Siena, Italy.

Activin, a member of a family of dimeric proteins originally identified in the reproductive system, has now been localized to many non-reproductive tissues and is a growth factor in a diverse range of cell systems. In humans, activin A is detected in amniotic and extraembryonic coelomic fluids and in maternal and fetal serum. Furthermore, activin b subunits and receptors have been colocalized in human fetal spinal cord and cerebrum. Taken together, these results suggest a role for activin in the development of the human nervous system. We hypothesized that activin levels may be altered in pregnancies affected by fetal neural tube defects (NTD).

Nine maternal serum (MS; 5 spina bifida, 4 anencephaly) and six amniotic fluid (AF) samples (4 spina bifida, 2 anencephaly), collected and identified through Women & Infants' prenatal serum screening program and at the University of Siena, were retrieved from freezer storage. Five unaffected samples were matched to each case for same completed week of gestation and approximate date of freezer storage. Total activin A levels were measured by Serotec assay (Oxford, UK) without operator knowledge of sample identity. The median activin A level in MS was 1.80 ng/mL (range 0.66-4.33) in unaffected pregnancy and 2.21 (0.68-3.51) in cases of NTD. The median activin A level in AF was 9.53 ng/mL (3.03-23.56) in unaffecteds and 12.03 (6.48-25.45) in cases of NTD. Activin A levels increased in unaffected MS (12% per week during 15-18 weeks gestation) and AF (18% per week during 17-22 weeks). After data were normalized for gestational age effects, levels of activin in MS from cases of NTD were not different from matched controls (median = 1.19 MoM,  $c^2 = 1.61$ ,  $p = 0.20$ ). However, levels of activin A in AF from cases of NTD were 44% higher (1.44 MoM,  $c^2 = 3.7$ ,  $p = 0.06$ ) than controls. Further studies are warranted to determine whether the level of activin A in amniotic fluid is a marker of NTD and to establish whether activin has a role in the development of the human nervous system.

**First Trimester Down Syndrome Screening in Twins: Moving From "Pseudo-Risk" to Real Risk.** *D.A. Krantz<sup>1</sup>, T.W. Hallahan<sup>1</sup>, E. Orlandi<sup>2</sup>, C. Rossi<sup>2</sup>, J.W. Larsen<sup>3</sup>, P.D. Buchanan<sup>4</sup>, V. Klein<sup>5</sup>, J.N. Macri<sup>1</sup>.* 1) NTD Laboratories, Huntington Stat, NY; 2) Centro di Diagnosi Prenatale, Palermo, Italy; 3) The George Washington Univ. Medical Center, Washington, DC; 4) GeneCare Medical Genetics Center, Chapel Hill, NC; 5) North Shore Univ., Manhasset, NY.

**Objective:** To develop a first-trimester Down syndrome screening method for twin pregnancies that factors in chorionicity along with the two nuchal translucency values and the free beta hCG and PAPP-A levels to calculate risks for each individual twin fetus, the risk that at least 1 twin might be affected and the risk that both twins might be affected and to determine if biochemical markers are necessary for this method. **Methods:** A series of 212 unaffected twin fetuses were used to develop reference data for the method. A Monte Carlo simulation of 100,000 sets of unaffected, discordant for Down syndrome and concordant for Down syndrome twins was performed. **Results:** In monozygotic pregnancies, at a fixed 5% false positive rate, the detection rate increased from 84% to 94% when biochemistry was included in addition to nuchal translucency while at a fixed 80% detection rate, the false positive rate was reduced from 3.0% to 0.5% by adding in biochemistry. In dichorionic pregnancies, in a population in which 2/3 of twins were dizygotic, the detection rate increased from 78% to 83% for discordant cases of Down syndrome and from 82% to 92% in concordant cases of Down syndrome when biochemistry was included in addition to nuchal translucency while at a fixed 80% detection rate for discordant cases, the false positive rate was reduced from 6.4% to 3.5% after adding in biochemistry. Results were similar for populations with a different percentage of twins that were dizygotic. **Conclusions:** This new method of screening for Down syndrome in twin pregnancy provides clinicians and patients with additional information compared to the current "pseudo-risk" screening method. Based on the data in this study the method is effective and the use of biochemistry can increase detection and/or reduce false positives compared to ultrasound alone.

**INTEGRATED PRENATAL SCREENING IN ONTARIO, CANADA.** *A.M. Summers, C. Meier, I. Lasis, P.R. Wyatt.* Genetics Program, North York General Hosp, Toronto, ON., Canada.

In 1999, Wald et al. described Integrated Prenatal Screening (IPS) for Down syndrome. IPS combined first trimester nuchal translucency (NT) and pregnancy associated plasma protein-A (PAPP-A) with triple or quadruple marker screening in the second trimester (*New Engl J Med* 341(7):461-7). IPS was expected to detect 85% of Down syndrome cases with a 1.5% positive rate if triple screening is used in the second trimester. This method of screening is dependent upon the woman receiving a single risk result at the end of screening in the second trimester. The purpose of this study was to confirm the estimated positive rate of IPS in a Canadian population and to assess feasibility and acceptability.

IPS was offered to women previously eligible for triple marker screening in the second trimester who presented before 13w6d gestation with a viable pregnancy. Screen positive women (risk > 1:200) were offered genetic counselling and amniocentesis with fluorescent in situ hybridization for chromosomes 13, 18 and 21 as well as full karyotyping. All women were offered a second trimester detailed ultrasound. Pregnancy outcomes are being obtained through hospital records.

Since November 1999, 2171 women have started IPS, 1875 women have completed 5 marker testing and 71 were screen positive. This gives a positive rate of 3.8%. Of the 71 positives, seven have been true positives for Down syndrome. The expected positive rate for IPS in this population (mean age = 32.3 yrs) would be ~3%. If this population of women had chosen triple marker screening, the positive rate would have been 15.8%. Results show that IPS performs as expected in terms of positive rate, and in our population, it is both feasible and acceptable.

**Maternal urine Invasive Trophoblastic Antigen (ITA) is a useful marker for Down Syndrome detection in the 1st Trimester.** *C.M. Strom<sup>1</sup>, G.E. Palomaki<sup>2</sup>, G.J. Knight<sup>2</sup>, L. Cole<sup>3</sup>, J.E. Lee<sup>1</sup>, R. Pandian<sup>1</sup>.* 1) Quest Diagnostics, San Juan, Capist, CA; 2) Foundation for Blood Research, Scarborough, ME; 3) U of New Mexico, Santa Fe, NM.

**Introduction:** Urinary ITA (u-ITA), a form of hyperglycosylated hCG has been reported to be elevated in Down Syndrome (DS) pregnancies in the 2nd trimester. We examined the utility of measuring u-ITA, urine total hCG (u-hCG) and urine beta core hCG (u-core) in the 1st trimester, either alone or in combination with established serum markers.

**Study Design:** A case-control set was created from specimens collected in a multicenter study of 4412 women having CVS or early amniocentesis at 9-15 weeks gestation (Haddow et al, NEJM 1998;338:955-61). Women with abnormal serum screens were excluded. Urine and serum samples were available from 17 DS pregnancies, and each case was matched with 5 controls. Urine was analyzed for u-ITA, u-core, u-hCG and normalized for creatinine. Serum values for total hCG (s-hCG), pregnancy associated plasma protein A (s-PAPP-A) and free beta hCG (s-beta) for these pregnancies were used for multivariate analyses.

**Results:** Univariately, the median u-ITA level in the 1st trimester was 3.16 MOM as compared to 2.52 MOM for u-hCG and 1.50 MOM for u-core. The observed detection rate (DR) for u-ITA at a false positive (FP) rate of 5% and 10% was 25% and 53% respectively, similar to that of u-hCG (24% and 53%) and much better than u-core (6% and 24%). Multivariately, the most powerful combination of 3 analytes was u-ITA with s-PAPP-A and s-beta yielding a DR of 74% and 81% at FP rates of 3% and 5% respectively. The DR is reduced from 81% to 74% if u-ITA is replaced by u-hCG.

**Conclusions:** Urinary ITA combined with s-beta and s-PAPP-A provides 1st trimester screening performance comparable to that obtained by 2nd trimester screening with 4 analytes (AFP, uE3,hCG,and dimeric inhibin A).

**A case study of prenatal phenotype of 48,XXXYY with elevated Maternal Serum Alpha-fetoprotein.** *B. Reddy<sup>1</sup>, S. Reddy<sup>2</sup>*. 1) MSAFP, Natl Medical Diagnostic Lab, Livonia, MI; 2) MGR Medical and Research Institute, Chennai, India.

It is a well documented fact that elevated maternal serum alpha-fetoprotein (MSAFP) is associated with various fetal abnormalities such as neural tube defects, ventral wall defects which affect intestines and other internal organs, congenital nephrosis, duodenal atresia, 48,XXYY syndrome and other abnormalities. In the present study we report a case of fetus with 48,XXXYY karyotype with elevated MSAFP. A 41 year old Asian Indian woman was referred for genetic counselling for advanced maternal age and consanguinity (marriage to 1st cousin). At 18 weeks of gestation MSAFP was elevated (3.32MOM). Pregnancy was terminated and post-mortem examination revealed a coarse facies with flat nose, epicanthic folds, low-set ears, VSD, clinodactyly of fifth fingers, kyphosis and proximal radio-ulnar synostosis. It has been previously reported that a prenatal phenotype of 48,XXYY was associated with elevated MSAFP. In the present report chromosomal analysis revealed a 48,XXXYY karyotype. It is not clear that how these chromosomal abnormalities are linked to elevated MSAFP. The role of consanguinity and various other plausible mechanisms involved in the elevated MSAFP are discussed.

**Simple and effective approach for detecting maternal cell contamination in molecular prenatal diagnosis. T.**

*Antoniadi<sup>1</sup>, C. Makatsoris<sup>1</sup>, P. Kaminopetros<sup>2</sup>, M.B. Petersen<sup>1</sup>.* 1) Dept Genetics & Molec Biology; 2) Dept Fetal Medicine, Mitera Maternity Hospital, Athens-Greece.

The presence of maternal cells in prenatal tissues is an important issue, as a serious potential source for prenatal misdiagnosis. Maternal cell contamination (MCC) is increased with placental penetration and operator inexperience. This study presents our approach for detecting MCC at prenatal diagnoses. We performed 112 prenatal diagnoses: 79 cases for b-thalassemia/sickle cell anemia (62CVS/17AF), 14 cases for cystic fibrosis (1CVS/13AF), 10 cases for achondroplasia (all AF) and 9 cases for prelingual deafness (4CVS/5AF). The potential MCC in the prenatal tissues was determined by screening for MCC only the fetuses found to be carriers of the maternal mutation after the initial mutation screening, in all cases, except those of achondroplasia, which as a dominant or de novo condition can be misdiagnosed due to MCC. DNA samples from both parents were obtained before the amniocentesis. From the 112 cases 45 were finally tested for MCC (26CVS/19AF). The 3-HVR/APO B and the D1S80 loci were tested because of their high heterozygosity and the simplicity of horizontal agarose electrophoresis. 2 of the 25 cases tested for the 3-HVR/APO B and 4 of the 22 cases tested for the D1S80 were not informative. 3 additional loci were also used: the VNTRI of the vWFI gene (6 cases, all informative), the THO1 (6 cases, 1 not informative) and the TPOX (1 case, informative). In 4 cases of CVS where MCC was detected, DNA obtained from CVS culture was subsequently tested for MCC; if results were negative (2 cases), mutation screening was repeated and no amniocentesis was done. In the cases of confirmation of MCC in the cultured cells, amniocentesis was performed for further testing. In conclusion, testing of one locus presented sufficient information to exclude MCC for more than 90% of the cases. The choice of the appropriate locus is thereby essential, while the simultaneous screening of both parents provides for distinguishing the non-informative sites from MCC. The resultfulness, the low cost, the simplicity and the speed make this approach applicable in every diagnostic laboratory.

**Performance characteristics of a second generation genomic micro-array for the detection of single copy gains and losses.** *S. Stegenga, G. Browne, H. Burkhardt, M. Bushen, M. Hackbarth, T. Halder, M. Lucas, H. Marble, R. Miller, J. Piper, J. Proffitt, T. Ruffalo, J. Schultz, S. Seelig, J. Tomisek, K. Wilber, S. Willie, W. King.* Vysis, Inc., Downers Grove, IL.

We have developed a second-generation genomic micro-array system with the capability of detecting single copy changes by comparative genomic hybridization technology. The potential clinical applications for the genomic microarray include comprehensive prenatal and postnatal testing for microdeletion syndromes, subtelomeric deletions, aneuploidies and unbalanced translocations in a single microarray assay. The specimen types targeted for this product include amniocytes, chorionic villi and peripheral blood cells. This array contains approximately 750-1000 elements spotted on a chrome-plated chip surface. The genetic loci include clones covering 41 subtelomeric regions, common microdeletion syndrome regions, tumor suppressor genes as well as oncogenes that are amplified in a variety of cancers. To ensure a high quality product for potential clinical applications, hybridizations to several test DNAs containing known chromosome copy number changes as well as classical microdeletion syndromes have been used to validate the sensitivity and performance of the micro-array. Data on additional quality measures will also be presented.

**Incomplete methylation of the inactivated X-chromosome in human chorionic villous samples..** *M.S. Penaherrera, H.L. McDonald, C.J. Brown, W.P. Robinson.* Dept. Medical Genetics, University of British Columbia, Vancouver, BC, Canada.

While X-chromosome inactivation (XCI) in somatic tissues is stably maintained and associated with methylation of most X-linked genes, the situation in placental tissues is less clear. Recent studies of XCI using a PCR based assay to examine methylation at the androgen receptor (*AR*) locus, have found evidence of lack of methylation for this gene in the stromal component of the placental chorionic villi. In an effort to investigate this issue, XCI status for several X-linked genes was evaluated in DNA extracted from 17 samples of cultured chorionic villi (CV) and 6 cord blood samples from normal female pregnancies. Five genes (*AR*, *FMRI*, *ARAF-1*, *MAOA* and *XIST*) were tested using methylation sensitive enzyme-based assays. Our results showed lack of methylation, demonstrated by failure to detect any PCR product after *HpaII* digestion, in 4/16 CV samples analyzed for the *AR* gene, 14/15 samples analyzed for *FMRI*, 15/15 samples analyzed for *ARAF-1* and 14/14 samples analyzed for *MAOA*. Lack of methylation was not observed in any of the 9 CV samples analyzed for the *XIST* gene. In contrast methylation was observed for all 5 genes analyzed using the 6 DNA samples extracted from cord blood.

These results demonstrate that lack of methylation is commonly observed for X-linked genes in human chorionic villous stroma. We hypothesize that genes located distant to the X-inactivation center may be more likely to lack methylation, and will test this by examining more genes. The significance of the hypomethylation to expression of X-linked genes is currently unknown. It is known that reactivation of X-linked genes occurs in extra-embryonic tissues and not in somatic tissues. However, the frequency of loss of methylation seen in the extra-embryonic tissue is surprisingly high if it reflects loss of silencing. We are therefore also investigating whether the methylation status is correlated with gene expression on the X-chromosome. The crucial role of the placenta in embryonic and fetal growth and development and the extensive use of CV sampling in prenatal diagnosis, highlights the relevance of understanding the mechanism of such a fundamental process as XCI in this organ.

**Prenatal and Preimplantation Genetic Diagnosis (PGD) for carriers of mtDNA mutations.** *H.J.M. Smeets<sup>1</sup>, J.G. Nijland<sup>1</sup>, L.J.A.M. Jacobs<sup>1</sup>, R.J.H. Galjaard<sup>2</sup>, H.R. Scholte<sup>2</sup>, H.F.M. Busch<sup>2</sup>, C.E.M. De Die<sup>1</sup>, J.P.M. Geraedts<sup>1</sup>, I.F.M. De Coo<sup>2</sup>.* 1) Dept Genetics and Cell Biology, Univ Maastricht, Maastricht, Netherlands; 2) Depts Child Neurology, Biochemistry and Clinical Genetics, Erasmus University, Rotterdam.

Options for carriers of mtDNA mutations to prevent transmission of these mutations to their offspring are limited. This is a major problem as it often concerns severe disorders with high recurrence risks. Recently, we screened the entire mtDNA of a patient with Leigh disease and identified the mtDNA T9176C mutation. Two other affected sibs carried the same mutation and mutation percentages varied between 93% and 97%. Their pregnant cousin also carried the mutation (55% in blood) and opted for prenatal diagnosis. Three criteria have been proposed for reliable prenatal investigations of mtDNA mutations: a close correlation between the proportion of mutant:wild-type mtDNA and disease severity; a uniform distribution of mutant mtDNA in all tissues; no change in mutant load in time. Based on existing, though limited data, the T9176C fulfils these criteria and the cut-off point for severe disease is about 90%. Prenatal investigations were performed on DNA from chorionic villus and amniotic cells and about 88% mutant mtDNA was detected in these tissues. Although the risk of a severely affected child was considerably, the pregnancy was continued. This family and data from literature illustrate that especially carriers with a high percentage mutated mtDNA are at risk of getting affected children. However, given the genetic bottleneck for mtDNA, these carriers may produce oocytes with low or absent amounts of mutant mtDNA. Therefore, we developed PGD protocols to select for embryos lacking mutated mtDNA. These protocols include the T8993G/C (NARP/Leigh), the T9176C (Leigh) and the A8344G (MERRF) mutation, but not the unpredictable A3243G (MELAS) mutation.

**Identification of alterations in the Huntington's gene using single cell PCR and the WAVE® nucleic acid fragment analysis system for pre-implantation genetic diagnosis.** *C. Akins*<sup>1</sup>, *S. Lilleberg*<sup>2</sup>, *M.C. Liu*<sup>3</sup>, *S. Kipersztok*<sup>3</sup>, *R.S. Williams*<sup>3</sup>, *K.C. Drury*<sup>3</sup>. 1) Transgenomic Inc., Houston, TX; 2) Applied Genomics and Molecular Genetics, Transgenomic Inc., Houston, TX; 3) Department of Obstetrics and Gynecology, University of Florida College of Medicine, Gainesville, FL.

Tri-nucleotide repeat expansion is the basis for a number of prevalent genetic disorders such as Huntingtons disease, Fragile X syndrome, and Myotonic Dystrophy. We investigated the use of single cell PCR to amplify a portion of the Huntingtons gene in order to develop a test system for pre-implantation genetic diagnosis (PGD). The amplification of CAG repeat sequences poses unique challenges due to the difficulty of denaturing high GC-content regions prior to PCR amplification. PCR modifications are necessary to carry out the amplification of GC-rich areas found in most tri-nucleotide expansions. We used a modified PCR protocol to efficiently amplify the expanded repeat sequence of the Huntington's gene. The amplified expanded CAG repeats were easily identified by denaturing high performance liquid chromatography (DHPLC) without the use of PCR primers labeled with fluorescent dyes. This technology shows great promise for sensitive and efficient detection of abnormal alleles in single cell samples.

**Limitations of preimplantation genetic diagnosis for a paternal carrier of a t(9;15) chromosome.** *V.A. Desilets<sup>1,2</sup>, S.L. Tan<sup>1</sup>, A. Ao<sup>1,2</sup>.* 1) OB/GYN, McGill University, Montreal, PQ, Canada; 2) Human Genetics, McGill University, Montreal, PQ, Canada.

**Introduction:** Preimplantation genetic diagnosis (PGD) is attractive to some parents who face a perceived high genetic risk. Its use is limited by the minute amount of material available.

**Case report:** This couple was referred to the McGill Prenatal Diagnosis Programme for preconception counseling regarding a paternal translocation (9;15) (p34;q11.2). They presented with primary male infertility for which intracytoplasmic sperm injection (ICSI) followed by in vitro fertilization (IVF) was planned. Our proband, aged 35 years, has severe oligospermia (CF negative) with unilateral varicocele. Blood karyotype revealed a translocation (9;15) (p24;q11.2). Subtelomeric FISH probe for 9p showed this segment to be translocated onto chromosome 15. His history was remarkable for a familial marker chromosome due to a 3:1 disjunction of t(9;15) in a grandparent, diagnosed prenatally with apparently normal outcome (published in 1989). His healthy wife was aged 35 years.

**Discussion:** The reproductive risks associated with the translocation included spontaneous abortion, unbalanced offspring and uniparental disomy (UPD). ICSI adds the risk of sex chromosome aneuploidy to that of autosomal aneuploidy due to maternal non-disjunction. As IVF/ICSI is planned as a treatment modality, PGD is available and may have possible benefit on implantation. Interphase fluorescence in situ hybridization (FISH) with specific probes for chromosome 9 and 15 can be performed on day 3 cleavage stage embryos to look for unbalanced chromosomal complement. Invasive PND is strongly recommended not only to confirm the results of preimplantation interphase FISH but for the following evaluations: subtelomeric probe for 9p deletion, UPD studies for 15q11.2, autosomal aneuploidy (maternal non-disjunction) or sex chromosome aneuploidy (ICSI).

**Conclusion:** Genetic counseling is an essential part of the PGD process to ensure informed consent from the parents.

**Predictive value of sperm chromosome analysis on the outcome of PGD for translocations.** *T. Escudero<sup>1</sup>, I. Addehadi<sup>2</sup>, M. Sandalinas<sup>1</sup>, S. Munn<sup>1</sup>.* 1) Preimplantation diagnosis, IRMS at Saint Barnabas, West Orange, NJ; 2) The Farah Hospital, Amman, Jordan.

Objective: To achieve a predictive relationship between the proportion of abnormal sperm and the proportion of abnormal embryos in couples with translocation male carriers. Setting: Private IVF center. Patients: 11 cases of reciprocal translocation male carriers. Intervention: Blood sample and sperm sample collection from each male partner. Embryo biopsy of the embryos produced in each cycle Main Outcome Measures: FISH on lymphocyte slides to characterize each translocation case. FISH with specific probes for each of the sperm sample with specific probes. Preimplantation genetic diagnosis of the translocations in the 11 cases. Results: Sperm results: A total of 11184 sperm were counted from the 11 patients included in the study. A total of 99 embryos from these 11 cases were biopsied, 93 giving results. Comparison between FISH Sperm Analysis and PGD Results indicated that there was no statistical difference between the segregation types observed in sperm and embryos. A correlation was found between the percentage of abnormal gametes and the percentage of abnormal embryos, and a predictive equation is proposed for this relationship:  $A = -55 + (1.9 \times B)$ , where A is the % of abnormal embryos and B the % of abnormal sperm. A total of 16 embryos were replaced in nine of the eleven cases. Four became pregnant, of which three are ongoing and one delivered a healthy normal baby. Conclusions: The predictive value of the sperm analysis is established with a proposed equation. Patients with 65% or less chromosomally abnormal sperm have a good chance at conceiving, while patients with higher rates would need to produce 10 or more good quality embryos to have reasonable chances at conceiving.

**FISH aneuploidy screen followed by translocation probe set on single blastomeres of embryos from translocation couple yield disappointing outcome.** *S.B. Olson<sup>1</sup>, H. Lawce<sup>1</sup>, N. Ouhibi<sup>2</sup>, D. Wolf<sup>2</sup>.* 1) Dept Mol & Med Genetics, Oregon Health & Sci Univ, Portland, OR; 2) Dept Obstetrics & Gynecology, Oregon Health & Sci Univ, Portland, OR.

With the application of FISH to the interphase blastomere as a screen for chromosomal imbalance, the opportunity has arisen for patients with balanced translocations to decrease the chance of miscarriage or an unbalanced child through embryo screening following IVF. Probe sets are designed, specific to the rearrangement, to potentially elucidate through a single hybridization, or through a hybridization, stripping and rehybridization sequence, all possible combinations of balanced and unbalanced segregation products. However, due to the high rate of aneuploidy in early embryos, further screening of the blastomeres for chromosomes such as 13,16,18,21,X and Y seems appropriate. A 31-year-old patient and her balanced 1p;8q translocation carrier husband produced 27 embryos. Twelve of these were frozen, leaving 15 for potential biopsy. Seven embryos progressed to day 3. Biopsy produced 6 blastomeres from 5 embryos appropriate for FISH. FISH for aneuploidy revealed one monosomy 21 male, one with only a single chromosome 13 signal, one haploid with an extra 13 (confirmed on a second blastomere), one uninformative and one balanced for the probe set. The balanced blastomere was rehybridized with the translocation probe set, which revealed 3 copies of the chromosome 1 short arm and 1 copy of the chromosome 8 long arm. What began as a promising venture with relatively young maternal age and a high yield of embryos resulted in no balanced embryos for transfer. Couples should be fully informed through extensive genetic counseling of the great possibility of disappointment.

**Polar Body Based Preimplantation Diagnosis for X-linked Disorders.** *Y. Verlinsky<sup>1</sup>, S. Rechitsky<sup>1</sup>, O. Verlinsky<sup>1</sup>, D. Kenigsberg<sup>2</sup>, J. Moshella<sup>2</sup>, V. Ivakhnenko<sup>1</sup>, C. Masciangelo<sup>1</sup>, C. Strom<sup>1</sup>, A. Kuliev<sup>1</sup>.* 1) Dept Molecular Genetics, Reproductive Genetics Inst, Chicago, IL; 2) Long Island IVF, Port Jefferson, NY.

Preimplantation diagnosis for X-linked disorders has been predominantly performed by gender determination, which, however, leads to discard of 50% unaffected male embryos. In an attempt to identify the X-linked mutation free embryos for transfer, we introduced preimplantation genetic diagnosis (PGD), using a sequential first and second polar body analysis, as an alternative to gender determination, which was offered to seven couples at risk for having children with X-linked genetic disorders, including hemophilia B, ornithine transcarbamylase deficiency, fragile- X syndrome, myotubular myotonic dystrophy and X-linked hydrocephalus.. The first and second polar bodies were removed following maturation and fertilization of oocytes in a standard IVF protocol and analyzed using a multiplex nested PCR, involving testing for mutations simultaneously with linked markers. Overall, 12 PGD cycles were performed, resulting in detection of 22 embryos with a predicted mutation free maternal contribution, which were transferred back to the patients in 12 cycles, yielding 4 clinical pregnancies, three already resulting in birth and one currently ongoing. The results suggest the clinical usefulness of polar body testing for X-linked disorders as an alternative to PGD by gender determination.

**Detection of expanded CAG repeats at the myotonic dystrophy (DM) locus in single cells by triplet primed PCR (TP-PCR) for preimplantation genetic diagnosis (PGD).** *P.F. Ray<sup>1</sup>, N. Frydman<sup>2</sup>, R. Frydman<sup>2</sup>, M. Vekemans<sup>1</sup>, A. Munnich<sup>1</sup>.* 1) Departement de genetique medicale, Hopital Necker, PARIS; 2) Service de genicologie-obstetrique, Hopital Antoine Beclere, Clamart, France.

