The American Society of Human Genetics (ASHG) hosted a first-annual, full-day Undergraduate Genetics Education workshop at the 2006 Annual meeting in New Orleans, LA. Biology faculty at undergraduate institutions surrounding the New Orleans area and ASHG members whose primary role is self-reported as teaching were recruited to attend. The workshop presented teaching techniques and genetic information that can contribute to effective teaching of genetics to undergraduate students. Assessment of the workshops immediate and long-term impact was an important goal. This was accomplished by 1) collecting anonymous feedback from participants at the end of the workshop and 2) collecting pre- and post-workshop survey data from those who attended. Pre-workshop data were obtained from 47 pre-registrants. Only 30 (64%) of these pre-registrants attended, and of these, 26 (87%) completed an anonymous paper-based survey following the workshop, which assessed its immediate impact. Eighty-one % (n=21) reported that their expectations for the workshop were met and 92% (n=24) reported they will implement some aspect of the workshop in their future teaching plans. Post-workshop data were collected at the end of the 2006-07 academic year to determine the degree of implementation of workshop material. Only 14 participants (47%) completed both the pre- and post-workshop surveys and these data are currently being analyzed to assess its longer-term impact. Additionally, data regarding its impact on student learning using a recently developed Genetics Literacy Concept Inventory have been collected from classes taught by four of the workshop participants.

Based on immediate, anonymous participant feedback and preliminary data analyses from the pre- and post-workshop surveys, the workshop was successful; it met participant expectations and nearly all participants reported intent to use some of the material in their own teaching. This is important for how the teaching of genetics and student learning might be improved, and as encouragement for future workshops. However, further analysis and additional data will be needed to fully assess the longer-term value.

Epistatic interaction between REST and BDNF is associated with cognitive functioning. *F. Miyajima[1], J. Quinn[2], N. Pendleton[3], M. Horan[3], W. Ollier[1], A. Payton[1]* 1) CIGMR, University of Manchester, Manchester, UK; 2) Neurotransmitter Biology Group, University of Liverpool, Liverpool, UK; 3) Clinical Gerontology, University of Manchester, Manchester, UK.

INTRODUCTION: Brain-derived neurotrophic factor (BDNF) is a pleiotrophic protein involved in neuronal proliferation, differentiation, synaptic plasticity and survival. Independent studies investigating association between the Val66Met and cognitive function have reported conflicting findings which may reflect additional polymorphic regulatory factors other than the Val66Met polymorphism which contribute towards overall gene expression. One of these factors is the RE1-silencing transcription factor (REST) which down-regulates BDNF expression. METHODS: We have looked for possible associations between several polymorphisms within the REST gene and cognitive abilities using a cohort of 746 community-dwelling older volunteers who have been followed-up for changes in cognitive performance at five year intervals for up to twenty years. RESULTS: We have identified a 3-locus haplotype located within the proline-rich domain not yet characterised. This contained a hexadecapeptide polymorphic motif with either four or five copies. Volunteers homozygous for the five repeat allele scored lower on all cognitive tests, reaching significance for the two tests of fluid intelligence (Heim part1, p=0.025 and Heim part2, p=0.032). Interaction analysis between the BDNF Val66Met and the REST VNTR revealed positive associations with all cognitive tests, except semantic memory. When the combined analysis was covariated with the general common factor, a significant global p-value was obtained following 10,000 shuffled permutations (p=0.0002). In contrast to the cross-sectional analysis, no significant results were observed in the longitudinal assessment. We are pursuing further confirmation of these findings in a sample of 1,400 subjects using a string of multidisciplinary approaches. CONCLUSION: Our results suggest that investigation of these polymorphisms in combination may reduce inconsistencies currently plaguing the literature, highlighting how a full appreciation of epigenetics is missing from our understanding.

Characterization of Pathogenic Huntingtin Fragments. *L. R. Smith[1,2], S. H. Li[1], X. J. Li[1]* 1) Department of Human Genetics, Emory University School of Medicine, Atlanta, GA; 2) Graduate Program in Genetics and Molecular Biology, Emory University, Atlanta, GA.

Huntingtons Disease (HD) is a dominantly inherited, late-onset neurodegenerative disorder characterized by the expansion of a polyglutamine (polyQ) repeat located in the N-terminal region of the huntingtin (htt) protein. Wild-type htt consists of less than 36 glutamine repeats whereas the mutant version of the protein has an expanded polyQ repeat of greater than 37 glutamines. Mutant htt shows nuclear accumulation and affects gene transcription whereas wild type htt largely remains cytoplasmic. It is evident that full-length htt is cleaved to a number of N-terminal fragments containing the polyQ domain. Previous studies have shown that small N-terminal htt fragments enter the nucleus more easily than full length htt. The size of the N-terminus of the pathogenic fragments that are able to accumulate in the nucleus, however, is unknown. To address this issue, we have generated various truncated mutant and wild type htt constructs with varying N-terminal lengths (212, 300 and 500 amino acids) that are tagged at the C-terminus with an HA tag. Using immunocytochemistry and nuclear fractionation methods, we have analyzed the localization of these various constructs as compared to the shorter N-terminal exon 1 fragment consisting of 67 amino acids. We have found that the small N-terminal htt fragments less than 212 amino acids are likely to accumulate in the nuclei. Characterization of the nuclear localization of these htt fragments will elucidate how the size of htt fragments influences their nuclear localization and nuclear effect on gene transcription.

Supported by NIH grants NS 045016 and NS41669.

Novel *HEY2* mutations in patients with left sided cardiac defects. *P.C. Paluru[1], N. Navabi[2], J. Garbarini[1], E. Goldmuntz[1, 2]* 1) Division of Cardiology, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) University of Pennsylvania, Philadelphia, PA.

The hairy/enhancer of split-related with YRPW motif (*HEY2*) gene plays an important role in mammalian heart development. Mice lacking *Hey2* expression exhibit several types of congenital heart defects. *HEY2* is an established downstream target gene for the Notch signaling cascade and functions as a repressor through its basic helix loop helix (bHLH) DNA binding domain. Because *NOTCH1* mutations have been found in humans with aortic valve disease, we hypothesized that mutations in *HEY2* would be found in patients with similar heart malformations. *HEY2* contains 5 exons encoding a protein of 337 residues. By direct sequencing we analyzed the coding region of the human *HEY2* gene in 289 unrelated subjects for mutations including: 66 with valvar aortic stenosis (AS), 105 with coarctation of the aorta (CoA), 18 with coarctation of the aorta and ventricular septal defect (CoA/VSD), and 100 with hypoplastic left heart syndrome (HLHS). Four nonsynonymous mutations were identified in six patients, of which three had AS and three had CoA. No mutations were found in the cohort with HLHS. These novel mutations were not observed in public SNP databases or in 200 ethnically matched control samples. Two of the unique mutations map into the bHLH domain and one in the conserved orange domain. In addition, five silent mutations and multiple known polymorphisms were seen in the patient cohort. Further studies are required to investigate the effects of these mutations on protein function. This study suggests that *HEY2* may be an important disease gene for valvar AS and CoA and further implicates the Notch signalling pathway in cardiovascular disease.

Evidence of genetic heterogeneity for Primary Ciliary Dyskinesia in an inbred Amish-Mennonite community.

M.A. Zariwala[1], M.W. Leigh[1], H. Lie[2], A. Lori[1], R. Herrin[2], A. Bowcock[2], T. Ferkol[2], M.R. Knowles[1] 1) Department of Pathology, Medicine, and Pediatrics, University of North Carolina, Chapel Hill, NC; 2) Department of Pediatrics and Genetics, Washington University, St. Louis, MO.

Primary ciliary dyskinesia (PCD) is genetically heterogeneous, autosomal recessive trait with impaired mucociliary clearance leading to sino-pulmonary disease and situs inversus in half of the patients (termed Kartagener syndrome). Ciliary ultrastructural analysis in most patients reveals defective outer dynein arms (ODA). Mutations in *DNAI1* and *DNAH5* (encode intermediate and heavy chain dyneins of ODA respectively) have been identified in 38% of PCD patients. We discovered an increased frequency of PCD in an inbred Amish-Mennonite community in Missouri and suspect that this population is enriched with novel disease-causing mutations. We identified nine patients (with seven sub-families) with an unequivocal diagnosis of PCD based on clinical evaluation and defective ODA. Majority of patients from this community could be traced back to two couples from the initial founders. Mutation analysis was carried out for known mutations in *DNAI1* and *DNAH5*. Three affected patients from three sub-families were heterozygous for *DNAI1* (IVS1+2_3insT) mutation, but full coding gene sequencing did not reveal the second mutant allele. Haplotype analysis of *DNAI1* using intragenic SNP and microsatellite markers showed no evidence of concordance for the second allele in any of these patients, implicating another gene as causative. Another sub-family harbored a monoalleliec *DNAH5* (10815delT) mutation in two affected sibs, and haplotype sharing at DNAH5 locus in both affected sibs suggests second mutant allele; full sequencing of *DNAH5* is underway. Analyses of several intragenic SNP and/or microsatellite genotyping confirmed that *DNAI1* and *DNAH5* and seven other candidate genes (*DNAH11*, *DNAH7*, *DNAH9*, *DNAI2*, *DNAL4*, *DNAH3* and *TCTEL1*) were not linked to PCD. In conclusion, we detected mutations in two genes in inbred Amish-Mennonite cohort. Additionally, there is an evidence for another mutation in *DNAH5*, plus, a novel gene. Supported by GCRC00046, MO1 RR00046-42, RO1 HL071798 (NHLBI), 5U54 RR019480 NCRR) and R21 HL07024.

Mutations of *FOG2* gene in patients with septal and conotruncal defects. *D.Y. Gibbs[1], P.C. Paluru[1], S. Woyciechowski[1], E. Goldmuntz[1, 2]* 1) Division of Cardiology, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) University of Pennsylvania, Philadelphia, PA.

Friend of *GATA2* is a zinc finger protein (*ZFPM2/FOG2*) expressed during early heart development which acts as a co-regulator of the transcription factor *GATA4*. Disease related mutations of *GATA4* and its molecular partner *NKX2.5* have been identified in patients with congenital heart defects. Studies in the mouse suggest an important role for *FOG2* in cardiac development. We hypothesized that patients with septal and conotruncal defects might have mutations in *FOG2*. The *ZFPM2/FOG2* gene maps to 8q23 and contains 9 exons encoding a protein of 1151 residues. We sequenced the coding region of *FOG2* for sequence variants in 494 patients with septal and conotruncal heart defects (97-double outlet right ventricle, 100-D-transposition of great arteries, 98-tetralogy of Fallot, 12-interrupted aortic arch, 29-truncus arteriosus, 63-ventricular septal defect, and 95-atrial septal defect). A total of twelve novel missense mutations were identified in 20 unrelated subjects, which were absent in 200 ethnically matched control samples and public databases. One mutation maps into the third zinc finger domain. Though the other mutations map outside of known conserved domains, seven of them alter amino acids conserved across all species including zebrafish, and four alter aminoacids conserved across all species other than zebrafish. The etiologic role of the novel mutations remains unclear. Functional analysis is needed in order to characterize these mutations and establish their role in altering the structure and function of the protein.

Multifactor Dimensionality Reduction 1.0. *J.H. Moore, B.C. White, N. Barney* Deptartment of Genetics, Dartmouth Medical School, Lebanon, NH.

Multifactor Dimensionality Reduction (MDR) was developed as a computational alternative to parametric statistical methods for detecting, characterizing and interpreting epistasis in genetic studies of common human diseases. MDR uses a constructive induction approach to change the representation space of the data to make interactions easier to detect using classification methods such as naive Bayes or logistic regression. Our goal was to make MDR available to the human genetics community for both applied and theoretical studies through a software package that is open-source, freely-available, user-friendly, and platform-independent. We released the first beta version of MDR in February of 2005 and made it freely available for download via the popular Sourceforge.net website. We describe here a mature version 1.0 of the MDR software that is the result of more than three years of development and testing. The MDR software has been downloaded more than 10,000 times placing it in the top 40 from more than 1,000 bioinformatics software packages maintained on Sourceforge.net. PubMed lists more than 100 published papers with MDR in the title or abstract making it one of the more commonly applied methods for detecting gene-gene interactions. An advantage of MDR is that it can detect epistasis in the absence of main effects. The MDR software provides powerful analytical methods that embrace, rather than ignore, the complexity of the genotype-phenotype mapping relationship that underlies a variety of commun human diseases.

Validation of single nucleotide polymorphism (SNP) array technique in 31 probands with chromosomal anomalies. *G.H. Thomas[1,2], E. Squibb[1], E. Lisi[2], A. Hamosh[2], K. Doheny[2], K. Hetrick[2], D. Valle[2], J. Pevsner[1], J.E. Hoover-Fong[2]* 1) Kennedy Krieger Institute, Baltimore, MD; 2) McKusick-Nathans Institute of Genetic Medicine, Baltimore, MD.

Objective: Our objectives were to 1: evaluate whole genome SNP genotyping to detect and define chromosomal abnormalities diagnosed by G-band karyotype or fluorescence in situ hybridization (FISH), and 2: determine the frequency and significance of previously undetected copy number variants (CNVs) in these subjects. Methods: Amplified gDNA from 60 individuals was hybridized to the Illumina HumanHap550 SNP genotyping array platform (~1 SNP/5kb). 31 probands with known chromosomal anomalies (i.e. deletion=20, duplication=4, complex deletion/duplication=2, unbalanced translocation=3, ring=1, aneuploidy=1) were analyzed. 29 relatives (26 parents, 2 children, and 1 sibling) of 17 probands were also studied. Results: We identified all previously detected cytogenetic anomalies in the 31 probands. The SNP analysis more precisely defined the location and nature (i.e. presence/absence of low copy repeats) of the breakpoints involved in these alterations. Compared to their familial proband, 23 of 29 relatives did not have the same SNP anomaly, while 6 of 29 (3 parents, 2 children, 1 sibling) did. A large number of previously undetected CNVs were also identified in all 60 subjects. Conclusion: The Illumina HumanHap550 SNP array platform had 100% sensitivity to detect all previously recognized chromosomal anomalies in these 31 probands. Many additional CNVs of uncertain significance were also detected in all subjects, including phenotypically normal relatives. Consideration of parental SNP array results and phenotype with that of their dysmorphic/mentally retarded child is essential to determine which de novo CNVs are potentially related to the probands phenotype. As SNP array resolution continues to increase and this technology becomes standard of care in the clinical setting, we must be cautious and diligent in our interpretation of the meaning of CNVs and their potential role in the continuum between disease and normal variation.

Integrated epigenomic analyses of neuronal MeCP2 reveal a role for long-range regulation of active genes. *S. Peddada[1], D.H. Yasui[1], M.C. Bieda[2], R.O. Vallero[1], A. Hogart[1], R.P. Nagarajan[1], K.N. Thatcher[1], P.J. Farnham[2], J.M. LaSalle[1]* 1) Medical Microbiology and Immunology and Rowe Program in Human Genetics, School of Medicine, University of California, Davis, CA; 2) Department of Pharmacology and Genome Center, School of Medicine, University of California, Davis, CA.

Mutations in *MECP2* cause the autism-spectrum disorder Rett syndrome. MeCP2 is predicted to bind methylated promoters and silence transcription. Contrary to this model, the first large-scale mapping of neuronal MeCP2 binding sites on 26.3 Mb of target imprinted and non-imprinted loci revealed that 59% of MeCP2 binding sites are outside of genes and only 5.9% are in CpG islands. Furthermore, integrated genome-wide promoter analysis of MeCP2 binding, CpG methylation, and gene expression revealed that 66% of MeCP2-bound promoters are actively expressed and only 6% are highly methylated. *JUNB*, an immediate early gene relevant to the pathogenesis of Rett syndrome, is one example of a highly active gene whose expression is modulated by distal and proximal binding to a partially methylated promoter. Therefore, these results support a predominant role for MeCP2 as a long-range modulator rather than a proximal silencer of gene expression.

Clinical Genetic Approach for Evaluation of Noncompaction Cardiomyopathy. *M.V. Zaragoza, R. Cox* Center for Molecular and Mitochondrial Medicine and Genetics and the Dept of Pediatrics, Division of Genetics and Metabolism, University of California, Irvine.

Noncompaction of the ventricular myocardium is a primary genetic cardiomyopathy characterized by prominent trabeculae and deep intertrabecular recesses in the myocardial wall. Noncompaction cardiomyopathy is thought to arise from a block in the embryonic process in which myofibrils compact during cardiogenesis. This is thought to result in the characteristic two layers consisting of compacted and noncompacted myocardium. Clinical manifestations are variable; patients may develop ventricular dysfunction, heart failure, arrhythmia or complications due to thromboembolism whereas others remain asymptomatic. The genetic etiology of noncompaction is heterogeneous. Mutations in *TAZ* on Xq28, *DTNA* on 18q12.1, *LDB3* on 10q23.2 and *LMNA* on 1q22 have been described in patients; genetic linkage to 11p15 has been reported in a single family. This report describes the clinical genetic approach for the evaluation of a two year-old girl who presented with new onset heart failure. Since noncompaction cardiomyopathy may be isolated or found as a feature of a genetic syndrome, clinical genetic examination is important and there are limited guidelines specifying how it should proceed. As illustrated in this report, noncompaction cardiomyopathy can be familial. The patient's family history revealed variable features of presentation of affected individuals and multiple family members at increased risk for inheriting the condition. Thus, we emphasize that clinical genetic examination, detailed pedigree analysis and cardiac screening of at least all first-degree relatives are essential in the evaluation of patients with noncompaction cardiomyopathy.

Fine-mapping of chromosome 19 for total cholesterol levels in Pima Indians. *A. Malhotra[1,2], C.N. LeClair[2], H.C. Looker[1,3], K.A. Yeatts[2], W.C. Knowler[1], R.L. Hanson[1], J.K. Wolford[2]* 1) Diabetes Epidemiology and Clinical Research Section, NIDDK, Phoenix, AZ; 2) Diabetes, Cardiovascular & Metabolic Diseases Division, TGen, Phoenix, AZ; 3) Endocrinology, Diabetes and Bone Disease Division, MSSM, New York, NY.

Abnormal lipid levels are a major risk factor for coronary heart disease, which is highly prevalent in the general population. While environmental factors such as poor diet and lack of exercise contribute to abnormal lipid levels, genetic factors also play a role. In a previous study, a genome scan of lipid levels in 998 Pima Indian sibling pairs showed evidence for linkage for total cholesterol levels on chromosome 19 (peak LOD score=3.68 at 19.5 cM with a 1-LOD support interval spanning 17-41 cM). To fine-map the region of linkage where a gene affecting cholesterol levels might reside, we identified and genotyped 346 SNPs approximately 150 kb apart under the linkage peak. Upon removal of genotyping errors and creation of a linkage map using CRIMAP, we performed variance components linkage analysis as implemented in the program Merlin, for a combined map with both the original microsatellite markers and the SNPs. This analysis reduced the size of the linkage interval by 9 cM with a 1-LOD support interval spanning 28-43 cM and also showed a slight increase in peak LOD score (3.71 at 34.4 cM) when compared to the results from the original genome-scan (microsatellite markers only). These results provide finer localization of the locus on 19p affecting cholesterol levels. Furthermore, the results show the utility of using a dense map of SNP makers in substantially narrowing a region for linkage to be followed up for future gene-based studies.

Construction of a SNP-Associated, Mitochondrial Haplogroup Database. *E.L. Stevens, R.I. Sanchez, M.V. Osier, D.L. Newman* Biological Sciences, Rochester Institute of Technology, Rochester, NY.

The 16.5 kb mitochondrial (mt) genome contains thousands of SNPs due to its high mutation rate. A subset of these SNPs have been used to define haplogroups that correlate with populations and are used to study population genetics, ancient human migrations, and disease associations. Much literature has been published that associates certain alleles with one or more haplogroups, but the public databases (e.g. Mitomap) do not associate particular SNPs with specific haplogroups. We are constructing a searchable, Web-based database that links SNP alleles with observed haplogroups and the location/functional consequences of each variant. We have already begun to populate the database using data gathered from literature and online databases to create a user-friendly, publicly accessible database. We are also adding information from our own research and will accept contributions from other investigators. The database includes links to references that document the sources of information. We have begun with the European haplogroups (H, I, J, K, T, U, V, W, X) but eventually plan to include all haplogroups. A search tool will enable the user to determine all alleles that have been associated with any particular haplogroup or sub-haplogroup, or to determine which haplogroups or sub-haplogroups are known to be associated with any particular SNP allele (note that not every SNP allele belongs exclusively to a single haplogroup). This information will be useful to researchers investigating inherited diseases associated with the mt genome. For example, if members of a certain haplogroup had increased susceptibility to a disease, this tool would be useful for quickly identifying candidate loci to investigate for potential functional consequences in the development of the disease.

The use of focus groups to increase participation when conducting epidemiologic studies that include a genetic component. *D.M. Williamson[1], L. Wagner[2], J. Henry[3]* 1) Division of Reproductive Health, CDC, Atlanta, GA; 2) Texas Department of State Health Services, Austin, TX; 3) Texas Department of Family and Protective Services, Austin, TX.

Participation in epidemiologic studies can be enhanced or diminished based on the study participants perception, knowledge and understanding of genetic testing. To address these issues, focus groups were convened to gain an understanding of risk perceptions and identify potential barriers to study participation in a case-control study examining the joint role of environmental exposures and candidate genes as potential risk factors of multiple sclerosis (MS). Individuals with MS, identified in a previous cluster study, were invited to participate in the focus group discussions. Participants were asked to provide comments regarding the proposed case-control study goals, recruitment methods, questionnaire topics, specimen collection and dissemination of results. A total of 9 individuals participated in the focus group discussion. The majority of participants (n=8, 89%) were female. Focus group participants expressed interest in participating in the case-control study. Participants stated they would be willing to provide a blood sample for the study. Participants expressed concern about the confidentiality of the results from the genetic testing and that the results would not be provided to them. Comments received from focus group participants were incorporated into the study protocol including study materials, questionnaire and obtaining a blood sample. Revised documents were sent to those participants who agreed to pilot test the materials. The proposed questionnaire was administered over the phone, additional areas needing improvement were noted, and the questionnaire modified accordingly. Focus groups can provide investigators with an opportunity to pilot their study protocol and materials before going into the field. This allows problems to be identified and corrected before recruitment begins. It also allows investigators the opportunity to modify/adjust protocols and materials to effectively meet the needs of potential study participants and promote participation.

Further evaluations of the NLGN3 and NLGN4 genes including a novel bioinformatic approach in autistic females with X inactivation skewness. *Z. Talebizadeh, M.F. Theodoro, M.G. Butler* Section of Medical Genetics, Children's Mercy Hospital and Clinics and University of Missouri-Kansas City, MO.

We previously reported two novel splice isoforms in X-linked neuroligins, NLGN3 and NLGN4, with a potential role in the etiology of autism spectrum disorders (ASD). The objective of our current study is: 1) to perform mutation screening for NLGN3 and NLGN4 genes in additional autistic females with X inactivation skewness, and 2) to evaluate potential regulatory sequences influencing mRNA splicing. Autistic females were ascertained from the AGRE. X inactivation status was determined using the AR assay on genomic DNA from peripheral blood. Subsequently, cDNA from lymphoblastoid cell lines was used for mutation screening. Sequence alignments and a novel bioinformatic approach were applied to identify potential regulatory elements. X inactivation skewness was confirmed for a group of 10 of 30 autistic females. No new mutation was detected in the NLGN4 gene; however, our previous study identified a NLGN4 transcript missing exon 4 in one autistic female. For NLGN3, RT-PCR screening confirmed that exons 3 and 4 are subject to alternative splicing resulting in an in-frame inclusion or exclusion of 20 amino acids for each of these two exons. In addition, we isolated a novel NLGN3 transcript with intron 2 retention adding 639 nt and introducing an early stop codon. Intron retention (IR) is a very rare form of alternative splicing and recent bioinformatic analyses suggest that specific sequence motifs such as intronic Gs may play a role in IR. We are examining sequence of intron 2 to identify factors contributing to its inclusion during mRNA processing. Furthermore, quantitative RT-PCR is underway to evaluate expression levels of the NLGN3 transcript with IR in autism compared with controls. As susceptibility genes for autism, it is important to understand the role of alternative splicing and contributing factors for the neuroligin genes. Our study suggests that cis or trans-acting elements are likely to play a crucial role in regulating formation of the observed alternative splicing (exon skipping and IR) in NLGN3 and NLGN4 genes impacting on encoded proteins in autistic subjects.

Genetic locus associated with white blood cell count in the Health, Aging, and Body Composition Study. *M.A. Nalls[1], J.G. Wilson[2], N.J. Patterson[3], A. Tandon[3], J. Zmuda[4], S. Huntsman[5], D. Hu[5], B. Beamer[6], K. Patel[1], J. Files[2], M. Akylbekova[2], C. Hardy[2], H. Taylor[2], D. Reich[3], T.B. Harris[1], E. Ziv[5]* 1) L.E.D.B., National Institute on Aging, Bethesda, MD; 2) Jackson Heart Study, Jackson, MS; 3) Broad Institute of Harvard and MIT, Cambridge, MA; 4) Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 5) Department of Medicine, University of California-San Fransisco, San Fransisco, CA; 6) Division of Geriatric Medicine, Johns Hopkins University, Baltimore, MD.

Background: White blood cell count (WBC) is an important clinical marker that varies among different racial/ethnic groups. African Americans are known to have lower WBC than European Americans. We surveyed the entire genome for loci underlying this difference in WBC using admixture mapping, taking advantage of the fact that African Americans are a population with West African and European ancestry. **Methods:** We analyzed data from African American participants in the Health, Aging, and Body Composition Study. All 863 individuals were genotyped at 1322 single nucleotide polymorphisms that were pre-selected to be informative for African vs. European ancestry and span the entire genome. We used the markers to estimate genetic ancestry in each chromosomal region and then tested the association between WBC and genetic ancestry at each locus. **Results:** We found a locus on chromosome 1q strongly associated with WBC levels ($p10^{-42}$). The strongest association was with a marker known to affect the expression of the Duffy blood group antigen. Participants who had both copies of the common West African allele had mean WBC of 4.9 (SD 1.3); participants who had both copies the common European allele had mean WBC of 7.1 (SD 1.3). This allele explained ~20% of the variation in WBC. **Conclusions:** We used admixture mapping, a novel method for conducting genetic association studies, to find a region on chromosome 1q that was significantly associated with WBC. Additional studies are needed to determine the biological mechanism of this effect and its clinical implications.

Dopamine Related Genes in Autism. *N. Schnetz-Boutaud[1], B.M. Anderson[1], M.L. Summar[1], J. Bartlett[1], M. Cuccaro[2], J.R. Gilbert[2], M.A. Pericak-Vance[2], J.L. Haines[1]* 1) Center for Human Genetic Research, Vanderbilt Univ, Nashville, TN; 2) Miami Institute for Human Genomics, Miami, FL.

Introduction: Autism is a severe neurodevelopmental disorder with a strong genetic component. Despite numerous genome screens and individual candidate gene studies, the underlying genetic etiology remains largely unknown. Increasing evidence suggests that autism is more genetically complex than previously thought, and that single gene approaches toward dissecting autism genetics may not be informative. We are taking the alternative approach of testing for interactive effects of multiple genes within the dopamine pathway. Methods: We tested 60 SNPs within 14 different genes related to dopamine including DRD1, DRD2, DRD3, DRD4, DRD5, DBH, YWHAB, and COMT. SNPs were chosen to represent the linkage disequilibrium patterns across each gene, and included when possible common coding variants. The dataset consists of over 345 multiplex families and 292 parent-child trios collected at two centers in the southeast United States. Initial analyses included single locus family-based association tests, considering both parental and proband gender. Subsequent analyses examined explicitly for gene-gene interactions using multifactor dimensionality reduction (MDR). Results: Single locus analyses generated marginally significant results for YWHAB and DBH. However, these did not survive correction for multiple comparisons. Preliminary two-way interaction analysis with MDR did not identify any significant interactive effects; higher-order interaction analyses are ongoing. Conclusions: As expected, none of the tested genes generated significant results when considered individually. The lack of a strong two-locus interactive effect suggests that either interactions among these genes do not exert a strong effect on autism, or the effect requires a higher order interaction.

Large-scale screening of X-linked synaptic genes in Tourette Syndrome cases. *J-B. Rivière[1], A. Piton[1], J. Gauthier[1], R. Joober[2], Y. Dion[3], G. Tellier[4], P. Lespérance[1], S. Chouinard[1,4], F. Richer[1], G.A. Rouleau[1,4]* 1) Centre for the Study of Brain Disease, CHUM Research Centre, Montreal, Quebec, Canada; 2) Douglas Hospital Research Centre, Montreal, Quebec, Canada; 3) McGill University Health Centre, Montreal, Quebec, Canada; 4) Sainte Justine Hospital, Montreal, Quebec, Canada.

Tourette Syndrome (TS) is a complex neurodevelopmental disorder with a strong genetic component often associated with various behavioral abnormalities such as obsessive-compulsive disorder (OCD) and attention deficit-hyperactivity disorder (ADHD). Decades of classical genetic studies in TS and other complex neurological disorders have had limited success in the identification of susceptibility genes, highlighting the necessity of new genetic approaches. Various evidence support an implication of X-linked genes in TS, and mutations in synaptic genes may account for the genetic predisposition in a significant proportion of TS cases. We therefore decided to directly sequence X-linked genes coding for synaptic proteins in 96 French-Canadian TS patients selected according to their familial history (including only families with a possible X-linked inheritance). Based on various methods and databases, we catalogued all the known genes potentially coding for synaptic proteins on the X chromosome. We selected more than 100 genes that are currently being screened according to several criteria including expression in brain tissues, involvement in synaptogenesis, animal models showing neurobehavioral abnormalities, association with related diseases, etc. We expect to identify several potentially functional variants that will be further investigated. Genetic validation will include functional prediction, screening of additional TS cases and unaffected controls, cosegregation analysis in TS families as well as association studies with potential sub-phenotypes (OCD, ADHD, anxiety, sleep disturbances, etc.). By the end of this study, we expect to identify several susceptibility genes for TS and its related comorbidities.

Collecting Family History of Cancer in a Primary Care Setting from a Middle-Income Country. *M.F. Prearo[1], M. Floria-Santos[1], E.M.M. Santos[2], L.M. Alvarenga[1], C.M. Cenzi[1]* 1) University of São Paulo at Ribeirão Preto College of Nursing, Department of Maternal-Child Nursing and Public Health, SP, Brazil; 2) Cancer Hospital A.C. Camargo, SP, Brazil.

Introduction: This study presents the first step of a broad project which aims to show the importance of family history collection to know the risk for hereditary and familial cancers in families attended by the Family Health Program in a Middle-Income country. This program is a governmental initiative established to ensure medical attention on a community-based approach to vulnerable populations, who had been neglected under an earlier strategy that emphasized hospital care. Methods: This is a descriptive exploratory study with a quantitative approach, where approximately 5,000 familial medical records will be searched for cancer registries. Families with cancer will be visited and interviewed, using structured questionnaire and pedigree. Tumors will be classified as sporadic, familial or hereditary, and qualitative risk assessment will be conducted for family members. Results: So far, we analyzed 670 familial medical records, 15% had cancer registries of breast (19%), skin (12%), head/neck (12%), colorectal (11%), uterus (7%), and prostate (6%) among others. Discussion: This study can provide resources to planning actions for early diagnosis and cancer prevention to low-income families in urban centers. Also, can aware those people regarding family health history as a risk factor of cancer and other diseases, improving prevention and health promotion.

siRNA-mediated suppression of wildtype and low molecular weight forms of cyclin E protein in NIH-OVCAR-3 ovarian cancer cells. *M.C. Todd, K. Meerbrey* Biology Department, Southwestern University, Georgetown, TX.

The mutually exclusive loss of the G1 cell cycle regulatory proteins, RB or p16, appears to play a role in the development of the majority of human cancers. In contrast, most ovarian cancers coexpress RB and p16 proteins. Although the latter finding suggests the absence of Rb pathway defects in these cells, we have shown that the cell cycle distribution profiles of RB/p16-coexpressing ovarian cancer cell lines are not affected by the adenoviral-mediated overexpression of functional p16, which indicates the existence of a defect(s) downstream of p16 in these cells. In the current study, we have shown overexpression of the wildtype and low molecular weight (LMW) forms of the cyclin E protein in the p16-insensitive (RB/p16- coexpressing) ovarian cancer cell line, NIH-OVCAR-3. Further, we determined that the high levels of cyclin E were not due to a reduction in the rate of degradation of the cyclin E protein. Following transient transfection of small interference RNA specific for cyclin E into NIH-OVCAR-3 cells we were able to inhibit wildtype expression by approximately 70 percent; and completely eliminate the expression of the LMW forms of cyclin E protein. Associated with the down-regulation of cyclin E expression, the cells underwent a marked shift in RB protein expression to the active, hypophosphorylated state. This contrasts with cells transfected with the non-targeting siRNA that showed no change in the phosphorylation status of the RB protein. These data provide evidence that cyclin E over-expression plays a major role in the loss of G1/S cell cycle control in NIH-OVCAR-3 ovarian cancer cells (and might well be implicated in the development of the subpopulations of other types of cancer that coexpress RB and p16) and that the suppression of cyclin E protein expression may prove effective in restoring regulation to this critical cell cycle restriction point.

Molecular Characterization of Deletion Breakpoints in Xp22-p21 Chromosomal Rearrangements. *Y.H. Zhang[1], B.L. Huang[1], L.L. McCabe[1], E.R.B. McCabe[1,2]* 1) Pediatrics, UCLA, Los Angeles, CA, USA; 2) Human Genetics, UCLA, Los Angeles, CA, USA.

Chromosomal rearrangements in Xp22-p21 typically involve the adrenal hypoplasia congenital (AHC), glycerol kinase (GK) and/or Duchenne muscular dystrophy (DMD) loci. The deletion sizes and breakpoints are unique within each family, and the genomic mechanism(s) for the submicroscopic chromosomal rearrangements remains unknown. The purpose of our investigation was to find patients deletion breakpoints and identify potential mechanism(s) responsible for the recombination events. To define precisely each breakpoint, primers were designed across the expected telemetric and centomeric breakpoint. PCR products were purified by the Qiagen Gel Extraction kit and were directly sequenced with an ABI 3700 automated sequencer and the BigDyeTM terminator cycle sequencing kit (Perkin-Elmer). After identifying the exact breakpoints, we used junction-specific PCR and STS-content PCR to confirm the breakpoints in carriers and normal samples, respectively. The sequence analysis of the breakpoints in the affected four males (A-D) have shown: patient A-4486 kb interstitial deletion involving IL1RAPL1, DAX1, GK and DMD; patient B-401 kb interstitial deletion involving IL1RAPL1 and DAX1; patient D-126 kb interstitial deletion also involving the DAX1 gene only; and patient D-7 kb interstitial deletion involving the DAX1 gene only. The patients phenotypes were consistent with the observed deletions in all the cases. Of the four patients, three of them inherited their mutations from carrier mothers and the fourth remains unknown. Patient A appeared to have the exact same breakpoints as another patient (AW) defined previously; however, mitochondria D-loop analysis suggested that the two were unrelated. The recombination breakpoints in these patients suggest the same mechanisim: non-homologous end joining (NHEJ) events with 2-3bp micro-homologies. Although NHEJ appears to be less precise, it is believed that NHEJ is the major pathway for double strand break (DSB) repair. Our data are consistent with the previous observations involving rearrangements in other chromosomes in the human genome.

Insights into the noncoding RNA transcriptome in the mammalian brain. *S. Sunkin[1], T. Mercer[2], M. Dinger[2], M. Mehler[3], A. Jones[1], J. Mattick[2]* 1) Allen Institute for Brain Science, Seattle, WA; 2) Institute for Molecular Bioscience, University of Queensland, St Lucia, Australia; 3) Institute for Brain Disorders and Neural Regeneration, Albert Einstein College of Medicine, New York, NY.

Within the adult mouse brain, the Allen Brain Atlas has comprehensively mapped the spatial expression patterns of protein-coding mRNAs by in situ hybridization, but has yet to systematically assess the expression profiles of noncoding RNAs (ncRNAs). NcRNA transcripts include small RNAs as well as long ncRNAs. While ncRNAs possess little or no protein coding capacity, they have been increasingly recognized for their modulatory roles within mammalian genomes particularly in relation to physiological functions, nervous system development, and various disease states.

MicroRNAs (miRNAs) are important regulators of mRNA translation and stability, and play central roles in many developmental and regenerative processes. It is also becoming clear that other types of ncRNAs may also play important, but as yet undefined, roles in mammalian biology. These include antisense RNAs, which are prevalent in the nervous system, suggesting the importance of these transcripts in regulating gene expression within the brain.

In this study, we show that miRNAs exhibit diverse expression patterns in the adult mouse brain, from widespread to regionally enriched profiles. We also describe over 1,000 long ncRNAs that display various expression profiles in the brain, including near ubiquitous, regionally enriched, and cell class specific patterns. In addition, some transcripts appear to be restricted to particular subcellular compartments. The spatial expression patterns of these long ncRNAs were also evaluated in relation to their genomic context (cis-antisense, intronic, and bi-directional pairs) and the identity of the corresponding or adjacent protein-coding genes, many of which are important in neural development, constitutive adult neurogenesis, behavioral functions and in the etiology of disease states. This study provides the first large-scale insight into the extraordinary complexity of ncRNA expression in the brain.

Is Keutel syndrome genetically heterogeneous? *B. Moghaddam[1], A. Yuksel[2], M. Bober[3], K. Bolton[4], S. Chan[1], J. Liu[1], C. Nauta[1], J.A. Rousseau[1], S.A. Boyadjiev[1]* 1) Section of Genetics, Department of Pediatrics, University of California, Sacramento, CA; 2) Cerrahpasa Medical Faculty, Department of Medical Genetics, Istanbul, Turkey; 3) A.I. Dupont Hospital for Children, Wilmington DE, USA; 4) Division of Human Genetics, The University of the Witwatersrand, Johannesburg, South Africa.

Keutel syndrome is an autosomal recessive disorder characterized by abnormal cartilage calcification, peripheral pulmonary stenosis, midfacial hypoplasia, and brachytelephalangy. To date, 24 patients from 16 families have been reported and a total of four mutations in *MGP* have been identified. *MGP* encodes vitamin K-dependent matrix Gla protein that acts as a calcification inhibitor by repressing *BMP2*. We present the clinical manifestation of three unrelated and previously unreported patients from Turkey, South Africa and South Korea. A novel homozygous nonsense mutation c.79G>T (E27X) in *MGP* was identified in the family from Turkey. Despite the predicted complete loss of function mutation the clinical manifestation in all three affected was relatively mild, suggesting functional redundancy of the mechanisms governing calcification of cartilage. No mutations were identified in the remaining two cases. Some features of Keutel syndrome, such as midfacial hypoplasia and ectopic abnormal calcification, may be due to prenatal exposure to phenytoin or warfarin or to genetic disorders such as vitamin K epoxide reductase deficiency and some forms of chondrodysplasia punctata. Clinical and additional laboratory analysis of these two cases did not confirm evidence of any of these conditions that could mimic Keutel syndrome. This raises the possibility of genetic heterogeneity of Keutel syndrome.

Duplication 22q11.2: Clinical and Cytogenetic Findings in 4 Families. *B.T. Wang, T.A. Boomer, F.Z. Boyar, X.J. Yang, M.M. El Naggar, C. Zapata, P.H. Kohn, B.J. White, A. Anguiano* Cytogenetics Dept, Quest Diagnostics,Nichols Inst, San Juan Capistrano, CA.

Duplication 22q11.2 syndrome has been identified relatively recently compared with 22q11.2 microdeletions. The phenotype can be mild to severe, with some overlaps with DiGeorge/velocardiofacial syndrome (DG/VCFS). We present the clinical and cytogenetic findings of 4 families with duplication 22q11.2.Blood samples from the 4 families were processed for standard chromosome analysis. FISH was performed using probes for the DG/VCFS critical region (TUPLE1). Routine karyotype analysis revealed no chromosome 22 abnormalities in families 1 to 3 and an apparent duplication 22q in family 4. Phenotypes ranged from mild to severe. The first proband was a 2-year-old boy with cleft palate and mild developmental and speech delay. Parental FISH studies showed that the duplication was inherited from the mother, who had mild mental retardation but no apparent physical manifestations. The second proband was an 18-month-old boy with hypotonia and developmental delay. Parental FISH studies indicated that the duplication was de novo. The third proband was a 20-month-old boy with developmental delay, ventricular septal defect, and dysmorphic features characteristic of DG/VCFS. FISH analysis indicated that the duplication was inherited from the mother, whose IQ was considered low-normal; the father did not have the duplication but had features of cleft lip and cleft palate. The last subject was a 22-year-old woman with mild mental retardation referred because her 2 children (one boy and one girl) had a dup(22q). In conclusion, all familial duplications were inherited maternally, consistent with the high ratio of maternal duplication reported previously. Duplication size may contribute to the phenotype but does not explain the wide phenotypic diversity observed within families, the high frequency of maternal inheritance, or the milder phenotype observed in females. Analysis of the duplication size with comparative genomic hybridization might provide a better understanding of the genotype-phenotype correlations in these families.

Evaluation of Commercial Platforms for Rapid Genotyping of Polymorphisms Affecting Therapeutic Warfarin Dose. *R. Porche-Sorbet[1], C. King[2], B. Gage[2], P. Ridker[3], A. Brown[4], Y. Renaud[4], M. Phillips[4], C. Eby[1,2]* 1) Department of Pathology & Immunology, Washington University School of Medicine, Saint Louis Missouri; 2) Department of Medicine, Washington University School of Medicine, Saint Louis Missouri; 3) Brigham and Women's Hospital, Harvard Medical School, Boston, Massachusetts; 4) Genome Quebec and Montreal Heart Institute Pharmacogenomics Center, Canada.

Warfarin initiation is challenging due to the risk of bleeding and the wide variability in therapeutic dose. A third of this variability is accounted for by patients genotypes for 3 single nucleotide polymorphisms (SNPs): 2 in cytochrome P450 2C9 (CYP2C9) gene that slow warfarin metabolism (*2 and *3), and 1 in the promoter of vitamin K reductase (VKORC1) that affects warfarin sensitivity. Our goal was to compare the accuracy and efficiency of 3 commercial genotyping systems for these SNPs in 112 DNA archived samples. We evaluated 3 commercial genotyping platforms: INFINITI (Autogenomics, Carlsbad, CA) automated multiplex microarray platform; Invader (Third Wave Technologies, Madison, WI) assay which employs Cleavase endonuclease enzymes; and Tag-it Mutation Detection Assay (Tm Bioscience, Toronto, CA) which uses microspheres on a Luminex 200 xMAP instrument (Austin, TX). The gold standard was Pyrosequencing (Uppsala, Sweden) and direct sequencing. All three platforms were accurate, but they differ based on other characteristics.

Characteristics of Reagent-Instrument Platforms

Platform	Time (Hrs)	Complexity	DNA (ng)	CYP2C9 SNPs	VKORC1 SNPs
INFINITI	8	Low	50	*2,3,5,6,11	-1639(8 more)
Invader	3	Moderate	250	*2,3	-1639
Tag-it	8	High	15	*2,3,5,6	-1639(6 more)

The Jackson Laboratory Repository: Models of Human Disease. *S. Rockwood, C. Lutz, M. Sasner, L. Donahue*
Genetic Research Science, The Jackson Laboratory, Bar Harbor, ME.

The Repository at The Jackson Laboratory (TJL) serves as a centralized source for mouse models of human disease. The longevity of the constituent programs organized under the Repository (est 1960s) has fostered the evolution of an infrastructure supporting the efficient importation, cryopreservation and distribution of mouse models to the biomedical community. Approximately 300 new strains are added annually to the over 3500 strains in the Repository. Although a broad spectrum of strain types are imported, several specific disease areas have been targeted for expansion, most notably Parkinsons Disease, Alzheimers Disease and Spinal Muscular Atrophy (SMA). The Parkinsons Disease Mouse Model Repository (PDMMR) and Alzheimers Disease Mouse Model Repository (ADMMR) projects serve similar functions for their respective disease areas within the main Mouse Repository. Under these programs, mice will be rederived to a high health status; key alleles moved to standard genetic backgrounds and distributed. When appropriate, aged mice will be made available. A database is available for researchers to retrieve information related to strains. Search results contain information describing phenotype, development, maintenance, licensing and references. To facilitate searches for strains related to human diseases, queries can be executed using OMIM search terms. Alternatively, researchers can conduct searches using the Mammalian Phenotype Ontology developed by the MGI group at TJL. In anticipation of a continued increase in the use of cre-lox mutants in human disease research, characterization of cre-expressing strains is being added. Using a lacZ reporter strain, photomicrographs of expression patterns in embryonic and postnatal tissues are being made available on-line. Donating a strain to the Repository fulfills the NIHs requirements for sharing of mice. Researchers wishing to have strains considered for inclusion in the Repository are encouraged to submit their strains at: http://www.jax.org/grc/index.html. Support is provided by the NCRR (RR09781, RR11083, RR16049), NIA, HHMI, The Ellison Medical Foundation and from private charitable foundations.

The Debré type of autosomal recessive cutis laxa is associated with brain dysgenesis or neurodegeneration and defective N-glycosylation. *L. Van Maldergem[1], M. Yuksel-Apak[2], H. Kayserili[2], E. Seemanova[3], S. Giurgea[4], J. Vigneron[5], M. Greally[6], E. Leao-Teles[7], L. Basel-Vanagaite[8], J. Jaeken[9], S. Mundlos[10], W.B. Dobyns[11]* 1) Ctr Génétique Humaine, Univ Liege, Liege, Belgium; 2) Div Med Genet, Instit Child Health, Univ Istanbul, Istanbul, Turkey; 3) Dpt Clin Genet, Motol Hospit, Charles Univ, Prague, Czech Republic; 4) Dpt Neurol, CHU Tivoli, La Louvière, Belgium; 5) Unité de génét méd, CHU Nancy, Nancy, France; 6) Coll Med & Med Sci, Arabian Gulf Univ, Manama, Bahrein; 7) Dpt Pediatr, Univ Porto, Porto, Portugal; 8) Dpt Med Genet, Schneider Children's Med Ctr, Petah Tikva, Israel; 9) Ctr Metabol Disord, Katholieke Univ Leuven, Leuven, Belgium; 10) Instit Med Genet, Charité, Campus Virchow, Berlin, Germany; 11) Dpt Hum Genet, Neurol & Pediatr, Univ Chicago, Chicago, Illinois.

Two main type of congenital cutis laxa are known. Both are very rare autosomal recessive conditions differing by presence or absence of pulmonary emphysema, clinical outcome and associated findings. We delineate the Debré type lacking pulmonary emphysema. It is associated with downward slant of palpebral fissures, megafontanelles, hip dislocation, inguinal herniae and developmental delay. Our follow-up data indicate that high myopia,generalized seizures associated with brain dysgenesis and defective glycosylation are also part of the clinical picture. Eleven patients from eight families are described. Clinical course was remarkable for progressive neurological impairment starting with psychomotor retardation, followed by onset of generalized seizures by the end of the first decade and a subsequent neurodegenerative course while skin overfolding becomes less pronounced. Frontoparietal pachygyria was observed on brain MRI in seven cases out of eight investigated and a Dandy-Walker malformation was observed in three cases. Although all unrelated patients had a type 2 isoelectrofocusing of serum sialotransferrins indicating defective N-glycosylation, linkage studies pointed to at least two different loci. We conclude that Debré type of cutis laxa is a N-glycosylation disorder with brain dysgenesis, a poor neurological outcome and is genetically heterogeneous.

The Charger Products Program, Practical Commercial Experience for Graduate Students in Biotechnology. *R.J. Zahorchak[1], L. Boyd[2], R. DuBreuil[3], T. Moore[3], H. Zappe[4]* 1) Partnership for Biotechnology Research, Huntsville, AL; 2) University of Alabama in Huntsville, Huntsville, AL; 3) Open Biosystems, Inc., Huntsville, AL; 4) Nektar Therapeutics, Huntsville, AL.

The Charger Products program is a unique, experientially-driven, educational program currently designed to offer an alternative funding opportunity for select Ph.D. graduate students and provide them with hands-on experience in the varied aspects of biotechnology product development, manufacturing, and marketing in a challenging, supportive business environment. The program is sponsored by the Partnership for Biotechnology Research (PBR) and seed funding has been obtained through grants from the Hudson Alpha Institute for Biotechnology and the Alpha Foundation. The program is currently a partnership between PBR, the University of Alabama in Huntsville and Open Biosystems, Inc. Students in the program deal directly with the challenges of converting "proof of concept" technologies into viable products in the biotechnology marketplace. All individuals who participate in the program are part of an application-friendly educational experience that will expand their realm of future employment opportunities and facilitate their more rapid integration into future employment situations in the commercial sector. Most of the products in development fill needs in genetics and cell development research or education. The revenues of the products manufactured and sold by Charger Products will feed back into the program to help support existing and new assistantships. Charger Products was established approximately two years ago and already has developed and launched one product, the Leopard Transfection Array (LTA v1.0) which is sold through Open Biosystems, Inc. Improvement of this product is ongoing. Two other products in development involve the development of stable shRNA cells line arrays for cancer and cell development research and educational kits for middle school, high school and college genetics and biotechnology laboratories.

Identification of new loci responsible for an SMS-like phenotype using whole genome array CGH. *S.R. Williams[1], S. Girirajan[1], D. B. Shin[1], N. Nowak[3], D. Tegay[4], R. Fisher[4], E. Hatchwell[4], S.H. Elsea[1,2]* 1) Department of Human Genetics, Virginia Commonwealth University, Richmond, VA; 2) Department of Pediatrics, Virginia Commonwealth University, Richmond, VA; 3) Department of Biochemistry and Center of Excellence in Bioinformatics and Life Sciences, State University of New York at Buffalo and Department of Cancer Prevention, Roswell Park Cancer Institute, Buffalo, NY; 4) Department of Pathology, SUNY at Stony Brook, NY.

Smith-Magenis syndrome (SMS) is caused by either mutation or deletion of the *RAI1* gene on chromosome 17p11.2. Our data indicate that *RAI1* mutation analysis for individuals without 17p11.2 deletion but with a phenotype consistent with SMS reveals a *de novo* nucleotide change in only ~20% of cases, even though the patients strongly resemble SMS. We have analyzed 60 non-mutation/non-deletion cases for 44 clinical characteristics, providing significant support for the clinical indication of SMS. These data provide the basis upon which additional molecular studies can be undertaken in this well-characterized cohort. Thus, we have sought alternative approaches to help better understand this SMS-like phenotype on a molecular level and to identify new loci of interest. Array comparative genomic hybridization (aCGH) has proven to be an effective tool in the identification of copy number aberrations in patients where traditional methods have failed to make a molecular diagnosis. Here, we present data from our validated aCGH which directly detects *de novo* deletions or duplications. This approach to whole genome evaluation has resulted in the identification of new loci that better help to understand the phenotypic impact of the identified molecular aberration. In addition to these discoveries, we are able to rapidly screen our growing cohort of non-mutation/non-deletion SMS-like cases in an attempt to identify new copy number changes that may play a role in their phenotypic presentation. With this approach to genomic copy number screening, we hope to tease out the players and pathways that contribute to the SMS and SMS-like phenotypes.

Variants in the ELMO1 gene are associated with diabetes and nephropathy in African Americans. *T.S. Leak[1], P.S. Perlegas[2], S.G. Smith[1], P.J. Hicks[2], L. Lu[3], C.D. Langefeld[3], K.L. Keene[1], M.M. Sale[1,4,5,6,7,8], B.I. Freedman[4], D.W. Bowden[1,2,3,4]* 1) Molecular Gen/Human Genetics; 2) Department of Biochemistry and Molecular Genetics; 3) Public Health Sciences; 4) Internal Medicine, Wake Forest Univ Sch Med, Winston-Salem, NC; 5) Center for Public Health Genomics; 6) Department of Public Health Sciences; 7) Department of Medicine; 8) Department of Biochemistry and Molecular Genetics, Univ of VA, Charlottesville, VA.

The engulfment and cell motility 1 (ELMO1) gene on chromosome 7p14.2-14.1 has been associated with type 2 diabetes mellitus (T2DM)-associated nephropathy in a Japanese cohort. Three hundred-one HapMap and 10 reportedly associated SNPs were genotyped in 577 African American (AA) T2DM patients with end-stage renal disease (ESRD), 596 AA controls without a current diabetes diagnosis or kidney disease, with an average density of 1 SNP every 2kb. Of the 311 SNPs tested, 98 (31.5%) showed suggestive evidence of association (P 0.05) in one or more tests of association: allelic, overall genotypic, dominant, additive, or recessive genotypic models, allelic, 2- and 3-SNP haplotypic analyses. Haplotype analysis revealed 8 and 11 overlapping 3 and 2-SNP haplotypes, respectively, containing a total of 12 and 22 independent SNPs spanning introns 1 and 13 that were associated with susceptibility to T2DM-ESRD (P 0.05). The associated SNPs were genotyped in independent populations of 564 AA controls, 328 AA with T2DM lacking nephropathy, 326 AA with non-diabetic forms of ESRD and 558 additional AA T2DM-ESRD subjects. Significant associations were detected between SNPs spanning introns 1 and 13 of the ELMO1 gene in T2DM without nephropathy (P range <0.0001 - 0.049), non-diabetic ESRD (P = <0.0001 - 0.049) and T2DM-ESRD (P = 0.001 - 0.049). In the combined analysis of 1135 T2DM-ESRD cases and 1160 controls also showed evidence of association (P = <0.0001 - P=0.049). We have observed evidence that ELMO1 is associated with T2DM and both diabetes and non-diabetes associated kidney disease. The consistent evidence of association suggest pleiotropic effects for this gene, possibly through metabolic syndrome- a phenotype common to each patient group.

Copy Number Variations in del22q11.2 Syndrome. *S. McGhee[1], M. Suchard[2], E.R.B. McCabe[1,2]* 1) Pediatrics, UCLA, Los Angeles, CA, USA; 2) Human Genetics, UCLA, Los Angeles, CA, USA.

Genetic polymorphisms, including single nucleotide polymorphisms, small insertions, and deletions, contribute to phenotypic changes and may be associated with disease. Large-scale copy number variations (CNVs) are a part of this variability and can be determined genome-wide using representational oligonucletoide microarray analysis (ROMA). Such CNVs are found in normal patients and new CNVs frequently arise in individual patients. We investigated the hypothesis that patients with del22q11.2 syndrome might have a broader susceptibility to larger or more frequent CNVs. CNVs and the del22q11.2 deletion both may arise from unequal crossing-over events, and we hypothesized that del22q11.2 patients may have an abnormal mechanism resulting in a predisposition to larger CNVs. 12 patients with del22q11.2 syndrome and 8 healthy controls were assessed for genome-wide copy number changes using ROMA. There was an average of 16 CNVs per genome and this average did not differ between del22q11.2 syndrome patients and controls (Wilcoxon p=0.516). The median CNV size also did not differ between patients and controls (157,555 vs. 153,157 respectively). We also determined whether patients with del22q11.2 syndrome were more likely to have larger CNVs. Here also, the frequency of CNVs greater than 500 Kb was not significantly different than controls (Fisher p=0.21, OR of 1.74, 95% CI 0.74-4.08). We conclude that patients with del22q11.2 syndrome do not differ from normal controls with respect to the frequency or size of CNVs, suggesting that the unequal crossing over event that produces both CNVs and the del22q11.2 deletion result from similar mechanisms in patients and controls.

Combinatorial Potential of Human Enhancers. *L.A. Pennacchio[1,2], A. Visel[1], E.M. Rubin[1,2]* 1) Genomics Division, MS84-171, Lawrence Berkeley National Laboratory, Berkeley, CA; 2) DOE Joint Genome Institute, 2800 Mitchell Drive, Walnut Creek, CA.

The expression of human genes are increasingly being found to be controlled by a modular architecture of multiple distant-acting enhancers that are individually sufficient to target gene expression to specific tissues. However, it is not known to what extent the local arrangement of enhancer modules with different specificities affects their individual impact on gene expression in time and space. To determine if enhancer modules can function in a combinatorial manner outside of their original genomic context, we concatenated developmental enhancers from different genes and defined how the artificial presence of heterologous enhancer modules affects their individual activities in transgenic mice. In all cases tested we observe compound patterns that are additive combinations of the individual enhancer activities and maintain their remarkable spatial and temporal precision, and we did not observe aberrant expression sites artificially created by potential positive interactions across enhancer modules. Conversely, even in cases where two elements drove expression in close anatomical proximity, such as within the developing limb bud, the compound patterns also showed no signs of cross-inhibition or interference between individual elements, indicating that mammalian enhancers do not commonly repress transcription in tissues where they are inactive. This additive modularity suggests that mammalian enhancers are discrete, functionally independent units with the potential to serve as fundamental building blocks of cis-regulatory architecture in evolution and synthetic biology.

Circulating cell-free placental mRNA in the maternal plasma as a predictive marker for twin-twin transfusion syndrome. *K. Miura[1], K. Yoshiura[2], S. Miura[1], K. Yamasaki[1], D. Nakayama[1], N. Niikawa[2], H. Masuzaki[1]* 1) Nagasaki University Graduate School of Biomedical Science, OB/GYN, Nagasaki, Japan; 2) Nagasaki Univ. Graduate School of Biomedical Science, Human Genetics, Nagasaki, Japan.

Objective:The purpose of the present study is to know whether cell-free mRNA (cf-mRNA) concentration in maternal plasma becomes a predictive marker of later Twin-twin transfusion syndrome (TTTS). Materials and Methods:The study participants included 17 pregnant women who visited Obstetrics Clinic of Nagasaki University Hospital at 12-21 weeks of gestation for management of their pregnancy with monochorionic diamniotic twins (MCDA-T). And, 135 singleton pregnant women were also included as control group. All of the participants gave written informed consent. Although all 17 cases of MCDA-T were not complicated by TTTS at the time of blood sampling, 5 cases subsequently developed TTTS (TTTS group), while the remaining 12 cases did not develop TTTS (no-TTTS group). Plasma concentrations of such cf-mRNA for human Placental Lactogen (PL) and for glyceraldehyde-3-phosphate dehydrogenase (GAPDH) were measured and converted into multiples of the median (MoM) of the controls adjusted for gestational age. Their differences between the TTTS and the no-TTTS groups were evaluated with Mann-WhitneyÅfs U test. Significant difference was defined as a p-value of less than 0.05. Results:The median (minimum-maximum) cf-PL mRNA MoM values were 1.80 (0.89-3.81) in the TTTS-group, 1.14(0.77-1.35) in the no-TTTS group and 1.00 (0.82-2.05) in the control group, respectively. The cf-PL mRNA concentration was significantly higher in the TTTS group than in the no-TTTS group at adjusted gestational age (Mann-WhitneyÅfs U test, p=0.035), while there was no significant difference of cf-PL mRNA concentration between the no-TTTS group and the control group (p=0.41) (Figure 1). In addition, the median cf-GAPDH mRNA MoM value in the maternal plasma was significantly higher in the TTTS group (2.20; range, 1.30-2.68) than in the no-TTTS group (1.09; 0.68-3.25) (p=0.045). Conclusion: A quantitative aberration of both the cell-free PL and cell-free GAPDH mRNA in maternal circulation may be a novel predictive marker for TTTS.

Selecting SNPs using Random Forests. *Y. Meng, L.A. Cupples, L.A. Farrer, K.L. Lunetta* Boston University, Boston, MA.

Lunetta et al. have shown that when unknown interactions among SNPs exist in a data set consisting of thousands of SNPs, random forest (RF) analysis can be significantly more efficient than standard univariate screening methods in ranking the true disease-associated SNPs from among large numbers of unassociated SNPs. In order to be practical for the analysis of real data, we need to address the question: what methods for selecting subsets of SNPs from a RF for further analysis are most powerful? Here, we evaluate two methods to select SNPs via RFs for further analysis - an iterative procedure (iterative RF), and a significance test of the IM measures (RF IM perm.p) obtained from a RF. We use two simulation datasets, each mimicking the Affymetrix 10k chip: (1) with multiple strong marginal genetic effects and no interaction (GAW 15); (2) with weak marginal genetic effects and strong interaction. The RF methods for choosing a subset of SNPs are compared with three additional methods: single SNP allelic analysis, exhaustive pair-wise allelic interactions analysis, and set association analysis.

For GAW data with strong main effects, but no interaction, RF IM perm.p and set association have the highest power. The power of iterative RFs and single SNP qvalue are lower. For our simulated model with weak main effects but strong interaction, iterative RFs and single SNP nominal p-value methods are similarly powerful; followed by RF IM perm.p, set association and exhaustive pair-wise allelic interactions analysis. We observe that either one of two RF SNP selection methods seem to perform under each of the two models, although no method is the best under both scenarios. Additional simulation models will be presented that clarify the scenarios under which each method performs best. For all procedures other than the iterative RF, the analyst must specify the number of variables or cutoff value for the variables to be selected. The iterative RF procedure provides an automated method for selecting SNPs that does not require pre-specification of selection criteria or the number of SNPs to select. Our simulations suggest that the procedure optimizes the selected number based on the signal:noise ratio in the dataset.

Founder Mutation in the PEX2 (PXMP3) Gene in the Jewish Karaite Population in Israel. *A. Singer[1], R.J.A. Wanders[2], A. Zung[3], C. Vinkler[4]* 1) Genetics Institute, Barzilai Medical Ctr, Ashkelon, Israel; 2) Department of Pediatrics, Academic Medical Centre, Emma Children's Hospital, University of Amsterdam, Amsterdam, The Netherlands; 3) Pediatric Endocrine Unit, Kaplan Hospital, Rehovot 76100, Israel; 4) Institute of Clinical Genetics, E. Wolfson Medical Center, Holon, Israel.