The amplification of large number of triplet repeats is challenging from microgram amounts of DNA but is impossible from single cells. Large pathologic alleles responsible for myotonic dystrophy (DM) can expand up to several thousands triplets but a maximum of 50-100 repeats can reliably be amplified from single cells. Thus, genetic analysis in the course PGD for couples at risk of transmitting myotonic dystrophy has so far mostly been based on the detection of the normal allele of the transmitting parent. This semi-indirect strategy, however, is only applicable when that allele is different in size from the propositus partner two alleles, from our experience, only about one fourth of the couples. Warner et al. (1996)\* described a fluorescent assay in which a primer internal to the triplet repeat itself was used and allowed the detection of expanded alleles. We utilized this strategy and developed a single cell hemi nested TP-PCR assay. The outer reaction mix contained a DM specific forward primer and the TP primer made of 7 CAG repeats tailed with an overhanging 20 bp specific primer. Aliquots of this reaction were reamplified with the same 5 fluorescently labeled primer and the 20 nucleotides specific primer. Fluorescent TP-PCR products were analyzed in an ABI 310 DNA analyzer. Expanded alleles were detected in 100% of the control lymphocytes analyzed and one PGD cycle was carried out. Following this procedure two embryos which had not shown amplification of the expanded allele were transferred. Positive hCG were detected two weeks later, indicating a successful uterine implantation of an embryo but the pregnancy was not sustained. Reliable detection of expanded CAG repeats was achieved from single lymphocytes and blastomeres by fluorescent TP-PCR. This single cell analysis technique is applicable to all couples at risk of transmitting myotonic dystrophy and similar protocols could be developed for the diagnosis of other trinucleotide expansion diseases. \* J Med Genet, 1996, (33) 1022-6.

**Clinical Assessment of Routine Chromosome Analysis and Rapid Interphase Fluorescence in situ Hybridization (FISH) in Prenatal Diagnosis: Evaluation of 993 New Cases.** *S.A. Ebrahim<sup>1</sup>, M.I. Evans<sup>2</sup>, A. Johnson<sup>1</sup>, M.P.*

*Johnson<sup>3</sup>, A.A. Al-Katib<sup>1</sup>, A.N. Mohamed<sup>1</sup>.* 1) Dept Pathology, Cytogenetics, Ob/Gyn, Wayne State Univ, Detroit, MI; 2) Dept Ob/Gyn&Human Genetics MCP Hahnemann Univ, PA; 3) Children's Hospital of Philadelphia, PA.

Over a 5-year period, we have carried out 1294 FISH studies on uncultured chorionic villous samplings, amniotic fluid, or fetal blood from women at high risk for having a child with a chromosomal anomaly. The results of the first 301 samples have been previously described (*Am J Med Genet* 2000;90:233-8). We presently report on an additional 993 new cases. FISH analyses have been routinely performed in our cytogenetics laboratory on uncultured fetal cells using the commercially available probes specific for chromosomes 13, 18, 21, X, and Y. Among the 5009 prenatal samples analyzed between July 1998 and May 2001, both FISH and conventional chromosome studies were performed on 993 (19.8%) cases. Aneuploidies were detected by FISH in 72 (7.3%) samples. Of those, 40% were trisomy 21, 28% trisomy 18, 9.7% trisomy 13, 9.7% monosomy X, 1.3% XXX, 1.3% XXY, 1.3% monosomy 21\*, and 8% were triploidy. All FISH results were reported in 8-48 hr. Subsequently, all FISH results were confirmed by chromosome analysis. In 18 (1.8%) cases with normal FISH results, chromosome analysis revealed abnormalities that could not be detected by FISH. However, in two cases with ultrasound anomalies, there was a discrepancy between FISH and the initial chromosome analysis. The first case was found to be trisomy 21 by interphase FISH, however, chromosome analysis revealed only a diploid 46,XY karyotype. FISH on metaphase cells revealed the presence of a cryptic unbalanced translocation: 46,XY,der(6)t(6;21)(q27;q22.2). The second case was determined to be monosomic for chromosome 21\* by interphase FISH. Subsequent chromosome and FISH analyses revealed a 46,XX, idic(21)(q22).ish idic(21)(q22.12)(D21S55-). Our data demonstrates the clinical utility and the accuracy of interphase FISH for rapid prenatal identification of specific chromosome aneuploidies, including rare chromosome rearrangements that likely would have been missed in the absence of FISH.

**First trimester maternal plasma detection of fetal specific DNA: Anti-coagulant influences sensitivity of real-time PCR.** *F.Z. Bischoff<sup>1</sup>, D.X. Dang<sup>1</sup>, D.A. Marquez-Do<sup>1</sup>, D. Lewis<sup>2</sup>, C. Horne<sup>2</sup>, A. Burke<sup>1</sup>, J.L. Simpson<sup>1,3</sup>.* 1) Depts of OB/GYN; 2) Immunology; 3) Molecular/Human Genetics, Baylor College of Medicine, Houston, TX.

Fetal DNA is present in maternal plasma and may be used for noninvasive prenatal genetic diagnosis. Although highly sensitive during the 2nd and 3rd trimesters, genetic testing during the 1st trimester has been considered less efficient due to relatively lower concentrations of fetal DNA. Because 1st trimester testing is preferable for early diagnosis and pregnancy management, determining optimal conditions for processing plasma DNA are necessary. **OBJECTIVE:** To determine whether anti-coagulant influences the detection of fetal sequences in 1st trimester samples. **METHODS:** Peripheral blood was obtained from women prior to CVS or amniocentesis at 10.9-21.7 weeks gestation (mean 15.9 wks). Blood was collected in vacutainers containing ACD (n=10), EDTA (n=5) or NaHep (n=11). In cases confirmed with a male fetus (n=28), plasma DNA was purified (Qiagen). Real-time PCR was performed using the TaqMan assay to detect the FCY (Yq11.2) and GAPDH (control) locus. Fetal DNA concentration (copies/ml plasma) was determined using the Sequence Detection System software (PE Applied Biosystems). **RESULTS:** See Table. **CONCLUSIONS:** EDTA improves efficiency of fetal sequence detection in 1st trimester cases. Combined with Real-time PCR, this approach may prove to be valuable for noninvasive prenatal detection of paternally derived sequences.

Anit-Coagulant	First Trimester	Second Trimester	Total
EDTA	4/4 (100%)	1/1 (100%)	5/5 (100%)
ACD	1/3 (33%)	4/7 (57%)	5/10 (50%)
NaHep	1/3 (33%)	5/8 (63%)	6/11 (55%)

**Personal preference assessments of prenatal diagnosis.** *W.A. Grobman, S.L. Dooley, E. Welshman, E. Calhoun, E. Pergament.* Northwestern University Medical School, Chicago, IL.

**Purpose:** The formulation that women should be offered invasive prenatal testing when the risk of having a child with Down syndrome exceeds the risk of having a procedure-related miscarriage is potentially specious. The underlying rationale is that women perceive the birth of a child with Down syndrome as a health state equal to that of a miscarriage. This rationale, developed without examining actual patient preferences, remains an unproven assumption. The objective of this study was to determine if patients' utility values (quantitative assessments of patients' perceptions of health states) support maternal age  $\geq 35$  years for the offering of invasive prenatal testing. **Method:** An interview-administered survey was conducted with 187 pregnant women receiving antepartum care at a university hospital to determine demographic characteristics, attitudes toward prenatal diagnosis, and utilities for spontaneous abortion (SAB) and the birth of a child with Down syndrome (DS) of varying clinical severity. Utility values were determined through the use of a standard gamble paradigm. Lower utility values reflect less desirable health states. **Results:** SAB of a pregnancy had a mean utility of .76. The utility for the birth of a child with DS decreased ( $p < .001$ ) as the clinical severity of DS increased from mild (.78) to severe (.65). The only factor that predicted a difference between the utility for birth of a child with Down syndrome and miscarriage was the desire for amniocentesis. Women who desired amniocentesis had a utility value for SAB (.79) that was significantly higher ( $p < .01$ ) than for the birth of a child with DS of unknown severity (.73), while women who did not desire amniocentesis did not show a difference in the utility values. **Conclusions:** Women who desire prenatal genetic testing do not perceive the birth of a child with DS and a miscarriage to be equivalent health states. The appropriateness of the 35-year-cut-off is debatable. Patient preferences may neither be congruent with economic interests of the health care system nor correspond to traditional risk vs benefit concepts based on maternal age.

**Non-invasive prenatal diagnosis of congenital adrenal hyperplasia through the use of fetal DNA in maternal plasma.** R.W.K. Chiu<sup>1</sup>, T.K. Lau<sup>2</sup>, Z.Q. Gong<sup>3</sup>, P.T. Cheung<sup>3</sup>, T.N. Leung<sup>2</sup>, Y.M.D. Lo<sup>1</sup>. 1) Department of Chemical Pathology; 2) Department of Obstetrics and Gynaecology, The Chinese University of Hong Kong; 3) Department of Paediatrics, The University of Hong Kong, Hong Kong SAR, China.

The presence of fetal DNA in maternal plasma has allowed the development of strategies for non-invasive prenatal diagnosis. However, as fetal DNA circulates in maternal plasma among a high background of maternal DNA, applications reported to date have been limited to the prenatal investigation of autosomal dominant, paternally-inherited genetic traits, such as rhesus D, myotonic dystrophy and achondroplasia. In this study, we investigated if maternal plasma analysis could be used for the prenatal diagnosis of autosomal recessive (AR) disorders, using congenital adrenal hyperplasia (CAH) as a model system. For AR conditions, the ability to detect a paternally-inherited mutation in maternal plasma does not aid in disease diagnosis, as it does not clarify whether the fetus is a homozygote or heterozygote. Consequently, we have taken the approach to detect the presence of the *normal* paternal allele through the use of polymorphic markers, whose presence in maternal plasma effectively excludes the diagnosis of the AR condition. A couple, whose first child was diagnosed with 21-hydroxylase (encoded by *CYP21*) deficiency, presented during their second pregnancy for prenatal diagnosis. Both intragenic and extragenic (HLA-haplotype) markers have been used to characterize the normal paternal allele. The family was found to be informative for 3 polymorphic sites in intron 2 of *CYP21*. Primers were designed to amplify the polymorphic sites, as well as HLA class II genes. Both the intragenic polymorphic markers and the HLA class II gene associated with the normal paternal allele were amplifiable in maternal plasma collected at 17 weeks of gestation, which supports the conclusion that the unborn baby is not a compound heterozygote for 21-hydroxylase deficiency. The results have been confirmed by HLA-typing and mutation analysis of amniotic fluid. The use of fetal DNA in maternal plasma for the non-invasive prenatal diagnosis of CAH is possible, and this approach could potentially be applied to other AR conditions.

**Genetic management of adverse outcomes in a semen bank.** *R.N. Dudovitz<sup>1</sup>, M. Ray<sup>2</sup>, R.E. Falk<sup>1</sup>.* 1) Medical Genetics-Birth Defects Center, Cedars-Sinai Medical Center, Los Angeles, CA; 2) California Cryobank, Los Angeles, CA.

A total of 355 adverse reaction reports (ARRs) from artificial insemination with donor sperm, collected by a single semen bank over a 14 year period, were examined to investigate the genetic management and implications of such cases. Data was reviewed by a single geneticist and classified regarding the likelihood of chromosomal, multifactorial, Mendelian, or other causation. Eighty-six ARRS reported chromosomal abnormalities, 172 were non-chromosomal, 56 described maternal complications (infection, fever), and 41 noted an unexplained fetal demise. Excluding multifactorial traits, 18 of 299 (6%) non-maternal ARRs were clearly donor related. Five of the 18 donor-related ARRs were chromosomal and could be avoided by cytogenetic analysis of potential donors. The semen bank was dependent on the client or her physicians for access to medical records and laboratory reports, limiting the accuracy of genetic risk assessment. Nearly 22% of ARRs did not identify the client or allow direct discussion with her. While 55% of ARRs were reported by the client, many allowed no contact with or reporting from the child's physicians. Overall, 70% of diagnoses remained vague or undocumented despite repeated attempts to obtain additional information. The interval between birth of the child and notification of the semen bank varied considerably as 66.7% of ARRs were reported within 1 year, 18% within 2-4 years and 9.5% by 4-9 years. In some cases this reflected late manifestation of the condition, while other cases were reported after considerable delay. As repeated use of a particular donor could lead to recurrence of a genetic condition, timely and accurate reporting of even potentially genetic adverse outcomes is critical. Although there are guidelines for screening semen donors, there are no regulations regarding donor screening or follow-up of reported abnormal outcomes at present. Continued use of a specific donor's semen after report of an adverse outcome raises a number of social and ethical issues which will be reviewed. These may influence policy decisions regarding regulation of donor screening and follow-up of adverse outcome reports in semen banking.

**Novel approaches for the prevention of Types A and B Niemann-Pick Disease: Enrichment of normal from mutant sperm in heterozygous mice.** *A. Butler, H.W. Snoeck, K.A. Kelley, R.E. Gordon, E.H. Schuchman.* Dept Human Genetics, Mount Sinai School of Medicine, New York, NY.

Types A and B Niemann-Pick disease (NPD) are lysosomal storage disorders resulting from the deficient activity of acid sphingomyelinase (ASM) and the subsequent accumulation of sphingomyelin and cholesterol. The carrier frequency for Type A NPD among Ashkenazi Jewish individuals is ~ 1:80, with a predicted 25% risk of an affected fetus being born to carrier couples. No treatment is currently available for this disorder. The goal of our research was to develop a pre-fertilization, gamete selection technique that could significantly reduce or eliminate the chance of producing an affected fetus from NPD carrier couples. Our laboratory previously constructed an ASM knockout mouse model of NPD and data obtained from *in vivo* mating studies suggested that NPD mice exhibited reduced fecundity. Investigation of male reproductive physiology by light and electron microscopy revealed accumulation of lipid filled vacuoles within Sertoli cells of the testes and epithelial cells of the epididymis of affected mice. Mature sperm from affected mice also showed various functional and physical abnormalities, including accumulation of lipid, reduced motility, "hairpin" structures, and increased cell death. While sperm from normal mice did not exhibit any of these findings, those from heterozygous mice exhibited several features that were intermediate between normal and affected mice. Consequently, we present data on the enrichment of normal sperm from heterozygous mice by (I) flow cytometry based on mitochondrial membrane potential, acrosome status, or general viability, and (II) physical separation techniques based on motility or density. These results suggest that adult male NPD patients and carriers may also have sperm abnormalities that lead to reduced fertility, and that ASM is essential for normal sperm development.

**Absent eyelids, micrognathia, digital and skeletal abnormalities and ambiguous genitalia: A new autosomal recessive syndrome.** *D. Chitayat*<sup>1,2,3</sup>, *C. Sherman*<sup>1,3</sup>, *S. Viero*<sup>1,3</sup>, *D. Myles-Reid*<sup>1,3</sup>, *A. Toi*<sup>1,3</sup>. 1) Mount Sinai Hospital; 2) Hospital for Sick Children; 3) University of Toronto, Toronto, ON, Canada.

Absent eyelids is a rare finding. We report male and female fetuses born to a consanguineous Pakistani couple with absent eyelids, skeletal abnormalities and absent external genitalia. The couple's first pregnancy was complicated with ultrasound findings of oligohydramnios, dolichocephalic skull, cardiac abnormalities, kyphoscoliosis and splaying of the lamina in the lower lumbar spine, at 19 weeks. The pregnancy was terminated and the autopsy showed a globular and hyperextended head, with prominent occiput, absent eyelids, small pointed nose, micrognathia, nuchal edema, webbed neck, absent clavicles, right axillary pterygia, hypoplastic thumbs with tapering fingers, partial syndactyly of the 3<sup>rd</sup> and 4<sup>th</sup> fingers, limitation in extension of both knees with popliteal pterygia, bilateral clubbed feet, syndactyly between the 4<sup>th</sup> and 5<sup>th</sup> toes, imperforated anus and prominent clitoris with labia or vaginal opening. Internal examination showed Ebstein cardiac anomaly, moderate hypoplasia of the left ventricle, hypoplastic lungs and unilobar left lung, and female internal genitalia. The karyotype was 46,XX. The couple's second pregnancy was a few months later. A fetal ultrasound at 20.1 weeks revealed fetal measurements consistent with 17.2 weeks gestation and multiple abnormalities including oligohydramnios, hypertelorism, dolichocephaly, lateral cerebral ventriculomegaly, hyperextended neck, flexed arms, lordotic thoracic spine, kyphotic lumbar spine, thin ribs, query absent clavicles, prominent right eye and a pterygium over the left elbow. The couple decided to terminate the pregnancy and autopsy was not consented. External examination showed the same manifestations as in the previous fetus. The karyotype was 46,XX. Although the findings have some features in common with Neu-Laxova syndrome, the absence of brain abnormalities, the abnormal genitalia, absent clavicles and normal skin differ between these conditions. This is thus a hitherto new autosomal recessive disorder.

**The Fragile X Syndrome: Screening and prenatal diagnosis.** *W.T. Brown, S. Nolin, G.E. Houck, X.H. Ding, A. Glicksman, S.H. Li, S. Brooks, C. Dobkin, E.C. Jenkins.* Dept Human Genetics, NYS Inst Basic Research, Staten Island, NY.

Fragile X syndrome is the most common inherited form of mental retardation. Its molecular basis is usually an expansion of a repetitive CGG triplet sequence located in the 5' untranslated region of the fragile X gene, FMR1. Because of its prevalence and medical importance, efficient means for accurate diagnostic screening and prenatal testing are needed. Polymerase chain reaction (PCR) is rapid and requires little DNA. We have carried out screening and prenatal diagnosis for the fragile X syndrome using a PCR protocol we have developed that accurately resolves normal alleles as well as detects premutations and most full mutations (>90%). Follow-up Southern blotting is carried out on prenatal samples and other selected samples. Testing of 2095 males with developmental delay of unknown etiology revealed 61 (3%) were positive for fragile X. Our prenatal experience now includes screening of 624 pregnant women, who had a family history of mental retardation of undetermined etiology. We have found 12 of the women to be carriers: 3 full mutations, 3 premutations and 6 with unstable borderline alleles. Two additional fragile X families were identified although the women were not carriers. Thus, 2.7% (14/624) of women were carriers or came from fragile X families or had unstable alleles. Additionally, 25 carriers (40%) with prior unknown carrier status were identified among 62 pregnant members of previously identified fragile X families. Prospective prenatal testing of 206 carrier women correctly detected 90 fetal samples with full mutations and 15 with premutations. Follow up information on all samples obtained so far, including approximately 30% of the terminated products of conception, indicates no false positive or negative results. Maternal cell contamination has presented problems in 3 cases. Thus, highly reliable screening of at-risk pregnant women for fragile X status and subsequent prenatal diagnosis is now possible.

**Genetic Counseling and Prenatal Diagnosis of X-Linked Hydrocephalus and Tetralogy of Fallot.** *M.T. Jodah<sup>1</sup>, B.G. Kousseff<sup>1</sup>, J.L. Angel<sup>2</sup>*. 1) Dept. of Pediatrics, USF Regional Genetics Program, Tampa, FL; 2) Florida Perinatal Associates, Tampa, FL.

Congenital hydrocephalus occurs in approximately 0.4-0.8/1,000 livebirths and stillbirths. It may be caused by chromosome abnormalities, neural tube defects, infections, teratogens, trauma, syndromic and non-syndromic conditions and mendelian disorders. X-linked hydrocephalus with aqueductal stenosis (HSAS; MIM #307000) is the most common genetic form of congenital hydrocephalus; incidence is estimated at 1/30,000. The phenotype shows mental retardation, macrocephaly and adducted thumbs; aqueductal stenosis may or may not be present. Approximately 5% of cases with hydrocephalus belongs to this type. The gene, L1CAM, (L1 cell adhesion molecule), was mapped to Xq28, along with three other genetic conditions: MASA (mental retardation, aphasia, shuffling gait), ACC (agenesis of the corpus callosum), and SPG1 (spastic paraplegia type 1). This represents allelic heterogeneity with mutations in the same gene resulting in different phenotypes. In HSAS, associated anomalies typically involve the central nervous system. To our knowledge, this is the first reported case involving prenatal diagnosis of X-linked hydrocephalus with Tetralogy of Fallot.

**Fetal diaphragmatic hernia and upper limb anomalies suggest Brachmann-de Lange syndrome.** *T. Marino<sup>1</sup>, P.G. Wheeler<sup>2</sup>, L.L. Simpson<sup>3</sup>, S.D. Craigo<sup>1</sup>, D.W. Bianchi<sup>2</sup>.* 1) Division of Maternal-Fetal Medicine, Obstetrics & Gynecology;; 2) Division of Genetics, Pediatrics; New England Med Ctr, Boston, MA; 3) Obstetrics & Gynecology, Columbia-Presbyterian Med Ctr, NY, NY.

With the routine use of ultrasound imaging for fetal structural anomalies, diaphragmatic hernia is now increasingly diagnosed prenatally. In the absence of associated anomalies, or when associated anomalies are not identified before birth, prospective parents are initially referred to a pediatric surgeon to discuss postnatal surgical options. The subsequent detection of associated fetal anomalies may create difficulties for a family that has been counseled with an emphasis on surgical repair, as opposed to a syndrome diagnosis.

We describe two independent cases of Brachmann-de Lange syndrome in which second trimester fetal ultrasound evaluation showed the presence of a diaphragmatic hernia and upper limb anomalies. In both cases the fetal karyotype was normal and the prospective parents were referred for pediatric surgical consultation. Intrauterine growth restriction developed in the third trimester. Postnatal and post-mortem physical examinations demonstrated typical physical findings associated with Brachmann-de Lange syndrome. The prenatal diagnosis of diaphragmatic hernia should prompt an intensive search for additional anomalies. If upper limb anomalies are detected an underlying diagnosis of Brachmann-de Lange syndrome should be considered.

**Investigation of prenatal samples with ultrasound findings suggesting dwarfing syndromes.** *A.Q. Hejmanowski<sup>1</sup>, A. Sommer<sup>2</sup>, T.W. Prior<sup>1</sup>*. 1) Pathology, Ohio State University, Columbus, OH; 2) Children's Hospital, Columbus, OH.

Thanatophoric Dysplasia (TD) is the most common form of lethal dwarfism. 48.4% (46 of 95) of the Molecular Pathology laboratory's prenatal samples are for a skeletal dysplasia panel, which includes achondroplasia (ACH), hypochondroplasia (HCH), and TD. 68.2% (28 of 41) of the TD samples mention abnormalities on ultrasound, especially micromelic limb shortening, macrocephaly with frontal bossing, and flattened vertebrae, as the reason for submission. Our lab tests for the two most common mutations causing TD: Lys650Glu, which is the only mutation known to cause TD type II, and Arg248Cys, the mutation most often found in TD type I. 86.9% (40 of 46) of our samples are negative for these mutations, as well as mutations that cause ACH or HCH. The present study was conducted to screen the negative patients for other mutations in the Fibroblast Growth Factor Receptor 3 (FGFR3) gene.

These samples were sequenced using PCR and the Applied Biosystems BigDye Terminator cycle sequencing kit. The FGFR3 coding sequence contains 19 exons. Exons 2 through 18 have been sequenced in 11 patients. Two (18.2%) were found to have the second most common TD I causing mutation, Ser249Cys. The other nine (81.8%) were found to have no mutations. Two other patients have been partially sequenced (three exons remain to be finished) with no findings. A test for the Ser249Cys mutation should be added to skeletal dysplasia screen, and is in development in the Molecular Pathology lab. In samples dating from March of 1997 through the present, we have found only five TD mutations following abnormal ultrasounds. This strongly supports the conclusion that ultrasound, though a powerful tool for diagnosis of some form of abnormality, is not specific enough to be used for a differential diagnosis of a specific dwarfing syndrome. Secondly, it shows that other genes may cause ultrasound findings that mimic TD.

**Sensitivity of fluorescence in situ hybridization to correctly identify chromosomal abnormalities in high risk obstetrical populations.** *K. Mujaibel<sup>1</sup>, H. Bruyere<sup>2</sup>, S. Langlois<sup>3</sup>, R.D. Wilson<sup>1,3</sup>.* 1) Obstetrics and Gynecology; 2) Pathology; 3) Medical Genetics, University of British Columbia, Canada.

**STUDY DESIGN:** A retrospective chart review of all patients seen between 1998-2000 who underwent a genetic amniocentesis and were offered FISH on uncultured amniocytes as an adjunct to conventional chromosomal analysis because of a gestational age >21 weeks or an ultrasound finding of a fetal anomaly highly suggestive of aneuploidy. The study population was divided into two groups: group I included cases with U/S finding of fetal anomalies and/or abnormal fetal growth and/or abnormal fluid volume; group II included cases with U/S findings of markers of aneuploidy, some of which also had positive triple screen or AMA. FISH results were then compared to the conventional chromosomal analysis. **RESULTS:** A total of 150 patients charts were evaluated. Mean maternal age at amniocentesis was 29.9 years. Mean gestational age at amniocentesis was 20 weeks. The rate of chromosomal abnormality in the total study population was 27% (40/150) as detected by the conventional karyotype. FISH identified 36/40 of the chromosomal abnormality with an overall sensitivity of 90%. In group I, FISH accurately identified the chromosomal abnormality in 92% (22/24) of positive cases. In group II, FISH was positive in 88% of the chromosomal abnormality cases (14/16). When evaluated by the type of the US abnormality, FISH was 100% accurate in identifying abnormal chromosomes in the group with CNS and GI abnormalities and 71% (5/7) sensitive in cases of abnormal CVS. In the presence of multiple major US findings, the sensitivity of FISH was 88% (7/8) and 83% (5/6) in cases of multiple markers of aneuploidy. There were 4 false negative results with FISH (4/40). Three were structural chromosomal abnormalities that would not be expected to be identified with the use of FISH (2 translocations and one mosaicism). The fourth result was reported as inconclusive and the final karyotype was trisomy 18. **CONCLUSION:** In a population at high risk for aneuploidy, FISH was a clinically useful rapid prenatal diagnostic test with a sensitivity of 90% and NPV of 96% in detecting significant chromosomal abnormalities.

**Severe Knee Hyperextension In A Fetus With Trisomy 21: Association or Coincidence?** *M.J. Huggins<sup>1</sup>, P.T. Mohide<sup>1</sup>, J. Bourgeois<sup>3</sup>, M.J.M. Nowaczyk<sup>2,3</sup>*. 1) Obstetrics and Gynecology; 2) Pediatrics; 3) Pathology and Molecular Medicine, Hamilton Health Sciences and McMaster University.