Zellweger syndrome (ZS), is the most severe form of the peroxisome biogenesis disorders (PBD). Milder phenotypes in the Zellweger spectrum are neonatal adrenoleukodystrophy (NALD); and infantile Refsum disease (IRD), the least severe. The clinical presentation in the neonatal period include profound hypotonia, characteristic facies, seizures, inability to feed, liver cysts with hepatic dysfunction, and chondrodysplasia punctata. Infants with this condition are significantly impaired and usually die during the first year of life, having made no developmental progress. Death is secondary to progressive apnea or respiratory compromise from infection in most cases. Prevalence of PBD is estimated to be 1:50,000 in the western population. Zellweger syndrome is inherited in an autosomal recessive mode. More than ten genes, most belong to the PEX family, were associated with PBD. The Karaites are a Jewish sect which does not recognize the authority of the post-Biblical tradition incorporated in the Talmud and in the latter Rabbinic works. In Israel the estimated number of Karaite Jews is 30-40,000. For many years they kept a close community life with high consanguinity rates and hence were at risk for genetic diseases. During the last decade we diagnosed a number of infants born to Karaite parents with neonatal ZS. Mutation analysis following complementation tests in fibroblasts and identifying the candidate gene revealed point mutation in the PEX2 gene. In all the cases studied a 550delC mutation was found. The identification of the mutation allows proper genetic counseling and prenatal diagnosis of ZS in this community. Population screening will allow us to calculate carrier rates in this community.

Breaking chromosomes and rules: Phenotypic abnormalities in a family with a seemingly balanced 11,22 translocation. *N. Shur[1], R. Marion[1], J. Greally[2]* 1) Montefiore Medical Center, Bronx, NY; 2) Albert Einstein College of Medicine, Bronx, NY.

Case report: The most common balanced translocation described in humans involves chromosome 11 and 22: t(11;22)(q23;q11). Previous molecular studies have shown that the breakpoints of the translocation are conserved among carriers, who are described as phenotypically normal and often remain undetected until they present with fertility problems. Balanced carriers incur the major risk of future progeny born with Emanuel syndrome, the result of abnormal segregation of the derivative chromosome 22, which leads to supernumerary der (22)t(11;22) syndrome. Clinical features include developmental disability (DD), malformed ears, and congenital heart defects. We report the case of a phenotypically normal female carrier whose son had DD and dysmorphic features: molecular testing confirmed that he is a carrier of the same translocation. Case report: A 37-year-old woman with known(t11;22)(q22.3q11.2) was counseled after amniocentesis that the fetus had her same translocation but was normal. She continued the pregnancy. During the first year of life significant hypotonia, dysmorphic features, and DD occurred, prompting referral for genetics evaluation. High-resolution chromosome analysis and comparative genomic hybdridization (CGH) failed to reveal additional abnormalities. An extensive work-up including Fragile X was negative. Discussion: Although the balanced translocation might be a serendipitous finding, this case raises the possibility that breaks in chromosomes, even those that are seemingly balanced, may cause disruptions through a variety of mechanisms, including break points on a critical gene, uniparental disomy, microdeletions, mosaicism, and epigenetic effects. Pinpointing whether subtle molecular variations among carriers exist proves difficult, although in the future improved CGH resolution and molecular diagnostics will certainly provide more complete translocation characterization. In the interim, families with 11,22 balanced translocations may benefit from counseling that even seemingly balanced translocations carry risk of phenotypic abnormalities.

Origin and Mechanisms of Formation of Fetus-in-fetu: Two Cases with Genotype and Methylation Analyses. *S. Miura[1], K. Miura[1], K. Yoshiura[2], F. Hirahara[3], M. Yamanaka[4], N. Niikawa[2], H. Masuzaki[1]* 1) Dept OB/GYN, Nagasaki Univ Biomed Sci, Nagasaki, Japan; 2) Nagasaki Univ. Graduate School of Biomedical Science, Human Genetics, Nagasaki, Japan; 3) Yokohama City Univ Sch of Med, OB/GYN, Kanagawa, Japan; 4) Kanagawa Childrens Hospital, OB/GYN, Kanagawa, Japan.

Fetus-in-fetu (FIF) is a condition in which a host infant has parasitic fetiform mass within its body cavity. We describe here results of molecular genetic analysis in two cases (FIF-1 and FIF-2) of fetus-in-fetu. In FIF-1, a male host had in his retroperitoneal cavity two fetiform masses with vertebral columns, and in FIF-2, a fetiform mass with the vertebral column was present in a cranial cavity of a male host. Genotyping of each case using microsatellite markers revealed that the host infant and its fetus(es) inherited one copy each of parental alleles and shares identical genotypes. These findings were confirmed by SNP analysis using Affymetrix GeneChip Human Mapping 50K Array, and support a monozygotic twin theory for FIF. Analysis of the methylation status was done in both cases at the differentially methylated region (DMR) within the human IGF2-H19 locus after bisulfite treatment, methylation-specific PCR and cloning of PCR products. Normally, only the paternal allele is methylated and the maternal allele unmethylated in DMR. However, in FIF-1, seven (46.7%) of 15 clones from a fetiform mass and six (66.7%) of nine clones from the other mass showed unmethylated paternal allele, while the methylation status of a host infant and its fetiform mass in FIF-2 was same in all clones examined and showed the normal patterns. These data suggest that in FIF-1, two isolated blastocysts both originated from one zygote may have been implanted into the other host blastocyst during an establishing process of methylation, and such abnormal implantation may have occurred in FIF-2 after the establishment of methylation. This is the first case of FIF showing different methylation patterns between a host infant and fetiform mass.

Identification of small molecules promoting the translation of FMR1 mRNA with expanded CGG repeats. *Y. Qin, P. Jin* Department of Human Molecular Genetics, Emory University School of Medicine, Atlanta, GA 30322.

Fragile X Syndrome, a common form of inherited mental retardation, is mainly caused by the expansion of CGG triplet repeats within the 5' untranslated region (5-UTR) of the fragile X mental retardation-1 (FMR1) gene. The loss of functional fragile X mental retardation protein (FMRP) is responsible for fragile X clinical phenotypes. Previously it has been shown that FMR1 mRNA with expanded CGG repeats produces less or no FMRP due expanded CGG repeats. It has been proposed that expanded CGG repeat RNA forms secondary structure and impede the 40S ribosome migration along the 5-UTR. To further understand the molecular mechanism of this translational suppression, we have taken a chemical biology approach. Here we have established a high-throughput assay that utilizes slot blot to monitor the level of FMRP in cells. A cell line carrying an unmethylated full-mutation CGG repeat that produces little FMRP protein was used for chemical screen with a collection of 2,000 FDA-approved, biologically active and structurally diverse compounds. The identified compounds in the initial screen were further confirmed using western blots and additional cell lines. We have identified and confirmed seven compounds that could promote the translation of FMR1 mRNA with expanded CGG repeats but do not change the level of FMR1 mRNA. Interestingly these compounds do not alter the translation of FMR1 mRNA with normal CGG repeat. We hypothesize that small molecules could alter the secondary structure of expanded CGG repeat RNA and promote the translation initiation of FMR1 mRNA. The elucidation of the action mechanism of these small molecules will be helpful to further understand the translation suppression of FMR1 mRNA with expanded CGG repeats.

Experience with laronidase in a bone marrow-transplanted patient with severe pulmonary disease. *V. Valayannopoulos[1], J. De Blic[2], N. Mahlaoui[3], B. Stos[4], A. Chabli[5], F. Jaubert[6], P. de Lonlay[1], A. Fischer[3]* 1) Metabolic Unit, Necker-Enfants Malades Hosp, Paris, France; 2) Pediatric Pneumology; 3) Immuno-Hematology; 4) Pediatric Cardiology; 5) Biochemistry Laboratory; 6) Pathology Laboratory.

Background: Mucopolysaccharidosis type I or Hurlers disease (MPS I-H) is a severe multi-organ lysosomal disease, which untreated is rapidly fatal. Long-term survival has occurred in children with MPS I-H after successful bone marrow transplantation (BMT). Laronidase, a recombinant human alpha-L-iduronidase, safely and effectively alleviates many systemic manifestations of this disease.Case Report: We describe a 14 years old MPS I-Hurler patient that underwent BMT twice, with his heterozygous twin. His clinical course was initially similar to other MPS I-BMT patients, but he developed 5 years ago, a progressive respiratory failure with life-threatening pulmonary hypertension. His pulmonary disease was multifactorial: bone disease responsible for thoracic and spinal deformities; infiltration of upper airways and sleep hypoventilation; interstitial infiltration of lungs with storage material in alveoli. Clinically he was polypneic, fatigable and wheelchair-bound. Methods and Results: We treated this patient for 24 months so far, with continuous oxygen therapy for pulmonary hypertension, nocturnal non-invasive ventilation and enzyme replacement therapy. The patients clinical condition improved dramatically. He can now stand and walk alone and climb stairs without significant fatigue or dyspnea. Pulmonary hypertension improved and oxygen therapy during daytime was discontinued. His thoracic CT-scan improved and an upper airways and tracheal endoscopy showed decreased obstruction. Urinary glycosaminoglycans decreased over 50 percent.Conclusion: Enzyme replacement therapy may be an interesting option for treating MPS I BMT patients who develop severe respiratory complications. Further studies should be done to assess the contribution of ERT in other visceral symptoms occurring in these patients.

Genome-wide association study and targeted follow-up studies for anthropometric measures of obesity. *E. Speliotes[1,2,3], H. Lyon[1,4], B. Isomaa[1,8], T. Tuomi[1,6], M. Ridderstrale[1,6], M. Kuokanen[6,9], C. Guiducci[1], R. Hacket[1], V. Salomaa[7], L. Palotie[6,7,9], L. Groop[1,5,6], J. Hirschhorn[1,3,4]* 1) on behalf of the Diabetes Genetics Consortium, Broad Institute, Cambridge MA; 2) Massachusetts General Hosp, Boston, MA; 3) Harvard Medical School, Boston MA; 4) Children's Hosp, Boston MA; 5) Lund University, Sweden; 6) University of Helsinki, Finland; 7) National Public Health Institute, Finland; 8) Malmska Municipal HC, Finland; 9) Broad Institute, Cambridge MA.

Obesity and its complications have reached epidemic proportions. Heritable anthropometric measures of obesity include body mass index (BMI), waist circumference (WC), waist hip ratio (WHR)and predict future risk of diabetes, cardiovascular disease, and death. We genotyped over 3000 individuals from Scandinavia that were part of a case/control study of diabetes (Diabetes Genetics Initiative) matched for age, gender and BMI using the Affymetrix 500K platform. 389,869 SNPs passed quality control filters (genotyping success in >95% of individuals using the BRLMM algorithm, minor allele frequency >0.01, HWE p>10 -6). We tested SNPs for association with measures of obesity under an additive genetic model using the PLINK software package. For obesity measures, overall inflation factors were low (1.00-1.11)indicating that the study was not substantially affected by technical biases such as population stratification. For most measures of obesity, we observed an excess of low p values but none achieved genome-wide significance, consistent with a model of multiple loci with modest effects, and suggesting that our top results consist of true obesity loci hidden among a larger group of loci that represent expected statistical fluctuations. To identify these obesity loci, we have begun by testing 100 SNPs with the best evidence of association to BMI, using a ,multistage replication strategy involving over 20,000 separate individuals. Furthermore, through collaboration we will combine our genome-wide association results with additional genome-wide data to further enrich for loci that contribute to obesity. Association results available at http://www.broad.mit.edu/diabetes/scandinavs/index.html.

Genetic variants in selenoprotein S are associated with inflammatory biomarkers and vascular calcified plaque in families from the Diabetes Heart Study. *A.B. Lehtinen, Y. Liu, J.T. Ziegler, C.D. Langefeld, B.I. Freedman, J.J. Carr, D.W. Bowden* Wake Forest University School of Medicine, Winston-Salem, NC.

Inflammation plays a role in the development and progression of common diseases such as diabetes and cardiovascular disease (CVD). Genetic variants in selenoprotein S (*SELS*) have been reported to be associated with plasma levels of inflammatory biomarkers in individuals of European ancestry, and *SELS* gene expression has been shown to be dysregulated in polygenic animal models with diabetes and glucose intolerance. We sought to replicate the association of *SELS* variants with inflammatory biomarkers in families enriched for type 2 diabetes mellitus (T2DM). Five single nucleotide polymorphisms (SNPs) in the *SELS* gene, G-105A, rs4965814 (3705GA), rs9874 (6218AG), rs7178239, and rs13313503, were genotyped in 937 European Americans from 375 families containing at least 2 siblings with T2DM. Four SNPs (rs4965814, rs9874, rs7178239, rs13313503) were significantly associated with IL-6 levels (0.004p0.049), 3 SNPs (G-105A, rs4965814, rs7178239) were significantly associated with ICAM1 levels (0.0001p0.014), and 2 SNPs (rs7178239, rs13313503) were significantly associated with MCP1 levels (0.0009p0.042) after adjusting for age, gender, diabetes affection status, smoking, and use of lipid-lowering medications. Because of the role of inflammation in the pathogenesis of CVD, we also evaluated the 5 *SELS* SNPs for association with quantitative measures of vascular calcified plaque as measured in the carotid artery (CarCP) and coronary artery (CCP), which show significant genetic correlation (0.520.11; p0.05) in the study population. All 5 SNPs were significantly associated with CarCP (0.005p0.042), and 3 SNPs were trending towards association with CCP (0.071p0.109). Taken together, these data suggest that *SELS* is involved in mediating inflammation and is likely involved in the inflammatory processes of CVD leading to calcification in the carotid and coronary arteries. The observation of these associations in a diabetes-enriched population suggests that this patient subset may be particularly susceptible to genetic variants that influence the inflammatory response.

Comparison of different methods to estimate genetic ancestry and control for stratification in genome-wide association studies. *E. Salvi[1,2], G. Guffanti[1], A. Orro[2], L. Milanesi[2], J. Turner[3], D. Keator[3], J. Fallon[3], S. Potkin[3], F. Macciardi[1]* 1) Department of Science and Biomedical Tecnology, University of Milan, Italy; 2) Institute of Biomedical Technologies CNR, Milan, Italy; 3) Department of Psychiatry and Human Behavior University of California, Irvine.

Population stratification can occur in case-control association studies when allele frequencies differ between cases and controls because of systematic differences in ancestry. It may lead to spurious associations due to population structure rather than association of genes with disease. The prevailing methods for dealing with stratification were Fst test, Genomic Control (GC) and STRUCTURE that are based on the usage of unlinked genetic markers. Recently new methods have been proposed that enable explicit detection and correction of population stratification on a genome-wide scale. EIGENSTRAT and PLINK detect population structure using data reduction techniques to model population genetic variability. We evaluate these methods using 317K SNPs (Illumina HumapHap300) in a case-control sample of about 200 subjects. Fst, STRUCTURE and GC did not detect a significant stratification in our sample, as well as EIGENSTRAT and PLINK. However, these last two methods, using a much larger information from the whole set of SNPs, suggested the presence of a not completely homogeneous population, probably due to admixture rather than to stratification. We used STRUCTURE software to assess the degree of admixture of our sample and we detected an alpha1 that seems to suggest admixed individuals. When we correct our data adjusting association statistics by 1) a uniform overall inflation factor (lambda) calculated on 400 unlinked genetic markers; 2) a uniform overall lambda calculated on 317K markers; 3) marker specific factors (ancestry based) obtained via computing residuals of linear regressions, we found a larger lambda value for those methods with the highest information content (EIGENSTRAT and PLINK).Even if these different strategies provide apparently similar informations, the larger amount of details of informations allows a more accurate estimate to control for heterogeneity factors although we can't identify precisely them.

Insight on the role of maternal age and recombination in chromosome 21 nondisjunction. *T. Oliver[1], E. Feingold[2], K. Yu[3], S. Sherman[1]* 1) Dept Human Genetics, Emory Univ, Atlanta, GA; 2) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA; 3) Division of Cancer Epidemiology and Genetics, National Cancer Institute, Bethesda, MD.

Human chromosome nondisjunction (NDJ) occurs at a high frequency in humans and is known to be influenced by maternal age and recombination. In previous studies, we found that the presence of a single meiotic exchange within the most telomeric 5.2Mb of 21q and the most proximal 3.5Mb of 21q were associated with maternal MI and MII NDJ respectively. In addition to the altered placement of recombination, increased maternal age is another risk factor for NDJ. We examined the association of these two known risk factors among maternal chromosome 21 NDJ stratified by meiosis I (MI, n=400) and meiosis II (MII, n=278) errors. Specifically we looked at the number of recombinant events and the location of recombination in women belonging to one of three maternal age groups: women <29, women 29-34 and women >34. Results showed that among women who experienced MI NDJ of chromosome 21 there was no difference in the distribution of the number of recombinant events between women belonging to our youngest and eldest age groups. In addition among cases with a single recombinant event, we found that as maternal age increased, the location of recombination shifted from the telomere towards the middle of the chromosome. Among women who experienced MII NDJ of chromosome 21 the number of cases with greater than 1 recombinant event increased with increasing maternal age. In addition among cases with a single recombinant we found that as maternal age increased the location of recombination shifted towards the centromere. These results suggest that multiple mechanisms lead to NDJ. For example, single telomeric exchanges appear to predispose to NDJ irrespective of maternal age. However, for MII errors, recombination-related factors appear to interact with maternal age related factors. In order to better understand recombination-related NDJ we have initiated studies to characterize recombination breakpoints of the maternal MI and MII susceptible recombinant events.

Quantitative Microsphere Hybridization (QMH): A High-throughput Assay for Multiplexed Detection of Genomic Disorders. *H.L. Newkirk[1], L.D. Cooley[2], D.C. Bittel[3], M.G. Butler[3]* 1) Genomics, Children's Mercy Hospital and Clinics, Kansas City, MO; 2) Cytogenetics Laboratory; 3) Section of Medical Genetics and Molecular Medicine.

We developed a novel multiplexed quantitative microsphere suspension hybridization (QMH) assay for determination of genomic rearrangements involving copy number variation as well as balanced rearrangements. Unique sequence genomic fragments are conjugated to spectrally-distinct microspheres and used in multiplex hybridization to detect homologous sequences in biotin-labeled genomic DNA. Hybridization is detected with phycoerythrin-labeled streptavidin and analyzed by flow cytometry. Copy number differences are made by comparing mean fluorescence intensities (MFI) of test probes with a disomic reference probe (eg, ACTB). QMH is an attractive option for clinical diagnostic tests with its high-throughput platform using a flow cytometer and minimal amounts of DNA are required. The resolution of QMH is 3 bp, which is significantly greater than conventional clinical tests. We developed a multiplexed QMH assay for 8 common genomic disorders including Down, Klinefelter, Turner, Prader-Willi syndromes, trisomy 13 and trisomy 18, cystic fibrosis and Duchene muscular dystrophy. Test probes specific for all disorders were hybridized with the reference probe to patients DNA. The relative average MFI ratios were 0.540.07 in subjects with cytogenetic deletions, 1.45 0.03 in subjects with duplications or aneuploidy and 0.990.08 for normal loci. To detect balanced reciprocal translocations, we used a modified QMH method involving a two-step hybridization procedure. For example, we analyzed a subject with PWS and a balanced reciprocal translocation, t(15:19)(q12;q13.41), and narrowed the breakpoint to a 207bp region. These studies illustrate the utility of QMH for high-throughput multiplexed detection of genomic disorders and should be a valuable tool for a precise recognition of subtle chromosome rearrangements and breakpoint assignments.

A Large Scale High-throughput Candidate Gene Association Study of Preterm Birth. *D.R. Velez[1,2], R. Menon[3], P. Thorsen[3], S.M. Williams[1,2], S.J. Fortunato[3]* 1) Division of Cardiovascular Medicine, Vanderbilt University, Nashville, TN, USA; 2) Department of Medicine and Center for Human Genetics Research, Vanderbilt University, Nashville, TN, USA; 3) The Perinatal Research Center, Nashville, TN, USA.

Spontaneous preterm birth (<37 weeks gestationPTB) occurs in ~12% of pregnancies in the United States, and is the largest contributor to neonatal morbidity and mortality. PTB is a complex disease, potentially induced by several etiologic factors from multiple pathophysiologic pathways. To dissect the genetic risk factors of PTB a large-scale high-throughput candidate gene association study was performed examining 1442 SNP in 134 genes of PTB pathways. Maternal and fetal DNA from 370 Caucasian (C) birth-events (172 cases and 198 controls) was examined. Single locus association analyses were performed separately on maternal and fetal samples. For maternal samples the strongest associations were found in genes in the coagulation-complement pathway that are likely related to decidual hemorrhage in PTB. In this pathway 3/6 genes examined had SNPs significantly associated with PTB. These include Factor V (F5) that was previously associated with PTB (rs9332624, p = 3.0x10-3) and Plasminogen activator tissue (PLAT). The single strongest effect was observed in PLAT marker rs879293 (allelic association p = 2.00x10-3; genotypic association p=2.0x10-6). The odds ratio (OR) for this SNP was 2.80 (CI 1.77 - 4.44) for a recessive model. Given that 6/8 markers in PLAT were statistically significant, sliding window haplotype analyses were performed and 4 marker haplotype in PLAT (p = 0.006) was found. The single strongest effect in C babies was observed in the inflammatory pathway at rs17121510 in the interleukin-10 receptor antagonist (IL-10RA) gene for allele (p = 0.01) and genotype (p = 3.34x10-4). The OR for the IL-10RA genotypic additive model was 1.92 (CI 1.15-3.19). Sliding window haplotype analyses of IL-10RA revealed several haplotypes associated with PTB. These results support a role for genes in both the coagulation and inflammation pathways, and potentially different maternal and fetal genetic risks for PTB.

Genetics Home Reference Information Rx Program. *S.M.M. Selmer[1], S.C. Calvo[2], M.L. Cheh[2], J.A. Mitchell[3]* 1) Lockheed Martin Corp., Rockville, MD; 2) Lister Hill National Center for Biomedical Communications, National Library of Medicine, Bethesda, MD; 3) University of Utah, Salt Lake City, UT.

Genetics Home Reference (GHR) is a consumer-friendly web site (http://ghr.nlm.nih.gov/) from the National Institutes of Health that seeks to educate patients, health professionals, and the general public about human genetics. Since 2003, this online resource has provided reliable information about genetic conditions and the gene or chromosome variations that contribute to those conditions. The public is increasingly looking for health information online, and GHR continues to address consumers need for clear, easy-to-understand information about the expanding field of human genetics. GHRs latest initiative, the Information Rx program, helps healthcare professionals point their patients to accurate, dependable health information on the Internet. Under this program, free Information Rx pads enable doctors and nurses to write "prescriptions" that direct patients to the GHR web site for an explanation of genetic disorders and related topics. Healthcare professionals can visit the Information Rx Store (http://www.informationrx.org/) to request supplies at no cost. The GHR Information Rx program is particularly relevant for families of infants undergoing newborn screening. GHR has recently added specific information about each of the 29 conditions recommended for newborn screening by the Health Resources and Services Administration (HRSA). The GHR Information Rx program can link new and prospective parents with consumer-friendly information about any of these conditions. Since the programs inception in late 2006, healthcare professionals have ordered more than 1,100 Information Rx pads to educate their patients about genetics topics. Evaluation of the GHR Information Rx program is planned with the families of patients diagnosed through newborn screening.

Novel Chromosome 20p12.3 Deletion Associated with Learning Difficulties and Dysmorphic Features in a Mother and Son. *J.V. Thakuria[1], S. Waisbren[2], G.F. Cox[1, 3]* 1) Div of Genetics, Children's Hospital, Boston, MA; 2) Dept of Psychiatry, Children's Hospital, Boston, MA; 3) Genzyme Corp, Cambridge, MA.

A 5 year old boy presented with a history of developmental delay, mild dysmorphic features, Wolff-Parkinson-White (WPW) syndrome, and hypoglycemic episodes. He was a former 8 lb term boy born by vaginal delivery to a 34 year old G4P2SAB2 mother following an uncomplicated pregnancy, labor, and delivery. Four hours after birth, he developed supraventricular tachycardia and was diagnosed with WPW, now controlled with sotalol. He has had 3 episodes of fasting-induced hypoglycemia, one associated with a seizure. EEG and a metabolic evaluation have been unrevealing. Brain MRI showed ventriculomegaly with benign external hydrocephalus. Dysmorphic features included macrocephaly, frontal upsweep, downslanting palpebral fissures, epicanthal folds, hypertelorism, long philtrum, microstomia, small ears with thick helices, and broad thumbs and toes with persistent fetal pads, features reminiscent of FG syndrome. He has moderate cognitive, gross motor, and speech delays as well as hyperactivity and sensory issues. Genetic evaluation included an apparently normal 46,XY male, fragile X testing, and PTEN mutation analysis. Chromosomal microarray testing (Baylor Version 6.1) revealed a microdeletion at 20p12.3, and subsequent high resolution karyotype and fine mapping of the breakpoints revealed a 2.33 Mb deletion. His mother carries the same microdeletion, but not his father or maternal grandparents. She also has a history of learning difficulties, similar facial features, and heart palpitations but without WPW by ECG and Holter monitoring. Further evaluations of WPW by stress testing and neuropsychological testing are being considered. In summary, we present a two-generation family with a de novo and apparently novel microdeletion that appears to be associated with learning difficulties, dysmorphic facies, and possibly WPW and hypoglycemic episodes. Recently a second case of WPW associated with a smaller deletion in the same region has been identified (Lalani, et al, this meeting). Further molecular analysis of this region may yield one or more genes responsible for these findings.

Whole genome association study in rheumatoid arthritis identifies TRAF1-C5 as a new susceptibility locus. *R.M. Plenge[1], E.F. Remmers[2], A.T. Lee[3], A. Liew[3], H. Khalili[3], A. Chandrasekaran[3], L. Davies[1], W. Li[3], C. Liu[4], C. Tian[7], W. Chen[5], D. Altshuler[1], J.P. Carulli[4], L.A. Criswell[6], C.I. Amos[5], M.F. Seldin[7], D.L. Kastner[2], P.K. Gregersen[3]* 1) Broad Institute; 2) National Institute of Arthritis and Musculoskeletal and Skin Diseases; 3) Feinstein Institute for Medical Research, North Shore L.I.J. Health System; 4) Biogen Idec; 5) Univ of Texas, M.D. Anderson Cancer Center; 6) Univ of California San Francisco; 7) Univ of California Davis.

BACKGROUND Rheumatoid arthritis (RA) is a common disease with a complex mode of inheritance. While HLA-DRB1 and PTPN22 are well-established susceptibility loci, and other genes conferring modest levels of risk have recently been identified, current evidence suggests additional genetic risk factors. Whole genome association is a powerful tool for systematically identifying new susceptibility loci. METHODS We applied the Illumina HumanHap550 genotyping array to RA patients seropositive for auto-antibodies against cyclic citrullinated peptides (CCP). We conducted an association study of SNP allele frequency with 502,757 polymorphic SNPs between 873 CCP+ RA cases and 1,196 controls. The most significantly associated SNPs were then replicated in an independent set of 537 CCP+ RA cases and 1,306 controls. We implemented statistical methods to correct for systematic differences in ancestry between case and control samples. RESULTS Aside from known associations with PTPN22 and the MHC region, we identified a SNP on chromosome 9 that is strongly associated with risk of developing CCP+ RA (rs3761847, OR=1.40 (95% CI: 1.27-1.54) and P=7x10-9 for all samples tested). The RA-associated SNP resides within a region of linkage disequilibrium containing two genes of known biological importance to chronic inflammatory states, TNF receptor-associated factor 1 (TRAF1) and Complement component 5 (C5). Conditional analysis across all 3,912 case-control samples demonstrates that a single allele can explain most of the genetic signal at this locus. CONCLUSIONS A common genetic variant at the TRAF1-C5 locus on chromosome 9 is associated with an increased risk of developing CCP+ RA.

Distinguishing inversions from insertions: balanced paracentric rearrangement of chromosome 9 (q32q34.3) capable of producing a viable monocentric recombinant dup(q21.3q31)/del(q32q33). *S.P. Yang[1], S.T. South[2,3], A.R. Brothman[2,3]* 1) U.C. Davis Medical Center, Sacramento, CA; 2) University of Utah, Salt Lake City, UT; 3) ARUP Laboratories, Salt Lake City, UT.

J.R. presented at birth with IUGR, microcephaly, dysmorphic facies, bilateral hip dislocations and foot deformities. High resolution karyotype showed an apparently balanced inv(9)(q32q34.3)mat. Subtelomere FISH and chromosome 9 painting probes indicated no cryptic terminal or interstitial translocation. The mother had some mild learning disabilities but her CGH microarray result was completely normal (Spectral Genomics, Inc. - 1 Mb Chip). The same CGH microarray study in J.R. revealed duplication of 14 BAC clones spanning 9q21.3 to 9q31 (11.9-13.4 Mb), and deletion of 4 BAC clones spanning 9q32 to 9q33 (4.0-6.4 Mb). These abnormalities were confirmed by specific FISH probes mapping to those regions of chromosome 9 (q21.3 and q32, respectively). Studies are underway to see if recombination occurred within a paracentric inversion, as opposed to a cryptic within-arm intra-chromosomal insertion. One rule-of-thumb to help distinguish between inversions and insertions is that the latter will always produce interstitial aneuploidy bracketed by the breakpoints in the rearranged parental chromosome. This case probably represents a paracentric inversion, based on the interstitial duplication/deletion stretching proximally beyond the 9q32 breakpoint. The mechanism of U-loop recombination (Chia et al.,1992) is possible if the inversion breakpoints are actually at q21.3 and q33. The recurrence risk for viable aneuploid offspring in the relatively common paracentric inversion carriers is very low, in contrast to the 15% or higher risk for those rare carriers of a cryptic within-arm intra-chromosomal insertion. These two alternatives are not easily separated even after extensive high resolution karyotype, FISH, CGH microarray, and haplotype analyses. Ascertainment of a familial paracentric rearrangement through the birth of an abnormal child challenges the clinician and the laboratory to define the correct underlying mechanism. Such parents are likely to be at significantly greater than background risk.

Identification of Gain 1q and 12 as the most common karyotypic changes in Wilms tumor: Analysis of 36 patients. *S. Subramaniyam[1,4], S.V. Nandula[1,4], J. Kandel[2], W. Middlesworth[2], D. Yamashiro[3,4], B. Tycko[1,4], V.V. Murty[1,4]* 1) Departments of Pathology; 2) Surgery; 3) Paediatric Oncology; 4) Institute for Cancer Genetics, Columbia University Medical Centre, New York, NY:10032, U.S.A.

Wilms tumor (WT) is the most common pediatric renal malignancy with an incidence about 1 in 10,000. Conventional treatment protocols results in 85-90% survival in these patients, but still a group of patients relapse indicating a need for intensive salvage regimens to improve their survival rates. Data from published literature indicates that cytogenetic and molecular genetic abnormalities have significant role in predicting prognosis of WT patients, for instance 1q gain in favorable histology predicts significant risk of relapse. The aim of the present study is to identify cytogenetic changes and assess their role in prognostic outcome. Forty-two tumor specimens from 36 patients ascertained from 1998 to 2005 were analyzed by conventional G-banding karyotype and Spectral karyotyping (SKY). Thirty-four tumors had an abnormal karyotype, histologically 3 cases had anaplastic changes (unfavorable histology) and 23 were classified into favorable histology group. Eleven cases had metastatic tumors infiltrating various organs. Combined analysis of Cytogenetics and SKY revealed that gains of chromosome 1q in 13/34 (38.2%) tumors with frequent breakpoints localized to 1q11-12 in 9 (69.2%). Whole chromosome gains were seen for chromosomes 8 in 9 (26.5%) tumors, 12 in 20 (59%) tumors and 13 in 9 (26.5%) tumors. Losses of chromosome 7p and 16q were seen in 8 (23.5%) and 9 (26.5%) tumors, respectively. All cases were treated and followed up according to standard protocols. Among them 6/13 (46%) cases with 1q gain, 6/20 (30%) with +12, 4/8 (50%) with 16q loss, 4/8 (50%) with 7p loss were either relapsed or died of disease (DOD). The data from the present study provides evidence in support of the hypothesis that chromosome 1q+, +12, 7p- and 16q- plays a role in WT tumorogenesis and predicts poor outcome.

African-American and Caucasian preterm and term pregnancies exhibit different patterns of cytokine expression. *S.M. Williams[1,2], D.R. Velez[1,2], T.L. Edwards[2], S.J. Fortunato[3], R. Menon[3]* 1) Division of Cardiovascular Medicine, Vanderbilt University, Nashville, TN, USA; 2) Center for Human Genetics Research, Vanderbilt University, Nashville, TN, USA; 3) The Perinatal Research Center, Nashville, TN, USA.

Pregnancy is regulated by homeostasis of multiple cytokines and chemokines. If this balance is disrupted it can induce a variety of outcomes including preterm birth (PTB). The rate of PTB also differs significantly between African Americans (AA) and Caucasians (C) and significant differences exist between AA and C amniotic fluid (AF) cytokine concentrations of both preterm and term mothers. We hypothesize that differences in patterns of cytokine gene expression contribute to the PTB racial disparity. Therefore, we examined correlations among several cytokine concentrations in AF previously associated with PTB. We examined pairwise correlations of cytokine AF concentrations between: Interleukin (IL)-1, IL-6, IL-8, IL10, Tumor Necrosis Factor-alpha (TNF-a), soluble TNF Receptors-1 and 2 (sTNFR1 and sTNFR2). Analyses were performed to test for differences in correlation coefficients between status and racial groups. Correlation differences were also evaluated in PTB where microbial invasion of the amniotic cavity (MIAC) was observed. Heterogeneity between correlation patterns was documented between C and AA in PTB and in controls (normal term births) for multiple cytokine correlations. In term births the strongest C/AA differences were between Th1/Th2-related cytokines, while in PTB differences were equally distributed between Th1/Th2-related and Th1/Th1 cytokines. Within AA PTB three correlations differed significantly between PTB with and without MIAC (IL-10/IL-1, TNF-a/IL-6, and sTNFR2/IL-1), while no differences were observed between C with and without MIAC. This suggests that while infection may play a prominent role in disruption of AA cytokine homeostasis, infection may not play as prominent a role C cytokine homeostasis. Data indicate that the coordination of cytokine networks differs greatly between C and AA and that network heterogeneity exists between PTB and term individuals within each race.

Massively Parallel Sequencing of Autism Candidate Genes. *S. Strom, J. ten Bosch, B. Merriman, Z. Chen, S.F. Nelson* Human Genetics, Univ California, Los Angeles, Los Angeles, CA.

Newly available techniques allow for the re-sequencing of 1 billion base-pairs of DNA in three days at a reasonable cost. While extremely powerful, this technology has not yet been wielded in a way that illuminates complex human traits. This requires tractable methods to selectively analyze genomic regions of interest and methods to combine DNA samples from multiple individuals into one experiment. Here we report initial findings on a direct approach to identify DNA variants in candidate genes for Autism Spectrum Disorder using the Solexa 1G Genetic Analyzer. This study focuses on two positional candidate genes for autism spectrum disorder on chromosome 17q11 identified in a whole-genome scan (Stone et al. 2004): myosin 1D (Myo1D) and amiloride-sensitive cation channel 1 (ACCN1). The design of the Solexa instrument facilitates the analysis of eight DNA samples in tandem, allowing for the sequencing of a maximum of 6.5Mb per sample with twenty times coverage, a capacity which far exceeds the scope of this study as the coding regions of both genes combined is approximately 4.5kb. The test sample is comprised of 69 male probands who share two alleles identical by descent (Z2) with an affected brother in the linkage region. This study serves to demonstrate the feasibility of large-scale candidate gene sequencing using massively parallel sequencing technology.

An enhancer in the intron 2 deletion regulates DCDC2 gene expression, and is associated with dyslexia. *H. Meng[1], J.R. Gruen[1], N.A. Cope[1], A. Citterio[2], G. Menozzi[3], M.L. Lorusso[2], M. Molteni[1], Y. Wang[4], J.J. LoTurco[4], C. Marino[2,3]*
1) Dept Pediatrics, Yale Univ, New Haven, CT; 2) Scientific Institute "Eugenio Medea", Dept Child Psychiatry, Bosisio Parini (LC), Italy; 3) CRULRG, Dept Psychiatry, Laval Univ, Québec, Canada; 4) Dept Physiology and Neurobiology, Univ of Connecticut, Storrs, CT.

Dyslexia is the most common neurobehavioral disorder of children. The prevalence is 5-20%, and heritability is 44-71%. We reported a deletion and highly polymorphic purine-rich compound STR (BV677278) in intron 2 of DCDC2 (DYX2) that showed strong TDT-association (p=0.00002) with dyslexia phenotypes in 153 families from the US (Meng et al, PNAS, 102: 17053). To test the hypothesis that BV677278 alleles modify DCDC2 expression, we first showed that competitively binding human brain nuclear extract to oligos in BV677278 shifted their electrophoretic mobility in-vitro. Next we showed a 3-fold range of in-vivo enhancer activity among the common BV677278 alleles in luciferase constructs paired with a DCDC2-specific promoter. Finally, to show that the enhancer assays had a significant clinical correlation, we tested an independent cohort of 218 dyslexic families from Italy (151 offspring with reading-related phenotypes). In this cohort, BV677278 alleles without DCDC2-specifc enhancer activity (null and allele 1) in the luciferase constructs, had the strongest association with a dyslexia phenotype, Single Non-word Spelling (QTDT analyses p=0.004, estimated additive effect= -0.659). These data confirm the DCDC2 association and dyslexia in a second non-English speaking sample, and show an inverse relationship between BV677278 enhancer activity and dyslexia association.

Connective Tissue Conundrum: The EDS IV Clinical Spectrum. *B.D. Rink, C.L. Blout, M.E. Nunes* Division of Genetics, Children's Hospital, Columbus, OH.

Ehlers-Danlos syndrome (EDS), vascular type (formerly EDS IV), an autosomal dominant condition attributed to abnormalities in type III collagen, presents with tissue fragility and characteristic physical features. Associated morbidity and mortality are due to vascular and/or visceral rupture. Penetrance is close to 100% for families identified with significant features. However, evaluation of families with *COL3A1* mutations and individuals with EDS IV features without biochemical abnormality argue for reduced penetrance. We present four such families illustrating the clinical difficulty in correlating genotype to phenotype. This provides further argument for broader clinical designation of type III collagenopathies, given the stigma associated with EDS IV. Through chart review and patient evaluation, several families were identified illustrating clinical and biochemical variability. Family 1, segregating a Gly814Arg *COL3A1* missense mutation, was ascertained by a mother suffering multiple arterial ruptures and cerebral aneurysm in her 30's. Both sons inherited the mutation, one with an obvious clinical diagnosis as a teenager and the other without any connective tissue or vascular features in his 20s. Family 2, segregating a R1024X *COL3A1* nonsense mutation, was ascertained via a cousin diagnosed with aortic aneurysm. Penetrance for vascular complication by age 50 in known mutation carriers is about 60% in this family. Family 3, evaluated for familial aortic root dilation, demonstrated classic stigmata of EDS IV. Family 4, segregating visceral rupture by the fifth decade, demonstrated identifiable but milder connective tissue features in two generations. Skin biopsy did not reveal a type III collagen abnormality in family 3 or 4. Ascertainment bias in laboratories evaluating type III collagen may overestimate the penetrance of severe features. Our families illustrate the diagnostic challenge clinicians face when evaluating patients with Ehlers-Danlos syndromes and suggest reduced penetrance and variable expressivity. A role for additional genes modifying the type III collagen phenotype is suggested. Further, *COL3A1* sequencing may provide additional diagnostic information for patients undetected by biochemical analysis.

Meta-analyses of Genetic Studies on Major Depressive Disorder. *C.M. van Duijn[1], S. Lopez-Leon[1], A.C.J.W. Janssens[2], A.M. Gonzalez-Zuloeta Ladd[1], J. Del Favero[3], S.J. Claes[4], B.A. Oostra[5]* 1) Epidemiology & Biostatistics, ErasmusMC, Rotterdam, Zuid Holland, Netherlands; 2) Department of Public Health, ErasmusMC, Rotterdam, Zuid Holland, Netherlands; 3) Applied Molecular Genomics Group, Department of Molecular Genetics, VIB, University of Antwerp, Antwerp, Belgium; 4) Department of Psychiatry, University of Leuven, Leuven, Belgium; 5) Clinical Genetics, ErasmusMC, Rotterdam, Zuid Holland, Netherlands.

The genetic basis of major depressive disorder (MDD) has been investigated extensively, but the identification of MDD genes has been hampered by conflicting results from underpowered studies. We reviewed all MDD case-control genetic association studies published before June 2007 and perform meta-analyses for polymorphisms that had been investigated in at least three studies. The study selection and data extraction were performed in duplicate by two independent investigators. The 183 papers that met our criteria studied 393 polymorphisms in 102 genes. Twenty two polymorphisms (6%) were investigated in at least three studies. Seven polymorphisms had been evaluated in previous meta-analyses, of which for five were new data available. Hence, we performed meta-analyses for 20 polymorphisms in 18 genes. Pooled odds ratios (ORs) with 95% confidence intervals (CI) were calculated. Statistically significant associations were found for the APOE 2 (OR, 0.51), GNB3 825T (OR, 1.38), MTHFR 677T (OR, 1.20), SLC6A4 44bp ins/del S (OR, 1.11), alleles and the SLC6A3 40bpVNTR 9/10 genotype (OR, 2.06). Our meta-analyses found significant evidence for five MDD susceptibility genes (APOE, GNB3, MTHFR, SLC6A3 and SLC6A4). Together with our previously published meta-analysis on DRD4 there is evidence for six MDD susceptibility genes. The low coverage of genetic variants of candidate genes makes it impossible, however, to exclude that the other genes studied are not involved at all in MDD. Further, there is a need to standardize the methodology in research of MDD and other complex traits.

Meta-analysis of 4552 type 2 diabetes (T2D) cases and 5576 controls on ~1.9 million genotyped and imputed SNPs spanning the human genome. *L.J. Scott[1], B. F. Voight[2,3], J.L. Marchini[4], R. Saxena[2,3], C.J. Ding[1], N.P. Burtt[2], G. Abecasis[1], E. Zeggini[5] for the FUSION, DGI, and WTCCC/UKT2D studies* 1) Dept Biostatistics and Center for Statistical Genetics, Univ Michigan, Ann Arbor, MI; 2) The Broad Institute of Harvard and MIT,Cambridge MA; 3) Massachusetts General Hospital, Boston MA; 4) Dept Statistics, Oxford Univ, Oxford, UK; 5) Oxford Centre for Diabetes and Wellcome Trust Centre for Human Genetics, Oxford Univ, Oxford, UK.

We have performed a meta-analysis of 1467 T2D cases and 1464 controls from the Diabetes Genetics Initiative (DGI), 1924 T2D cases and 2938 controls from the Wellcome Trust Case Control Consortium (WTCCC) and 1161 T2D cases and 1174 controls from the Finland United States Investigation of NIDDM genetics (FUSION) studies. The DGI and WTCCC samples were genotyped on the Affymetrix GeneChip500K Array Set and the FUSION samples on the Illumina HumanHap300 BeadChip. We imputed genotypes for ~2.0 million additional SNPs from the phased CEU HapMap data using the Mach 1.0 and IMPUTE programs. For all high quality genotyped and imputed SNPs with allele frequency > 1 % in each sample, we combined the T2D odds ratios using a fixed-effects meta-analysis. Of the ~1.9 million SNPs analyzed, 107 had p-values < 1×10^{-6} (1.9 expected) and 263 had p-values < 1×10^{-5} (19 expected). An initial association analysis by the DGI, WTCCC, and FUSION recently identified and confirmed multiple loci associated with T2D. After excluding SNPs from these regions we continued to observe an excess of significant results; 23 SNPs from five regions had p-values < 1×10^{-6} (1.9 SNPs expected) and 101 SNPs from 12 regions had p-values < 1×10^{-5} (19 SNPs expected). Of the 12 regions, four were identified based solely on imputed SNPs and six were identified based on genotyped SNPs from at least two of the studies. As an initial follow-up of the strongest novel T2D associations, we are genotyping SNPs on stage2/replication samples of 10,037 T2D cases and 12,389 controls. Our results suggest that additional genes for T2D will likely be identified from this more comprehensive approach.

A New Method for Detecting CpG Methylation Status Using High-Resolution Melting. *L. Zhang, S. Dandekar, J.C. Papp* Human Genetics, David Geffen School of Medicine, University of California, Los Angeles, CA.

Cytosine methylation of CpG dinucleotides in CpG islands is an important mechanism of gene regulation in vertebrates. CpG methylation plays a role in both developmental and cancer biology. Abnormal methylation of CpG sites results in developmental abnormalities in humans. Abnormal methylation of CpG islands in tumor-suppressor genes promotes the development and growth of cancerous cells. Current methods available for detecting CpG methylation patterns require extensive manual processing or the use of expensive dual-labeled probes. We describe a new high-throughput, quantitative, low-cost technique which utilizes recent developments in high-resolution melting (HRM) technology to ascertain methylation status with no further manual manipulation after the PCR step. Unmethylated cytosine in the DNA sample is deaminated to form uracil by treatment with bisulfite. In subsequent PCR amplification the uracil is replicated as thymine. Methylated cytosine in the DNA sample is protected from reacting with the bisulfite, and the cytosine remains after PCR amplification. A pure sample of PCR product from bisulfite treated unmethylated DNA, with its cytosine converted to thymine, has a markedly different melting profile from the methylated DNA PCR product with its unconverted cytosines. In addition, the heterogeneous mixture of unmethylated and methylated DNA has a different melting profile from either of the pure samples. Using HRM analysis software, the degree of methylation of an unknown sample can be quantified by comparing the melting profile of the unknown sample to standards with known percent methylation. Using this technique on two genes which are commonly hypermethylated in a wide variety of cancers, hMLH1 and $P16^{INK4}$, we are able to detect as little as 1% of the methylated allele.

Variants in the LDL receptor gene are associated with LDL cholesterol in the Multi-Ethnic Study of Atherosclerosis. *W. Post[1], J.C. Mychaleckyj[2], L. Raynor[3], K.D. Taylor[4], X. Guo[4], K.E. Watson[5], C. Hedrick[2], J. Polak[6], M. Tsai[3], S.S. Rich[2], J.I. Rotter[4], J.S. Pankow[3]* 1) Johns Hopkins Univ, Baltimore, MD; 2) Univ of VA, Charlottesville, VA; 3) Univ of Minnesota, Minneapolis, MN; 4) Cedars-Sinai, Los Angeles, CA; 5) UCLA, Los Angeles, CA; 6) Tufts, Boston, MA.

LDL cholesterol (LDL-C) is a complex trait influenced by multiple genes. Rare mutations in the LDL receptor gene (LDLR) lead to familial hypercholesterolemia and premature CVD, but account for little variability in LDL-C in the general population. We hypothesized that common variants in LDLR influence LDL-C. Eleven tagging SNPs and one nonsynonymous coding SNP spanning 48 kb were selected in LDLR. Genotyping was completed using Illumina GoldenGate Assay in 2880 men and women, age 45-84 yrs, without known CVD from the Multi-Ethnic Study of Atherosclerosis (MESA), including equal numbers of White(W), Black(B), Hispanic(H) and Chinese(C) US subjects. Associations between each SNP and LDL-C were determined using multivariate regression, adjusting for age, gender and lipid medications, stratified by race/ethnicity and combined. All SNPs met HWE assumptions within each ethnic group. The minor allele of rs2228671 was associated with lower LDL-C in W(12% MAF), H(6% MAF),and B(1% MAF)($p<0.03$, 0.02, 0.06, additive model). In the combined cohort, this allele was associated with a 5 mg/dL lower mean LDL-C ($p<0.004$). In the combined cohort, the minor alleles of 3 additional SNPs (rs8104576,rs2304182,rs1433099) that were not in significant LD were also associated with lower LDL-C ($p<0.007$, 0.002, 0.03) We also observed a rare nonsynonomous SNP(rs5928)in these populations, with only 6 heterozygotes (HETs) in the combined cohort. For this SNP the mean LDL-C was 19% higher in the HETs, compared to homozygotes for the major allele ($p<.03$). In summary, minor alleles of 4 common SNPs in LDLR are associated with lower LDL-C in the general population. Heterozygosity for a rare nonsynonymous coding SNP is also associated with higher LDL-C. We conclude that common variants in LDLR influence LDL-C variation in the general population across multiple ethnic groups.

Ignoring Imprinting Effects Can Severely Jeopardize Detection of Linkage. *Y.J. Sung*[1, 2], *DC. Rao*[1, 2, 3] 1) Division of Biostatistics, Washington University in St Louis, St Louis, MO; 2) Department of Psychiatry, Washington University in St Louis, St Louis, MO; 3) Department of Genetics, Washington University in St Louis, St Louis, MO.

Genes with imprinting (or parent-of-origin) effects inherited from the mother express differently than those inherited from the father. Some genes that affect development and behavior in mammals are known to be imprinted. We have developed parametric linkage analysis with imprinting and implemented it in the lm_twoqtl program in the MORGAN package. The program offers computationally tractable analysis of general pedigrees with many markers. To study the impact of imprinting on linkage analysis, we simulated data sets where imprinting contributes 0%, 25%, 50%, and 75% of the variance of a QTL effect. To study misspecification of imprinting, we analyzed each data set with all 4 different models. The correct model with imprinting provided the highest lod scores with all max lod scores over 4. The incorrect model with no imprinting provided the lowest lod scores with max lod scores of 2.23, -1.13, and -5.21 with 25%, 50%, and 75% imprinting, respectively. Cases with max lod > 3 from the correct model with imprinting and max lod < -2 from the incorrect model with no imprinting occurred in 60 out of 100 cases. Models with misspecified imprinting produced lod scores intermediate between those of the models with correct imprinting effects and no imprinting. These simulations show that accounting for imprinting can substantially improve linkage detection.

Whole-genome association study in the Old Order Amish identifies *STK39* as a novel hypertension susceptibility gene. *Y. Wang, P.F. McArdle, E. Rampersaud, H. Shen, X. Shi, N.I. Steinle, B.D. Mitchell, A.R. Shuldiner, Y-P.C. Chang* Division of Endocrinology, Univ Maryland, Baltimore, MD.

Hypertension (HTN) is a major risk factor for cardiovascular and renal diseases. However the specific genes that confer predisposition to HTN remain elusive. We conducted a genome-wide association study of systolic blood pressure (SBP) and diastolic blood pressure (DBP) by analyzing 93,087 SNPs in 551 subjects from the Amish Family Diabetes Study (AFDS). Twelve of the SNPs most strongly associated with SBP and DBP were located within the gene *STK39* in 2 overlapping linkage disequilibrium blocks. One representative SNP from each block was then genotyped in an expanded set of 743 nondiabetic AFDS subjects. Both SNPs showed strong association with BP traits (p-value $<10^{-8}$ for SBP and 10^{-5} for DBP). The at-risk allele was associated with an estimated 5 and 2 mmHg increases in SBP and DBP, respectively. As an independent replication, we then analyzed SNPs from the two associated blocks in a third independent set of Amish (n=868) that were younger and healthier than the AFDS population. Again, we detected strong association, in the same direction as seen in AFDS, between these SNPs and baseline SBP levels, as well as with other more sensitive measures of vascular function, including SBP response to cold pressor test (p-values $< 10^{-5}$). In addition, analyses of BP traits by the BROAD Institute (http://www.broad.mit.edu/diabetes/scandinavs/metatraits.html) also demonstrates significant association between the same *STK39* SNPs and SBP level and HTN status ($p<0.02$). *STK39* encodes serine threonine kinase 39 and is known to stimulate the activity of Na^+-K^+-$2Cl^-$ co-transporter (NKCC1) in the distal nephron. Furthermore, mutations in *WNK1* and *WNK4*, which phosphorylate and activate NKCC1 through *STK39*, can cause a monogenic form of HTN. In summary, evidence from analyzing the Old Order Amish as well as more outbred populations showed that variants in *STK39* are strongly associated with BP levels. Some associated SNPs are located within highly conserved putative regulatory elements and are excellent candidates for functional analyses of this novel HTN susceptibility gene.

MLL amplification is a distinct biological entity in patients with MDS/AML carrying complex chromosomal changes and predicts poor prognosis. *V. Nandula[1,3], E. Ritchie[4], D. Savage[2], B. Alobeid[1], G. Bhagat[1,3], V.V. Murty[1,3]*
1) Departments of Pathology; 2) Medicine; 3) Institute for Cancer Genetics, Columbia University Medical Center, New York, NY:10032; 4) Department of Medicine, Weill Cornell Medical Center, New York, NY:10021.

Acute myeloid leukemia is a disease that is heterogeneous in morphology and prognosis. Complex karyotypes account for 10-20% of all the AML cases and in 50% of the therapy related AML and MDS cases, increasing with age. Despite intensive treatment their median overall survival is less than 6 months. MLL amplification has been frequently reported in MDS/AML patients. The aim of the present study is to identify specific karyotypic and molecular alterations among this subset of patients and correlate the changes with treatment outcome. MDS/AML cases (N=72) with complex chromosomal rearrangements ascertained from 1998 to 2004 were included in the study. Of these, 12 cases had material available for further evaluation. Using molecular cytogenetic methods (FISH and SKY) we studied MLL status along with the frequently reported losses (5q, 7q, 12p and 17p) and gains (8, and 21). Eight of the twelve cases (65%) had MLL amplification (copy number ranging from 6-20copies) while 50% of these cases had ATM gene co amplified with the MLL locus. All cases had loss of chromosome 5q. 50% of the cases had gains of chromosome 8. 17p loss was seen in 50% cases. All the cases that had 17p deletion had over expression of TP53. 12p deletions were found in 40% of the cases. All the cases had a very less overall survival from few days to few months. The present study with losses of 5q, 12p and 17p and gains of MLL form a morphological-cytogenetic entity and identifies a subset of MDS/AML patients with poor prognosis.

A *COL2A1* mutation in a patient with unknown skeletal dysplasia: unclassified type II collagenopathies. *A. Sathienkijkanchai[1], N.H. Robin[1,2]* 1) Dept Genetics,; 2) Dept Pediatrics, Univ Alabama at Birmingham, Birmingham, AL.

The skeletal dysplasias are a group of more than 250 disorders characterized by abnormal formation of the skeleton because of intrinsic derangement of the growth, development, and/or differentiation. Disease-causing genes have been identified in more than 150 diseases such as *FGFR3*, *COL2A1*, and *COMP* gene. The type II collagenopathies are a heterogeneous group of disorders resulting from mutations in the collagen 2 gene. There is a wide spectrum in severity in this group ranging from invariably lethal (achondrogenesis II/hypochondrogenesis) through spondyloepiphyseal dysplasia congenital (SEDC), Kniest dysplasia, and Strudwich type SE(M)D to more mildly affected Stickler dysplasia. The unifying findings in type II collagenopathies are, in common, involvement of the spine (platyspondyly) and epiphyseal of the long bones (spondylo-epiphyseal pattern).

Here, we present a patient with skeletal dysplasia. The patient is a seven-year-old Caucasian female presenting at birth with severe short stature and respiratory distress. Additionally, she was found to have cleft palate, bilateral clubfeet, large PDA with ASD, and hearing loss. Initially, her skeletal survey was interpreted as hypochondrogenesis which is the condition that most patients do not survive the first 6 months of life. However, finally, the diagnosis of unclassified type II collagenopathies has been raised after her recent skeletal survey was reviewed and demonstrated platyspondyly, metaphyseal flaring, absence of the capital femoral epiphyses, unossified pubic bones with relatively normal bones of hands and feet. The diagnosis has been confirmed by finding a mutation in *COL2A1* gene which is c.1421G>A. So, she has carried a Gly471Glu substitution. Therefore, identification of disease gene (molecular diagnosis) on this patient would help us to provide better care and treatment as well as improving understanding of the disease and making this distinction important for counseling the family.

MicroRNA genes on the X-chromosome of patients with neuropsychiatric disorders. *J. Yan[1], J. Feng[1], K. Noltner[1], W. Li[1], C. Schwartz[2], S. Sommer[1]* 1) Dept Molecular Genetics, City of Hope, Duarte, CA; 2) J.C. Self Research Institute, The Greenwood Genetic Center, SC, USA.

Individual microRNAs (miRNAs) moderately down regulate many genes, typically by two- to four-fold. Disruption of a miRNA binding site in the SLITRK1 gene has been associated with Tourettes syndrome. To explore the role of miRNAs in neuropsychiatric disease, six microRNA genes on the X chromosome (let-7f-2, mir-384, mir-223, mir-224, mir-325 and mir-361) were analyzed in 96 males with schizophrenia, 90 patients with autism (67 males and 23 females) and 70 males with mental retardation and 192 male controls and 190 female controls (716.5 kb of total sequence). A transition in the let-7f-2 mature miRNA sequence was found in a patient with schizophrenia. The variant occurs at a nucleotide conserved through C. elegans. The variant was not found in 10,000 control chromosomes without schizophrenia. mir-384 was deleted in one patient with mental retardation and not in 556 male controls. In addition, single base substitutions were found in mir-224 in a patient with autism and in mir-325 in a patient with psychosis. These variants were not found in 10,000 control X-chromosomes. In summary, three different ultra rare single base substitutions were found on sequence analysis of 256 (272 chromosomes) neuropsychiatric cases and zero ultra rare variants in 572 control chromosomes. In addition, the whole miRNA deletion was found in one male patient with mental retardation and zero of 556 male controls.

High Risk Cohort Specific Variants in DISC1 are Identified and Associated with Schizophrenia with an Estimated Attributable Risk of 2%. *W. Song[1], J. Feng[1], W. Li[1], J. Longmate[1], L. Heston[2], S. Sommer[1]* 1) Dept Molecular Genetics, City of Hope, Duarte, CA; 2) Department of Psychiatry, University of Washington, Seattle, WA.

The association of DISC1 gene mutations with schizophrenia is controversial. In a large Scottish pedigree, a balanced translocation t(1;11)(q42.1;q14.3) disrupting the DISC1 gene segregates with major mental illness, including schizophrenia and unipolar depression. A frame-shift C-terminal deletion was reported in another Scottish family, but subsequently found in two controls. In addition, a few common structural variants have variably been associated with less than a two-fold increased risk for schizophrenia, but no large scale case control genotyping analysis has been performed. We have analyzed the regions of likely functional significance in the DISC1 gene with DOVAM-S and direct sequencing in 288 patients with schizophrenia (274 Caucasian, 14 African-American) and 288 Caucasian controls (5 megabases total). Six Cohort-Specific missense variants were found in patients with schizophrenia ($p=0.01$), and not in 6000 control samples, respectively ($p<0.0001$). In addition, two common missense variants were found in cases with significant excess (p0.05). We conclude that uncommon structural variants in DISC1 impart a high relative risk of schizophrenia with an attributable risk of 2%, while certain common structural variants increase risk slightly.

Characterizing satellite I and satellite III sequences on human chromosome 21. *R. Patel[1], K. Gregori[1], P. Chennamaneni[1], S. Xavier[1], R. Hettinger[1], J. Bavarian[1], R. Ennesser[1], M. Cummings[2], J. Doering[1]* 1) Loyola Univ Chicago; 2) Univ. of Illinois, Chicago.

The human genome sequence does not include the heterochromatic regions, although these sequences comprise 10-15% of the genome. We are constructing a detailed physical map of the HC21 centromere and short arm as a model for the organization of these regions. Our previous work identified two subfamilies of satellite I (sat I) on HC21 which share 80% sequence identity. The N6 subfamily is located solely on the p arm distal to the rDNA cluster, while pTRI-6 sequences are present both in the p arm proximal to the rDNA and in the centromere. The HC21 centromeric sat I cluster has been physically mapped, and portions of it have been now been sequenced. It is 0.3 Mb long and flanked on its p arm end by 760bp of a Y chromosome-specific sat I subfamily and 1kb of a TA simple repeat. Its q arm end is located within 76kb of the major alphoid cluster, D21Z1. Internally, the sat I cluster consists of tandemly repeated pTRI-6 sequences frequently interrupted by other sat I sequences that have only 80% identity to pTRI-6. There is a high degree of sequence heterogeneity between monomers in the cluster and no obvious higher order repeat. These newly-identified sat I sequences are quite distinct from the N6 subfamily or any other sat I sequences in the database, indicating they represent a new subfamily. This centromeric sat I cluster is not found on other chromosomes, and is thus a strong candidate for an HC21-specific centromeric marker. Satellite III (sat III) sequences are found on the p arm of HC21 both proximal and distal to the rDNA. We have identified at least five distinct sat III clusters on HC21p, three proximal to the rDNA and two distal. They are all less than 90kb in length. Sequencing reveals that all these clusters are members of sat III subfamily I and have highly heterogeneous organizations with no obvious higher order repeats. BLAST comparisons showed that these sat III sequences have no more than 80% identity to each other or with any other currently known sat III sequence in the human genome. Thus, they are candidates for HC21p-specific probes.

DNA resequencing microarrays identify mutations causing severe combined immunodeficiency (SCID). *E.S. Mansfield[1], T. Lebet[2], S. Venkatapathy[1], R. Chiles[1], J.A. Warrington[1], J.M. Puck[2]* 1) Advanced Applications and Standards R&D, Affymetrix, Santa Clara, CA; 2) Pediatrics Dept., UCSF, San Francisco, CA.

Early onset of recurrent infections is the hallmark of severe combined immunodeficiency (SCID), which is generally fatal in the first year of life unless treated by bone marrow transplantation, enzyme replacement or gene therapy. Recognizing SCID early is essential successful treatment, but immunologic confirmation and DNA sequencing are expensive, laborious and available only in specialized laboratories. There are 12 presently known disease genes for SCID, with many possible mutations in each gene. To test whether microarray technology can identify mutations efficiently from genomic DNA samples, we produced a custom GeneChip microarray representing the full coding and splice regions of 20 genes underlying SCID and other primary immunodeficiencies. Long range PCR was used to make enriched genomic DNA templates, which were fragmented, labeled and hybridized to arrays. After washing and scanning, data was analyzed by GCOS software. In a pilot with IL2RG, JAK3 and IL7R genes, we tested DNAs from 61 SCID previously genotyped patients and 55 obligate carriers. Overall nucleotide correct call rates were 99.5% for X-linked haploid (XSCID) and 98% for diploid sequence. Of 35 known XSCID samples, mutations were recognized in 34 (97%) with the precise mutation defined in 33 (94%). In heterozygous maternal carrier samples, 21 of 22 mutations were flagged (95%) with the exact mutation defined in 19 (86%). Known autosomal mutations were also found. Importantly, 7 of 7 DNAs from SCID patients not previously genotyped had mutations identified by the array and later confirmed by conventional sequencing, including 3 with previously unreported XSCID defects and a compound heterozygous JAK3 case. Certain nucleotides in regions of high GC content could not be called automatically by the software. However, with further development and experience several primary immunodeficiency diseases might ultimately be diagnosed using microarray-based methodology.