**CASE REPORT:** A 28 year old woman in her 2nd pregnancy was referred after abnormal findings on a screening 18 week ultrasound. Detailed sonographic evaluation revealed a singleton fetus with hyperextended knees and feet. Fetal echocardiography confirmed the presence of tetralogy of Fallot with a large perimembranous/outlet ventricular septal defect and aortic override. The nuchal fold measured 6.4 mm at 20 weeks of gestation. Interphase FISH of amniocytes showed that 90% of cells had an additional hybridization signal indicative of trisomy 21. Following genetic counselling, the couple requested pregnancy termination. **RESULTS:** Postmortem examination of the fetus revealed typical facial features of trisomy 21, with low set ears, short palpebral fissures, broad face and short nasal bridge. There were bilateral single palmar creases and clinodactyly. The cardiac findings were tetralogy of Fallot with overriding aorta, VSD, and small left ventricular outflow tract. There was hyperextension of the knees bilaterally, with possible hypoplasia of the anterior cruciate ligaments. **DISCUSSION:** The association between Down syndrome (DS) and joint hyperflexibility is well documented, but mainly confined to the cervical region and the hip joints. The severe hyperextension of both the knees seen in this case has not been previously reported as a prenatal feature of DS, although in view of other joint abnormalities in DS, this unusual finding may be consistent with that diagnosis. This case would suggest that a sonographic finding of hyperextended knees should be considered a possible indication for fetal karyotyping.

**Pitfalls in prenatal diagnosis of the 21-hydroxylase deficiency congenital adrenal hyperplasia (CAH) due to complicated gene conversion and rearrangements.** *R. Mao<sup>1</sup>, L. Nelson<sup>1</sup>, R. Kates<sup>2</sup>, C. Miller<sup>3</sup>, W. Tang<sup>1</sup>, K. Ward<sup>1</sup>.*  
1) DNA Diagnostic Lab, Univ Utah, S.L.C., UT; 2) Tri Cities Maternal Fetal Medicine, Richland, WA; 3) Medical Genetics, Univ Utah, S.L.C., UT.

Steroid 21-hydroxylase deficiency is the cause approximately 90% of the CAH patients. Although biochemical testing remains the primary method of postnatal diagnosis, DNA analysis has assumed a central role in prenatal assessment of at-risk pregnancies due to its accuracy in mutation identification. Pitfalls to prenatal diagnosis can be related to the presence of the highly homologous 21-hydroxylase pseudogene, CYP21P, adjacent to the functional gene, CYP21. We report two cases of complex gene conversion and rearrangement between the CYP21 and CYP21P posing unique prenatal diagnostic challenges. **Patients:** In Family 1, a 5 y/o girl was diagnosed in an early infancy with CAH several weeks after presenting with dehydration and salt wasting. She had an enlarged clitoris and elevated 17-hydroxy progesterone level. The 18-month-old boy in Family 2 was identified by an elevated 17-hydroxy progesterone level upon newborn screening. Both of the families requested prenatal testing for the current pregnancies. **Methods:** Analysis of eight common mutations and the deletion in the CYP21 gene is accomplished using PCR followed by specific enzyme digestion and Southern Blot. Linkage analysis was performed using the microsatellite markers flanking the CYP21 gene. **Results:** Results from the mutation detection indicated a complicated gene conversion and rearrangement in the affected individual in both of the families. Interpretation of these changes made it difficult to determine whether the fetus(es) in the current pregnancies would be affected with CAH. Linkage study revealed that each fetus had inherited both mutated alleles from the parents and was therefore predicted to be affected with CAH. **Conclusion:** As observed in the two reported cases, gene conversion or rearrangement between the CYP21 and CYP21P can provide limitations to the scope of information yielded from DNA. We suggest that supporting the direct mutation detection with linkage study will provide more comprehensive information for the family.

**Experience in the prenatal diagnosis of the fetus with holoprosencephaly.** *D. Mayen<sup>1</sup>, S. Garza<sup>2</sup>, R. Garcia-Cavazos<sup>1</sup>, T. Leis<sup>1</sup>, M.J. Zavaleta<sup>1</sup>.* 1) Dept Genetics, Inst Nacional de Perinatologia, Mexico City, Mexico; 2) Dept Neurology, Hosp Infantil de Mexico "Federico Gomez, Mexico City.

**Introduction:** Holoprosencephaly (HPE) is a spectrum of cerebral abnormalities resulting from incomplete cleavage of the forebrain. Up to 45% have chromosomal abnormalities, 25% monogenic syndromes and other aetiologies (teratogenic agents diabetes mellitus). **Purpose:** Describe the perinatal management of the fetus with HPE in a mexican population. **Methods:** All pregnant women with a fetus with hydrocephaly and /or medium-line craneofacial anomalies detected with conventional ultrasound during the period between june 1993 and april 1999 were included. We studied family history and performed physical examination of both parents and high resolution ultrasound with videofilmation, amniocentesis for chromosomal analysis and fluorescence *in situ* hybridization. At birth we comfirmed the diagnosis by physical examination, transfontanelar ultrasound, CT/MRI or autopsy. **Results:** We detected 120 cases with hydrocephaly and/or medium-line craneofacial malformations, of which 20 cases(16.6) were HPE(16 alobar and 4 semilobar): The mean gestational age at the comfirmation of the diagnosis were 27.4 weeks(range 15 to 36.5). Five cases(0.25) were associated with maternal diabetes, six(0.30) had chromosomal anomalies: 5 were associated with the critical points for HPE(two with partial monosomy 18p and cyclopia). **Conclusion:** HPE is a common cause of fetal hydrocephaly and the correct diagnosis and perinatal management required a multidisciplinary group.

**Cultivation of fetal erythroid precursors out of maternal blood: Their isolation and characterisation with PCR and FISH.** *H. Hohmann<sup>1</sup>, S. Michel<sup>1</sup>, W. Reiber<sup>2</sup>, C. Kaehler<sup>3</sup>, U. Claussen<sup>1</sup>, F. von Eggeling<sup>1</sup>.* 1) Inst Human Genetics, Univ Jena, Jena, Germany; 2) Private Gynecologist, Univ Jena, Germany; 3) Institute of Gynecology, Univ Jena, Germany.

The cultivation of fetal cells out of maternal blood may be an alternative in non-invasive prenatal diagnostic. The percentage of fetal cells could be improved in vitro by increasing their number with a selective culture medium. In our experiments 10 ml blood was used from 22 women carrying a male fetus. We used triple density gradient centrifugation to isolate mononuclear cells and the fraction containing most erythroblasts. The pooled cells were cultivated 10 to 14 days in haematopoietic growth medium. Red (CFU-E, BFU-E) and white coloured cell clones were individually collected by micromanipulation. A part of each clone was characterised by Y-specific PCR-systems, using the Amelogenin- and the SRY-detection System. If the PCR result was Y-positive the remaining cells of the clone were used to carry out fluorescence in situ hybridisation (FISH) to detect XY-positive interphase nuclei and metaphases. PCR results showed that with SRY PCR 12.3 % (n = 40/323) of the collected red clones tested were of fetal origin and 6.1 % (n = 32/522) of the clones analysed by Amelogenin PCR were Y-positive. In contrast all collected white cell clones were Y-negative. FISH analyses of PCR-positive clones revealed that within one individual clone only up to 30% of the cells are of fetal origin. No Y-PCR positive red clone showed exclusively fetal cells, which might be a kind of contamination or more possible it could be characteristic for clonal fetal cell growth as they may require maternal cells for stimulation. Our results show that the cultivation and preparation of fetal progenitor cells is possible but still need to be improved for reliable prenatal diagnosis.

**Molecular characterization of  $\alpha$ -thalassemia genes in an Iranian population.** *M.A. Kerachian<sup>1</sup>, M. Houshmand<sup>2</sup>, A. Bani-Hashem<sup>3</sup>, M. Gholamin<sup>1</sup>, R. Vakili<sup>1</sup>, M.R. Abbaszadegan<sup>1</sup>.* 1) Dept. of Human Genetics, Bu-Ali Res Ins, Mashad Univ. Med. Sci., Mashad, Iran; 2) NRCGEB, Tehran, Iran; 3) Sheik Children's Hospital, Mashad, Iran.

Alpha-thalassemia is the most common inherited disorder of hemoglobin (Hb) synthesis in the world. More than 95% of recognized  $\alpha$ -thalassemia involves deletion of one or both  $\alpha$ -globin genes from chromosome 16p13.3. Determination of the underlying genotype is especially important for reproductive planning because parents with two gene *cis* deletions ( $\alpha/--$  or  $- \alpha/--$ ) can have offspring with the fetal condition hemoglobin (Hb) Bart's hydrops fetalis ( $--/--$ ) or Hb H disease ( $- \alpha/--$ ). We used polymerase chain reaction (PCR) to identify couples at risk of conceiving fetuses afflicted with Hb H disease or Hb Bart's hydrops fetalis syndrome. Furthermore, specimens of suspected patients for  $\alpha$ -thalassemia were studied. This study sought to detect three different  $\alpha$ -thalassemia deletions ( $-\alpha^{3.7}$ ,  $-\alpha^{4.2}$  and  $--SEA$ ) among a population in northeastern Iran, Mashad. Our study indicates that more than one of two couples experience  $\alpha$ -thalassemia. However, about 5% are  $\alpha$ -thalassemia trait. Amongst patients ( $n=46$ ), there were no  $\alpha$ -thalassemia with  $-\alpha^{4.2}$  and  $--SEA$  deletions. Sequencing the amplified fragments verified our results. Therefore, the PCR approach may have major implications for population screening at prenatal diagnosis programs aimed at secondary prevention of  $\alpha$ -thalassemias.

**Prospective Study of Molecular Fragile X Syndrome Prenatal Diagnosis.** *J. Mallolas<sup>1</sup>, C. Badenas<sup>1</sup>, M. Rife<sup>1</sup>, A. Soler<sup>1</sup>, A. Borrell<sup>2</sup>, A. Sanchez<sup>1</sup>, M. Mila<sup>1</sup>.* 1) Genetics, Hospital Clinic, Barcelona, Barcelona, Spain; 2) Unidad de Diagnostico Prenatal Hospital Clinic. Barcelona.

Since 1992, sixty-five prenatal diagnoses for fragile X syndrome have been performed. Among them, 51 correspond to fragile X syndrome pedigrees (41 belonging to a carrier mother and 10 to at risk mothers). The remaining 14 corresponded to mothers with no expansion in the FMR1 gene, where the molecular study was simultaneously done in the mother and fetus due to a family story of mental retardation. A parallel cytogenetic and molecular study was performed in all cases. Molecular study consisted in both PCR and Southern blot (StB12.3 probe after double digestion with EagI and EcoRI). When necessary, indirect study was done using AC1, AC2 DXS548 and DXS297. We were able to reach a diagnosis in all cases but one (98.4%). In 7(10.7%) cases a second sample was obtained due to abnormal methylation patterns. Regarding the 41 pregnancies from carrier mothers, 20 were normal (10 males and 10 females), 18-affected carrying a full mutation (11 males and 7 females), and 2 NTM. An induced abortion was done in 3 cases (4.6%) due to another pathology (46,XY 18q-, Duchenne muscular dystrophy and cardiopathy). The CGG expansion was confirmed in all aborted fetuses of Fragile X families and newborns.. The sample should be obtained after 13 weeks of pregnancy when the methylation patterns are well established, then molecular prenatal diagnosis of fragile X syndrome is safe and reliable. This work was supported by grant Marato TV3 (98/310 IP.MM).

**Prenatal diagnosis of SMA-I utilizing a newborn screen dried blot specimen: A case report.** *K.B. Lescale, M.J. Erickson, K.M. Smith, F. Gilbert, M.F. Cabbad.* Department of Obstetrics and Gynecology, The Brooklyn Hospital Center, Brooklyn, NY.

Spinal muscular atrophy (SMA) is a disorder characterized by degeneration of the anterior horn cells of the spinal cord. It is a lethal, autosomal recessive disease with a frequency of approximately 1/20,000. The disease is classed into three types with Type I presenting in early infancy. Prenatal diagnosis for this disorder, by DNA testing, is available for at-risk couples. About 95% of affected individuals will have a homozygous deletion of exons 8 and/or 7 in the SMN gene on chromosome 5q and these can be detected by DNA analysis of amniocytes or chorionic villi. However, due to the reported incidence of intragenic mutations, *de novo* mutations, and the difficulty in distinguishing between a carrier and an affected individual on prenatal testing, the protocol for prenatal diagnosis requires haplotyping of the affected child and the parents to provide the most accurate result. In this case, the affected child was deceased and haplotyping had not been performed prior to his death. The patient was a 39 y.o. whose second child was diagnosed, at a few weeks of age by DNA analysis, to have deletions of exons 7 and 8 and died at 5 months of age. The patient presented to genetics approximately 18 months after the child's death and follow-up with the original diagnostic lab revealed that DNA was stored for a 12 month period only. In this case, the New York State newborn screen dried blood spot specimen was available. Haplotyping analysis of the dried blood spot and the parental bloods identified informative markers for linkage so the prediction of disease status would be possible for this couple in future pregnancies. Through the use of CVS, disease status was confirmed in two subsequent pregnancies. To our knowledge this is the first reported prenatal diagnosis of SMA-I utilizing the newborn screen blot of a deceased affected individual.

**Perinatal Hospice: An important option for families continuing pregnancies following the diagnosis of lethal conditions.** *R.J. Hopkin<sup>1</sup>, M.E. Walker<sup>1</sup>, H.M. Saal<sup>1</sup>, E.K. Schorry<sup>1</sup>, L. Tucker<sup>2</sup>*. 1) Dept Human Genetics, Children's Hosp Medical Ctr, Cincinnati, OH; 2) StarShine Hospice, Children's Hosp Medical Ctr, Cincinnati, OH.

Families faced with prenatal diagnosis of trisomy 18, 13, or other lethal conditions must make difficult decisions. For many pregnancy termination is not an acceptable option. Such families face the emotional burden of continuing a pregnancy while anticipating the death of their child. They often express feelings of confusion and anger, and may have little sense of control over what happens to them or their child. To address the needs of these families we have initiated a perinatal hospice program as a collaborative effort between the Division of Human Genetics and the StarShine Hospice at Children's Hospital in Cincinnati. The program includes genetic counseling, guidance for families in developing a detailed birth plan, coordination of communication between the family and their obstetric and pediatric care providers, coordination of home care and funeral arrangements, provision of comfort care to the affected infants, and grief counseling. Participating specialists include genetic counselors, hospice nurses, social workers, chaplains, and clinical geneticists. Of the 5 families enrolled in this program, 4 have delivered children with lethal chromosomal anomalies, and 1 a child with alobar holoprosencephaly. The perinatal hospice program empowers families in several ways: **1.** Families have tangible tasks to accomplish in the prenatal period. **2.** Writing a detailed birth and postnatal care plan aids in processing the natural history information provided through the genetic counseling. **3.** Decisions regarding management of apnea, feeding, and heart disease are made prospectively rather than in reaction to crisis. **4.** Follow up counseling and care are provided by professionals who have established relationships with the families. We believe this innovative program can serve as a model for the management of families who are continuing pregnancies following the prenatal diagnosis of lethal conditions.

**Prenatal marker chromosome identification utilizing the combination of G-banding, SKY and FISH.** *H.H. Heng<sup>1</sup>, J-W. Yu<sup>2</sup>, S. Ebrahim<sup>3</sup>, G. Liu<sup>1</sup>, C.J. Ye<sup>4</sup>, S. Bremer<sup>1</sup>, W. Lu<sup>1</sup>, M. Hughes<sup>1,3</sup>, S. Krawetz<sup>3</sup>, A. Johnson<sup>3</sup>.* 1) CMMG, School of Medicine, Wayne State Univ, Detroit, MI; 2) Eleanor Roosevelt Inst, Dever, CO; 3) Division of Reproductive Genetics, Ob/Gyn, Wayne State Univ, Detroit, MI; 4) SeeDNA Biotech Inc. Windsor, Ont, Canada.

The development of 24-color spectral karyotyping (SKY) has provided a more reliable method to identify marker chromosomes in prenatal diagnosis. However, due to the high cost of performing SKY and the current limited accessibility of facilities, it is not practical to perform SKY on every prenatal diagnostic sample. Therefore a compromised approach is needed to take advantage of the strengths of each method and yet is economically practical in the current clinical setting. We propose the use of routine G-banding for the preliminary examination of patients followed by SKY characterization if any marker chromosomes are detected by G-banding or if the patient is at risk. Verification if desired, would then be done with FISH once the origin of each element of the marker chromosome was determined by SKY. To demonstrate how this algorithm can be practically applied, we have analyzed amniocentesis fluid slides with the combination of G-banding, SKY and FISH tests. 20 cases were examined and the combination of tests was then evaluated for their effectiveness in determining a prenatal diagnosis and the results compared with the current conventional method of using G-banding alone then verifying with FISH. We have further tested new protocols that enable the re-use of conventional FISH or G/C-banded slides for the purpose of administering SKY. Our results show that the selective use of SKY serves as an important adjunct to current prenatal chromosomal analysis.

**Jumping translocation involving 21p in an amniotic fluid sample.** *S.L. Wenger<sup>1</sup>, O.C. Bleigh<sup>1</sup>, S.A. McAdoo<sup>2</sup>, B.K. Boyd<sup>2</sup>.* 1) Dept Pathology, West Virginia Univ, Morgantown, WV; 2) Dept Obstetrics, West Virginia Univ, Morgantown, WV.

Jumping translocations have been reported in individuals with chromosomal abnormalities, involving areas rich in repetitive DNA sequences. Recently, two tissues from spontaneous abortions were reported with jumping translocations (Levy et al., *Cytogenet Cell Genet* 88:25;2000). We report the first case identified in cultured amniocytes.

The patient was at risk for a fetus with Down syndrome due to maternal age (35 years). Amniotic fluid cells collected at 16 weeks gestation were set up and cultured. Only two colonies were identified as growing. Because of the limited number of cells, cultures were not analyzed by the coverslip method, but were trypsinized and harvested by the flask method. While many cells were normal, a few showed unbalanced rearrangements involving material attached to 21p. A total of 60 cells were analyzed; forty-four cells were normal 46,XX, six cells had an i(21)(q10), three cells were monosomy 21, two cells had 21ps-, and five single cells each had different additional chromosomal material on 21p. Both parents had normal karyotypes and a repeat amniocentesis at 19 weeks gestation for repeat karyotype of cultured amniocytes grew poorly. Only six metaphase cells could be analyzed; five normal and one with del(9)(q12), the latter most likely being tissue culture artifact. The last ultrasound at 26 weeks gestation did not identify any fetal abnormalities. The delivery date is early August. At that time, plans are to collect cord blood, umbilical cord for fibroblasts, and placenta. Each tissue will be examined for the jumping translocation, in order to determine if this finding is due to tissue mosaicism for a constitutional chromosome abnormality or pseudomosaicism in the amniocytes.

**Prenatal interphase analysis of translocation carriers using sub telomeric probes.** *M.J. Pettenati<sup>1</sup>, P. Mowrey<sup>2</sup>, S. Schwartz<sup>3</sup>, P.N. Rao<sup>4</sup>, J. Rosnes<sup>5</sup>.* 1) Dept Ped, Wake Forest Univ Sch Medicine; 2) Lab Corp of America; 3) Dept Human Genetics, Case Western Univ; 4) Dept Pathology, UCLA; 5) Dept Obs/Gyn, Wake Forest Univ Sch Medicine.

Reciprocal translocation carriers are fairly common. Most translocations have an intermediate risk (5-10%), some a fairly low risk (~1%), others no risk but a high likelihood of miscarriage, while a few have risks as high as 20% for an abnormal outcome. While reliable, rapid prenatal analysis using FISH for chromosomal aneuploidy is available; it may not be of primary concern to a translocation carrier.

Subtelomere probes now allow for the analysis of terminal chromosome rearrangements. We tested the ability of subtelomeric probes (ToTelVysion-Vysis) to rapidly detect prenatally the carrier status of a fetus when a parent carries a known chromosome translocation. Initially, the probes ability/hybridization efficiency was tested on balanced/unbalanced chromosome translocations on 12 control cases. Prospective prenatal interphase subtelomeric FISH analyses were performed on uncultured amniocytes and CVS (1) from 6 cases (5 reciprocal/1 Robertsonian). Appropriated translocation dependant probe sets were selected. Three of the cases were identified as being abnormal and later verified by cytogenetic analysis. The abnormalities included partial trisomies for 4q (amnio), 15q (amnio/CVS) and complete trisomy 13 (Robertsonian).

These analyses demonstrated the utility of FISH using these probes to rapidly and correctly identify balanced and unbalanced chromosome anomalies prenatally that can result from parental translocations. Caution is recommended with regards to insuring a careful cytogenetic analysis/review of the parental chromosome anomaly prior to selection of the probes. Subtelomeric FISH analysis represents a new rapid prenatal test available for known chromosome translocation carriers whose primary concern is the presence of a chromosomally balanced or unbalanced fetus.

**First trimester combined screening for chromosomal trisomies in Finland.** *M.A. Ryyanen<sup>1</sup>, M. Suonpaa<sup>4</sup>, M. Seppala<sup>4</sup>, M. Niemimaa<sup>1</sup>, A. Perheentupa<sup>1</sup>, P. Laitinen<sup>2</sup>, H.L. Kokkonen<sup>1</sup>, S.T. Heinonen<sup>3</sup>.* 1) Obstetrics & Gynecology, Oulu University Hospital, Oulu, Finland; 2) Clinical Chemistry, Oulu University Hospital, Oulu, Finland; 3) Obstetrics & Gynecology, Oulu University Hospital, Kuopio, Finland; 4) PerkinElmer Wallac, Turku, Finland.

**Background.** With current social trends toward smaller families and delays in childbearing, prenatal diagnosis has an important role in the management of most pregnancies. We wished to study in the first trimester the efficacy of separately and combining maternal serum test and fetal nuchal translucency measurement in screening for trisomies in Finland.

**Methods.** Written informed consent was obtained from all participating women. The screening test, PAPP-A and b-hCG and ultrasound were offered free of charge. Blood samples were analysed in PerkinElmer Wallac and the estimated risk for trisomies was calculated using Wallac 1T program.

**Results.** The participants comprised 4 489 volunteer pregnant women in eastern and northern Finland during the 10th-13th weeks of pregnancy in 1999-2000. Among the screenees there were 12 cases of trisomy 21 and 6 cases of trisomy 18 and 1 case of trisomy 13 and 15 each. Nuchal translucency was measured in 3 052 pregnancies. Eight cases of trisomy 21 and 5 cases of trisomy 18 and no cases of trisomy 13 or 15 were found in that group. 17.5% of the pregnant women were older than 35 years, a figure that conforms exactly to the average Finnish pregnancy statistics. Biochemical and nuchal translucency combined. In the screened population, a total of 238 women (5.3%) constituted the risk group for trisomies at 1:125 cut off level. Eleven out of twelve fetuses affected by Down's syndrome, 92%, and the 3 out of 6 fetuses with trisomy 18 were detected on the basis of the combined screening when algorithm for Down syndrome screening was used. Neither of trisomies 13 or 15 was detected.

**Conclusion.** This prospective study suggests that combined screening promises a better sensitivity than the current testing procedures used in Down's syndrome screening.

**Quantitative analysis of fetal DNA in maternal plasma in physiological pregnancies.** *G. Restagno<sup>1</sup>, L. Sbaiz<sup>1</sup>, F. Lagona<sup>5</sup>, M. Smid<sup>5</sup>, L. Maniscalco<sup>5</sup>, A. Ferrari<sup>5</sup>, G. Calori<sup>6</sup>, E. Viora<sup>2</sup>, M. Campogrande<sup>2</sup>, M. Pagliano<sup>3</sup>, M. Brizzolara<sup>3</sup>, T. Todros<sup>4</sup>, A. Vassallo<sup>7</sup>, M. Ferrari<sup>7</sup>, L. Cremonesi<sup>7</sup>.* 1) Dept Clinical Genetics; 2) Ecography, AO OIRM-S. Anna, Torino; 3) Cattedra A Obs Gynecol; 4) Unit materno-fetale, Univ Torino; 5) Dept Obs Gynecology; 6) Epidemiology; 7) Genetics and Molecular Diagnostics, H S Raffaele, Milano, Italy.

Recent studies demonstrated the presence of fetal DNA in maternal plasma, which represents a source of fetal genetic material obtained noninvasively. Before clinical application of this approach, it is crucial to assess whether fetal DNA can be retrieved from all women at any gestational age. We recruited 417 pregnant women with physiological pregnancy from the 6<sup>th</sup> to the 38<sup>th</sup> week of gestation. Fetal DNA quantification was carried out through real-time PCR on the SRY gene in male-bearing pregnancies. Mean and median fetal DNA concentration were 33.2 and 13.25 genome equivalents/ml of maternal plasma, respectively (range 0-361.2 ge/ml). Fetal DNA concentration increased with advancing gestational age and a statistically significant correlation was found between fetal DNA and gestational week ( $P=0.0001$ ). Fetal DNA analysis from maternal plasma displayed an overall 87% sensitivity, 100% specificity, 100% positive predictive value and 85% negative predictive value in fetal gender determination. We focused on two groups of pregnant women, the first one sampled at gestational ages ranging from the 11<sup>th</sup> to the 13<sup>th</sup>, the second from the 15<sup>th</sup> to the 17<sup>th</sup> week (most of prenatal diagnosis invasive procedures are performed in these periods). In the first group fetal DNA analysis had 60% sensitivity and 73% negative predictive value (mean and median fetal DNA concentration 30.7 ge/ml and 11.9 ge/ml respectively). In the second group, both sensitivity and negative predictive value were 84% (mean and median fetal DNA concentration 22.9 and 9.1). A number of demographic, anamnestic and clinical variables were examined. No statistically significant correlation was found between fetal DNA and maternal age, smoking habit, maternal blood group, Rhesus factor and previous obstetric history (particularly male-bearing pregnancies). Funded by Telethon.

**Enrichment and identification of fetal cells in maternal blood by the ISET technique: a non-invasive approach for prenatal diagnosis.** G. VONA<sup>1</sup>, C. BEROUD<sup>2</sup>, A. BENACHI<sup>3</sup>, JP. BONNEFONT<sup>4</sup>, A. QUENETTE<sup>2</sup>, S. ROMANA<sup>4</sup>, A. MUNNICH<sup>4</sup>, M. VEKEMANS<sup>4</sup>, Y. DUMEZ<sup>3</sup>, B. LACOUR<sup>2</sup>, P. PATERLINI-BRECHOT<sup>1,2</sup>. 1) INSERM Unit U370; 2) Biochemistry Unit; 3) Obstetric Unit; 4) Department of Genetics, Hopital et Faculté Necker, Paris, FRANCE.

Fetal cells circulate in the blood of pregnant women and therefore are of potential interest for early and non-invasive analysis. This approach has yet been hampered by the rarity of these cells (around 1 per ml). This difficulty can be overcome by enriching the blood sample in fetal cells, based on the size of epithelial (trophoblastic) cells.

Fetal cell enrichment was carried out using the ISET (Isolation by Size of Epithelial Tumoral cells) method. 2 ml of blood from 6 mothers carrying a male fetus were analysed at 11-12 weeks gestation. After morphological characterisation, 23 presumably-fetal single cells were microdissected. Their DNA was analysed with Y-specific (23 cells) and STR-specific primers (11 cells). In all mothers, we found a variable number of Y-positive cells (overall 15/23) while STR analysis showed a "biparental" pattern in 6/11 analysed cells. Taking into account the estimated number of fetal cells in the maternal blood (1 per ml, i.e. 1 per  $10^7$  WBC), we have obtained a 6.6- million fold enrichment (1 per 1.5 large isolated cell). Moreover, only one fifth of the single cell DNA amount was used for fetal origin assessment, leaving enough material for further genetic testing.

As a model, cultured tumoral cells (HuH6) were mixed with a blood sampling of a female control, enriched by ISET, microdissected and submitted to DNA analysis. We reproducibly detected a beta-catenin gene mutation by PCR, and we identified Y-positive cells by FISH in single HUH6 microdissected cells.

In conclusion, we have developed a reliable procedure to prove the fetal origin of circulating cells irrespective of the fetus gender, and to target a DNA analysis in these cells. This method seems to be a promising non-invasive approach for prenatal diagnosis of genetic disorders.

**It's Not Always Down's Syndrome - Chromosome Results After Amniocentesis.** *F. Stewart, B. Trainor, G.W. Smith, N.C. Nevin.* Dept Medical Genetics, Level A, Belfast City Hosp, Belfast, Northern Ireland.

The majority of women undergoing amniocentesis are hoping to find out whether or not their baby has Down's syndrome. We have recently audited the karyotypes obtained at amniocentesis in Northern Ireland over the last ten years. In the period 1990-1999 inclusive, 5516 amniocentesis samples were analysed by the prenatal cytogenetic laboratory in Belfast City Hospital. 5091 normal karyotypes were obtained. 87 showed normal variants of no clinical significance. In 62 cases cell culture failed and the amniocentesis was repeated. During this period 140 autosomal trisomies were detected: 89 trisomy 21; 39 trisomy 18 and 12 trisomy 13. A further 136 abnormal karyotypes were detected. A brief summary of these results is given here. 47 pregnancies had a balanced translocation all of which were clinically insignificant. 5 pregnancies had an unbalanced translocation, which would result in fetal abnormality. 7 pregnancies had triploidy. Other structural autosomal abnormalities were found in 41 cases. 36 pregnancies had a sex chromosome abnormality. Of these, 23 were 45, X Turners syndrome. Six had 47, XXX and one 47, XYY. Five had 47, XXY Klinefelters. The majority of cases with a clinically significant autosomal abnormality were tested because of an abnormal scan or an abnormal serum screen result. Our centre is considering the introduction of Fluorescent In Situ Hybridisation (FISH) to look at chromosomes 13, 18, 21, X and Y instead of conventional karyotyping. This would give rapid results on amniocentesis samples. Our findings suggest that the FISH technique would be unlikely to miss many clinically significant abnormalities provided that the ultrasound scan is normal. 32 abnormal results (non-trisomy) were obtained on women attending purely for maternal age. These included balanced rearrangements and sex chromosome abnormalities. Obstetricians need to be aware of the possibility of a non-Downs abnormal result. They need to arrange referral for genetic counselling in these circumstances to help these women make appropriate choices about the further management of their pregnancy.

**Prenatal diagnosis, outcome and imprinting in mosaic trisomy 16 pregnancies.** *P.J. Yong<sup>1</sup>, I. Barrett<sup>2</sup>, D.K. Kalousek<sup>3</sup>, W.P. Robinson<sup>2</sup>.* 1) Medicine; 2) Medical Genetics; 3) Pathology, University of British Columbia, Vancouver, Canada.

Statistical analysis was carried out on data from 174 prenatally diagnosed mosaic trisomy 16 pregnancies. The cases are from an ongoing study of trisomy mosaicism in Vancouver (n=62) and from other published reports (n=112). Additional cases with a paternal origin of trisomy, partial trisomy, or concomitant aneuploidy were excluded. Of the cases with information on pregnancy outcome (n=169), 67.4% resulted in live births, 12.4% in intrauterine deaths, and 20.1% in terminations. Among cases where weight or phenotype was known (n=87, n=134), the average weight at birth, intrauterine death or termination was 2.05 s.d. below the gestational-age corrected mean weight, and 46% had malformations. Since published cases and cases referred to the Vancouver study may be biased towards poorer outcome, these results should be interpreted with caution.

The presence of non-mosaic trisomy on CVS (direct or culture) was associated with lower weight compared a mosaic CVS finding (t=2.70, df=61, p=0.009). Likewise, the presence of trisomy on amniocentesis was associated with lower weight (t=4.15, df=66, p<0.001), and with an increased risk of major malformation (Fisher Exact test, n=103, p=0.010; RR=1.70). Of 66 cases of prenatal, postnatal or autopsy assessment of trisomy in blood, only one case tested positive. Of 40 cases of postnatal or autopsy assessment of trisomy in skin, 27.5% tested positive; however, the presence of trisomy in skin was not associated with any outcome variables. In contrast, among cases with determination of maternal uniparental disomy 16 (upd(16)mat) status (n=87), the presence of upd(16)mat was associated with lower weight (t=2.23, df=49, p=0.030), and with an increased risk of malformation (Fisher Exact test, n=79, p=0.022; RR=1.59). Male fetuses with upd(16)mat had a particularly poor outcome.

These results confirm that CVS and amniocentesis findings can be useful predictors of outcome, and neither cordocentesis or fetal skin biopsy is indicated after prenatal diagnosis of trisomy 16. Moreover, there is preliminary evidence for imprinting on chromosome 16.

**First trimester screening: the genetic implications on nuchal translucency (NT).** *E. Pergament, K. DeMarco, N. Ginsberg, R. Sabbagha.* Northwestern University Medical School, Chicago, IL.

**Purpose:** In conjunction with the NIH-sponsored, multicenter study on the efficacy of first trimester screening for Down syndrome, we undertook an analysis of the genetic implications of increased NT present in fetuses between 11 weeks 3 days and 14 weeks gestation. **Method:** The cytogenetic and/or phenotypic outcomes for patients at Northwestern (Chicago) for whom the NT exceeded 3.5mm were determined. **Results:** A total of 2,330 patients underwent first trimester screening; the NT of 21, or 0.9 percent, measured greater than 3.5mm (range: 3.6-7.5mm; median: 4.3mm). Nine, or 43 percent, were chromosomally abnormal (trisomies 13, 18, 20 and 21); two, or 10 percent, presented at birth with significant developmental disabilities; and, one, or 5 percent, exhibited a severe cardiac complex requiring transplantation. **Conclusions:** Adverse pregnancy outcomes involving chromosome aberrations, cardiac defects and syndromes associated with developmental disabilities occurred in nearly 60 percent of fetuses with a NT greater than 3.5mm. NT measurements applied to all pregnant women in the first trimester has the potential of causing a paradigm shift with regard to the timing, sensitivity and range of genetic and developmental disorders prenatally identified.

**Modification of Individual Risk with Second Trimester Ultrasound after Positive Maternal Serum Screen. D.**

*Siciliano<sup>1</sup>, K. Lim<sup>2</sup>, L. Ainsworth<sup>2</sup>, L. Arbour<sup>1</sup>*. 1) Medical Genetics, UBC, Vancouver, BC, Canada; 2) Division of Maternal Fetal Medicine, UBC, Vancouver, BC, Canada.

Maternal serum screen (MSS) for alpha-fetoprotein, unconjugated estriol and human chorionic gonadotropin between 15 and 20 weeks gestation is often utilized to modify individual risk for Down syndrome (DS). The determination of a positive result varies and is set by individual programs, but generally 5-8% of those taking the test will be offered an amniocentesis. Unnecessary amniocentesis is costly, both from a monetary and fetal loss perspective. To determine if 2nd trimester ultrasound following a positive MSS could more precisely predict which pregnancies were affected, ultrasound findings of those with a true positive MSS were compared with findings of those with a false positive MSS. Methods: A retrospective case-control study was carried out. From the provincial MSS data base, pregnancies with a positive MSS were chosen. Those confirmed with trisomy 21 were the cases whereas the next 4 consecutive positive MSS pregnancies without trisomy 21 were the controls. Only those who had an ultrasound prior to the karyotype results being known were included in the study. Ultrasound findings were compared in cases and controls and considered abnormal if there were structural abnormalities and/or at least one marker of aneuploidy. Results: 34 cases and 143 controls met the inclusion criteria. The sensitivity and specificity of prenatal ultrasound for detection of DS (most done at the BC Womens Health Centre) was 71%, (95% CI 55-86) and 83% (95% CI 77-89). An abnormal ultrasound in an MSS positive pregnancy increased the risk of trisomy 21 by a likelihood ratio (LR) of 4.20 (95% CI 2.8-6.4). A negative ultrasound decreased the risk by a LR of 0.35 (95% CI 0.21-0.60). MSS risk was modified retrospectively based on ultrasound results and although 30% of trisomy affected pregnancies had normal ultrasounds; all affected would have remained eligible for amniocentesis. Conclusion: In British Columbia, a targeted prenatal ultrasound can significantly modify the risk for trisomy 21 in a MSS positive pregnancy without reducing the over-all sensitivity of MSS.

**Biochip based enrichment of fetal cells from maternal blood.** *D.T. Yamanishi, P.J. Hujsak, J. Xu, Z. Yang, X-B. Wang, M. Huang, WP. Yang, L. Wu.* AVIVA Biosciences Corporation, San Diego, CA.

Previous studies have investigated different strategies for the isolation and enrichment of fetal cells from maternal peripheral blood as a method for non-invasive prenatal diagnosis. Our fetal cell enrichment system consists of a set of novel biochips that are capable of producing physical forces on the cells. Fetal cells from maternal blood were enriched on biochips based on physical and immunological characteristics. We have carried out separations on 20-40 mls of maternal blood from women during the first trimester of gestation, and identified variables such as antibodies, magnetic beads, and time of processing, that affected the sensitivity and enrichment for the separation procedure. In the initial studies, fetal cells were enriched using a density gradient followed by CD71 magnetic enrichment and dielectrophoresis separation. The enriched cells were put on a slide, and fetal cells were identified using antibodies to gamma and epsilon hemoglobin and X and Y chromosome interphase FISH. Our recent studies have utilized a physical separation unit as a replacement for the density gradient. Our data demonstrates that biochip based separation is an effective approach for enriching rare fetal cells from maternal blood samples.

**Fetal Hydranencephaly Following Exposure to Mifepristone.** *D.N. Saller Jr<sup>1</sup>, M.S.T. Qureshi<sup>2</sup>, C.J. Peterson<sup>1</sup>, P.C. Eggers<sup>2</sup>, E.A. Schaff<sup>2</sup>, R.K. Miller<sup>2</sup>.* 1) OB/GYN, Div Maternal-Fetal Med, Strong Memorial Hosp, Rochester, NY; 2) OB/GYN, University of Rochester School of Medicine, Rochester, NY.

A 26 year old Gravida 4 Para 1111 female entered a medical termination of pregnancy trial at 5 weeks and 4 days of gestation by last menstrual period confirmed by ultrasound. She took 200 mg of mifepristone (formally known as RU-486) orally. She subsequently experienced heavy bleeding and did not take the misoprostol prescribed to complete the termination. She was then lost to follow-up, under the impression that her termination was completed. She presented one week later with complaints of nausea. A viable pregnancy was confirmed by ultrasound and the patient opted to continue the pregnancy. Transabdominal and transvaginal ultrasound at 11 weeks revealed a simple cystic mass occupying the entire intracranial space. The findings suggested hydranencephaly. The patient proceeded with surgical pregnancy termination, but pathologic evaluation was not performed. Hydranencephaly is the absence of cerebral hemispheres. It is thought to occur through an early insult to the developing brain, usually due to an ischemic insult or overwhelming viral infection. The timing of such an ischemic insult would fit temporally with the exposure to mifepristone. Mifepristone is a progesterone antagonist, which increases myometrial activity and disrupts the corpus luteum. Additionally, it causes decidual necrosis and detachment of trophoblast, and thereby interferes with production of placental chorionic gonadotropin, lactogen and progesterone. As mifepristone is used for pregnancy termination, limited information is available as to its teratogenic effects. We are aware of eight reported cases of ongoing pregnancy following exposure to mifepristone. One previous case of congenital malformations following exposure to mifepristone has been reported to include sirenomelia (caudal regression) associated with facial clefting. These two cases demonstrating an association of congenital malformations with in utero exposure to mifepristone suggest that genetic counseling and prenatal diagnosis should be considered in ongoing pregnancies following exposure to mifepristone.

**Prenatal diagnosis from fetal urine in fetuses with bladder outlet obstruction.** *A.E. Donnenfeld, D. Lockwood, T. Custer, A.N. Lamb.* Genzyme Genetics, Philadelphia, PA, Framingham, MA, Santa Fe, NM.

From 1995-2001 we identified 79 fetal urine samples obtained via percutaneous bladder aspiration submitted for prenatal chromosome analysis. On 4 occasions, chromosome analysis from fetal urine was cancelled prior to laboratory evaluation. 75 fetal urine specimens underwent laboratory examination. Traditional cytogenetic analysis was attempted on all 75 specimens. FISH was attempted on 31 samples. Both cytogenetic and FISH analysis were performed according to standard techniques, utilizing the same protocol as for amniotic fluid samples. Traditional cytogenetic analysis was successful on 71/75 (95%) of samples. The absence of cell growth in culture occurred on 4 occasions. FISH evaluation was successful on 20/31 (65%) of specimens. In one case, traditional cytogenetic analysis was unsuccessful but FISH was informative. Chromosome information was obtained on 72/75 (96%) of fetal urine specimens. Of the 11 unsuccessful FISH studies, all were due to insufficient cells. The mean gestational age was 20.3 weeks (range 15-32) and the mean sample volume was 22.5 mL (range 4.5-50). The mean turn-around-time was 8 days (range 5-14) for cytogenetic analysis and 2 days (range 1-5) for FISH. Chromosome abnormalities were detected in 6/78 (7.7%) pregnancies with bladder outlet obstruction. There were two trisomy 21's, one trisomy 13, one interstitial deletion of chromosome 13, one unbalanced translocation (20p+), and one apparently balanced de novo reciprocal translocation. Conclusion: traditional cytogenetic analysis from fetal urine is readily achievable with a high success rate, in our series, 95%. The addition of FISH resulted in a 96% success rate. FISH was unsuccessful in one third of cases due to insufficient cells. However, the rapid turn-around-time achievable with FISH allows for expedient clinical management of bladder outlet obstruction, including placement of a vesico-amniotic shunt, when applicable, approximately 6 days sooner than would be possible if waiting for traditional cytogenetic results to become available. For this reason, FISH is warranted in the management of fetal bladder outlet obstruction. A 7.7% chromosome abnormality rate was identified.

**A derived benefit of the FASTER Trial: early sonographic detection of fetal anomalies.** *S.M. Carter<sup>1</sup>, S.J. Gross<sup>1</sup>, A. Monteagudo<sup>2</sup>, F. Malone<sup>3</sup>.* 1) Reproductive Genetics, Montefiore Medical Ctr, Bronx, NY; 2) New York University Medical Center, New York, NY; 3) Columbia-Presbyterian Medical Center, New York, NY.

The FASTER trial is a multicenter, US-based study to assess the efficacy of first trimester screening using nuchal translucency measurements and maternal serum analysis of free BHCG and PAPP-A to screen for Down syndrome. To date more than 15000 patients have been screened. Ultrasound (transabdominal or transvaginal) and serum marker analysis are performed from 10 weeks 4 days to 13 weeks days of gestation (CRL 36-79 mm). A suggested benefit of this study is the early detection of pregnancy loss, twins, and fetal anomalies. By protocol, women who are identified with any of these conditions are excluded from the FASTER study and are managed appropriately. The aim of our study was to review the diagnosis and pregnancy outcome of the these excluded cases in the setting of first trimester prenatal sonography. From more than 216 patients deemed ineligible, we have identified 5 cases of cystic hygroma, 2 cases of holoprosencephaly, 1 case of severe multiple congenital anomalies, and 1 set of monozygotic monoamniotic twins with severe cord entanglement. Early identification of these conditions allowed for cytogenetic analysis, further consultation, and termination for lethal disorders. Additionally, early evaluation of the fetus allowed for more accurate assessment of small for gestational age fetuses in the 3rd trimester. We present the cases along with cytogenetic results and/or pregnancy outcomes.

**Nuchal Translucency: a matter of transient jugular lymphatic distension.** *M.C. Haak<sup>1</sup>, M.M. Bartelings<sup>2</sup>, D.G. Jackson<sup>3</sup>, S. Webb<sup>4</sup>, A. Gittenberger de Groot<sup>2</sup>, J.M.G. van Vugt<sup>1</sup>.* 1) Obs/Gyn, VU medical center, Amsterdam, the Netherlands; 2) Anatomy/Embryology, Leiden Medical Center, the Netherlands; 3) Institute of Molecular Medicine, John Radcliff Hospital, Oxford, UK; 4) Anatomy & Developmental Biology, St.George Hospital, London, UK.

**BACKGROUND:** Ultrasonographic measurement of the fetal nuchal translucency (NT) is a widely used screening method for chromosomal abnormalities in pregnancy. This screening method is used in many countries to identify fetuses that are at risk for having Downs syndrome. When the fetal karyotype is proved to be normal the increased NT is still associated with a diversity of other fetal malformations. The mechanism explaining the abnormal fluid accumulation and the transient nature of NT remain unexplained. **METHODS:** The nuchal regions of human fetuses and trisomy 16 mouse embryos were examined for (lympho)vascular abnormalities using immunohistochemical markers against lymphatic (LYVE-1) and smooth muscle (1A4) and endothelial (CD34) cells. Additionally an ultrasonographic study was carried out on 17 fetuses with an increased NT. **RESULTS:** In both human and mouse specimens we found a mesenchyme lined cavity within the posterior nuchal region as well as bilaterally enlarged jugular LYVE-1 positive lymphatic sacs. The persistence of jugular lymphatic sacs was also confirmed by ultrasound in 14 human fetuses with increased NT. **CONCLUSION:** Our findings indentify the cause of increased NT as mesenchymal oedema in the presence of distended jugular lymphatic sacs, detected by the hyaluronan receptor LYVE-1. The delayed organisation and connection of these lymphatic sacs to the venous circulation might explain the transient nature of NT. Once lymphatic organisation has been established the excess of nuchal fluid can drain away leading to a disappearance of the enlarged nuchal translucency.

**Post-zygotic origin of complete maternal chromosome 7 isodysomy and consequent loss of placental PEG1/MEST expression.** *M. Miozzo<sup>1</sup>, F.R. Grati<sup>1</sup>, G. Bulfamante<sup>3</sup>, F. Rossella<sup>1</sup>, M. Cribiù<sup>3</sup>, T. Radaelli<sup>2</sup>, B. Cassani<sup>3</sup>, T. Persico<sup>4</sup>, E. Ferrazzi<sup>4</sup>, I. Cetin<sup>2</sup>, G. Pardi<sup>2</sup>, G. Simoni<sup>1</sup>.* 1) Medical Genetics, Dept. of Medicine, Surgery & Dentistry, University of Milan, S.Paolo School of Medicine, Milan, Italy; 2) Obstetrics and Gynecology, Dept. of Medicine, Surgery & Dentistry, University of Milan, S.Paolo School of Medicine, Milan, Italy; 3) Pathology, Dept. of Medicine, Surgery & Dentistry, University of Milan, S.Paolo, Milan, Milan, Italy; 4) Obstetrics and Gynecology, Biomedical Science Institute L.Sacco, University of Milan, Milan, Italy.

Maternal UPD of chromosome 7 is associated with pre- and post-natal growth retardation (IUGR, PNGR) and Silver-Russell syndrome (SRS [ MIM 180860]). We report a case of IUGR in a new-born with SRS stigmata. Using combined haplotyping and cytogenetic-FISH studies we characterised the lymphocytes, umbilical cord and four placental cotyledons. The results are consistent with complete maternal isodisomy 7 and trisomy 7 mosaicism of post-zygotic origin. The trisomic cell line was prevalent in trophoblast cells from two placental cotyledons. Trisomy 7 of post-zygotic origin is a frequent finding, but maternal isodisomy 7, due to trisomic rescue has never been reported. PEG1/MEST expression was evaluated on placenta cDNA and a specific transcript was revealed only in the cotyledons with a high percentage of trisomic cells and the presence of the paternal chromosome 7 contribution, but not in the placental biopsies with maternal isodisomy 7. The histological features of the four placental fragments revealed that isodisomy 7 correlates with a pattern of cotyledonary hyper-ramification due to an increase of the branching angiogenesis, which could be the result of a defect of angiogenesis caused by the absence of PEG1 product. The severe hypo-ramification of the two cotyledons, showing trisomy 7 mosaicism, may be due to the triplicate dosage of genes on chromosome 7. The delayed fetal growth could be the phenotypic effect of the imbalance between imprinted and non-imprinted genes on chromosome 7 in the fetus or the result of abnormal placental function during pregnancy.

**Identification of a second mechanism of X-linked recurrent spontaneous abortion (RSA): Tissue-selective cell disadvantage.** *C.A.G. Scacheri<sup>1,2</sup>, M.C. Lanasa<sup>3</sup>, J.M. Giron<sup>1</sup>, M.M. Thouin<sup>1</sup>, C. Romig<sup>2</sup>, W.A. Hogge<sup>3</sup>, E.P. Hoffman<sup>1,2</sup>.* 1) Children's National Medical Center, Washington, DC; 2) The George Washington Univ, Washington, D.C; 3) Magee-Womens Hospital, Pittsburgh, PA.

Approximately 2% of women have highly skewed X-chromosome inactivation (XCI), with preferential use of one X chromosome in >90% of cells studied. We previously showed that skewed XCI patterns are heritable (Pegoraro et al (1997)), and found concordance in skewing patterns between the primary blood and oral mucosal cells in individuals tested. In a recent case-control study, we showed that a higher proportion of women experiencing first trimester RSA displayed highly skewed X inactivation (14%) (Lanasa et al, 2001). Here, we report two newly ascertained families with apparent X-linked recurrent spontaneous abortion (RSA), where the RSA trait co-segregates with extremely skewed X inactivation in blood nucleated cells, and with random X inactivation patterns in oral mucosal cells. Also, losses in these families occurred in the second trimester of pregnancy, and all sexed cases were male. In one family, polyhydramnios was noted in several pregnancies, and one male fetal demise had mild ventriculomegaly. The other family shows no apparent phenotypic findings. There was no history of immune deficiency or other symptoms suggesting XSCID or other hematologic disorder. In both families, the maternally inherited X-chromosome is preferentially inactivated in peripheral blood, which is consistent with an X-linked lethal gene that shows growth disadvantage in a subset of cells in female carriers. In conclusion, we have now identified two different types of X-linked lethal traits: (1) those showing complete skewing of X-inactivation in all tissues in female carriers, with first trimester loss of males inheriting the trait; and (2) those showing complete skewing in blood, but not oral mucosal cells in female carriers, with second trimester loss of males inheriting the trait. Female carriers are asymptomatic in both types of X-linked recessive RSA. These findings further encourage molecular testing of recurrent aborters for X inactivation abnormalities (see <http://www.cnmcxcis.org>).

**Aminoglycoside antibiotics ameliorate exon skipping associated with a nonsense mutation.** S. Tsujino, T. Miyamoto, N. Kanazawa. Inherited Metabolic Diseases, National Inst Neuroscience, Tokyo, Japan.

Exon skipping is occasionally associated with premature nonsense codons amid exonic sequences. The mechanism is, however, as of yet unclear. On the other hand, it is known that aminoglycoside antibiotics allow the reading of full coding sequences through premature termination codons, and this phenomenon may be applied for therapy of human genetic diseases with premature terminal codons. We previously reported an exonic nucleotide change C-to-T, resulting in a nonsense mutation R179X, in the mitochondrial ornithine transporter gene, *ORNT1*, of a patient with hyperornithinemia, hyperammonemia and homocitrullinuria (HHH) syndrome (MIM 238970). This mutation leads to skipping of exon 4, which contains the nucleotide change. In this report, we observed by RT-PCR that G418 ameliorate the exon skipping due to R179X in cultured skin fibroblasts from the patient. Furthermore, G418 partially restored the function of ornithine transporter in the cells, estimated by a <sup>14</sup>C-ornithine incorporation assay, indicating not only amelioration of the exon skipping but also read-through of the premature termination codon, because only the return of exon 4 resuscitates the nonsense codon and a truncated *ORNT1* product should not function more than that from the exon skipping mRNA. Although aminoglycosides are known to inhibit self-splicing of prokaryotic group I introns, our results are the first to show that aminoglycosides have an effect on RNA splicing in human cells.

**Preclinical Treatment Approaches in Succinic Semialdehyde Dehydrogenase (SSADH) Deficiency.** *M. Gupta<sup>1</sup>, H. Bartels<sup>1</sup>, R. Greven<sup>1</sup>, H. Senephansiri<sup>1</sup>, B. Hogema<sup>1,2,3</sup>, C. Jakobs<sup>3</sup>, W. Froestl<sup>4</sup>, T. Bottiglieri<sup>5</sup>, O.C. Snead<sup>6</sup>, M. Grompe<sup>1</sup>, K.M. Gibson<sup>1</sup>.* 1) Molecular and Medical Genetics, Oregon Health Sciences Univ, Portland, OR; 2) Erasmus Univ, Rotterdam, The Netherlands; 3) Clin Chem, Free Univ, Amsterdam, The Netherlands; 4) Novartis Pharma, Basle, Switzerland; 5) Inst of Metab Dis, Baylor Univ Med Center, Dallas, TX; 6) Dept Neurol, Hosp for Sick Children, Toronto, Ontario, Canada.