Parental perceived value of a diagnosis for Mental Retardation (MR): A qualitative comparison of families with and without a diagnosis for their childs MR. *N.L. Makela[1], C.A. Marra[2], P. Birch[1], D.A. Regier[2], J.M. Friedman[1]* 1) Human Genetics, University of British Columbmia, Vancouver, B.C., Canada; 2) Centre for Health Evaluation and Outcome Sciences, Providence Health, UBC, Vancouver B.C., Canada.

Background: Although the adoption of Array Genomic Hybridization (AGH) for diagnosis of submicroscopic genomic copy number alterations that cause mental retardation (MR) is likely to affect practice, its value to families of children with MR is largely unknown. We used qualitative methods to investigate the value that families of a child with MR place on obtaining a precise genetic diagnosis. Method: Using telephone interviews, 161 parents of children between the ages of 5 and 10 years with MR were interviewed to determine the value they place on receiving a precise genetic diagnosis. 24.8%(N=40) had a child with chromosomal abnormality identified cytogenetically, 4.3%(N=7) had a child that was diagnosed clinically but could not be confirmed by laboratory testing, and 70.8% (N=114) had a child with idiopathic MR. 65 of the idiopathic MR cases had a condition that explained some of the child's symptoms but did not provide an etiological diagnosis of the MR. Twenty of the families (10 with a genetic diagnosis and 10 without a diagnosis) also participated in taped interviews to provide a qualitative comparison. Results: No differences on the value placed on obtaining a precise genetic diagnosis could be found between the two groups. Most parents in both groups strongly valued a genetic diagnosis, but a few did not. Reasons included the avoidance of stereotypes and prejudice. Many felt that the timing of diagnostic testing was important, and higher values were placed on early testing provided that the families were emotionally ready. Parents' perceptions of what a precise diagnosis can offer were not always realistic, and many perceived it as critical in obtaining support and services for their children. Few cited family planning as a strong factor. Conclusions: Parents of children with MR strongly valued obtaining a precise genetic diagnosis. Most cited access to support services as the reason.

Four most Frequent PXE Mutations in the ABCC6 Gene are not Associated with an Increased Prevalence of Coronary Artery Disease in the Ludwigshafen Risk and Cardiovascular Health Study. *B. Struk[1], W. Renner[2], K. Lindpaintner[3], B.R. Winkelmann[4], B.O. Boehm[5], W. Maerz[2]* 1) Helios-Clinic, Charité and Max-Delbrueck-Centrum, Berlin, Germany; 2) Clinical Institute of Medical and Chemical Laboratory Diagnostics, Medical University, Graz, Austria; 3) Hoffmann-La Roche Ltd, Roche Genetics, Pharmaceuticals Division, Basel, Switzerland; 4) Cooperation Unit Pharmacogenomics, Applied Genomics, University of Heidelberg, Heidelberg, Germany; 5) Division of Endocrinology and Diabetes, University of Ulm, Ulm, Germany.

Background: Mutations in *ABCC6* cause Pseudoxanthoma elasticum (PXE), a mendelian disorder that affects the elastic tissue in skin, eye and the cardiovascular system and leads to premature cardiovascular disease. Recently, the most frequent mutation, *R1141X*, was shown to be associated with a strong increase in the prevalence of premature coronary artery disease (CAD) in a Dutch case control study. However, since *R1141X* has distinct founder haplotypes and allele frequencies in different populations, it is possible that the association found is based on a specific founder effect of *R1141X* within the Dutch population. **Methods:** To further evaluate potential associations of *ABCC6* mutations and single nucleotide polymorphisms (SNP) with cardiovascular disease in the general population, we genotyped the four most frequent PXE mutations (*R1141X*, e23-29 deletion, *R1164X*, *Q378X*) and two SNP (*V614A, R1268Q*) in a total of 3316 participants of the LURIC study, a prospective cohort study. **Results:** We identified 14 carriers (0.4%) of PXE mutations in the study population (n=3290), that were equally distributed among cases (11/2564 = 0.4%) and controls (3/726 = 0.4%). Furthermore, there was no allelic association of *V614A* and *R1268Q* genotypes with the CAD phenotype in cases versus controls. **Conclusions:** Contrary to previous results, our data do not demonstrate an increased risk of premature CAD in the general population in heterozygous carriers of PXE mutations in *ABCC6*. Additionally, two common missense SNPs are not associated with CAD. Therefore, common and PXE-specific variants of *ABCC6* do not represent susceptibility markers for common CAD risk.

Novel mouse model for nonsense mutation bypass therapy shows geneticin generates a dramatic multi-day response. *C. Yang[1], J. Feng[1], W. Song[1], J. Wang[1], B. Tsai[1], Y. Zhang[1], K. Hill[1,4], P. Margaritis[2], K. High[2,3], S. Sommer[1]* 1) Beckman Res Inst, Molec Gen, City of Hope, Duarte, CA; 2) Department of Pediatrics, University of Pennsylvania School of Medicine and Division of Hematology, The Childrens Hospital of Philadelphia, Philadelphia, PA, USA; 3) Howard Hughes Medical Institute, Philadelphia, PA, USA; 4) Department of Biology, the University of Western Ontario, London Ontario Canada N6A 5B7.

Aminoglycosides can suppress nonsense mutations and are the prototypic agents for translational bypass therapy (TBT). Initial results demonstrate the need for more potent drugs and for an in vivo model system for quantitative assessment of successful translational bypass. Herein, we devise an in vivo system for quantitating TBT in the presence and absence of nonsense-mediated decay and we use the system to show that treatment with geneticin can elicit a multi-day in vivo response. Application of the system reveals that geneticin is much more efficacious in vivo than gentamicin. After two doses of geneticin, residual factor IX (F.IX) antigen can be detected after three weeks. These data demonstrate the utility of the mouse system for evaluating nonsense suppressors in vivo. In addition, this model may be helpful for testing inhibitors of nonsense-mediated decay, as a combination of geneticin and a decay inhibitor therapy may produce a therapeutic response in the R29X models. Furthermore, geneticin, its metabolites or better tolerated analogues should be evaluated as a general multi-day treatment for severe genetic disease due to nonsense mutation.

A large proportion of unclassified variants of the mismatch repair genes *MSH2* and *MLH1* are associated with splicing defects. *I. Tournier[1], M. Vezain[1], A. Martins[1], F. Charbonnier[1], S. Baert-Desurmont[1], J. Soret[2], J. Tazi[2], S. Olschwang[3], Q. Wang[4], M-P. Buisine[5], T. Frebourg[1], M. Tosi[1]* 1) Inserm U614, Faculty of Medicine and Department of Genetics, University Hospital, Institute for Biomedical Research, Rouen, France; 2) IGMM, CNRS UMR 5535, Montpellier, France; 3) Inserm UMR 599, Institut Paoli-Calmettes, Marseille, France; 4) Molecular Oncology Unit, Centre Léon Bérard, Lyon, France; 5) Laboratory of Biochemistry and Molecular Biology, University Hospital, Lille, France.

Numerous variants of unknown biological significance have been found in *MSH2* and *MLH1* involved in Lynch /HNPCC syndrome. Some of these variants may have an effect on pre-mRNA splicing by altering degenerate positions of splice site sequences. Moreover, exonic splicing enhancers (ESE) have been proposed to be frequent in *MSH2* and *MLH1*. To determine the consequences of these variants on splicing, we have developed a functional assay performed on genomic DNA. For each variant, mutant and wild-type exons to be tested, PCR amplified from genomic DNA together with ~150 bp of flanking sequences, were inserted into a splicing reporter minigene. After transfection into HeLa cells, the effects of mutations were evaluated by RT-PCR and sequencing analysis. We have examined 85 different UVs (54 missense, 10 silent, 3 deletions of a single codon and 18 intronic variants) detected in 84 HNPCC families and found that 22 (26%) affect splicing. Four exonic variants were found to affect putative splicing regulatory elements. We then analysed short stretches (~30 nt) around the latter variants or the corresponding wild type sequences by cloning them into the ESE-dependent central exon of a three exon splicing minigene and we showed that the wild-type short sequences contain functional ESEs. Moreover, using this construct, we examined short stretches around 14 additional *MSH2* or *MLH1* variants previously described as affecting putative exonic regulatory elements and we found that they contain functional ESEs. In absence of reliable bioinformatics predictions, these splicing assays represents a valuable tool for the interpretation of UVs and should contribute to the optimization fo the Lynch syndrome.

Residual genetic effects beyond germline p53 mutations in Li-Fraumeni syndrome. *C.C. Wu[1], S. Shete[1], J. Ma[1], C.I. Amos[1], L.C. Strong[2]* 1) Dept Epidemiology, Univ Texas MD Anderson CA Ctr, Houston, TX; 2) Dept Cancer Genetics, Univ Texas MD Anderson CA Ctr, Houston, TX.

Germline p53 mutations have been identified in many families with Li-Fraumeni syndrome (LFS). Even in the presence of a stable germline p53 mutation segregating in a family, the age of cancer onset and multiplicity of tumors is highly variable, suggesting the presence of additional genetic effects. In a preceding study, we identified a sex difference in cancer risk in LFS patients with germline p53 mutations (Cancer Research, 66(16): 8287-92, 2006). Here, we investigate the residual genetic basis of risk beyond germline p53 mutations on LFS that might account for the observed genetic and phenotypic heterogeneity of LFS. We investigated 6 pedigrees with hereditary germline p53 mutations from a series of families described previously and analyzed with a single combined phenotype of invasive cancer (excluding nonmelanoma skin cancer and in situ carcinoma). In those kindreds, a total of 62 germline p53 mutation carriers have been identified. To determine the hypothetical genetic model for any unobserved non-p53 gene(s) or cancer risk modifier(s) in the presence of germline p53 mutations, we applied a complex segregation analysis based on Cox proportional hazards model and a Bayesian Monte Carlo Markov chain (MCMC) method implemented in the G.A.P. and Loki programs, respectively. The statistical approaches allowed us to associate the simultaneous effects of germline p53 mutations and unobserved gene(s) underlying LFS with cancer incidence in these families. Our findings from the segregation analysis showed that the plausible genetic models allowing for interaction between an unmeasured major gene, p53, and sex significantly improve the corresponding models with no interaction term, thus providing strong evidence for at least one modifier locus interacting with germline p53 and sex. In the MCMC analysis, we found that one or two susceptibility genes in addition to germline p53 mutations contribute to the variance in age of cancer onset in LFS.

Autism associated alleles affect the transcriptional regulation of *ENGRAILED 2*. *J. Millonig[1, 2, 3], R. Benayed[1, 2], P. Matteson[1, 2], J. Choi[1, 2], N. Gharani[3], L. Brzustowicz[3]* 1) Center for Advanced Biotechnology and Medicine, UMDNJ-RWJMS, Piscataway, NJ; 2) Department of Neuroscience and Cell Biology, UMDNJ-RWJMS, Piscataway, NJ; 3) Department of Genetics, Rutgers University, Piscataway, NJ.

We have previously demonstrated that two intronic SNPs (*rs1861972* and *rs1861973*) in the homeobox transcription factor, *ENGRAILED 2*(*EN2*), are consistently associated with Autism Spectrum Disorder (ASD) in 3 separate datasets (A-C haplotype; *P*=0.000000427; 518 families)(Gharani et al., 2004; Benayed et al., 2005). Population Attributable Risk calculations for the associated haplotype determined that the *EN2* risk allele contributes to ~40% of ASD cases. Hapmap LD data indicate that *rs1861973* is not in strong LD with any SNP within 2Mb of *EN2* (r^2.45) identifying the associated haplotype as a candidate risk allele. Previous resequencing and LD analysis of *EN2* support this possibility.

Because risk alleles for other common diseases affect the transcriptional regulation of the associated gene, luciferase reporters for the *EN2* intron were generated and transiently transfected into 3 cell types: HEK293T cells, PC12 cells and primary cultures of mouse cerebellar granule neurons. In all three cell types the intron functioned as a transcriptional repressor (P.0001; two tailed paired Students T test). To test for a functional difference between the associated A-C and non-associated G-T haplotypes, both versions of the intron were cloned into luciferase reporters that contained either a minimal SV40 promoter or the *EN2*promoter. These constructs were transfected into the same 3 cell types and in all experimental conditions the non-associated G-T intron was a stronger repressor than the associated A-C version (P.005; two tailed paired Students T test). EMSAs using granule cell extracts were performed which identified proteins binding specifically to the associated alleles. These data indicate that *EN2* is an ASD susceptibility gene and that the A-C haplotype is a risk allele responsible for *EN2* association with ASD.

Association between ACE pathway genes and carotid atherosclerosis in the Multi-Ethnic Study of Atherosclerosis (MESA). *X. Li[1], Y. Chen[1], T. Howard[2], J. Mychaleckyj[3], Y.I. Chen[1], S.J. Shea[4], J. Polak[5], J.R. Rotter[1]*
1) Cedars-Sinai Medical Center; 2) Wake Forest University; 3) University of Virginia; 4) Columbia University; 5) Tufts-New England Medical Center.

Angiotensin I-converting enzyme (ACE) is a key factor involved in blood pressure (BP) regulation. Since hypertension is a risk factor for atherosclerosis, variations in ACE pathway genes (ACE, AGT, AGTR1, and NOS3) may be associated with atherosclerosis development. In the MESA study, subclinical atherosclerosis is evaluated by carotid ultrasound of intima-media thickness (IMT) of the common carotid artery (CCA IMT) and of the internal carotid artery (ICA IMT). We genotyped 2847 subjects, including all 4 ethnic groups (712 African Americans, AFA, 712 European Americans, EUA, 718 Chinese Americans, CHN, and 705 Hispanic Americans, HIS), to examine the association between 61 tag SNPs of ACE pathway genes and IMT. Association tests were considered for additive models if the generalized model (2df) was significant. Multiple linear regression was first adjusted for age, gender, BMI, and then adjusted for BP. ACE genes variation was associated with CCA IMT in CHN for 2 SNPs (rs4459610, p=0.007 and rs8066276, p=0.008). AGT did not yield any significant associations. AGTR1 was associated with IMT differentially in different ethnic groups. In AFA, 1 SNP was associated with CCA IMT (rs4488792, p=0.005) and 1 SNP was associated with ICA IMT (rs6801836, p=0.007). In EUA, 1 SNP was associated with CCA IMT (rs275645, p=0.021). And in HIS, only after adjusting for BP, 2 SNPs were associated with ICA IMT (rs275645, p=0.033 and rs2638363, p=0.038) and one was overlapping with CCA IMT (rs275645, p=0.030). Most interestingly, 1 specific NOS3 SNP was significantly associated with CCA IMT in AFA (rs743507, p=0.005) and in all ethnic groups combined (p=0.003). In summary, the association between IMT and ACE pathway genes was different across ethnic groups for most of genes studied. However, the NOS3 SNP rs743507 was associated with CCA IMT in all ethnic groups combined. The association was independent of any BP effect. These results suggest different susceptibilities to atherosclerosis at different artery segments.

Systematic screening of synaptic X chromosome genes as candidates for autism and schizophrenia. *A. Piton[1], J. Gauthier[1], F. Hamdan[2], Y. Yang[1], D. Spiegelman[1], E. Henrion[1], O. Diallo[1], S. Laurent[1], L. Destroismaisons[1], J. Duguay[1], L. Karemera[1], F. Kuku[1], M. Cote[1], J. Roussel[1], K. Lachapelle[1], P. Drapeau[3], G. Rouleau[1]* 1) Centre for the Study of Brain , CHUM Research Centre Notre-Dame Hospital, Montréal, Québec, Canada; 2) Division of Medical Genetics, Hopital Sainte-Justine, Montreal, QC; 3) Universite de Montreal, Department of Pathology and Cellular Biology, Montreal, QC.

Autism (AUT) and schizophrenia (SCZ) are two common neurodevelopmental disorders, which result from the combination of genetic and environmental factors. Linkage studies on the whole genome and association studies with candidate genes have failed to clearly identify the genes involved in the pathogenesis of these two diseases. We hypothesize that several different rare variants in numerous genes, including de novo variants, could lead to these diseases. Such variants cannot be identified by classical genetic methods. Therefore, we decided to directly sequence, in 288 AUT and SCZ patients, genes coding for proteins involved in the synapse, as defects in synaptic processes can lead to impairment in cognitive function. We decided to focus on the X chromosome, as evidence supports its implication in the predisposition to AUT especially, but also to SCZ. Using various methods and sources, we established a complete list of 183 synaptic and potentially synaptic genes located on this chromosome and we ranked them according to their relevance for the diseases (role in synapse formation, expression in brain tissues or impairment in learning in human or in animal models). We selected in this way 104 X-linked candidate genes that are currently being sequenced in our cohort of 288 patients. We expect to identify more than 200 variants that will be further analyzed genetically. The most interesting ones will be validated functionally using animal models (zebrafish, fruitfly, worm or mice neurons). By the end of this study, we expect to identify and validate several causative variants for AUT or SCZ in different synaptic genes, that will allow a better understanding of mechanisms underlying the development of these two common neurodevelopmental diseases.

Novel mutations in BHD and expansion of the spectrum of phenotypes in 50 new families with Birt-Hogg-Dubé Syndrome. *J. Toro[1], M. Weinreich[1], G.M. Glenn[1], O. Toure[1], P. Pinto[2], M. Merino[3], M. Turner[4], S.M. Steinberg[5], P. Choyke[6], L.S. Schmidt[2,7], M.H. Wei[1], W.M. Lihenan[2]* 1) Genetic Epidemiology Branch, DCEG; 2) Urologic Oncology Branch, CCR; 3) Laboratory of Pathology, CCR; 4) Dermatology Branch, CCR; 5) Biostatistics and Data Management Section, CCR; 6) Department of Diagnostic Radiology, CCR, NCI, Bethesda, MD; 7) Basic Research Program, SAIC-Frederick Inc., Frederick, MD 21702.

Birt-Hogg- Dubé syndrome (BHDS) (OMIM #135150) is an autosomal dominant predisposition to the development of follicular hamartomas (fibrofolliculomas), lung cysts, spontaneous pneumothorax, and kidney neoplasms. In this study we characterize the BHD gene mutation spectrum and phenotypes of 50 new families with BHDS. Patients had a medical exam and computed tomography (CT) scans of the chest and abdomen to screen for pulmonary abnormalities and renal tumors. We performed a dermatologic evaluation to screen for cutaneous fibrofolliculomas and other skin lesions. Bidirectional DNA sequencing was used to screen for mutations in the BHD gene. Insertion and deletion mutations were confirmed by subcloning. Genotype-phenotype correlations were investigated. The mutation detection rate was 88% (51/58) in the BHDS families tested. Mutations were distributed across coding exons (4-13) except exon 8 and 10. Of the 26 different germline mutations identified, 18 were novel consisting of: nine deletions/insertions, four splice site mutations, three missense and two nonsense. Three unrelated families carried a putative splice-site mutation in the BHD gene within intron 7 (IVS7+1 GT) and 6/8 of the family members had renal tumors. Thirty-five percent of families presenting with histologically confirmed FFs had kidney tumors. Fifty-one percent (26/51) of families had individuals with a history of pneumothorax and 88%(45/51) of families had lung cysts on CT scans. Ninety percent (46/51) of the families had individuals with histologically confirmed fibrofolliculomas. Missense BHD gene mutations are present in families BHDS expanding the spectrum of mutations associated with BHDS. BHDS is characterized by a variable expression of phenotypes among and within families.

Analysis of Candidate Genes for Age-related Macular Degeneration on Chromosome 16p. *K.L. Spencer[1], L.M. Olson[1], P. Gallins[3], M.A. Hauser[2], S. Schmidt[2], W.K. Scott[3], N. Schnetz-Boutaud[1], A. Agarwal[1], E.A. Postel[2], M.A. Pericak-Vance[3], J.L. Haines[1]* 1) Ctr for Human Genetics Research, Vanderbilt University, Nashville, TN; 2) Ctr for Human Genetics, Duke University, Durham, NC; 3) Institute for Human Genomics, University of Miami, Miami, FL.

Age-related macular degeneration(AMD) is a complex disease of the central retina caused by both genetic and environmental risk factors. The association of Y402H in the complement factor H gene on chromosome (chr) 1, A69S in LOC387715 on chr 10 , and R32W of complement factor B on chr 6 with AMD have been well-documented. While Y402H and A69S increase risk for AMD, R32W provides protection from disease. Consistent with the results of several genomic screens, we also have evidence of another AMD susceptibility locus that resides on chr.16p. We genotyped 312 SNPs across chr. 16 in a dataset of 127 multiplex families as part of a genome-wide screen. In an independent dataset of 584 cases and 248 unrelated controls we genotyped a subset of 137 SNPs that are concentrated between 10-31 Mb to follow up on linkage results in this region. Based on these data and gene expression, we selected 4 candidate genes for further consideration: CACNG3, HS3ST4, IL4R, and Q7Z6F8. We genotyped ~10 additional SNPs per gene, and tested these SNPs for association in the families using Association in the Presence of Linkage (APL) and chi-square tests in the case-control dataset. Variants in CACNG3 and Q7Z6F8 were associated with AMD in both the family-based and case control datasets (smallest CACNG3 APL p=0.007, p=0.01 case-control; smallest Q7Z6F8 APL p=0.02, p=0.006 case-control). In addition to being associated with AMD in both datasets, rs757200 in CACNG3 was also strongly linked to disease (APL haplotype p=0.01, allelic p=0.046 in individuals who carry at least one risk allele at Y402H and A69S, two-point nonparametric LOD=3.34). Variants in CACNG3 and Q7Z6F8 may be associated with AMD, but confirmation of these findings in independent datasets will be necessary.

A major genetic risk factor of periodic limb movements and restless legs syndrome. *H. Stefansson[1], D. Rye[2], A. Hicks[1], H. Petursson[1], A. Ingason[1], T.E. Thorgeirsson[1], S. Palsson[1], T. Sigmundsson[3], A.P. Sigurdsson[3], I. Eiriksdottir[4], L.M. Trotti[2], D. Bliwise[2], J.M. Beck[2], A. Rosen[2], S. Waddy[2], U. Thorsteinsdottir[1], A. Kong[1], J. Gulcher[1], D. Gudbjartsson[1], K. Stefansson[1]* 1) Dept Population Genomics, Decode Genetics, Reykjavik, Iceland; 2) Department of Neurology and Program in Sleep, Emory University; 3) Landspítalinn University Hospital, 101 Reykjavik, Iceland; 4) Clinical Research Center, Nóatún 17, 105 Reykjavik, Iceland.

We have discovered a variant associated to periodic limb movements in sleep (PLMs) and Restless Legs Syndrome (RLS). RLS, a major cause of sleep disruption, is a common neurologic disorder characterized by an irresistible urge to move the legs. PLMs are detectable in most RLS subjects and represent an objective physiologic metric. In an Icelandic RLS discovery sample of subjects with RLS and PLMs, we observed a genome-wide significant association to SNP rs3923809 (P = 2x10-9, OR = 1.8) in an intron of the BTBD9 gene on 6p21.2. This association was replicated in a second Icelandic sample (P = 4x10-4, OR = 1.8) and a U.S. sample (P = 4x10-3, OR = 1.5). For RLS with PLMs, the population attributable risk of this variant is approximately 50%. Association of the variant to PLMs without RLS, and lack of its association to RLS without PLMs suggests that we have identified a genetic determinant of PLMs (P = 1x10-17, OR = 1.9). Ferritin index, a measure inversely related to body iron stores, was increased by 5.5% per A allele of marker rs3923809 (95% CI 1%-10%, P = 0.02). In line with this observation, serum ferritin was decreased by 13% per A allele (95% CI 5%-20%, P = 0.002). The inverse correlation with iron stores is consistent with the suspected involvement of iron depletion in the pathogenesis of the disease. This is the first susceptibility variant discovered for PLMs and RLS, supporting that RLS with PLMs is a genuine syndrome with an ascertainable phenotype and biologic basis.

Linear Scleroderma en coup de sabre (LScs). Report of 2 cases and a literature review. *E.J. Ramirez-Lizardo[1,2,3], S.E. Totsuka-Sutto[1,3], M.C. Islas-Carbajal[1], T.A. Garcia-Cobian[1], E.G. Cardona-Muñoz[1]* 1) Unidad de Investigación Cardiovascular. Centro Universitario de Ciencias de la Salud. Universidad de Guadalajara; 2) Departamento de Genética Instituto Jalisciense de Cirugía Reconstructiva. Secretaria de Salud Jalisco; 3) Instituto de Genética "Dr. Enrique Corona" CUCS. Universidad de Guadalajara. Guadalajara Jalisco México. elizardo@cucs.udg.mx.

Scleroderma is a rare disease of unknown etiology in which increased collagen deposition occurs and results in dermal thickening. Involvement may be diffuse (systemic sclerosis) or localized to skin (localized scleroderma). Linear scleroderma represents a unique form of localized scleroderma that primarily affects the pediatric population, with 67% of patients diagnosed before 18 years of age. When linear scleroderma occurs on the head, it is referred to as linear scleroderma en coup de sabre, given the resemblance of the skin lesion to the stroke of a sabre. LScs is a descriptive term denoting linear scleroderma of the frontoparietal or frontal area of the face and scalp. In most cases with LScs, disorders such as seizures, uveitis, dental anormalities, cerebral abnormalities and ocular muscle dysfunction are associated We describe 2 pediatric patients with linear scleroderma en coup de sabre. Our patients presented a typical skin lesion on the frontoparietal area. One patient presented furthermore skin discoloration and depression on her chin. Both family noted echymotic color change and depression becoming progressively more prominent affecting theirs forehead, nasal and chin areas. The present cases show 2 families everyone with one proposita with LScs support on the clinical date of skin discoloration and depression on the typical area for the LScs. Both are sporadic case. The differential diagnosis included the Parry-Romberg syndrome. The clinical presentation and etiology hypotheses are reviewed.

Targeted chromosomal microarray analyses (CMA) in 639 newborn patients. *X. Y. Lu, M. T. Phung, C. A. Shaw, K. Pham, T. Sahoo, P. Stankiewicz, A. C. Chinault, A. L. Beaudet, J. R. Lupski, A. Patel, S. W. Cheung* Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Chromosomal abnormalities are a leading cause of birth defects including multiple congenital anomalies (MCA), dysmorphic features (DF), congenital heart disease, congenital diaphragmatic hernia, and cleft lip/palate. To investigate genomic imbalance as a potential etiology in neonatal patients, we implemented a targeted BAC and oligo array that interrogates over 150 common disease loci, pericentromeric and subtelomeric regions, and the remainder of the genome as backbone coverage. Using this chromosomal microarray analysis (CMA), we analyzed a total of 639 patients aged 1 month or younger between June 2005 and May 2007. Clinically significant abnormalities were detected in 15.5% of the patients (99/639). Ten patients (1.6%) were found to have a common chromosomal aneuploidy, trisomy 21 (n=5), trisomy 13 (n=3), and trisomy 18 (n=2); thirty-two patients (5.0%) had microdeletion or microduplication including the most common ones, involving chromosomes 22q11.2 (n=14), 5p15.3 (n=7), 4p16.3 (n=5) and 15q11-q12 (n=4). Fifty-two patients (8.1%) had interstitial or terminal segmental aneusomies that were distributed among the other relatively rare disease loci covered by the array. The remaining five cases (0.7%) were mosaic for trisomy 9 (n=3), trisomy 22 (n=1) and 45,X/46,X,i(Y)(q10) (n=1). In addition, a total of 67 cases (10.5%) (67/639) exhibited copy-number variations (CNVs) with uncertain clinical significance. After family studies and comparison with the public CNV databases, 19 (2.9%) were reported as benign moderately common variants, 22 (3.4%) were interpreted as rarer familial variants (a phenotypically normal parent has the variant), and the remaining 26 (4.0%) still await parental studies. This study demonstrates that the targeted CMA is a valuable clinic diagnostic tool in newborns, especially for those with neonatal presentations of DF and/or MCA. CMA is valuable for comprehensive neonatal care, enabling precise and reliable diagnosis, prognostic information, and recurrence risk estimates.

Searching for genes contributing to autism in WAGR syndrome by oligo array CGH. *S. Xu[1], J. Han[2], A. Morales[1], C. Menzie[2], K. Williams[3], Y. Fan[1]* 1) Cytogen R&D Lab, MC Child Dev, Univ Miami, Miami, FL; 2) National Institute of Child Health Human Development, NIH, Bethesda, MD; 3) International WAGR Syndrome Association, Manassas, VA.

WAGR syndrome (Wilms tumor, Aniridia, Genitourinary anomalies and mental Retardation) is a genomic disorder caused by a deletion in 11p12-14 region. Autistic features are seen in about 25% of patients. While deletion of PAX6 and WT1 results in aniridia and an increased risk of Wilms tumor, the genes contributing to mental retardation and autism remain undetermined. We have characterized the 11p12-14 region in 25 WAGR patients with CGH using an array containing >44,000 oligo probes. 11 of the patients had autism spectrum disorder (ASD). Our study revealed a deletion in 11p12-14 in all 25 patients with a size of 2.65-19.13 Mb involving 30-70 mapped genes. In addition to PAX6 and WT1, the deletions involved several genes known to be related to neuron development and brain function, including PRRG4, BDNF and SLC1A2 (in 25 cases, 100%; 14 cases, 56%; and 16 cases, 64% respectively). Of the 11 patients with ASD, 7 had deletion of BDNF (64%), 7 had deletion of SLC1A2 (64%), and 5 had deletion of both BDNF and SLC1A2 (45%). Genome-wide linkage analyses have suggested linkage of 11p11.2-13 region with autism. There is evidence that BDNF is a crucial signaling molecule between microglia and neurons. The recent results of linkage and CNV analysis have implicated 11p12-13 as the candidate locus that includes PRRG4 and SLC1A2. Both PRRG4 and SLC1A2 are related to glutamate synaptic function and brain development. The mapping positions of the autism candidate genes relating to WAGR can be described as tel-BDNF-PAX6-WT1-PRRG4-SLC1A2-cen. Our results suggest that haploinsufficiency of PRRG4, BDNF and SLC1A2 may contribute to mental retardation and autism in WAGR patients. Further expansion and statistical analysis of our data in correlating patient's sex, age of onset and inheritance of the deletion may provide additional insights about the possible mechanisms involved in development of autism in WAGR patients.

Detection of large rearrangements in the CFTR gene by multiplex ligation-dependent probe amplification (MLPA) assay in cases where sequencing fails to detect two disease-causing mutations. *A.M. Svensson[1, 2], L.S. Chou[2], C. Miller[3], J. Robles[3], I. Sinitsyna[3], K.V. Voelkerding[1, 2], R. Mao[1, 2], E. Lyon[1, 2]* 1) Department of Pathology, University of Utah, Salt Lake City, UT; 2) ARUP Institute for Clinical and Experimental Pathology, Salt Lake City, UT; 3) ARUP Laboratories, Salt Lake City, UT.

Over 1,300 mutations have been identified in the Cystic Fibrosis Transmembrane Conductance Regulator (CFTR) gene. Most of these are point mutations or small deletions/insertions which may be detected by sequencing. Large gene rearrangements in CPTR have recently been reported. Purpose: The CFTR sequencing protocol at ARUP Laboratories interrogates the entire 27 exons and partial intronic regions of the gene. The present study was undertaken to determine whether testing for large gene rearrangements could improve the mutation detection rate. Methods: Nine cases with abnormal quantitative pilocarpine iontophoresis sweat chloride (SC) values (>60 mEq/L) and 20 cases with borderline SC levels (40-60 mEq/L) with only one or no mutations detected by the ACMG panel followed by sequencing, were tested using a multiplex ligation-dependent probe amplification (MLPA) assay (MRC-Holland, Amsterdam, The Netherlands). Forty-three probe pairs tagged with universal primer sequences hybridize to adjacent target sequences and are then joined by thermostable ligase. The probe products are amplified by multiplexed PCR using a FAM fluorescent dye-labeled consensus primer pair. The amplicons are then separated by capillary electrophoresis. Peak profiles for each amplicon are normalized and compared to a control sample. The calculated relative peak height is then used to determine the copy number of each target sequence. Results: One deletion was detected among the 9 cases with high SC values. None of the cases with borderline SC levels showed rearrangements. Conclusion: MLPA was able to identify one deletion among 9 patients with SC>60, that had previously been tested with sequencing. We conclude that the MLPA assay for detection of large rearrangements is of value in the laboratory workup of CF cases where one or no mutations have been identified by sequencing.

A Block of Autophagy in Lysosomal Storage Disorders. *C. Settembre[1], A. Fraldi[1], L. Jahreiss[2], C. Spampanato[1], C. Venturi[3], D. Medina[1], R. de Pablo[1], C. Tacchetti[3], D. Rubinsztein[2], A. Ballabio[1,4]* 1) TIGEM, Fondazione Telethon, Naples, Italy; 2) Dept. of Medical Genetics, Cambridge Institute for Medical Research, Cambridge, UK; 3) MicroSCoBiO Research Center, University of Genoa, and IFOM Center of Cell Oncology and Ultrastructure, Genoa, Italy; 4) Medical Genetics, Dept. of Pediatrics, Federico II University, Naples, Italy.

Most lysosomal storage disorders (LSDs) are caused by deficiencies of lysosomal hydrolases. While LSDs were among the first inherited diseases for which the underlying biochemical defects were identified, the mechanisms from enzyme deficiency to cell death are poorly understood. Here we show that lysosomal storage impairs autophagic delivery of bulk cytosolic contents to lysosomes. By studying the mouse models of two LSDs associated with severe neurodegeneration, Multiple Sulfatase Deficiency (MSD) and Mucopolysaccharidosis type IIIA (MPSIIIA), we observed an accumulation of autophagosomes resulting from defective autophagosome-lysosome fusion. An impairment of the autophagic pathway was demonstrated by the inefficient degradation of exogenous aggregate-prone proteins (i.e. expanded huntingtin and mutated -synuclein) in cells from LSD mice. This impairment resulted in massive accumulation of polyubiquitinated proteins and of dysfunctional mitochondria. These data identify LSDs as autophagy disorders and suggest the presence of common mechanisms in the pathogenesis of these and other neurodegenerative diseases.

Multi-locus analysis of whole genome association studies, and ridge regression to account for linkage disequilibrium. *N. Malo[1], O. Libiger[1], N.J. Schork[1,2]* 1) Scripps Genomic Medicine, The Scripps Research Institute, La Jolla, CA; 2) Medical School, University of California, San Diego, La Jolla, CA.

The use of whole genome association (WGA) studies for the identification of genes and genetic variations that influence common, complex diseases such as hypertension, cancer, and depression will continue to grow as cost-effective high-throughput genotyping technologies are developed. As a result, appropriately flexible yet robust data analysis strategies for analyzing WGA data will be essential. We emphasize the need to accommodate phenomena such as linkage disequilibrium via simple extensions of traditional regression models. We describe the use of regression analysis models for WGA that are very intuitive and flexible. We propose the use of ridge regression, a special case of Bayesian regression, to account for correlation. We showcase the utility of the method on previously published WGA data, and via a simulation study. We also consider limitations of the proposed approach as well as areas for further research.

Cost-effectiveness of population-based *BRCA1/2* testing and ovarian cancer prevention for Ashkenazi Jews. *W.S. Rubinstein[1], H. Jiang[2], L. Dellefave[3], A. Rademaker[2]* 1) Evanston Northwestern Healthcare, Evanston, IL; 2) Northwestern University, Chicago, IL; 3) Univ. of Chicago, Chicago, IL.

Background Identification of *BRCA1/2* carriers rests solely on family history. Yet, family history fails to identify half of carriers, as shown by breast cancer case-based studies in several populations including Ashkenazi Jews (AJs). Three prevalent founder mutations account for 40% of ovarian cancer (OC) and 10% of breast cancer in AJs, suggesting that a marked reduction in cancer burden is attainable. Population-based genetic screening may be feasible given the high prevalence of founder mutations, low cost of genetic testing and historical acceptance of Tay-Sachs disease screening among AJs. Purpose To examine the effect of population-based gene testing on life-savings and medical costs when considering ovarian cancer treatment and prevention. Methods Decision analysis using the parameters: Screening program participation rate=0.9; Mutation carrier rate=0.025; Probability that a 40 year-old carrier will have prophylactic bilateral salpingo-oophorectomy (PBSO)=0.50; OC penetrance=0.16; PBSO effectiveness=0.96; Sporadic OC probability=0.016; Mean age at OC diagnosis 58.8 (carriers), 63 (sporadic); Commercial cost of gene testing=$460; Cost of PBSO and OC treatment as per Anderson et al.2006; OC mortality rate based on SEER 2004 data. Results Our model suggests that a population-based genetic screening program could prolong average survival by 384 days for a 40-year-old female AJ *BRCA1/2* carrier having PBSO and save non-discounted costs of ~$100 per woman screened. Conclusions Our model predicts a significant life-saving potential for a genetic screening program. The costs of breast cancer surveillance, prevention and treatment and effect on life expectancy must also be taken into consideration. While additional costs of a screening program would need to be factored in, the cost of genetic testing seems to be balanced by the savings of avoiding OC diagnosis and treatment. We think that a dialogue should begin among Jewish stakeholders, genetics professionals, and public health leaders to determine whether a population-based *BRCA1/2* genetic screening program should be pursued.

Use of High Density Oligo Array CGH to Characterize Chromosomal Aberrations Associated with Unexplained Clinical Presentations. *M.M. Li[1, 2, 3], X. Hu[3], T. Narumanchi[1,2], C. Dvorak[1,2], D. Mercer[1], G. Pridjian[1,2], H. Andersson[1,2]* 1) Hayward Genetics Ctr;; 2) Dept. of Pediatrics, Tulane Univ. Sch. Med; 3) Louisiana Cancer Research Consortium, New Orleans, LA.

Many chromosomal aberrations identified through conventional cytogenetic studies do not completely explain patients phenotype. Cryptic copy number variations (CNVs) have been suggested to be responsible for the discrepancies. We have recently used high density oligo array CGH (aCGH) to characterize a series of cytogenetic aberrations associated with dissonant phenotypic presentations. A patient with a balanced t(15;22) showed developmental delay and growth defects. aCGH identified a 3.3 Mb deletion adjacent to the chromosome 15 breakpoint. A young girl with Williams syndrome exhibited severe developmental delay, absence of speech, and an inability to crawl or walk. aCGH revealed a 4 Mb deletion including the Williams critical region. A newborn diagnosed prenatally to have a 4q- displayed Pierre Robin sequence, facial and digital anomalies, and undescended testes. aCGH uncovered that the 4q- was in fact an der(4)t(3;4)(q27.2;q32.2). Two twin brothers were identified as carrying a r(9)(p22.3q34.3). However, the phenotype of the twins resembled 9p deletion syndrome: craniosynostosis, thick eyebrows and synophrys, cleft palate, and gastroesophageal reflux. aCGH revealed a 14.5 Mb deletion on the short arm of the ring and no deletion of the long arm. We also studied a der(20)t(16;20)(q22.3;p13) in a patient with midface hypoplasia, gastroesphageal reflux, and hearing and vision impairments. Using aCGH we demonstrated a 16 Mb duplication of 16q and no copy number change on the 20p, showing that the phenotype of this patient was actually the result of partial trisomy 16q. Our experiences have demonstrated that high density aCGH is far superior to conventional cytogenetics and FISH in the diagnosis and phenotype/genotype correlations of multiple congenital anomalies, developmental delay, and mental retardation. With continuously increasing array density and decreasing array cost, high density whole genome aCGH will soon become the primary and preferred method for the diagnosis of genomic CNVs.

Evidence that the oxytocin receptor plays a role in preterm labor. *K. Stirling[1], M. Johnson[1], M. Cooper[2], M. Marazita[2], M. Shi[3], J. Dagle[1], J. Murray[1]* 1) Pediatrics, University of Iowa, Iowa City, IA; 2) University of Pittsburgh, Pittsburgh, PA; 3) NIEHS/NIH, Research Triangle Park, NC.

Prematurity as a consequence of preterm labor (PTL) affects more than 500,000 infants each year in the US. Oxytocin and its receptor regulate uterine contractions and may contribute to the initiation of labor. We hypothesized that allelic variations in the genes for oxytocin, the oxytocin receptor (OXTR), and oxytocinase (LNPEP) might play a role in genetic predispositions to PTL. Samples for DNA were collected from preterm infants and parents. TaqMan assays were performed to characterize allelic variations in single nucleotide polymorphisms (SNPs) in the oxytocin, OXTR, and LNPEP genes in 476 preterm infant/parent trios (22-36 weeks). TDT analysis using two week sliding windows of gestational age (GA) was used to look for associations with varying GA. To look for the presence of novel genetic variations as a cause of preterm birth, resequencing was done on the oxytocin gene (3 exons) and OXTR gene (4 exons) in 94 early preterm infants and mothers, 180 late preterm infants, and 94 Caucasian controls. We identified one SNP (rs4686301) in the OXTR gene that is significantly associated with birth at 35-36 weeks gestation (p=0.0011). A 2 degree of freedom test for maternal effect on preterm birth revealed two significant SNPs in the OXTR gene (rs237887 and rs237897). Sequencing of conserved noncoding regions in and near the OXTR gene revealed 3 known SNPs and 8 novel sequence variants. Sequencing of OXTR coding sequence revealed 5 rare missense mutations, 4 novel and 1 named. The novel variants were more common in cases than in controls. Our finding of a SNP in OXTR correlating with delivery at 35-36 weeks is preliminary evidence that genetic variation in OXTR plays a role in late preterm birth. The increased frequency of missense mutations in cases also suggests a role for rare variants in OXTR contributing to PTL. Additional genotyping and sequencing of these high yield areas will further characterize critical gene regions that might be associated with PTL and perhaps help to identify high risk populations.

Association of FOXP2 genetic markers with Procedural Learning and Language. *J.B. Tomblin[1], M.H. Christiansen[2], J.B. Bjork[3], S.K. Iyengar[4], J.C. Murray[3]* 1) Dept Speech Pathology and Audiology, U of Iowa, Iowa City, IA; 2) Dept Psychology, Cornell University, Ithaca, NY; 3) Dept Pediatrics, U of Iowa, Iowa City, IA; 4) Dept Epidemiology and Biostatistics, Iowa City, IA.

Procedural learning is an implicit mechanism for acquiring skills, unconsciously setting into memory task-oriented procedures without explicit knowledge of how the skill was acquired. Both Liegeous (2003) and Ullman and Pierpont (2005) have proposed that products of the FOXP2 gene influence procedural learning. These claims are based on language and neuroimaging data from members of the KE family, who have a point mutation in the DNA binding domain of FOXP2. To date, studies of FOXP2 have been limited to a few families. Further, studies using quantitative traits and other direct measures of procedural learning have not been associated with FOXP2. We used a Serial Recall Task (SRT), generally regarded as a measure of procedural learning and associated learning rates, to examine allelic variation among SNP markers within FOXP2. The participants were eighth-grade students (N=123). Stimuli comprised sequences of images presented in both random and predictable order. Participant response was measured by reaction time, and learning was reflected in decreased reaction time on the patterned trials. Genomic DNA from the subjects was used to evaluate a set of six SNPs selected to provide coverage of the principal haplotype blocks within the FOXP2 gene. A significant association was found between SNP variants and SRT learning rate for SNPs rs1916988 $F(2, 821)=6.37$, $p<0.001$, and rs7785701 $F(2, 565)=3.32$, $p=0.037$. In both cases the individuals with the CC genotype demonstrated poorer learning than those with the TT or heterozygote forms. Additionally, one other SNP (rs1005958) approached significance $F(2, 925)=2.10$, $p=0.123$. The rs1916988 SNP lies in the promoter region of FOXP2 and rs7785701 and rs1005958 are intronic SNPs. These results provide evidence that FOXP2 genotypic variants are associated with individual differences in the procedural learning system as measured by the SRT task. These results provide the first direct evidence of an association between FOXP2 and procedural learning.

Molecular mechanisms underlying congenital scoliosis. *K. Staehling-Hampton[1], A.S. Cornier[2], K.M. Delventhal[1], J.F. Caubet[3], J.B. Emans[3], H. Welsh[1], P. Turnpenny[4], O. Pourquie[5]* 1) Molecular Biology, Stowers Institute for Medical Research, Kansas City, MO; 2) Department of Genetics, San Juan Bautista School of Medicine, Puerto Rico; 3) Department of Orthopaedic Surgery, Children's Hospital Boston, Boston, MA; 4) Clinical Genetics Department,Royal Devon & Exeter Hospital, Exeter, UK; 5) Stowers Institute for Medical Research/HHMI, Kansas City, MO.

Congenital vertebral malformations are rare, occurring in 1 to 2 out of every 10,000 births. Conditions that fall into this category include: generalized vertebral malsegmentation (e.g., spondylothoracic dysostosis), regionalized conditions (e.g., Klippel-Feil syndrome) or conditions involving only one or two vertebrae (e.g., Alagille syndrome). Although most cases of congenital scoliosis were previously thought to be sporadic, recent evidence points to a considerable genetic component. To date, three genes have been associated with vertebral malformations in humans. All of these genes are associated with NOTCH signaling, which is involved in the segmentation of the spine. Using a candidate gene approach, we selected genes associated with NOTCH signaling and vertebral anomalies in mouse mutants and humans. We then sequenced these genes in a cohort of 30 patients with vertebral malformations from Boston Children's Hospital. We identified a novel homozygous mutation in a 12-year-old female of Puerto Rican descent with Jarcho Levin syndrome, a severe form of spondylothoracic dysostosis (STD). This patient harbors an E103stop mutation in the gene coding for the transcription factor MESP2. Sequencing of Mesp2 in a broader sampling of Puerto Rican patients indicates that this mutation is a common mutation in STD patients in the Puerto Rican population. In conclusion, we have identified a founder effect mutation accounting for the classical Puerto-Rican form of Jarcho-Levin syndrome.

Mosaicism for a PKD1 gene mutation revealed through family genetic analysis for a living related donor transplant for autosomal dominant polycystic kidney disease (APKD). *P.W. Lunt[1], C. Dolling[1,2], Y. Patel[3], L. Meredith[4], Athena Diagnostics[5], A. Gardner[6], A. Connor[7], C. Dudley[7]* 1) Clin. Genetics Dept, St Michaels Hosp, Bristol BS2 8EG, UK; 2) (now at) W.Midlands Reg.Genet.Service, Birmingham Womens Hosp, Birmingham B15 2TG, UK; 3) Nat.Genet.Ref.Lab.(Manchester), St.Marys Hosp., Manchester M13 0JH, UK; 4) Inst.Med.Genet., Univ.Hosp.of Wales, Cardiff CF14 4XW, UK; 5) Athena Diagnostics, Worcester, Mass. USA; 6) Bristol Genet. Labs.,Southmead Hosp., Bristol BS10 5NB, UK; 7) Richard Bright Renal Unit, Southmead Hosp., Bristol BS10 5NB, UK.

The 25yr-old HLA-matched sister of a 28yr female with renal failure due to APKD, inherited from their mother, wished to donate a kidney to her sister. Renal ultrasound and MRI scans were clear, but under age 30 yrs leave a 15% residual risk of APKD; too high to be considered as a donor. Mutation in two genes can cause APKD; 85% PKD1 on 16p; 15% PKD2 on 4q. Linkage analysis with close flanking markers was uninformative at PKD2 gene, but indicated a shared maternal allele at PKD1 gene. As PKD2 mutation would also tend to give a milder phenotype, this result suggested the clinically unaffected sister could share a PKD1 mutation, and be unsuitable as a donor. Full gene sequencing (Athena Diagnostics) was undertaken, revealing a nonsense mutation (Glu313X) in exon 5 of PKD1 gene in the affected sister and in the mother. Surprisingly, this was absent in DNA from the potential donor sister. However, the mutation appears at reduced dosage in the 50yr mother, who has multiple renal cysts, but is otherwise clinically asymptomatic. Renal scans in the grandparents had been normal, and on DNA testing neither carries the PKD1 mutation. The apparent conflicting genetic results are explained by somatic and germline mosaicism for the PKD1 mutation in the mother, which was confirmed on quantitative analysis of her leukocyte and buccal cell DNA. Recognition of this enabled a successful fully-matched sibling renal transplant. We recommend that mosaicism be considered in apparent 2-generation APKD families, and highlight the necessity for mutation identification in families considering related living donor transplantation.

Multivariate dependence functions for genetic analysis of developmental disorders. *L.E.M. Sucheston[1,2], B.A. Lewis[3], C. M. Stein[4], L.A. Freebairn[3], A.J. Hansen[3], S.K. Iyengar[4]* 1) Dept of Biostatistics, SUNY-Buffalo, Buffalo, NY; 2) Dept of Cancer Prevention and Control, Roswell Park Cancer Institute, Buffalo, NY; 3) Behavioral Pediatrics and Psychology, Rainbow Babies and Childrens Hospital, Cleveland, OH; 4) Dept of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH.

We have developed an approach for the genetic analysis of longitudinal measures of developmental disorders, with specific application to a longitudinal pedigree study of children with Speech Sound Disorder(SSD). Analysis of this cohort is complicated by non-normal trait distributions and a potentially non-linear cognitive developmental trajectory. As an alternative to longitudinal analysis, we use multivariate dependence functions, called copulas, to develop a cross-sectional model to test for a polygenic age interaction. These functions separate a multivariate joint distribution into two parts: the correlation and the margins. Using these functions for analysis simultaneously addresses the non-normality problem, as the margins can be modeled with a wide variety of parametric probability distributions, and the developmental trajectory question, as we can incorporate age into the analysis through the use of a correlation function. The parameter estimate of this correlation function can be tested for significant deviation from zero, indicating a gene age interaction, specifically testing if development is linear over time. The psychometric measures administered to all participants assessed speech sound production, language comprehension and expression skills, and reading and phonological abilities. Of the 13 traits analyzed the likelihood ratio test statistic indicates that the polygene age copula model provided a significantly better fit than the polygene copula model for 4 tests: Nonsense Word Repetition (p=.02), Digit Span (p=.03), Digit Symbol-Coding (p=.0008), and Test of Written Spelling-Unpredictable Words (p=.04). Short term memory plays an important role in each of these tests, thus providing preliminary evidence that the genetic contribution to phenotypic variance of tasks involving memory is not stationary in children 6-18.

Reverse-hybridization-based genetic testing for the prediction of anticoagulant dose requirement. *H. Puehringer[1], C. Stoellberger[2], Q. Berisha[2], A. Dossenbach-Glaninger[3], W. Krugluger[3], C. Oberkanins[1]* 1) ViennaLab Diagnostics GmbH, Vienna, Austria; 2) Second Medical Department, Rudolfstiftung Hospital, Vienna, Austria; 3) Department of Clinical Chemistry, Rudolfstiftung Hospital, Vienna, Austria.

Coumarin derivatives (Warfarin, Phenprocoumon, Acenocoumarol) are the most widespread oral anticoagulant drugs for the prevention and treatment of arterial and venous thromboembolic disorders. However, these vitamin K antagonists have a narrow therapeutic range and a wide inter-individual variability in dose requirement. Despite adjustment for clinical variables, adverse events, such as delay in achieving a stable maintenance dose or bleeding complications, are frequently encountered during the initial phase of therapy. Genetic polymorphisms in the drug-targeted vitamin K epoxide reductase complex 1 (VKORC1) and in the drug metabolizing cytochrome P450 isozyme CYP2C9 have been reported to account for the majority of variations in the therapeutic response to warfarin. We have developed a genetic test (PGX-Thrombo StripAssay) for the detection of -1639 G/A and 3730 G/A in the VKORC1 gene, and 430 C/T and 1075 A/C in the CYP2C9 gene. The assay is based on multiplex PCR, followed by reverse-hybridization of biotin-labeled amplification products to a parallel array of allele-specific oligonucleotides immobilized on membrane teststrips. Genotyping for VKORC1 polymorphisms and the functionally defective CYP2C9 variants *2 and *3 allowed us to classify our patients into distinct groups of high, intermediate and low dose responders to phenprocoumon (Marcumar), the most commonly used oral anticoagulant in Central and North European countries. Favourable properties, such as the rapid DNA extraction protocol, ready-to-use reagents and teststrips, as well as the potential for automation of the hybridization/detection step, make the StripAssay convenient and easy to perform within less than 6 hours. The results obtained in our study will assist clinicians to achieve a more individualized anticoagulant therapy. (oberkanins@viennalab.co.at).

Quantitative chimerism detection technology. *D. Merrill* Applied Biosystems, Foster City, CA.

Here we present a highly sensitive assay technology to detect and quantitate the presence of two different genomes in a chimeric or mixture sample derived from varied source. For this, quantitative allele specific real time PCR assays were developed and validated for a fixed set of markers; each assay can confidently identify the presence of 0.1% of a minor allele or genome in a potentially chimeric DNA sample. Highlighting the utility of the technology is the versatility to use the same panel of markers and assays for a wide array of applications, including but not limited to research in transplants of bone marrow and stem cells, stem-cell line quality control, forensic identification and rare variant discovery and validation. The concept involves an initial screening of pre-selected genomic insertion deletion markers to provide a genotypic profile for one or both genomes to be detected using a panel of validated genotyping assays. The markers were selected to be able to distinguish any two given genomes with a statistical probability of 99.9% or greater. Using the resulting genotypic profiles, an informative marker is chosen based on criteria specified for the given application. An allele specific PCR assay for the chosen marker is run on the unknown or chimeric sample, quantitatively detecting the presence of both the minor component genome as well as the majority component genome. Results from the initial test site presented here, regarding post bone marrow transplant monitoring has demonstrated the utility, sensitivity and ease of workflow that will enable researchers to quickly and accurately go from sample to result. For this test site, the application involved assaying post bone marrow transplant samples to detect the possible regeneration of the patients original genome. Key to this application is the detection of this regeneration early on, requiring the identification of as little as 1 copy of the original recipient genome in a majority of 1000 copies of transplanted donor genome. The quantitative chimerism detection technology described within demonstrated with high confidence the ability to detect at this level of sensitivity, beyond the capabilities of current technologies such as FISH and STR assays.

Pilot survey on patient attitudes toward pharmacogenetic testing. *J. O'Daniel[1], P. Deverka[1], J. Lucas[2], G. Silvey[3], D.F. Lobach[3], S.B. Haga[1]* 1) Inst for Genome Sci & Policy, Duke Univ Med Ctr, Durham, NC; 2) Inst of Statistics & Decision Sciences, Duke Univ, Durham, NC; 3) Dept of Community and Family Medicine, Duke Univ Med Ctr, Durham, NC.

The successful integration of pharmacogenetic (PGx) testing into clinical care will require attention to patient perceptions and attitudes toward these tests. In this study, we aimed to identify the major reasons patients would or would not undergo PGx testing and whether these factors differed by socioeconomic and medical history variables. To achieve this goal, we developed a survey offered on hand-held computer tablets. The survey was evaluated by two focus groups for understandability and ease-of-use and piloted on the adult patient population of the Duke Family Medicine Center. Seventy-five completed surveys were collected. Seventy-two percent of respondents were female and 65% were African-American. Forty-nine percent were employed full-time, 42% had a high school education or less, and 57% had an annual income of $40,000 or less. About a third of respondents had a previous history of a side effect. The data were analyzed using linear-by-linear logistic regression after responses were clustered to achieve an ordinal relationship. Higher education was positively correlated with being more likely to consider PGx testing to reduce the risk of mild side effects only (p= .002), but was negatively correlated if respondents did not believe the test would help their doctor select which medication would work best or be safest (p=.004). Higher income was positively associated with being likely to consider PGx testing to determine which medicine is safest (p=. 001). Respondents with government insurance were more likely to request further information about PGx testing than those with no insurance or private insurance (p=.0012). Also, of the 23% of respondents who were unsure or unlikely to take a PGx test, only 18% of these respondents would change their mind if the test were not gene-based. These preliminary findings provide a glimpse into the attitudes of patients with diverse ethnic and economic backgrounds towards PGx testing and warrant further exploration.

Mutations in UPF3B, a member of the nonsense mediated mRNA decay surveillance complex, cause Lujan-Fryns and FG phenotypes and non-syndromic X-linked mental retardation. *J. Rodriguez[1*], P.S. Tarpey[2*], L.S. Nguyen[3*], F.L. Raymond[4*], A. Hackett[5], L. Vandeleur[3], R. Smith[4], C. Shoubridge[3], S.S. Bhat[1,9], M. Corbett[3], M.E. Porteous[6], G. Hoganson[7], D. Superneau[8], G. Turner[5], R.E. Stevenson[1], C.E. Schwartz[1], P.A. Futreal[2], M.R. Stratton[2], J. Gécz[3], A.K. Srivastava[1], *Contributed equally* 1) Greenwood Genet Ctr, Greenwood, SC, USA; 2) Cancer Genome Project, Wellcome Trust Sanger Inst, Hinxton UK; 3) Dept of Genet Med, Womens and Childrens Hosp., N. Adelaide, Australia; 4) Cambridge Inst of Med Res, Cambridge UK; 5) GOLD Service, Hunter Genet,Waratah NSW, Australia; 6) SE Scotland Genet Service, Edinburgh, Scotland; 7) Med Genet, Rockford Mem. Hosp., Rockford, IL, USA; 8) Genet Services of LA, LLC, Baton Rouge, LA 70884 4260, USA; 9) Pres add: Inst of Genet Med, Johns Hopkins Med Inst, Baltimore MD, USA.

We have recently identified two frameshift mutations, one nonsense mutation, and one missense mutation at a conserved amino acid in UPF3B in 4 of 368 families with putative X-linked mental retardation (PS Tarpey et al. submitted). Two families were diagnosed with Lujan-Fryns syndrome, one family had a FG phenotype and one family had non-syndromic X-linked mental retardation. Three of the mutations lead to the introduction of a premature termination codon and subsequent low levels of mutant UPF3B mRNA. Western blot analysis, using patient lymphoblastoid cell line protein lysates, revealed an absence of the wild-type or predicted truncated protein in two families with the frameshift mutations. A low level of the predicted truncated protein was detected in the family with the nonsense mutation. The family with the missense mutation showed apparently normal to mild overexpression of both UPF3B transcript and protein. UPF3B is an important component of the nonsense mediated mRNA decay (NMD) surveillance machinery and is expressed in a variety of tissues including brain and at different developmental stages. Our results show that NMD is only partially compromised in absence of UPF3B protein function and thus point to at least partial redundancy of NMD pathway. More importantly, the data therefore directly implicate mutations in a component of the NMD complex in human disease.

Mecp2 deficiency leads to altered _Htr2c_ pre-mRNA editing and HTR2C isoform distribution in mouse hippocampus and cerebellum. *M. Landers[1], Z. Yu[1], I. Van den Veyver[1,2]* 1) Obstetrics and Gynecology; 2) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Rett Syndrome (RTT) is a neurodevelopmental disorder caused by mutations in *MECP2*, a methyl-CpG binding protein and transcriptional repressor. CpG methylation plays an important role in genomic imprinting since imprinted genes are regulated by regions of differentially methylated CpGs (or ICs). A well studied imprinted region is the one on chr 15q11-q13, involved in Prader-Willi (PWS) and Angelman (AS) syndromes, disorders characterized by several degreees of mental and motor retardation. Many AS cases are caused by deletions or mutations of the maternal copy of *UBE3A*. *UBE3A* regulation has been linked to a brain-specific paternally expressed antisense transcript (*UBE3AAts*) in human and mouse. *Ube3aATS* in mouse appears to be controlled by the PWS-IC and exons (*U*) upstream of *Snrpn*. By a complex splicing pattern, *Ube3aATS* also serves as host for several types of paternally expressed snoRNAs: *MBII13,MBII52* and *MBII85*. *MBII52* has been shown to affect pre-mRNA editing of the serotonin receptor 2C (*Htr2c*). Combinations of *Htr2c* editing (sites A,B,E,C,D) result in the expression of up to 24 HTR2C isoforms with different G protein-coupling functions. Since RTT and AS share autism-spectrum disorder features we decided to assess *MBII52* expression in a mouse model of RTT. qRT-PCR assays showed no significant differences in *MBII52* levels in hippocampus (Hp) and cerebellum (Cb) from P53-P64 *Mecp2*$^{-/y}$ and *Mecp2*$^{+/y}$ mice. We identified, however, higher edited *Htr2c* mRNA levels over sites A,B and C in *Mecp2*$^{-/y}$ Hp and lower levels over sites A,B,E and D in *Mecp2*$^{-/y}$ Cb. Further analysis revealed that hyperediting of *Htr2c* mRNA in *Mecp2*$^{-/y}$ Hp leads to a 20% increase in the levels of HTR2C INV,VNI,VNV and VSV isoforms and a 58% decrease of the unedited INI isoform. Also, altered editing levels in *Mecp2*$^{-/y}$ Cb lead to a slight decrease of the INV,VNI,VNV and VSV isoforms and a 2.5-fold increase of the INI isoform. Since HTR2C edited isoforms display a reduced ability to activate the phospholipase C signalling cascade, our results support a role for the serotonergic pathway in the pathology of RTT.

Mapping Promoter of Endothelial Lipase Gene and Functional Studies of Two SNPs in the Regulatory Regions.
D. Slavov, H. Razzaghi Department of Medicine, University of Colorado, Aurora, CO.

A low concentration of high-density lipoprotein cholesterol (HDL-C) is a significant risk factor for atherosclerosis, leading to coronary heart disease. Understanding the mechanism by which genetic factors influence HDL-C levels are therefore very important. Endothelial lipase (LIPG) plays a major role in HDL metabolism. We investigated the role of possible regulatory elements within 5 and 3 regions flanking LIPG gene using luciferase assay. Fragments spanning 1409 bp upstream of ATG codon and 2388 bp downstream of stop codon were cloned with luciferase reporter gene. Serial deletions of 300bp and 60bp were made in order to study different regions of promoter. The results indicate that the region -61 to -120 plays an essential role for promoter activity. It contains the critical CCAAT element and the consensus sequence for Oct1 binding site. The region -1 to -60 contains elements that resemble the consensus Inr site and TATA box. However this region by itself has no promoter activity. DNA sequences upstream of position -120 cause variations in promoter activity, suggesting presence of additional regulatory elements. The nature of these elements is currently under determination by EMSA and mass spectrometry. Two SNPs in LIPG regulatory regions (position -384 A/C and +2237 A/G) have been previously reported to have an association with HDL-C levels in Asian population. We evaluated the role of these SNPs in cellular model. Each one alone showed an increase in luciferase expression. When both SNPs were combined in the same construct, the effect on expression was higher, indicating that they work in synergy manner. The allele frequencies, A=1.00 for -384 A/C and G=0.32 for +2237 A/G in our high and low HDL groups of Whites and Hispanics were different than the reported allele frequencies, A=0.88 for -384 A/C and G=0.64 for +2237 A/G in Asian population. We did not find a significant association of +2237 A/G SNP with either high or low HDL group. In summary we reported a functional map of regulatory regions of the LIPG gene and characterization of two of its SNPs.