Gamma-hydroxybutyrate (GHB), increasingly consumed as an illicit euphoric agent with potentially serious side effects, is the biochemical hallmark of human SSADH deficiency. To explore preclinical treatment approaches, our laboratory developed SSADH-deficient mice. These mice have up to 100-fold increase in tissue GHB levels, are developmentally delayed and atactic, suffer from seizures and die 3 weeks postnatally. We attempted pharmacologic rescue with vigabatrin (50-800 mg/kg), CGP-35348 (a GABAB receptor antagonist; 100-2000 mg/kg) and taurine (2000-5000 mg/kg). Taurine was selected based upon correlation of death with the weaning period. All interventions led to significant survival (22-33%;  $p < 0.05$ ). Simultaneously, we assessed locomotor and behavioral activity to monitor clinical efficacy. Analysis of seven independent locomotion variables and fifteen behavioral paradigms based upon the Irwin test battery indicated that vigabatrin > taurine > CGP 35348 in relation to clinical efficacy. CGP 35348 appeared to exacerbate hyperactivity and agitation associated with stress inducing situations in SSADH-deficient mice. Whereas vigabatrin has been linked to visual field defects, taurine is readily available, well tolerated, and possesses numerous neuroprotective features and receptor interactions. Taurine may have therapeutic relevance for SSADH deficiency and illicit GHB consumption (supported by: NS 40270 and March of Dimes #1-FY00-352).

**Huntingtin inhibits acetyltransferases and histone deacetylase inhibitors suppress *in vivo* pathogenesis.** J.S.

Steffan<sup>1</sup>, L. Bodai<sup>2</sup>, J. Pallos<sup>2</sup>, M. Poelman<sup>1</sup>, B.L. Apostol<sup>1</sup>, A. Kazantsev<sup>3</sup>, E. Schmidt<sup>1</sup>, Y. Zhu<sup>1</sup>, M. Greenwald<sup>1</sup>, R. Kurokawa<sup>4</sup>, D.E. Housman<sup>3</sup>, G. Jackson<sup>5</sup>, J.L. Marsh<sup>2</sup>, L.M. Thompson<sup>1</sup>. 1) Dept Psychiatry and Human Behavior, University of CA, Irvine, Irvine, CA; 2) Dept Developmental and Cell Biology, University of CA, Irvine, Irvine, CA; 3) Dept Biology, Massachusetts Institute of Technology, Cambridge, MA; 4) Dept Cellular and Molecular Medicine, University of CA, San Diego, La Jolla, CA; 5) Dept Neurology, University of CA, Los Angeles, Los Angeles, CA.

Transcriptional dysregulation and loss of function of the transcriptional co-activator CREB-binding protein (CBP) have been implicated in the pathogenesis of Huntington's Disease (HD) and other neurodegenerative diseases caused by proteins with expanded polyglutamine repeats. We find that the polyglutamine-containing domain of Huntingtin, Httex1p, directly interacts with the acetyltransferase domains of CBP and p300/CBP Associated Factor (P/CAF), and inhibits acetyltransferase activity *in vitro*. Expression of Httex1p in cultured cells reduces the level of acetylated histones H3 and H4, and this reduction can be reversed by administration of histone deacetylase (HDAC) inhibitors. *In vivo*, HDAC inhibitors arrest progressive polyglutamine-induced neuronal degeneration and reduce lethality in a *Drosophila* model of polyglutamine diseases. These findings raise the possibility that HDAC inhibitor therapy may prove efficacious in slowing or preventing the progressive neurodegeneration seen in HD and other polyglutamine repeat diseases, even after onset of disease symptoms.

**Transplantation of precursor cells for hepatobiliary cells from the salivary gland as treatment of Wilson disease in LEC (Long-Evans cinnamon) rats, rat model of Wilson disease.** *K. Okumura<sup>1</sup>, K. Nakamura<sup>1</sup>, Y. Kimoto<sup>1</sup>, K. Matsumoto<sup>2</sup>, K. Terada<sup>3</sup>, T. Sugiyama<sup>3</sup>, F. Endo<sup>1</sup>.* 1) Department of Pediatrics, Kumamoto University School of Medicine; 2) Institute for Animal Experimentation, Tokushima University School of Medicine, Tokushima, Japan; 3) First Department of Biochemistry, Akita University School of Medicine, Akita, Japan.

Cell transplantation is an effective therapy of inherited diseases, and the liver is one target for stem cell therapy. Hepatic oval cells induced by chemical carcinogens are candidates of adult liver stem cells. However, identification of stem cells in the adult liver remained to be attained. Recent studies indicated that there are stem cells for hepatocytes in a fraction of hematopoietic stem cells. We attempted to identify precursors of hepatobiliary cells in the salivary gland, and cell transplantation was done in LEC rats, a model for Wilson disease. Male SD rats or LEA (Long-Evans agouti) rats were used as donors. Salivary glands were treated by collagenase / hyaluronidase digestion, and prepared into single cell suspensions. Recipient female rats were administrated 2AAF (2-acetylaminofluorene), according to the 2AAF/PH (partial hepatectomy) protocol. The salivary gland cells were transplanted immediately after 2/3 partial hepatectomy. We detected donor cell derived oval cells at 1-2 weeks after transplantation as determined. In the recipient liver, donor-derived hepatocytes and bile duct epithelial cells were visible from 2 weeks after the transplantation, as determined by in situ hybridization of the Y-chromosome sry gene. Alternatively, we isolated and cultured epithelial cells from the salivary gland of male LEA rats, and the cultured cells were transplanted into hepatectomized female LEC rats. Thus, the cultured cells transdifferentiated into hepatocyte and bile duct epithelia. Stem cell-like cells for the liver apparently present in the salivary gland.

**Bone marrow transplantation to treat liver damage in LEC rats, a model of Wilson disease.** *Y. Kimoto<sup>1</sup>, K. Nakamura<sup>1</sup>, K. Okumura<sup>1</sup>, K. Matsumoto<sup>2</sup>, T. Yamamoto<sup>3</sup>, F. Endo<sup>1</sup>.* 1) Department of Pediatrics, Kumamoto University School of Medicine, Kumamoto, Japan; 2) Institution for Animal Experimentation, Tokushima University School of Medicine, Tokushima, Japan; 3) Division of Molecular Pathology, Graduate School of Medical Science, Kumamoto University School of Medicine, Kumamoto, Japan.

Bone marrow cells can transdifferentiate into different cell types. Recent studies demonstrated that bone marrow derived cells can transdifferentiate into hepatocytes in rodents and in humans. We used the LEC (Long-Evans Cinnamon) rat as a model of Wilson disease. LEC rat carries a mutation on *Atp7b*, a homologue of human *ATP7B* and the clinical and biological features of LEC rats resemble findings in patients with this disease, including such ceruloplasmin deficiency and hepatitis. We attempted to determine if bone marrow derived cells would overcome the clinical and biochemical abnormalities seen in LEC rats. We used male LEA (Long-Evans agouti) rats as an immunocompatible donor for the cell transplantation. After the bone marrow transplantation, recipient female LEC rats were killed. Genomic DNA from donor cells was PCR detected in bone marrow and liver. In situ hybridization revealed that cells derived from donor rats were expanded in the liver. Hence, bone marrow transplantation for treatment of Wilson disease warrants further attention.

**Enzyme replacement therapy with recombinant alpha-galactosidase A in Fabry disease : Preliminary experience in patients with end-stage renal disease or post transplant.** *D.P. Germain, P. Bonfils, P. Boutouyrie, N. Brion, M. Froissart, C. Jacquot, X. Jeunemaitre, C. Orssaud, P.F. Plouin, B. Richalet, J.F. Toussaint, J.N. Fiessinger.* Dept Genetics, European Hospital Georges Pompidou, Paris, France.

**Background:** Fabry disease, lysosomal alpha-galactosidase A (a-Gal A) deficiency, results from the progressive accumulation of globotriaosylceramide (GL3) and related glycosphingolipids. Involvement of the vascular endothelium leads to early demise of classically affected patients from microvascular disease of the kidney, heart, and brain. A Phase 3 multi-center, randomized, double-blind, placebo-controlled study, recently showed that recombinant human a-Gal A (r-haGalA) replacement completely cleared accumulated GL3 from the vasculature of the kidney, skin and heart in 98%, 95% and 75% respectively, of the patients evaluated (Eng et al., N Engl J Med 2001). Patients with serum creatinine > 2.2 mg/dL, on dialysis, or transplanted were excluded from the Phase 3 trial, and have not previously been evaluated following enzyme replacement therapy. **Patients and Methods:** R-haGal A safety and efficacy were evaluated in an open-label study of 8 Fabry patients who received 0.8-1.2 mg/kg of r-haGal A (Fabrazyme, agalsidase beta) intravenously at 0.25 mg/min biweekly for 16 weeks (8 infusions). Six patients had advanced disease including 4 patients post renal transplant, one patient on peritoneal dialysis, and one patient on hemodialysis. Baseline assessments included medical history, physical examination, routine chemistries, plasma and urinary GL3, EKG, echocardiogram, and glomerular filtration rate. In addition, the following parameters which were not evaluated during the phase 3 trial were assessed: cardiac MRI, cerebral MRI, cochleovestibular involvement, and radial artery intima-media thickness. **Results:** No adverse events or infusion reactions were observed during the first 4 months of treatment. Immunologic evaluation including IgG seroconversion is ongoing. **Conclusion:** R-haGal A replacement appears safe in Fabry patients, including those on dialysis or post transplant. Efficacy will be evaluated at 6 months and one year.

**Analysis and Treatment of Pulmonary Pathology in the Acid Sphingomyelinase Deficient Mouse Model Of Niemann-Pick Disease.** *R.K. Dhami<sup>1</sup>, R. Gordon<sup>2</sup>, E.H. Schuchman<sup>1</sup>*. 1) Human Genetics, Mount Sinai School of Medicine, New York, NY; 2) Pathology, Mount Sinai School of Medicine, New York, NY.

Types A and B Niemann-Pick disease (NPD) are lipid storage disorders caused by the deficient activity of acid sphingomyelinase (ASM). Type B NPD is associated with pulmonary function decline and frequent respiratory infections. There is currently no treatment for either form of this disease. The ASM knockout (ASMKO) mouse is a model for NPD, but the lung pathology has not been adequately characterized. The overall goal of this study was to investigate pulmonary disease in the ASMKO mouse model and to compare the therapeutic effects of systemic (intravenous) delivery of recombinant ASM versus direct lung delivery (intratracheal). Using bronchoalveolar lavage, we found dramatically elevated levels of sphingomyelin (SPM) and inflammatory cells (mostly alveolar macrophages [Mf]) in the airspaces of the ASMKO mice. Furthermore, the ASMKO Mf were shown to have a reduced ability to produce superoxide, which could be corrected with ASM, and an increased propensity for cytokine secretion. Interestingly, we found no evidence of fibrosis in the ASMKO mice despite the presence of large numbers of inflammatory cells in the airways. In vitro studies demonstrated that the uptake of ASM by ASMKO alveolar Mf was reduced compared to alveolar Mf from normal mice, and also was reduced compared to ASMKO peritoneal Mf. This discrepancy in enzyme uptake may be a function of an alteration in mannose and mannose-6-phosphate receptors on the surface of SPM-loaded alveolar Mf from ASMKO mice as determined by competitive inhibition studies. In a direct comparison of lung-directed versus intravenous enzyme replacement in the ASMKO mice, we found that intravenous delivery was more effective in distributing enzyme to the lung tissue and reducing the numbers of alveolar Mf. We conclude that direct delivery of ASM to the lungs may not be a feasible strategy for the treatment of pulmonary pathology in Type B NPD due to cell surface alterations of lung Mf, but that intravenous delivery could be efficacious.

**Enzyme replacement therapy in Fabry disease: pathologic, biochemical, and immunologic results at 6 and 12 months of the Phase 3 extension study.** *R.J. Desnick*<sup>1,2</sup>. 1) Dept Human Genetics, Mount Sinai Sch Medicine, New York, NY; 2) The International Fabry Disease Study Group.

Fabry disease results from the deficient activity of  $\alpha$ -galactosidase A ( $\alpha$ -Gal A) and subsequent pathologic accumulation of globotriaosylceramide (GL-3). Based on the results of a Phase 1/2 clinical trial (Eng et al. *Am. J. Hum. Genet.*, 68:711, 2001), a Phase 3 multicenter, multinational, randomized, double-blind, placebo-controlled trial was conducted with 58 classically affected patients receiving approximately 1 mg/kg of recombinant human  $\alpha$ -Gal A (r-haGal; produced by CHO cells by Genzyme Corporation) every two weeks for 20 weeks. The primary endpoint, the proportion of patients with clearance of accumulated GL-3 from renal interstitial capillary endothelial cells, was achieved ( $p < 0.001$ ) as were secondary endpoints for mean GL-3 clearance in the microvasculature of the skin ( $p < 0.001$ ) and heart ( $p < 0.001$ ). All 58 patients were treated with  $\alpha$ -Gal A in an ongoing open-label extension study. Infusion times have been reduced to approximately 3 hr. After 6 months, the placebo-crossover patients showed complete GL-3 clearance from their microvasculature (Eng et al., *N. Eng. J. Med.*, in press). Additional blinded pathologic assessments showed markedly reduced GL-3 levels from other renal cell-types (mesangial cells, glomerular capillary endothelium, non-capillary endothelium, and interstitial cells), as well as demonstrated reduction from the vascular smooth muscle cells, tubular epithelium, and podocytes, albeit at a slower rate. In addition, GL-3 reductions were observed in the endothelial cells of deep vessels of the skin, and from the cells of the perineurium. Plasma GL-3 levels were also measured. Importantly, the accumulated plasma GL-3 was cleared to below detectable limits in most patients at 6 and 12 months of the extension study. After 12 months of the extension study, 7/58 were seronegative, 8/58 patients who seroconverted were low-responders, and 67% of the remaining 43 patients reduced IgG titers at least two-fold, suggesting that patients may tolerize over time. These studies further demonstrate the safety and efficacy of  $\alpha$ -Gal A therapy for Fabry disease.

**A Phase I/II Randomized, Double Blind, Two Dose Group Study of Recombinant Human N-Acetylgalactosamine-4-Sulfatase (rhASB) Enzyme Replacement Therapy in Patients with Mucopolysaccharidosis (MPS) VI (Maroteaux-Lamy Syndrome).** *P. Harmatz<sup>1</sup>, C.B. Whitley<sup>2</sup>, K. Belani<sup>2</sup>, L. Waber<sup>3</sup>, R. Pais<sup>4</sup>, R. Steiner<sup>5</sup>, B. Plecko<sup>6</sup>, J. Simon<sup>1</sup>, J. Thompson<sup>7</sup>, J. Waterson<sup>1</sup>, E. Lammer<sup>1</sup>, R. Rowe<sup>1</sup>, S. Koseoglu<sup>1</sup>, R. Cohen<sup>1</sup>, H. Rosenfeld<sup>1</sup>, H. Gutierrez<sup>1</sup>, J. Hopwood<sup>8</sup>.* 1) Children's Hosp Oakland, CA; 2) U of Minnesota Medical School, Minneapolis; 3) U of Texas SW Med Center, Dallas, TX; 4) East Tennessee Children's Hosp, Knoxville; 5) Oregon Health Sciences U, Portland; 6) U Kidnerlinik Graz, Austria; 7) U of Alabama, Birmingham; 8) Women's and Children's Hosp Adelaide, Australia.

MPS VI is a lysosomal storage disease in which the affected patient lacks the enzyme N-acetylgalactosamine-4-sulfatase (ASB), leading to substrate accumulation in a wide range of tissues. This accumulation causes enlargement of liver and spleen, skeletal deformities, coarse facial features, upper airway obstruction, joint deformities, poor growth, progressive clouding of the cornea, communicating hydrocephalus, and heart disease. Death may occur in the second decade of life in more severely affected individuals. Currently there is no treatment for this disorder, other than symptomatic care and bone marrow transplant. Enzyme replacement therapy (ERT) with human recombinant ASB (rhASB) has been found to be effective in a feline model of MPS VI with few side effects. To assess the safety and efficacy in humans, a randomized, two-dose, blinded study of weekly treatment with rhASB is currently underway. Following a 2-week baseline evaluation period, subjects were randomized to high (1.0 mg/kg) or low (0.2 mg/kg) dose ERT which is administered intravenously once per week. Safety and efficacy assessments include cardiac evaluation, pulmonary function tests, overnight sleep study, joint range of motion, abdominal CT scan for liver volume and bone density, visual exam, exercise tolerance, routine laboratory analysis, and urinary glycosaminoglycans. Six subjects (3M, 3F; age range 7-16 years) have completed at least 12 weeks of therapy with no allergic or other serious adverse reactions noted. An analysis of the data of all subjects will be reported. (Sponsored by BioMarin Pharmaceutical).

**Growth improvement in response to enzyme replacement therapy (ERT) among children with Gaucher disease: The Gaucher Registry.** *P. Kaplan, H.C. Andersson, J. Charrow, E.H. Kolodny, P. Mistry, G.M. Pastores, B.E. Rosenbloom, C.R. Scott, R.S. Wappner, N.J. Weinreb.* International Collaborative Gaucher Group.

The Gaucher Registry is the largest database of patients (pts) with Gaucher disease (GD). This report describes the improvement in Z-scores (SD) and Annual Growth Rate (AGR) in response to ERT with alglucerase and imiglucerase among children with Type 1 GD.

Z-scores adjusted for age and gender were calculated using December 2000 Centers for Disease Control US Growth Charts. Two cohorts were analyzed:[1]193 prepubertal children (102 males up to age 9 yrs and 91 females up to 8 yrs),to minimize the bias of puberty.[2]AGR was assessed for 196 children (112 males and 84 females) by differences between heights measured at the beginning and the end of each 1-year period (increment in cm/12 mos). Velocity Z-scores adjusted for age and gender were calculated with reference to standardized distributions. Pts < 2.5 yrs were not included because of age limits in the velocity reference data.

Immediately prior to ERT, pts were almost two standard deviations below the expected height for an age-adjusted normal population (Z-score=-1.71). At 6 mos of ERT, improvements in growth were seen (Z-score=-1.41). At 30 mos through 48 mos, pts were <1 SD below the expected height for an age-adjusted normal population. The mean (SD) AGR after 12 mos of ERT was 8.0 cm (4.2). At the end of 24, 36, and 48 mos, the mean (SD) AGRs were 6.6cm (2.0), 7.0cm (1.8), and 6.3cm (1.9), respectively. The velocity Z-score after 12 mos of ERT was 1.02, approximately 1SD above the expected velocity for an age-adjusted normal population, confirming the catch-up growth reported by many physicians. After 48 mos,pts were <1SD above the expected velocity for an age-adjusted normal population. Expanding on previous studies in smaller cohorts of children, these data indicate that Z-scores and AGR for children with Type 1 GD, who are treated with ERT, approached the expected age-adjusted height for normal children. Furthermore, velocity Z-scores confirm that growth rates of Type 1 children treated with ERT often catch-up to the age-adjusted normal population.

**Alendronate disodium improves bone mineral density in adults receiving enzyme replacement therapy (ERT) for Gaucher disease.** *R.J. Wenstrup<sup>1</sup>, L. Bailey<sup>1</sup>, G.A. Grabowski<sup>1</sup>, S. Guo<sup>2</sup>*. 1) Human Genetics, Children's Hosp Research Fndn, Cincinnati, OH; 2) Wright State University, Dayton, OH.

Patients with Gaucher disease [glucocerebrosidase (GCase) deficiency] who have significant clinical manifestations are treated with injectable forms of the human enzyme. ERT results in remarkable decreases in lipid storage in liver, spleen, and bone marrow, but the severe generalized osteopenia present in many adult patients is often refractory to ERT. To determine whether the osteopenia present in most adults with Gaucher disease can be corrected by the bisphosphonate alendronate disodium (Fosamax<sup>TM</sup>) we performed a double blind, two-arm placebo controlled trial of alendronate (40 mg/day) on adults with Gaucher disease who had been treated at least 24 months with ERT. Thirty-six subjects (18-50 yrs.) receiving enzyme therapy (15-60 U/kg/q 2 weeks) were randomized to alendronate or placebo arms for up to 24 months; subjects in both trial arms received supplemental doses of calcium and vitamin D. Alendronate was well tolerated; there were seven dropouts [2 pregnant, 4 refused travel, 1 with GI symptoms (placebo)]. Both alendronate and placebo groups were 29% male. The mean age was 39.5 7.4 years in the alendronate group and 33.0 9.9 years in the placebo group. The mean baseline lumbar bone mineral density (BMD) was identical for both groups. For the primary study endpoint (lumbar BMD by dual energy X-ray absorptiometry), there were significant group differences. At six months DBMD at the lumbar spine was +0.035 0.023 grams/cm<sup>2</sup> for the alendronate group and +0.005 0.021 for the placebo group (p= 0.001). At 12 months, DBMD was +0.059 0.043 grams/cm<sup>2</sup> for the alendronate group and +0.009 0.037 for the placebo group (p= 0.006). Analysis of available BMD data from a more limited cohort who were followed for up to 24 months indicate that the group differences in lumbar BMD continue to increase. These data indicate that anti-resorptive therapy with bisphosphonates is a useful adjunctive therapy in combination with ERT for the treatment of Gaucher related osteopenia in adults.

**Preliminary findings in patients with juvenile Pompe's disease treated with recombinant human alpha-glucosidase from rabbit milk.** *L.P.F. Winkel<sup>1</sup>, H.J.M.P. van den Hout<sup>1</sup>, J.H.J. Kamphoven<sup>2</sup>, A.J.J. Reuser<sup>2</sup>, O.P. van Diggelen<sup>2</sup>, W.F.M. Arts<sup>1</sup>, P.A. van Doorn<sup>1</sup>, A.G. Vulto<sup>1</sup>, G. de Jong<sup>1</sup>, A.T. van der Ploeg<sup>1</sup>.* 1) Depts. of Pediatrics, Neurology, Hospital Pharmacy and Internal Medicine, University Hospital, Rotterdam, The Netherlands; 2) Dept. of Clinical Genetics, Erasmus University Rotterdam, The Netherlands.

Pompe's disease or Glycogen storage disease type II (GSDII) is an inherited myopathy. The characteristic lysosomal glycogen accumulation is caused by alpha-glucosidase deficiency. Childhood and juvenile forms of Pompe's disease present as a progressive muscle weakness with involvement of respiratory muscles. There was no treatment until now. Our research has focussed on the development of enzyme replacement therapy for Pompe's disease and has led to large-scale production of human recombinant alpha-glucosidase in milk of transgenic rabbits. In a phase II study this therapy was given to four patients with the most severe infantile form of Pompe's disease. Treatment appeared safe and effective (The Lancet 2000; 356: 397-8 and presented at the ASHG annual meeting in 2000). The alpha-glucosidase activity in muscle normalized, tissue morphology improved, cardiomyopathy resolved significantly and all 4 patients are still alive at age 2,5-3 years. In parallel, three patients with juvenile Pompe's disease received treatment. They were 12, 16 and 32 years old at start. Their clinical symptoms varied. They were all wheelchair bound. The two older patients were ventilator dependent and showed a significant deterioration of pulmonary function before start of treatment. After 1.5-2 years of treatment their pulmonary function has stabilized or improved. The alpha-glucosidase activity in muscle increased. The best improvement of muscle strength and function was obtained in the youngest and least affected patient. This patient started to walk after 4 years of wheelchair dependency. All patients report less fatigue and more energy. In conclusion, recombinant human alpha-glucosidase from rabbit milk has a positive effect in late onset Pompe's disease. There is all reason to continue the development of enzyme replacement therapy.

**A new approach to generate mice tolerant to recombinant human proteins.** *N. Raben<sup>1</sup>, A. Lee<sup>1</sup>, N. Lu<sup>1</sup>, K. Nagaraju<sup>1</sup>, Y. Rivera<sup>1</sup>, B. Yan<sup>1</sup>, A.A. McKinney<sup>2</sup>, E. Ponce<sup>2</sup>, W.M. Canfield<sup>2</sup>, P.H. Plotz<sup>1</sup>.* 1) ARB, NIAMS, NIH, Bethesda, MD 20892; 2) Novazyme Pharmaceuticals, Inc., Oklahoma City, OK 73104.

When knockout (ko) mice are used to test the efficacy and toxicity of recombinant human proteins, the animals develop antibodies to the human enzyme, precluding long-term pre-clinical studies. This has been a problem with a number of ko models, for example, the evaluation of gene or enzyme replacement (recombinant human acid alpha-glucosidase: rhGAA) therapies in a ko (GAA<sup>-/-</sup>) model of Pompe disease. In this disease, the lack of enzyme results in lysosomal glycogen storage, particularly in skeletal and cardiac muscle. In trying to rescue the phenotype of GAA<sup>-/-</sup> mice, we have expressed hGAA cDNA in the liver or skeletal muscle of these mice using a tetracycline-controllable system. Whereas high production of hGAA from the transgene in the liver in two lines led to secretion and metabolic cross-correction in muscle and heart, in one line with low GAA activity in the liver, (1-3% compared to wt), glycogen was cleared only in the liver but not in any other organ. Glycogen accumulation in the heart and skeletal muscle was similar to that in GAA<sup>-/-</sup> mice. Thus, this transgenic line retains the biochemical and morphological characteristics of the original ko mice, except for glycogen clearance in liver.

When HP-rhGAA (highly phosphorylated rhGAA, 1mg/kg) was injected i.v. weekly into GAA<sup>-/-</sup> mice or into animals in which the transgene expression was suppressed, high levels of antibodies were detected after 4 injections. In contrast, the low liver expresser mice did not develop antibodies or any adverse effects after 8 injections. This tolerant ko mouse model should be useful for evaluating the rhGAA in pre-clinical studies. Furthermore, mice in which the transgene expression was restricted to skeletal muscle were tolerant to the HP-rhGAA, too. The findings suggest that confining the expression of a transgene to a particular tissue or keeping its expression at non-therapeutic levels may prove a generally useful way for generating tolerant mouse models for other diseases or for other immunological studies.

**Gene therapy for lysosomal acid lipase deficiency in the mouse model.** *H. Du<sup>1</sup>, M. Heur<sup>1</sup>, J. Mishra<sup>1</sup>, J. Brannock<sup>1</sup>, D. Witte<sup>1</sup>, J. Rethmeier<sup>2</sup>, D. Ameis<sup>2</sup>, G. Grabowski<sup>1</sup>.* 1) Division of Human Genetics, Division of Pathology, Children's Hosp Medical Ctr, Cincinnati, OH; 2) Dept Medicine, Univ. Hospital Eppendorf, Hamburg, F.R.G.