Prenatal Diagnosis of Mosaic Variegated Aneuploidy with Premature Chromatid Separation (MVA with PCS).
P.L. Sinanaj, S. Whitmer, J.B. Ravnan Genzyme Genetics, Santa Fe, NM.

Amniotic fluid was received for chromosome analysis from a 35-year-old Asian female. Clinical indications included advanced maternal age, positive maternal serum screen for trisomy 18, and multiple abnormalities noted on ultrasound including a possible heart problem, nuchal thickness, microcephaly, and abnormal cisterna magna. Interphase FISH analysis showed no abnormalities of chromosomes 13, 18, 21, X, and Y. Cytogenetic analysis of 15 colonies from six independent cultures showed varying aneuploidies in every cell examined with no normal cells seen. Two colonies were 47,XX,+7 with the remainder of the colonies showing different abnormalities. Trisomy 7 and trisomy 17 were the most common trisomies, usually seen in conjunction with other aneuploidies. In addition to the aneuploidies, many metaphase spreads showed a distinct morphology with the chromatids completely separated and lying side by side. A cytogenetic diagnosis of mosaic variegated aneuploidy with premature chromatid separation (MVA with PCS) was reported.

Characteristic features of MVA with PCS include microcephaly, growth deficiency, CNS anomalies, mental retardation, flat and broad nasal bridge, low-set ears, eye and skin abnormalities, and ambiguous genitalia in male patients. Diagnosis is usually made in infancy, but some adults have been diagnosed as well. Almost 1/3 of individuals with MVA with PCS have been reported to develop leukemia, rhabdomyosarcoma, or Wilms tumor in childhood. Approximately twenty-five probable or definite cases have been reported world-wide. Inheritance appears to be autosomal recessive with affected sibs in a few families. Parental chromosome studies showed increased levels of premature chromatid separation in both, suggesting they are carriers of the PCS trait.

Mutations in the BUB1B gene encoding BUBR1, a key protein in the mitotic spindle checkpoint have been found in some families with MVA with PCS. Blood from the parents was sent to a research laboratory for mutation analysis of the BUB1B gene.

Expression, purification and evaluation of activities of human EGF-IL-18 fusion protein. *J. Lu[1], Z.J. Zheng[1], J.H. Pan[1], Y. Peng[1], Y. Bai[1, 2]* 1) Dept Medical Genetics, Wenzhou Medical Col, Wenzhou, Zhejinag, China; 2) Dept Celluar and Structural Biology, UTHSCSA, San Antonio, Texas, USA.

We report here the expression, purification, and in vitro and in vivo analysis of activities of EGF-IL-18 fusion protein. The epidermal growth factor (EGF) and Interleukin-18 (IL-18) cDNA was fused together and cloned in an expression vector. The recombinant EGF-IL-18 fusion protein was processed and then purified. The resulting EGF-IL-18 fusion protein was shown to be able to induce IFN expression and secretion in KG-1 cells, and promote PBMNC proliferation. This fusion protein also stimulated activation of CD4+ T cells, and increased the percentage of B and NK cells in PBMNC challenged with tumor antigens. Moreover, EGF-IL-18 fusion protein could induce significant tumor regression in SMMC-7721-xenografted Balb/c nude mice when administered together with peritumoral injection of X-Ray-irradiated NK-92 cells. The present observation indicates a promising therapeutic approach against cancer.

Method for identifying ethnic outliers among samples genotyped for genomewide or large-scale association studies. *R. McGinnis[1], W. McLaren[1], WTCCC[2], P. Deloukas[1], M. Inouye[1]* 1) Wellcome Trust Sanger Institute, Cambridge, UK; 2) Wellcome Trust Case-Control Consortium.

Genomewide association scans can be improved by minimizing genotype and allele frequency differences between cases and controls caused by ethnic admixture rather than disease susceptibility. Yet the need to collect and handle thousands of DNA samples occasions the inclusion within cases or controls of sporadic samples whose ethnicity differs from the main bulk of samples in an intended study design (such as the British Caucasian samples of the Wellcome Trust Case Control Consortium [WTCCC]). In addition to inflating disease association statistics, inclusion of ethnic outliers can also produce SNP departures from Hardy-Weinberg equilibrium, thereby complicating assessment of genotyping platform quality. Here we report a very effective method for identifying ethnic outliers that works by examining autosomal SNPs with (a) zero heterozygote genotype counts and few counts for the rarer homozygote or (b) zero counts for the rarer homozygote and very few for the heterozygote. We tabulated (a)-type and (b)-type SNPs separately for each set of WTCCC disease cases among 6 diseases genotyped on the AFFY500K chip and among the 4 other diseases genotyped on a 14000+ mainly non-synonymous SNP panel. By summing counts of the infrequent genotype in (a)-type or (b)-type SNPs separately for each case in a particular disease set, we identify ethnic outliers as those samples with high total counts separated from the main body of the distribution. For example, from one set of 1970 cases genotyped on AFFY500K, three samples each gave >200 counts for the rarer homozygote of (a)-type SNPs with the next highest sample giving only 28 counts. Among the SNPs contributing >200 counts, 47 SNPs were shared by at least two of the three prospective outlier samples and when HAPMAP genotype frequencies were examined these SNPs were found to be monomorphic in CEU and CHB/JPT but highly polymorphic in YRI, thus illustrating the methods effectiveness. We will present similarly definitive results from (b)-type SNPs and from other WTCCC disease sets and will explain our method in detail.

Aberrant DNA hypermethylation of Integrin a4 in cholangiocarcinoma. *E. Lee, K. Uhm, Y. Lee, H. Kim, S. Park*
anatomy, college of medicine, korea univ., seoul, Korea.

Aberrant DNA methylation of 5'-CpG islands located at gene promoter region has been identified as a mechanism for transcriptional inactivation of genes. To ascertain the DNA hypermethylation in cholangiocarcinoma (CC), we investigated promoter methylation status of Integrin a4 in 19 CCs, 19 adjacent non-tumor tissues, and 7 normal liver tissues using methylation-specific PCR (MSP). The frequencies of DNA methylation of Integrin a4 were: 57.9% (11 of 19) in CCs, 5.3% (1 of 19) in adjacent non-tumor tissues, and 0% (0 of 7) in normal liver tissues respectively. There was a statistically significant difference between CCs and adjacent non-tumor tissues ($p<0.0001$). In additionally, restoration of Integrin a4 expression in CC cell lines was achieved by treatment with the DNA methyltransferase inhibitor 5-aza-2'-deoxycytidine. These results suggest that the transcriptional inactivation by aberrant DNA methylation of Integrin a4 may contribute to the tumorigenesis of CC.

Bayesian Mapping of Quantitative Trait Loci for Multiple Complex Traits Using Variance Components. *J. Liu[1], Y.J. Liu[1], X.G. Liu[1,3], H.W. Deng[1,2,3]* 1) Dept Basic Medical Sci, Univ Missouri, Kansas City, MO; 2) Laboratory of Molecular and Statistical Genetics, College of Life Sciences, Hunan Normal University, Changsha, Hunan 410081, P. R. China; 3) The Key Laboratory of Biomedical Information Engineering of Ministry of Education and Institute of Molecular Genetics, School of Life Science and Technology, Xi'an Jiaotong University, Xi'an, Shanxi 710049, P.R. China.

Joint mapping of quantitative trait loci (QTL) for multiple correlated traits plays an important role in unraveling genetic architecture of complex traits. Compared with the single-trait analysis, joint mapping addresses more questions and has advantages on power of QTL detection and precision of parameter estimation. Some statistical methods have been developed to map QTL underlying multiple traits, most of which are based on maximum-likelihood methods. We develop here a multivariate version of the Bayes methodology for joint mapping of QTL using Markov chain Monte Carlo algorithm. We adopt a variance component method to model complex traits in outbred populations. The method is robust, can deal with an arbitrary number of alleles with arbitrary patterns of gene actions, and allows for multiple phenotype data of various types in the joint analysis. Under a Bayes framework, parameters including the number of QTL are estimated based on their marginal posterior samples, which are generated through two samplers, Gibbs sampler and reversible jump MCMC. In addition, we calculate the Bayes Factor related to each identified QTL to test coincident linkage vs. pleiotropy. The performance of our method is evaluated in simulations with full-sib families. The results show that our proposed Bayes joint mapping method performs well for mapping multiple QTL in situations of either bivariate continuous traits or mixed data types. Compared to the analysis for each trait separately, Bayes joint mapping improves statistical power, provides stronger evidence for QTL detection and increases precision in estimation of parameter and QTL position. We also applied the proposed method to a set of real data for further assessing our proposed method.

Methylation pattern of several tumor suppressor genes in various cell lines. *Y. Lee, K. Uhm, E. Lee, S. Park, H. Kim*
anatomy, human genetics, col. of medicine, korea univ., Seoul, Korea.

Gene expression is mostly controlled at the level of the transcription initiation. It is well known that thousands of genes are deregulated in cancer cells. During malignant transformation, the malignant cell accumulates epigenetic abnormalities that do not alter the DNA sequence but modify genes expression. It is established that epigenetic alterations and the resulting inactivation of tumor suppressor genes often contribute to the development of various cancers. Until now, however, there is lack of information about methylation profiles differences between normal and tumors. In order to gain insights into the function of DNA methylation, here, we investigated the methylation profile of several tumor suppressor genes in 8 normal and 8 cancer cell lines. Several tumor suppressor genes among tested, such as ATM, DLC-1, SFRP-1 were hypermethylated in breast tumor MCF7 cells. However, these were not methylated in Cos7, ST3L1, NIH3T3, C2C12 normal cells. Unexpectedly, p16INK4a, well known tumor suppressor genes, was hypermethylated in 7 normal cell lines. In summary, this genome-wide epigenetic approach to the methylation patterning of tumor suppressor genes will accelerate understanding of causation and will impact on clinical assessment in the areas of both prevention and treatment. Our findings also emphasize the usefulness of DNA methylation as a marker for differential environment for normal and tumor, and as a tool for evaluation of tumor progression.

The human Y-encoded testis-specific protein (TSPY) interacts functionally with the eukaryotic translation elongation factor 1A (eEF1A), a putative oncoprotein. *Y. Lau, T. Kido* Dept Medicine/ VAMC-111C5, Univ California, San Francisco, San Francisco, CA.

Testis specific protein Y-encoded (TSPY) gene is a candidate for the gonadoblastoma locus on the Y-chromosome (GBY). It is expressed in normal testicular germ cells and tumor germ cells in gonadoblastoma cells of XY sex-reversed females and testicular germ cell tumors (TGCTs). It is hypothesized to serve a normal function(s) in male germ cell proliferation and early meiotic division, dysregulation of which could contribute to tumorigenesis. TSPY belongs to the TSPY/SET/NAP1 protein family and harbors a highly conserved SET/NAP-domain. SET/TAF-I, the best characterized TSPY/SET/NAP1 family member, is located in the nucleus and is demonstrated to regulate transcription by interacting with histones and transcription factors, such as COUP-TF, CREB-binding protein and ER1. TSPY is located on both cytoplasm and nucleus. To explore the possible function(s) of TSPY in tumorigenesis, we performed a yeast two-hybrid screen of a fetal gonadal cDNA library using the TSPY SET/NAP domain as bait. The translation elongation factor, eEF1A, was consistently identified as a binding partner for TSPY. eEF1A is essential for protein elongation of the protein synthesis machinery. It is also a putative oncoprotein involved in the development of ovarian and breast cancers. TSPY and eEF1A were colocalized in the cytoplasm and were coimmunoprecipitated from transfected COS7 cells. Immunostaining of human TGCTs demonstrated that TSPY and eEF1A were highly expressed and colocalzied in both the premalignant precursor, carcinoma in situ (CIS), of both seminomas and nonseminomas and tumor germ cells of seminomas. Significantly, over-expression of eEF1A increased the expression of a reporter gene in cultured cells. Such enhancement could be further amplified in the presence of TSPY. Since cell proliferation requires significant metabolism and growth nutrients, the interaction between TSPY and eEF1A accelerates the protein synthesis machinery, thereby exacerbating the respective tumor-promoting functions in TGCTs.

Modifying effects of age, QTc interval, and androgen receptor gene variation in patients with hypertrophic cardiomyopathy. *J.M. Lind[1], C. Chiu[1,2], J. Ingles[1], N. Cochrane[1,2], S.E. Humphries[3], A.K. Heather[4], C. Semsarian[1,2,5]*
1) Agnes Ginges Centre for Molecular Cardiology, Centenary Institute, Sydney, Australia; 2) Faculty of Medicine, University of Sydney, Australia; 3) Centre for Cardiovascular Genetics, Royal Free and University College Medical School, United Kingdom; 4) Gene Regulation Group, The Heart Research Institute, Sydney, Australia; 5) Department of Cardiology, Royal Prince Alfred Hospital, Sydney, Australia.

Hypertrophic cardiomyopathy (HCM) is a clinically heterogenous disease, which suggests a number of factors exist which modify disease outcome. The magnitude of left ventricular hypertrophy is an important predictor of prognosis in patients with HCM. The aim of this study was to determine the contribution of a number of potential modifying factors, including age, blood pressure, QTc interval, presence of a sarcomere mutation, and genetic variation in sex hormone receptors, to the development of left ventricular hypertrophy in HCM. The study population included 174 unrelated individuals from an Australian HCM cohort. Clinical evaluation was performed, including clinical history, physical examination, ECG and 2D/M-mode echocardiography. Genetic analysis of repeat number variations within the androgen receptor (*AR*), estrogen receptor 1, estrogen receptor 2, and cytochrome P450 subfamily XIX genes, was performed in all patients. Younger age ($P<0.001$), a longer QTc interval ($P<0.001$), and fewer (CAG)n repeats within the *AR* gene ($P=0.023$) were significantly associated with higher maximal left ventricular wall thickness (LVWT) in males, in multivariate analysis. Younger age was the only significant predictor of higher maximal LVWT in females ($P=0.014$). A prolonged QTc interval ($P=0.008$) and age ($P=0.036$) were also significantly associated with presence of left ventricular out flow tract obstruction, adjusting for gender. We report three key factors, namely, age, QTc interval, and genetic variation in the *AR* gene, as potential modifiers of left ventricular hypertrophy in HCM. Understanding the impact of modifying factors will be helpful in the risk stratification and clinical management of patients with HCM.

Importance of population substructure characterization in linkage studies of admixed populations. *C. Thompson, C. Gray-McGuire* Epidemiology & Biostatistics, Case Western Reserve Univ, Cleveland, OH.

Genetic admixture and the resulting population substructure are known to increase the type I error rate in association studies. However, little work has been done to assess the impact of admixture and population substructure on linkage analysis. Genetic heterogeneity, where underlying genetic factors for disease differ between populations, has been demonstrated in many complex diseases. Currently, in an attempt to create more genetically homogeneous subpopulations, investigators often stratify their linkage analyses by race. However, self-reported race may not accurately reflect ethnicity and its use is controversial. Many algorithms exist for clustering individuals into more genetically homogeneous subpopulations. To understand the effects of admixture and population substructure on linkage, we performed simulations and evaluated the type I error and power of a model-free sibling pair linkage method in a variety of scenarios representing characteristics of admixed populations. The results of the simulations indicate that stratification on inferred subpopulation is an effective way of reducing heterogeneity. Results further indicate that stratification yields the most gain when assortive mating occurs, and when the sample sizes of the subpopulations are large in relation to the number of subpopulations in the sample. As expected, stratification does not work well in cases where the genetic susceptibility locus is the same for all subpopulations or where the lack of distinct subpopulations makes stratification more difficult.

Novel Mutations in Carnitine Palmitoyltransferase II gene. *B.Z. Yang, J.H. Ding, N. McNeill, R.J. Chai, L. Sweetman, J. Bennett-Firmin, C.R. Roe.* Inst Metabolic Disease, Baylor Research Institute, Dallas, TX.

Carnitine palmitoyltransferase II (CPT II) deficiency, one of the inherited defects of fatty acid -oxidation, has three distinct clinical forms: the adult-onset (muscular) form, milder infantile form and severe neonatal form which may result in sudden unexplained death. In this report, a 10-month old patient with CPT II deficiency has been investigated for the molecular defects. All five CPT II exons and their flanking intronic sequences were amplified from probands DNA. The PCR products were purified and sequenced directly. The sequencing analysis revealed that this patient was a compound heterozygous. A previous reported mutation 452 G>A (R151Q) was detected in one allele. A novel mutation 1933-34 insG was identified at exon 5 in another allele, which results in a frameshift. The mutations were also verified by DNA amplification/enzyme digestion method, but were not detected in the normal control subjects. in our group, thirty-eight unrelated families with CPT II deficiency were identified by CPT II enzyme assay and/or by Acylcarnitine levels measured by tandem mass spectrometry (MS/MS). The molecular aspects had been summarized, including two novel mutations P504L and K389fs in one Pilipino family.

NPL analysis in 3-generation Brazilian families multipli-affected with aggressive and chronic periodontitis. *G.E. Rapp[1], A. McQuillan[2], B. North[3], P. Brett[2], M.S. Tonetti[4]* 1) Clinical Dentistry, Federal University of Bahia, Salvador, Bahia, Brazil; 2) University College of London, United Kingdom; 3) Imperial College of London, United Kingdom; 4) European Research Group on Periodontology, Italy.

Background: Periodontitis is a multifactorial inflammatory disease, presenting a rare aggressive (AgP) and a more common chronic form (CP). Both forms compromise few or several teeth and may lead to tooth loss. A genetic susceptibility has been shown for various disease phenotypes in several populations around the world. The aim was to test linkage of polymorphisms in candidate genes to periodontitis on a set of 3-generation Brazilian families. Material and Methods: Three large pedigrees were selected after confirmed diagnoses of AgP in the proband. A 6 site/tooth full-mouth probing was performed by a calibrated examiner in the 58 pedigree members (all non-smokers). The phenotype was defined based on questionnaire (total edentulisms) and clinical attachment loss 4mm due to pocketing in at least 4 sites of different teeth, what includes CP. In total, 17 were considered affected, 26 non-affected and 15 with unknown diagnosis because of low age (14 years). SLINK simulation method (AD; Θ=0; F= 0.98, 0.75, 0.5; P=0, 0.02) showed maximum expected lod scores of 9.67 in all pedigrees. A multipoint NPL to D1S1595, FcG3A, FcG3B65, FcG3B36, D1S1679, D7S1802, IL6-1750, IL6-1363, IL6-572, IL6-174, D7S1802, IL13954, VDR-312 was tested using Simwalk 2.91. Results: The most significant values were found for D1S1595 (p=0.0157) and D1S1679 (p=0.0124). Conclusions: Bearing in mind the unknown underlying genetic model of periodontitis, the findings provided interesting positional information on human chromosome 1 for future additional genomic screening. A possible common genetic background of both studied clinical forms of periodontitis may exist. Ministry of Education of Brazil CAPES 2622/03-3.

Inherited homozygous paracentric inversion affecting both arms of chromosome 12. *L. Martelli[1, 2], I. Gomy[2], L.A.F. Laureano[2], M. Yoshimoto[3], E.S. Ramos[1, 2], M.S.J. deVozzi[1], J.A. Squire[3]* 1) Department of Genetics, University of Sao Paulo, Ribeirao Preto, SP, Brazil; 2) Medical Genetics Division, Clinical Hospital of Ribeirao Preto, SP, Brazil; 3) University Health Network, Toronto, Canada.

In general, carriers of paracentric inversions are phenotypically normal, although individual reports have described occurrence of infertility, miscarriages and mental retardation in inversion carriers. Inversions involving chromosome 12 are rare, not correlated to phenotypic findings and have been recognized in some benign tumors. The proband was born to a 30 years old G4P2A2 woman at term, after an uncomplicated pregnancy. The parents are consanguineous, second degree cousins. He was delivered by cesarean section due to cephalopelvic desproportion, weighting 4000g. The boy was referred to the Medical Genetics Division at 9yo due to developmental delay and dysmorphic features. Physical examination showed macrossomy with obesity, H=151cm (p>97) and W=58400g (p>97), brachycephaly, facial dysmorphism characterized by hypertelorism, downward slanting palpebral fissures, broad nasal bridge, large ears (7.5cm), preauricular pit, tapering phalanges, toe position anomaly and unilateral cryptorchidism. Delayed developmental milestones were evident, presenting hyperactivity and mild mental retardation. Conventional cytogenetic analysis by GTG banding showed 46,XY chromosomes and paracentric inversion affecting both arms of the pair 12. M-band results confirmed that both chromosomes 12 were identical, with the same rearrangements and final karyotype 46,XY,der(12) inv(12)(p11.2p12.3)inv(12)(q21.1q24.1)x2. Parental chromosome analysis showed that the patient's mother carried an identical karyotype and his father was inversion heterozygote. The aberrations in the child implicate that subtle genomic alterations resulting from the inversion may have contributed to his phenotype. Supported by CAPES and FAEPA, HCFMRP-USP.

A New Case of Prenatally Diagnosed Trisomy 12 Mosaicism: Physical and Developmental Follow-up. *Y. Watanabe[1], Y. Kudo[1], K. Egami[1], Y. Koteda[1], K. Suda[1], S. Yano[2], M. Yoshino[1], T. Matsuishi[1]* 1) Pediatrics and Child Health, Kurume University School of Medicine, Kurume , Fukuoka, Japan; 2) Genetics Division, Pediatrics LAC+ USC Medical Center, University of Southern California Los Angeles, CA.

Prenatal diagnosis of trisomy 12 mosaicism poses serious counseling problems since it is a rare condition and outcome of the pregnancy is reportedly quite variable. At least 27 cases have been reported. Approximately half of the cases underwent termination. Five out of 27 cases were reportedly associated with major anomalies including dysmorphic facies, congenital heart defects, and pigmentary dysplasia of the skin. Seven out of 27 cases were reportedly grossly normal at birth. There have been only four reported liveborn cases who were physically and developmentally normal up to age 5 months to 7 years. We report another liveborn case prenatally diagnosed with this condition, showed multiple anomalies and developmental delay at age 4 months. Case report: Patient is a 2 9/12 year-old female born to healthy non-consanguineous parents. The mother was a 25 year-old G2P1-2Ab0 female who was in good health. The mother was diagnosed with polyhydramnios. The patient was a 37week, 2989g infant born by NSVD. The mother had prenatal studies including amniocentesis which revealed trisomy 12 mosaicism (46, XX[23]/ 47, XX+12 [21]). Chromosome studies were repeated with cord blood and peripheral blood at birth, which revealed normal results. The patient was noted to have congenital nystagmus and ASD at birth. Global developmental delay was noted at 4 months. PE at age 6 months revealed abnormal skin pigmentation covering the bilateral ankle area to the buttock area following the Blaschkos line, a high arched palate, and dysmorphic facies with hypertelorism. Chromosome studies with skin fibroblasts revealed mosaic trisomy 12 (46, XX[58]/ 47, XX+12 [2]).DQ at age 19 months was 49. Conclusion: Reporting postnatal outcome of infants who are prenatally diagnosed with trisomy 12 mosaicism is important to provide more information for better genetic counseling.

Evaluation of Different Array-CGH Procedures for Preimplantation Diagnosis. *Y. Yang, M.J. Simovich, W. Jin, M.L. cooper, K.L. Pham, S.W. Cheung* Department of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX.

Screening for chromosome abnormalities in preimplatation diagnosis (PGD) is currently performed by Fluorescent in situ hybridization (FISH), which can detect aneuploidy for chromosomes 13, 15, 16, 18, 21, 22, X and Y. This detection efficiency can be improved by utilizing the novel array-CGH technology, which scans the whole genome for large deletions and duplications. However, performing single cell array-CGH for PGD has a number of challenges. First, the amplified DNA from single cells should have a good coverage of the entire genome. Second, the amplified products from samples and references should be as similar as possible in order to reduce noisy hybridization signals caused by bias genome representations during amplification. Third, the turn-around time for the test should be within 48 hours. We are evaluating different protocols in order to optimize conditions for single cell array-CGH in PGD. Single cells were obtained from discarded embryos on day 6. These embryos had undergone PGD for aneuploidy screening by FISH on day 3 at 6-8 cell stage and chromosomal abnormalities were identified. The whole genome amplification was performed by both ligation-mediated PCR and multiplex displacement amplification (MDA) using Phi29 DNA polymerase. Different reference samples including normal single cells as well as different concentrations of purified DNA were used. Array-CGH was performed using Baylor CMA array version 5, which is consisted of 853 BAC clones. The hybridization results will be compared and the optimized procedures for array-CGH in PGD will be proposed.

Detection of 7q11.23 microdeletion in a Williams-Beuren syndrome patient carrying a severe supravalvular pulmonar stenosis and mild supravalvular aortic stenosis. *I. Trabelsi[1], M. Cherif[3], S. Kammoun[1], T. Rebai[2], N.B. Abdelmoula[2]* 1) Cardiology Dept, Hedi Chaker Hosp, Sfax, Tunisia; 2) Histology Lab, University of Medicine, Sfax, Tunisia; 3) Genetic Laboratory, Tunis, Tunisia.

Williams-Beuren syndrome is a multisystemic developmental disorder which usually occurs sporadically. Phenotypes include a dysmorphic face and congenital heart disease. These features are caused by deletion of the Williams-Beuren syndrome critical region at chromosomal position 7q11.23 on either the maternal or paternal chromosome 7. Only the elastin gene is associated with a phenotype which is supravalvular aortic stenosis. Here, we report a Tunisian 2-year-old boy referred to us for cytogenetic evaluation of elfin facies, growth retardation and congenital heart disease. He was the first child of healthy non-consanguineous parents. The paternal age was 26 and the maternal age was 24 years. He was born par caesarean section at 38 weeks gestation of an uneventful pregnancy. Birth weight was 2400 g. Apgar scores were 6 at one minute and 10 at five minutes. He was born with the two superior middle teeth. On examination at 9 months, the boy had growth and psychomotor developmental retardation (weight at -3DS). At 2 years, he doesnt walk and only the word papa is spoken. Cardiac evaluation showed severe supravalvular pulmonar stenosis and mild supravalvular aortic stenosis. Clinical evaluation disclosed squint, periorbital fullness, bitemporal narrowness, small upturned nose, full nasal tip, long philtrum, full cheeks, full lips, wide mouth, and small jaw. The boy had a particular cognitive and behavioural profile including mild mental retardation, delayed expressive and receptive language abilities, attention deficit, hyperactivity and anxiety. Williams-Beuren syndrome was suspected. Chromosomal analysis demonstrated a 46,XY karyotype. Fluorescent in situ hybridization was performed using a probe directed to the elastin gene and another marker probe directed to band 7q36. Submicroscopic deletion of the williams syndrome locus was found and the diagnosis was confirmed. FISH analysis at the mother and the father did not show any deletion.

A powerful test of association of multiple markers with disease using kernel scores. *I. Mukhopadhyay*[1], *A. Thalamuthu*[2], *E. Feingold*[3], *D.E. Weeks*[4] 1) Department of Statistics, Burdwan University, Burdwan, West Bengal, India, 713104; 2) Genome Institute of Singapore, 60 Biopolis Street, #02-01, Genome, Singapore 138672; 3) Department of Human Genetics and Biostatistics, 130 DeSoto Street, A305 crabtree Hall, Pittsburgh, PA 15261, USA; 4) Department of Human Genetics and Biostatistics, 130 DeSoto Street, A303 crabtree Hall, Pittsburgh, PA 15261, USA.

When multiple genes might influence disease risk, it can be useful to globally test for the simultaneous effect of the multiple genes on disease risk. Based on kernels we propose a powerful test for testing association of multiple markers acting simultaneously on disease, using case-control data. We used the idea of analysis of variance (ANOVA) with the scores of symmetric kernel functions on genotypes of each marker (Schaid et al, 2005) as observations. We compare the variation between cases and controls and the variation within each class that would eventually led us to propose a testing procedure for the detection of association. We study each marker separately and combine them to get a global statistic that is finally used to test for disease-marker association. We carried out a simulation to calculate the Type I error and power of our new statistic, varying liability loci from one to five out of a total of ten markers. For a variety of relative risks and allele frequencies, our proposed statistic has much higher power than some other statistics in the literature. We studied several different kernels and it appears that no particular kernel turns out to be the best in all models; however there is very little difference in power among them.

Interaction and Association Analysis of -, - and -opioid Receptor Genes in Substance Dependence Using A Pattern Discovery-based Method. *Z. Li[1,2], H. Zhang[3,4], H.R. Kranzler[7], X. Luo[3,4], J. Gelernter[3,4,5,6]* 1) Department of Computational Genetics, High Throughput Biology, Inc, Livingston, NJ; 2) Center for Computational Biology and Bioinformatics, Columbia University, New York, NY; 3) Department of Psychiatry, Yale University School of Medicine, New Haven, CT; 4) Department of Genetics, Yale University School of Medicine, New Haven, CT; 5) Department of Neurobiology, Yale University School of Medicine, New Haven, CT; 6) VA Connecticut Healthcare System, West Haven Campus, CT; 7) Department of Psychiatry, University of Connecticut School of Medicine, Farmington, CT.

Polymorphisms in the -, - and -opioid receptor genes (OPRM1, OPRD1 and OPRK1, respectively) have been reported to be associated with substance dependence (SD). In the present study, we assessed the joint effect of all three receptor genes on alcohol, cocaine, and opioid dependence (AD, CD and OD, respectively) using a pattern discovery-based association test. Genotype data for 13 OPRM1 single nucleotide polymorphisms (SNPs), 11 OPRD1 SNPs and 7 OPRK1 SNPs were obtained from 382 European Americans (EAs) affected with SD (among them, 318 with AD, 171 with CD, and 91 with OD) and 338 EA control subjects. Specific marker and haplotype patterns (consisting of marker alleles of the three receptor genes) were found to be significantly more frequent in cases than in controls. Additionally, both marker- and haplotype-based gene-gene interaction analyses demonstrated an interactive effect of OPRM1 SNPs (located in haplotype block 1) and OPRD1 SNPs on AD and CD, and an interactive effect of OPRM1 SNPs (located in haplotype block 2) and OPRK1 SNPs on AD and OD. Taken together, findings from this study support previous biological findings that the interaction of the three opioid receptors can modulate the action of opioid and non-opioid drugs and alcohol. Future study is needed to investigate the joint effect of the three receptor genes on the individual response to specific pharmacotherapies for SD.

Sharing research results from complex disease genetics studies: A community based participatory research approach. *K.K. McGlone, E.M. Drew, G.V. Mohatt, R.L. Pasker, B.B. Boyer* Center for Alaska Native Health Research, Institute of Arctic Biology, University of Alaska Fairbanks.

The Center for Alaska Native Health Research (CANHR) conducts studies in Yupik Eskimo communities in order to understand the interactions between genetic, nutritional and psychosocial risk factors for obesity and diabetes. CANHR employs a community-based participatory research (CBPR) approach, in which participating community leaders are viewed as co-researchers and are involved in all steps of the process from generating a common research question to the interpretation and dissemination of overall results. Collaboration on procedures for sharing results is imperative to the partnership underlying CBPR, as it builds capacity within the community to understand and utilize study results. CANHR investigators have collaborated with regional healthcare providers, tribal leaders, and university-, local- and national-IRBs to identify culturally appropriate mechanisms for sharing general research progress. Using a CBPR approach to disseminate results of multifactorial disease genetics studies is yet unprecedented. NBAC guidelines and the NHLBI working group (Bookman *et al*, 2006) recommend that genetics results should only be disclosed to participants under limited circumstances. This guidance conflicts with the goal of the community as co-researcher that is fundamental to CBPR. We plan to apply our CBPR process to genetics research, to avoid ethical dilemmas and to sustain the relationship of trust among partners, while respecting NBAC recommendations. To do so, we will hold several meetings, including a traditional scientific presentation among CANHR investigators, followed by focus groups with tribal leaders, and then with selected participants to identify and resolve ethical issues and to develop a culturally and ethically appropriate presentation to convey emerging results to all participating communities. We conclude that both researchers and participants should benefit from population-based genetics research, and that it is essential to move forward as co-researchers in the CBPR enterprise.

A unified association analysis approach for family and unrelated samples correcting for stratification. *X. Zhu[1], S. Li[2], R.C. Elston[1]* 1) Epidemiology & Biostatistics, Case Western Reserve Univ, Cleveland, OH; 2) Cleveland Clinic Foundation, Cleveland, OH.

There are two common designs for association mapping of complex diseases: case-control and family-based designs. A case-control sample is more powerful than a family -based sample that contains the same number of persons, although additional markers may be required to control for spurious association. When family and unrelated samples are available, statistical analyses are often performed in the family and unrelated samples separately, resulting in reduced power. In this report, we propose a unified approach allowing for both family and case-control samples and at the same time correcting for population stratification. We apply the principal components of a marker matrix to adjust for the effect of population stratification. This unified approach is more powerful than the analysis for unrelated and family samples separately, or meta-analysis performed by combing the results of separate analyses. This property is demonstrated in both simulations and real data. The proposed approach can be applied in the analysis of both qualitative and quantitative traits.

Analysis of single nucleotide polymorphisms and haplotypes in TBX20 gene within the susceptible region 7p14-15 of Fallot's tetralogy. *G. R. Qiu[1], N. Xin[1], L.G. Gong[1], Y.H. Yuan[2], X.M. Han[3], H.B. Liu[4], X.Y. Xu[1], K.L. Sun[1]* 1) Department of Medical Genetics, Basic Medicine, China Medical University, Shenyang, Liaoning, China; 2) Department of Cardiac surgery, the 1st affiliated Hospital, China Medical University; 3) Department of Cardiavascular medicine, Military District Hospital; 4) Department of Health Statics, College of Public Health, China Medical University.

Objective:In the candidate region 7p14-15 where the susceptibility gene of Fallots tetralogy might be according to our previous studies, we chose four single nucleotide polymorphisms (SNPs) in TBX20 gene to investigate single SNP and haplotypes distribution in patients and normal people in order to confirm whether or not TBX20 gene is the susceptibility gene in the candidate region. Methods: Four SNPs in the coding-region of TBX20 gene, including rs3999941, rs6950175, rs13237089 and rs336283, were chosen, and the genotypes of 4 SNPs in 215 patients and 300 normal people were analyzed by denaturing high performance liquid chromatography. Legally constituted authority statistical analysis was applied to analyze SNP genotype frequency and gene frequency in patients and control group. Then we established haplotypes and analyzed their frequency in two groups by PHASE software. Results: C/T polymorphism at rs336283 was not detected; A/G polymorphism at rs3999941 and G/T polymorphism at rs6950175 had significant difference between patients and normal people, the A allele frequency at rs3999941 and the G allele frequency at rs6950175 in patients were higher than those in healthy controls (chi square=9.39 P<0.005;chi square=9.78 P<0.005); the distribution of frequencies of 6 haplotypes showed significant difference (chi square=22.78 P<0.005) between two groups, and AGG haplotype was more common in patients. Conclusion: rs336283 and rs3999941 located in the coding-region of TBX20 gene were associated with Fallots tetralogy, the risk of Fallots tetralogy in the persons with A allele at rs3999941 and the G allele frequency at rs6950175 was higher. The AGG haplotype might be linked with the susceptibility gene of Fallots tetralogy.

Association between FGF20 and Parkinson's disease and Genome-wide association study using 27,158 microatellite by The Japanese PD Susceptibility Gene Consortium. *W. Satake[1, 2], I. Mizuta[1, 3], Y. Hirota[1], A. Oka[4], M. Watanabe[5], A. Takeda[6], K. Hasegawa[7], S. Sakoda[2], M. Yamamoto[8], N. Hattori[9], M. Murata[10], H. Inoko[4], T. Toda[1,3]*
1) Div Clinical Genetics, Osaka Univ Grad Sch Med; 2) Dept Neurol, Osaka Univ Grad Sch Med; 3) CREST, JST; 4) Dept Mol Life Sci, Tokai Univ Sch Med; 5) Dept Neurol, Univ Tsukuba; 6) Div Neurol, Tohoku Univ Grad Sch Med; 7) Dept Neurol, Sagamihara National Hosp; 8) Dept Neurol, Kagawa Prefectural Central Hosp; 9) Dept Neurol, Juntendo Univ Sch Med; 10) Dept Neurol, Musashi Hosp, NCNP, Japan.

Parkinson's disease (PD) is one of the most common neurodegenerative diseases. A genetic association between the fibroblast growth factor 20 (FGF20) gene and PD has been found by the pedigree disequilibrium test. However, this association was not replicated by a case-control association study. In order to clarify the association between FGF20 and PD, we attempted to replicate this association by a case-control association study using a large number of Japanese samples (1388 patients and 1891 controls). rs1721100 exhibited a significant difference in allele C versus G (P=0.0089), and in genotype CC+CG versus GG (P=0.0053). These results suggest that FGF20 is a susceptibility gene for PD in the Japanese population. Moreover, to identify another susceptibility genes for PD, we performed three step-wise association studies with DNA samples of 624 PD patients and 624 controls (1st screening,124 samples each, 2nd 250 each, 3rd 250 each) using the pooled DNA method and 27,158 microsatellite markers(MS) throughout the genome, and 280 MS showed associations throughout all three screenings. We have been confirming the associations of these MS using individual samples of 624 PD patients and 624 controls (Tier 1). We have performed individual genotyping of 164 markers with Tier 1 samples, and 24 markers still showed an association (p 0.01), of which 7 markers showed a stronger association (p 0.001). In parallel, we have been genotyping samples of 779 PD patients and 1,217 controls (Tier 2) on these markers. Genes in linkage disequilibrium with these markers may be associated with the pathogenesis of PD.

Detection of circulating fetal cells utilizing automated microscopy for non-invasive prenatal diagnosis of chromosomal aneuploidies. *A. Seppo[1], V. Frisova[2], Y. Kim[1], M.I. Evans[3], A. Antsaklis[4], K.H. Nicolaides[2], T. Tafas[1], P. Tsipouras[1], M.W. Kilpatrick[1]* 1) Ikonisys Inc, New Haven, CT; 2) Harris Birthright Research Ctr, Kings College Hospital, UK; 3) Comprehensive Genetics & Mt. Sinai School of Medicine, New York, NY; 4) First Dept. of ObGyn, National University of Athens, Greece.

Our objective is to identify fetal cells in peripheral blood samples from pregnant women for detection of chromosomal aneuploidies. This could be accomplished either through detection of a fetal cell specific marker or, alternatively, through the detection of aneuploid FISH signals. To that effect we utilized an automated microscopy system developed to identify and enumerate cells based on their FISH signal complement. For FISH-based scanning, verified fetal cells are identified based on a dual FISH probe labeling approach. Previously we showed that dual labeling reduces the false positive rate below 0.00005% when scanning for rare nuclei. Fetal nuclei are identified at low mag based either on the presence of a Y chromosome signal or on aneuploid FISH signals for chromosome 21. These nuclei are verified at high mag utilizing two FISH probes for the chromosome of interest. In addition, density gradient centrifugation was investigated for enrichment of fetal cells. FISH- based scanning identified fetal cells in 28 out of 29 maternal samples, 11 first trimester and 18 second. A range of 1-10 fetal cells were detected in unenriched samples and 1-20 in enriched samples. On average 0.5 and 2.3 fetal cells per million nucleated maternal cells were detected in unenriched and enriched samples, respectively. Thus simple density gradient centrifugation achieved a 4-5 fold increase in the number of fetal cells detected. Our data demonstrate that automated microscopy was able to detect fetal cells in greater than 95% of maternal samples, both first and second trimester. This was achieved utilizing dual FISH probes for the chromosome of interest. This suggests that automated scanning for aneuploid FISH signals could form the basis of a credible clinical test for non-invasive prenatal diagnosis, eliminating the need for a fetal cell specific biomarker.

Neurobehavioral profile and brain imaging study of the 22q13.3 deletion syndrome. *A. PHILIPPE[1], N. BODDAERT[2], L. VAIVRE-DOURET[3], L. ROBEL[3], V. MALAN[1], O. RAOUL[1], M.C. de BLOIS[1], M. PRIEUR[1], V. CORMIER-DAIRE[1], S. LYONNET[1], B. BENZACKEN[4], D. HERON[5], B. GOLSE[3], M. VEKEMANS[1], M. ZILBOVICIUS[2], A. MUNNICH[1]* 1) INSERM U 781 & Département de Génétique, Hôpital Necker-Enfants Malades, Paris; 2) INSERM URM 0205, CEA, Orsay, France; 3) INSERM U483 et Service de Pédopsychiatrie, Hôpital Necker-Enfants Malades, Paris; 4) Service dHistologie Embryologie Cytogénétique et Biologie de la Reproduction, Hôpital Jean Verdier, Bondy, France; 5) Département de Génétique, Hôpital de la Pitié Salpêtrière, Paris.

The 22q13.3 deletion syndrome (MIM 606232) is a neurodevelopmental disorder including hypotonia, severely impaired development of speech and language, autistic-like behavior and minor dysmorphic features. Although the number of cases reported is increasing, the 22q13.3 deletion remains under-diagnosed due to failure both to recognize the phenotype on clinical examination and to detect the 22qter deletion in routine chromosome analysis. Our objective is to improve the description of the neuro-behavioral and brain characteristics of this microdeletional syndrome. We report an overall neuro-behavioral assessment of 8 children with a 22q13.3 deletion. The assessment involved analysis of neuromotor, sensory, language, communication and social development, cerebral magnetic resonance imaging, and study of regional cerebral blood flow measured by positron emission tomography. Although the severity of symptomatology differs between children, the 22q13.3 deletion syndrome has a clinically distinctive developmental profile associated with hypoperfusion of left temporal polar lobe and amgydala. Although autism was suspected in 7/8 subjects in our cohort during the first year of their lives, it is not confirmed later subsequently. Our study shows that the paralinguistic clues of interaction and the nature of the repetitive behaviors suggested a particular pattern distinct from autism. More than clinical observation at a given time, the progression of symptoms and their assessment according to developmental and chronological age are particularly valuable for the diagnosis of deletion 22q13.3 syndrome.

Positive selection within the schizophrenia-associated $GABA_A$ receptor $_2$ gene. *W.S. Lo[1], Z. Xu[1], Z. Yu[2], F.W. Pun[1], S.K. Ng[3], J. Chen[1], K.L. Tong[1], C. Zhao[3], X. Xu[3], S.Y. Tsang[1], M. Harano[4], G. Stöber[5], V.L. Nimgaonkar[6], H. xue[1]* 1) Department of Biochemistry, Applied Genomics Laboratory and HKH Bioinformatics Center; 2) Graduate program of Atmospheric, Marine, and Coastal Environment; 3) and Graduate Program of Bioengineering, Hong Kong University of Science and Technology, Hong Kong China; 4) Department of Neuropsychiatry, Kurume University School of Medicine, Fukuka, Japan; 5) Department of Psychiatry and Psychotherapy, University of Würzburg, Würzburg, Germany; 6) Departments of Psychiatry and Human Genetics, University of Pittsburgh School of Medicine, and Graduate School of Public Health, Pittsburgh.

The $GABA_A$ receptor plays a major role in inhibitory neurotransmissions. SNPs and haplotypes in *GABRB2*, the gene for $GABA_A$ receptor $_2$ subunit are associated with schizophrenia, and correlated with the expression of two alternatively spliced $_2$ isoforms. In this study, using chimpanzee as an ancestral reference, high frequencies were observed for the derived (D) alleles of the four schizophrenia-associated SNPs in *GABRB2*, suggesting the occurrence of positive selection for these derived alleles. Coalescence-based simulation showed that the population frequency spectra and the frequencies of H56, the haplotype having all four D alleles, significantly deviated from neutral-evolution expectation in various demographic models. The variations in DD-genotype frequencies in five human populations suggested that the positive selections of the D alleles are recent and likely ongoing. The divergence between the DD-genotype profiles of schizophrenic and control samples pointed to the schizophrenia-relevance of positive selections, with the schizophrenic samples showing weakened selections compared to the controls. These DD-genotypes were previously found to increase the expression of $_2$, especially its long isoform. Electrophysiological analysis showed that this long $_2$ isoform favored by the positive selections is more sensitive than the short isoform to the inhibition of the receptor function by energy depletion. These findings represent the first demonstration of positive selection in a schizophrenia-associated gene.

KBAT: Kernel-based association test. *H.C. Yang[1], H.Y. Hsieh[2,3], C.S.J. Fann[2,3]* 1) Institute of Statistical Science, Academia Sinica, Taipei, Taiwan; 2) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan; 3) Institute of Public Health, Yang-Ming University, Taipei, Taiwan.

Disease gene association mapping is a powerful tool for positional cloning of genes susceptible to complex disorders. We propose a kernel-based association test (KBAT) which is a composite function of p-values of single point association tests and kernel weights related to intermarker distances and/or linkage disequilibrium. KBAT is a general form of many existed test statistics. This method can be applied to study candidate genes as well as scan whole chromosomes by incorporating a sliding window procedure with a proposed selector of optimal window sizes. We evaluated performance of KBAT by using comprehensive simulation studies which considered evolutionary parameters, disease models, sample sizes, kernel functions, test statistics, windows attributes and genetic/physical maps. The results of simulations with 10,000 simulation replications for each condition showed that KBAT had high test power and well controlled type 1 error compared with many existed methods. In addition, KBAT was also applied to study a large authentic data set of alcoholism dependence (COGA) provided by GAW14. Results of the genomewide analysis not only confirmed previous findings but also identified some novel regions. In summary, strengths of KBAT are multi-folds: (1) Robust to inclusion of nuisance markers; (2) Scale-invariance to map scale; (3) Accommodated to different study designs; (4) Amenable to pooled DNA association mapping and allelic imbalance detection; (5) Applicable to meta-analysis. Utilities of the proposed methods are integrated in user-friendly software KBAT.

Epigenetic regulation of expression of Septin 9 isoforms in cancer cells. *C. Montagna[1], D. Connolly[1], S. Nguyen[1], M. Suzuki[1], K. Nagata[2], N. Suhr[1], J. Glass[1], J.M. Greally[1], S.B. Horwitz[1], P. Verdier-Pinard[3]* 1) Albert Einstein College of Medicine, Bronx, New York 10461, USA; 2) Aichi Human Service Center, 713-8 Kamiya-cho, Kasugai 480-0392, Japan; 3) Faculté de Pharmacie, 13005 Marseille, France.

Septin 9 is a cytoskeleton-associated protein whose function in normal and cancer cells remains largely unknown. Our previous comparative cytogenetic analysis performed on a variety of mouse models for breast cancer revealed that amplification of the Sept9 locus occurred in the form of double minute chromosomes and resulted in Sept9 over-expression. The Sept9 locus is also amplified and over-expressed in human breast and ovarian tumors. Some septin genes can generate multiple splice variants for which the regulation of expression and functional significance are poorly understood. 18 possible transcripts can be encoded at the Sept9 17q25.3 gene locus. We identified CG clusters mapping to isoform transcription start sites prompting the hypothesis that methylation at specific CG di-nucleotides is one of the mechanisms involved in the regulation of isoform expression. A synergistic approach combining proteomic, genomic and epigenetic analyses was implemented to decipher the mechanism regulating the expression of the multiple Sept9 isoforms. Treatment of A549, a lung cancer cell line, and of MDA-MB-231, a breast cancer cell line, with compounds interfering with DNA methyltransferase activity had profound effect on Sept9 isoform expression. This was detected at the protein level by 2D Western blotting and by real time PCR where an up-regulation of pan-Sept9 mRNA levels was detected. Pyrosequencing analysis is being performed to quantify differential levels of methylation in untreated versus treated cell lines. Consequences of this differential isoform expression on Sept9 cellular localization are also being investigated and identification and quantification of the isoforms differentially expressed by quantitative capillary PCR and mass spectrometry are ongoing. These experiments will generate insights into the epigenetic regulation of Sept9 isoform expression and its potential role in cancer development.

Mutations in BMP4 are associated with subepithelial, microform, and overt cleft Lip. *S. Suzuki[1,2], M.L. Marazita[3], N. Miwa[2], A. Jugessur[2], N. Natsume[1], K. Shimozato[1], M. Shi[2], N. Ohbayashi[1], Y. Suzuki[1], T. Niimi[1], M. Yamamoto[1], T.J. Altannamar[4], T. Erkhembaatar[4], H. Furukawa[1], S. Daack-Hirsch[2], A. Vieira[3], A.C. Lidral[2], J.F. Martin[5], J.C. Murray[2]* 1) Aichi-Gakuin University, Nagoya 4648651, Japan; 2) University of Iowa, Iowa City, IA 52242, USA; 3) University of Pittsburgh, Pittsburgh, PA 15219, USA; 4) Maternal and Children's Health Research Center Hospital, Ulaanbaatar, Mongolia; 5) Institute of Biosciences and Technology, Texas A&M Health Science Center, 2121 Holcombe Blvd., Houston, TX 77030, USA.

Nonsyndromic cleft lip with or without cleft palate (CL/P), a common birth defect, is a complex trait, arising from the influence of genetic and environmental factors. Evidence is also mounting that the phenotypic spectrum of CL/P includes both microform and subepithelial lip defects. A conditional knockout of the mouse BMP4 gene results in a phenocopy of human microform/subepithelial lip defects. To pursue the role that BMP4 might play in human CL/P we sequenced BMP4 in individuals with subepithelial, microform and overt CL/P defects, plus controls, from several populations. We also assessed association with polymorphic SNP variants in and near BMP4 in a large collection of families from multiple countries in Asia, North America, South America, and Europe. Missense or nonsense mutations were identified in the BMP4 gene in 1 of 30 cases of microform clefts, 2 of 87 cases with subepithelial defects in the orbicularis oris muscle, and in 5 of 968 cases of overt CL/P. No amino acid sequence variants were seen in 529 controls. Differences between case and control groups were assessed with standard chi square tests including Yates corrections applied due to small cell sizes. The frequency for microform plus OO cases was significantly greater than for controls ($p=0.003$). Further, the BMP4 mutation frequency in overt CL/P cases was significantly less than the rate in microform plus OO cases ($p=0.01$).This study supports the role of BMP4 in nonsyndromic CL/P, with mutations in BMP4 associated with microforms and OO, and polymorphic variants increasing the susceptibility to overt CL/P.

The ordered penetrance test for detecting single-locus association and gene-gene interaction. *M. Song[1], D.L. Nicolae[2]* 1) Department of Statistics, The University of Chicago, Chicago, IL, USA; 2) Department of Medicine and Statistics, The University of Chicago, IL, USA.

In genome-wide studies that search for loci affecting complex traits, two stage strategies, where the analyses in the second stage are done only on markers associated in the first stage have become a common choice for researchers. In this talk, we propose methods for detecting association and interaction in a 2-stage strategy which is shown to be more powerful than the classic approaches. Our method makes use of the fact that many traits are monotone in penetrance and mean and incorporating this knowledge can dramatically increase power. For qualitative traits, we develop likelihood ratio tests for both association and interaction where the asymptotic distributions for both cases are shown to be Chi-bar-squared (i.e. weighted sums of chi-squared distributions). Our simulation studies for various models show that the ordered penetrance tests are more powerful compared to other popular tests especially at genome-wide scale. For quantitative traits, analogous tests based on ordered means are proposed and asymptotic results are obtained. We will also show an important extension of our method to testing untyped variation.

Dosage-sensitive genome instability: A comprehensive genetic screen in *Saccharomyces cerevisiae* to identify heterozygous mutations that impact chromosome stability. *S.E. Plon[1], E.D. Strome[2], X. Wu[3], M. Kimmel[3]* 1) Dept Pediatrics, Baylor Col Medicine, Houston, TX; 2) Molecular and Cellular Biology Graduate Program, Baylor Col Medicine, Houston, TX; 3) Dept Statistics, Rice University, Houston, TX.

Aneuploidy is a common feature of human cancers and many of the genes whose disruption results in aneuploidy were first identified in budding yeast based on the phenotypes of haploid strains containing null mutations. In contrast, increased cancer susceptibility is often seen in heterozygous mutation carriers. To directly identify dosage sensitive genes that mediate genomic stability, we performed a comprehensive genome-wide screen in *Saccharomyces cerevisiae* for heterozygous mutations which increase chromosome instability in a checkpoint-deficient background. We used two assays for spontaneous events sensitive enough to detect the impact of heterozygous mutations: (1) increased sectoring of colonies based on loss of a chromosome fragment (CF) and (2) quantitative assessment via fluctuation analysis of loss or recombination of an endogenous chromosome. Of the 30,000 heterozygous strains screened, 170 demonstrated CF loss. Of this group, 45% also conferred modest but statistically significant instability of endogenous chromosomes. Further analysis of heterozygous deletions of a subset of genes demonstrated that the majority increased chromosome instability in both checkpoint deficient and wild-type backgrounds. Strains heterozygous for the genes encoding the conserved COMA kinetochore complex were particularly unstable. Over 50% of the genes identified in this screen have human homologs and several have already been associated with cancer susceptibility including *CHEK2* and *TOPBP1*. Given their potential impact on spontaneous chromosome instability, the homologous gene list should be included in epidemiologic studies of cancer susceptibility and genetic modifiers of other known cancer loci. These results also support further analyses of heterozygous phenotypes in yeast as models of human disease resulting from haploinsufficiency.

***SUMO1* and primary palatogenesis in humans and mice.** *H. Mishima[1], M.A. Mansilla[1], M.K. Johnson[1], S.A. Bullard[1], T. Busch[1], L.M. Moreno[1], M. Arcos-Burgos[2], C. Valencia[3], A. Hing[4], E.J. Lammer[5], M. Jones[6], M.L. Marazita[7], J.C. Murray[1], A.C. Lidral[1]* 1) U. Iowa, IA; 2) NIH, MD; 3) U. Antioquia, Colombia; 4) Children's Hosp., Seattle, WA; 5) Children's Hosp., Oakland, CA; 6) Children's Hosp., San Diego, CA; 7) U. Pittsburgh, PA.

Purpose: *SUMO1* (2q33.1) is a gene involved in posttranslational modification of proteins. A recent report of a patient with cleft lip and palate with a balanced translocation breaking *SUMO1* has suggested that *SUMO1* has a causal role in CL/P. Inactivation of *Sumo1* in mice also supported a role in secondary palatogenesis. However its role in primary palatogenesis is still unclear. Human studies of *SUMO1* have not been reported. This characterized *Sumo1* expression during primary palatogenesis using mouse embryos. Human studies were performed to assess association between *SUMO1* and CL/P; and search for mutations in coding sequence of *SUMO1*. **Methods:** C57BL/6 mouse embryos were evaluated via in situ hybridization for *SUMO1* expression between embryonic days E9.5 and E12.5. Colombian (546), Filipino (372), and US (301) familial triads having probands affected with CL/P were genotyped for 3 SNPs nearby *SUMO1*. Statistical testing for association was performed using FBAT. *SUMO1* was also sequenced in 184 cases and 183 controls. **Results:** At E9.5, no specific signal was detected. At E10.5, the nasal processes had weak expression. At E11.5, *Sumo1* was expressed in the maxillary, medial nasal and lateral nasal processes as they are fusing. At E12.5, expression was not observed in the fused primary palate, whereas the nasal pits and primary choanae had moderate expression. Human studies revealed significant association only in the Colombian families with a SNP (rs13383137, p=0.0016). Sequencing of *SUMO1* revealed three novel noncording SNPs. **Conclusions:** *SUMO1* is expressed during the later stages of primary palatogenesis. Human studies reveal that *SUMO1* variants may contribute to CL/P. However, the discrepancy between study populations suggests genetic heterogeneity of CL/P at this locus. These data provide evidence that *SUMO1* is important for primary palatogenesis. **NIH grants:** R01-DE014667, K02-DE015291, R37-DE08559, P50-DE016215.

Copy number analysis of patients with gonadal dysfunction using high-density microarrays and MLPA. *S.J. White[1], S.E. Gustin[1], C.A. Smith[1], S. Forrest[2], M. Bahlo[3], H. Bengtsson[3], K. Bell[1], T.P. Speed[3], A.H. Sinclair[1]* 1) Murdoch Children's Research Institute, Melbourne, Australia; 2) Australian Genome Research Facility, Melbourne, Australia; 3) Walter and Eliza Hall Institute, Melbourne, Australia.

Intersex disorders, ranging in severity from genital abnormalities to complete sex reversal, are surprisingly common and as such represent a major paediatric concern. The cause of these problems is most often the failure of the complex network of genes that regulate development of testes or ovaries. However, we understand relatively little of this regulatory network. Mutations in the critical testis-determining genes SRY and SOX9 account for approximately 20% of XY females with gonadal dysgenesis. We have little idea about what other genes may be involved to account for the remaining 80% of patients. In contrast, 90% of XX males with gonadal dysgenesis are due to Y translocations that include SRY. DNA from 15 sex-reversed patients with gonadal dysgenesis (XX males lacking SRY and XY females without mutations in SRY) has been collected. We have used the Affymetrix 500K SNP arrays to screen the genome of sex-reversed patients for copy number changes. In these 15 patients 26 deletions and duplications were detected that covered at least one gene. These and other candidate regions are currently being confirmed with MLPA, and de novo status is being checked in parental DNA. This powerful approach will identify new genes involved in sex determination.

A novel form of cerebellar ataxia with increased free sialic acid in cerebrospinal fluid. *F. Mochel[1,6], F. Sedel[2], U.F.H. Engelke[3], J. Barritault[4], E. Morava[5], M. Timmons[6], F. Seguin[4], A. Brice[1,7], R. Schiffmann[6], A. Durr[1,7], R.A. Wevers[3]* 1) INSERM U679, Hôpital La Salpêtrière; 2) Fédération des Maladies du Système Nerveux, Hôpital La Salpêtrière; 3) Laboratory of Pediatrics and Neurology, Radboud University Nijmegen Medical Center; 4) INSERM E324, Hôpital La Milêtrie, Poitiers, France; 5) Department of Pediatrics, Radboud University Nijmegen MC, Nijmegen, The Netherlands; 6) NINDS, NIH, Bethesda, USA; 7) Département de Génétique et Cytogénétique, Hôpital La Salpêtrière, Paris, France.

In vitro Nuclear Magnetic Resonance (NMR) spectroscopy has contributed to the identification of new inborn errors of metabolism. We used 1H-NMR spectroscopy to identify new metabolic markers in cerebrospinal fluid (CSF) and urine of a large cohort of patients with complex neurodegenerative disorders for which extensive metabolic and genetic work-up was negative. In 5 adult patients, including 2 sisters, 1D and 2D 1H-NMR analyses revealed a significant elevation of free sialic acid in the CSF, ranging from 37.5 to 62.0 mol/l. Normal free sialic acid in CSF, in 190 controls and patients with various neurodegenerative conditions, was 8.9 4.0 mol/l. Urine sialic acid excretion was normal and no mutation was found in the SLC17A5 and UDP-GlcNAc 2-epimerase genes, excluding the 2 known free sialic acid storage diseases. Other disorders associated with increased free sialic acid levels in CSF (pyogenic meningitis, brain tumors) were ruled out. The phenotype of all patients associated cerebellar ataxia, peripheral neuropathy and cognitive decline. Other features included myoclonic dystonia (1/5), deafness (2/5), pigmentary retinopathy (1/5), growth retardation (2/5) and glomerulosclerosis (1/5). On cerebral MRI, periventricular (3/5) and cerebellar (4/5) white matter was abnormal, with variable cerebellar atrophy (5/5). Bilateral hyperintensities of the basal ganglia (2/5) and the brainstem (3/5) were also observed. Despite clinical and radiological heterogeneity, even manifest in the 2 affected sisters, our NMR findings are consistent with a new sialic acid storage disease for which cerebellar ataxia is the leading symptom.

Identifying candidate markers for follow-up studies to genome-wide association: beyond nonsynonymous SNPs.
M.A. Levenstien, R.J. Klein Cancer Biology and Genetics, Memorial Sloan-Kettering Cancer Center, New York, NY.

With the advent of cost-effective genotyping technologies, genome-wide association studies allow researchers to examine hundreds of thousands of single nucleotide polymorphisms (SNPs) for association with human disease. Recently, many researchers applying this strategy have detected strong associations to disease with SNP markers that are either not in linkage disequilibrium with any non-synonymous SNP or large distances from any annotated gene. In such cases, no well-established standard practice for effective SNP selection for follow-up studies exists. We aim to identify and prioritize groups of SNPs that are more likely to affect phenotypes in order to facilitate efficient SNP selection for follow-up studies. Based on the annotations available in the Ensembl database, we categorize SNPs in the human genome into functional classes including promoter regions, splice sites, and coding regions. Using SNP density and the distribution of derived allele frequencies within each class, we assess the relative strength of natural selection for each class. Within the HapMap ENCODE regions, we find that the SNP density for all three classes is significantly less than that for the genome as a whole. Interestingly, each functional classs distribution of its member SNPs derived allele frequencies in these regions generally did not differ significantly from that of the genome. It will be important to explore additional classes such as regions which are highly conserved among related species for evidence of selective pressure.

Comparative sequence analysis of primate subtelomeres. *K. Rudd[1], R. Endicott[1], C. Friedman[1], M. Walker[1], J. Young[1], K. Osoegawa[2], R. Blakesley[3], P. de Jong[2], E.D. Green[3], B. Trask[1]* 1) Fred Hutchinson Cancer Res Ctr, Seattle, WA; 2) Children's Hospital of Oakland Res Inst, Oakland, CA; 3) NHGRI, NIH, Bethesda, MD.