Lysosomal acid lipase (LAL) is an essential enzyme for the hydrolysis of triglycerides (TG) and cholesteryl esters (CE) in lysosomes. Its deficiency produces human two phenotypes: Wolman disease (WD) and cholesteryl ester storage disease (CESD). We created a LAL null (*lal*<sup>-/-</sup>) mouse model that closely mimics human WD and CESD. To test the potential for gene therapy, an adenoviral vector expressed human LAL (Ad-hLAL) was injected through tail vein to *lal*<sup>-/-</sup> mice at age of 2 months or 4 months with a single dose of viral particles  $3 \times 10^8$ /mouse or  $5 \times 10^9$ /mouse. Mice were sacrificed at 6, 20 and 47 days post-injection. All *lal*<sup>-/-</sup> mice injected with Ad-LAL or PBS survived. Compared to the PBS injected controls, the Ad-hLAL injected mice showed a reduction of plasma TG and CE levels, an increase in hepatic LAL activity of 272-fold at 6 days, and 62-fold at 20 days. Immunohistochemical staining with anti-hLAL antibody detected hLAL expression in hepatocytes and sinusoid lining cells in the liver, sinusoidal cells in the spleen, macrophages in the lung, and cortical cells in the adrenal glands. Hepatomegalies in *lal*<sup>-/-</sup> mice were reduced by 49% at 6 days, by 93-100% at 20 and 47 days in 2 months mice. The reductions of hepatomegaly in 4 months old mice were less significant (5.4%). Histological analyses of a variety of tissues showed reductions of lipid storage in hepatocytes and Kupffer cells in the liver and macrophages of the small intestine and the spleen. Biochemically, TG and cholesterol in liver and small intestine were reduced by ~75% at 6 days, ~95% at 20 days, and ~89% at 47 days in 2 months old mice. However, in 4 months old mice TG only was reduced in liver and small intestine by 50% and cholesterol concentration was unchanged. These studies provide "proof of principle" for adenoviral gene therapy in human WD and CESD.

**Correction of mitochondrial defects of human cells carrying mtDNA-encoded ND4 subunit by the yeast NDI1 gene.** *Y. Bai*<sup>1</sup>, *P. Hájek*<sup>1</sup>, *A. Chomyn*<sup>1</sup>, *E. Chan*<sup>1</sup>, *B. Seo*<sup>2</sup>, *A. Matsuno-Yagi*<sup>2</sup>, *T. Yagi*<sup>2</sup>, *G. Attardi*<sup>1</sup>. 1) Biology, Caltech, Pasadena, CA; 2) Division of Biochemistry, Department of Molecular and Experimental Medicine, The Scripps Institute, La Jolla, CA.

It is shown here that the gene for the single subunit, rotenone-insensitive and flavone-sensitive internal NADH-quinone oxidoreductase of *Sacchomyces cerevisiae* (NDI1) can completely restore the NADH dehydrogenase activity in mutant human cells that lack the essential mitochondrial DNA (mtDNA)-encoded subunit ND4. In particular, the NDI1 gene was introduced into the nuclear genome of the human 143B.TK<sup>-</sup> cell line derivative C4T, which carries a homoplasmic frameshift mutation in the ND4 gene. Two transformants, with a low or high level of expression of the exogenous gene, were chosen for a detailed analysis. In these cells, the corresponding protein is localized in mitochondria, and, in perfect correlation with its abundance, restores partially or fully NADH-dependent respiration, that is rotenone-insensitive, flavone-sensitive, and antimycin A-sensitive. Thus the yeast enzyme has become coupled to the downstream portion of the human respiratory chain. Furthermore, the P:O ratio with malate/glutamate-dependent respiration in the transformants is approximately two-thirds of that of the wild-type 143B.TK<sup>-</sup> cells, as expected from the lack of proton pumping activity in the yeast enzyme. Finally, while the original mutant cell line C4T fails to grow in the medium containing galactose instead of glucose, the high NDI1-expressing transformant has a fully restored capacity to grow in galactose medium. The present observations substantially expand the potential of the yeast NDI1 gene for the therapy of mitochondrial diseases involving complex I deficiency.

Program Nr: 2903 from the 2001 ASHG Annual Meeting

**Mutation-independent therapeutic strategies for Osteogenesis Imperfecta.** *G.J. Farrar, S. Millington-Ward, C. Allers, P. Conget, P.F. Kenna, P. Humphries.* Genetics, Trinity College Dublin, Dublin, Ireland.

Osteogenesis Imperfecta (OI) is a debilitating brittle bone disease which to date remains incurable. It is inherited in an autosomal dominant manner and is thought to affect 1/24,000 people. Over 150 and 80 mutations in the two type one collagen genes, COL1A1 and COL1A2 respectively, are known to give rise to the disease. Therefore developing mutation-specific gene therapies for this immensely heterogeneous disease may not be feasible. For this reason mutation-independent gene therapies for COL1A1 associated OI utilising hammerhead ribozymes are actively under development. A hammerhead ribozyme has been designed to suppress one allele of a common polymorphic variant of the Collagen 1A1 gene and therefore in principle this agent should be able to treat approximately 60% of patients with Collagen 1A1-linked OI. These ribozymes, administered via retroviruses, have now been tested in appropriate human cell lines and results from this study will be presented.

**AAV gene transfer in the GM2 gangliosidosis (Sandhoff disease) animal model.** *C. Bourgoïn<sup>1</sup>, P. Montanucci<sup>2</sup>, C. Emiliani<sup>2</sup>, R.A. Gravel<sup>3</sup>, L. Poenaru<sup>1</sup>, C. Caillaud<sup>1</sup>.* 1) Genetics, CHU Cochin, Paris, France; 2) Cellular and Molecular Biology, Perugia, Italy; 3) Research Institute, Montreal Children's Hospital, Montreal, Canada.

Sandhoff disease is an autosomal recessive neurodegenerative disease characterized by the intralysosomal accumulation of GM2 ganglioside. It is due to mutations in the HEXB gene, that encodes the hexosaminidases b-chain and results in a hexosaminidases A and B deficiency. Hex A and B are lysosomal hydrolases that are involved in ganglioside catabolism. Hex A is a heterodimer ab and Hex B a homodimer bb. Sandhoff disease predominantly affects the central nervous system, but also peripheral organs, such as liver. Specific AAV vectors, containing the human HEXA and HEXB cDNAs under the control of the CAG hybrid promoter, were constructed and their functionality was checked in vitro. They were then injected in the murine model of Sandhoff disease. Intramuscular administration of AAV-HEXB alone led to a restoration of Hex A and B activities in the injected muscle, but the coadministration of both AAVs led to a significantly enhanced Hex A specific activity. No secretion was observed in the peripheral blood system, as shown by serum and liver assays. AAVHEXB intravenous injections were performed in neonate Sandhoff mice. An increased hexosaminidases activity was found in the serum of the animals. It was stable for at least 2 months, reaching up to 30 % of the normal mouse activity. The liver hexosaminidases activity of the treated mice reached 60-90% of the normal. These results show that the liver is an efficient organ for the secretion of hexosaminidases, when transduced with AAV vectors. AAV-HEXB was also injected intracerebrally in *hexb*<sup>-/-</sup> neonates. Histological staining was performed with an artificial substrate coupled with a naphthol residue, showing a high enzyme activity in widely diffuse areas. Total hexosaminidases activity in the whole brain was restored to about the normal level, but Hex A reached only 20% of normal. The coadministration of HEXA and HEXB vectors will now be tested for its ability to provide therapeutic levels of both hexosaminidases A and B in the central nervous system.

**Analysis of SR proteins as therapeutic agents for SMA.** C.J. DiDonato<sup>1</sup>, P. Young<sup>2</sup>, C. Lorson<sup>2</sup>, R. Kothary<sup>1</sup>. 1) Ottawa Health Research Inst., Ottawa, Canada; 2) University of Arizona, Tempe, AZ, USA.

Mouse models of SMA have provided the most definitive evidence for the importance of full-length SMN (FL-SMN) transcripts and hence exon 7. They have demonstrated that SMN2 can rescue the embryonic lethality in *Smn*<sup>-/-</sup> mice, however high copy number of the SMN2 gene is required for complete rescue. This is consistent with the observation that the more copies of SMN2 present in SMA patients, the milder the disease. Thus, the presence of intact SMN2 gene(s) in SMA patients provides a natural target for therapeutic intervention. Identification of factors that enhance the production of FL-SMN from the SMN2 gene would be a major step towards the attenuation of the disease phenotype in SMA patients. One could search for agents that either upregulate the expression of SMN2 or suppress the alternative splice of SMN2 exon 7. Both would increase production of FL-SMN protein. We have focussed our efforts on the second approach.

A number of splicing factors, known as the SR proteins, have been shown to be involved in constitutive and alternative splicing. We have used a cell culture system and are characterizing two SR proteins that induce SMN2 exon 7 inclusion, Htra2-beta1 and SRp30C. The identification of these factors as modulators of SMN exon 7 alternative splicing is a crucial first step toward the possibility that they can be used to enhance the production of FL-SMN from the SMN2 gene of SMA patients. However, it is imperative that these factors be thoroughly characterized in a cell culture system and tested in the context of a whole animal. We have to be able to demonstrate that Htra2-beta1 and SRp30C can perform a "molecular rescue" of the SMN2 exon 7 alternative splice not only in SMA patient cell lines but also in a mouse model.

We will present our work on the cell culture characterization of Htra2-beta1 and SRp30C, and our progress towards creating transgenic mice that will be crossed to our SMN2 minigene mice that we have recently produced and characterized. This work has major implications on the *in vivo* therapeutic potential of these splicing factors.

**a- and b-sarcoglycan Delivery by AAV: Efficient Rescue of Muscle, but Differential Persistence of Gene**

**Expression.** *D. Dressman*<sup>1,2</sup>, *L. Liu*<sup>3</sup>, *E. Engvall*<sup>3</sup>, *K. Araiishi*<sup>4</sup>, *M. Imamura*<sup>4</sup>, *T. Sasaoka*<sup>4</sup>, *E. Ozawa*<sup>4</sup>, *E.P. Hoffman*<sup>1,2</sup>.  
1) Ctr Gen Med, Children's Natl Med Cntr, Washington, DC; 2) Univ of Pittsburgh, Dept Mol Gen & Biochem, Pittsburgh, PA; 3) Burnham Inst, La Jolla, CA; 4) Natl Inst Neuroscience, Tokyo Japan.

The sarcoglycanopathies are four autosomal recessive muscular dystrophies (LGMD 2D, 2E, 2C and 2F), caused by mutations in a, b, g and d sarcoglycan (SG) genes, respectively. Primary sarcoglycanopathies are estimated to account for 10-20% of muscular dystrophies in patients with normal dystrophin findings. To date, most adeno-associated virus (AAV) based gene delivery efforts in the muscular dystrophies have used the d-SG deficient hamster; however, primary d-sarcoglycanopathies are exceedingly rare in humans with only two patients reported in the US. We describe the construction and utilization of AAV vectors containing a- and b-SG, the most common of the human SG deficiencies. We show widespread genetic, biochemical and histological rescue of both a- and b-SG deficient knockout mouse muscle. We compared the persistence of expression in 36 AAV a-SG and 22 AAV b-SG injected mice. There was no evidence of decreased b-SG expression 133 days after injection. However, mice injected with a-SG showed dramatic loss of transduced myofibers at 28 days to 41 days post-injection. Loss of immuno-positive fibers was correlated with significant inflammation of macrophage >> CD4 or CD8 cells. To determine if the clearance of a-SG positive fibers was due to an immune response or was caused by a cytotoxic effect, immune deficient SCID mice were injected with either a- or b-SG AAV or sham injected. These experiments revealed that overexpression of a-SG causes significantly more cytotoxicity than either the sham injection or overexpression of b-SG. We hypothesize that overexpression of a-SG using a CMV-promoter-driven AAV construct results in cytotoxicity, while overexpression of b- or d-SG does not. This interpretation is consistent with emerging biochemical models of the hierarchical order of assembly of the SG complex and suggests that even closely related proteins may require different levels of expression to achieve tissue rescue.

**Functional correction of adult *mdx* mouse muscle using gutted adenoviral vectors expressing full-length dystrophin.** C. DelloRusso<sup>1,3</sup>, J. Scott<sup>3</sup>, D. Hartigan-O'Connor<sup>3</sup>, C. Barjot<sup>2</sup>, G. Salvatori<sup>2</sup>, A. Robinson<sup>2</sup>, S. Brooks<sup>1</sup>, J. Chamberlain<sup>3</sup>. 1) Departments of Physiology and; 2) Human Genetics, University of Michigan, Ann Arbor; 3) Department of Neurology, University of Washington, Seattle.

Duchenne muscular dystrophy is a degenerative lethal muscle disorder caused by mutations in the dystrophin gene. Adenoviral vectors are promising tools that may be used to express dystrophin in affected muscle. We have constructed 3 gutted adenoviral vectors devoid of all viral genes and containing a full-length human (HDys) or mouse (MDys and GEbDys) dystrophin cDNA driven by a muscle specific promoter. Virus was injected into 1 year old *mdx* mouse TA muscles and a novel lengthening contraction (LC) protocol was used to test for restored muscle function. This protocol reveals the high susceptibility of *mdx* TA muscles to contraction-induced injury; after 1 LC, wild type muscle force is reduced by 10% while *mdx* muscles show a 72% force loss. After 5 days, HDys injected muscles were significantly protected from injury and expressed high levels of dystrophin in contrast to sham injected control muscles. However, 25 days after injection, significant decreases in force generating capacity were detected. This loss of force was similar to that observed after injection of a first generation virus containing a LacZ transgene (CNb). MDys and GEbDys injected muscles demonstrated high levels of dystrophin protein expression and no functional defects after 25 days. In addition, MDys injected muscles were able to produce 62% of wild type force levels after 1 LC that, in contrast, reduced *mdx* and sham injected control muscles to 38 and 29% of wild type force, respectively. FACS sorting revealed the least amount of CD4+ and CD8+ cells in MDys injected muscles, 1/3 more immune cells in HDys injected muscles, and the highest number in muscles injected with CNb. Collectively, these data demonstrate 1) gutted adenoviral vectors are successful in transducing dystrophin in TA muscles of 1 year old *mdx* mice, 2) evidence for an immune response against human dystrophin that causes atrophy and loss of function, and 3) a partial functional correction of adult *mdx* mouse muscle after delivery of full-length mouse dystrophin.

**Pharmacodynamic and pharmacokinetic properties of retrovirus vector particles: Distribution after systemic delivery in vivo.** *G. Guibinga, C.-S. Park, T. Friedmann.* Pediatrics, UC San Diego, La Jolla, CA.

The development of safe, efficient and targeted gene transfer vectors for gene therapy will require increased knowledge of the pharmacological properties of the vectors and their mechanisms of target cell recognition and uptake. Retrovirus- and lentivirus vectors represent attractive gene transfer tools for in vivo gene delivery, but while the in vivo transducing properties of such vectors are coming to be characterized, little information is available on the physical distribution of the virus particles in vivo. Retrovirus and lentivirus preparations contain many non-infectious virus-like particles that may affect the toxicity and immunogenicity of the preparation and the resulting host response, but little information is available on the pharmacokinetic and pharmacodynamic properties of such retrovirus particles. It is therefore important to use methods independent of transgene expression to characterize the in vivo fate of retrovirus particles, their sites of accumulation and sequestration and their role in immune and non-immune related toxicity following systemic administration. In the current study, we have injected VSV-G pseudotyped MLV-based virus preparations expressing the lacZ transgene into Balb/c mice and have used immunohistochemical methods and deconvolution microscopy to characterize the distribution of viral gag protein as well as the sites of gene transfer by histochemical detection of lacZ activity. These studies were supported by grant HL64730 from the National Heart Lung and Blood Institute.

**Efficient cell attachment and infection by VSV-G pseudo-typed Moloney murine leukemia virus requires cell surface heparan sulfate.** *T. Friedmann, A. Miyanojara, G. Guibinga.* UCSD School of Medicine, La Jolla, CA 92093.

Infection of target cells by retrovirus is thought to be initiated by an interaction of a viral envelope protein with one or more specific and non-specific cell surface receptors followed by the fusion of the viral and the cell membranes and cell entry. We have shown that the initial attachment of retrovirus- and lentivirus vectors is independent of the known specific retrovirus receptors. To identify the cell membrane molecules involved in initial virus attachment, we have used deconvolution microscopy to examine the effect of glycosaminoglycans (GAG) on the initial attachment of envelope protein-free and VSV-G pseudotyped murine leukemia virus-based retrovirus vectors in vitro. Heparin effectively inhibits the attachment and infection of envelope-free and VSV-G pseudotyped retrovirus vector in human HT1080 cells. Furthermore, enzymatic digestion of heparan sulfate on the surface of target cells with heparinase I partially inhibits attachment and infection by both envelope protein-free and VSV-G pseudotyped retrovirus vector respectively. Digestion with chondroitinase ABC that specifically removes other GAG cell membrane produces no significant reduction of virus particle attachment. Interestingly, a CHO mutant cell line completely deficient in GAG (A-745) shows approximately 50% inhibition of attachment, but such cells are susceptible to infection by VSV-G pseudotyped retrovirus vectors. These data indicate the existence of redundant and alternative mechanisms of attachment of retrovirus particles that involve cell surface heparan sulfate and possibly other GAG molecules and phosphatidyl serine in conjunction with electrostatic interactions. The elucidation of the roles of these receptors in initial attachment and subsequent virus uptake and cell infection has obvious important implications for an understanding of vector pharmacokinetics and pharmacodynamics and for the design of targeted retroviral vectors. These studies were supported by grant HL64730 from the National Heart, Lung and Blood Institute.

**Gene therapy of Fanconi Anemia groups A and C by lentiviral vectors using mouse as an experimental model: Comparison with retroviral vectors.** *F. Galimi*<sup>1</sup>, *M. Noll*<sup>2</sup>, *Y. Kanazawa*<sup>1</sup>, *T.P. Lax*<sup>2</sup>, *R.L. Bateman*<sup>2</sup>, *A. D'Andrea*<sup>3</sup>, *I. Verma*<sup>1</sup>, *M. Grompe*<sup>2</sup>. 1) The Salk Institute for Biological Sciences, San Diego, CA; 2) Dept. of Molecular/Medical Genetics, Oregon Health Sciences University, Portland, OR; 3) Harvard Medical Institute, Boston, MA.

Fanconi Anemia (FA) is an autosomal recessive disorder characterized by birth defects, increased incidence of malignancy, progressive bone marrow failure and cellular hypersensitivity to DNA cross-linking agents. Bone marrow transplantation (BMT) is currently considered the treatment of choice for patients with FA, if a suitable donor is available. Therefore, gene therapy is an attractive alternative approach. In most genetic disorders, hematopoietic gene therapy would require correction of a large percentage of cells to be clinically effective. In FA we have potentially exploited the biology of the disorder itself. Previously, we have shown that bone marrow repopulation in FA mice was strong and rapid when direct selective pressure was applied in the form of low dose cyclophosphamide (CPA)/ablation (IR) which have previously been applied to FA patients. Recently, we used a VSVG pseudo-typed MMLV vector expressing the human FANCC cDNA to transduce *fancc*<sup>-/-</sup> marrow cells. We have shown that a single dose of CPA produced significant selection of retrovirally corrected HSCs. In the current study, we demonstrate the benefits of in vivo selection with third-generation lentivirus-derived vectors. These vectors might be the vectors of choice for HSC gene therapy since they allow efficient and stable gene transfer into quiescent stem cells with minimal manipulation of HSCs in comparison to the retrovirus. Our results show that a single dose of CPA produced significant selection of lentivirally corrected HSCs, with the integration of ~1 copy per genome. We have also generated the *fanca* knock-out mice and currently we are in process of carrying out similar in vivo selection procedures in these mice. Our preliminary data show that in vivo selection of the transplanted wild-type HSCs could be achieved at nonmyeloablative doses of CPA or IR in FAAKO mice also. Details of these results will be discussed.

**Gene Transfer by Receptor-Associated Protein / Polylysine Conjugates into HepG2 Cells.** *J.H. Kang<sup>1</sup>, T.G. Kim<sup>1</sup>, T.M. Yoo<sup>1</sup>, S.Y. Kang<sup>1</sup>, K.K. Jung<sup>1</sup>, M.Y. Cho<sup>1</sup>, J.I. Kim<sup>1</sup>, S.C. Jung<sup>2</sup>.* 1) Dept. of Pharmacology, National Institute of Toxicological Research, Korea Food and Drug Administration, Seoul, Korea; 2) Korea National Institute of Health, Seoul, Korea.

The 39-kDa receptor-associated protein (RAP) is a ligand for all members of the low density lipoprotein receptor family and is also able to be internalized into cells via receptor-mediated endocytic trafficking, which is an attractive mechanism for efficient gene delivery. In the present studies, we have developed a novel gene transfer agent using the RAP as a targeting ligand. The cDNA of partial RAP<sub>1-126</sub> (pRAP) except C-terminal heparin binding domain was amplified by PCR from human liver cDNA library and was re-amplified to add sequences of two cysteine residues at the carboxyl end to facilitate its conjugation to polylysine (PL), the DNA condensing carrier molecules. The RAP was purified at high yields using a bacterial expression system and coupled to polylysine via the heterobifunctional cross-linker SPDP. pRAP-PL conjugate, and PL as control, was condensed with a DNA expression plasmid containing the luciferase reporter gene driven by the CMV promoter under various salt conditions. Transfection into HepG2 cells by pRAP-PL/DNA complexes resulted in significantly higher expression levels in comparison to PL/DNA. Thus, this pRAP-PL conjugate may be useful as a nonviral gene delivery vector.

**Study of the Helper-Dependent Adenoviral Vector in the Delivery of a Therapeutic Intracellular Transgene Expressed in a Liver-specific Manner.** A. Mian, B. Mull, L. Pastore, G. Toietta, O. Bodamer, A. Beaudet, B. Lee. Molecular & Human Genetics, Baylor College of Medicine, Houston, TX.

Developing liver-directed gene replacement therapy is an important alternative for treatment of cell autonomous enzymatic defects such as citrullinemia and other urea cycle disorders. These diseases require high-level gene expression and hepatocyte transduction. We have developed adenoviral vectors containing the human argininosuccinate synthetase (ASS) cDNA (mutant in citrullinemia) driven by ubiquitous and liver-specific promoters. In order to prolong transgene expression and decrease toxicity *in vivo*, we have employed a helper-dependent adenoviral vector (HDV). Transgene activity is evaluated in tissue culture using a  $^{14}\text{C}$ -labeling assay to follow the production of argininosuccinate from aspartate. XC cells lacking endogenous ASS were transduced with HDV expressing ASS from the BOS promoter. These cells expressed ASS at levels similar to controls infected with the first generation adenoviral vector (FGV) expressing ASS from the CAG promoter. *In vivo* evaluation of these vectors in C57BL/6 mice showed comparable vector-specific ASS mRNA levels between FGV- and HDV-treated mice at 3 days post-injection. The HDV-treated mice did not show evidence of liver dysfunction at day 3, in contrast to FGV-treated mice, which showed marked hepatitis. Expression of ASS in FGV-treated mice was lost at 8 weeks post-injection, but in HDV-treated mice expression persisted at 8 weeks, albeit at significantly lower levels compared to the day 3-time point. Persistence of the vector was confirmed by southern and FISH analyses. Persistence of vector DNA concomitant with reduction in ASS expression from the HDV may be explained by a cytotoxic T-lymphocyte response against ubiquitously expressed ASS. We found that ASS expressed from the liver-specific albumin promoter in a FGV persisted in C57BL/6 mice in contrast to ASS expressed from the ubiquitous CAG promoter. Hence, our data suggest that liver-specific expression of an intracellular transgene using HDV may confer high-level and long-term expression that is required for correction of hepatic enzymatic defects like the urea cycle disorders.

**Isolation and characterization of a side population from adult mouse skin.** *F. Montanaro*<sup>1,2</sup>, *J. Volinski*<sup>1,2</sup>, *L.M. Kunkel*<sup>1,2</sup>. 1) Genetics, Children's Hospital, Boston, MA; 2) Genetics, Harvard University, Boston, MA.

Staining of bone marrow and skeletal muscle cells with the DNA binding dye Hoechst 33342 has been used to identify by FACS a Side Population (SP) of cells with stem cell properties. These cells express markers such as SCA-1 and CD34 associated with a non-committed phenotype, and when injected into lethally irradiated mdx mice are able to reconstitute the bone marrow and participate in skeletal muscle regeneration. Using this same staining paradigm, we identified SP cells in the skin of adult mice. These cells express the same surface markers as SP cells isolated from skeletal muscle, and like muscle SP cells are negative for markers specific to hematopoietic stem cells, such as c-kit, CD45, and CD 43. Furthermore, some markers that are expressed by muscle and skin SP cells are not found on bone marrow SP cells. Experiments by Watt and colleagues have shown that neonatal dermal fibroblasts can fuse with skeletal muscle fibres in vivo. In a series of preliminary experiments aimed at determining the trans-differentiation potential of skin SP cells, congenic dystrophic female mice were intravenously injected with male-derived skin SP cells and the contribution of skin SP cells to skeletal muscle regeneration was examined by Y-chromosome fluorescence in situ hybridization. Skin is an attractive source of stem cells since it is readily accessible and allows the combination of gene and cell therapy approaches while minimising the risks of immune rejection.

**In vivo selection from a phage display library of peptides capable of targeting the retina.** *M. O'Reilly, S. Millington-Ward, P.F. Kenna, A. Stitt, D. Allman, P. Humphries, G.J. Farrar.* Ocular Genetics Unit, Smurfit Institute of Genetics, Trinity College, Dublin, Ireland.

A 12-mer peptide library displayed on the PIII coat protein of M13 was systemically injected into a mouse. Retinas were harvested and the extracted phage re-injected. Following four rounds of enrichment the phage inserts were sequenced. 50% of the sequences were identical. Another peptide was selected 18% of the time and a third peptide 11% of the time. All three most common peptides have a small consensus epitope. The efficiency of targeting the retina by these selected peptides was analysed by comparing their homing capacity with peptides which were not selected by the enrichment process. EM studies were carried out to localise the phage within the retina. These peptides may have potential for use as tags for selective delivery of drug/gene therapeutics to specific tissues.

**Mutation-independent ribozyme-based therapies for Retinitis Pigmentosa.** *B.G. O'Neill, M. O'Reilly, S. Millington-Ward, G. Tuohy, P.F. Kenna, P. Humphries, J. Farrar.* Genetics, Trinity College Dublin, Dublin, Ireland.

A significant hurdle essential to overcome for the successful development of gene therapies for dominantly inherited diseases is the immense intragenic heterogeneity commonly associated with such disorders. The large number of distinct mutations that give rise to various dominant diseases makes the development of tailor-made mutation-specific therapeutics not economically feasible. Dominantly inherited forms of Retinitis Pigmentosa (RP) which are a group of hereditary degenerative diseases of the retina are no exception. For example, over 100 different mutations in the rhodopsin gene can give rise to adRP. In 1997, we published 3 mutation-independent ribozyme based 'suppression and replacement' strategies<sup>1</sup> (termed GeneXchange) which circumvent the difficulties of genetic heterogeneity thus enabling one therapeutic, in theory, to treat all patients suffering from adRP regardless of the primary defect. In these studies, hammerhead ribozymes have been used to achieve suppression. A battery of mutation independent hammerhead ribozymes directed to human rhodopsin transcripts have been designed and analysed in vitro. Kinetic parameters were determined to establish the most efficient ribozymes in vitro. To facilitate further experimentation, stable COS-7 cell lines expressing human rhodopsin RNA were generated. Stable COS-7 cell lines were transiently transfected with rhodopsin-specific monomeric ribozymes (Rz10 and Rz40) and a connected-type multimeric ribozyme (RzMM). Preliminary analysis indicates that one ribozyme, Rz40, is highly efficient achieving up to 40% reduction in rhodopsin mRNA. In addition, a murine model simulating the human form of adRP expressing both the wild-type human rhodopsin transgene, the Pro23His human transgene on a mouse rho<sup>-/-</sup> background has been generated for ribozyme analysis. Transgenic animals and viruses expressing Rz40 and replacement constructs encoding wild-type rhodopsin protein but masked from ribozyme suppression have been developed and are currently being tested in vivo. 1. Millington-Ward & O'Neill et al. Strategies in vitro for gene therapies directed to dominant mutations. *Hum Mol Genet.* 1997;6:1415-1426. <sup>1</sup>.

**Antisense hammerhead ribozymes for the down-regulation of the COL1A1 gene in murine models of osteogenesis imperfecta.** *M.W. Kilpatrick<sup>1</sup>, I. Toudjarska<sup>1</sup>, J. Niu<sup>1</sup>, R.J. Wenstrup<sup>2</sup>, P. Tsipouras<sup>1</sup>.* 1) Dept Pediatrics, UConn Health Ctr, Farmington, CT; 2) Human Genetics, Children's Hospital Research Foundation, Cincinnati, OH.

Osteogenesis imperfecta (OI) is a systemic heritable disorder of connective tissue whose cardinal manifestation is bone fragility. OI is caused by a mutation in one of the genes for type I collagen. Studies on the molecular pathology of OI have identified two mechanisms of collagen type I defects. In chain exclusion, the mutant chain is not incorporated into the collagen triple helix, while in chain non-exclusion, it is. The dominant-negative effect of non-excluded mutations must be taken into account in strategies aimed at correcting the collagen defects in OI individuals. Antisense hammerhead ribozymes are small catalytic RNA molecules that can be targeted to any RNA molecule containing a putative cleavage site. This has led to their application to the down-regulation of a variety of gene products, and to the proposal that they might be applied to the selective elimination of mutant gene products particularly those that exert a dominant-negative effect. Hammerhead ribozymes targeted to mutant type 1 collagen are therefore potential therapeutic agents for OI. Ribozymes were designed to selectively target the mutant minigene transcript expressed in MC3T3-C3 cells, a murine calvarial osteoblast cell line stably expressing a human COL1A1 minigene deleted for exons 6-46. This minigene has been used to create a transgenic mouse model of OI. Active, and control inactive ribozymes were tested in vitro both on mutant and normal targets and on total RNA from MC3T3-C3 cells. Active ribozyme cleaved its target with high efficiency and specificity in both a time and dose dependent manner. Following transfection of a ribozyme expressing construct into MC3T3-C3 cells, intracellular ribozyme was detected along with a relative reduction of mutant transcript level. As the effect of the ribozyme on its target is highly dependent on the ribozyme to target ration, multimeric ribozyme cassettes have been constructed and are being tested for efficacy in cell culture prior to their application in transgenic OI models.

**Delivery of Functional Four-Repeat Micro-Dystrophin to *Mdx* Muscle Via Different AAV Serotypes.** *S. Harper*<sup>1</sup>, *C. DelloRusso*<sup>1</sup>, *R. Crawford*<sup>1</sup>, *H. Harper*<sup>1</sup>, *J. Engelhardt*<sup>2</sup>, *D. Duan*<sup>2</sup>, *J. Chamberlain*<sup>1</sup>. 1) Dept of Neurology, University of Washington, Seattle, WA; 2) Dept of Anatomy and Cell Biology, University of Iowa, Iowa City, IA.

The goal of this study was to evaluate the correction of Duchenne muscular dystrophy (DMD) in the *mdx* mouse model using different serotypes of AAV carrying extremely small dystrophin genes (~3.5 kb vs. the full-length 14 kb). The rod domain of dystrophin is composed of 24 spectrin-like repeats, and natural, in-frame deletions of this region lead to a milder form of dystrophy called Becker MD. Based on our prior analysis in transgenic mice, we created several rod domain and C terminal deletions that resulted in dystrophin cDNAs small enough to fit into AAV. AAV is a highly efficient vector that does not elicit an immune response in dystrophic muscle if it is carrying a gene driven by a muscle-specific promoter. AAV-2 is the most prevalent and well-characterized system, but recent studies show that serotypes 1, 5, and 6 boost gene expression 100- to 1000-fold in mouse muscle. We generated transgenic mice expressing several different micro-dystrophin clones containing only four repeats, and analyzed their ability to correct muscular dystrophy by both morphological and physiological assays. Two of three transgenes significantly reduced the amount of dystrophy observed in the *mdx* limb and diaphragm muscles. The best transgene (DR4-R23) produced muscle with wild-type levels of central nuclei, membrane integrity, resistance to contraction-induced injury, and the ability to run on a treadmill. No areas of fibrosis nor monocyte infiltration were observed. We subsequently demonstrated that highly functional micro-dystrophins can be successfully delivered via AAV-2 to muscles of young adult *mdx* mice. We are currently testing gene expression of our best micro-dystrophin with alternate AAV serotypes, a more efficient Kozak sequence, and a highly active, mutant form of the muscle creatine kinase promoter (CK6). Functional correction of muscular dystrophy using these vectors will be compared to results obtained with our gutted adenovirus vector system that expresses full-length dystrophin.

**Gene Transfer with VSV-G/Plasmid Complexes and with Ternary Complexes of VSV-G, plasmid and Envelope Protein-free Retrovirus-like Particles.** *A. Miyano-hara, T. Friedmann.* Pediatrics, UCSD School of Medicine, La Jolla, CA.

We have previously demonstrated that the G protein of vesicular stomatitis virus (VSV-G) forms complexes with liposomes to produce stabilized particles with enhanced transfection capability. We have also demonstrated earlier that VSV-G can convert non-infectious, envelope protein-free virus-like ("bald") particles to infectious form in cell-free conditions in vitro. We demonstrate now that VSV-G interacts with plasmid DNA alone to produce complexes with 100-1000 fold increased transfection properties in several cell types compared with plasmid alone. Interaction of VSV-G and plasmid with non-infectious bald particles produces ternary complexes that display gene transfer properties. The polycation polybrene is required for the formation of these transfection-competent complexes. We interpret these results to indicate that VSV-G is able to provide a structural as well as a fusiogenic function to complexes with naked DNA and to immature virus-like bald particles, that such complexes are thereby able to enter target cells and display enhanced gene transfer properties. We suggest that these techniques can help elucidate mechanisms of virus assembly and aid in the development of a variety of novel gene transfer methods. These studies were supported by grant HL64730 from the National Heart, Lung and Blood Institute.

**Long term correction of lipid storage in multiple organs of Fabry mice by direct injection of AAV vectors into skeletal muscle.** *T. Shimada<sup>1</sup>, H. Takahashi<sup>1</sup>, Y. Hirai<sup>1</sup>, K. Takahashi<sup>1</sup>, M. Migita<sup>1</sup>, H. Sakuraba<sup>2</sup>, R. Kase<sup>2</sup>, Y. Hashimoto<sup>3</sup>.* 1) Biochem. Mol. Biol., Nippon Medical School, Tokyo, Japan; 2) The Tokyo Metropolitan Institute of Medical Science, Tokyo, Japan; 3) The Institute of Physical and Chemical Research, Saitama, Tokyo, Japan.

Fabry disease is an X-linked inherited metabolic disorder due to a deficiency of the lysosomal enzyme,  $\alpha$ -galactosidase A ( $\alpha$ -gal A). The enzyme defect leads to the systemic accumulation of neutral glycosphingolipids predominantly ceramide trihexoside (Gb3). Clinical trials of enzyme replacement therapy are now being conducted. As an alternative approach, we are studying the feasibility of adeno-associated virus (AAV) vector mediated gene therapy. We injected the AAV vector containing the  $\alpha$ -gal A gene driven by the CAG promoter ( $1.5 \times 10^{11}$  particles) into the right quadriceps muscles of Fabry knock-out mice (12 weeks old). A time course study showed that  $\alpha$ -gal A activity in plasma was increased to approximately 20 % of the normal mice that persisted for up to at least 38 weeks. In parallel with the plasma concentration, the  $\alpha$ -gal A activities in multiple organs including liver, heart, and kidney were continued to be 5-15 % of those observed in the normal mice. Finally, quantitative measurement of glycolipids showed that the concentrations of Gb3 decreased to normal levels in various organs including kidney at 38 weeks. The reduced Gb3 level was also confirmed by immunohistochemical analysis using the anti-Gb3 specific antibody. These results indicate that  $\alpha$ -gal A secreted from transduced muscle cells entered into affected tissues and efficiently cleared lipid. The safety of direct injection of AAV vectors into skeletal muscle has been well established. AAV mediated muscle directed gene therapy should be a clinically relevant therapeutic approach for Fabry and other lysosomal disorders.

**Amelioration of dystrophic phenotypes in transgenic *mdx* mice expressing truncated dystrophin cDNA.** *M. Sakamoto, K. Yuasa, T. Yokota, S. Masuda, Y. Miyagoe-Suzuki, S. Takeda.* Molecular Therapy, Natl Inst Neurosci NCNP, Kodaira, Tokyo, Japan.

Duchenne Muscular Dystrophy (DMD) is an X-linked, lethal disorder caused by a defect in the *dystrophin* gene. Progressive muscle weakness, cardiomyopathy and early death characterize the disease. Dystrophin is localized at the inner surface of the plasma membrane and forms the complex with dystrophin-associated proteins (DAPs) to stabilize the sarcolemma by linking the cytoskeleton to the extracellular matrix. Dystrophin has a central rod domain, which consists of 24 triple-helical repeats and 4 hinge segments, and accounts for 76% of the molecule. It has been shown that a large in-frame deletion in this domain results in a mild allelic form of the disease, Becker muscular dystrophy (BMD).

Adeno-associated virus (AAV) vector-mediated micro-dystrophin cDNA transfer is one of attractive approaches for the treatment of DMD. AAV vector allows long-term expression of the transferred gene without significant immune responses, while it has a limited insertion size up to 4.7-4.9 kb. Therefore, we cannot accommodate a full-length dystrophin cDNA (14 kb) into AAV vector. To find a functional, but small-sized dystrophin, we generated a series of rod-truncated micro-dystrophin cDNAs with one rod repeat and two hinges (named M3 construct), three rod repeats and two hinges (AX11 construct), and four rod repeats and three hinges (CS1 construct). We have generated transgenic *mdx* mice expressing micro-dystrophins and evaluated their function to improve dystrophic phenotype. Histological examination showed that CS1 construct recovered DAPs at the sarcolemma and significantly reduced muscle degeneration in the hind limb muscles and diaphragm. On the other hand, M3 construct could not ameliorate *mdx* phenotype in spite of recovery of DAPs at the sarcolemma. These data suggest that the rod structure, especially its length is critical for function of micro-dystrophin. We are now investigating the phenotypes of AX11-transgenic *mdx* mice. Our goal is to identify a functional micro-dystrophin and transfer it into dystrophin-deficient dystrophic muscles using AAV vector.

**Inhibition of caspase activity and prevention of apoptosis in 661W cone photoreceptor cells.** *G. Tuohy, P.F. Kenna, P. Humphries, G.J. Farrar.* Genetics, Trinity College Dublin, Dublin, Ireland.

Retinitis pigmentosa (RP) is an hereditary group of degenerative retinopathies with an incidence world-wide of approximately 1 in 4000. Over 30 distinct genes have been implicated in the etiology of RP to date however, despite such genetic heterogeneity, apoptosis appears to be a final common pathway of photoreceptor cell death in these disorders. RP may be additionally characterised by its primary effect on the rod cell population of the retina with patients initially reporting a narrowing of the visual field and loss of scotopic vision. Rod cell loss is generally followed by a further wave of apoptotic cell death in the cone cell population eventually leading to loss of photopic vision. Extending the longevity of cone cells in the retina, despite rod photoreceptor cell loss, represents a potentially valuable therapeutic goal in limiting a number of the more severe medical consequences of RP. 661W cone cells represent a photoreceptor transformed cell line originally derived from a transgenic mouse expressing the SV-40 T antigen in the retina. 661W cells have been shown to express opsin, arrestin, phosphodiesterase (PDE),  $\gamma$ -transducin and rds/peripherin. In this study cultures of 661W cells were exposed to a variety of apoptotic stimuli including UV irradiation and chemotherapeutic agents. Cultures pre-treated with as little as 80  $\mu$ M Z.VAD.FMK and 400ng baculoviral p35 showed significant resistance to apoptotic cell death following induction by UV and daunorubicin. Survival rates for 661W cells treated with 80  $\mu$ M Z.VAD.FMK and 400ng baculoviral p35 were 72.360.93% and 64.151.80% respectively compared to controls where survival was 6.991.35% and 17.491.55% for Z.VAD.FMK and p35 respectively. Therapeutic strategies directed at modulating caspase activity may thus present a viable means of blocking apoptotic cone cell death in the context of degenerative retinopathies.

**Gene therapy for Fabry disease.** *R. Ziegler<sup>1</sup>, N. Yew<sup>1</sup>, C. Li<sup>1</sup>, M. Cherry<sup>1</sup>, M. Przybylska<sup>1</sup>, D. Armentano<sup>1</sup>, R.J. Gregory<sup>1</sup>, S.C. Wadsworth<sup>1</sup>, R.J. Desnick<sup>2</sup>, Y.A. Ioannou<sup>2</sup>, S.H. Cheng<sup>1</sup>.* 1) Genzyme Corp, Framingham, MA; 2) Mt. Sinai Sch. of Med. New York, NY.

Fabry disease is a monogenic X-linked disorder caused by a deficiency of the lysosomal enzyme  $\alpha$ -galactosidase A. Clinical manifestations are due to progressive accumulation of the substrate globotriaosylceramide (GL-3) in the vascular endothelium of heart, kidney, skin, and nervous system. Feasibility of gene therapy for treating Fabry disease was established using systemic delivery of a recombinant adenoviral vector encoding  $\alpha$ -galactosidase A into Fabry mice. This resulted in correction of both the enzymatic and lysosomal storage defects in all affected organs. However, there was significant liver toxicity associated with administration of this vector, and transgene expression was transient. We are currently developing alternative vectors with improved safety and expression profiles such as pseudo-adenoviral vectors, adeno-associated viral vectors as well as synthetic vectors. Systemic administration of  $5 \times 10^{11}$  particles of AAV/CMVHIgal into immunosuppressed Fabry mice resulted in expression of approximately 10% normal levels of  $\alpha$ -galactosidase A in the liver and significant reductions in GL-3 levels in most organs. By replacing the CMV promoter with a liver-specific promoter (albumin) we obtained levels of  $\alpha$ -galactosidase A that were within the normal range in livers of immune competent Fabry mice. In contrast to studies using the CMV promoter, only very low titers of anti- $\alpha$ -galactosidase A antibodies could be measured when the enzyme was transcribed using this liver-specific promoter. We have also developed improved synthetic vectors. Significantly higher and more persistent expression has been obtained by optimizing transcription cassettes, and by reducing the inflammatory characteristics associated with CpG motifs on the pDNA. After IN administration of the optimized vector,  $\alpha$ -galactosidase A expression from pGZCUBI-HAGA (containing a hybrid CMV enhancer-ubiquitin promoter) increased over time and by day 35 was 10- to 15-fold higher than starting levels. These two improved vector platforms show promise for a safe, efficacious gene therapy treatment for Fabry disease.

**Partial correction of murine hemophilia A by murine factor VIII cDNA delivered via AAV vector.** *R. Sarkar<sup>1</sup>, W. Xiao<sup>2</sup>, H.H. Kazazian<sup>1</sup>*. 1) Dept Genetics, Univ Pennsylvania Sch Medicine, Philadelphia, PA; 2) Division Of Hematology, Children's Hospital of Philadelphia, Medicine, Philadelphia, PA.

Hemophilia A is an X linked clotting recessive disorder that affects 1 in 10,000 males. Earlier, using first generation adenoviral vectors, we reported partial long-term correction of murine hemophilia A with murine FVIII. Despite phenotypic correction, the immune system still recognized a species-specific transgene protein as a neo-antigen, eliciting a cytotoxic T cell response. Recombinant AAV vectors are known to maintain long-term gene expression without eliciting destructive cell-mediated immune responses. These features in association with AAV's lack of pathogenicity and broad tissue tropism make it an attractive vector for human gene therapy. Unlike the successful development of AAV vectors for gene delivery in hemophilia B, applications to hemophilia A have been limited by the size constraint of the parvovirus (5kb). In this study we designed an AAV vector system that could successfully deliver FVIII cDNA and potentially correct the bleeding phenotype in hemophilic mice. The AAV-FVIII cassette contains a short basic albumin promoter (0.2kb), a B domain-deleted murine cDNA with an intron (4.4kb), and a short poly A signal (0.1kb). The entire cassette is flanked by ITRs of 145bp each. FVIII knockout mice were injected with  $1 \times 10^{11}$  viral particles/mouse via the spleen. The mice were bled initially at 2 weeks, and followed at monthly intervals up to six months post injection of either the FVIII cDNA virus alone or the FVIII cDNA virus in combination with a second virus bearing an albumin enhancer. Of 24 mice, 14 mice survived the tail clip at 3 months with FVIII activities of 2.5 to 3 percent. At six months these mice continued to express FVIII activity at levels 2.5 to 3 percent. 10 mice with 0 to 2.5 percent FVIII activities at 3 months did not survive tail clip. No differences were observed between the mice receiving FVIII cDNA alone and those receiving both FVIII and the enhancer. Further studies are ongoing on these mice and others given FVIII via portal vein and tail injection.

**TREATMENT OF THE MOUSE MODEL OF MPSI BY TRANSPLANTATION OF BONE MARROW AND OF GENETICALLY MODIFIED BONE MARROW.** *Y. Zheng*<sup>1</sup>, *J. Zhou*<sup>1</sup>, *R. Rozengurt*<sup>2</sup>, *S. Ryazantsev*<sup>1</sup>, *H.H. Li*<sup>1</sup>, *D.B. Kohn*<sup>3</sup>, *E.F. Neufeld*<sup>1</sup>. 1) Dept. of Biological Chemistry, UCLA School of Medicine, Los Angeles, CA; 2) Dept. of Pathology & Laboratory Medicine, UCLA School of Medicine, Los Angeles, CA; 3) Dept. of Molecular Microbiology and Immunology, Childrens Hospital Los Angeles, Los Angeles, CA.

Mucopolysaccharidosis I (MPS I,  $\alpha$ -L-iduronidase deficiency) includes the Hurler syndrome and the less severe forms, Hurler-Scheie and Scheie syndromes. Bone marrow transplantation is known to alter the course of the disease in Hurler patients, and direct administration of recombinant  $\alpha$ -L-iduronidase (Idua) to MPS I patients is currently undergoing clinical trial. To test the potential of gene therapy, we developed an MPS I mouse model by homologous recombination, inserting *neo*<sup>r</sup> in place of exon 6, as had been previously done by Clarke et al (Human Mol Genet 6:503, 1997). The mutant *Idua* was placed on a C57BL/6 background. Bone marrow transplantation with wild-type or mutant bone marrow was performed when the *Idua* <sup>-/-</sup> mice were 6-8 weeks old. For genetic modification, the bone marrow was transduced with human *IDUA* cDNA in an MND retroviral vector or sham-transduced with the same vector carrying *EGFP*. Recipient mice were sacrificed 2 and 6 months later for analyses. The liver and spleen of animals receiving wild type bone marrow had a level of enzyme that was considerably below normal, but sufficient to reduce to normal the accumulation of soluble glycosaminoglycans (GAG) and the secondary elevation of b-hexosaminidase. Only a marginal amount of Idua appeared in the kidney and none at all in the brain. On the other hand, when the bone marrow was transduced with *IDUA*, not only did the liver and spleen contain many times the normal level of Idua, but so did the kidney, with concomitant normalization of GAG. Even in the brain, the level of Idua was normal or higher in the three mice analyzed. The morphology of the liver, examined by EM, had returned to normal, but the effect of the enzyme on the pathology of the brain has not yet been determined. The results encourage us to think that optimization of the procedure may permit vector-containing cells to reach many tissues. (Supported in part by NIH grant DK 38857).

**Adeno-associated virus vector-mediated gene transfer into anterior horn cells.** *G. Acsadi<sup>1,2</sup>, H. Yang<sup>1</sup>, R. Anguelov<sup>1</sup>, G. Toht<sup>1</sup>, Y. Wang<sup>1</sup>, M.E. Shy<sup>2</sup>*. 1) Dept. Pediatrics, Wayne State Univ, Detroit, MI; 2) Dept. of Neurology, Wayne State Univ., Detroit, MI.

In gene therapy for motor neuron diseases, such as spinal muscular atrophy and amyotrophic lateral sclerosis, the target cells for gene transfer are skeletal muscle cells and neurons. Previously, we showed that recombinant adenoviruses (ADV) are efficient vectors for gene transfer into muscle, and (by retrograde transport) into motor neurons of neonatal mice, but with a lower efficiency in adult mice. AAV is known to transduce both immature and mature muscles without causing a significant immunoreaction. However, the ability of AAV to transfer genes into lower motor neurons has not been investigated yet for gene therapy purposes. The objective of this study was to determine whether AAV could be efficiently used to transfer foreign genes into spinal cord motor neurons. We have constructed AAV with CMV-EGFP (green fluorescent protein) and GDNF expression cassettes, using a helper virus free system. The AAV was grown and purified to high titer and injected into hindlimb muscles of neonatal and adult mice. EGFP expression was analyzed from muscle and spinal cord by a fluorescent microscope and GDNF expression was analyzed by chemiluminescent ELISA and real-time PCR. EGFP and GDNF expression was detected in both neonatal and adult muscles three weeks after vector administration. Furthermore, EGFP was detected in large number of spinal cord motor neurons at both ages, suggesting that a retrograde transport of transgene product and/or AAV genome has occurred after intramuscular administration. We conclude that AAV, similarly to ADV, can be used to introduce transgenes into muscle cells and motor neurons. Since AAV causes less of an inflammatory response than ADV, it may have an advantage over ADV in developing effective gene therapy for motor neuron diseases. Supported by MDA.

**Generation of Transplantable Cells for Ex vivo Gene Therapy of Globoid Cell Leukodystrophy (Krabbe disease).**

*M.A. Rafi, M. Zaka, H.Z. Rao, P. Luzi, D.A. Wenger.* Department of Neurology, Thomas Jefferson University, Philadelphia, PA.

Globoid cell leukodystrophy (GLD) or Krabbe disease is a disease of humans and several animal species caused by the deficiency of galactocerebrosidase (GALC) activity. This deficiency results in the accumulation of a cytotoxic substrate called psychosine and a severe decrease in central and peripheral nervous system myelin. At this time treatment in humans is limited to bone marrow transplantation. The use of stem cells that have been transduced to produce high GALC activity might be ideal for treating GLD. In order to generate transplantable cells with high GALC expression that can be traced through a reporter gene, we initially prepared several retroviral constructs containing a combination of human (h) or murine (m) GALC cDNA, internal ribosomal entry site (IRES), green fluorescent protein (GFP) and puromycin resistant gene (Puro) sequences. Each time an extra element was added to the viral construct, considerable decline in GALC activity was observed. By generating two MFG-based viral vectors to co-infect the target cells, followed by puromycin selection, we have developed a method for obtaining cells that maintain high GALC expression while they also express GFP and are puromycin resistant. We have placed both human and mouse GALC cDNAs in the MFG vector, which lacks a selectable marker. Amphotropic viral particles were produced after transfection into psi-CRIP cells. Using these viral particles, we have previously shown that infectious virus can successfully transduce many deficient cell types including astrocytes and oligodendrocytes resulting in high GALC activity and normal phenotype. In a separate experiment, psi-CRIP cells were transfected with MFG vector containing GFP-IRES-Puro, and viral producing colonies were selected with puromycin. Subsequent co-infection of dividing cells with both viral vectors followed by selection with puromycin resulted in cells expressing GFP alone or GFP and exogenous GALC. Colonies expressing high GALC were selected by enzyme assay and expanded for injection into the mouse models of GLD.

**Autoimmune scurfy mice, the ortholog of human IPEX, are rescued by transplantation of bone marrow or T cells.** R.S. Wildin, S. Smyk-Pearson. Molecular & Medical Genetics, Oregon Health & Science Univ, Portland, OR, USA.

**PURPOSE:** We assessed the therapeutic value of bone marrow or peripheral T cell transplantation for treating the fatal autoimmune disorder in the *sf* mouse. **BACKGROUND:** The syndrome of Immunodysregulation, Polyendocrinopathy, Enteropathy, X-linked (IPEX) is a T cell-mediated autoimmunity disorder due to mutation of *FOXP3*. IPEX is generally fatal in infancy. One patient responded to a bone-marrow transplant despite limited engraftment. Thus, normal cells may suppress the antigen hyper-reactivity of *FOXP3*-deficient T cells. The scurfy (*sf*) mouse is a natural mouse model for IPEX and shares clinical features including lymphadenopathy and eczema. Untreated *sf* mice die at 21 - 28 days. **METHODS:** We injected  $5 \times 10^6$  syngeneic normal bone marrow cells IP into 5 newborn *sf/Y* mice after 5 Gy (sublethal) irradiation (BMT). We injected  $2 \times 10^7$  syngeneic normal T cells into 6 additional *sf/Y* mice at 12 days of age without conditioning (TCT). We observed treated and control mice for disease features and lifespan. **RESULTS:** Most BMT and TCT mice developed scurfy skin features in a delayed fashion. BMT mouse 1 had little skin disease but died at 30 days. The absence of spleen, lymph nodes and thymus suggested that death was due to engraftment failure rather than scurfy disease. BMT mouse 2 was euthanized at 64 days due to severe tail eczema, but lymph nodes, thymus, and spleen appeared normal, suggesting that *sf*-like lymphoproliferation had been eliminated. BMT mouse 3 died at 47 days. BMT mice 4 and 5 currently survive (76 and 22 days) with eczema but are behaving normally and the skin of the older mouse is improving. Three TCT mice lived 5 days longer than PBS-injected controls. The other TCT mice currently survive at 75, 52, and 28 days. The eldest appears nearly normal. **CONCLUSIONS:** Bone marrow transplantation in the newborn scurfy mouse can slow disease and prevent death. BMT may prove generally useful in treating IPEX patients. T cell transplantation in scurfy mice may prolong life. Normal T cells can suppress the abnormal reactivity of *Foxp3*-deficient T cells *in vivo*, raising the possibility of alternative treatments for IPEX patients.