Subtelomeric regions are among the most structurally complex, variable, and dynamic areas of the genome. Subtelomeres are the transition zones between chromosome-specific sequences and the arrays of telomere repeats at the end of chromosomes. The identity, arrangement, and polymorphism of the blocks of subtelomeric sequence shared among multiple chromosomes suggest that subtelomeric duplications spread recently. We traced the evolutionary history of the chromosome-15 subtelomere in the genomes of human, chimpanzee, gorilla, orangutan and macaque using FISH, PCR, and sequencing of genomic clones. The ancestral locus lies internally on macaque chromosome 7; however, a chromosome fission event gave rise to two acrocentric chromosomes in the common ancestor of the great apes. Sequence originating at this fission site now resides at the terminus of 15q and the pericentromere of 14q in great apes. Subsequent exchanges have added and removed subtelomeric material on chromosome 15q, as well as transferred large subtelomeric regions to other chromosomes. At least 250 kb from the fission site region transferred to the end of chromosome 4 in the ancestor of chimpanzee and gorilla. This hybrid subtelomere contains sequences orthologous to the human 4q and 15q. Interestingly, the proximal 4q-like subtelomeric region is associated with facioscapulohumeral muscular dystrophy in humans. Eight olfactory receptor (OR) genes encompassing 125 kb have been lost from the end of the 15q subtelomere in the human and chimpanzee genomes. A terminal subtelomeric region containing a highly conserved gene has been affixed to the 15q subtelomere in the human lineage only. The orangutan chromosome 15 subtelomere is very similar to the ancestral locus, and the gorilla 15q subtelomere has lost a subset of ORs. Our detailed analysis of the chromosome 15 subtelomere has shown significant structural changes in each lineage, demonstrating that subtelomeres are one of the most rapidly evolving regions of the genome.

Study of the MAGE Family in Carcinogenesis and Clinical Application of Human Colorectal Cancer. *M.J. Yang[1], J.Y. Wang[2,3], S.R. Lin[4,5]* 1) Graduate Institute of Medicine; 2) Department of Surgery, Kaohsiung Medical University Hospital; 3) Faculty of Medicine, College of Medicine; 4) Graduate Institute of Medical Genetics, College of Medicine; 5) BioMedi Innovation Incubation Center, Kaohsiung Medical University, Kaohsiung, Taiwan.

Purpose: Melanoma antigens (MAGE) are a group of tumor antigens that have tissue specific expression. In our previous study, we have found several genes of the MAGE family potentially applicable for early diagnosis, post-surgery track and prognosis evaluation of the lung cancer. In this study, we plan to analyze the mRNA expression of MAGE family and its correlation with clinicalpathological features in colorectal cancer (CRC) patients. Furthermore, we purpose to find new molecular markers for the clinical applicability in MAGE Family and explore the molecular mechanism in the carcinogenesis of CRC. Materials and Methods: We collected 97 colorectal cancer tumor tissues and their tumor-free colon tissues. Following, we used membrane array method to compare the mRNA expression profile of the MAGE family genes between colorectal cancer tissue and normal tissue. In addition, we used immunohistochemical stain to investigate the protein expression of the MAGE family and its localization. Finally, we compared the clinicalpathological features with the MAGE family genes. Results: We found 9 genes overexpressed in CRC and are shown as follows, MAGE-A2, 84.8%; -A5, 63.6%; -A8, 78.8%; -A9, 69.7%; -A12, 72.7%; -B2, 63.6%; -B3, 69.7%; -B4, 66.7%; -F1, 87.9%. After comparing the clinicopathological features with the expression of MAGE genes, we found all CRC patients express at least one of the MAGE genes except MAGE-D4. Interestingly, MAGE-D4 do not express in tumor tissue nor in normal tissue. We also found MAGE-B10 expressed in late-stage CRC(III & IV stage)(p=0.045), MAGE-C3 expressed when tumor size is below 5 cm(p=0.027). Meanwhile, MAGE-A10 had a contrary performance to MAGE-C3. Conclusion: This result suggested that MAGE-A2 and MAGE-F1 were highly-expressed and may serve as novel tumor markers in CRC. MAGE-B10 and MAGE-C3 may associate with carcinogenesis and cell proliferation but its mechanism still needs further analysis.

Development of a diagnostic gene chip for detection of Mycobacterium tuberculosis. *C.S. Sun[1], S.R. Lin[2], C.C. Chen[1], I.W. Chong[1,3]* 1) Graduate Institute of Medicine; 2) Graduate Institute of Medical Genetics; 3) Department of Internal Medicine, Kaohsiung Medical University Hospital, Kaohsiung, Taiwan.

Background and purpose: Tuberculosis (TB) is an old-age, widespread disease which is one of the major causes of death throughout the world. Therefore, it is a critical issue to alleviate the growing worldwide TB epidemic. Recent biotechnological advances have fuelled a revolution in the diagnosis of infectious disease but is still limited that each genetic marker must be detected separately. Thus, our goal is to develop a sensitive, time-saving, and high-throughput active TB chip for detection of Mycobacterium tuberculosis. Materials and Methods: Total of 48 sputum samples were collected from Kaohsiung Medical University Hospital. We have applied L-J medium culturing and auramine-rhodamine staining in primary sputum smears. In order to characterize each of the isolates, we applied PCR and RFLP to identify each of its genotypes. Furthermore, the PCR amplicons were sequenced and confirmed by the BLAST analysis that the amplified products represent the specific region of interest. The diagnostic value of the candidate genes of active TB chip was evaluated with 30 M. tuberculosis DNA samples by membrane array method. Results: All of the 48 isolates were L-J medium culture-positive and acid-fast stain positive. We further analyzed the distribution of each genotype of the isolates in Taiwan by PCR-RFLP. As a result, 52.1%(n=25)have been identified as M. tuberculsosis, 22.91%(n=11)have been identified as NTM and 22%(n=12)did not belongs to Mycobacterium species. In this study, we selected 11 candidate genes for active TB chip and constructed the prototype of the chip. Overall, the sensitivity of the active TB chip was 80% and the specificity was 85%. Conclusion: With the establishment of the active TB chip, it can speed up the whole process of diagnosing tuberculosis patients and differentiate the various species of Mycobacterium tuberculosis complex. Hence, we suppose the active TB chip may have a great potential for clinical applications.

Development of a SNP Chip for genotyping of multiple single nucleotide polymorphisms simultaneously. *Y.H. Yang[1], T.L. Cheng[2,3], S.R. Lin[1,4], M.C. Hsieh[1,5]* 1) Graduate Institute of Medical , Kaohsiung Medical University, Kaohsiung, Taiwan; 2) Faculty of Biomedical Science and Environmental Biology, Kaohsiung Medical University, Kaohsiung, Taiwan; 3) National Sun Yat-sen University-Kaohsiung Medical university joint research center, Kaohsiung, Taiwan; 4) BioMedi Innovation Incubation Center, Kaohsiung Medical University, Kaohsiung, Taiwan; 5) Division of Endocrinology and Metabolism, Department of Internal Medicine, Kaohsiung Medical University Hospital, Kaohsiung, Taiwan.

Background and purpose: Recently, the relation between SNPs and diseases susceptibility are extensively studied. By multiple SNPs genotyping, people can know their susceptibility to certain disease. Development of a SNP Chip that is convenient, inexpensive, and fast for multiple SNPs genotyping is necessary. Methods: Four oligonucleotide probes are designed for each SNP. Two of them are SNP specific oligonucleotides, and the other two are the quality controls which contain only a point mutation. Those oligonucleotides were individually blotting on nylon membrane to form the SNP chip. Target SNP-containing regions of AGT (angiotensinogen), CETP (cholesteryl ester transfer protein), and APOE (apolipoprotein E) were amplified by multiple PCR. The multiple PCR productions were labeled with DIG-UTP. The DIG-labeled PCR products would hybridize with the SNP chip, following by Anti-DIG-AP (alkaline phosphatase) binding and color development by NBT/BCIP. The SNP genotypes are decided acording to the color expression on SNP Chip. Results: The genotypes of AGT, CETP and APOE analyzed by SNP Chip are highly consistent of direct sequencing. The accuracy of SNP Chip is more than 99 %. Conclusions: We have successfully established a SNP screening chip which is convenient, inexpensive, and high-throughput. This SNP chips can be used to screen patients for risk of disease and predict the onset and prognosis of disease.

Mutations in the Walker-Warburg Syndrome genes *POMT1, POMT2, FKRP* and *fukutin* are differentially distributed in populations of Middle Eastern and European descent. *M.C. Manzini[1], D. Gleason[2], B.S. Chang[1], R.S. Hill[1], A. Bodell[1], K. Apse[1], A. Poduri[3], S. Currier[1], W.B. Dobyns[4], M.A. Salih[5], M.Z. Seidahmed[5], P. Galvin-Parton[6], L.R. Shapiro[7], K. Schmidt[8], J.G. Davis[9], C.A. Walsh[1, 2]* 1) Neurology and HHMI, BIDMC, Harvard Medical School, Boston, MA; 2) Genetics, Childrens Hospital, Boston, MA; 3) Neurology, Childrens Hospital, Boston, MA; 4) Human Genetics, Neurology and Pediatrics, University of Chicago, Chicago, IL; 5) Pediatric Neurology, King Kahlid University Hospital, King Saud University, Riyadh, Saudi Arabia; 6) Pediatrics, Stony Brook University Medical Center, Stony Brook, NY; 7) Pediatrics, Westchester Medical Center, Valhalla, NY; 8) Genetics, Childrens Hospital of Pittsburgh, Pittsburgh, PA; 9) Pediatrics, Weill Cornell Medical College, New York, NY.

Walker-Warburg syndrome (WWS [MIM 236670]) is an autosomal recessive disorder characterized by type II (cobblestone) lissencephaly, hydrocephalus, severe cerebellar and ocular malformations, and congenital muscular dystrophy (CMD). WWS is the most severe form of CMD, leading to significant developmental delay and life expectancy of less than 3 years. While WWS presents with a relatively homogeneous phenotype, it is genetically heterogeneous and mutations have been identified in several glycotransferases that modify -dystroglycan. We analyzed a cohort of patients of diverse ethnic origin with classic WWS (41 patients from 38 families) and sequenced WWS genes (*POMT1*, *POMT2*) and genes that are more rarely mutated in this disease, such as *fukutin* and fukutin related protein (*FKRP*). A striking difference was observed in the geographic distribution of mutations. Middle Eastern families most commonly carried *POMT1* mutations, while a diverse range of mutations in *POMT1*, *POMT2*, *fukutin* and *FKRP* was found in the European and American cases. Moreover, in contrast to previous data suggesting that only 10-20% of WWS cases can be explained by mutations in these genes, we found that 39.5% of patients in our cohort carried *POMT1*, *POMT2*, *FKRP* or *fukutin* mutations.

High-Density Association Analysis of the CETP Locus and HDL-C in Families of African Ancestry. *I. Miljkovic-Gacic[1], X. Wang[2], C. Kammerer[2], C. Nestlerode[1], L. Yerges[1], A. Kuipers[1], L. Goodrich[1], L. Kuller[1], C. Bunker[1], A. Patrick[3], V. Wheeler[3], R. Evans[1], J. Zmuda[1]* 1) Department of Epidemiology, University of Pittsburgh , Pittsburgh, PA; 2) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA; 3) The Tobago Health Studies Office, Scarborough, Tobago.

Decreased HDL cholesterol is a major risk factor for cardiovascular disease. A recent genome-wide association analysis identified a single nucleotide polymorphism (SNP) near cholesteryl ester transfer protein (CETP) gene as the most promising locus for HDL-C in Caucasians, but the role of genetic variation in CETP as a determinant of HDL levels in African populations is still unclear. We assessed the heritability of fasting HDL-C and its association with 19 tagging and 2 SNPs from the literature across a 32 kilobase region encompassing CETP among 402 Afro-Caribbeans (mean age=42yrs) from 7 multigenerational families (median family size 51 individuals; 3535 relative pairs). Residual heritability for HDL-C after adjusting for age, sex, BMI, current smoking, alcohol intake, and physical activity was 0.550.11 ($P<0.001$). Residual heritability of HDL-C was higher in men (0.580.18, $p<0.001$) than in women (0.360.15, $p=0.002$), although this difference did not achieve statistical significance. After adjusting for significant covariates, individuals homozygous for the rs9926440 minor G allele (frequency,0.28) and for the rs289717 minor A allele (frequency,0.12) had 17.2% and 17.7% lower HDL-C, respectively, whereas individuals homozygous for the rs708272 minor A allele (frequency,0.26) had 13.5% higher HDL-C compared to the individuals homozygous for the major allele ($P<0.01$).The pairwise correlation coefficient (r2) among the 3 SNPs ranged 0.01-0.24, suggesting independent effects. Genotypes for rs9926440, rs289717 and rs708272 accounted for 3%, 1.4% and 1.1% of the total phenotypic variability in HDL-C, respectively. Our findings support the hypothesis that genetic factors are a major determinant of HDL levels among individuals of African origin, especially in men, and also suggest an association of the CETP locus with HDL-C in this population.

Population structure of human linkage disequilibrium patterns. *D.J. Witherspoon, J. Xing, W.S. Watkins, Y. Zhang, W. Tolpinrud, L.B. Jorde* Human Genetics, University of Utah, Salt Lake City, UT.

Patterns of linkage disequilibrium (LD) vary between human populations due to their different demographic histories. As a result, SNPs chosen for their utility in one population may prove less useful in another population. The degree to which different populations share a common LD structure must be understood in order to perform genome-wide association studies in different populations. We examined patterns of linkage disequilibrium in 19 independent 100-kb regions of the genome in 20 populations (334 individuals) from Europe, East Asia, and sub-Saharan Africa, including several African Pygmy populations. As expected, LD is lowest in the sub-Saharan group, where the average r2 between markers is 2/3 of that observed in the group with the highest LD (East Asians.) By comparing measures of LD obtained using our samples with those derived from the HapMap samples, we are able to determine how well they generalize to independent samples from the same or different populations. Estimates of LD patterns are quite similar for samples drawn from the same populations: r2 estimates for the same marker pairs in different samples from the same continents (i.e., our African samples vs. HapMap Yoruban YRI, our Asian samples vs. HapMap Japanese and Chinese JPT/CHB, and our European samples vs. HapMap CEPH CEU) show product-moment correlations exceeding 95%. These correlations decrease significantly for comparisons between continental populations. The correlation between r2 estimates for the same marker pairs in Pgymy vs. Asian or European populations is ~75%. That correlation rises to >90% between the YRI HapMap population sample and our Pygmy sample. These results suggest that the HapMap information will generalize well to most human populations, including even genetically distinct Pygmy populations. Supported by NIH Grant GM-59290 and NSF Grant BCS-0218370.

Identifying which young women affected with breast cancer are at high risk of carrying a germline mutation in *BRCA1*. *M. Southey[1], S. Ramus[2], J. Dowty[3], G. Dite[3], G. Byrnes[3], G. Giles[4], M. McCredie[5], J. Hopper[3]* 1) Department of Pathology, University of Melbourne, Australia; 2) Translational Research Laboratory, Institute for Womens Health, University College London, UK; 3) Centre for Molecular, Environmental, Genetic and Analytic Epidemiology, The University of Melbourne, Australia,; 4) The Cancer Council Victoria, Australia; 5) The University of Otago, Dunedin, New Zealand.

Only a small proportion of women diagnosed with breast cancer at a young age carry germline mutations in *BRCA1*. In our population-based study of breast cancer diagnosed before the age of 40 years in Australian women we have estimated that only 3.8% (95% CI 0.3-12.6%) of cases is attributable to mutations in *BRCA1* and that family cancer history alone is not a strong predictor of carrier status. In a subset of 66 women with a strong family history (2 or more affected first- or second-degree relatives affected with breast or ovarian cancer) only 10 (15%) carry germline *BRCA1* mutations.

We sought to devise a practical strategy for identifying women at high risk of carrying a germline mutation in *BRCA1* that could be applied at the time of diagnosis, irrespective of family history, using morphological and immunohistochemical data that are routinely collected at diagnosis. Tumours arising in women participating in our population-based study were systematically reviewed and scored for morphology features and ER and PR status was collected for each cancer.

Using a simple morphology based scoring system we identified the *BRCA1* mutation carriers amongst 500 early-onset breast cancer cases and also in the subset of women with a strong family history. Sensitivity was 90% and 100% respectively and specificity was 33% and 63%. In addition we used logistic regression on the same dataset and identified a model with 3 key covariates that predicts *BRCA1* mutation carrier status with a high degree of reliability (area under the ROC curve of 0.93). These approaches offer a simple, cost-effective and practical way of identifying young women affected with breast cancer at high risk of carrying a *BRCA1* germline mutation.

Identification of microRNAs involved in hematopoietic stem cell differentiation. *G.A. Molfetta[1,3], D.L. Zanette[2,3], D.G. Pinheiro[1,3], M.A. Zago[2,3], W.A. Silva-Jr[1,3]* 1) Dept of Genetics, School of Medicine from Ribeirao Preto-USP, Brazil; 2) Dept of Clinical Medicine, School of Medicine from Ribeirao Preto-USP, Brazil; 3) Center for Cell-Based-Therapy/CEPID/FAPESP, Brazil.

miRNAs are a class of small endogenous non-coding RNAs that recognize target sequences of imperfect complementarity in cognate mRNAs and either destabilize them or inhibit translation. Emerging evidences show that miRNAs play important role in stem cell self-renewal and differentiation. We sought to identify miRNAs that regulate the early stage of hematopoietic stem cell differentiation. CD34+ cells were purified from bone marrow and differentiated into myeloid and erythroid lineages; we have extracted RNA after 12h and 40h of culture. Analysis of gene expression was carried out by SAGE using I-SAGE Kit and to access a miRNA profile we used TaqMan MicroRNA Assays Human Panel. Fold-change was calculated using 2^{-Ct} method where undifferentiated CD34+ cells were used as calibrator. A higher set of expressed miRNAs was found in myeloid 40h and in erythroid 12h. The two most highly expressed miRNAs in both myeloid and erythroid samples were miR-124a and miR-15b. In myeloid sample both miRNAs were expressed only at 40h while erythroid sample showed higher expression of miR-15b at 12h and miR-124a at 40h. We also looked for predicted miRNA target genes in our SAGE libraries and correlated miRNA expression with the expression of its target genes. For myeloid sample, the majority of miRNA target genes are transcription factors. We selected TFDP2 as a target for myeloid lineage; DP2 function as binding partner for E2F transcription factor regulating its activity. E2F inhibits the NFkB survival signal suggesting NFkB role in myeloid differentiation. We selected EVI1 as a target for erythroid lineage. EVI1 has important role in leukemogenesis and megakaryocytic differentiation. This gene is downregulated by its miRNA in erythroid sample raising the hypothesis of miRNAs blocking myeloid commitment and activating erythroid commitment. We describe that the same miRNA is required for modulation of different target genes depending on the differentiation pathway taken by the cell. Financial Support: FAPESP.

Copy number variations and gene expression in the mouse. *A. Reymond[1], C. Henrichsen[1], N. Vinckenbosch[1], E. Chaignat[1], S. Zoellner[2], H. Kaessmann[1]* 1) Center for Integrative Genomics, University of Lausanne, Lausanne, Switzerland; 2) Department of Biostatistics, University of Michigan, Ann Arbor, Michigan.

Copy number variations (CNVs), defined as large stretches of DNA that vary in number of copies among phenotypically normal individuals, have recently gained considerable interest as a possible source of phenotypic variation. Previous studies using BAC arrays to identify CNVs have produced datasets that only partially overlap, suggesting that copy number variation vastly remains uncatalogued To obtain a finer resolution, we used whole-genome oligonucleotide array comparative genome hybridization (CGH), with a median probe spacing of 6 kb, to identify CNVs in 13 inbred mouse strains and in 21 wild mice caught throughout the European, Middle-Eastern and Northern African range of Mus musculus domesticus subspecies. Using a hidden Markov model, we identified some 700 CNV candidate regions, which we subsequently validated using a custom-made array with probe density increased to one every 550 bp, thus multiplying by more than eight-fold the number of copy-number variable regions reported in the mouse genome. We identified functional categories of genes that were enriched within CNVs using the Gene Ontology (GO) database. Significantly enriched GO categories include host defense and immunity, as well as neurotransmission. To address whether CNVs affect gene expression, we assessed the expression levels of 45037 transcript units in liver, kidney, brain, heart, lung and testis of three individuals for each of six commonly used laboratory inbred mouse strains. We found that the variance of the expression levels for each of the recorded tissues is significantly larger for genes mapping inside than for genes mapping outside of CNVs, suggesting that copy number variation affects the variability of gene expression and must be taken into account when considering phenotypic differences between strains. A more detailed analysis of the effect of CNVs on gene expression will be presented.

Loss of function of the *ACTN3* gene alters muscle metabolism and has been selectively favored during recent human evolution. *D.G. MacArthur[1], J.M. Raftery[1], G.A. Huttley[2], J.T. Seto[1], K.G.R. Quinlan[1], S. Easteal[2], N. Yang[1], K.N. North[1]* 1) Institute for Neuromuscular Research, Childrens Hospital at Westmead, Westmead, NSW, Australia; 2) John Curtin School of Medical Research, The Australian National University, Canberra, ACT, Australia.

The protein -actinin-3, encoded by the *ACTN3* gene, is a highly conserved component of fast muscle fibres. Remarkably, a nonsense variant in the human *ACTN3* gene (R577X) results in complete deficiency of -actinin-3 in ~16% of the global human population. This variant is rare in Africans but approaches a frequency of 50% in Eurasian groups. We have previously shown that R577X is associated with human performance, with the XX null genotype being under-represented among elite sprint athletes, over-represented among elite endurance athletes, and associated with poorer muscle strength and sprint performance in non-athlete cohorts.

Given the effects of the 577X allele on muscle function and its high frequency in non-Africans we investigated whether this allele has been subject to natural selection in European and East Asian populations. Sequencing revealed low haplotypic diversity specifically associated with the 577X allele in both populations. In addition, analysis of HapMap data revealed a region of complete homozygosity associated with the 577X allele spanning more than 350 kb in Europeans, further than that associated with any of 17,000 frequency-matched control SNPs. The presence of low diversity and extended homozygosity associated with the 577X allele suggests that this allele reached its high frequency in a recent, rapid expansion, almost certainly driven by natural selection.

To characterise the mechanisms by which R577X affects muscle function we have generated a knockout mouse model of -actinin-3 deficiency. Knockout mice have reduced grip strength and increased endurance capacity, consistent with the phenotype of 577XX humans. The muscle of knockout mice displays a marked metabolic shift towards the more efficient oxidative pathway. We propose that the effects of -actinin-3 deficiency on muscle metabolism underlie recent positive selection on the 577X allele in humans.

Molecular determination of mutations in the *GLA* gene in Mexican patients with Fabry's disease. *B.A. Rodriguez-Espino[1], D. Olvera-Castillo[2], J. Morales[3], J. Granados-Arriola[4], A.E. Cataneo-Davila[2], R. Correa-Roter[2], M. Ramos-Kuri[1]* 1) Molecular Biology, Medical School, Universidad Panamericana, Mexico City, Mexico; 2) Nephrology and Mineral Metabolism; 3) Genetic; 4) Immunology and Rheumatology, Instituto Nacional de Ciencias Médicas y Nutrición Salvador Zubiran. Mexico City, Mexico.

Introduction. The Fabry disease is a recessive metabolic illness, caused by mutations in the *GLA* gene (locus Xq22.1), that codifies for the lysosomic enzyme -galactosidase A (-GAL). The affected individuals show incapacity for catabolizing lipids with -galactosyl terminal residues, which are accumulated gradually in the vascular endothelium and the visceral tissues of the body. There are more than 400 known mutations for Fabry disease, but in most cases they are unique for each family and there are not registers in Mexican population. **Objective**. To determine the type of mutations in the *GLA* gene in three positive Mexican index cases for Fabry disease. **Methods**. Genomic DNA was isolated from male patients and a control group of healthy and ethnically related individuals. All the seven exons of the *GLA* gene were amplified by means of PCR using specific oligonuclotides. The amplified products were sequenced and compared against international data bases. **Results**. In one patient the loss of an A in position 260 of the codifying DNA was detected (*c*.260delA), this produces a framework shift in the polypeptide translation. In the second patient, the change of a G by C in the 243 codon replaces the amino acid L by F (*p*.L243F). In the third patient there were not mutations. **Conclusions**. It is the first molecular study of the *GLA* gene in Mexican population, in which a new mutation is reported (*c*.260delA). These studies altogether with the enzymatic analyses, would allow to improve the early detection, to define the status of carrier in asymptomatic individuals, to select probable familiar kidney donors, and to identify the molecular variables of the disease in Mexico.

AAV based site-specific integration mediated gene therapy in the hereditary tyrosinemia type I (HT1) mouse model. *Z. Wang[1], T. Storm[2], M. Finegold[3], M. kay[2], M. Grompe[1]* 1) Oregon Stem Cell Center, Oregon Health & Science University, Portland, OR; 2) Department of Pediatrics and Genetics, Stanford University, Stanford, CA; 3) Texas Children's Hospital, Houston, TX.

Recombinant adeno-associated virus (AAV) vectors are mostly episomal and rarely integrate into the host genome. Integration occurs randomly throughout the genome. For therapy of genetic diseases, an integrating vector with site-specificity would be ideal. An AAV vector in which a human fumarylacetoacetate hydrolase (Fah) expression cassette is flanked by ~ 1 kb of homology to rDNA in the region of the I-Ppo site was generated. We tested the hypothesis that an AAV genome can be targeted to this location by homologous recombination. **RESULTS**: Adult $Fah^{-/-}$ mice injected with a dose of $3x10^{11}$ particles (high dose) gained weight after NTBC withdrawal while control mice died after 4-6 weeks. 10^9 AAV (low dose) rescued $Fah^{-/-}$ mice after initial weight loss, followed by weight gain. The hepatocytes of weight-stabilized mice were serially transplanted into secondary $Fah^{-/-}$ recipients. All recipients displayed weight gain after transplantation indicating stably integrated Fah expression cassette. DNA from completely repopulated animals was analyzed by Southern blot. Junction fragment analysis indicated that about 50% of integration events were site-specific in the rDNA locus in AAV8 injected mice and less in AAV2 mice. Considering the polymorphysisms in the rDNA repeats, majority of the integration events could be site-specific integration. The sequence results of the junction fragment generated by site-specific PCR exactly match the predicted junction sequence. The similar results were obtained in neonatal mice. Next, coinjection of AAV with Adeno-IPpoI show that no clear enhancement of the already high percentage of site-specific integration was seen. Dose dependent comparison study between AAV2-rDNA-Fah and AAV2-Fah showed that AAV2-rDNA-Fah can rescue the Fah-/- mice with about 1/30-1/10 dose of AAV2-Fah. Thereby, AAV-rDNA is superior to the regular AAV vector with high percentage site-specific integration and with low rescue dose, providing a new, clinical oriented strategy for genetic disease therapy.

Evaluation of cytogenetic markers in peripheral blood lymphocytes of asbestos exposed workers. *S. Yadav[1], A.B. Pant[1], M. Yunus[2], Q. Rahman[1]* 1) Industrial Toxicology Research Centre, M.G. Marg, Lucknow 226 001, India; 2) Babasaheb Bhimrao Ambedkar University, Rae Bareli Road.

Asbestos is an established genotoxicant known to give rise to DNA damage and chromosomal aberrations but the exact mechanisms for the genotoxicity are still unknown. The aim of this study was to investigate the genotoxic risk to workers occupationally exposed to asbestos in milling and grinding area (unorganized unit of Beawar and Deogarh, Rajsthan, India). We studied cytogenetic biomarkers associated with asbestos exposure. During the study micronucleus (MN) formation and chromosomal aberrations (CA) in 63 male workers were analyzed. Fluorescent in situ hybridization (FISH) was also carried out to see clastogenic and aneugenic nature of asbestos induced damage. Confounding factor such as smoking found to modulate genetic damages with asbestos exposure. Therefore, to determine whether cigarette smoke has any modulatory effect on toxicity of asbestos exposure, we divided our study in two categories, exposed smokers and exposed non-smokers. The results were compared with a control group of 16 healthy male individuals without exposure to any known genotoxic agents. In result the mean frequencies of MN and CA were significantly higher in workers (in both groups- exposed smokers and exposed non smokers) than in the control group. In addition, prominent clastogenic nature of the genetic damage was reported. The data obtained from this study clearly showed cytogenetic damages in the lymphocytes of asbestos exposed workers and also reported synergistic effect of cigarette smoke. This genetic damage might be attributed to the cumulative effects of several substances due to chemical complexity of the asbestos and cigarette smokes that contains several genotoxicants. Study suggested that smoking makes genetic material/ apparatus of the cells more vulnerable to the deleterious effects of asbestos in exposed population.

Colobomatous microphthalmia and a cyst associated with a nonsense *NF2* gene mutation. *T. Mononen[1], K. Kaarniranta[2], K. Tuppurainen[2]* 1) Dept Clinical Genetics, Kuopio Univ Hosp, Kuopio, Finland; 2) Dept Ophthalmology, Kuopio Univ Hosp, Kuopio, Finland.

Neurofibromatosis type 2 (NF2)-specific ocular findings include cataracts, epiretinal membranes, optic nerve sheath meningiomas, disc gliomas, and hamartomas. We report a rare association of optic disc coloboma, microphthalmia, and a retrobulbar cyst in an infant with NF2.

A male infant was born at 38 weeks gestation to a 31-year-old gravida 1 para 0 mother and a 35-year-old father after an uneventful pregnancy. Microphthalmia and strabismus of the left eye were observed at birth. Ophthalmologic evaluation revealed posterior lens opacities and optic disc coloboma in the microphthalmic left eye which appeared blind. There was a small, anomalous optic disc in the right eye and the visual acuity was decreased, 0.07 on Teller's line test. Magnetic resonance imaging revealed a microphthalmic left eye with optic disc coloboma and a retrobulbar cyst. In addition, a small schwannoma of the left vestibular nerve was observed. No hearing impairment was detected. The karyotype was normal male 46,XY. The molecular genetic testing of the *NF2* gene in leukocyte DNA revealed a nonsense mutation c.169CT (p.Arg57X) confirming the diagnosis of NF2. The same mutation was not detected in the parents' blood samples and there was no family history of NF2.

The ocular abnormalities in this patient indicate that altered *NF2* gene dosage may cause developmental anomalies of the optic disc ranging from hypoplasia to coloboma, associated with microphthalmia and a cyst.

Phenotypic analysis of the *Crtap-/-* mice: the first animal model for recessive osteogenesis imperfecta. *R. Morello[1], J. Lennington[2], S. Kakuru[1], M. Jiang[1,4], Y. Chen[1,4], D. Keene[3], B. Lee[1,4]* 1) Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX; 2) Texas Children's Hospital, Baylor College of Medicine, Houston, TX; 3) Shriners Hospital for Children, Portland, OR; 4) Howard Hughes Medical Institute, Houston, TX.

We recently described the skeletal phenotype of the *Crtap-/-* mice consisting in a severe osteochondrodysplasia, with low bone mass, kyphosis and shortening of the long bones. Crtap interacts with prolyl 3-hydroxylase 1 (P3h1) and is essential for proper type I and II collagens post-translational modification. The phenotype of *Crtap-/-* mice closely resembles that of OI patients and mutations in the *CRTAP* gene cause recessive osteogenesis imperfecta (OI). Here we further the phenotypic analysis of our mutant mice to obtain a better understanding of the Crtap role during development and adulthood. Adult *Crtap* null mice showed marked craniofacial abnormalities, consisting in shortening and compression of the anterior portion of the cranium, and increased skin laxity compared to WT littermates as revealed by a decreased thickness of the dermis accompanied by a decreased matrix density with collagen fibrils of increased diameter, as seen in Ehlers Danlos syndrome. Histological analyses of organs showed abnormal lung morphology, with alveolar dilatation associated with thinning of the alveolar walls, a feature seen in Marfan syndrome. Moreover, the kidney glomerular basement membrane appeared to have an expanded lamina lucida and reduction of the lamina densa with mesangial proliferation. These data suggest CRTAP may exert more widespread effects on collagen homeostasis including types V in skin and type IV in kidney. The lung phenotype raises the question of whether this unique post-translational modification may also effect TGFb signaling. Finally characterization of the cartilage dysplasia in the *Crtap-/-* mice identified an increase in chondrocyte proliferation in the zeugopod growth plates of E15.5 *Crtap* null mice compared to controls, though this was not noted in the stylopod. These studies point to the requirement for 3-prolyl-hydroxylation in the widespread regulation of collagen structural and signaling function.

Comprehensive analysis of aberrantly spliced exons in myotonic dystrophy type 1 using Affymetrix Exon Array.

Y. Yamashita[1], T. Matsuura[1], J. Shinmi[1], T. Ibi[2], M. Kinoshita[3], T. Kimura[4], O. Yahara[4], K. Sahashi[5], K. Ohno[1] 1) Div Neurogen & Bioinfo, Nagoya Univ Grad Sch Med, Nagoya, Japan; 2) Aichi Med Univ College of Nursing, Aichi, Japan; 3) Faculty of Health Sciences, Tokyo Metropolitan Univ, Tokyo, Japan; 4) Dept Neurol, National Dohoku Hosp, Asahikawa, Japan; 5) Dept Neurol, Aichi Med Univ, Aichi, Japan.

Myotonic dystrophy type 1 (DM1) is the most common form of adult-onset muscular dystrophies and affects multiple organs. DM1 is caused by expanded CTG repeats in the 3' untranslated region of the *DMPK* gene located in 19q13.3. In DM1, the expanded CUG repeats form a stem and loop structure and leads to misregulation of trans-acting splicing regulators, such as MBNL1 and CUG-BP1, which then causes aberrant splicing of target exons of these regulators. Although DM1 exhibits diverse symptoms, no more than twenty aberrantly spliced exons have been reported to date. We here attempted to extensively identify aberrantly spliced exons using the Human Exon 1.0 ST array (Affymetrix) by comparing three DM1 and three normal skeletal muscles. We initially used two kinds of commercially available analysis software, but noticed that these pick up a lot of false positives. We then developed our own algorithm, in which exonic probesets only on the NCBI or Ensembl database are considered, and the variability of splice indices in a given gene was taken into account. The splice index is the signal intensity of a given probeset normalized for the expression level of the gene carrying the probeset. We additionally narrowed down candidate exons by the fold-change values and by the t-test scores as in other algorithms. We picked up 13 candidate exons with a stringent condition, and found by RT-PCR that 12 were indeed aberrantly spliced. Using less stringent conditions, we identified a total of 21 aberrantly spliced exons. Eleven of these were found even in other myopathies, whereas ten were unique to DM1. Identification of the entire catalog of aberrantly spliced exons will elucidate molecular mechanisms of diverse symptoms in DM1, and will lead to development of rational therapies to normalize the aberrantly spliced genes.

Nonsense polymorphisms in Japanese population. *Y. Yamaguchi-Kabata[1], N. Kamatani[1,2]* 1) Lab for Statistical Analysis, SNP Research Center, Minato-ku, Tokyo, Japan; 2) Institute of Rheumatology, Tokyo Womens Medical University, Tokyo.

Genetic variations in the human genome are maintained by the balance of mutation, selection and random genetic drift. Nonsense mutations, which cause premature stop codons in protein-coding regions, result in truncated proteins or absence of gene product. From the standpoint of evolution, a nonsense mutation can be a cause of pseudogene if it is fixed in the population. How nonsense polymorphisms, even with profound effects on phenotypes, are maintained in human populations is little understood. In this study, we intended to clarify how many nonsense mutations exist on the genome, focusing on the Japanese population. We conducted data analysis using bioinformatics resources such as dbSNP, JSNP, and H-InvDB to retrieve data of possible nonsense SNPs. The number of nonsense SNP candidates was more than 1200 by selection of SNPs from the bioinformatics resources. Then, we selected SNPs that are polymorphic in the Japanese population with allele frequency data from JSNP and HapMap. For more than 200 nonsense SNP candidates for Japanese, we checked whether classification of SNP is appropriate. The results show that there are at least 90 nonsense SNPs in the Japanese population. Frequency distribution of the nonsense alleles were much biased toward lower frequencies. However, some of the nonsense SNPs are very common and also found in other ethnic groups. We also examined the positions of the nonsense polymorphisms in gene structure to see whether the premature stop codon cause nonsense-mediated decay. By these analyses, we estimate the average number of null mutations by nonsense mutations for the typical person.

FISH confirmation of array-detected microduplications: an assessment of discrepancies with real-time qPCR findings. *N. Riendeau[1], C. Harvard[2], Y. Qiao[2], X. Liu[3], J.J.A. Holden[3], S. Lewis[1], E. Rajcan-Separovic[2]* 1) Department of Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 2) Department of Pathology and Laboratory Medicine, University of British Columbia, Vancouver, BC, Canada; 3) Department of Psychiatry and Physiology, Queen's University, Kingston, ON, Canada.

Microarray comparative genomic hybridization, or array-CGH, can identify microdeletions and microduplications at the whole genome level in individuals affected with a variety of disorders. In addition to detecting clinically relevant changes, array-CGH reveals a large number of apparently benign copy number variants (CNVs), which are then catalogued in a public database (http://projects.tcag.ca/variation/). Interpretation of CNVs can be challenging as very few of the >6000 normal CNVs have been confirmed using independent methods. In our study of subjects with Autism Spectrum Disorders (ASD), we aim to confirm all new CNVs by real-time quantitative PCR (RT-qPCR) and/or FISH. Here we describe the assessment of 7 microduplications using both methods and discuss the reasons for discrepant findings. Briefly, 3/7 array-detected microduplications had been confirmed by RT-qPCR (clones RP11-808H17, RP11-105C15 and RP11-91A13) and 4 had not (clones RP11-2L22, RP11-212I21, RP11-278A4 and RP11-366M24). FISH results were concordant with RT-qPCR results for all clones. Using FISH we could explain the discrepancy for 2/4 discrepant clones (RP11-2L22 and RP11-212I21) as they hybridized to two pairs of homologous chromosomes. For the remaining 2/4 discrepant clones, FISH was not suggestive of a microduplication and we will provide possible explanations for the array vs RT-qPCR and FISH discrepancy. Our findings suggest that all novel CNVs need to be confirmed, sometimes using two independent methods, to select those that are potentially clinically relevant. Ideally, all CNVs already listed as normal variants should also be confirmed, to minimize the possibility that clinically relevant changes are discarded as previously reported normal copy number variants, when some may be artifacts.

A novel deletion variant of gamma D-crystallin with reduced solubility and nuclear relocalization leads to congenital cataract. *G.H.F. Yam, L.Y. Zhang, D.S.P. Fan, P.O.S. Tam, D.S.C. Lam, C.P. Pang* Department of Ophthalmology & Visual Sciences, Chinese University of Hong Kong, Hong Kong China.

Purpose: To investigate the properties of a novel gamma D-crystallin (CRYGD) variant identified in a family with the lamellar type of autosomal dominant congenital cataract (ADCC). Methods: A Chinese family with 5 affected members diagnosed with lamellar cataract and 4 unaffected members were recruited for the mutational screening of 15 known ADCC candidate genes. Two-point linkage analysis with 39 single nucleotide polymorphisms and 22 microsatellite markers flanking these genes, together with direct sequencing was applied to identify the disease-causing mutation. Recombinant N-terminal FLAG-tagged wildtype and mutant CRYGD were expressed in COS-7 cells, respectively. The cellular expression, distribution and detergent solubility were analyzed by western blotting and confocal double immunofluorescence. Results: Linkage analysis located the candidate region in gamma C- and D-crystallin gene cluster. Direct sequencing identified c.494delG in CRYGD being co-segregated with the disease in all affected members. Neither unaffected family members nor 103 unrelated controls carried this deletion mutation, which causes a frameshift and results in early termination of the polypeptide to become Gly165AlafsX3. Significant reduced solubility was observed for this mutant protein. Unlike the wildtype protein which is cytoplasmic, Gly165AlafsX3 was predominantly located to the nuclear envelope and colocalized with lamin A/C. Conclusions: We have identified a novel mutation c.494delG in CRYGD associated with lamellar congenital cataract. This is the first characterized deletion mutation of CRYGD to be disease-causing for ADCC. The mutant protein with loss of detergent solubility and apparent impairment of stability is the first CRYGD variant found to localize in the nucleus.

Identification of differentially expressed proteins in the plasma of heroin abusers. *H. Zhou[1,2], H. Zhu[3], J. Liu[4], J. Xu[5], J. Li-Ling[2], M. Li[6], S. Jia[1]* 1) Peking University Shenzhen Hospital, Shenzhen 518036, China; 2) Department of Medical Genetics, China Medical University, Shenyang 110001, China; 3) Chronic Disease Prevention and Cure Station of Bao'an, ShenZhen 518133, China; 4) Center for Disease Prevention and Control, Shenzhen 518020, China; 5) Shenzhen Detoxification Center, Shenzhen 518019, China; 6) Proteomics Laboratory, Sun Yat-sen University, Guangzhou 510060, China.

Aim: To identify differentially expressed proteins in the plasma that may be used as biomarkers for heroin addiction through a two-dimensional (2-D) gel electrophoresis/mass spectrometry approach. Method: Following removal of albumin and IgG, plasma from 5 abusers and 5 normal controls were separated by 2-D gel electrophoresis using pH 4~7 drystrip and PAGE. Gel images were analyzed using ImageMaster Elit 5.0. Differential proteins were selected and analyzed through tandem mass spectrometry. Results: Average spot number for samples was 56323. Five spots that differed by more than 1.5 fold between the two groups were obtained through image analysis. Through tandem mass spectrophotometric fingerprinting, above spots were identified as fibrinogen gamma (increased by 5 fold), human -1-B-glycoprotein (decreased by 1.8 fold), uncleaved alpha 1-antitrypsin (increased by 2.5 fold), chain D of transthyretin (decreased by 2.0 fold) and ceruloplasmin (increased by 6.6 fold). Conclusion: Difference between heroin abusers and normal controls was identified as a component of blood plasma proteome. Some of these proteins may have a role in the damage to central nervous system through heroin abuse. Such proteins may provide novel biomarkers for diagnosis and therapeutic targeting, as well as clues for understanding the mechanism of heroin abuse.

Classification of BRCA1 and BRCA2 variants using gene expression profiling of lymphoblastoid cell lines treated with ionizing radiation is affected by mutation type. *N. Waddell[1], A. Ten Haaf[1], M. Gongora[2], S. Grimmond[2], G. Chenevix-Trench[1, 3], A.B. Spurdle[1], and kConFab* 1) Queensland Inst Medical Res, Brisbane, Australia; 2) Institute for Molecular Biosciences, Brisbane, Australia; 3) Peter MacCallum Cancer Centre, Melbourne, Australia.

BRCA1 and BRCA2 mutations confer a high risk of breast cancer. Truncating mutations are usually assumed to be pathogenic, but the consequences of missense variants are difficult to predict. We used Illumina bead microarrays to expression profile 65 lymphoblastoid cell lines (LCLs) after exposure to 10Gy irradiation. The LCLs were derived from women carrying pathogenic truncating or missense mutations in BRCA1 (n=22) or BRCA2 (n=22), or from affected, non-BRCA1/2 women (BRCAX, n=21). The genes that could discriminate between BRCA1 or BRCA2 LCLs, versus all BRCAX LCLs, were determined and the data visualised using hierarchical clustering. In addition, genes specific to mutation type were elucidated because missense and truncating mutations could also be separated for both BRCA1 and BRCA2. We used Support Vector Machines with Leave One Out cross-validation to determine if the mutation status of LCLs known to carry pathogenic mutations, comparing predictions using missense-associated, truncating-associated and truncating-specific gene lists. Accuracy of prediction was improved when the gene list used for prediction was appropriate to the mutation type (truncating or missense) being tested. Pathogenic truncating mutations of BRCA1 and BRCA2 were predicted with only 53% and 84% accuracy using missense-associated gene lists, but this increased to 77% and 84% using truncating-specific gene lists. Missense mutations of BRCA1 and BRCA2 were predicted with 100% accuracy using missense-associated lists, but with only 80% and 33% using truncating-specific gene lists. This study illustrates the potential of using gene expression profiling as a predictive tool to assess the likely pathogenicity of sequence variants of BRCA1 and BRCA2 of unknown clinical significance, but highlights the importance of using classifiers that take into account mutation type.

Unstable siRNA duplex is a prerequisite for accurate prediction of siRNA efficiency - Proposal of a new parameter based on the linear regression model -. *K. Ohno[1], M. Ichihara[2]* 1) Division of Neurogenetics and Bioinformatics, Center for Neurological Diseasses and Cancer, Nagoya Univ Grad Sch Med, Nagoya, Japan; 2) Department of Biomedical Sciences, College of Life and Health Sciences, Chubu University, Aichi, Japan.

Short interfering RNA (siRNA) is an essential tool to analyze gene function. Some siRNAs efficiently knock down the gene expression, but some cannot. The siRNA efficiency is determined by the position of siRNA on the target gene. Several different algorithms have been developed to design the most efficient siRNAs, but none can predict the siRNA efficiency with near 100% accuracy. We therefore usually have to synthesize two or more different siRNAs for each gene. We here developed a new siRNA-designing parameter, the i-Score, by applying the linear regression model on 2431 siRNAs reported by Huesken et al. (*Nat Biotechnol*, 23, 995, 2005). We validated the prediction accuracy of the i-Score using 419 siRNAs reported by others. We also compared the i-Score with other algorithms reported by Huesken, Reynolds, Ui-Tei, Amarzguioui, Katoh, Hsieh, and Takasaki. Among these, the BioPredSi by Huesken et al. was the most efficient predictor of siRNA, and the i-Socre was as good as the BioPredSi. An advantage of the i-Score over the BioPredSi, which employs the neural network modeling, is that we can visually inspect which nucleotides at which positions are beneficial or deleterious. We also found that the stability of the siRNA double helix is an important parameter that determines the siRNA prediction accuracy. When the siRNA double helix is unstable, we can readily predict its knock-down efficiency, whereas when it is stable, we cannot accurately predict it. To our surprise, this is true for other parameters and for most siRNA datasets. We also developed the SELL/pDaul system with which we can test siRNA efficiency of any artificial sequence, and validated some siRNAs with it.

Common disease related genetic variations associate with the level of expression of DCIR mRNA isoforms. *M. Ronninger, C. Eklöw, J.C. Lorentzen, L. Klareskog, L. Padyukov* Medicin, Karolinska Institutet and Hospital, Stockholm, Sweden.

To identify possible regulatory regions in a gene showing association to rheumatoid arthritis we analyzed mRNA expression pattern of DCIR in interferon-gamma treated leukocytes together with fine mapping across the locus. This also included validation and recognition of expressed transcripts since four known variants have to date been found for DCIR. Controls (44) and patients (44) with rheumatoid arthritis (RA) included in our study were genotyped for 21 common SNPs in DCIR and flanking chromosome region. mRNA expression of individual isoforms was determined by transcript specific quantitative PCR. In addition, semi-quantitative PCR with primers based on flanking exons was performed to obtain expression of all isoforms in one reaction. Our data show that IFN-g down regulates DCIR expression in PBMCs and the average expression of isoform DCIR_v1 and DCIR_v4 is significantly lower after stimulation in patients (non-stimulated vs. stimulated, p 0.0001 for DCIR_v1, p 0.005 for DCIR_v4, Wilcoxon Signed Rank test). Expression of mRNA DCIR isoforms showed strong association with common variations in the recombination block which corresponds to the area between upstream and promoter region and the third exon of DCIR. This association was represented by significant different level of DCIR_v4 expression in both patients and controls (p 0.001 and p 0.01 respectively, Kruskal-Wallis test for rs2024301). In addition to the four known forms of DCIR, a novel transcript was detected with the sequence lacking third and fourth exons. This data illustrates the influence that common genetic variations may have regarding the expression of the DCIR gene, variations that can act through transcription regulation mechanisms. This could result in different functional activity due to the change in level of expression of the receptor isoforms.

Co-transcription of genes into single transcripts: another regulatory mechanism for gene expression in vertebrates. *T.D. Taylor, T.P. Srivastava, V.K. Sharma, Y. Nishida, T. Fujikake, T. Takeda, R. Ozawa, M. Mushiake, R. Okumura, Y. Sakaki* Computational and Experimental Systems Biology Group, RIKEN Genomic Sciences Center, 1-7-22 Suehiro-cho, Tsurumi-ku, Yokohama, Kanagawa 230-0045, Japan.

Co-transcription of two distinct genes (child genes) into a single transcript (conjoined gene) has not been well explored. Either it is a somewhat rare phenomenon, or the current methods of genome annotation are not sensitive enough to identify such genes. Towards this we have designed a new computational algorithm "Conjoin" for the identification of conjoined genes in any genome given its messenger RNA or EST information. Applying *Conjoin* to the human genome, we have identified nearly 900 conjoined genes of variable lengths, some with multiple isoforms. We have so far confirmed the existence of 195 of these conjoined genes using RT-PCR and sequencing. In view of the fact that we observed several cases of conjoined genes occurring in the human genome, it appears that these conjoined transcripts are arising out of novel functional requirements and are not merely artifacts of transcription. However, the underlying mechanism controlling the formation of such conjoined genes in human and other vertebrate genomes remains to be explored. In order to confirm the presence of conjoined genes in other vertebrates, we implemented the *Conjoin* algorithm on both the mouse and chimpanzee genomes. It is remarkable to observe that the number of conjoined genes in mouse is far less than that in human, even though there is roughly the same amount of mRNA/EST data available. Thus it appears that the conjoined genes might be performing some novel functions and are contributing to human complexity as compared to other lower organisms. Therefore, we carried out a detailed functional analysis of the human conjoined and participating child genes. Further, in order to explore the intrinsic mechanisms of this process, the 5' and 3' flanking regions of the child genes were analyzed to search for the presence of any alternate or common regulatory elements that might be controlling the formation of conjoined genes.

Profiles of Resistance to Insulin in Multiple Ethnicities and Regions (PRIMER) study. *A. van der Merwe[1], G.W. Towers[2], A. Olckers[1, 2]* 1) DNAbiotec (Pty) Ltd, Pretoria , Gauteng, South Africa; 2) Centre for Genome Research, North-West University (Potchefstroom Campus), Pretoria, South Africa.

In order to elucidate the genetic, biochemical and physiological determinants of insulin resistance (IR) and impaired glucose tolerance (IGT) and in turn the effect of these factors on susceptibility towards type 2 diabetes (T2D) and the Metabolic Syndrome, the PRIMER study was undertaken. The ultimate aim of this investigation is the elucidation of the biochemical and genetic profiles of disease risk in the black South African population. By investigating the interplay between these two factors it will be possible to describe the underlying mechanisms of T2D pathogenesis.

The PRIMER study is a multi-disciplinary longitudinal prospective study over 12 years. Sample collection is scheduled for years 0, 5 and 10. The first collection phase of the PRIMER study was conducted from August to November 2005. Circa 500 individuals were collected with informed consent. It consisted of individuals from both rural and urban environments of the North West province and the cohort is defined as follows: predominantly Tswana individuals; 36% male and 64% female; 65% younger than 45 years, 34% between 45 and 54 years, and 1% between 55 and 64 years of age.

Individuals collected were apparently healthy. Each individual had to have been fasting for at least 10 hours prior to a two hour oral glucose tolerance test (OGTT), with sampling and glucose measurement at 0, 30, 60, 90 and 120. Glycosylated haemoglobin (HbA1c) was measured via high performance liquid chromatography (HPLC) to determine an individuals glycaemic control. Participants completed a questionnaire to determine individual risk towards the Metabolic Syndrome. Whole blood, plasma, serum and urine were collected via appropriate methodologies. This investigation consists of the largest cohort of 5-point OGTTs in the black South African population.

The extended phenotypic spectrum of 9p deletion (partail monosomy 9p) syndrome. *M. Michelson[1], C. Vinkler[1,2], M. Yanoov-Sharav[1,2], T. Lerman-Sagie[2,3], D. Lev[1,3]* 1) Genetics Inst, Wolfson Medical Ctr, Holon, Israel; 2) Metabolic Neurogenetic clinic, Wolfson Medical Ctr, Holon, Israel; 3) Pediatric Neurology Unit, Wolfson Medical Ctr, Holon, Israel.

Structural aberration of chromosomes is associated with various syndromes. Partial deletion of short arm of chromosome 9(9p-)or partial monosomy 9p is a rare but specific clinical entity. Phenotypic presentation is variable. The clinical features include mental retardation, craniofacial malformations,short neck,heart defects and behavioral problems. Trigonocephaly and upward slanting palpepbral fissures are found virtually in all patients. Non ketotic hyperglycemia was described in some cases. Most of the cases are de novo deletions. Few cases are due to unbalanced rearrangements. We present a two and a half year-old girl with developmental delay, dysmorphic features, neonatal hypoglycemia, ventricular septal defect, cleft palate and severe congenital dislocation of hips. Karyotype in leucocytes was normal, 46 XX. Comparative genomic hybridization (A-CGH) analysis revealed deletion of 9 pter; with breakpoints between RP11-1036k24 and RP11-1057121. Parental studies are normal. Although most clinical features of the patient are consistent with monosomy 9p- syndrome, our patient presents with distinct malformations that have not been described previously: including severe neonatal hypoglycemia and congenital hip dislocation resistant to therapy.

AMPD2 deficient mice: A murine model for minimal change nephropathy. *T. Morisaki[1], K. Toyama[1], J. Cheng[1], H. Kawachi[2], F. Shimizu[2], M. Ikawa[3], M. Okabe[3], H. Morisaki[1]* 1) Department of Bioscience, National Cardiovascular Center Research Institute, Suita, Osaka, Japan; 2) Department of Cell Biology, Institute of Nephrology, Niigata University Graduate School of Medical and Dental Sciences, Niigata, Japan; 3) Genome Information Research Center, Osaka University, Suita, Osaka, Japan.

AMP deaminase (AMPD), an enzyme catalyzing AMP to IMP, plays an important role in purine metabolism, especially in maintaining adenylate energy charge. AMPD2 gene, a member of the AMPD gene family in vertebrates, is widely expressed in non-muscle tissues and cells including kidney, though its function has not been fully understood. In this study, we have established the AMPD2 knockout mouse at the first time to identify the gene function. In the AMPD2 knockout mice, the AMPD2 protein was not detectable and the AMPD activity was significant decreased in kidney. Also, we found the changes of nucleotide metabolism in kidney, such as increased AMP and decreased ATP and GTP. In addition, proteinuria was found in mice lacking AMPD2 in 3 week-old mice, followed by further increment of proteinuria at the peak levels in 6 week-old and then decreased but sustained proteinuria in AMPD2 knockout mice. Since the major protein composition in the proteinuria of AMPD2 KO mice was demonstrated to be albumin, it was suggested that AMPD2 could have a key role for glomerular filtration. Indeed, the ultra-structure study of glomerulus showed effacement of the podocyte foot processes, though microscopic analysis did not exhibit apparent morphological abnormality of glomerulus. These changes resemble to those found in minimal change nephropathy in human. Based on these results, we conclude that AMPD2 deficiency induces not only unbalance of nucleotide metabolism but proteinuria probably due to the dysfunction of podocytes.

The detection of C677T gene polymorphism of methylenetetrahydrofolate reductase with real time PCR combined with probe melting curve and the study of its association with liver cirrhosis. *G.Z. Liu[1], Y. R. Li[2]* 1) Suizhou Central Hospital,Sui Zhou,Hubei P.R.China, Sui Zhou,Hubei, hubei, China; 2) Union Hospital, Tongji Medical College, Huazhong University of Science and Technology,Wuhan.

Objective To set up a real time fluorescent PCR to detect the C677T gene polymorphism of methylenetetrahydrofolate reductase(MTHFR) and to investigate the correlation between the C677T gene polymorphism of MTHFR and liver cirrhosis. Method The real time detection of the C677T gene polymorphism of MTHFR was performed in 60 healthy volunteers and 64 patients with liver cirrhosis and 42 patients with liver disease excluding liver cirrhosis with double probe hybrid combined with probe melting curve, then compare it with traditional PCR-RFLP. Results There are three genotypes(C/C, C/T and T/T) in the C677 position of MTHFR. For the patients with liver cirrhosis, the rate of C/C, C/T and T/T is 18.8%, 50% and 31.3% respectively. It is 45.2%, 40.5% and 14.3% respectively in patients with liver disease excluding liver cirrhosis as well as 53.3%, 33.4% and 13.3% in healthy volunteers. There is significant difference of genotype frequency of MTHFR between the group of liver cirrhosis and liver disease excluding liver cirrhosis as well as healthy volunteers(2=16.7553, P<0.01; 2=9.4664, P<0.01).T allele frequency is 56.3% in the patients with liver cirrhosis and the frequency is higher that that in the patients with liver disease excluding liver cirrhosis and healthy volunteers((2=13.14, P<0.01; 2=0.34, P>0.05), furthermore the T allele frequency correlates with the occurrence of liver cirrhosis significantly(OR=2.73, 95% credit region: 1.43~5.19). The results came from real time PCR consists with that of traditional PCR-RFLP completely. Conclusion Real time fluorescent PCR combined with probe melting curve is an effective and a rapid method to detect the C677T gene polymorphism of MTHFR. T allele frequency in C677 position in the patients with liver cirrhosis is higher than that in the patients with liver disease excluding liver cirrhosis and in the healthy volunteers. Furthermore the T allele frequency correlates with the occurrence of liver cirrhosis closely.

Factors associated with telomere length in a bi-racial population of older adults: The Health ABC Study. *O.T. Njajou[1], W-C. Hsueh[1], P. Holvoet[2], F. Harris[1], E.H. Blackburn[1], T.B. Harris[3], E. Simonsick[3], A. Newman[4], R. Li[5], J. Zmuda[4], P-Y. Kwok[1], N. Schork[6], S.R. Cummings[7], R.M. Cawthon[8], for the Health ABC Study[1]* 1) University of California, San Francisco, CA; 2) Katholieke Universiteit Leuven, Belgium; 3) NIH, Bethesda, MD; 4) University of Pittsburg, PA; 5) University of Tenessee at MEMPHIS, TN; 6) University of California, San Diego, CA; 7) California Pacific Medical Center, San Francisco, CA; 8) University of Utah, Salt Lake City, UT.

Telomeres are DNA capping structures at the ends of chromosomes, which shorten at each somatic cell division in humans. Previous studies suggest that telomere shortening may contribute to aging and poorer survival in humans. Oxidative stress accelerates telomere attrition in cultured cells, leading to cellular senescence. However, it is not yet clear what factors may affect telomere length (TL) in humans. We used data from 2,721 participants of the Health ABC study (age range: 68 to 80 years, 51% female, 1,605 white and 1,116 black participants) to address this question. We tested the association of several environmental and host factors with TL, including sex, oxidative stress, race, smoking, alcohol use, levels of physical activity, and socio-economic status (SES). TL in leukocytes was measured using a validated quantitative PCR method. Levels of ox-LDL (a marker of oxidative stress) were measured using a standard ELISA in the blood plasma. As observed previously, TL was negatively correlated with age ($r = -0.7$, $p < 0.001$) and was shorter in men (4,697bp 34bp) compared to women (5,124bp 34bp) ($p < 0.001$). TL was shorter in smokers, alcohol drinkers and people with high ox-LDL (all $p < 0.005$). Interestingly, after adjusting for age and sex, ox-LDL levels were negatively associated with telomere length (= -171 34bp, $p < 0.001$), even after adjustment for LDL-cholesterol. Race, physical activity, and SES were not related to TL. In summary, we found that oxidative stress and some modifiable factors are associated with telomere length. Both biological and environmental factors can influence TL in humans, and perhaps consequently, aging.

CAPN10 haplotypes detected in high frequencies in type 2 diabetes patients and controls in the black South African population, in contrast to non-African populations. *G.W. Towers[1], A. van der Merwe[2], P.E.H. Schwarz[3], A. Olckers[1, 2]* 1) Centre for Genome Research, North-West University (Potchefstroom Campus), Pretoria, South Africa; 2) DNAbiotec (Pty) Ltd, Persequor Park, Pretoria, South Africa; 3) Department of Endocrinopathies and Metabolic Diseases, Medical Faculty Carl Gustav-Carus, Technical University Dresden, Dresden, Germany.

Objective: To elucidate the role of three reported calpain 10 (CAPN10) single nucleotide polymorphisms (SNPs) i.e. University of Chicago (UC) SNP-43, -56 and -63, in genetic type 2 diabetes (T2D) susceptibility within the black South African population.

Methods: Using a case-control strategy to determine association to T2D, a diabetic cohort (n=218) and a control cohort (n=217) of adult black South African individuals were screened for the aforementioned SNPs via real-time polymerase chain reaction. Genotypes were evaluated for adherence to Hardy Weinberg equilibrium and association testing was achieved by standard statistical methods. A subset of 100 female individuals underwent a two hour oral glucose tolerance test (OGTT) with measurements of glucose, insulin, c-peptide, proinsulin, free fatty acids and adiponectin to determine the biochemical effects of the CAPN10 SNPs.

Results: Protection towards T2D was observed in the black South African cohorts harbouring the wild type homozygote at the UCSNP-56 locus. Individuals harbouring the 2,2 genotype at this locus presented with increased c-peptide levels. Furthermore it was determined that the previously reported at-risk haplotypes in the Caucasian population were at much lower frequencies in the black South African cohort. This implies that alternative T2D susceptibility factors are present in these two populations.

Conclusions: This investigation highlights the importance of population history in the investigation of T2D genetic susceptibility. This is most likely due to the very different evolutionary pressures that these populations have experienced. Therapeutic strategies for T2D should therefore be developed in a population specific manner.

Linkage studies in a large German family with restless legs syndrome. *K. Lohmann[1], Y. Lu[1, 2, 3], S. Winkler[1], A. Kleensang[4], T. Lohnau[1], A. Rakovic[1], H. Muhle[2], I.R. König[4], P.L. Kramer[5], U. Stephani[2], A. Ziegler[4], C. Klein[1]* 1) Neurology, University Lübeck, Lübeck, Germany; 2) Neuropediatrics, University of Kiel, Germany; 3) Geriatrics, The First Affiliated Hospital of Chongqing Medical University, Chongqing, China; 4) Medical Biometry and Statistics, University of Lübeck, Germany; 5) Neurology, OHSU, Portland, OR, USA.

Restless legs syndrome (RLS) is a common sensory-motor disorder characterized by paresthesias and an intense urge to move the legs. It exhibits a considerable familial aggregation. To date, no gene mutation has been found, although five gene loci have been mapped in primary RLS to chromosomes 12q, 14q, 9p, 2q, and 20p (RLS1-5). We identified a four-generational German RLS family with 37 family members including 15 affected cases. Mode of inheritance follows an autosomal dominant pattern. Disease onset was mainly in childhood or adolescence. We performed a detailed linkage analysis using microsatellite markers. In a first step, we screened the five known loci and excluded linkage to RLS1, 2, 4, and 5. However, we identified a likely new RLS gene locus (RLS3*) on chromosome 9p. A haplotype centromeric to RLS3, flanked by D9S974 and D9S1118, was shared by all twelve investigated patients and generated a maximum LOD score of 3.60 by model-based multipoint linkage analysis. Eleven of these patients carried a common haplotype extending telomeric to D9S2189 that is located within RLS3. Only one unaffected child carried this disease-associated haplotype. In a second step, we carried out a genome-wide scan and found hints for linkage to an 8.2Mb region on chromosome 10 where all but one affected shared a haplotype. Four unaffected relatives, including three children also carried this haplotype. We are currently sequencing candidate genes in the linked regions but have not yet identified any mutation in the first ten tested genes on chromosome 9p. The high frequency and the broad phenotypic spectrum of RLS probably hamper the identification of a causative gene. Our family with a relatively homogeneous phenotype and very early disease onset represents a unique opportunity to further elucidate the genetic causes of the frequent RLS.