**A double blind therapeutic trial in Angelman syndrome using betaine and folic acid.** CA. Bacino, J. Goddard-Finegold, M. Turcich, D. Glaze, W. O'Brien, AL. Beaudet. Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX.

Angelman Syndrome (AS) is caused by maternal deficiency of the UBE3A; this gene encodes E6-AP ubiquitin-protein ligase and is subject to genomic imprinting with paternal silencing in the brain. It is known that expression of UBE3A from the maternal copy of chromosome 15q11-q13 is essential to prevent AS. In 1998 a patient with methylene-tetrahydrofolate reductase (MTHFR) deficiency was described with clinical features indistinguishable from AS. This could suggest that abnormalities in the folic acid pathway might result in abnormalities of DNA methylation that affect expression of UBE3A causing genocopies of AS. The rationale of this protocol is based on activating the silent paternal allele for UBE3A in AS patients, perhaps by silencing the antisense transcript in this region and increasing the "leakiness" of the paternal allele. A total of 20 patients with AS are currently being enrolled in a randomized, double blind protocol using 6 or 12 gm/d of betaine and 15 mg/d folic acid versus placebo. The plan is to continue treatment for one year with careful evaluation of neurologic, nutritional, and developmental status, including language, motor, and adaptive domains. The evaluation includes a neurologic exam and EEG. Gait, station, abnormal movements, and progression of neurologic signs over time are assessed. The Revised Bayley Scales of Infant Development are used to provide psychomotor and mental developmental indices. We are also using the Vineland Inventory to assess behavioral and emotional development Blood studies include, CBC, BUN, methylation studies of DNA, and levels of red cell folate, homocysteine, methionine and betaine. Thus far, 12 children with AS have been enrolled. Initial results and protocol rationale will be discussed. The strategy of activating silenced alleles for treatment of genetic deficiency of imprinted genes could be considered in other disorders such as Prader-Willi syndrome.

**Improvement in sterol levels with cholesterol therapy in Smith-Lemli-Opitz syndrome (SLOS).** *M. Irons*<sup>1</sup>, *E.R. Elias*<sup>2</sup>, *C. Bay*<sup>3</sup>, *B. Pober*<sup>4</sup>, *G.S. Tint*<sup>5</sup>, *G. Salen*<sup>5</sup>. 1) Children's Hospital, Boston, MA; 2) Children's Hospital, Denver, CO; 3) Children's Hospital, Pittsburgh, PA; 4) Yale-New Haven Medical Center, New Haven, CT; 5) VA Medical Center, East Orange, NJ.

SLOS is an autosomal recessive disorder of cholesterol biosynthesis characterized by decreased levels of cholesterol and increased levels of the cholesterol precursors, 7-dehydrocholesterol (7-DHC) and 8-dehydrocholesterol (8-DHC). Treatment with supplemental cholesterol was initiated to determine if such treatment could improve sterol levels and ultimately the clinical problems seen in affected patients. Seventeen patients (11 females/6 males, currently ages 1-20 years) have been treated with a suspension of crystalline cholesterol in oil (50-300 mg/kg/day). Initial cholesterol levels range from 8-154 mg/dl. Ages at initiation of therapy range from birth to 15 years, and durations of therapy range from 3 months to 7.5 years. Patients were divided into mild (7), moderate (5), and severe (5) groups based on pretreatment cholesterol levels and severity of clinical presentation. Levels of cholesterol and the ratio of cholesterol to total sterols increased significantly for all patients combined ( $p < 0.0001$  for each), as well as within each clinical severity subgroup ( $p < 0.05$ ). 7-DHC ( $p = 0.009$ ) and 8-DHC ( $p = 0.003$ ) levels decreased significantly for all patients combined as well as for patients in the moderate group. Significant decreases in 7-DHC ( $p = 0.014$ ) and 8-DHC ( $p = 0.006$ ) were noted when combining the moderate and severe groups. Overall, 7-DHC and 8-DHC were reduced by 36% and 44% respectively, while cholesterol and the ratio of cholesterol to total sterols increased by 61% and 27%, respectively. Clinical response was variable. No toxicity has been noted in over 7 years of therapy. In summary, treatment of patients with SLOS with a suspension of crystalline cholesterol in oil results in improvement in sterol levels without long-term toxicity.

**Endothelial dysfunction in patients with MELAS: role of oxidative stress to stroke.** *Y. Koga<sup>1</sup>, H. Matsuoka<sup>2</sup>, R. Fukiyama<sup>1</sup>, I. Ueki<sup>1</sup>, Y. Akita<sup>1</sup>, T. Imaizumi<sup>2</sup>.* 1) Dept Pediatrics & Child Health, Kurume Univ Sch Medicine, Fukuoka, Japan; 2) Department of 3rd Internal Medicine, Kurume University School of Medicine, Fukuoka, Japan.

Mitochondrial angiopathy demonstrating degenerative change with increased abnormal mitochondria in the endothelial cells of intramuscular small arteries and arterioles have been reported in many MELAS patients. However, the primary cause of the young MELAS strokelike episodes is still controversial. Since abnormal mitochondria generates superoxide anion, we hypothesized that vascular complications in MELAS may be associated with endothelial dysfunction caused by oxidative stress. Six patients have an A3243G mutation, and one patient has a T3271C mutation in the mitochondrial tRNA<sup>Leu</sup>(UUR) gene. In this study, we examined flow-mediated vasodilatation, as a non-invasive measure of endothelial function, and effects of an antioxidant, vitamin C in patients with MELAS. We also studied the pharmacological effect on the clinical course, and biochemical parameters after administration of L-arginine to a patient in the acute phase of stroke on three separated occasions and, and on the functional aspects of the cerebral hemodynamics using SPECT. Flow-mediated vasodilatation was significantly less (10% of the age-matched controls) in MELAS patients. Endothelium-dependent vasodilatation induced by glyceryl trinitrate was also impaired. Vitamin C administration significantly restored flow-mediated dilation and glyceryl trinitrate-induced vasodilatation to near-normal levels in MELAS but did not affect them in controls. After the administration of L-arginine, all the symptoms were clinically improved, and the intracranial hemodynamics were also improved in the ischemic area (in the left temporal lobe), but unchanged in the brain stem (thalamus). Our data demonstrated that angiopathy seen in MELAS involved abnormality in the capacity of vasodilatation in the endothelial system, which may play an important role in causing strokelike episodes in this disorder.

**Toward Repair of Retinal Degenerations with Differentiated and Embryonic Stem (ES) Cells.** *S.H. Tsang<sup>1,2</sup>, D.S. Salchow<sup>2</sup>, M. Jiang<sup>2</sup>, J. Kong<sup>2</sup>, M. Redmond<sup>3</sup>, S.P. Goff<sup>2</sup>, P. Gouras<sup>2</sup>, D.B. Farber<sup>1</sup>.* 1) UCLA, Los Angeles, CA; 2) Columbia U, NY, NY; 3) NIH, Bethesda, MD.

Leber Congenital Amaurosis (LCA) is a recessive dystrophy resulting from defects in either the retinal pigment epithelial (RPE) or photoreceptors. We are studying two mouse models of LCA: *Rpe65<sup>TM</sup>/Rpe65<sup>TM</sup>* mice carry a null mutation in *Rpe65* (Redmond et al., Nat Genet 20, 344) and, *Pdeg<sup>TM</sup>/Pdeg<sup>TM</sup>* mice (Tsang et al, Science, 272, 1026) carry a targeted disruption in *Pdeg*, the gene encoding the g subunit of the cGMP phosphodiesterase (PDEg). Both animal models have ERG features seen in individuals with LCA. We are testing whether transplantation of RPE cells into *Rpe65<sup>TM</sup>/Rpe65<sup>TM</sup>* mice, and ES cells into *Pdeg<sup>TM</sup>/Pdeg<sup>TM</sup>* mice have therapeutic effects. In the latter case, we are probing if ES cells can differentiate into photoreceptors after transplantation in *Pdeg<sup>TM</sup>/Pdeg<sup>TM</sup>* mice. A GFP cassette has been placed under the control of the opsin gene in ES cells. This GFP reporter will only be active if the ES cells differentiate into rod photoreceptors and its expression can be followed using a scanning laser ophthalmoscope (SLO). Following subretinal injection of wild-type RPE or ES cells ( $5-10 \times 10^4$  cells) expressing the green fluorescent protein (GFP) with the polymerase II or the opsin promoter into one eye, dark-adapted corneal ERGs of both eyes were performed at different ages. In the *Rpe65<sup>TM</sup>/Rpe65<sup>TM</sup>* model, RPE transplantation increased ERG responses. Although transplanted ES cells were found in the *Pdeg<sup>TM</sup>/Pdeg<sup>TM</sup>* mice, preliminary studies suggest naive ES cells fail to express sufficient levels of GFP detectable by SLO. Teratocarcinomas frequently associated with ES cell transplantation have not been observed in our animals. Transplanted RPE cells can slow degeneration in *Rpe65<sup>TM</sup>/Rpe65<sup>TM</sup>* mice. Naive ES cells are able to survive in the subretinal space of *Pdeg<sup>TM</sup>/Pdeg<sup>TM</sup>* mice. We are now testing transplanted ES cell-derived embryoid bodies for photoreceptor differentiation. Transplantation of RPE and/or differentiated ES cells could become a therapy for selected individuals with LCA and associated retinal dystrophies.

**Modulation of muscular dystrophy by inhibitors of apoptosis.** *S. Abmayr, R.W. Crawford, J.S. Chamberlain.* Dept Neurology, Univ Washington, Seattle, WA.

Duchenne muscular dystrophy (DMD) is a human X-linked recessive disorder caused by mutations in the dystrophin gene. DMD is characterized by a progressive loss of muscle function, leading to death in the early twenties. The relationship between the protein deficiency and the late clinical onset of muscle pathology remains unclear. Several lines of evidence support the hypothesis that cell death of dystrophin deficient muscle might be initiated by apoptosis, followed by necrotic processes. We have been studying the role of proteins that repress apoptosis or/and enhance muscle regeneration for their ability to modulate the dystrophic phenotype in conjunction with gene replacement therapy. We have generated transgenic mice that overexpress ARC, an apoptosis inhibitor, almost exclusively expressed in skeletal muscle and heart. ARC was shown previously to interact selectively with caspases and to prevent hypoxia-induced release of cytochrome c from mitochondria. Morphology studies were performed to determine the level of de- and regeneration of muscle fibers of ARC transgenic/*mdx* mice in comparison with *mdx* controls. Tg/*mdx* mice displayed a clear pattern of *mdx* pathology. We performed immunohistochemistry analysis to compare the level of activated caspase-3 in *mdx* and transgenic/*mdx* muscle and detected no significant difference in the levels of activation. Caspase-3 positive fibers displayed membrane damage as assessed by uptake of the vital dye Evans blue, suggesting apoptotic pathways may be activated as a result of membrane leakage. Together the results suggest that overexpression of ARC does not overtly protect *mdx* muscle from dystrophic pathology. Currently we are investigating if ARC plays an inhibitory role in hypoxia-induced apoptosis in muscle, which might contribute to improved muscle function in less sedentary animals. In a complementary approach, we are examining the role of IGF-I in muscle and its ability to modulate the *mdx* muscle pathology. IGF-I has been shown to enhance muscle regeneration and to prevent age-related declines in muscle mass and function. We have generated adenoviral vectors expressing IGF-I and dystrophin and are studying their effects in preventing and reversing dystrophic pathology in *mdx* mice.

**Response to olanzapine influenced by genes in neurotransmitter receptors.** *M.J. Arranz<sup>1</sup>, S. Staddon<sup>1</sup>, D. Mancama<sup>1</sup>, J. Munro<sup>1</sup>, S. Osborne<sup>1</sup>, M. Beperet<sup>2</sup>, I. Mata<sup>2</sup>, R. Kerwin<sup>1</sup>.* 1) Dept. Psychological Medicine, Institute of Psychiatry, London, England; 2) Fundacion Argibide, Instituto de Salud Mental de Navarra, Pamplona, Spain.

In the last decade pharmacogenetic studies have shown that response to drug treatment can be influenced by genetic variants in target sites. Several studies have shown that polymorphisms in dopaminergic and serotonergic receptors can influence general response to antipsychotics (Arranz et al., 1998; Wong et al., 2000) and development of side effects (Basile et al., 2000). In a previous study we also reported that response to the potent antipsychotic clozapine could be predicted by a combination of polymorphisms in key receptor genes (Arranz et al., 2000). In the present study we report the investigation of the relation of polymorphisms in serotonergic and dopaminergic receptors and response to the atypical antipsychotic olanzapine. A group of 100 patients treated with olanzapine were genotyped for polymorphisms in HTR2A, HTR2C, HTR6, hSERT and DRD3 genes. Genotype and allele distributions between olanzapine responders and non-responders resembled those described for clozapine response. Strong associations were observed between a DRD3 Ser9Gly polymorphism and improvement of positive symptoms particularly in a subgroup of patients of basque origin ( $p < 0.01$ ). In addition, combination of these information resulted in the prediction of olanzapine response with more than 80% success ( $p = 0.04$ ). We are expanding these studies to other antipsychotic drugs in the hope of being able to genetically select the most beneficial drug for each individual even before starting the treatment.

**Aclarubicin stimulates production of full length SMN from the SMN2 gene and restores normal SMN protein levels to cells from type I SMA patients.** *C. Andreassi, D.D. Coover, U.R. Monani, A.H.M. Burghes.* Dept. of Molec. and Cell. Biochemistry and Dept. of Neurology, College of Medicine and Dept. of Molecular Genetics, College of Biological Sciences, The Ohio State University, Columbus, OH.

Proximal spinal muscular atrophy (SMA) is a common autosomal recessive disorder characterized by degeneration of a-motor neurons in the spinal cord. SMA is caused by mutation of the telomeric survival of motor neuron gene SMN1 but not mutation of the centromeric copy SMN2 which is retained in all patients. The SMN1 and SMN2 genes are virtually identical differing functionally by a single nucleotide. This change affects the activity of a splicing enhancer in exon 7. As a result the majority of the transcript from SMN2 lacks exon 7. We have screened a library of compounds in order to identify ones that alter the splicing pattern of the SMN2 gene.

Using a semi-quantitative RT-PCR assay, we show that the compound aclarubicin increases the incorporation of exon 7 into the transcripts from the SMN2 gene in fibroblasts derived from type I SMA patients. This effect is time- and dosage-dependent and it lasts up to 48 hrs from the withdrawal of the drug. Western blot and immunofluorescence analysis demonstrate that SMN protein levels and localization patterns are restored to normal in type I SMA cells after treatment with aclarubicin. We also show that this compound does not alter the splicing pattern of other genes and that this effect is not caused by a stress response on the cells. Serine/arginine-rich (SR) proteins play an important role in constitutive and alternative pre-mRNA splicing. The activity of these proteins is regulated by phosphorylation and we are currently investigating whether the effect of aclarubicin on SMN2 splicing is related to modification of the phosphorylation status of some SR proteins.

To our knowledge no drugs that modulate RNA splicing patterns have been previously reported. Our results suggest that compounds that alter specific splicing patterns of genes may represent a new group of targets for the development of drugs in disease therapy.

**Evaluation of pharmacological therapy in the ALD mouse: reduction of VLCFA levels without increased VLCFA degradation.** *M.C. McGuinness, J.-F. Lu, H.-P. Zhang, K.D. Smith.* Department of Neurogenetics, Kennedy Krieger Institute, Baltimore, MD.

X-linked adrenoleukodystrophy (XALD) is an inherited neurometabolic disease associated with elevated levels of saturated very long chain fatty acids (VLCFA: C>22:0) in plasma and tissues, and reduced peroxisomal VLCFA  $\beta$ -oxidation in fibroblasts, white blood cells and amniocytes from XALD patients. The XALD gene at Xq28 encodes a protein that is related to the ATP-binding cassette (ABC) transmembrane half-transporter proteins. The function of ALDP is unknown and its role in VLCFA accumulation unresolved. In our ALD mouse model, fibroblasts and tissue VLCFA levels are elevated. ALD mouse fibroblast VLCFA  $\beta$ -oxidation activity is reduced, as expected, but ALD mouse tissue  $\beta$ -oxidation activity is normal suggesting that ALDP is not required for VLCFA  $\beta$ -oxidation. We show that: **1)** 4-phenylbutyrate (4PBA), **2)** a structural analog of 4PBA, styrylacetate (SAA), and **3)** a functional analog of 4PBA, trichostatin A (TSA) treatment results in a decrease in VLCFA levels and an increase in VLCFA  $\beta$ -oxidation activity in human and mouse fibroblasts *in vitro*. In addition, we investigate the effect of these drugs *in vivo*: **1)** 4PBA (0.16g/kg/day), **2)** SAA (2.8g/kg/day), and **3)** TSA (3.04mg/kg/day and 0.30mg/kg/day) on both VLCFA accumulation and  $\beta$ -oxidation in ALD mouse liver, brain and adrenals. These pharmacological agents were tolerated well by the mice for up to 20 weeks. We show that each of these treatment regimens results in a decrease in VLCFA levels but has no effect on VLCFA  $\beta$ -oxidation activity providing further evidence that ALDP is not directly involved in VLCFA  $\beta$ -oxidation and that the levels of VLCFA are not determined by the rate of VLCFA  $\beta$ -oxidation. These studies contribute to a better understanding of the role of ALDP in VLCFA accumulation, and may lead to the development of more effective pharmacological therapies for XALD.

**Idebenone reduce cardiac hypertrophy in Friedreich ataxia.** *P. Rustin<sup>1</sup>, A. Munnich<sup>1</sup>, A. Rotig<sup>1</sup>, D. Sidi<sup>2</sup>.* 1) INSERM U-393, Hopital Necker Enfants Malades, Paris, France; 2) Service de Cardiologie Pdiatrique, Service de Cardiologie, Hpital Necker-Enfants Malades, Paris, France.

Friedreich ataxia (FRDA) is an autosomal recessive neurodegenerative disease causing limb and gait ataxia and cardiomyopathy. The disease gene encodes a protein of unknown function, frataxin. The loss of frataxin is due to a large GAA trinucleotide expansion in the first intron of the gene and causes an oxidative stress with a combined deficiency of a Krebs cycle enzyme, aconitase, and three mitochondrial respiratory chain complexes (I-III). Idebenone, a short-chain quinone acting as an antioxidant, has been originally shown to protect heart muscle against oxidative stress (Rustin et al, 1999, Lancet 354:477-9). We have carried out a study in a series of FRDA patients aiming to determine the factors that potentially control the effect of the drug on the left ventricular mass and function. Idebenone (5 mg/kg/day) was given orally to 38 FRDA patients aged 4-22 years (20 boys, 18 girls). Heart ultrasound parameters were recorded on the same scanner prior to and after idebenone treatment. After six months, heart ultrasound indicated a more than 20% reduction of left ventricular mass in about 50% of patients ( $p < 0.001$ ). The shortening fraction first decreased in 6/38 subjects (11-26%) and then improved in 5/6 individuals. In one patient, the shortening fraction only responded to 10 mg/kg/day of idebenone. No correlation between responsiveness to idebenone and age, sex, initial ultrasound parameters or number of GAA repeats in the frataxin gene was found. These data indicate that none of the parameters studied has a predictive value for the effectiveness of the treatment. This suggests that idebenone is worth trying in FRDA patients irrespective of the size of the GAA expansion or the initial ultrasound parameters.

**SMN2 gene stimulations give differential expression in SMA and control cultured cells.** *P. Burlet, E. Vial, L. Violette, C. Huber, A. Munnich, S. Lefebvre.* INSERM U393, IFREM, Hopital Necker Enfant, Paris, France.

The Survival Motor Neuron (SMN1) gene is absent in the majority of patients with Spinal Muscular Atrophy (SMA) and a highly homologous copy (SMN2) is still present. We showed a tight correlation between the SMN2 protein level and the clinical severity, suggesting that SMN2 acts as a major modifier gene. There is no cure for this devastating disease and an attractive therapeutic strategy could be to up-regulate SMN2 gene expression. First, a computer search allowed us to identify several binding sites for transcription factors in the nearly identical SMN1 and SMN2 promoters. By immunoblot analysis, two compounds out of eight triggered a two-fold increase of the SMN protein level in fibroblast and lymphoblastoid cell lines from SMA patients and control individuals. The effects on the SMN protein were further investigated by immunocytochemistry analyses and subcellular fractionation experiments. The SMN protein is located both in the nucleus and in the cytoplasm. Interestingly, one molecule increased the cytoplasmic pool of SMN while the other acted on the nuclear pool. The role of the different subcellular fractions of the SMN protein and which altered compartment is responsible for SMA is still poorly understood. The current study should help at identifying which SMN pool is the most relevant when screening pharmacological molecules in order to find a treatment for SMA.

**System analysis of the energies of the triple base triplets.** *S.Q. Liu<sup>1</sup>, J. Yang<sup>1</sup>, C.L. Bai<sup>2</sup>, C.Q. Liu<sup>1</sup>*. 1) Laboratory of cellular and molecular evolution, Kunming Institute of Zoology, Chinese Academy of Sciences, Kunming YN, 650223, P. R. China; 2) Chemistry Institute, Chinese Academy of Science, Beijing, 100081, P. R. China.

The oligodeoxyribonucleic acid (ODN) directed triple helix formation could be used to control transcription, DNA replication, and recombination, it has widely been applied in therapeutics, diagnostics and antigene strategy. TBT is a kind of structural constituent of triplex DNA. It contains three deoxyribonucleic acid strands; each of them comprises three bases (a codon). The TBT can be observed as three layers of base triplets. 64 sets of 3D models of DNA triplex base triplets were built by homologous modeling method. According to the nucleotide sequence of TBT is symmetric or asymmetric, and the orientations of the third ODN strand binding to target duplex DNA in parallel or antiparallel direction, the 4 groups of energy data of monomers and water-K<sup>+</sup>-TBT ternary complexes of TBT were calculated and analyzed. The results showed: i. the energies of the symmetric parallel ternary complexes of TBT are higher than those of the symmetric antiparallel ternary complexes of TBT; ii. No matter TBTs are monomers or ternary complexes, the energies of asymmetrical parallel TBTs are generally lower than those of the asymmetrical antiparallel TBTs; iii. The duplex DNA of which any strand contains at least a couple of A or T has a preference for selecting the ODN strand containing abundant T to form TBT. iv. The duplex of which any strand contains at least a couple of G or C has a preference for selecting ODN containing abundant G to form symmetric antiparallel TBT, but selecting ODN containing abundant C to form asymmetric parallel TBT. v. The duplex of which any strand contains only one of A, T, G or C has a preference for selecting ODN containing at least a couple of pyrimidines to form antiparallel TBT. our result suggests the sequences of the TBTs and the orientations of the third ODN strands are two of key factors that can influence formation and stability of TBT, it provides directive significance for designing ODN strand in the fields of therapeutics and antigene drug design.

**Construction and Characterization of a replication competent Retroviral Shuttle Vector.** *J. Oh, S.H. Hughes.* HIV Drug Resistance Program, NCI at Frederick, Frederick, MD.

We constructed a RCAS-based retroviral shuttle vector, RSVP (RCAS Shuttle Vector Plasmid), containing either the zeocin or blasticidin resistance gene. In this vector, the drug resistance gene is expressed in avian cells from the LTR promoter, whereas in bacteria the same gene is expressed from a bacterial promoter. The vector contains a bacterial origin of replication (ColE1) to allow replication in bacteria. The vector also contains the lac operator sequence, which binds to the lac repressor protein allowing simple and rapid purification of the vector DNA. Plasmid RSVP, therefore, contains the following sequence: 5'(LTR, gag, pol, env, drug resistance gene, lac operator, ColE1, LTR) 3'. After this vector was transfected into DF-1 cells, we were able to rescue the circularized unintegrated viral DNA from RSVP simply by transforming the HIRT DNA into *E. coli* cells. Furthermore, we were able to rescue the integrated viral DNA. DNA from infected cells was digested with an appropriate restriction enzyme (ClaI) and the vector containing segments were enriched using lac repressor protein and then self ligated. These enriched fractions were used to transform *E. coli*. The vector is relatively stable upon passage in avian cells. Southern Blot analyses of genomic DNAs derived from several viral passages under selective or nonselective conditions showed that the cassette (drug resistance gene-lac operator-ColE1) insert was present in the vector up to third viral passage for both drugs, which suggests that the RSVP vector is stable for approximately 3 viral passages. Together, these results showed that RSVP vector is useful tool for cloning unintegrated or integrated viral DNAs.

**Adenoviral Vector Systems for Delivery of Dystrophin cDNA Expression Constructs to Mouse Skeletal Muscle.**

*J.M. Scott, D.J. Hartigan-O'Connor, C. Barjot, S.Q. Harper, A.S. Robinson, C. DelloRusso, R.W. Crawford, J.S. Chamberlain.* Neurology, University of Washington, Seattle, WA.

Gene therapy using viral vectors holds promise for several human genetic diseases but much remains to be learned about which vector system will meet all of the requirements of such a treatment. Our laboratory has focused on modification of adenoviral (Ad) vectors in order to improve the efficiency of delivering expression constructs to skeletal muscle with respect to transgene expression levels, persistence, immune response, and tissue-specific vs. constitutive promoters. Improvements in first generation Ad vectors that carry mini-dystrophin cassettes was achieved by deleting the viral polymerase gene which rendered the vector replication defective and eliminated viral late gene expression in transduced cells. We have also made gutted Ad vectors lacking all viral ORFs, and adeno-associated virus (AAV) containing a micro-dystrophin expression cassette. These systems are compared using the *mdx* mouse model of Duchenne muscular dystrophy whereby skeletal muscle is injected and assays are performed to evaluate dystrophin protein expression levels, persistence of the transgene, immune cell infiltration, and integrity of the muscle fiber membranes. Our results indicate that gutted Ad vectors containing a dystrophin expression cassette driven by a strong muscle-specific promoter (modified MCK) lead to significantly increased transgene expression and decreased immune response compared to the first generation viruses. We find that the MCK promoter is highly effective in reducing the antigen-specific immune response against Ad vectors despite the muscle cell death and antigen-presenting cell infiltration in dystrophic muscle. A gutted Ad vector expressing full-length utrophin is also being compared with the dystrophin vector for function, persistence and immunogenicity. Additional improvements have been noted using an AAV vector which exhibits robust expression of dystrophin and even less immune response than that elicited by Ad vectors. These results show that modified Ad and AAV vectors can lead to significant and prolonged gene expression in dystrophic muscle.