Copy number variants and one novel susceptibility region identified in a genome-wide association study of autism in an isolated population. *K. Rehnström[1,2], H. Kilpinen[1], E. Gaál[1], T. Ylisaukko-oja[1], R. Vanhala[3], L. von Wendt[3], T. Varilo[1,2], L. Peltonen[1,2,4]* 1) Department of Molecular Medicine, National Public Heath Institute, Helsinki, Finland; 2) Department of Medical Genetics, University of Helsinki, Helsinki, Finland; 3) Unit of Child Neurology, Hospital for Children and Adolescents, Helsinki, Finland; 4) Program in Medical and Population Genetics, Broad Institute of Harvard and Massachusetts Institute of Technology, Cambridge, MA, USA.

Autism spectrum disorders (ASDs) have a strong genetic component, but only a small number of rare genetic causes have been identified so far. Results of recent genome-wide association scans have highlighted the role of copy-number variations in the etiology of autism. To identify genes predisposing to autism, we genotyped 54 ASD probands from families originating from an internal isolate of Finland and 37 regionally matched controls using the Illumina HumanHap 300 BeadChip. All probands have at least two grandparents originating from Central Finland, and 19 of these families form an extended pedigree, that can be traced back to the same farm in a small village in Central Finland in the 18th century. This would provide an ideal setting for the use of shared haplotype strategy in the identification of high impact rare alleles, enriched in this isolate. Association analysis of single markers as well as shared allelic haplotypes performed using PLINK software identified a putative susceptibility locus at 6p22.2. Further, analysis of the 54 cases indicated five copy number variants (CNVs) exceeding 1Mb, resulting in a frequency of 9% for large CNVs. Three of the CNVs were gains of chromosome 15q11.2-q13.1, all exceeded 5Mb. Two other gains were also quite sizable, one at 1q42.13-42.2 spanning approximately 2 Mb and one at 9q21.33 approximately 1.5 Mb. None of the CNVs were identified in the controls. The results of CNV analysis support the role of CNVs in the etiology of autism. Additional SNPs at 6p22.2 are being genotyped in the whole Finnish autism sample to confirm the validity of the initial haplotype sharing.

Interaction of Down syndrome-related gene product SIM2 and circadian rhythm protein BMAL1. *Y. Shimizu[1], A. Yamaki[1], M. Ikeda[2], J. Kudoh[3], N. Shimizu[4]* 1) Dept Medical Genetics, Kyorin Univ Fac Health Sci, Hachioji, Tokyo, Japan; 2) Res Center for Genomic Med, Saitama Med School, Saitama, Japan; 3) Dept Mol Biol, Keio Univ School of Med , Shinjuku, Tokyo, Japan; 4) GSP Center, The Leading Institute of Keio Univ, Tsukuba, Japan.

Human *SIM2* gene locates on Down syndrome chromosomal region, 21q22.2, and the protein product belongs to the family of bHLH (basic helix-loop-helix)/PAS (Per-Arnt-Sim) transcription factors. It has been shown that SIM2 protein forms heterodimer with ARNT or ARNT2 to inhibit the expression of target genes and that BMAL1 forms heterodimer with CLOCK to activate the transcription of target genes, such as *PER1*.

To find new partner of SIM2 heterodimer, we tested the possibility of interaction with BMAL1. After the transient expression of SIM2 and BMAL1 in HEK293 cells, SIM2 was immunoprecipitated with BMAL1 using the tag peptide antibodies. Experiments using a series of deletion constructs of SIM2 revealed that the region of nuclear localization signal was required for the interaction of SIM2 and BMAL1.

In the promoter region of *PER1*, there are three E-boxes as cis-elements for BMAL1/CLOCK heterodimer to increase Luciferase activity. We found that SIM1 or SIM2 alone enhanced the promoter activity and BMAL1 affected more positively in the case of SIM1, but not in the case of SIM2. Furthermore, we examined the effect of BMAL1 on *SIM2* promoter activity. BMAL1/CLOCK inhibited by 40% and the addition of CRY1 inhibited by 60%. The transcription factors related to the circadian rhythm, such as BMAL1, CLOCK and CRY1, may play significant roles in the regulation of SIM2 transcription.

Gene expression profiling reveals complement mediated regeneration in skeletal muscle from Leigh syndrome patients with a SURF1 mutation. *H. Smeets[1], R. Van Eijsden[1], R. Mineri[2], P. Lindsey[1], L. Eijssen[1], C. van den Burg[1], E. de Wit[3], T. Ayoubi[1], C. di Blasi[2], J. Zeman[4], M. Zeviani[2], I. de Coo[3], W. Sluiter[3], V. Tiranti[2]* 1) Dept Genetics & Cell Biol, GROW, Univ Maastricht, Maastricht, NL; 2) Unit Molec Neurogenet & Neuromusc Dis, Neurol Inst C Besta, Milano, I; 3) Dept Biochem & Neurol, Mitoch Res Unit, ErasmusMC, Rotterdam, NL; 4) Dep Pediatr, 1st Fac Medic, Charles Univ, Prague, CZ.

Leigh syndrome is an early-onset, progressive and often fatal neurodegenerative disorder, characterized by necrotic lesions in the brain basal ganglia. Leigh syndrome with a decreased cytochrome c oxidase (COX) activity is frequently caused by mutations in the SURF1 gene, which disturb COX-assembly. To characterize molecular pathophysiological processes, gene expression profiling was performed in skeletal muscle biopsies from SURF1 Leigh syndrome patients and controls. No significant alterations in transcription levels of oxidative phosphorylation (OXPHOS) genes were observed. Altered processes were protein synthesis, DNA metabolism, cell cycle, skeletal muscle development, and intriguingly, the complement system. Genes of the classical complement pathway (C1R, C1S, and C3) - not only involved in immune response, but also in tissue regeneration - were significantly upregulated. This regenerative response is also observed in gene expression changes in other processes. Most likely, SURF1 mutations lead to increased production of reactive oxygen species (ROS), causing protein damage and increased turnover. This could trigger complement activation and induce a process of muscle regeneration as a rescue process. A causative relation has to be established, but our data provide new insight in the molecular processes occurring in muscle of SURF1 patients, which could be involved in other OXPHOS disorders as well.

Auto-regulation of *GTF2IRD1* contradicts its proposed role in the causes of Williams syndrome. *S.J. Palmer[1], N. Santucci[1], E.S. Tay[1], J.W. Hook[2], F.A. Lemckert[2], P.W. Gunning[2,3], E.C. Hardeman[1]* 1) Muscle Development Unit, Children's Medical Research Institute, Sydney, NSW, Australia; 2) Oncology Research Unit, The Children's Hospital at Westmead, Sydney, NSW, Australia; 3) Discipline of Paediatrics and Child Health, Faculty of Medicine, University of Sydney, NSW, Australia.

Williams-Beuren syndrome (WBS) is a complex disorder resulting from a hemizygous microdeletion within chromosome 7q11.23 involving 20 genes. Supravalvular aortic stenosis is a common feature and is caused by haploinsufficiency of elastin, but the remaining physical and neurological symptoms have no known specific genetic cause. Recent reports have associated many of the symptoms with two related DNA-binding proteins, GTF2IRD1 and GTF2I, and one report has linked GTF2IRD1 to the craniofacial abnormalities. We have generated a *Gtf2ird1* knockout mouse by deletion of the first coding exon and analysed expression levels by Q-RTPCR and northern blotting. We found that the mutant *Gtf2ird1* allele produces a deleted transcript and transcript levels are 2 to 3 times higher in mutant animals than in their normal siblings. On the assumption that direct auto-regulation may explain this finding, we conducted a phylogenetic footprinting analysis of *Gtf2ird1* and found a highly conserved region adjacent to the transcription start site, which contains a cluster of canonical Gtf2ird1 binding sites. We have shown by electrophoretic mobility shift assays that Gtf2ird1 binds to this region with high affinity. Interestingly, the binding reaction is dependent on the presence of multiple sites since reduction to a single site abrogates binding. To test for auto-regulation in humans, we obtained lymphoblastoid cell lines from six WBS patients and six controls and examined expression of *GTF2IRD1*, *CYLN2*, *GTF2I* and *GAPDH*. While *CYLN2* and *GTF2I* transcript levels in the WBS group are half the levels of the normal controls, *GTF2IRD1* levels are indistinguishable from normal. Therefore, although only one copy of *GTF2IRD1* remains in WBS patients, it escapes haploinsufficiency by up-regulation of its own promoter, thus redefining its potential role in the disease.

Identification of novel heterozygous nonsynonymous variations of (*ANG*), *VEGF* and *ALS2* in sporadic ALS (SALS) patients and its implication in the genetic risks of SALS. *Y. Takahashi, J. Goto, S. Tsuji* Department of Neurology, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan.

[Background] Although the molecular basis of SALS has been mostly unknown, recent molecular genetic researches have indicated that rare variations of disease-related genes such as angiogenin (*ANG*) are associated with genetic risks of SALS. We have conducted the comprehensive analysis of disease-related genes in SALS patients to seek for such variations potentially associated with SALS. [Methods] Genomic DNA samples from 33 sporadic ALS patients in whom mutations of *SOD1* or *DCTN1* were excluded were used in this study, consisting of 18 definite ALS, 9 probable ALS, 3 possible ALS, and 3 ALS-plus patients based on the El Escorial and the revised Airlie House diagnostic criteria. DNA samples from 238 controls were also used. We have screened all the exonic and flanking intronic sequences of *ANG*, *VEGF* and *ALS2* using a DNA microarray-based resequencing system and direct nucleotide sequence analysis method. The screening of controls was conducted using denatured high-performance liquid chromatography (DHPLC). [Results] In 33 SALS patients, 7 novel heterozygous nonsynonymous variations including 1 variation in *ANG*, 1 in *VEGF* and 5 in *ALS2* were identified. Three of the 7 variations, 1 nonsynonymous variation in *ANG* (N49S) and 2 nonsynonymous variations in *ALS2* (Q435L and P1016T), were not found in 476 control chromosomes. [Conclusion] This study revealed 3 novel nonsynonymous variations in *ANG*) and *ALS2* which were only found in SALS patients. Further large-scale case-control studies or functional studies of these variations are necessary to clarify their relevance to the pathogenesis of SALS. This study suggested that the comprehensive resequencing is a promising approach to identify rare variations potentially associated with the genetic risks of SALS.

Correlation between dried blood spot thin layer chromatography and plasma high performance liquid chromatography of leucine/isoleucine levels among Filipino patients with Maple Syrup Urine Disease. *C.D. Padilla[1], J.Y. Lee[2], M.A. Demata[1], K.T. Dela Cruz[1], M.D. Chiong[1], C.C. Cavan[1]* 1) Institute of Human Genetics, National Institutes of Health Philippines, Manila, Philippines; 2) Metabolic Service, Genetic Health Services, Victoria, Australia.

Management of patients with maple syrup urine disease (MSUD) includes low protein diet supplemented with special formulas and constant monitoring of branched chain amino acids (BCAA). The gold standard for monitoring BCAA is plasma amino acid analysis using High Performance Liquid Chromatography (HPLC). In a developing country like the Philippines, however, the cost of this test is prohibitive to majority of the patients. In our center, dried blood spot leucine/isoleucine(leu/ile) level by thin layer chromatography (TLC) is often used to diagnose and monitor these patients. This study was done to determine the correlation of leu/ile levels using the two analyses (TLC and HPLC). Paired samples (dried blood spot and plasma) of twelve MSUD patients were collected. There were 8 males and 4 female with ages that range from 6 weeks to 4.9 years. Majority had the classical type of MSUD and the protein diet was restricted between 0.6 gram/kg/day to 1 gram/kg/day of natural protein. Results showed a significant linear correlation (Spearman correlation=0.800) between the two methods (p- value <0.05). A dried blood spot leu/ile level by TLC is an alternative method that can be used in the diagnosis and monitoring of MSUD patients especially in a developing country.

NRAMP1 polymorphisms and susceptibility to tuberculosis in Turkish children. *F. Ozkinay[1], A. Y. Ekmekci[1], H. Onay[1], H. Cosar[1], O. Cogulu[1], A. R. Bakiler[2], E. Turker[1], C. Gunduz[1], C. Ozkinay[1]* 1) Ege University Faculty of Medicine, Izmir, Turkey; 2) Adnan Menderes University Faculty of Medicine, Aydin, Turkey.

Tuberculosis (TB) is an important public health problem worldwide causing significant morbidity and mortality all over the world. The researches have shown that genetic factors as well as environmental factors contribute to the development of this devastating disease. The natural resistance-associated macrophage protein 1 (NRAMP1) is one of the most extensively studied gene in the susceptibility to tuberculosis. The results of the NRAMP1 studies in the association with tuberculosis are inconclusive and the role of this gene in the pathogenesis of tuberculosis in humans is debated. We aimed to investigate the association between 3 polymorphisms (D543N and 3 UTR and 5(CA)n) of the NRAMP1 gene and TB susceptibility in Turkish children. This study included 43 children with TB (mean age 7.02 4.56) and 70 age matched controls. Polymerase chain reaction (PCR) and restriction fragment length polymorphism analysis were used to type the polymorphisms D543N and 3 UTR. Genotyping for the polymorphism 5(CA)n was performed by using ABI 3100 sequencer (Applied Biosystems, Foster City, CA, USA) after PCR amplification of genomic DNA with the FAM-labelled specific primers. The genotype and allele frequencies of the 3UTR polymorphism were significantly different in patient group and control group (p=0.0354 and p= 0.0373 respectively). Only allele 200 among the alleles of the microsatellite 5(CA)n marker was significantly higher in patient group (p=0.0374). No significant differences were found between the genotype and allele frequencies of patient and control groups for the polymorphism D543N. As a conclusion NRAMP 1 gene may play a role in the susceptibility or resistance to TB in children.

Preliminary Screening for Susceptibility Genes for Congenital Anomalies of the Genitourinary System at 22q11.2. *J. Li-Ling[1], Y. Zhao[1], J. Zhang[1], Y. Fu[1], A. Qian[1], B. Wu[2]* 1) Department of Medical Genetics, China Medical University, Shenyang 110001, China; 2) Department of Urological Surgery, Second Affiliated Hospital, China Medical University, Shenyang 110004, China.

Substantial proportions of 22q11.2 microdeletion carriers have been observed to have congenital malformation of the genitourinary system ranging from renal malformations, metanephric duct/urinary bladder blockage/backflow to hypospadia and/or cryptorchidism. Although the etiology still remains unclear, it has been postulated that particular gene(s) from the DiGeorge syndrome critical region (DGCR) may predispose to such malformations in both syndromic and isolated forms. Using semi-quantitative real-time PCR, we have systematically analyzed expression of murine homologs of 29 DGCR genes within kidney tissues obtained at days 13, 15, 17 and 19 of mouse development as well as adulthood. Through K-means analysis, expression pattern of these genes were clustered into six groups. Notably, certain genes, known to locate within close proximity, e.g., Serpind1 and Lztr1; Pnutl1 and Tbx1; Pcqap and Pik4ca, respectively, showed similar expression patterns, which seems to suggest that they share common regulatory mechanisms. It was discovered that, nine genes have no expression at all time points. For the remainders, most have very low level of expression during development but not at the early stages. Whilst Pnutl1, Ranbp1 and Mapk1 have relatively higher level of expression at all time points, four genes, including Cdc45l, Hira, Snap29 and Ube2l3 only expressed at critical stages of kidney development. Preliminary mutation screening in 10 patients with isolated genitourinary malformations has revealed that, in one patient featuring isolated cryptorchidism, there have been frequent mutations within exon 2 of SNAP29 gene, affecting codons 5, 6, 9, 40, 44 and 48, among which the one in codon 6 was of nonsense type. Conclusion: A number of DGCR genes, in particular CDC45L, HIRA, SNAP29 and UBE2L3 may play important roles in the development of genitourinary system. In addition to its roles in the pathogenesis of syndrome, the SNAP29 gene may also be involved in the pathogenesis of genitourinary malformations.

Mosaicism of a duplication 1q due to de-novo translocation 1/14: Studies on origin and development of the pathologic cell line. *G. Schwanitz[1], D. Hansmann[2], U. Gamerdinger[3], U. Paetzold[1], N. Schönherr[4], G. Knöpfle[5], T. Eggermann[4]* 1) Institute of Human Genetics, University of Bonn, Germany; 2) Institute of Prenatal Medicine and Genetics, Meckenheim - Bonn, Germany; 3) Institute of Pathology, University Medical Center of Giessen and Marburg, Germany; 4) Institute of Human Genetics, RWTH Aachen, Germany; 5) Department of Pathology, University of Bonn,Germany.

Pure duplications of 1q are extremely rare. We report for the first time mosaicism for duplication 1p11 to 1qter in a malformed fetus. An additional long arm of chromosome 1 was translocated onto the constitutive heterochromatin of chromosome 14p (karyotype: mos46,XY,der(14)t(1;14)(p11;p11.2)/46,XY). Mosaic formation in the partial trisomy 1 (duplication 1q) was investigated in different somatic tissues of first and second trimester pregnancy. The phenotype of the fetus was in good accordance with findings from the literature. The distribution of the pathologic cells was unequal, ranging from 4 to 93%. To exclude an in-vitro effect which leads partially to an increase of the cells with normal karyotype we compared the results of chromosome analyses with molecular results of the different tissues. The duplicated region could be delineated as paternal in origin. We present a proposal for the complex formation mechanism and the development of the pathologic cell line in this rare type of chromosome disorder.

Characterization of the ETHE1 protein by cellular and animal models: towards an understanding of its role in Ethylmalonic Encephalopathy. *V. Tiranti[1], R. Mineri[1], C. Viscomi[1], C. Tiveron[2], F. Forlani[3], M. Rimoldi[4], M. Zeviani[1]* 1) Molecular Neurogenetics Unit, IRCCS Foundation Neurological Institute C.Besta, Milan, Italy; 2) Foundation EBRI Rita Levi-Montalcini Disease Modelling Facility, Rome, Italy; 3) Department of Molecular and Agroalimentar Sciences, University of Milan, Italy; 4) Biochemistry and Genetics Unit, IRCCS Foundation Neurological Institute C. Besta, Milan, Italy.

The ETHE1 gene is responsible for Ethylmalonic Encephalopathy (OMIM #602473), a severe mitochondrial disorder reported in children originating from the Mediterranean area and the Middle East. We have been collecting more than 50 patients from 40 families, presenting a fairly homogeneous clinical and biochemical presentation, in spite of a wide spectrum of ETHE1 mutations. All patients showed the presence of a combination of symptoms including petechial purpura, orthostatic acrocyanosis, chronic diarrhoea, and necrotic lesions in the basal ganglia and other regions of the brain, which was associated with high levels of C4 and C5 acylcarnitines in blood, and of ethylmalonic acid in urine. An isolated defect of cytochrome c oxidase was present in skeletal muscle. The ETHE1 protein, is a cysteine-rich metallo-protein located in the mitochondrial matrix, structurally homologous to, but functionally different from, glyoxalase II, a cytosolic thioesterase involved in glutathione recycling. In silico modelling suggests that the ETHE1 protein may also be a thioesterase, acting on a still unknown substrate. By atomic-spectrometric analysis we could show that ETHE1 coordinates a single atom of iron. The possibility for ETHE1 to be a novel mitochondrial esterase is further supported by the observation that the purified wild-type (wt) recombinant protein promoted the formation of the fluorescent dye 2,7-dichlorofluorescein, by hydrolyzing its tri-acetylated precursor ester. Concordant results were also obtained using wt vs. mutant fibroblasts. We have recently produced ETHE1 knockout mice, which seem to recapitulate the main clinical and biochemical features of the human disease.

Direct to Consumer Genetic Testing: A Report from Japan. *M. Watanabe, A. Tsuchiya, T. Ohata, T. Sumida, F. Takada* Clinical Genetics, Graduate School of Medical Sciences, Kitasato Univ, Sagamihara, Kanagawa, Japan.

The goal of the proposed presentation is to discuss the challenges of constructing appropriate regulation for Direct-to-Consumer genetic testing in a society, based on the experience of Japan.
The market of DTC genetic testing service in Japan began around the year 2000, and today there are about 10 providers. At the moment, there is no regulatory system specifically designed for provision of genetic testing in Japan. However, the committee organized voluntarily by industries dealing with human genetics is now constructing a voluntary standard on the provision of genetic testing. Nevertheless, the result of our survey shows that the majority of citizens in Japan prefer governmental regulation for the provision of genetic testing.

Preference in Types of Regulation for DTC Genetic Testing

Governmental Regulation	66.8%
Guidelines by Academic Societies	23.77%
Guidelines by Industry Associations	5.9%
Self-regulation of each company	1.73%
No regulation necessary	1.8%

The proposed presentation aims to present a case of policy making for genetic testing and its difficulty, by providing an analysis of Japanese experience.
(Direct-to-Consumer genetic testing can include both genetic testing advertised directly and sold directly to consumers. However, in this paper, DTC genetic testing indicates only such genetic testing sold directly to consumers.).

Chronological changes of serum creatine kinase (CK) levels in molecularly confirmed Duchenne muscular dystrophy cases and examination of the cases with deviated CK levels. *Y. Okizuka, Y. Takeshima, M. Yagi, Y. Oyazato, H. Awano, Z. Zhang, M. Matsuo* Dept Pediatrics, Kobe Univ, Kobe, Hyougo, Japan.

Objective Elevation of serum creatine kinase (CK) level is a well known hallmark of Duchenne muscular dystrophy (DMD). However, changes of its level have not studied in DMD cases whose diagnosis is molecularly confirmed. The present study is aimed at establishing standard levels of serum CK according to age in molecularly confirmed DMD cases. Furthermore, cases with the deviated CK levels from the standard were examined for its molecular background. Methods 121 DMD cases diagnosed by both clinical and molecular findings were enrolled in this study. Their age varied from ages 2 to 18 years. CK levels were examined by the Oliver-Rosalki method at 316 points. Means and standard deviations of CK levels were calculated per age-class. All statistical analyses were done following a transformation of CK to Napierian logarithmic. Furthermore, 78 uncertain dystrophinopathy cases were examined for the validity of the standard. Results and Discussions Average CK levels were maintained at extremely high level from 2 to 6 years old. The average CK levels declined sharply after 7 years old, whereas the decline became slow after 13 years old. In the analyses of 78 uncertain dystrophinopathy cases, remarkably, two cases were found to have significantly low CK level (<-2.5SD). Clinicaly these two cases showed mild phenotype, but their mutations of in the dystrophin gene were nonsense mutation and 4bp deletion, respectively, compatible with severe DMD. Extensive molecular analyses disclosed that one case had the nonsense mutation in C-terminal region and the other had productions of in-frame dystrophin mRNA, compatible with mild phenotype. Chronological changes of serum CK in DMD cases diagnosed by both clinical and molecular analyses were first established. In two cases with deviated CK levels, molecular backgrounds were clarified, therefore, our results were useful in evaluation of dystrophinopathy.

Combined effect of hemostatic gene polymorphisms and the risk of myocardial infarction in patients with advanced coronary atherosclerosis. *E. Trabetti[1], M. Biscuola[1], N. Martinelli[2], U. Cavallari[1], M. Pinotti[3], O. Olivieri[2], S. Cheng[4], M. Sandri[2], S. Friso[2], F. Pizzolo[2], C. Bozzini[2], P. Caruso[3], F. Bernardi[3], R. Corrocher[2], D. Girelli[2], P.F. Pignatti[1]* 1) Dept Mother-Child & Biol-Genetics, Univ Verona, Italy; 2) Dept Clinical and Experimental Medicine, Univ Verona, Italy; 3) Dept Biochemistry and Molecular Biology, Univ Ferrara, Italy; 4) Dept Human Genetics, Roche Molecular Systems, Inc., Alameda, CA, United States.

Relative little attention has devoted until now to the combined effects of gene polymorphisms of the hemostatic pathway as risk factors for Myocardial Infarction (MI), the main thrombotic complication of Coronary Artery Disease (CAD). We studied a total of 804 subjects, 490 of whom with angiographically proven severe CAD, with or without MI (n=306; n=184; respectively). An additive model considering ten common polymorphisms [F2 20210G>A, PAI1 4G/5G, FGB -455G>A, F5 Leiden and R2, F7 -402G>A and -323 del/ins, Platelet ADP Receptor P2Y12 -744T>C, ITGA2 873G>A, and ITGB3 1565T>C] was tested. The prevalence of MI increased linearly with an increasing number of unfavorable alleles (2 for trend = 10.68; P = 0.001). In a multiple logistic regression model, the number of unfavorable alleles remained significantly associated with MI after adjustment for classical risk factors. As compared to subjects with 3-7 alleles, those with few (2) alleles had a decreased MI risk (OR 0.34, 95%CIs 0.13-0.93), while those with more (8) alleles had an increased MI risk (OR 2.49, 95%CIs 1.03-6.01). The number of procoagulant alleles correlated directly (r=0.49, P=0.006) with endogenous thrombin potential. The combination of prothrombotic polymorphisms may help to predict MI in patients with advanced CAD.

Offering carrier screening for fragile X syndrome to non-pregnant women. *S. Metcalfe[1,2], A. Archibald[1,2], J. Cohen[3], V. Collins[1], A. Henry[1], A. Jaques[1], K. McNamee[4], L. Sheffield[1,5], H. Slater[1,6], S. Wake[5]* 1) Genetics Education & Health, MCRI, Royal Children's Hosp, Melbourne, Australia; 2) Dept Paediatrics, University of Melbourne, Melbourne, Australia; 3) Fragile X Alliance, Melbourne, Australia; 4) Family Planning Victoria, Melbourne, Australia; 5) Genetic Health Services Victoria, Melbourne, Australia; 6) Victorian Clinical Genetics Services Pathology, Melbourne, Australia.

Population-based carrier screening for fragile X syndrome (FXS) remains controversial despite fulfilling many criteria. Concerns surround perceived difficulties communicating complexities of FXS. This three-phase study assessed acceptability and feasibility of offering FXS carrier screening to non-pregnant women attending a family planning clinic. Phase 1: staff and female patients participated in focus groups to discuss their views, understanding, interest and concerns about offering FXS carrier screening. Overall, women and staff were positive towards screening. These data informed production of a brochure, two questionnaires (Q1/Q2) and testing protocols. Validated questionnaires included demographics, awareness, knowledge of FXS, attitudes towards carrier screening, decision-making, and anxiety. Phase 2: women were recruited, completed Q1, and offered FXS screening. Q2 was completed one month later. Phase 3: a sample of women completing both questionnaires took part in follow-up interviews discussing their experiences in participation. Of 338 women recruited, 94% completed Q1, 59% completed Q2, to date, and 31 have been interviewed. Of the women tested (n=65; 20%), three grey-zones and one pre-mutation were found. Womens understanding of FXS was reasonably good (45% scored 8/10 or greater). They were overwhelmingly in favour of FXS screening being available to all women, although fewer had screening for a variety of reasons. Women need time to deliberate to make a decision about testing. Offering testing in this type of health setting is feasible and acceptable, and raises awareness, so that women who choose to wait for the appropriate life-stage (eg when planning a pregnancy) are already informed to consider being tested.

Interferon- gene and interferon- receptor-1 gene polymorphisms in tuberculosis children from Turkey. *H. Onay[1], A.Y. Ekmekci[1], B. Durmaz[1], E. Sayin[1], H. Cosar[1], N. Bayram[1], D. Can[2], H. Akin[1], C. Ozkinay[1]* 1) Ege University Faculty of Medicine, Izmir, Turkey; 2) Dr. Behcet Uz Childrens Hospital, Izmir, Turkey.

It has been reported that macrophage activation by interferon- (IFN-) is important in mycobacterium tuberculosis infection. In this study, the relationships of the +874 T/A polymorpism in the first intron of IFN- (IFNG) gene and intronic (CA)n polymorphic microsatellite marker of the interferon receptor 1 (IFNGR1) gene to tuberculosis susceptibility were investigated in children. Forty four children (mean age: 7.02 4.56) with tuberculosis (TB) and 75 age matched controls were included in the study. The IFNG gene was genotyped for the polymorphism +874 T/A found in the first intron by using amplification refractory mutation allele-specific polymerase chain reaction method. For the intronic (CA)n polymorphism of the IFNGR1 gene, genomic DNAs were amplified using specific FAM-labelled primers and the polymerase chain reaction products were genotyped by ABI 3100 sequencer (Applied Biosystems, Foster City, CA, USA). There were no significant differences between the allele frequencies and genotype frequencies of patient and control groups for the polymorphism +874 T/A in the IFN gene. We identified 13 (CA)n alleles for the intronic (CA)n microsatellite of IFNGR1 in both TB children and controls. Only one allele was different in both groups. A significant difference was found for the allelic markers (170 and 180) between the TB children group and control group. The allele 170 was significantly associated with the susceptibility to TB (p=0,0212), whereas the allele 180 was significantly associated with the protection to TB in children (p=0.0199). In conclusion no significant association was observed between the +874 T/A polymorphism found in the first exon of IFN- gene and TB susceptibility in Turkish children. Allelic variants of the (CA)n polymorphism in the sixth intron of IFNGR1 gene may be associated with susceptibility to TB or protection against TB.

Midkine siRNA as anti-tumor molecules against osteosarcoma. *H. Maehara[1], T. Kaname[2,3], K. Yanagi[2], H. Hanzawa[1], I. Owan[1], K. Naritomi[2,3], F. Kanaya[1]* 1) Dept Orthopedics, Univ Ryukyus, Okinawa, Japan; 2) Dept Medical Genetics, Univ Ryukyus, Okinawa, Japan; 3) SORST, JST, Kawaguchi, Japan.

It is important to find a suitable molecular target for tumor therapy to make improvements in osteosarcoma. On the previous meeting, we reported a heparin-binding growth factor, midkine, is overexpressed in osteosarcoma, the level of midkine expression correlates with the prognosis of patients with osteosarcoma. In addition, we also presented that functional antibodies or a small interfering RNA (siRNA) against midkine effectively inhibit growth of osteosarcoma cells in vitro and the growth inhibition by midkine siRNA is participated in apoptosis. To apply such anti-tumor molecules for the therapy, in vivo study should be needed. Thus, we investigated whether the midkine siRNA has a potential to prevent the growth of osteosarcoma in vivo. Saos-2 osteosarcoma cells (2×10^6 cells with Matrigel) were injected and transplanted into the subcutaneous region of each nude mouse (BALB/c). After seven weeks from injection, the mice in which the tumor was transplanted and increased appropriate size were separated into two groups, a treatment group and a non-treatment group. The midkine siRNA solution or the control solution was injected into around the tumor region in each mouse for the treatment group or non-treatment group, respectively. The injection was performed every two weeks for eight-week-therapy. The body weight, tumor volume, serum alkaline phosphatase (ALP) value, and serum midkine value were measured in each mouse every two weeks. After eight weeks of therapy started, the mice were killed and the tumors were dissected. Then, the tumor weight was measured and histological examination was preformed. In mice of non-treatment group, tumor volume significantly increased more than 30 fold of the initial volume and the value of serum ALP was also increased. In contrast, the tumor volume significantly reduced in mice of treatment group. In mice had the most obvious effectiveness by the siRNA, the tumor was almost disappeared and the value of serum ALP was not changed. Our results may suggest that the midkine siRNA is effective for tumor therapy in osteosarcoma.

CYP gene polymorphism is associated with essential hypertension in Koreans. *D. Shin, J. Han, Y. Bae, J. Ahn, S. Park, D. Choi, J. Ha, Y. Jang* Cardiovascular Genome Ctr, Yonsei Col Medicine, Seoul, Korea.

The cytochrome P450 (CYP) enzyme pathway produces arachidonic acid metabolites that are vasoactive, that effects on renal sodium handling and water transport. Recent studies have been proposed to play a mechanistic role in essential hypertension (EH). We preformed a case-control study to evaluate the presently controversial question of whether CYP gene polymorphisms are associated with hypertension in Koreans. We studied a sample population of 515 Koreans, comprising of 300 controls and 215 cases with EH, which were recruited from Cardiovascular Genome Center in Korea. We analyzed 7 single nucleotide polymorphisms (SNPs) of CYP genes [CYP3A4 (rs2246709, rs4646437 and rs4646440), 2C9 (rs1057910 and rs4918758), 2D6 (rs16947), and 2J2 (rs2280274)]. All subjects were genotyped for these variants with by SNP-IT assays using the SNPstream 25K System. The allele and genotype frequencies of CYP3A4 T16090C (rs2246709) polymorphism were significantly different between the hypertensive and the normotensive subjects (P = 0.0010, P = 0.0020). The CYP3A4 T16090C genotype, in comparison with the other CYP genotypes, was strongly associated with hypertension. In multiple regression analysis, the T allele was related to significant odds ratios for hypertension in a dominant model [0.645; 95% confidence interval (CI) = 0.453-0.919, P = 0.0150] and in a recessive model (0.365; 95% CI = 0.192-0.695, P = 0.0020), respectively. These findings suggest that the CYP3A4 T16090C polymorphism may be associated with regulation of blood pressure, and imply that this polymorphism is a protective factor for EH in Koreans. The functional role of CYP3A4 as a genetic contributor to hypertension susceptibility warrants further research.

Heterotopic ossification as a clue to the underlying pathogenesis of osteogenesis imperfecta type V. *L.H. Seaver[1,2], J. Brumblay[1], D.K. Kwock[2], K.N. Kon[1], R.M. DiMauro[1]* 1) Kapi'olani Medical Center for Women and Children, Honolulu, HI; 2) Department of Pediatrics, John A. Burns School of Medicine, Honolulu, HI.

Osteogenesis imperfecta (OI) type V is a recently recognized type of brittle bone disease characterized by mild to moderate fracture tendency, hyperplastic callus (HC) formation, ossification of the interosseous membrane (IOM) of the forearm, radial head dislocation, normal sclerae, radiodense metaphyseal band, unique bone histology and autosomal dominant inheritance. The genetic basis is unknown. The purpose of this report is to call attention to this rare type of OI and suggest that the heterotopic ossification is a clue to the underlying pathogenesis.

A previously healthy 6-month-old female presented with an acute rib fracture. Skeletal survey revealed additional healing rib fractures, osteopenia, vertebral compression of T9 and T11, slender diaphyses with flared metaphyses, subtle wormian bones and ossification of the interosseous membrane of the forearm bilaterally. Physical examination revealed length and weight at 10th centile, OFC 50th centile, large anterior fontanelle, slightly grey sclerae, but no radial head dislocation. Family history, physical examination and forearm radiographs of the parents were unremarkable. Collagen 1 synthesis and secretion was normal.

OI type V is unique, in that it is characterized by heterotopic ossification in the setting of osteopenia and bone fragility. Ossification of the IOM is striking and present in all reported cases. Similar changes can be seen in skeletal fluorosis, which is associated with heterotopic ossification of soft tissues and osteopenia in some cases. In vitro and animal studies have shown fluorosis stimulates activation and proliferation of osteoblasts and osteoblast-like tissue. HC can occur spontaneously in OI type V, without antecedant fracture. These observations suggest that the genetic basis and pathogenesis of OI type V may be due to a defect in regulation of bone development and mineralization by osteoblasts.

The combined effect of multiple common type 2 diabetes variants on disease risk. *H. Lango[1], E. Zeggini[2], T.M. Frayling[1], N.J. Timpson[2], C.M. Lindgren[2], K.S. Elliott[2], J.R.B. Perry[1], N.W. Rayner[2], R.M. Freathy[1], C.N. Palmer[3], A.D. Morris[3], A.T. Hattersley[1], M.I. McCarthy[2], M.N. Weedon[1], UK Type 2 Diabetes Genetics Consortium, The Wellcome Trust Case Control Consortium* 1) Peninsula Medical School, Exeter, UK; 2) University of Oxford, UK; 3) University of Dundee, UK.

Recently published genome-wide association studies have increased the number of confirmed common variants that influence risk of type 2 diabetes (T2D) to nine. Individually, the polymorphisms only moderately increase risk of disease (between ~10 to 40%) and they are thought to be unhelpful in assessing subjects risk clinically; however, the combined effect of these variants may allow the identification of subgroups of the population at substantially differing risk of disease. To assess the combined impact of these variants on T2D risk we assessed the impact of these nine variants in 3005 controls and 2655 cases from the population-based GoDarts study. Risk allele frequencies ranged from 0.27 to 0.90. Individual allele odds ratios ranged from 1.05 to 1.35. We found no evidence of deviation from additivity at individual SNPs (P0.01), and no evidence of gene-gene interaction (P0.01). There was an approximately multiplicative increase in odds of T2D with increasing numbers of risk alleles, with each additional risk allele increasing the odds of disease by 1.15 (1.12,1.18) times. The 3% of subjects with 12 risk alleles have an OR = 4.21 (2.80,6.33) against the 4% of subjects with 6 risk alleles. The area under the receiver operator curve, a measure of the discriminatory ability of these variants, was 0.59. This is lower than the 0.61 from the initial GWAS, probably reflecting an upward bias from the winners curse and enriched sampling, and falls short of the 0.75 considered clinically useful. In conclusion, many more T2D risk variants will need to be identified before genetic testing on a population-based level will be considered clinically useful; however, combining information from several known common risk polymorphisms does allow the identification of subgroups of the population with markedly differing risks of developing T2D.

Disease prediction with multiple common variants. *E. Ziv, D. Hu, L. Fejerman* Dept Medicine, Institute for Human Genetics, Comprehensive Cancer Center, Univ California, San Francisco, San Francisco, CA.

In the era of whole genome association studies, numerous common variants are being identified as risk factors for complex traits such as cancer, diabetes mellitus, and autoimmune diseases. One of the potential benefits of these discoveries is the identification of enough risk factors in the population to predict disease risk in pre-symptomatic individuals who can then receive preventive interventions. The effectiveness of such risk prediction depends on the predictive power of the combination of variants identified. We develop a framework to consider the risk prediction of a combination of common variants. We use the C-statistic, a commonly used measure of model discrimination, as our measure of predictive power of a multi-gene test. The C-statistic can be interpreted as the probability that an individual with disease is considered higher risk based on their risk score compared to an individual without disease. The C-statistic ranges between 0.5 (equivalent to chance) and 1 (perfect predictive power). It is equivalent to the area under the receiving operator characteristic (ROC) curve. We model a combination of common variants (allele frequency >3%) with moderate susceptibility (multiplicative RR: 1.1 - 2) each of which leads to a set value of the population attributable risk. We consider how, starting with the same population attributable risk, the number of variants, their frequency and their relative risk affects the C-statistic. We find that for a simple 1 gene model, the optimal C-statistic for any given population attributable risk is usually when the high risk allele is at a frequency of 0.1 - 0.2. We find that even for genes with high population attributable risk (0.5), the C-statistic is often low (<0.6). The framework that we develop can be used to judge the predictive utility of single gene and multi-gene tests for risk prediction.

Assessing biological pathways using genome-wide association data reveals evidence for excess association of variants in the cell cycle, Wnt signaling and Adherens Junction pathways with type 2 diabetes. *J.R.B. Perry[1], H. Lango[1], N.J. Timpson[2], E. Zeggini[2], R.M. Freathy[1], C.M. Lindgren[2], K.S. Elliott[2], N.W. Rayner[2], B. Shields[1], C.J. Groves[2], A.T. Hattersley[1], M.I. McCarthy[2], T.M. Frayling[1], M.N. Weedon[1]* 1) Peninsula Med School, Exeter, UK; 2) OCDEM, Oxford, UK.

Initial results from genome wide association studies indicate that many genuine risk alleles may not reach genome wide significance. This means replication is important and methods are needed to decide how best to prioritise SNPs for follow up. After selecting the most significant SNPs, one approach is to identify biological pathways where there was a significant excess of associations compared to that expected under the null distribution. The Wellcome Trust Case Control Consortium (WTCCC) recently completed a GWAS comparing 1924 UK type 2 diabetes patients and 2938 UK population controls using the Affymetrix GeneChip Human Mapping 500k Array Set. We used data from the WTCCC, and the Kyoto Encyclopedia of Genes and Genomes (KEGG) to test 198 human pathways. We totaled the trend test chi-sq for all SNPs in all genes (as defined by the NCBI and 25kb flanking sequence) in a KEGG defined pathway. This observed chi-sq total was compared to that of a distribution of 100,000 permuted chi-sq totals from an equivalent-sized random selection of genic SNPs from across the genome. The pathways showing the strongest association were the WNT signaling ($P<0.00001$), Adherens Junction ($P<0.00001$), and cell cycle ($P < 0.00001$) pathways. The WNT signaling and Adherens Junction pathway associations remained even when TCF7L2 variants were removed from the analyses ($P = 0.03$). The cell cycle pathway association was not explained by the recently identified CDKN2A/B or CDKAL1 signals ($P=0.00002$). There was no evidence for other candidate pathways, for example oxidative phosphorylation $P = 0.99$. In conclusion, identifying pathways with an excess of association signals may be an effective way of prioritizing SNPs for follow up of genome wide studies.

Pooling-based Genomewide Association Study Identifies Loci for Systemic Lupus Erythematosus. *T. Tahira[1], M. Masumoto[1], Y. Kukita[1], T. Horiuchi[2], K. Hayashi[1]* 1) Res Ctr Genetic Info, Med Inst Bioreg, Kyushu Univ. Fukuoka, Japan; 2) Med. and Biosys. Science, Grad. School of Med. Sciences, Kyushu Univ. Fukuoka, Japan.

A genetic predisposition has been implicated in the occurrence of systemic lupus erythematosus (SLE). IRF5 gene has been shown to strongly associate with the disease among Europeans. We confirmed this association in Asians, but the risk conferred by this variant is smaller in Asians compared to those in Europeans, due to lower frequency of the responsible allele. To identify other susceptibility genes, we carried out a genomewide screening by microarray genotyping analysis of pooled DNA of Japanese. Two case pools (n=264; n=183) and three control pools (n=426; n =253; n=432) were genotyped each for three times by Affymetrix 500K chip. The averaged median intensity signals for perfect-match probes were used to evaluate the allele frequency difference between cases and controls. Relative Allele Signal score (RAS) was used as quantitative major instead of absolute allele frequency, and the values for sense (RAS1) and antisense (RAS2) directions were independently evaluated. We calculated z-scores from the RAS values between case and control, and then evaluated them using a median score at sliding window sizes of 3, 5, 10, 20, and 40 SNPs. We selected 39 SNPs as candidate from the windows that showed high score. Quantitative PCR-SSCP analysis using the same set of pooled samples confirmed the association ($P < 10^{-4}$) for 12 SNPs in three regions. The strongest association was found for a SNP (rs17634369) in the intergenic region 23 kb upstream of IKZF1 (Ikaros) on chromosome 7p. This association was confirmed by individual genotyping of cases (n = 445) and controls (n = 679). Allelic OR was 1.56 (95% CI 1.32-1.84) and P-value was 1.5×10^{-7}. Ikaros proteins are zinc finger transcription factors that are considered master regulators of lymphocyte differentiation and its role in SLE pathogenesis indicated by this study should help understanding the disease mechanism. Association study using other Asian populations is in progress.

Identification of nuclear genes associated with mitochondrial functions by transcriptional profiling of human cell lines lacking mtDNA. *R. Mineri[1], N. Pavelka[2], P. Ricciardi-Castagnoli[2], M. Zeviani[1], V. Tiranti[1]* 1) Molecular Neurogenetics Unit, IRCCS Foundation Neurological Institute C. Besta, Milan, Italy; 2) Department of Biotechnology and Bioscience, University of Milano-Bicocca, Milan, Italy.

Mitochondrial biogenesis is under the control of two different genetic systems: the nuclear and the mitochondrial genome (mtDNA). To identify which nuclear transcripts were subjected to retrograde regulation in a mammalian system, we performed a comparative microarray analysis of global RNA expression profiles in two immortal human cell lines and in their rho cell derivatives, i.e. cells that had been completely depleted of mtDNA by exposure to ethidium bromide (EthBr) a DNA intercalating agent. Affymetrix HG-U133A GeneChips, designed to interrogate the expression of more than 22000 genes, were used to probe cRNAs extracted in triplicate from rho and parental cells. Using a highly stringent statistical approach, we identified 191 genes the expression of which was significantly and consistently different in both rho cell lines, versus their parental cell lines. In order to determine whether our gene cohort were significantly enriched in gene products associated with specific molecular functions, sub-cellular compartments or biological processes, we analyzed the functional annotations of the 191 differentially expressed transcripts by using their associated Gene Ontology terms. Four functional categories were identified: protein synthesis (14 genes), mitochondrial proteins (16 genes), mRNA processing (4 genes), and cell cycle and chromatin structure (12 genes). Three major achievements were obtained from this analysis indicating that the absence of mtDNA determines: i) a reduction of the cell replication rate, ii) a down-regulation of nuclear-encoded subunits of complex III of the respiratory chain and iii) a down-regulation of a gene described as the human homolog of Elac2 of E. coli, which encodes a protein that we show to also target to the mitochondrial compartment by standard immunofluorescence and mitochondrial import assays in transfected cell lines.

Global assessment of microRNA related variation on expression QTLs. *C.M. Lindgren[1,2], F. Pettersson[1], M. Jain[1,3], J.M. Taylor[1], J.L. Min[1], A.L. Gloyn[2], J.C. Barrett[1], J. Broxholme[1], M.I. McCarthy[1,2], K.T. Zondervan[1], L.R. Cardon[1]* 1) WTCHG, Oxford, UK; 2) OCDEM, Oxford, UK; 3) NHGRI, NIH, USA.

MicroRNAs (miRNAs) are endogenous, small noncoding RNAs that regulate target mRNA by binding to regulatory sites in 3 untranslated regions (UTR) of their targets. Genetic variation in miRNA sequences or their targets has been shown to disturb their interaction and result in diverse phenotypes spanning from massive meatiness in sheep to Tourettes syndrome in humans. We hypothesize that genetic variations in and immediately surrounding the 475 miRNA sequences are associated with expression quantitative trait loci (eQTL) in humans, which could subsequently contribute to various phenotypic differences. Thus, we tested the genotypes of 147 miRNA related single nucleotide polymorphisms (SNPs) in HapMap against expression levels from ~47,000 different gene transcripts collected from lymphoblastoid cell lines of 60 unrelated CEU HapMap individuals (public data, Stranger et al Science 2007) using linear regression. Nominally significant results were further tested in 90 Chinese and Japanese (CHB+JPT) and 60 Yoruba (YRI) unrelated HapMap samples. Our analyses in the CEU population show 42 SNPs that are nominally associated with 90 transcript levels ($p<10^{-5}$). Expression levels of two transcripts in the mitochondrial ribosomal protein gene L43 (*MRPL43*) are associated with a SNP (rs4919510) in the mature *miRNA-608* sequence ($p<10^{-6}$ & $p<10^{-8}$, respectively) of which one replicates in both the CHB+JPT ($p<10^{-13}$) and YRI ($p<10^{-13}$) populations, after Bonferroni corrections. The data indicates expression of *miRNA-608*, which is needed for regulation of target genes and *MRPL43* is non-conservatively predicted to harbor a *miRNA-608* binding site (RNA22, IBM). Thus, we report cis-regulation of *MRPL43* by variation located in the mature *miRNA-608* sequence replicated in replicated in three independent and ethnically diverse populations. Effects on eQTLs through genetic variation in miRNA could provide further insights to how they contribute to phenotypic variation, including disease susceptibility in man.

Third patient with paternal isodisomy for chromosome 7 and cystic fibrosis. *C. Le Caignec[1], B. Isidor[1], U. de Pontbriand[2], V. David[2], M.P. Audrezet[3], C. Ferec[3], A. David[1]* 1) Service de Genetique Medicale, CHU, Nantes, France; 2) Clinique Médicale Pédiatrique, CHU, Nantes, France; 3) Laboratoire de Génétique Moléculaire, CHU, Brest, France.

Many patients with maternal isodisomy of chromosome 7 (isoUPD7) have been described, mainly with intrauterine and postnatal growth retardation or with Silver-Russell syndrome. In contrast, only two cases of paternal isoUPD7 and cystic fibrosis have been reported. Here, we describe the third patient with paternal isoUPD7 and cystic fibrosis. At 3 years of age, the young girl had bronchitis with chronic respiratory disease and exocrine pancreas insufficiency. At clinical examination she had no dysmorphic features and normal growth and psychomotor development. A positive sweat chloride test confirmed the clinical diagnosis of cystic fibrosis. Molecular analysis of the CFTR gene showed homozygosity for the F508del mutation. Her father was heterozygous for the F508del mutation, while unexpectedly her mother did not carry the mutation, but was homozygous for the normal allele. For 16 informative microsatellite markers along the length of chromosome 7, the child was homozygous for one of the paternal alleles, whereas these alleles were absent from the mother. These results confirmed the paternal isoUPD7. At 6 years of age, her height and weight remained normal at +1 SD. She had normal psychomotor development. To date, only two cases of paternal isoUPD7 and cystic fibrosis have been published. The first patient (Pan et al. 1998) had two different recessive disorders, namely cystic fibrosis and primary ciliary dyskinesia with dextrocardia and situs inversus totalis. Pre and postnatal growth were normal. A homozygous F508del mutation with paternal isoUPD7 was identified in this patient. The second patient (Fares et al. 2006) developed severe postnatal growth retardation but this was most likely secondary to his serious medical problems. The child was homozygous for the G542X mutation but molecular analysis of his parents showed paternal isoUPD7. Together with our report, these findings support the hypothesis that paternal isodisomy for human chromosome 7 may have no phenotypic effect on growth.

Refinement of a candidate locus for dyslexia on chromosome 7q31-q34. *H. Matsson[1], K. Tammimies[1], H. Anthoni[1], M. Zucchelli[1], G. Schulte-Körne[2], J. Nopola-Hemmi[3], H. Lyytinen[4], M.M. Nöthen[5], A. Warnke[6], J.W. Gilger[7], G.W. Hynd[7], J. Kere[1, 8], M. Peyrard-Janvid[1]* 1) Dept of Biosciences & Nutrition, Karolinska Institute, Huddinge, Sweden; 2) Dept of Child & Adolescent Phychiatry and Psychotherapy, Univ of Marburg, Germany; 3) Dept of Pedriatrics, Jorvi Hospital, Finland; 4) Dept of Psychology & Child Reasearch Center, Univ of Jyväskylä, Finland; 5) Dept of Genomics, Life & Brain Center, Univ of Bonn, Germany; 6) Dept of Child & Adolescent Psychiatry and Psychotherapy, Univ of Würzburg, Germany; 7) Collage of Education, Dept of Educational Studies, Purdue Univ, West Lafayette, IN, USA; 8) Dept of Medical Genetics, Biomedicum, Univ of Helsinki, Finland.

Dyslexia is the most common childhood learning disorder and may have significant social consequences from early school years throughout life. The specific reading and spelling deficits are manifested in spite of normal intelligence, senses, education and social environment. At least nine loci (DYX1-9) contributing to dyslexia phenotypes have been mapped. We recently identified two genes from the DYX3 locus, C2ORF3 and MRPL19, associated with dyslexia and currently there are six candidate genes described. Our previous genome scan (Kaminen et al. 2003) suggested linkage to chromosome 7q31-q34 with a non-parametric linkage (NPL) score of 2.8 in 11 Finnish families with dyslexia as categorical diagnosis. Next, a more detailed analysis restricted the linkage peak to approximately 12 cM (max. NPL=2.5). In order to replicate these findings in an independent population we then genotyped 10 microsatellite markers throughout the region using 251 German families with a total of 429 dyslectics. The results did not support linkage of the markers to the German samples. To pinpoint the risk variants in the linked region suggested by the Finnish sample set, we have now saturated a 20 Mb region on chromosome 7q31-q34 with 158 SNPs, all with a minor allele frequency >0.25. Potential candidate genes were selected on the basis of known functions in brain development affected in dyslexia and were specifically targeted with tagging SNPs. We are currently analysing the genotyping results from 280 individuals of both Finnish as well as US origins.

Evolutionary analysis of pre-synaptic genes. *L. M. Pardo[1], Z. Bochdanovits[1], R. Toonen[2], M. Verhage[2], P. Heutink[1]*
1) Section Medical Genomics, Department of Clinical Genetics, VU University Medical Center, 1081 BT Amsterdam, The Netherlands; 2) Department of Functional Genomics, Center for Neurogenomics and Cognitive Research (CNCR), Vrije Universiteit (VU) Amsterdam and VU University Medical Center, 1081 HV Amsterdam, The Netherlands.

Single Nucleotide Polymorphisms (SNPs) are the most common source of genetic variation in humans, but only a fraction of these has effects on human traits. From an evolutionary perspective, gene variants with an effect on the fitness of individuals will deviate from a pattern of neutral evolution. Natural selection is one of the forces behind the departure from neutral molecular evolution of gene variants, and has been shown to be relevant in humans. A robust approach to measure the effect of natural selection is to estimate the ratio of non-synonymous to synonymous substitutions (denoted as w) in a protein-coding gene across different species. A ratio significantly different from 1 indicates that selective pressures operate on the gene or at specific amino acid residues. This approach may be used to choose candidate SNPs to test in association with specific human traits. We are analyzing the protein coding regions of more than 200 presynaptic genes to estimate the selective pressure at individual codons. We chose 279 human presynaptic proteins to study in relation to human behaviour-like traits. These protein sequences were used to BLAST the RefSeq protein database to retrieve putative vertebrate orthologs. The orthologous coding sequences were aligned using CLUSTALW and MUSCLE. To estimate w we used codon-based maximum likelihood methods implemented in PAML that allows the estimation of w under different models of evolution (negative, neutral and positive selection). Our analysis showed that although several genes are under strong selective constraint, w is not constant across sites. In addition, for other genes we observed a few residues that were subjected to positive selection. Our results suggest that this approach may be used to identify a priori candidate functional SNPs related to common diseases for association studies.

VEGF gene increases susceptibility to endometriosis. *W. Y. Lin[1], S. H. Juo[1,3], R. Wu[1], C. Y. Long[4], E. M. Tsai[2,4]* 1) Institutes of Medical Genetics, Kaohsiung Medical University , Kaohsiung, Kaohsiung, Taiwan; 2) Graduate Institute of Medicine; 3) Department of Medical Research; 4) Department of Obstetrics and Gynecology, Kaohsiung Medical University Hospital, Kaohsiung, Taiwan.

Background: It is believed that angiogenesis is essential for the development of endometriosis. Vascular endothelial growth factor (VEGF) is believed to be a pivotal angiogenic factor with endothelial cell-specific mitogenic and vascular permeability activities. We conducted a case-control study to test whether the polymorphisms of the VEGF gene increase susceptibility to endometriosis. Methods: Three common functional polymorphisms were chosen, which were -2578C/A (rs699947), -634G/C (rs2010963), and +936C/T at the 3UTR (rs3025039). We recruited 120 patients with endometriosis and 400 women free of the disease. The diagnosis of endometriosis was based on both clinical and pathology evidence. The data were analyzed by multivariate regression analysis with adjustment for age, parity and body mass index. Haplotype analyses with adjustment for covariates were performed using the Hap-Clustering program. Results: All the 3 SNPs were in Hardy-Weinberg equilibrium. The genotypic distributions of promoter SNP rs2010963 were significantly different between cases (40% GG, 52.5% GC and 7.5% CC) and controls (36.8% GG, 46.8% GC and 16.4% CC). We found that the C allele carriers of this SNP had a lower risk for endometriosis (CC vs GG adjusted OR=0.34; p =0.02, and CG vs GG adjusted OR=0.77; p=0.35). Since the C allele appeared to have a dose effect, we further calculated the C allele genetic effect assuming an additive model. The result demonstrated an adjusted OR for C allele of 0.64 (p=0.028). The other two SNPs did not yielded any significant results. The haplotype composed by the two promoter SNPs (rs2010963 and rs699947) did not yield a better result (global p=0.08) than the result from the significant SNP rs2010963. Similarly, the haplotype analysis based on all three SNPs did not show significant results. Conclusions: The present study showed that the promoter SNP at VEGF may confer risk for endometriosis.

Spatiotemporal expression in mouse brain of *Kiaa2022*, a gene disrupted in two patients with severe mental retardation. *A.M. Lossi[1], V. Cantagrel[1], R. Haddad[1], P. Ciofi[2], D. Andrieu[3], L. van Maldergem[4], J.C. Roux[1], L. Villard[1]* 1) Faculté de Médecine, INSERM U491, Marseille, France; 2) INSERM U378, Bordeaux, France; 3) CNRS UMR6156, IBDML, Campus de Luminy, Marseille, France; 4) Centre de Génétique Humaine, Université de Liège, Liège, Belgium.

We previously reported two male patients suffering from severe mental retardation in whom the *KIAA2022* gene was disrupted by an intrachromosomal rearrangement and no longer expressed. Virtually nothing is known about the function of *KIAA2022*, encoding a predicted protein of 1516 aminoacids with no homology to other known proteins. Therefore, to better understand the function of *KIAA2022* in brain function, we have cloned its murine ortholog, *Kiaa2022*. We have determined its genomic structure and we have studied its expression during mouse development. Using quantitative RT-PCR and in situ hybridization, we show that *Kiaa2022* is preferentially expressed in the central nervous system although its transcript can also be detected in other tissues. The expression of *Kiaa2022* is temporally and spatially regulated. It is initially detected at E11 in postmitotic neurons of the central nervous system. The expression increases rapidly during the development to reach a maximum at P3 where *Kiaa2022* is expressed in the hippocampus, the entorhinal cortex and very strongly in the ventral premammillary nucleus. After P3, the expression of *Kiaa2022* decreases rapidly and is maintained at low levels during adulthood. These results suggest that *Kiaa2022* plays a role in postmitotic neurons during brain development.

The direct characterisation of breakpoints : a new approach for the segregation analysis of paracentric inversions in human sperm. *S. Bhatt[1, 5], K. Moradkhani[3, 5], K. Mrasek[4], J. Puechberty[1, 3], G. Lefort[3], J. Lespinasse[6], P. Sarda[3, 5], T. Liehr[4], S. Hamamah[1,2,5], F. Pellestor[1,2,5]* 1) INSERM U847, Montpellier, France; 2) Departement of Reproduction Biology, CHU Montpellier, Montpellier, France; 3) Department of Medical Genetics, CHU Montpellier, Montpellier, France; 4) Institute of Human Genetics and Anthropology, Jena, Germany; 5) University of Montpellier I, Montpellier, France; 6) Laboratory of Cytogenetics, CHR Chambery, Chambery, France.

We report the sperm FISH analysis of two paracentric inversions of chromosome 14 and chromosome 5, based on the direct breakpoint identification by the use of BACs spanning the inversion breakpoints. Sperm analysis was performed by multicolor FISH. Total of 7670 and 4807 spermatozoa were scored for inv(14) and inv(5) respectively. The breakpoints for inv(14) case were found to be in 14q23.2 and 14q32.13. The breakpoints for inv(5) case were found to be in 5q13.3 and 5q33.1.The breakpoints for both inversions were found to be in G light region. The inverted segment length for inv(14) was 31 Mb and 29% of the total length of the chromosome was involved in the inverted segment. The frequency of sperm harbouring normal, inverted, deleted, duplicated chromosome 14 was found to be 49.62%, 46.66%, 3.43% and 0.29% respectively. The inverted segment length for inv(5) was 75 Mb and 42% of the total length of the chromosome was involved in the inverted segment. The frequency of sperm harbouring normal, inverted, deleted, duplicated chromosome 5 was found to be 45.64%, 44.67%, 8.73%, 0.96% respectively.This study shows that the breakpoint characterisation could be an efficient approach for segregation analysis of paracentric inversion. Using the BACs spanning the breakpoints, the percentage of normal, inverted, duplicated deficiency and deleted segregation product could be accurately estimated.*Supported by a INTAS research grant (03-51-4060)* .

Height as the exemplar polygenic trait: a genome-wide association study of 10,737 UK individuals reveals multiple loci of small effect. *M. Weedon[1], C. Lindgren[2], R. Freathy[1], C. Wallace[3], G. Lettre[4], D. Evans[5], M. Mangino[6], S. Stevens[6], A. Hall[6], N. Samani[6], W. Ouwehand[5], J. Hirschhorn[4], M. Caulfield[3], P. Munroe[3], A. Hattersley[1], M. McCarthy[2], T. Frayling[1], Cambridge GEM Consortium, The Height-Genetics Consortium* 1) Peninsula Medical School, Exeter, UK; 2) University of Oxford, UK; 3) Barts and the London, UK; 4) Broad Institute, US; 5) University of Cambridge, UK; 6) Blood Services and University of Cambridge Common Controls, UK.

Human height is a classic polygenic trait but the genes responsible remain largely unknown. The recent and increasing availability of data from genome-wide association studies (GWAS) offers new opportunities to identify genes influencing height. These genes may provide important insights into how best to dissect the genetics of polygenic quantitative traits. Initial data from 4921 GWAS subjects, together with 29000 individuals in replication studies, show that rs1042725 of HMGA2 associates with height ($P4x10^{-16}$). In the initial scan only HMGA2 had a $P 5x10^{-7}$. To identify further genetic variants influencing adult height we extended our analyses to 10737 people from the WTCCC and an obesity case control study. We performed an inverse-variance meta-analysis of within-sex Z-score summary statistics for 432030 SNPs genotyped on the Affymetrix 500K chip. We identified eight independent signals at $P5x10^{-7}$. Effect sizes ranged from ~0.53 to 0.65 cm per allele. The most strongly associated variant ($P=1x10^{-13}$) is located in ZBTB38. Combining information from these eight signals showed that they explained 3% of the variance of height, with a ~5cm difference in height between the 4% of people with 5 height increasing variants compared to the 5% of people with 10. Multiple lines of evidence, including principal components analysis, demonstrate that the associations are not due to population stratification. These results suggest that by analyzing GWAS data from many thousands of individuals, it will now be possible to dissect the genetics of this classic, highly heritable polygenic trait. Combining data from multiple GWAS is a powerful approach to identifiying polygenic variants.

A Bayesian multipoint allele sharing method for genome-wide studies. *Z. Su, P. Donnelly, J. Marchini* Department of Statistics, University of Oxford, Oxford, Oxfordshire, United Kingdom.

Genome-wide association studies are set to become the method of choice for uncovering the genetic basis of human diseases. For complex traits, we expect the effect sizes of the underlying risk variants to be relatively small. Environmental effects, allelic heterogeneity and failure to type the causal locus will introduce substantial noise into the relationship between phenotype and genotype. It is therefore important to develop statistical methods that can extract as much information from the data as possible to detect the causal locus. The literature in this area is large and complex; there is no consensus on the best method and often powerful methods are computational intractable for large-scale association studies. We present a novel approach to association testing that is applicable to large-scale genotype data and is more powerful than popular methods currently available to detect disease causing variants.

Our approach is based on the idea of measuring allele sharing between individuals in the study and is analogous to the IBD methods used in linkage analysis. We calculate the extent of allele sharing at all typed and untyped variants across a region and use novel Bayesian methods of testing for association that are robust to allelic heterogeneity. A novel aspect of our method is that we condition upon a fine-scale recombination map so that allele sharing at a given locus is measured using information from all markers, but in a way that decreases with genetic distance from the locus. This avoids the decision faced by some other methods as to how many markers to use, or how to use them, or over what physical distance to define haplotypes for haplotype analyses.

We have found that our approach provides a marked boost in power (5-20% increase) over single-SNP and multi-marker prediction based approaches for a single-SNP model of disease risk and can be even more powerful under a model of allelic heterogeneity. We illustrate our method using the genome-wide association studies carried out as part of the Wellcome Trust Case-Control Consortium (WTCCC).

Genome-wide linkage study for INSULIN RESISTANCE in an isolated population of Mongolia. *H. Park[1], Y.S. Ju[1], J.S. Seo[1,2]* 1) Department of Biochemistry and Molecular Biology, Seoul National University College of Medicine, 28 Yongon-Dong, Chongno-Gu, Seoul 110-799, KoreaDept Biochemistry, Seoul National Univ, Seoul, Korea; 2) Macrogen Inc., Korea.

As metabolic syndrome has been spotlighted in the field of medical science recently, insulin resistance has become one of the most interesting subjects. Metabolic syndrome is known as major risk factor of cardiovascular disease, which is very prevalent not only in western society, but also in developing countries. Metabolic syndrome includes type 2 diabetes mellitus, hypertension, hyperlipidemia, obesity and other abnormalities. These disorders coexist frequently, and it is suggested that there is common pathophysiological background among them, which is insulin resistance.

We have analyzed data with Mongolian individuals from large extended families in genetically isolated population. A total of 1029 individuals (441 males and 588 females) from 196 families were enrolled. After genotyping by use of 389 microsatellite markers, we performed a genome-wide linkage search with variance component analysis. We calculated Homeostasis Model Assessment II(HOMA II) index as an indicator of insulin resistance.

Variance component analysis provided estimates of heritability of insulin resistance, revealing insulin resistance was under significant genetic influences. The overall heritability of the insulin resistance cholesterol was 0.40. We found several significant quantitative locus of traits. Among them, the locus with highest LOD score was on chromosome 14q11-12 with LOD score 2.29.

Further analysis of these positive regions by fine mapping and association analysis is warranted to identify specific genes. To our knowledge, this study represents the first genome-wide linkage scan for insulin resistance in an Asian in the region of Asia.

***SLC26A3* and *CFTR* variants in men with unknown infertility.** *S. Wedenoja[1,2], O. Hovatta[3], J. Toppari[4], C. Holmberg[2], J. Kere[1,3], P. Höglund[1]* 1) Department of Medical Genetics, University of Helsinki, Helsinki, Finland; 2) Hospital for Children and Adolescents, University of Helsinki, Helsinki, Finland; 3) Department of Biosciences at Novum, Karolinska Institute, Huddinge, Sweden; 4) Department of Physiology, University of Turku, Turku, Finland.

A rare autosomal recessive disease congenital chloride diarrhea (CLD) is caused by mutations in the solute carrier family 26 member 3 (*SLC26A3*) gene. It is located on chromosome 7q22-31.1, near the cystic fibrosis transmembrane conductance regulator (*CFTR*) gene, and it encodes for an apical epithelial Cl^-/HCO_3^- exchanger. As for duodenum and ductal systems, interaction between the STAS domain of SLC26A3 and the R domain of CFTR stimulates the activity of both transporters, resulting in increased epithelial secretion of HCO_3^- and fluid. SLC26A3 and CFTR show highly similar expression profiles at multiple sites of the male reproductive tract. CLD-males with the homozygous Finnish founder mutation V317del are subfertile, possessing a low concentration, and poor motility and morphology of sperm, high seminal plasma Cl^- with a low pH, and spermatoceles. Although the major cause of male infertility in cystic fibrosis is absence of the vas deferens, a low seminal plasma pH and poor sperm quality emerge. The mildest manifestation of homozygosity, or even heterozygosity, for *CFTR* mutations is male infertility. We aimed to study whether *SLC26A3* variants - alone or together with those of *CFTR* - are associated with unknown male infertility. Direct sequencing of *SLC26A3* exons in men with unknown infertility (n=138) and controls (n=211) revealed 7 novel heterozygous variants: 2 in the promoter and 5 in exons. Among males with unknown infertility, an increased frequency of carriership of any *SLC26A3* variants (p=0.008), or coding variants (n=4) alone (p=0.03) or together with one 5T allele of *CFTR* (p=0.06) emerged. *CFTR* mutations were excluded by appropriate assays. *SLC26A3* variants may be associated with idiopathic male infertility. Functional role of the novel variants is unknown. One infertile man carried, however, both 5T allele of CFTR and V317del mutation for CLD, which both account, in a homozygous form, for male subfertility.

Novel *MFSD8* mutations in variant late-infantile neuronal ceroid lipofuscinosis. *E. Siintola[1,2], M. Kousi[1,2], M. Topcu[3], N. Aula[1,2], H. Lohi[1,4], B.A. Minassian[4], A.D. Paterson[4,5], X.-Q. Liu[4], C. Wilson[6], U. Lahtinen[1,2], A.-K. Anttonen[1,2], S.E. Mole[7], A.-E. Lehesjoki[1,2]* 1) Folkhälsan Institute of Genetics, Finland; 2) Neuroscience Center, University of Helsinki, Finland; 3) Department of Pediatrics, Hacettepe University, Faculty of Medicine, Section of Child Neurology, Turkey; 4) Genetics and Genome Biology, Hospital for Sick Children, Toronto, Canada; 5) Department of Public Health Sciences, University of Toronto, Canada; 6) Starship Childrens Hospital, Auckland, New Zealand; 7) MRC Laboratory for Molecular Cell Biology, University College London, United Kingdom.

Neuronal ceroid lipofuscinoses (NCLs) are a group of childhood-onset inherited neurodegenerative disorders of which the late-infantile onset group (LINCLs) is genetically the most heterogeneous with mutations identified in five genes. LINCL presents clinically with onset at 2-7 years of age, epileptic seizures, myoclonus, psychomotor deterioration, loss of vision, and premature death. A variant form of LINCL (vLINCL) in Turkish patients was initially considered a distinct clinical and genetic entity (CLN7). Recently, we reported mutations in the *CLN6* and *CLN8* genes in a subset of Turkish patients with vLINCL. In the majority of families, however, the disease is not linked to any of the known NCL loci. After a genome-wide single nucleotide polymorphism scan, homozygosity mapping, and candidate gene sequencing in mainly Turkish families, we identified mutations in the *MFSD8* gene as a novel gene underlying vLINCL. MFSD8 is a novel lysosomal transmembrane protein that belongs to the major facilitator superfamily, members of which have various transporter activities. The substrate specificity and the cellular function of the protein encoded by this novel NCL gene are not known. Subsequently, we have screened the *MFSD8* gene in several additional families with vLINCL and identified new mutations accounting for the disease in patients of various ethnic origins. This implies that MFSD8-associated vLINCL is not limited to the Turkish population.

Evidence for spontaneous chromosome breakage syndrome in a case of multiple early-onset tumors of the genitourinary tract. *N. Le Meur[1], A. Rossi[1], B. Resch[2], S. Baert-Desurmont[3], T. Frebourg[3]* 1) Laboratory of Cytogenetics, EFS-Normandy, Bois-Guillaume, France; 2) Department of Gynecology, University Hospital, Rouen, France; 3) Department of Genetics, University Hospital, Rouen, France.

A 39 years old patient simultaneously presented a large squamous cell cervical carcinoma, a chromophobe renal cell carcinoma and a low grade vesical tumor. Her father developed an head and neck tumor at the age of 58 and her mother died from lung metastasis of unknown origin at age 59. There was no other familial history of cancer. This remarkable tumor association led us to perform a caryotype because constitutional chromosome 3 translocations have been described in hereditary forms of renal cancer, although of the clear cell type. Unexpectedly, chromosome analysis, performed on peripheral blood lymphocytes, revealed in 53% of the cells, multiple structural chromosomal aberrations including translocations, inversions, deletions and dicentric chromosomes. Most chromosomes were involved in the rearrangements. The level of chromosome breakage was not increased by alkylating agents. Fanconi anemia (FA) is a clinically heterogeneous disorder characterized by congenital malformations, progressive bone marrow failure, and predisposition to malignancies, especially acute myeloid leukaemia and squamous cell carcinoma mostly of the head, neck, and esophagus. Early-onset squamous-cell carcinoma of the lower female genital tract have already been reported in some patients with FA. The association of early-onset multiple primary tumours including squamous cell cervical carcinoma and multiple structural chromosomal aberrations in this patient is strongly suggestive of a Fanconi disease, even in the absence of a typical phenotype and even if the rate of chromosomal rearrangement did not increase in presence of cross-linking agents, considering the possibility of somatic mosaicism. Western blot analysis of FANCD2 ubiquitination is underway. This case report highlights the importance to perform caryotype analysis in patients presenting early-onset primary tumours which cannot be explained by a known mendelian form of cancer.

Identification of sequence variants in miRNA target sites of NTRK3 associated to anxiety disorders. *M. Muinos-Gimeno[1], M. Guidi[1], B. Kagerbauer[1], M. Gratacòs[1], R. Martín-Santos[2], M. Torrens[2], M.P. Alonso[3], J.M. Menchón[3], X. Estivill[1, 4], Y. Espinosa-Parrilla[1]* 1) Genes and Disease Program, CeGen and CIBERESP (CRG-UPF); 2) Pharmacology Research Unit and Psychiatry Department, IMIM-Hospital del Mar; 3) Psychiatry Department, Hospital Bellvitge; 4) Pompeu Fabra University, Barcelona, Catalonia, Spain.

Neurotrophins and their receptors have been implicated in the pathophysiology of anxiety disorders. Genetic and functional data point to the neurotrophin-3 receptor gene (*NTRK3*) as a candidate for psychiatric disease. Post-transcriptional regulation by miRNAs has been recently shown to contribute to the differential regulation of *NTRK3* isoforms. The requirement of a perfect base pairing between the miRNA seed region and its target mRNA, indicates that allelic variants in target sites could contribute to susceptibility to disease. We suggest that functional allelic variants at 3'UTRs of *NTRK3* may be predisposing to anxiety disorders. Interrogation of the 3UTRs of two different *NTRK3* isoforms for miRNA target sites using TargetScan, miRanda and PicTar prediction programs resulted on 65 miRNAs as candidate regulators of *NTRK3*. Re-sequencing of 5 kb corresponding to two different 3'UTRs of *NTRK3* isoforms was performed in DNA samples of 60 patients with panic disorder and 60 patients with obsessive-compulsive disorder (OCD). Twelve new allelic variants and 2 known SNPs were identified, 5 in predicted target sites for 6 different miRNAs on the truncated isoform. Three of these allelic variants are located within the seed region and are thought to disrupt the repression of the *NTRK3* gene by the predicted miRNA. Functional validation of these 6 putative miRNA target sites was performed by dual luciferase assays in HeLa cells. Case-control studies, in 450 patients with different types of anxiety disorder and 350 controls, revealed that one of the variants was only present in a patient with panic disorder and none of the controls. Moreover, association of another *NTRK3* miRNA variant to OCD hoarding type was shown. Functional mutagenesis studies are being performed. Supported by Spanish Government (FI05/00061,R&C program) and Generalitat de Catalunya.

Efficiency of microsatellite markers in linkage disequilibrium mapping for a disease variant. *J. Ohashi* Dept Human Gen, Grad Sch Med, Univ Tokyo, Tokyo, Japan.

Linkage disequilibrium (LD) mapping for identifying a disease variant has been applied to candidate gene approach and genome-wide screening in association studies. Two genetic markers, single nucleotide polymorphism (SNP) and microsatellite markers, can be used for LD mapping. Although SNP markers, which are the most abundant genetic marker in the human genome, are suitable for detecting a common disease variant with high population frequency, common SNP markers with minor allele frequency (MAF) of more than 15% are hard to detect a rare disease variant due to the low LD between the two loci (i.e., low r2). For such a rare variant, microsatellite marker with multiple alleles may show high statistical power in association studies because one of alleles may be in strong LD with the variant. However, as the number of alleles at microsatellite marker increases, the statistical power may decrease due to the increase in degree of freedom in the chi-square test for comparing allele frequencies between cases and controls. This largely depends on the relationship or LD structure between the microsatellite marker and the disease variant. In this study, taking the LD structure achieved by population history (e.g., random genetic drift, mutation, and recombination) into consideration, we examined the efficiency of microsatellite markers in LD mapping for disease variant. We have used the SelSim software developed by Spencer and Coop (2004) to obtain the simulated haplotype data under the assumption of a symmetric single step mutation model for a microsatellite marker. Our calculations show that microsatellite markers with high mutation rate (e.g., 10-3 per transmission) have more power to detect LD, regardless of the allele frequency of the disease variant, than do microsatellite markers with low mutation rate (e.g., 10-5 per transmission) under otherwise equivalent conditions. The present results suggest that microsatellite markers with multiple alleles can detect LD with a closely located disease variant with low allele frequency.

Newborn Screening for Pompe Disease using tandem mass spectrometry. *K. Tuschl[1], A. Muhl[1], J. Keutzer[2], K. Zhang[2], J. Orsini[3], V. DeJesus[4], O.A. Bodamer[1]* 1) General Pediatrics, University Children's Hospital , Vienna, Austria; 2) Genzyme Inc, Boston; 3) New York State Laboratory, Albany; 4) CDC, Atlanta.

Background: With the advent of novel treatment modalities in lysosomal storage diseases (LSD) such as bone marrow transplantation and/ or enyzme replacement therapies, newborn screening for LSD has become a focus point. From a technological perspective high-throughput newborn screening for LSD may be feasible using different analytical approaches. Among these, screening by tandem-mass spectrometry using unique, specific substrates and internal standards seems to be the most promising method as enzyme activities can be readily measured in dry blood spots from neonatal filter cards. In particular newborns with Pompe Disease are amenable to early enzyme replacement therapy and would potentially benefit the most from newborn screening. Methods: Routine neonatal screening filter cards were punched into 96 well plates and extracted with methanol. Unique Pompe specific substrate and internal standard were added to the solution and the plates incubated overnight at 37OC. Following liquid/liquid and solid phase extraction steps 10 l of solution were injected into the MS/MS. The formation of product and internal standard were monitored using MRM. Results: GAA activity in 1560 dry blood spot samples: 15.50 + 7.86 umol/l/h; median 14.06; GAA activity in 3 adult Pompe Disease: mean 0.37 umol/l/h (0.16-0.93); median 0.19. Conclusion: Although newborn screening for Pompe Disease using MS/MS may be technically feasible, additional pilot studies have to demonstrate its validity, sensitivity, specificity and the potential to multiplex with additional LSD. In addition, strategies for confirmatory testing, treatment, follow-up care and scientific evaluation have to be defined and agreed upon at an international level.

Heterogenous and differential spectrum of mutations in CFTR gene in Indian Cystic fibrosis and obstructive azoospermia population. *R. Prasad[1], N. Sharma[2], G. Kaur[3], S. Singh[4], N. Acharya[5], M. Singh[6]* 1) Biochemistry, PGIMER, Chandigarh, India; 2) 1; 3) Physiology, GMCH, Chandigarh, India; 4) Urology, 1; 5) 4; 6) Pediatrics,1.

Cystic fibrosis (CF) is caused by mutations in the gene encoding the cystic fibrosis transmembrane conductance regulator (CFTR) gene. We conducted a study to characterize mutations in the CFTR gene in Indian CF and obstructive azoospermia population. Fifty CF and 25 obstructive azoospermia subjects were included. Obstructive azoospermia patients had no clinical symptoms of CF, except unilateral/bilateral absence of vas deferens. Age at the time of diagnosis was significantly higher in CF patients. Sweat chloride was raised in 47 CF and 14 azoospermia subjects. Mutation analysis was performed on genomic DNA isolated from peripheral blood of CF patients. Sixteen substitution, 3 deletion, 3 insertion, 1 splice site, 2 nonsense and 2 intronic mutations were detected. Delta F508, the most common mutation, had a frequency of 24.0% in Indian CF population. However, increased number of patients (n=18) were found heterozygous for deltaF508 mutation in obstructive azoospermia population. Other mutations like G551D, R553X, N1303K, R117H and 3849+10kbC-T had a frequency less than 2%. On SSCP and direct sequencing, mutations detected were 1161 del C, 3986 delC, 1580 Ins A, 1792 Ins A, 4333InsG, L69H, F87I, G126S, F157C, S158N, Q493L, Y517C, V520F, I530L, S549N, E1329Q, Y1381H, 3120+1G-A, L218X, R553X, 876-4delACAG. Nine mutations were found novel. Genotype-phenotype correlation indicated that Class I, II and III mutations were severe. Haplotyping revealed that all analysed delta F508 chromosomes carried the same KM19-GATT-M470V-T854T-TUB20 haplotype. We report a heterogenous and differential spectrum of mutations in CFTR gene in CF and obstructive azoospermia cases. We confirm the existence of CF in Indian population and it is proposed that decreased incidence of delta F508 mutation among CF patients is due to under diagnosis, environmental differences, dietary factors and the role of modifier genes.

Characterization of susceptibility locus for preeclampsia on chromosome 2p25. *H. Peterson[1], H. Laivuori[2], K. Kivinen[3], E. Kerkelä[4], H. Jiao[1], V-V. Mäkelä[1], L. Hiltunen[5], R. Kaaja[6], O. Ylikorkala[6], V. Rasi[5], J. Kere[1]* 1) Dept of Biosciences and Nutrition, Karolinska Institute, Sweden; 2) HUSLAB Dept Clinical Genetics, Finland; 3) The Wellcome Trust Sanger Institute, Cambridge, UK; 4) Institute for Regenerative Medicine, University of Tampere, Finland; 5) Finnish Red Cross Blood Service, Finland; 6) Dept of Obstetrics and Gynecology, Helsinki University Central Hospital, Finland.

Preeclampsia is a pregnancy-specific, potentially life-threatening disease characterized by hypertension and proteinuria. Its cause remains unknown, but the epidemiology of preeclampsia suggests a partially genetic basis for the disorder. We have previously mapped three candidate susceptibility loci for preeclampsia on chromosomes 2p25, 4q32 and 9p13 (Laivuori et al. 2003) and verified linkage to the chromosome 2 locus by adding microsatellites at 1 cM intervals (NPL score 4.09, p= 0.00036). Our aim since has been to evaluate potential candidate genes within our linked regions as well as to assess other previously reported susceptibility loci for preeclampsia. A recent report suggested association of the STOX1 gene on chromosome 10q22.1 with preeclampsia in the Dutch population (van Dijk et al. 2005), but we were unable to validate STOX1 as a common preeclampsia susceptibility gene (Kivinen et al. 2007). Within our 1.4 Mb linkage region on 2p25, SNPs covering five genes were genotyped in a Finnish nationwide sample set consisting of 340 cases and 350 matched controls. Haploview was used to calculate single-marker and haplotype associations and three genes were selected for sequencing based on the association results and functional information. Sequencing of one gene in revealed 20 variations, five of which were selected for genotyping in the nationwide sample set and in a data set containing 100 cases and 100 controls from Finland. Unfortunately, association analyses were inconclusive and do not support strong genetic effect in this gene. However, we are underpowered to detect more common variants with weaker genetic effects and are in progress of collecting a nationwide data set with at least 1500 trios with affected mother and 1500 matched control trios.

Analysis of X chromosome inactivation in autism spectrum disorders. *E. Maestrini[1], X. Gong[2], F. Blasi[1], E. Bacchelli[1], C. Toma[1], DM. De Luca[1], M. Rossi[3], I. Jarvela[3], T. Bourgeron[2], The International Molecular Genetics Study of Autism Consortium (IMGSAC)* 1) Dept Biology, Univ Bologna, Italy; 2) Institute Pasteur, Paris, France; 3) Dept of Medical Genetics, Univ Helsinki, Finland.

Autism spectrum disorders (ASD) are a group of complex neurodevelopmental disorders more frequent in males than females, with an approximate ratio of 4:1. Skewed X chromosome inactivation (XCI) is observed in females carrying mutations involved in several X-linked disorders. In this study, we aimed to estimate the role of X-linked genes in ASD susceptibility by ascertaining the XCI pattern in a large sample of mothers of children with ASD. The study sample included 547 informative mothers of ASD children (256 multiplex and 290 singleton families) and 181 affected females, from the Paris Autism Research International Sib-pair study, the Finnish study group for ASD, and the IMGSAC. The control group included 144 adult females with a similar age distribution to the mothers group. To determine the pattern of XCI we examined the differential methylation status of the human androgen receptor gene. We did not identify a different distribution of skewed XCI rate between mothers of affected children and the control group. Interestingly, two mothers and one girl carrying known mutations in X-linked genes (NLGN3, ATRX, MECP2) showed highly skewed XCI, suggesting that ascertainment of XCI could reveal families with X-linked mutations. Linkage analysis was carried out in the subgroup of multiplex families with skewed XCI (80:20), using the available Affymetrix 10K SNP data generated by the Autism Genome Project (AGP). No significant linkage was detected in this subgroup, and only a modest increased allele sharing was detected in the Xq27-Xq28 region. Mutation screening of MECP2 failed to identify any causative mutations in the skewed XCI subgroup. In summary, our results suggest that there is no major X-linked gene subject to XCI conferring susceptibility to ASD. However , the possibility that rare mutations in X-linked genes could contribute to ASD cannot be excluded. We propose that the XCI profile could be a useful criteria to prioritize families for mutation screening of X-linked candidate genes.

Status of HFE and other iron homeostasis gene in iron overload thalassemia patients and liver cirrhotic patients in India. *D. Tiwari, S. Agarwal* Genetics, Sanjay Gandhi post graduate Institute of Medical S, Lucknow, U.P, India.

Hereditary hemochromatosis is an autosomal recessive disorder and most commonly inherited single gene disorder among Caucasians with a prevalence of 5 per 1000 and carrier frequency of 1 in 10. Two HFE point mutations are described and referred as C282Y and H63D. In the present study as per the classification of Beutler, we have analyzed DNA samples of North Indian subjects for HFE gene (C282Y & H63D), Ferroportin (A77D), Transferrin receptor 2 (Y250X), Hepcidine (C70R) and Hemojuvelin gene (G320V) by PCR-RFLP. Total numbers of samples screened were 1358 [436: cryptogenic cirrhosis, 410 thalassemia and 512: control]. Of these no allele of C282Y gene was found However, We found percent prevalence of H63D gene mutation in our cirrhosis group 11.5% (50 out of 436), in thalassemia group 13.4% (55 out of 410) and in control group 9.5 % (46 out of 512). Ferroportin SLC40A1 (A77D) mutation was for the first time reported by us in thalassemia patients. A significant association of H63D mutation with iron overload was observed [$p < 0.01$] The overall frequency of H63D in North Indian population is 11.2%, which is similar to the reported incidence in Northern Europe. The study emphasizes the value of routine screening of the HFE mutation in thalassemias and cirrhotic patients to modify treatment modalities occurring due to iron overload.

Its in your hands - a combined clinical, molecular and developmental approach to the diagnosis of radial ray defects. *R. A. Newbury-Ecob[1], A. Sharif[2], M. Logan[3]* 1) Clinical Genetics, St Michaels Hospital , Bristol, United Kingdom; 2) Molecular Genetics, City Hospital, Hucknall Rd, Nottingham, United Kingdom; 3) National Institute for Medical Research, The Ridgeway, Mill Hill, London, United Kingdom.

Abnormalities of the upper limb are the second commonest congenital malformation. The last decade has seen the identification of a number of genes which cause syndromic radial ray defects (TBX5, SALL4, SALL1, RECQ4, FANC, del 1q21) allowing more accurate diagnosis and genetic counselling as well as delineation of the associated phenotypes. Knowledge of the role of these genes in normal and abnormal development comes from studies in various model systems. We have recently reviewed clinical information provided for over 100 cases presenting with radial ray defects for a diagnostic opinion and molecular genetic testing. Diagnostic criteria developed from clinical studies were shown to be highly predictive of a positive mutation result for patients with HOS, Okihiro and TAR) and allowed directing of further investigation. Phenotypic features such as the presence of additional malformations were significant as was the precise pattern of abnormality. In addition it is possible to draw on studies of the interactions and expression patterns in normal and knockout mice (e.g. SALL4, TBX5) which show correlation to the human phenotypes to aid diagnosis. With increasing pressure to justify the validity of diagnostic molecular genetic testing, a tailored approach to diagnosis in patients with radial ray defects utilising predominantly clinical assessment is presented.

Increased risk of stomach and nervous system cancers in Finnish prostate cancer families. *S. Pakkanen[1], M. Matikainen[2], E. Pukkala[3], P. Koivisto[1], T. Tammela[2], J. Schleutker[1]* 1) Laboratory of Cancer Genetics, Institution of Medical Technology, University of Tampere and Tampere University Hospital, Finland; 2) Department of Urology, Tampere University Hospital and Medical School, University of Tampere, Finland; 3) Finnish Cancer Registry, Helsinki, Finland.

Clinical features of families with prostate cancer (PCa) and other malignancies associated with this disease are not well known. A family with PCa is characterized as two or more PCa cases among first degree relatives. The aim of this study was to assess weather primary tumors other than prostate carcinoma aggregate in Finnish families with PCa or weather this disease can be considered site specific. Based on the national population based Finnish Cancer Registry (FCR), we calculated standardized incidence ratios (SIR) for 5546 members of 202 Finnish families with PCa with confirmed genealogy, either using the first diagnosed PCa among brothers as a single index or multiple indexes. Information of family members were confirmed from population registry and cancer data from hospital records and Finnish Cancer Registry respectively. The total number of cancers (all sites) among males was 552 (SIR 1.79) in single index group, 234 (SIR 0.94) in multiple index group and among females 205 (SIR 0.98). The number of PCa cases was 373 (SIR 6.73) in single index group and 71 (SIR 1.21) in multiple index group. The sisters of the index person had more stomach cancer than expected (SIR 2.12, 95% confidence interval 1.02-3.90) the mothers of the indexes had increased number of central nervous cancers in the age group of 60-69 years (SIR 19.4, 2.35-70.08) when compared general population. Spouses had no increased risk to any cancer, suggesting that special environmental risk factors can be excluded. In most of the families with excess numbers of prostate cancer the disease appears to be site specific. However in a subgroup of families, a suggestive tendency towards gastric and central nervous cancers was detected. Further analysis is warranted to carry out multivariate analysis based on selected clinical and family characteristics, possibly enabling separation of families with sporadic cases to a different cohort.

Unusual association of combined pituitary hormone deficiency with deafness in a patient with two novel mutations in the LIM-homeodomain transcription factor LHX3. *M-L. Sobrier[1], C. Heinrichs[2], M-P. Luton[1], S. Rose[1], S. Amselem[1]* 1) Inserm U654, Hopital A Trousseau, Paris, France; 2) Pediatric Endocrinology, Reine Fabiola Children Hospital, Bruxelles, Belgium.

LHX3 encodes a LIM-homeodomain transcription factor that plays important roles in the proper development of the pituitary and motoneurons. Only seven LHX3 mutations have so far been reported in humans. All of them were found in the homozygous state in patients with combined pituitary hormone deficiency (CPHD) (involving GH, TSH, PRL, FSH/LH , and sometimes ACTH); all but one mutations were identified in patients with a rigid cervical spine, a phenotypic feature believed to result from a LHX3-dependent neurological defect that is not rescued by the closely related protein LHX4. Here, we report the identification of two new LHX3 gene defects found in a compound heterozygous state in a patient presenting not only with CPHD and a rigid cervical spine, but also with persistent motor delay and profound sensorineural hearing loss. One defect (c.252-3 C>G) affects the acceptor splice site preceding exon 3, while the other is a missense mutation (p.C123Y) involving a well-conserved amino acid of the LIM2 domain. To determine the consequences of the c.252-3C>G mutation on the splicing of LHX3 transcripts, HEK293 cells were transfected with expression vectors containing the normal or the mutant LHX3 minigene consisting of a genomic fragment spanning exon 1b to exon 5. RT-PCR amplification of LHX3 transcripts isolated from those cells revealed an abnormal splicing of transcripts that, if translated, would lead to a severely truncated protein. The missense mutation was found to be associated with a partial loss of transcriptional activity on several pituitary gene promoters. Taken together, these data demonstrate that these two novel sequence variations are not rare polymorphisms but represent disease-causing mutations. The unusual report of a hearing loss in this patient, who was born to a non-consanguineous union, now prompts us to investigate the possible role of LHX3 in the proper development of the auditory system in humans.

Linkage Disequilibrium extension analysis on the Xq13 region in the island of Corsica. *M.S. Ristaldi[1], G. Sole[1], L. Varesi[2], G. Vona[3], A. Cao[1], V. Latini[1]* 1) INN-CNR, Consiglio Nazionale delle Ricerche, Monserrato , Cagliari, Italy; 2) Universitè de Corte, Corsica, France; 3) Dipt. Biologia Sperimentale, Università di Cagliari.

The identification of genes involved in the pathogenesis of multifactorial diseases would help to shed some light on their physiopathology with significant aid in on the prevention and development of new therapeutic approaches. Genetic isolates with a history of a small founder population, long-lasting isolation and population bottlenecks represent exceptional resources in the identification of disease genes. In these populations the disease allele reveals Linkage Disequilibrium (LD) with markers over significant genetic intervals, therefore facilitating disease locus identification. In a previous work we have examined the LD extension on the Xq13 region in three sub-populations of Corsica belonging to the internal mountainous region of the island. Here we have extended the analysis to the Corsican population of the coast. We found a decreasing of LD in this area. This result indicate a cline of LD inside the island which could be useful for the fine mapping of a gene contributing to a complex disease first mapped using the isolated, high LD, population of the same region. Moreover we reported the frequencies of a particular haplotype (DXS1225-DXS8082) in Corsican population which is typical of the island is not common in other European populations.

Genotype - Phenotype Correlation in Czech Osteogenesis Imperfecta Patients. *I.J. Mazura[1,2], I. Marik[3], F. Mazurova[3], V. Baresova[4], S. Mazurova[4], O. Hudakova[3], P. Novosad[5]* 1) Department of Antropology and Human Genetics, Charles Univ. The Faculty of Science, Vinicna 7,128 44 Prague, Czech Republic; 2) Institute of Computer Science, Academy of Sciences CR , Pod vodarenskou vezi 2, 187 02 Prague 8,Czech Republic; 3) Ambulant Centre for Locomotor System Diseases, Olsanska 7, 130 00 Prague 3, Czech Republic; 4) Charles University Prague, 1st Medical Faculty, Katerinska 32, 120 00 Prague 2, Czech Republic; 5) Mediekos Labor,Ltd.,Antoninova 4464, 760 01 Zlin, Czech Republic.

Osteogenesis imperfecta (OI) is an autosomal dominant or recessive connective tissue disease characterized by extremly high bone fragility (brittle bone disease). The incidence of this disease is 1:10-50 000 newborns. Heterogenous syndrome with variable phenotypic expression is defined by clinical findings (skeletal and soft tissue manifestation, eye symptoms, hearing loss, dental defects and cardiovascular and pulmonary system involvement). OI is dividend into four basic clinical types (I.-IV.). We have analyzed 37 czech osteogenesis imperfekta patients with basic molecular genetic techniques (e.g. DNA extraction from leukocytes, specific amplification methods, sequence analysis) in five selected exons of COL1A1 gene (collagen alpha 1 chain of the gene). The sequence analysis was done in 37 DNA patient symple (21 girls, 16 boys). Mutations were found in 18 patients (substitutions and deletions). Some of the patients had more than one mutation in collagen alpha 1 chain gene. Most of watched patients were clinically classified as type I of osteogenesis imperfekta.We verify that more mutations in one genetic area (in one patient DNA sample) are not in correlation with clinical severity of the disease. We haven't found out any characteristic marker between compared patients with the same mutation. The results were supported by grant no. LN 00B107 of Ministry of Education, Youth and Sport, Czech Republic.

A multistage genome-wide association study with follow-up study provides strong evidence for 4 susceptibility loci in schizophrenia. *M.C. O'Donovan[1], N. Craddock[1], G. Kirov[1], I. Nikolov[1], N. Norton[1], H. Williams[1], T. Peirce[1], V. Moskvina[1], L. Carroll[1], L. Georgieva[1], M. Hamshere[1], P. Holmans[1], N. Williams[1], I. Giegling[2], H. Jürgen Möller[2], D. Morris[3], A. Corvin[3], M. Gill[3], D. Rujescu[2], M. Owen[1]* 1) Psychological Medicine, Cardiff University, Cardiff, United Kingdom; 2) University of Munich, Munich, Germany; 3) Trinity College, Dublin, Ireland.

Introduction: Several candidate susceptibility genes for schizophrenia have been reported but most of the genetic risk for schizophrenia remains to be attributed to specific genes. With the aim of identifying novel risk genes, we have undertaken a multi-stage association study based upon a total of ~ 9000 subjects.

Methods: Collaborating with the Wellcome Trust Case Control Consortium (WTCCC), we conducted a GWA study on a discovery sample of 476 UK schizophrenic cases and 3000 UK controls (Stage 1a) and supplemented the findings for our top hits ($p<10^{-5}$)in an additional UK 170 cases (Stage 1b). Associations that remained at a threshold $p<10^{-5}$ were genotyped in an additional 1600 cases and 3700 controls (Stage 2)

Results: Six regions after stage 1b contained SNPs at p< 10-5, of which 4 had p<5x10-7. For the most significant SNP at 4 of the 6 loci, we replicated the association to the risk allele in stage 2, an observation unlikely by chance ($p=1.5x10^{-5}$). Three are entirely novel, the other has been previously proposed by others. Our study identifies and replicates associations at 4 schizophrenia loci.

Additional Authors: Jonathan Marchini (Uni of Oxford), Chris Spencer (Uni of Oxford), Hin-Tak (Uni of Cambridge), Annette M Hartmann, Emma Quinn.

Acknowledgement: We would like to thank the WTCCC which undertook much of the pre and post genotyping QC, sampling handling, and who scored all the genotypes in this study.

Genetic studies on an isolate region of Sardinia unravels history and evolution of its population. *G. Pistis[1], C. Fraumene[2], N. Pirastu[2], E. Mocci[2], M.T. Manias[2], V. Cabras[2], R. Stradoni[1], M. Cosso[2], D. Farris[2], F. Marras[2], R. Atzeni[2], A. Angius[1,2], M. Pirastu[1,2]* 1) Inst Population Genetics, Alghero, Italy; 2) Shardna Lifesciences, Cagliari, Italy.

In Sardinia the mountainous secluded area of Ogliastra has always been described as an Island within an Island implying a high genetic homogeneity. We studied 9 different villages (15000 inhabitants) within this region characterized by high endogamy (from 70 to 90%), low immigration, remote origin and 400 years of genealogical records. In each village, we reconstructed all genealogical maternal lineages representing more than 90% of the present day population. The Dloop region of mtDNA was sequenced in 885 samples (the entire mtDNA in a subset of them) chosen to analyze the different branches in each individual pedigree. Haplogroups analysis shows that in each village there is a limited number of maternal founders and only a few of them shared between the different isolates. Multiple correspondence analysis on the haplogroups reflects the geography of the region and shows that the two closest villages (Talana and Urzulei) seem to have a different origin than the other ones. We calculated LD genome wide (D, r2, LDU) using 500k SNP on 50 samples from each of the 6 villages. We found that the isolates farthest from the sea have a higher LD probably due to an higher isolation. Talana, which is highest on the mountains, showed 298 LDU while Baunei, close to the sea, 566 LDU even thought they are only few miles away. Looking at the LDU map it is clear that there is a common underling pattern of cold and hot recombination spots. This is even more clear if we use those markers which are informative in both our population and the CEU from HapMap, probably showing the effect of evolution on the genome. Preliminary data on LD blocks structure similarities suggest that this depends more on the environment the populations live in, than phylogenic relations between them. The understanding of the genetic makeup of these different populations will be instrumental to better approach the study of common diseases, considering the interaction between history, evolution and changes in today life style.

Parental mosaicism detected in a MCA/MR family using molecular cytogenetic analysis. *M.R. Nelen, M. Eleveld, P.A. Terhal, W.A. Harts, I. de Valk, M. Poot, P.F.R. Hochstenbach, J.K. Ploos van Amstel* Dept Medical Genetics, UMC Utrecht, Utrecht, Netherlands.

Mosaicism is a major albeit uncertain determinant of recurrence risks in sporadic/isolated genomic diseases. Therefore, the genetic counselor is left with a difficult question when patients ask about the recurrence risk in case of a de novo variation. Here we describe a MCA/MR (multiple congenital anomalies associated with mental retardation) proband of which the mother shows mosaicism. A 6 year old MCA/MR patient was presented to us for Array-CGH analysis. Routine karyotyping did not reveal chromosomal abnormalities. Array-CGH analysis showed loss of signal intensity for BAC-clone RP11-190A12. The region involved, chromosome 1q23.2, is not known to contain neutral copy number variations. FISH analysis using an adjacent clone, RP11-10P13, confirmed the deletion in all cells analyzed. To determine whether the deletion had occurred de novo, interphase FISH on cells of both parents has been performed. The mother showed segmental aneuploidy for 1q23.2 in 29 out of 100 cells analyzed. Using Array-CGH the mother revealed a reduced signal intensity for clone RP11-190A12 but within the normal range. This reduction corresponds to the degree of somatic mosaicism as identified by FISH. Upon clinical examination the mother did not shown any MCA/MR manifestations. Molecular cytogenetic analysis has revealed that microdeletions / duplications in the human genome are a major cause of MCA/MR. Segmental aneuploidy in a sporadic patient with MCA/MR can be considered most probably causal for the phenotype when it has occurred de novo. However, the frequency of parental mosaicism for the de novo segmental aneuploidies has still to be elucidated. Follow-up studies such as interphase FISH as shown will however unambiguously identify parental mosaicism. Finally, mosaicism as cause of phenotypic variability and even MCA/MR needs further investigation. Using the current normal range in Array-CGH analysis, mosaics will however largely go unnoticed as possible cause of MCA/MR.

MicroRNA profiling in hypoxia identifies HSA-MIR-210 as an independent prognostic predictor in breast cancer. *C. Camps[1], F. Buffa[2], S. Colella[1], J. Moore[2], H. Sheldon[2], A.L. Harris[2], J. Gleadle[3], J. Ragoussis[1]* 1) Genomics, Wellcome Trust Centre for Human Genetics, Oxford , OXXON, United Kingdom; 2) Cancer Research UK Molecular Oncology Laboratories, Weatherall Institute of Molecular Medicine, University of Oxford, John Radcliffe Hospital, United Kingdom; 3) Oxygen Sensing Group, The Henry Wellcome Building for Molecular Physiology, University of Oxford, Oxford OX3 7BN, United Kingdom.

Many cancers are characterised by areas of hypoxia, enhanced HIF levels and increased expression of hypoxically regulated genes, all of which correlate both with tumour aggression and patient outcome. Recently MicroRNA expression alterations have also been associated with carcinogenesis.We used microarrays to determine changes in microRNA expression under hypoxia and validations were performed by quantitative-PCR. hsa-miR-210 was identified as a hypoxically, early induced microRNA in MCF7 cells. This induction (4-fold, $p<0.001$) was also confirmed in a range of other cancer cells. Using siRNA against HIF1 and HIF2 as well as RCC4 cells transfected with VHL we demonstrated that the regulation by hypoxia was mediated by the HIF1 -VHL transcriptional system but not HIF2. We analysed the expression of hsa-miR-210 and hsa-miR-21, as a control, in 219 early breast cancers with long term clinical follow up. Correlation with clinical parameters was performed using Pearson and Spearmans rank tests, univariate and Cox multivariate analysis. We determined that the hsa-miR-210 expression correlated with a previously identified hypoxia signature based on the expression of 96 genes in 73 samples (Spearman=0.54, p2-tailed<0.001). The expression of has-miR-210 correlates highly significantly with recurrence free and overall survival, both in univariate and multivariate analysis (Log Rank (Mantel-Cox) 2=16.6, df=1, $p<0.001$) in contrast to has-miR-21. In conclusion hsa-miR-210 expression is induced by hypoxia in a HIF-1 and VHL dependent fashion and is an independent prognostic predictor in breast cancer.

No association of sudden infant death syndrome with congenital central hypoventilation syndrome (Ondines curse). *M. Osawa[1], A. Sasaki[2], F. Satoh[1], I. Hasegawa[1], R. Kimura[1], K. Hayasaka[2]* 1) Forensic Medicine, Tokai University School of Medicine, Isehara, Kanagawa, Japan; 2) Department of Pediatrics, Yamagata University Faculty of Medicine, Yamagata, Japan.

Congenital central hypoventilation syndrome (CCHS), also known as Ondines curse, is an autosomal dominant disorder, characterized by hypoventilation during sleep with an onset in infants. Characteristics of the clinical features suggest that undetected CCHS is potentially involved in cases of sudden infant death syndrome (SIDS). However, no evidence of real cases has been reported because it is difficult to make a postmortem diagnosis of CCHS. Recent studies indicate that the expansion of a polyalanine repeat in the PHOX2B gene is relevant to the pathogenesis of the disorder. However, it has been difficult to detect the repeated tract by conventional PCR because its high GC content (88%) inhibits amplifying reactions. In this study, a bisulfite treatment for DNA was developed to reduce the GC content, in which uracil is obtained by deamination of unmethylated cytosine residues. The converted DNA permitted direct PCR amplification using primers specific to the deaminated sequence of the coding strand, in which dropouts of expanded alleles were completely prevented. It yielded a product of 123 bp for the common 20-residue repetitive tract with converted T from original C by sequencing. In addition to the common 20-residue repeat, contracted alleles of 13- and 15-residue repeat were distributed at a frequency of 0.04 in the Japanese population group. The majority (90%) of clinically diagnosed CCHS patients carried heterozygous expansions of 25- to 33-residues at the polyalanine tract of PHOX2B. In contrast, analysis revealed no expansions in SIDS victims and healthy subjects. Table summarizes the detected number of chromosome (allele frequency) of PHOX2B in subjects of the CCHS, SIDS and control groups. These results suggest that the major pathogenesis of SIDS is distinct from that of CCHS.

Genome-wide linkage analysis in 152 sib-pair families with schizophrenia from Indonesia. *D.B. Wildenauer[1], Irmansyah[2], Heriani[2], M. Knapp[3], S.G. Schwab[4]* 1) CCRN, University of Western Australia, Claremont, WA, Australia; 2) Department of Psychiatry, University of Indonesia, Jakarta; 3) Institute for Medical Biometry, Informatics and Epidemiology, University of Bonn, Bonn, Germany; 4) WAIMR, University of Western Australia, Nedlands, WA, Australia.

Schizophrenia has a milder outcome and course in developing countries as compared to developed countries. In addition to social and familial factors, there may be a contribution of genetic factors. We have collected a sample with 152 families with two or three affected siblings and parents with schizophrenia for linkage- and family based association studies in Indonesia. Clinical diagnosis of schizophrenia was made using DSM and ICD criteria. Genomic DNA was isolated from blood cells. A genome-scan was performed by Marshfield Research Organisation, using the panel with 402 Short tandem repeat markers. Linkage analysis was performed with GENEHUNTER and MERLIN using 140 independent sib-pairs. A maximum MLS score of 3.5 (P = 0.00006) was obtained on chromosome 3p24.1. Additional minor linkage peak were detected at chromosome 1q23.1 (P=0.0057), 5q33-34 (P=0.012), and 10q26-qter (P=0.018). The locus at Chromosome 3p is supported by findings of a meta analysis. Loci on 1p, 5q, and 10q are reported by a number of linkage studies and are therefore interesting for follow-up studies . These findings will be the starting point for fine mapping as well as for studies of association/linkage disequilibrium with schizophrenia.

Novel MFN2 mutations and phenotypic variability in patients with Charcot-Marie-Tooth disease type 2A. *M. Muglia[1], F. Boaretto[2], A. Martinuzzi[3], G. Vazza[2], L. Piva[2], A. Vettori[2], A. Patitucci[1], C. Bertolin[2], G. Siciliano[4], A. Quattrone[1,5], M.L. Mostacciuolo[2]* 1) ISN-CNR, Mangone Cosenza, Italy; 2) Department of Biology, University of Padova, Italy; 3) IRCCS E. Medea, Conegliano Research Center, Italy; 4) Dept. of Neuroscience, Neurological clinic, University of Pisa, Italy; 5) Department of Neurology, University Magna Graecia, Catanzaro, Italy.

Mutations in the MFN2 gene have been reported as the primary cause of Charcot-Marie-Tooth disease type 2. In our study we intend to better characterize the divergence of phenotypes associated with MFN2 mutations in order to explore possible genotype-phenotype correlations. A mutation screening of MFN2 gene has been performed on a cohort of CMT2 patients. We identified 4 MFN2 mutations,3 of them have not been reported before. The first one is a missense mutation leading an amino acid change in exon 11(p.A383V). Interestingly this mutation has been detected in two independent families originating from Southern Italy. Haplotype reconstruction evidenced a disease haplotype shared by both families, thus suggesting that the mutation may have been inherited from a common ancestor. Clinical and neurophysiological examinations showed an extremely variable expression in respect to age at onset and severity of symptoms. The second mutation is an amino acid change in exon 19 (p.A738V) and has been identified in a family with a severe CMT2 phenotype. The third one is a point mutation in intron 13 affecting the conserved consensus sequence of the donor splice site. The mutated allele generates an aberrant transcript that is likely translated in a truncated protein. This mutation seems associated to a late onset CMT2 phenotype with typical features, but two patients of the family experienced a rapid worsening of symptoms and died suddenly after few months. The last mutation is a substitution in exon 8 causing an amino acid change in the GTPase domain(p.R250Q). Although already reported, this mutation does not cosegregate with the disease in the family suggesting that other genetic factors may contribute to the disease in this family(Supported by a Telethon-grant to MM).

Molecular and cellular dissection of ABCA12: the major cause of Harlequin Ichthyosis. *A.C. Thomas, C. Sinclair, M. Patel, E.A. O'Toole, D.P. Kelsell* Cutaneous Research, Queen Mary University of London, London, United Kingdom.

Harlequin ichthyosis(HI) is the most severe form of autosomal recessive congenital ichthyosis. Infants born with this skin condition have hard, thick skin covering most of their body as well as distortion of the lips, eyelids, ears and nose. Due to the impaired cutaneous barrier function, neonates struggle to control water loss, regulate temperature and are more susceptible to infection. Using SNP chip technology and subsequent sequencing, we have previously shown that mutations in the ABCA12 [(ATP)-binding cassette transporter] gene underlie HI and to date over 50 patients analysed have mutations in this gene. Additionally complex mutations, such as a heterozygous whole exon deletion and a multiple exon duplication, have been identified via CGH oligo array and multiplex PCR. The presence of these complex mutations shows the need for thorough investigation when considering pre-natal testing for HI. Our studies also show that there are ethnic-specific mutations in individuals of Pakistani, White British and Balkan origin. In order to elucidate the role of ABCA12 in epidermis, siRNA mediated knockdown was performed in keratinocytes. These cells were used to create 3D organotypic co-culture skin models that mirror many of the phenotypic changes observed in HI patient skin including abnormal lipid content and thickened epidermis. Evidence suggests ABCA12 is involved with lipid transport (Glucosylceramides) in the lamellar granule network of the skin. Additionally, our results from immunostaining experiments on HI skin and the skin model show that the programme of epidermal differentiation is severely impaired compared to control skin. Markers of late epidermal differentiation such as Keratin 2e, involucrin and transglutaminase appear in the lower and often basal layers of the skin suggesting loss of ABCA12 triggers early terminal differentiation but without the signals to form the cornified envelope. These data suggest the abnormal skin barrier function related to abnormal lamellar granule formation and subsequent abnormal lipid transport seen in HI skin may, in part, be due to the dysregulated keratinocyte differentiation programme driven by absent ABCA12.

Essential Hypertension is associated to several worldwide genetic factors in a Sardinian genetic isolate. *E. Mocci[1], V. Cabras[1], N. Pirastu[1], M.P. Concas[2], C. Fraumene[1], M. Adamo[1], I. Persico[1], G. Biino[1,2], M. Pirastu[1,2], A. Angius[1,2]*
1) Shardna Lifesciences, Cagliari, Italy; 2) Inst Population Genetics, Alghero, Italy.

Essential hypertension (EH) affects approximately 20% of the adult population and has a multifactorial origin. Epidemiological survey of 9 villages in the secluded area of Ogliastra revealed that in the genetic isolate of Talana there is the highest EH prevalence (26%). We performed medical examination on the whole population and identified 98 affected individuals with high diastolic blood pressure (>95 mmHg), which belong to a single 12 generation pedigree. This large family was divided in 12 three generation pedigrees comprehensive of 185 members including 71 patients. We performed a genome wide linkage analysis on these families using 1000 microsatellites. Recombination maps and allele frequencies were calculated in the same population using 800 people. Statistical analysis, with Simwalk2, allowed the identification of 6 loci on chromosome 2, 8, 17, 18, 22 (-log(P)>3); all of them but the one on chr 22 have been already described in association with EH in several population even with the same most significative markers. Genome wide search was replicated on different family structure with 16k SNPs evenly distributed every 150 Kb. For statistical analysis we used Merlin because LD modelling is a concern with highly dense marker maps. With this approach we were able to confirm and refine all the loci but the one on chr18. We are currently carrying out fine mapping in all the positive loci using high density SNPs. On chr 22 locus we identified a gene involved in cardiovascular development which shows a strong association with EH. Preliminary results of GWA using 90 cases and 90 controls, genotyped with 500k SNPs, showed several genes linked to EH i.e. NEDD4L, TGFA, ADIPOQ, which have been already associated with EH in other studies. To replicate these results we collected a large cohort of 450 cases and 450 controls from 9 different villages in Ogliastra. Our data indicate that several genetic factors common to worldwide population contribute to EH in Talana.

Polysome fractionation suggests that a fraction of Txfrags is translated. *S. Nikolaev[1], S. Deutsch[1], R. Genolet[2], L. Parand[1], B. Conne[1], P. Descombes[3], J-D. Vassalli[1], J. Curran[2], S.E. Antonarakis[1]* 1) Genetic Medicine and Dev., University of Geneva, Switzerland; 2) Microbiology and Molecular Medicine, University of Geneva, Switzerland; 3) NCCR Genomics platform, University of Geneva, Switzerland.

Recent studies have shown extensive transcriptional activity across the human genome, a substantial fraction of which is not associated with any functional annotation (Txfrags). However, very little is known regarding the post-transcriptional processes that operate in different classes of RNA molecules. To characterize the translational behavior of transcriptional units in the the entire non-repetitive human chromosome 21 and the ENCODE region ENm001, we separated RNA molecules of 3 cell lines (GM06990, HelaS3 and SKNAS) in a sucrose gradient according to their association with ribosomes. Pools of fractions representing translated RNA (associated with 2 or more ribosomes) and total RNA were hybridized to a 22 bp-resolution custom-made genomic tiling array. Positive signals were extracted using a conservative algorithm requiring at least 3 consecutive probes being above the 99% confidence threshold. We observed that 3.5 - 6% of HSA21 is transcribed in each cell line, and a total of 8% is transcribed in at least 1 cell line. On average 62% or the transcribed regions correspond to annotated regions (mRNAs + ESTs), whereas the remaining 38% do not overlap with any previous annotation (Txfrags). In addition, 85% of Refseq exons were detected in at least one cell line, suggesting that the arrays had a good sensitivity to detect transcription. To estimate the translation level for each exon (or transcriptional unit), we calculated the ratio of expression between polyribosomal and total RNA. We observed a wide distribution of ratios in all cell types. As expected, Refseq exons are significantly more translated than Txfrags; however, there was a large overlap between the 2 distributions suggesting that many transfrags are likely to be translated. Additional analyses are ongoing. Our study provides an initial functional characterization of Txfrags and underscores that they are unlikely to be mere transcriptional noise.

Parkinsonian spectrum associated with glucocerebrosidase mutations. *E. Sidransky[1], G. Lopez[2], M. Hallett[2], O. Goker-Alpan[1]* 1) MGB/NHGRI/NIH, Bethesda, MD; 2) NIA/NIH, Bethesda, MD.

Alterations in the gene encoding for the lysosomal enzyme glucocerebrosidase (GBA) result in Gaucher disease (GD). Clinical, pathologic and genetic studies suggest that mutant glucocerebrosidase is associated with a phenotype characterized by parkinsonism and progressive neurologic deterioration. To define the neurologic spectrum among subjects with parkinsonism carrying GBA mutations, nine subjects (6M:3F), were followed up to 36 months in a prospective study. Cognitive function, oculomotor and motor deficits were tested by the same team. Olfactory evaluation was done using University of Pennsylvania Smell Identification Test. Genotypes were confirmed by DNA sequencing. The N370S mutation was the most common GD allele. Others included L444P, c.84insG and a recombinant allele. The mean age of onset of parkinsonian manifestations was 50 (40 -65) and disease duration was 7.4 years (1.2 -16). At presentation, four subjects had tremor, 5 had symptoms related to bradykinesia and rigidity, and one also had apraxia. Six were diagnosed with classical PD, three with the akinetic-rigid type. Three subjects were considered to have parkinson plus syndrome because of early cognitive changes and hallucinations. All, but one were L-Dopa responsive. Other atypical manifestation included myoclonus, EEG abnormalities and clinical seizures. Autonomic dysfunction was observed in three, and five of 6 subjects tested had olfactory loss. In half, cognitive changes were reported later in the disease course, often accompanied by depression. Glucocerebrosidase mutations are associated with a spectrum of parkinsonian phenotypes, frequently with loss of olfaction. This spectrum ranges from classic PD, mostly the akinetic type, to a less common phenotype characteristic of Lewy Body Dementia.

Distribution and immuno-localization of the NPC protein p62 in human and mouse brains. *N. Shoshani[1,2], L. Basel-Vanagaite[1,2], S. Liraz-Zaltsman[3,4], A. Biegon[3,5], G. Rechavi[2,6], N. Amariglio[2,6], A.J. Simon[6], M. Shohat[1,2]* 1) Department of Medical Genetics, Rabin Medical Center, Petah Tikva, Israel; 2) Sackler Faculty of Medicine, Tel Aviv University, Israel; 3) Joseph Sagol Neuroscience Center, Sheba Medical Center, Israel; 4) Department of Pharmacology, Hebrew University, Jerusalem, Israel; 5) Brookhaven National Laboratory, NY; 6) Institute of Hematology, Cancer Research Center, Sheba Medical Center, Israel.

p62 protein, encoded by the nup62 gene, is an important component of the nuclear pore complex (NPC). Mutated nup62 causes autosomal recessive Infantile Bilateral Striatal Necrosis (IBSN), characterized by symmetrical degeneration of the caudate nucleus, putamen, and occasionally the globus pallidus, with little involvement of the rest of the brain. The aims of our study were to examine postmortem stability and distribution of p62 in the human brain, specifically in basal ganglia, and its cellular immuno-localization in normal human postmortem and mouse brains. For human brain, cortical and basal ganglia regions were dissected from a coronal slice from a neuropathology-free female aged 59 years at death, with a postmortem delay (time from death to freezing) of 38 hours. For mouse brain, total brain was dissected from a coronal slice without postmortem delay. Series of consecutive cryostat sections from both brains were prepared. p62 expression and immuno-localization studies were performed using Western blot and immuno-fluorescent analyses, using specific antibodies against p62, GFAP and NeuN. p62 was detected in all human brain regions examined by Western blot. Its immuno-localization in the putamen of both brains was confined to the nuclear envelope. p62 was expressed in neurons, as detected by its co-expression with NeuN, but its expression in astrocytes, when co-expressed with GFAP, was weaker than in non-astrocyte neighboring cells. The results indicate that the NPC in human brain frozen up to 38 hours postmortem is preserved, and p62 is expressed in human and mouse basal ganglia with cellular localization to the nuclear envelope. The neuronal expression of p62 in mouse brain suggests that mutated p62 in IBSN affects primarily the neurons of basal ganglia.

USF1 influences lipid and metabolic traits in subjects with FCHL and CAD in a sex-dependent manner. *D. Weissglas[1], J.C. Lee[1], J.S. Sinsheimer[1], T.W.A. de Bruin[2], A.J. Lusis[1], M. Brennan[3], M.M.J. van Greevenbroek[2], C.J.H. van der Kallen[2], S.L. Hazen[3], P. Pajukanta[1]* 1) Department of Human Genetics David Geffen School of Medicine, University of California, Los Angeles, Los Angeles, CA; 2) Department of Medicine and the Cardiovascular Research Institute Maastricht, Academic Hospital, Maastricht, the Netherlands; 3) Cleveland Clinic, Departments of Cardiovascular Medicine and Cell Biology, and Center for Cardiovascular Diagnostics & Prevention, Cleveland, OH.

Familial combined hyperlipidemia (FCHL) is a common dyslipidemia predisposing to coronary artery disease (CAD). FCHL is characterized by elevated levels of serum total cholesterol, triglycerides (TGs), or both. Recently, the upstream transcription factor 1 (USF1) was identified to be linked and associated with FCHL and elevated TGs in Finnish FCHL families. The strongest association was observed in TG affected males for the common alleles of a single nucleotide polymorphism (SNP) rs3737787 or SNPs in linkage disequilibrium with this SNP. The aim of this study was to evaluate the sex specific effect of rs3737787 in Dutch FCHL families with 532 family members and in a cohort of 1367 U.S. Caucasian subjects who underwent diagnostic coronary angiography. Significant sex-dependent association with serum TGs and metabolic syndrome related traits were observed in both studies (P_{FCHL}=0.03-0.006, P_{CAD}=0.05-0.002). Furthermore, using two factor ANOVA in the unrelated subjects with CAD and the penetrance option of the Mendel package in the Dutch FCHL families, we observed a significant genotype-sex interaction with serum TGs ($P_{FCHL}=3x10^{-4}$, $P_{CAD}=5x10^{-3}$) in both studies as well as with body mass index in the unrelated subjects with verified CAD ($P=4x10^{-3}$). In conclusion, the SNP rs3737787 influences serum TG levels in FCHL and in subjects with verified CAD. Furthermore, the detected significant sex-genotype interaction highlights the importance of investigating sex-specific differences in CAD.

Clinical characteristics of patients with mucopolysaccharidosis type II: the Hunter Outcome Survey (HOS). *J.E. Wraith[1], B.K. Burton[2], J. Muenzer[3], M. Beck[4], R. Giugliani[5], J. Clarke[6], R. Martin[7] on behalf of the HOS investigators*
1) Royal Manchester Childrens Hospital, Manchester, UK; 2) Childrens Memorial Hospital, Chicago, IL, US; 3) University of North Carolina, Chapel Hill, NC, US; 4) Childrens Hospital, University of Mainz, Mainz, Germany; 5) Hospital de Clinicas de Porto Alegre, Porto Alegre, Brazil; 6) Hospital for Sick Children, Toronto, Ontario, Canada; 7) Saint Louis University, Saint Louis, MO, US.

Mucopolysaccharidosis type II (MPS II; Hunter syndrome) is a rare, X-linked metabolic disorder caused by deficiency of the enzyme iduronate-2-sulfatase and characterized by the progressive accumulation of glycosaminoglycans throughout the body. To assess the natural history of MPS II and the long-term safety and efficacy of enzyme replacement therapy (ERT), a global survey, the Hunter Outcome Survey (HOS), was initiated in 2006. As of May 2007, HOS contained data on 263 patients with MPS II, 63 of whom were receiving ERT. Mean ages (SD) at enrollment, onset of symptoms and diagnosis were 13.5 (8.4), 1.8 (1.6) and 4.3 (4.2) years, respectively. Patients had many signs and symptoms; facial dysmorphia was reported in 95%, enlarged liver/spleen in 89%, neurological manifestations and joint stiffness in 84%, chest and lung symptoms in 83%, cardiovascular manifestations in 82%, hernia in 78%, enlarged tonsils/adenoids in 68%, nasal obstruction in 34%, seizure disorders in 18% and hydrocephalus in 17% of patients for whom data were available. Many of these manifestations were present before diagnosis. Among patients with cardiovascular manifestations, 57% reported valve disease, 53% murmur and 8% cardiomyopathy. The prevalences of tachycardia (7%), bradycardia (2%) and arrhythmia (4%) were low. On average, patients developed cardiovascular manifestations 3.0 (0.6) years after diagnosis. By 6 years of age, approximately 50% of patients had developed cardiovascular abnormalities, increasing to 90% by age 15 years. HOS is proving to be a valuable resource to help better understand the clinical features of MPS II. Future analysis of HOS data should be able to determine the long-term impact of ERT and allow the development of evidence-based clinical management guidelines.

Intrathecal Enzyme Replacement Therapy in a child with mucopolysaccharidosis VI and symptomatic spinal cord compression. *M.V.R Munoz[1], D. Horovitz[2], T. Vieira[1], R. Costa[1], L. Vedolin[1], S. Fagondes[1], L. Jardim[1], J. Llerena[2], R. Giugliani[1]* 1) Medical Genetics Service, Hospital de Clinicas de Porto Alegre, Porto Alegre, RS, Brazil; 2) Centro de Genética Medica, Instituto Fernandes Figueira/FIOCRUZ - Rio de Janeiro, Brazil.

In MPS VI, deficiency of Arilsulfatase B and subsequent glycosaminoglycan storage can cause spinal cord compression within the cervical meninges. Surgical treatment carries a high risk of morbidity and mortality. As intravenous enzyme replacement therapy (ERT) is not likely to cross the blood-brain barrier, we investigated the use of intrathecal recombinant human Galsulfase(IT rhASB) in an MPS VI patient with spinal cord compression. To our knowledge, IT therapy has not been attempted previously for MPS VI. Purpose: To evaluate the safety and efficacy of IT rhASB for spinal cord compression caused by cervical meningeal storage in a MPS VI child. Methods: We assessed a 7 year-old child with MPS VI, presenting important spinal cord compression, at baseline with clinical, neurological and biochemical evaluations, 12 minute walk test (12MWT) and conventional MRI and diffusion tensor imaging (DTI) studies of the CNS. He was monitored for changes in these parameters during 4 IT infusions of rhASB administered monthly via lumbar puncture (LP). Patient received 1.5 mL of rhASB dilluted on 3.0 mL of Elliotts B solution at each infusion. The patient had never received intravenous ERT. Results: No adverse events were observed. After 3 infusions he presents improvements in cord compression signs, improved sensibility tests, ability to rise from his bed and to walk longer distances when aided. There were no clinically significant changes in serum chemistries or CSF protein, glucose, or cell count. 12MWT does not present clinically significant improvement so far, despite several important neurological changes. Systemic effects have also been preliminarly observed, especially reduction in liver and spleen. Further evaluation is ongoing, and available results will be presented. Conclusions: These preliminary results suggest that IT rhASB appears to be a safe new therapy for spinal cord compression for this MPS VI patient.

Replication of *FTO* variant with childhood obesity in Hong Kong Chinese. *C.H.T. Tam, M.C.Y. Ng, V.K.L. Lam, W.Y. So, R.C.W. Ma, J.C.N Chan* Dept Medicine & Therapeutics, Chinese Univ of HK, Hong Kong, China.

Two recent studies in European populations suggest that *FTO* (fat mass and obesity associated) gene located on chromosome 16q12.2 are associated with both childhood and adult obesity, as well as type 2 diabetes. Each risk allele confers 31 to 47% increased risk for obesity. In this study, we aim to replicate the association at *FTO* with obesity using a proxy SNP rs8050136 in a random Chinese adolescent population from Hong Kong.

We genotyped rs8050136 at *FTO* in 976 adolescents [age mean SD = 15.3 2 years, % males = 47] that participate in a health screening program. Associations of rs8050136 at additive model with metabolic traits including body mass index (BMI), waist circumference (WC), percentage body fat as measured by bioelectric impedance (FAT), systolic and diastolic blood pressure, lipids (total cholesterol, triglyceride, HDL, LDL), glucose at OGTT for 0, 60 and 120 min and fasting insulin were assessed by linear regression adjusted for covariates age and sex.

We found that the reported risk allele A of rs8050136 (P = 0.0013-0.011) was consistently and significantly associated with increased adiposity related traits (BMI: geometric mean (95% CI) = 20.6 (17.8-23.9) kg/m^2 for AA carriers, 20.2 (19.7-20.6) kg/m^2 for AC carriers, 19.5 (19.2-19.7) kg/m^2 for CC carriers; WC: geometric mean (95% CI) = 68.0 (60.7-76.1) cm for AA carriers, 69.0 (67.9-70.0) cm for AC carriers, 67.4 (66.8-68.0) cm for CC carriers; FAT: mean SD = 22.9 7.9 % for AA carriers, 21.7 7.5 % for AC carriers, 20.7 7.0 % for CC carriers). However, we did not observe any association between rs8050136 and other metabolic traits. In summary, our study support *FTO* as a susceptibility locus influencing childhood obesity in Chinese population.

Association of *CDKAL1* variants with early phase insulin secretion in Hong Kong Chinese. *M.C.Y. Ng, C.H.T. Tam, V.K.L. Lam, W.Y. So, R.C.W. Ma, J.C.N. Chan* Department of Medicine and Therapeutics, The Chinese University of Hong Kong, Shatin, Hong Kong.

Recently, several genome-wide association studies in diverse Caucasian populations have found association between variants at cyclin-dependent kinase 5 regulatory subunit associated protein 1-like 1 (*CDKAL1*) and type 2 diabetes. The association was further replicated in 1500 type 2 diabetic patients and 1000 controls from our Chinese population in a previous study. It is speculated that CDKAL1 may inhibit CDK5/p35 complex in pancreatic cells and alter insulin response to glucotoxicity. This study aimed to investigate for the association of *CDKAL1* variants and insulin response in Hong Kong Chinese.

We studied 616 healthy subjects without diabetes for 3 tagging SNPs (rs7752906, rs7756992 and rs9356744, r^2 0.8) in the associated linkage disequilibrium block reported in the previous studies. We assessed the SNP association with insulin resistance (HOMA_IR) and insulinogenic index during OGTT [(insulin 30 min - 0 min) / (glucose 30 min - 0 min)] using linear regression with adjustment for age and gender.

We did not observe association of any *CDKAL1* SNPs with HOMA_IR. However, significant associations to insulinogenic index were observed for two correlated SNPs (r^2 = 0.77), rs7752906 and rs9356744 (P = 0.009-0.014). The risk allele A of rs7752906 showed the strongest association with reduced insulinogenic index under an additive model [geometric mean (95%CI) = 76.8 (63.9-92.4) for AA carriers; 84.7 (78.6-91.2) for AG carriers and 99.4 (92.3-107.0) for GG carriers].

Our results support others finding that variants at *CDKAL1* influence early phase insulin secretion, which may affect susceptibility to type 2 diabetes.

An autosomal dominant spontaneous and preterm delivery in a large multigenerations family. *R. Uppala[1], J.V. Solanki[2], U.C. Patel[2], R. Memon[1], A.K. Maiti[3], S.K. Nath[4], U. Radhakrishna[1]* 1) Green Cross Voluntary blood bank and Genetic Research Centre, Paldi, Ahmedabad-380014; 2) Department of Animal Genetics & Breeding, Veterinary College, Gujarat Agriculture University, Anand, India; 3) Sealy Center for Molecular Biology, University of Texas Medical Branch, Galveston, TX 77550, USA; 4) Arthritis and Immunology Research Program, Oklahoma Medical Research Foundation, 825 N.E. 13th Street, Oklahoma City, USA.

A full-term pregnancy is called when the babies are born between 38 to 42 weeks. Births that occur at less than 37 weeks of pregnancy are called premature or preterm. Preterm birth remains the leading cause of neonatal morbidity and mortality. The frequency of preterm birth (PTB) varies between populations, in the United States; ~12 percent of babies are born prematurely. The etiology of PTB is largely unknown but is believed to be complex, involving both multiple genetic and environmental determinants. It is associated with various risk factors including, intrauterine growth retardation, social, environmental, medical and genetic. There are several sporiadic cases and small families reported with PTB. We have studied one large multigenerations Indian pedigree, with an autosomal dominant mode of inheritance and a history of PTB. The family consists of 72 individuals including 11 affecteds. Family history revealed that there are fourteen preterm deliveries occurred in this family and all pregnancies were ended between 22 to 32 weeks. There were no consanguineous marriages observed in this pedigree. None of the PTB babies survived and all died immediately after birth. No other associated anomalies observed in this family. Cytogenetic analysis of three affected individuals did not show any abnormality. Markers on chromosome 19q13.4 region in the vicinity of candidate gene NALP7 was excluded by linkage and haplotype analyses. We are planning to perform a high-density genome-wide linkage analysis to identify the responsible preterm birth PTB susceptibility locus. Email: madam_fille@yahoo.com.

Detection of constitutional genomic imbalances with the Affymetrix GeneChip Human Mapping 250K Nsp array: Data analysis using three software packages. *I. Simonic, L. Willatt* Medical Genetics Department, Cambridge University Teaching Hospital NHS Trust, Hills Road, Cambridge CB2 2QQ, United Kingdom.

Genotyping SNP arrays are widely used in genome-wide association studies, homozygosity mapping of rare autosomal recessive disorders, and for loss of heterozygosity (LOH) studies in malignancies. Several recent studies have shown that whole-genome SNP arrays can also be used to identify submicroscopic DNA copy number changes. We studied 50 patients with developmental delay and/or facial dysmorpism/congenital malformations using the Affymetrix GeneChip Human Mapping 250K_Nsp array and used three different software packages to analyse the results for copy number changes. Firstly we analysed all the array data with CNAG software. CNAG uses SNP genotypes generated by a DM algorithm for detection of copy number changes and allows multiple patient displays in a single window. Rapid visualisation of abnormalities, exclusion of common copy number variants and batch related array artefacts was possible. We then re-analysed all the array data with the Affymetrix CNAT and the IdeogramBrowser software packages using SNP genotypes generated by the BRLMM algorithm for copy number analysis. We concluded that CNAT was not suitable for data analysis in our diagnostic laboratory as the analysis was extremely time consuming, with a large number of false positive calls that were strongly correlated with the test sample genotype call rates. IdeogramBrowser detected all the abnormalities identified by CNAG, however the displays, particularly for some of the large abnormalities (>3Mb in size), differed significantly between CNAG and IdeogramBrowser. Furthermore, IdeogramBrowser using the analysis parameter of a minimum of 3 consecutive SNPs, identified several additional copy number variants of <0.5Mb not detected using the other software packages. All copy number changes were followed up by FISH and the potential clinical significance of these abnormalities will be presented.

A Constrained Regression Approach for Studying Haplotype-Specific Association. *J.Y. Tzeng, H. Bondell*
Department of Statistics, North Carolina State University, Raleigh, NC.

In the haplotype analysis of refine-stage studies such as candidate-gene or candidate-region studies, the central goal is to understand the effects of specific haplotypes so to identify etiological variants and infer biological explanations. One common approach for studying haplotype-specific effect is to examine if haplotypes have significant regression coefficients. However, such analysis only reveals the effect of a haplotype with respect to the reference haplotype that is often arbitrarily defined. Consequently the results can be sensitive to the choice of the reference haplotypes, and little information is learned about the relationship among non-reference haplotypes. Another popular strategy is to create a binary variable that records "haplotype of interests" versus "the else", and use this variable to study the effect of the target haplotype. This strategy can be problematic especially when each of these "else" haplotypes has different or even opposite effects on the phenotypes. Ideally, a thorough haplotype-specific analysis should call for pair-wise comparisons among all haplotypes, same procedures as in the post-hoc analysis of ANOVA. However, this thorough pair-wise comparison may suffer from power loss due to the multiple comparison adjustment, and often yields a contradictory conclusion on which haplotypes share the same level of effects. To address these concerns, we consider a constrained-regression approach that performs the ANOVA-type of post-hoc analysis to study haplotype effects. The method uses constraints that encourage haplotypes with similar effect sizes to be estimated with exact equality, and transfers the post-hoc analysis from a multiple-comparison procedure to a variable-selection framework. Through simulation, we evaluate the performance of the proposed approach and illustrate how the output can be used to characterize the haplotype-specific associations.

Overlap between genome-wide linkage and association scan signals: insights from type 2 diabetes. *E. Zeggini[1], N.J. Timpson[1], T.M. Frayling[2], M.N. Weedon[2], K.S. Elliott[1], C.M. Lindgren[1], H. Lango[2], J.R.B. Perry[2], N.W. Rayner[1], R.M.. Freathy[2], A.T. Hattersley[2], M.I. McCarthy[1], UK Type 2 Diabetes Genetics Consortium, Wellcome Trust Case Control Consortium* 1) University of Oxford, UK; 2) Peninsula Medical School, Exeter, UK.

Linkage analysis has, until recently, been the only feasible approach to obtain a genome-wide overview of disease susceptibility. Genome-wide association scans (GWAS), made possible by advances in the field, now allow comprehensive examination of common variation at a higher resolution. Over 30 linkage scans have been carried out for type 2 diabetes (T2D), highlighting a handful of regions with evidence for linkage (chr 1q, 2q, 3q, 8p, 10q, 12q, 20q). Causative variants remain to be identified for these. As part of the Wellcome Trust Case Control Consortium, we recently completed a GWAS for T2D, which, together with 4 further published scans, has increased the number of proven genes to 9 (*PPARG*, *KCNJ11*, *TCF7L2*, *HHEX/IDE*, *SLC30A8*, *CDKAL1*, *CDKN2A*, *IGF2BP2*, *FTO*). We examined the overlap between the location of previously reported T2D linkage peaks and GWAS signals. We compared the observed and expected total number of independent associations (with $p<0.001$ in the WTCCC scan) within regions demarked by 1-LOD-drop intervals under T2D linkage peaks and found no convincing evidence of regional over-representation ($p>0.16$). The number of expected hits was derived from the total number of association signals and the number of independent loci (conservatively set at $r^2<0.8$) in each linkage region. The only region for which we observed some evidence (albeit not significant at $p=0.16$) for an excess of independent associations was 10q (in which *HHEX* and *TCF7L2* reside). Importantly, however, none of the GWAS signals could generate a detectable linkage signal, as shown by estimating lambda(s) values attributable to each one (ranging from 1.002 [*SLC30A8*] to 1.025 [*TCF7L2*]). It is possible that rarer, more penetrant variants on 10q are responsible for the observed linkage, but establishing this will require extensive resequencing efforts. In conclusion, we observed little/no overlap between linkage and association scan signals for T2D.

Identification of mutations causing severe motoneuron disease. *H.O. Nousiainen[1], M. Kestilä[1], N. Pakkasjärvi[1], H. Honkala[1], S. Kuure[2], J. Tallila[1], K. Vuopala[3], J. Ignatius[4], R. Herva[5], L. Peltonen[1,6,7]* 1) Department of Molecular Medicine, National Public Health Institute, Helsinki, Finland; 2) Biochemistry and Developmental Biology, Institute of Biomedicine, University of Helsinki, Helsinki, Finland; 3) Department of Pathology, Lapland Central Hospital, Rovaniemi, Finland; 4) Department of Clinical Genetics, University of Oulu, Oulu, Finland; 5) Department of Pathology, Oulu University Hospital, Oulu, Finland; 6) Department of Medical Genetics, University of Helsinki, Helsinki, Finland; 7) The Broad Institute, MIT, Boston, MA, USA.

Motoneurons are affected in several neurological disorders with variable severity and age of onset. The most severe forms of motoneuron disease manifest already in utero and are characterized by arthrogryposis and fetal immobility. Among the lethal arthrogryposes are two entities called LCCS (MIM 253310) and LAAHD, which are caused by the lack of anterior horn motoneurons. Fetuses affected with LCCS present with joint contractures and pulmonary hypoplasia. Histopathological analysis reveals severe atrophy of the anterior horn motoneurons of the spinal cord and muscle atrophy. In LAAHD the neuropathological findings are similar to LCCS, but the degeneration of muscles and the spinal cord is less severe. Both syndromes are inherited autosomally recessively. We previously mapped the LCCS locus to 9q34 in Finnish LCCS families. By monitoring for shared haplotypes of affected individuals, we restricted the critical DNA region to 1Mb between markers D9S1827 and D9S752. We sequenced all 30 genes on this critical DNA region and identified mutations causative of both LCCS and LAAHD in one of them. The mutation-carrying gene is of known biological function and reveals a distinct pathway defective in motoneuron disease. In situ hybridization showed low ubiquitous expression of this gene in mouse embryonic tissues and marked expression in the ventral cell population of the neural tube, from which motoneurons differentiate. In vitro expression studies and analysis of expression array data are ongoing to collect functional evidence of the critical importance of this gene/pathway to normal motoneuron function.

Mutational analysis of UBE2B in men with dyskinetic spermatozoa. *A. Moore[1, 2], E. Escudier[2], L. Wakselman[1], P. Duquesnoy[1], A-M. Bridoux[1], M. Albert[3], S. Amselem[1], D. Escalier[3]* 1) Inserm U654, Hopital A Trousseau, Paris, France; 2) Inserm U841, Hopital H Mondor, Créteil, France; 3) AP-HP, Hopital Bicetre, Le Kremlin-Bicetre, France.

Several knockout mice have revealed the involvement of factors potentially linked to the ubiquitin/proteasome system in the assembly of sperm flagellar structures in mammals. Among them, mice deleted of the ubiquitin conjugating enzyme Ube2b present a unique sperm flagellar phenotype characterized by an ectopic localization of the longitudinal columns of the fibrous sheath. A similar sperm flagellar phenotype exists in some infertile men, but its molecular basis is still to be identified. The data on Ube2b reported in mice, therefore, prompted us to analyze the orthologous UBE2B gene in those patients. Five patients with a sperm phenotype similar to that of Ube2b-/- mice were investigated. Direct sequencing of all UBE2B coding exons and exon/intron boundaries did not reveal any mutation. The study of further patients is therefore needed to determine whether mutations of UBE2B can concern some men with anomalies of the longitudinal columns of the fibrous sheath.*Ube2bUBE2B*.

Molecular genetics of Meckel syndrome. *J. Tallila[1], R. Salonen[2], L. Peltonen[1,3,4], M. Kestilä[1]* 1) Department of Molecular Medicine, National Public Health Institute, Helsinki, Finland; 2) Department of Medical Genetics, Väestöliitto, Helsinki, Finland; 3) Department of Medical Genetics, University of Helsinki, Helsinki, Finland; 4) The Broad Institute, MIT Boston, MA, USA.

Meckel syndrome (MKS, MIM 249000) is a lethal developmental disorder characterized primarily by a combination of occipital meningoencephalocele, large polycystic kidneys, fibrotic changes of the liver and polydactyly. The inheritance mode is autosomal recessive. Although the frequency varies greatly among populations, MKS represents the most common form of syndromic neural tube defects (NTDs). In Finland the estimated frequency is 1:9000. The genetic heterogeneity of MKS is well established and the *MKS1* (17q23) and *MKS3/TMEM67* (8q21.13-q22.1) genes were characterized recently. In addition, the *MKS2* gene has been localized to chromosome 11q13. The founder mutation in the novel *MKS1* gene is a 29 bp intronic deletion that is mainly found in Finnish patients, but also in other Caucasian patients. This deletion interrupts the splicing, which causes a frame shift leading to a non-functional protein. We have additionally identified two novel mutations in the *MKS1* gene. In 70% of the Finnish MKS families the patients are homozygous for the founder mutation and the remaining 30% of the families represent mutation(s) in other gene(s). As we have several families without a mutation in the *MKS1* gene and with no linkage to the MKS2 or MKS3 loci, we are currently in search of new MKS locus/loci by using Illumina SNP arrays (317K) to map the disease loci. Because *MKS1* and *MKS3* are known to encode polypeptides having roles in cilia function, we will first analyze positional candidate genes that are known to be linked to cilia. Identification of the first MKS proteins moved the link between cilia and neural tube closure beyond animal models and into the area of human disease. Because the cellular role of cilia is poorly understood in human embryonic development, MKS serves as an excellent model for ciliary dysfunction. Studies of MKS will undoubtedly provide new insights into early embryonic development; information critical for better understanding of molecular details behind several human malformation syndromes.

Amniotic Bands, Cleft Lip and Palate, and Supernumerary Nipple: A Rare Phenotype? Literature Review and Discussion. *P.D.R.D. Nicola[1], F.R. Ferreira[1], C.A. Barbosa[2], L.R.J. Silva[1], D. Brunoni[1]* 1) Morphology, Universidade Federal de São Paulo, São Paulo; 2) Pediatrics, Hospital Geral Vila Nova Cachoeirinha, São Paulo.

The amniotic band sequence (ABS) is a condition where the normal fetus is under influence of destructive mechanisms causing a variety of congenital anomalies (syndactyly, limb and digital amputation, constriction rings, craniofacial clefts, and limb-body wall complex). Here we report a 1 year old Brazilian girl, only child born to a non consanguineous young parents, with typical amniotic band sequence (ABS), with limb defects and constriction bands. At the neonatal period this patient had a complete left cleft lip and palate, a supernumerary nipple on the left, and two skin papillae on the proximal right arm and on the lumbosacral region. The neuropsicomotor development and the behavior were normal. In 2000, Guion-Almeida e Richieri-Costa (Clinical Dysmorphology) reported a 14 years boy, born to consanguineous parents, presenting ABS, bilateral cleft lip and palate, preaxial polydactyly and supernumerary nipple. In 2005, Robin et al (American Journal of Medical Genetics) described a girl, born to non consanguineous parents, with ABS anomalies, cleft lip and palate, preaxial polydactyly, supernumerary nipple and skin papilla. Now, we report another child with nearly identical phenotype to these two cases previously described.

A new Androgenetic Alopecia genetic predisposing factor. *D.A. Prodi[1], N. Pirastu[1], G. Maninchedda[1], A. Mossa[1], A. Sassu[1], A. Picciau[1], M.A. Palmas[1], G. Biino[1,2], L. Casula[2], M. Adamo[1], A. Angius[1,2], M. Pirastu[1,2]* 1) Shardna Lifesciences, Pula, Cagliari, Italy; 2) Inst Population Genetics, Alghero, Italy.

Androgenetic alopecia (AGA) is a common disorder which affects mostly men. Despite a clear genetic predisposition, the aetiopathogenesis remains still unknown. An epidemiological survey of 7 genetic isolates in the secluded region of Ogliastra (Sardinia) demonstrates high prevalence of AGA (47.7%). It also clusters very well within families and has usually an early age of onset (70% <35 yrs). Candidate gene approach has been carried out analyzing several polymorphisms (CAG and GGN repeats and StuI RFLP rs6152) in the X-linked androgen receptor gene which have been previously associated with AGA in different populations, although these results are still controversial. For our study we selected 500 cases (age of onset <30,IV degree of AGA Norwood scale) and 500 controls (age>40 and no sign of AGA). For statistical analysis we used CC-QLS which can correct association values based on the kinship coefficient. When tested on the whole sample, StuI gave a pvalue of 2x10-19 (OR=4.2) while the repeats gave a weaker association (GGN pval=0.007,CAG =2.2x10-4). StuI showed the strong association in all the villages separately but one (Triei). LD pattern revealed that AR is in strong LD with a gene 900kb centromeric:EDA2R. We chose to test the only validated EDA2R nsSNP rs1385699 in our samples. This SNP reached an even stronger association than StuI (pval=8.9 x 10-31; OR=5.5) and gave a positive result on all populations including Triei. EDA2R, through TRAF3-6, activates JNK which can stimulate c-juns expression which is important for AR trans-activation. The absence of the predisposing allele in the African HapMap samples may justify the low prevalence of AGA in men of African descent. However, the AR and EDAR2R genes do not explain all the genetic susceptibility to AGA. In order to find other genetic factors involved we selected 25 families coming from the village of Talana for linkage analysis both with 1000 microsatellites and 16k SNP genomewide. This way we found 3 loci on Chr 1, 6 and 7 which contain candidate genes related to the same pathway as both AR and EDA2R.

Identification of a novel mutation for Cleidocranial dysplasia (CCD). *M.T.M. Lee[1], C.H. Chou[1], F.M. Sun[1], J.Y. Wu[1], F.J. Tsai[2], Y.T. Chen[1]* 1) National Genotoyping Ctr, Academia Sinica, Taipei, Taiwan; 2) China Medical University, Taichung, Taiwan.

Cleidocranial dysplasia (CCD; MIM 119600) is a rare autosomal dominant human skeletal disorder. The clinical features of CCD are facial and dental malformations characterized by delayed closure fontanelles, frontal bossing, absent clavicles, short stature, late eruption and supernumerary permanent teeth and other skeletal anomalies. Mutations causing CCD has been mapped to the RUNX2 (also known as CBFA1, PEBP2A and AML3) gene located on chromosome 6p21. It is one of the three mammalian homologs of the Drosophila runt gene, which is a transcription factor required for osteoblast differentiation. RUNX2 spans a region over 220-kb in 6p21 and is composed of 8 exons. Heterozygous loss of function of CBFA1 appeared to be sufficient to cause CCD. A number of patients with CCD phenotypes also exist without any identifiable mutations in the RUNX2 gene. We recruited a family with CCD phenotypes from the China Medical University. The affected members of this family had the rarer CCD phenotype such as hypoplasisa in the distal phalanges and middle phalanges had cone-shaped epiphyses in addition to the phenotypes described above. Direct sequencing analysis revealed no mutations in the promoter, coding regions and the splice sites of RUNX2. Deletions in the RUNX2 gene were rare, nonetheless, the possibility of RUNX2 deletion in this family could not excluded by sequencing. Real Time quantitative PCR was performed to determine the copy number of each of the exons and 3UTR. qPCR results and revealed that RUNX2 for the CCD patients in this family was deleted from exon 1 to exon 6 as indicated by the copy number of 1 while the normal individuals had normal copy number of 2. This was then confirmed by Southern blot analysis and the exact breakage point was mapped by sequencing the circular DNA generated from inverse PCR around the cleavage site. The deletion mutation presented in this study was the first intragenic deletion described for CCD. Use of qPCR was more sensitive than FISH analysis and could explain some of the CCD patients without any identifiable mutations in RUNX2.

Assessment of Current Information Resources for Newborn Screening Conditions. *E.S. Reese, B. Chen* Division of Laboratory Systems, National Center for Preparation, Detection, and Control of Infectious Diseases, Centers for Disease Control and Prevention (CDC), Atlanta, GA.

Background: In 2005 the American College of Medical Genetics (ACMG) recommended a national uniform newborn screening (NBS) panel. Many states have adopted these recommendations, resulting in an increased need by healthcare professionals and the public for information regarding diagnosis, intervention, and management of the disorders. However, the desired information may not always be publicly available. Based on recommendations from the CDC-hosted Quality, Access, and Sustainability of Biochemical Genetic Testing Working Meeting in October 2006, we assessed the current information resources for NBS diseases and related genetic testing and explored ways to develop a common information portal for general practitioners, specialists, laboratories, and the general public. Methods: Twenty commonly used websites were assessed for information regarding basic information, genetic testing information, laboratories, testing algorithm and availability, sensitivity/ specificity of genetic tests, interpretation of test results, and disease management for the 84 diseases on the ACMG NBS panel. Findings: The quality and quantity of the information varied among the websites. Five websites contained information provided by external links, two contained restricted access, and two contained no applicable information. The most common information elements were basic information and availability of genetic tests for newborn genetic diseases. Many websites lacked information on test algorithms, sensitivity/specificity, interpretation, and disease management. Conclusions: Availability and accessibility of NBS information is an increasing public health need. Using the information compiled, we have developed a searchable database, available on the CDC website, that can direct users towards general and disease-specific information about NBS conditions.

Auriculo-Condylar Syndrome (ACS): Mapping of the first locus (ACS1)and genetic heterogeneity. *M.R. Passos-Bueno[1], C. Masotti[1], K. G. Oliveira[1], F. Poerner[2], A. Splendore[3], J. Souza[2], R. Freitas[2], R. Zechi-Ceide[4], M.L. Guion-Almeida[4]* 1) Dept Gen & Evol Biol, Univ De Sao Paulo, Sao Paulo SP, Brazil; 2) Integral Attending Center to the Cleft Lip and Palate Affected (CAIF), Curitiba, Paraná, Brazil; 3) Department of Genetics, Stanford University, California, USA; 4) Hospital de Reabilitação de Anomalias Craniofaciais, Universidade de São Paulo, Bauru, São Paulo, Brazil.

Auriculo-condylar syndrome (ACS), an autosomal dominant disorder of first and second pharyngeal arches, is characterized by malformed ears (question mark ears), prominent cheeks, microstomia, abnormal temporomandibular joint and mandibular condyle hypoplasia. Penetrance seems to be complete, but there is high inter and intra-familial phenotypic variation, with no evidence of genetic heterogeneity. We herein describe a new multigeneration family with 11 affected individuals (F1), in whom we confirm intrafamilial clinical variability. Facial asymmetry, a clinical feature not highlighted in other ACS reports, was highly prevalent among the patients in F1. The locus responsible for ACS is still unknown and its identification will certainly contribute to the understanding of human craniofacial development. No chromosomal rearrangements have been associated with ACS, thus mapping and positional cloning is the best approach to identify this disease gene. In order to map the ACS gene, we conducted linkage analysis in 2 large ACS families (F1 and F2, described by Guion-Almeida et al., Am J Med Genet 2002; 112:209). We have first excluded through segregation analysis the four known loci associated with disorders of the 1st and 2nd branchial archs. Next, we performed a wide genome search and we observed evidence of linkage in F2 through two-point and multipoint analysis (Lod max 3.2 at *=0). Interestingly, this locus was shown not to be linked to the phenotype segregating in F1. Therefore, our results led to the mapping of the first locus of auriculo-condylar syndrome (ACS1) and also showed genetic heterogeneity for this condition, suggesting that there are at least two loci responsible for this phenotype. CEPID/FAPESP, CNPq.

Whole genome maps of USF1 and USF2 binding and histone 3 acetylation reveal new aspects of promoter structure and candidate genes for common human disorders. *C. Wadelius[1], A. Rada Iglesias[1], A. Ameur[2], P. Kapranov[3], S. Enroth[2], J. Komorowski[2], T. Gingeras[3]* 1) Dept Genetics & Pathology, Uppsala Univ, Uppsala, Sweden; 2) Linnaeus Centre for Bioinformatics, Uppsala, Sweden; 3) Affymetrix, Inc., Santa Clara, USA.

USF1 is a transcription factor associated with familial combined hyperlipidemia (FCHL) and binds as a heterodimer with USF2. Binding sites for USF1, USF2, and regions of histone 3 acetylation (H3ac) were mapped in HepG2 cells across the genome using ChIP and tiling arrays. High resolution was achieved by sonicating the enriched DNA to average sizes of 300 bp and the array design. Regions with signal significantly higher than negative controls were identified and subsequent Q-PCR in such regions showed <1% false positives for each factor. Regions bound by USF1, USF2 and H3ac were characterized against a range of annotated genomic features. Genes with promoters bound by USFs were analyzed using gene ontology classification and three biological pathways were identified that contained genes that are excellent candidates for FCHL. H3ac signal was found at 10.900 regions, 50% of them <1kb from TSS of protein coding genes (PCG). The footprint of this signal showed a bimodal pattern with a major peak downstream of TSS at +600 - +800bp and a smaller peak symmetrically located upstream of the TSS. There is a high frequency of bidirectional promoters on the genome and footprints for unique and bidirectional promoters were identical downstream of the TSS but the upstream signal was significantly lower for unique promoters. The ChIP-chip signals were compared to the expression pattern of 18 000 genes and the height of the downstream peak was positively correlated with gene expression. USF1 and USF2 preferentially bound -300 to -100bp i.e. upstream of TSS of PCG. In bidirectional promoters USF1 and USF2 bind between the two TSS and the peak of H3ac is downstream of each TSS. Footprints of H3ac around the TSSs of mRNAs/spliced ESTs for CpG island positive transcripts showed a peak downstream of TSS which suggests that they are true promoters. These lines of high resolution analysis will aid annotation of promoters in the genome.

Significant difference in the distribution of allele frequency among independent Japanese populations including HapMap-JPT. *T. Taniguchi[1], M. Nakano[1], Y. Ikeda[2], N. Omi[1], M. Tanaka[1], K. Mori[2], S. Kinoshita[2], K. Tashiro[1]* 1) Department of Genomic Medical Sciences; 2) Department of Ophthalmology, Kyoto Prefectural University of Medicine, Kyoto, Japan.

Purpose: The International HapMap Project provides a haplotype map from four human populations to share common tags on the human genome as a resource for all populations in the world. Although most of the haplotypes occur in all populations, their frequencies differ among each, and thus it is necessary to refer each data of minor allele frequency (MAF) to help clarifying disease-related genes by whole-genome association studies using a chip-based SNPs genotyping system. Each HapMap data is, however, relying on the data from a single group of not more than a hundred individuals. In this study, to confirm the reliability of the HapMap data, we prepared two independent groups of Japanese and precisely compared with the HapMap counterpart, HapMap-JPT. **Methods:** We recruited 718 volunteers of unrelated Japanese from Kyoto, Japan, with written informed consent. SNPs were genotyped by Affymetrix Mapping 500K Array Set. We selected 5,805 and 5,036 SNPs on chromosome 21 and 22, respectively, with over 95% call rate/SNP to exclude SNPs that showed poor clustering. The MAF for each SNP between our two groups (n=300 or 418) and HapMap-JPT (n=45), obtained from the NetAffx Analysis Center, was compared quantitatively. **Results:** We observed a tight correlation of MAF between our two groups and HapMap-JPT (r^2>0.93), irrespective of the difference in groups or chromosomes. No significant difference of the mean MAF was observed among three groups. However, the distribution of MAF significantly differed between our groups and HapMap-JPT, especially in the range of 0 to 5% (^{2} test, p<0.05). **Conclusion:** The overall correlation among three Japanese populations supported the usefulness of the data from HapMap-JPT. However, although the Japanese is less heterogeneous than the other populations, we found a slight, but a significant difference in the distribution of the low MAF. We should be aware of it that such difference would also appear in the other populations, especially when we focus on the SNPs of low MAF.

Charcot-Marie-Tooth X-linked: five novel mutations in Italian patients. *A. Patitucci[1], A. Magariello[1], A.L. Gabriele[1], R. Mazzei[1], F.L. Conforti[1], T. Sprovieri[1], C. Ungaro[1], L. Citrigno[1], P. Valentino[2], C. Rodolico[3], A. Mazzeo[3], A. Toscano[3], M. Muglia[1]* 1) ISN-CNR, Mangone Cosenza, Italy; 2) Institute of Neurology, University Magna Graecia, Catanzaro, Italy; 3) Department of Neurology, University of Messina, Italy.

Charchot Marie Tooth disease represents a clinically and genetically heterogeneous group of disorders affecting the peripheral nervous system. The most common form, CMT1A, is usually due to a 1.4 Mb duplication in the chromosome 17p11.12 containing the PMP22 gene. CMT X-linked is the second most common form of CMT disease caused by mutations in the gap junction protein beta 1 (GJB1) gene encoding for the connexin 32 (Cx32) located in the X-q13 region. We studied nine subjects from unrelated Italian families with a possible X-linked peripheral neuropathy, and one sporadic subject with clinical and electrophysiological features similar to those observed in X linked neuropathy. The coding region of the GJB1 gene was amplified using primers reported by Bergoffen et al. Three reactions were performed to obtain three overlapping fragments and analyzed by Denaturing High Liquid Chromatography WAVE system (DHPLC-Transgenomic). Direct sequencing of the exons with variant profiles was performed with a BigDye terminator cycle sequencing ready reaction kit (Applied Biosystems) on the ABI3130 sequencer. The screening of the GJB1 gene revealed in ten unrelated Italian index cases five novel mutations (Ser49Phe, Ala88Val, Ser128Leu, Arg164Leu, and Phe153Leu) and five known mutations (Tyr7Cys, Arg164Gln, Arg183Hys, Arg183Cys, and Met194Val). The sporadic patient carried the Ser49Phe mutation that is a de novo mutation because it was not found in his mother. The Ser49Phe occurs in the first EC domain of the Connexin 32 protein which is thought to play a role in interconnecting Cx32 hemichannels. Phe153Leu and Arg164Leu occur in the EC domain too, instead Ser128Leu and Ala88Val occur in the intracellular domain and transmembrane domain respectively; however all five aminoacids are also highly conserved in the GJB1 proteins among all mammalian species suggesting a functional role for the above mentioned aminoacids at these positions.

Heterozygous *LRP5* mutations in children with fractures. *A. Saarinen[1], M. Mäyränpää[2], A.-E. Lehesjoki[1], O. Mäkitie[1,2]* 1) Folkhälsan Institute of Genetics and Department of Medical Genetics, University of Helsinki, Finland; 2) Metabolic Bone Clinic, Hospital for Children and Adolescents, University of Helsinki, Finland.

Background: Mutations in *LRP5*, coding for the low density lipoprotein receptor-related protein 5, have been shown to cause a variety of disorders including autosomal recessive Osteoporosis-pseudoglioma syndrome (OPPG), autosomal dominant High Bone Mass disorder, and Familial Exudative Vitreoretinopathy (FEVR). While homozygous *LRP5* mutations result in OPPG, characterized by severe osteoporosis and blindness, heterozygous *LRP5* mutations may result in milder osteoporosis. In this study we assessed *LRP5* genotypes and skeletal phenotypes in a cohort of Finnish children with fractures. **Patients and Methods:** The study included all children aged 0-16 yrs who were assessed at the Helsinki University Hospital during a 12 month period because of a new fracture and had experienced i) at least two low-energy long bone fractures before the age 10, ii) three low-energy long bone fractures before the age 16 or iii) one low-energy vertebral fracture. Children with previously diagnosed osteogenesis imperfecta were excluded from the study. Patients were assessed for bone mineral density (BMD) by DXA, for vertebral morphology by spinal radiographs and for relevant blood biochemistry. DNA samples were obtained and the 23 exons and exon-intron boundaries of the *LRP5* gene were analyzed by sequencing. **Results:** Seventy-five children fulfilled the inclusion criteria and DNA samples were obtained from 66 of them. Three different heterozygous missense mutations were identified. In addition to these mutations, a variety of rare polymorphisms was identified. Only some of these were observed in control samples (N=500) suggesting that they may have functional implications. **Conclusions:** Three heterozygous missense mutations and several rare polymorphisms in *LRP5* were found in 66 children with fractures. These results are in accordance with previous findings suggesting that even heterozygous *LRP5* mutations may result in symptomatic osteoporosis and confirm the importance of intact Wnt-signalling for normal bone development.

Defective chromosome segregation and telomere dysfunction in aggressive Wilms tumours. *Y. Stewénius[1], Y. Jin[1], I. Øra[2,3], A. Frigyesi[4], J. Alumets[5], B. Sandstedt[6], A.K. Meeker[7], D. Gisselsson[1]* 1) Department of Clinical Genetics, Lund University Hospital, Sweden; 2) Department of Pediatric Oncology, Lund University Hospital, Sweden; 3) Department of Human Genetics, AMC, the Netherlands; 4) Department of Cardiology, Lund University Hospital, Sweden; 5) Department of Pathology, Lund University Hospital, Sweden; 6) Department of Pathology, Karolinska Hospital, Stockholm, Sweden; 7) Department of Pathology, Division of Genitourinary Pathology, The Johns Hopkins Institutions, Baltimore, MD, USA.

Wilms tumour (WT) is a paediatric renal tumour with a 5-year survival rate at approximately 90 %. One of the challenges in WT management is to refine the risk assessment on which treatment is based. In other childhood neoplasms it has been possible to define prognostic subgroups based on the pattern of chromosome changes in the tumour cells. In WT, such sub-classification has been hampered by the fact that WT exhibits a diverse and relatively unspecific pattern of chromosomal imbalances. In adult tumours, complex genomic changes are often generated by abnormal mitotic segregation of chromosomes, caused by disrupted telomeric protection. We here show that similar mechanisms of mitotic instability are present in a sub-group of WT. Molecular cytogenetic analysis of 12 WT showed a strong association between abnormal telomere shortening, karyotypic complexity, and specific cell division abnormalities, including anaphase bridges and multipolar mitoses. Anaphase bridges led to structural rearrangements and single chromosome losses, whereas multipolar mitoses led to more extensive variation in chromosome number. Assessment of mitotic figures in tissue sections from 41 WT revealed that anaphase bridges and multipolar mitoses were predominantly, but not exclusively, present in blastemal predominant and diffuse anaplastic tumours. The presence of anaphase bridges and multipolar mitoses in the primary tumour was a significant predictor of poor event-free and overall survival, independent of stage. Thus, chromosomal instability is rare in WT but may nevertheless have an important pathogenetic role by accelerating clonal evolution in cases that respond poorly to therapy.

Genome-wide approaches to T2D gene identification: how useful are assessments of biological candidacy? *N. W. Rayner[1], E. Zeggini[1], N.J. Timpson[2], C.M. Lindgren[1], C.J. Groves[1], M.N. Weedon[2], T.M. Frayling[2], R.M. Freathy[2], J.R.B. Perry[2], H. Lango[2], B. Shields[2], A.T. Hattersley[2], M.I. McCarthy[1], K.S. Elliott[1]* 1) WTCHG, Oxford Univ, UK; 2) Peninsula Med Sch, Exeter, UK.

Linkage and association studies for type 2 diabetes (T2D) have implicated many genes, but there have, until recently, been few widely-replicated findings. However, large scale genome-wide association scans (GWAS) have led to the discovery of true disease loci. For many of these, prior evidence of their biological candidacy is limited. We can now take stock of the current knowledge of T2D candidacy and ask: how useful are assessments of biological candidacy in finding T2D loci? Using data from the Wellcome Trust Case Control Consortium GWAS (1924 cases, 2938 controls, 393,453 SNPs), we tested the relationship between T2D associations genome-wide and biological candidacy using the GeneSniffer program. GeneSniffer uses a range of online literature and databases to assign a T2D candidacy score based on the co-occurrence of gene-specific and disease phenotype-related terms. For each gene (coding seq +/- 50kb: n=18767) we derived the strongest SNP-specific association test statistic. Linear regression was used to test the association between statistic and GeneSniffer score. We excluded previously known T2D genes *TCF7L2*, *PPARG* and *KCNJ11*, as published studies would lead to secondary inflation of their candidacy. GeneSniffer scores for the 6 novel T2D loci were variable: *CDKAL1*[0], *SLC30A8*[304], *CDKN2A*[1073], *IGF2BP2*[609], *HHEX*[385], *FTO*[0] (average score=200 range 0-25354). We found a small but robust (r2=0.04, p<10-4) positive correlation between the test statistic and T2D candidacy score. We accounted for the correlation correlation of gene length (and number of SNPs per gene) with the highest chi squared per locus (r2=0.25, p<10-4) by adjusting the statistic, and found a significant association with gene candidacy (p<10-4). The analysis showed that GeneSniffer score has some limited predictive value for gene association (goodness of fit for linear regression, r2=0.002). Our current understanding of diabetes aetiology remains a tentative predictor of the location of disease variants.

Combined Family Based and Case-Control association studies in four European Populations shows that several neurotrophin genes are involved the susceptibility to eating disorders. *J.M. Mercader[1], E. Saus[1], M. Gratacos[1], R. de CId[1], A. Carreras[1], A. Puig[1], J.R. Gonzalez[1], M. Bayes[1], F. Fernandez-Aranda[2], E. Cellini[3], B. Nacmias[3], J. Hebebrand[4], A. Hinney[4], C. Boni[5], P. Gorwood[5], X. Estivill[1,6]* 1) Genes and Disease Program, CeGen and CIBERESP, Center for Genomic Regulation (CRG-UPF), Barcelona, Barcelona, Catalonia, Spain; 2) Psychiatric Service, Ciutat Sanitaria Bellvitge, L'Hospitalet, Catalonia, Spain; 3) University of Florence, Florence, Italy; 4) University of Duisburg-Essen, Essen, Germany; 5) Hospital Louis Mourier, Paris, France; 6) Pompeu Fabra University, Barcelona, Catalonia, Spain.

Animal models and association studies propose BDNF and its high affinity receptor, NTRK2, as a key regulator of eating behaviour. To study the involvement of other neurotrophins as susceptibility factors for eating disorders, we have performed a family based and population based association study for Nerve Growth Factor (NGF), Brain-Derived Neurotrophic Factor (BDNF), Neurotrophic Tyrosine Kinase Receptor type 1 (NTRK1), Neurotrophic Growth Factor Receptor (NGFR), Neurotrophin 5 (NT4/5), Tyrosine Kinase Receptor type 3 (NTRK2), Neurotrophin 3 (NTF3), Neurotrophic Tyrosine Kinase Receptor type 3 (NTRK3), Ciliary Neurotrophic Factor (CNTF), and Ciliary Neurotrophic Factor Receptor (CNTFR). The clinical samples included 420 trios, 408 index cases and 385 controls from four European countries: Spain, Italy, France and Germany. Tag SNPs were selected from the CEU HapMap project dataset, and all SNPs were genotyped using SNPlex technology. We performed Family Based Association Studies using the FBAT software and SNPassoc software to analyze the effect of SNPs on minimum body mass index and to perform the case-control studies. When taking eating disorders as a whole group, 14 nominal associated SNPs were found, in NGF, NTF3, NTRK3, P75, CNTFR and NTRK2. Interestingly, there were 6 nominal associated SNPs in NTRK3, one of which was significantly associated after Bonferroni Correction ($p = 9.6$ E-5). These results suggest the involvement of other neurotrophin genes apart from BDNF and NTRK2 in the susceptibility of eating disorders.

Novel de novo SOX2 mutations in patients with severe eye defects and associated developmental abnormalities.

M-P. Vié-Luton[1], M-L. Sobrier[1], C. de Barace[2], E. Feigerlova[3], S. Rose[1], N. Idres[2], S. Odent[4], M. Tauber[3], S. Amselem[1] 1) Inserm U654, Hopital A Trousseau, Paris, France; 2) Paediatric Unit, Hospital Center, Saint-Brieuc, France; 3) Children's Hospital, Toulouse, France; 4) Medical Genetic's Unit, CHU Rennes, France.

SOX2 is a transcription factor involved in the regulation of embryonic development and cell fate determination. Although mice carrying a targeted disruption of Sox2 in the heterozygous state have abnormal anterior pituitary development with reduced levels of GH, LH and TSH, and no eye defect, the few heterozygous SOX2 mutations identified in humans can cause bilateral anophtalmia-microphtalmia and/or developmental delay, defects of the corpus callosum, esophageal atresia, sensorineural hearing loss. Here, we investigated two independent patients with severe eye defects; the first one had right anophtalmia and left optic nerve hypoplasia, while the second, who was born to a consanguineous union, had bilateral anophtalmia associated with hypogonadotropic hypogonadism and short stature. Brain magnetic resonance imaging revealed a thin corpus callosum in the first patient, and, in the second patient, a cyst of the septum pellucidum, whereas pituitary morphology was normal. The two patients were found to carry novel de novo SOX2 mutations in the heterozygous state: patient #1 bears a missense mutation (p.W51R) involving a residue located in the HMG domain of the protein and that is highly conserved throughout evolution. A single base deletion (c.540delC) was identified in patient #2; this latter defect would result in a frameshift that introduces 21 novel amino acids before a premature stop codon at position 202, thereby leading to a truncated protein. Additional studies are underway to assess the functional consequences of these two novel SOX2 defects.

A novel missense mutation p.R178Q in the SLC40A1 gene encoding ferroportin is present in 28% of a Belgian cohort of autosomal-dominant hemochromatosis families. *X. Pepermans[1], V. Lambot[1], M. Lambert[2], G. Matthijs[3], K. Dahan[1]* 1) Center for Human Genetics, Cliniques Universitaires Saint-Luc, Bruxelles, Belgium; 2) Department of Internal Medicine, Cliniques Universitaires Saint-Luc, Bruxelles, Belgium; 3) Department of Human Genetics, University of Leuven, Leuven, Belgium.

Inherited iron overload, a very common condition is characterized by a large genetic heterogeneity with at least 4 responsible genes, HFE1, HJV, HAMP and SLC40A1. Even if it is usually an autosomal-recessive pattern of transmission, 15 mutations (14 missenses and one in-frame deletion) in the SLC40A1 gene have been identified so far in patients with an autosomal-dominant hemochromatosis. In this study, we screened 7 probands with a family history of at least more than two individuals on two generations with either a precocious raised ferritin or an accumulation of iron in the liver by magnetic resonance imaging for mutation in the SLC40A1 gene. We identified in 2 of them a novel heterozygous misses change (c.533G>A) in exon 6 resulting in the arginine to glutamine substitution at amino acid 178 (p.R178Q).This mutation altered a highly conserved residue within the third extracellular domain of the ferroportin was not found in 370 control alleles making it unlikely that it represents a rare polymorphism. Subsequently a panel of 230 samples from individuals with iron overload unlinked to pathogenic mutations in HFE1 gene was tested for the p.R178Q allele. Analysis revealed one additional individual with the same change (1/230, 0.4%). This mutational study shows a mutation detection rate of 28% ; in a small cohort of autosomal-dominant hemochromatosis families, making it sense to propose the SLC40A1 gene screening in patients with a family history of raised ferritin. At contrary, its contribution in the pathogenesis of iron overload without family criteria appears to be low in this Belgian cohort of patients.

Novel deletion in chromosome 22 in schizophrenia patients from an internal isolate of Finland. *O.P.H. Pietilainen[1,2], T. Paunio[1,3], A. Loukola[1], A. Tuulio-Henriksson[4,5], J. Suvisaari[4,5], T. Varilo[1,2], J. Lönnqvist[3,4], H. Stefansson[6], L. Peltonen[1,2,7]* 1) National Public Health Institute, Dept of Molecular Medicine, Helsinki, Finland; 2) University of Helsinki, Dept of Medical Genetics, Helsinki, Finland; 3) University of Helsinki and Helsinki University Central Hospital, Dept of Psychiatry, Helsinki, Finland; 4) National Public Health Institute, Dept of Mental Health and Alcohol Research, Helsinki, Finland; 5) University of Helsinki, Dept of psychology, Helsinki, Finland; 6) deCODE genetics, Reykjavik, Iceland; 7) The Broad Institute of MIT and Harvard, Cambridge, MA, USA.

Schizophrenia (SZ) is thought to result from an interaction between numerous genes and environment. Copy Number Variations (CNVs) may confer risk to complex diseases by disrupting gene functions either qualitatively or quantitatively. The new era of high-throughput genotyping platforms provides the first generation of tools to collect information on CNVs in a genome-wide manner. We utilized genome-wide SNP-array data from Illumina 317K genotyping platform on a Finnish sample of 200 cases and 200 controls with well established genealogy to search for CNVs potentially predisposing to SZ. Half (47%) of the sample originated from an internal isolate of Finland with an exceptionally high prevalence of SZ (3% versus 1.2% for the general population) representing an outcome of multiple population bottle necks. The sample was a part of a large international EU funded consortium, SGENE, a collaboration of total of 1500 SZ patients and 1600 controls of European origin. In the Finnish sample we identified a novel 238 kb heterozygous deletion in chromosome 22 in 13 patients and three related controls (P=.025) all originating from the isolate. Among the patients with deletion, 11 had generalized cognitive impairment. We assessed the prevalence of the deletion in samples of non-Finnish origin by extending the investigations to the rest of SGENE sample and 14,000 additional Icelandic individuals. From the total of 15,600 individuals the deletion was found in four individuals implying that this deletion is enriched especially in SZ patients in this population isolate. Detailed analyses of the regional gene are ongoing.

Genome-wide association studies on Multiple system atrophy (MSA). *Y. Nakahara[1,2], Y. Momose[1,2], Y. Takahashi[1], J. Goto[1,2], S. Tsuji[1,2]* 1) Department of Neurology, Univ. of Tokyo, Tokyo, Japan; 2) JAMSAC (Japan Multiple System Atrophy research Consortium).

Background: Multiple system atrophy (MSA) is a sporadic neurodegenerative disorder characterized by various combinations of autonomic failure, cerebellar symptoms, parkinsonism and pyramidal signs. Although the discovery of alpha-synuclein has been identified as a major component of the glial cytoplasmic inclusions (GCIs), a pathologic hallmark for MSA, the etiologies of MSA remain to be elucidated. To obtain clues as to the genetic factors for MSA, we have conducted genome-wide association studies on MSA cases and controls.Design/Methods: We have established a consortium focusing on multiple system atrophy (JAMSAC; JApan MSA Research Consortium), to obtain longitudinal clinical information and genomic DNA. We genotyped 166 patients with MSA and 95 neurologically normal controls, using Affymetrix Gene Chip Human Mapping 500K Array Set.Results: Genotype data (334,278 SNPs) fulfilling the following conditions are processed for statistical analyses; the call rate exceeding 0.9 in MSA patients and controls, p value for Hardy-Weinberg equilibrium exceeding 0.01. The number of the SNPs with significant p values of 2 test are as follows; ($p<0.05$: 14,362 SNPs, $p<0.01$: 3,196 SNPs, $p<0.001$: 396 SNPs, and $p<0.0001$: 46 SNPs). To identify susceptibility genes for MSA further replication with independent data set will be required.

High frequency of SDHB mutations in a series of head and neck paraganglioma from Belgium. *A. Persu[1], V. Grégoire[2], P. Garin[3], H. Reychler[4], G. Mortier[5], J.-F. De Plaen[1], M. Hamoir[6], M. Vikkula[7]* 1) Nephrology Dept; 2) Radiotherapy Dept, Clin univ St-Luc, UCL, Brussels, Belgium; 3) Otolaryngology Dept, Clin univ Mont-Godinne, UCL, Yvoir, Belgium; 4) Oral and Maxillofacial Surgery, Clin univ St-Luc, UCL, Brussels, Belgium; 5) Center for Medical Genetics, Gent University Hospital, Gent, Belgium; 6) Otolaryngology Dept, Clin univ St-Luc, UCL, Brussels, Belgium; 7) Laboratory of Human Molecular Genetics, de Duve Institute, UCL, Brussels, Belgium.

Mutations of SDH genes encoding subunits of complex II of the mitochondrial respiratory chain are involved in the pathogenesis of paraganglioma (PG) and pheochromocytoma. While SDHD is more frequently involved in the pathogenesis of head and neck PG, SDHB mutations are mainly associated with malignant and/or extra-adrenal pheochromocytoma. To look for the nature and frequency of SDH mutations as well as for possible genotype-phenotype correlations in head and neck PG from Belgium, screening of the coding parts of SDHD and SDHB was performed in 31 patients without familial history of PG and 6 families including 18 subjects with known PG. The screening done by SSCP, heteroduplex analysis and/or DHPLC, was followed by sequencing whenever a shift was observed. Eight different SDHD mutations (3 deletions, 2 splice site mutations and 3 substitutions) were found in 10 different patients including the 6 familial cases and 4 apparently sporadic cases. Furthermore, 6 different SDHB mutations (1 deletion, 1 splice site mutation and 4 substitutions) were found in 8 unrelated patients with apparently sporadic PG. One of them, found in 3 of the 8 subjects, had been already described in a family with malignant pheochromocytoma. (Young et al. 2002). Surprisingly, in this Belgian series, SDHB mutations were almost twice as frequent as SDHD mutations (26 vs. 13) in sporadic head and neck PG without evidence of dissemination, partly due to a single mutation previously associated with familial metastatic pheochromocytoma. (alexandre.persu@card.ucl.ac.be).

QTL-ALL: software for robust QTL linkage analysis in nuclear families. *N. Mukhopadhyay[1], S. Bhattacharjee[1], C-L. Kuo[1], B.H. Reck[2], D.E. Weeks[1], E. Feingold[1]* 1) Dept Human Genetics, Univ Pittsburgh/Sch Pub Health, Pittsburgh, PA; 2) Genetics Analysis, GlaxoSmithKline, RTP, NC.

There has been extensive development of new statistics for quantitative trait locus (QTL) mapping over the last few years, but a number of the most promising new methods are not yet available in end-user software. This is particularly true of methods such as score statistics that are important for studies using selected (non-population) samples. Our new "QTL Analysis and Linkage Library" (QTL-ALL) is a software package designed to make as many as possible of these new statistics widely available. The list of statistics consists of many score statistics, some of which use higher moments of the trait distribution (skewness and kurtosis), and a number of other statistics for special designs. QTL-ALL contains several computational advances that dramatically accelerate the computations. QTL-ALL is highly automated: starting from input data files in a slightly modified LINKAGE format, it guides the user through a set of simple menus to select marker and trait loci for analysis, does error checking, lets the user select from a list of statistics appropriate for the pedigree structures in the data, and then computes the selected statistics on the data, providing readable, formatted text output as well as graphical plots of p-values. The current version can handle sibling pair and sibship data, including specialty designs such as discordant and concordant (affected) pairs. Here, we present the results of analyzing a part of the Rheumatoid Arthritis data provided to the GAW15 participants. We have included both microsatellite markers and SNPs in our analysis. The QTL-ALL package is available at http://watson.hgen.pitt.edu/register/.

Identification of a possible new locus on chromosome 17p13.2 as a novel candidate for autism, through array-based comparative genomic hybridisation. *S. Raskin[1, 2], A. Stachon[3], C.R. Marshall[4], S.W. Scherer[4]* 1) Department of Genetics, Pontificia Universidade Catolica, Curitiba, Parana, Brazil; 2) Laboratorio Genetika, Curitiba, Parana, Brazil; 3) Department of Psychiatry, University of Toronto, Centre of Addiction and Mental Health, Clinical Genetics Research Program, Toronto, Ontario,Canada; 4) The Centre for Applied Genomics, Hospital for Sick Children, Toronto, Ontario, Canada.

Autism spectrum disorders (ASD) refer to a broader group of neurobiological conditions, pervasive developmental disorders.. Despite several arguments for a strong genetic contribution, the molecular basis of a most cases remains unexplained. A patient presenting with non-syndromic ASD was investigated using a DNA microarray constructed from large insert clones designed to target clinically significant areas of the genome, in addition to all the telomere and pericentromeric regions, for a total of 622 discrete loci. Also, the DNA sample was assessed for the copy number variation (CNV) content using signal intensities obtained from Affymetrix 500K SNP arrays and multiple CNV calling algorithms. The CNVs detected were compared against the Database of Genomic Variants as well as a set of 1500 unpublished controls to determine the significance of results. Validation experiments typically included performing quantitative PCR and/or FISH The method was able to identify a 17p13.2 deletion. The distal extent of the deletion could be 160 Kb away. The two clones found to be deleted in this patient are approximately 4Mb distal from the NLGN2 gene. These results show that array comparative genomic hybridisation should be considered to be an essential aspect of the genetic analysis of patients with nn-syndromic ASD. Moreover, besides their importance for diagnosis and genetic counselling, they may allow the delineation of new contiguous gene syndromes associated with ASD. Finally, the detailed molecular analysis of the rearranged regions may pave the way for the identification of a new ASD gene.

Association of Single Nucleotide Polymorphism in the *Interferon Gamma Receptor 1* gene with Japanese Cedar Pollinosis. *M. Sakashita[1,2], T. Hirota[1], M. Harada[1], M. Tamari[1], S. Fujieda[2], Y. Nakamura[3]* 1) Lab Genetics Allergy, RIKEN SNP Research Ctr, Yokohama, Japan; 2) Department of Otorhinolaryngology, Fukui University, Matsuoka, Fukui, Japan; 3) The institute of Medical Science, University of Tokyo, Tokyo, Japan.

The marked increase in the incidence of Japanese cedar (Cryptomeria japonica; JC) pollinosis is a social problem in Japan. The prevalence is considered more than 20% in Japanese adult people. JC pollinosis (JCPsis) is a complex disorder caused by combination of genetic and environmental factors. Clinical and experimental evidence indicates barrier effect of respiratory epithelial cells play crucial role of developing allergic diseases. To clarify the genetic factor implicated in the etiology of JCPsis, we have conducted case-control study using SNPs of genes related infection and innate immunity. We recruited 331 cases with nasal allergy symptoms on JC pollen season whose CAP RAST score to JC pollen was above 2. We also recruited 183 controls with negative CAP RAST score to seven inhaled antigens who have no complications of other allergic disease including seasonal or perennial allergic rhinitis. We have found a significant association between JCPsis and promoter SNP of *Interferon Gamma Receptor 1* (*IFNGR1*) (p=0.013). This promoter SNP also revealed positive association with adult bronchial asthma (case 371, control 743). These findings suggested this promoter SNP might have important role in development of airway allergic inflammation. Functional analysis of the SNP using real-time quantitative RT-PCR, transient transfection reporter gene assays, EMSA are on going.

Comprehensive Copy Number Variant (CNV) analysis of neuronal pathways genes in psychiatric disorders. *E. Saus[1], A. Brunet[1], M. Gratacos[1], J.R. Gonzalez[1], L. Armengol[1], X. Estivill[1,2] on behalf of the Psychiatric Genetics Consortium* 1) Genes and Disease Program, CeGen and CIBERESP, Center for Genomic Regulation (CRG-UPF), Barcelona, Catalonia, Spain; 2) Pompeu Fabra University, Barcelona, Catalonia, Spain.

A Copy Number Variation (CNV) is defined a DNA segment that is one kilobase or larger and present at variable copy number in comparison with a reference genome. Because CNVs can confer risk to complex disease traits, their study in psychiatric disorders is of great interest. The aim of this work was to perform a comprehensive screening of CNVs in different groups of psychiatric patients. The sample analyzed consisted of 170 patients of each group: affective disorders, eating disorder, anxiety disorders and schizophrenia, as well as 170 control individuals. Based on the Central Nervous System transmitter systems, we selected 364 genes involved in neuronal pathways, including metabolyzing enzymes, receptors, transporters, proteins interacting with the transmitter receptors and proteins involved in its signal transduction. We used the Database of Genomic Variants to identify genes predicted to be in CNVs. We designed four Multiple Ligation Probe Amplification assays to detect variations in their copy number between patients and controls. The results were analyzed with MLPAstats, a new package from R software, developed by our group. Seventy-five genes were included in the analysis. We did not find significant differences between cases and controls when single genes were analyzed. When comparing the total number of gains and losses in psychiatric patients versus control subjects, we found that controls tend to carry a higher number of CNVs. These initial results, although needing replication in larger samples, may indicate the involvement of neuronal pathways genes contained in CNVs in psychiatric disorders.

DNA pooling in a Whole-Genome case-control study. *S. Lupoli[1], C. Barlassina[2], F. Martinelli Boneschi[1], A. Orro[3], F. Esposito[1], F. Torri[2], J. Turner[4], S. Potkin[4], G. Comi[1], F. Macciardi[2]* 1) ISPE, San Raffaele Scientific Institute, Milan, Italy; 2) University of Milan, Dept. of Science and Biomedical Technology; 3) CILEA Consortium, Segrate Milan Italy; 4) University of California, Irvine.

Pooling genomic DNA samples within clinical classes of disease, followed by genotyping on whole-genome SNP microarrays, allows for rapid and less expensive genome-wide association studies. Aims of the study: 1) to measure the correlation within pools replicates, and between pools and individual genotyping, 2) to explore whether the degree of correlation is influenced by other factors, such as the minimum allele frequency (MAF) of SNPs. We created a total of 8 pools of DNA samples within a case-control study of schizophrenic patients. To assess variance in allele frequencies attributable to the pooling procedure we created each pool twice: 2 case pools and 2 control pools, 28 and 35 subjects for pool. Moreover, to assess if the number of DNAs in each pool could influence the allele frequencies, we splitted our DNA samples into 4 pools: 2 case pools and 2 control pools, 14 subjects for the 2 case pools, and 17, 18 subjects for each control pool. Each pool has been replicated four times, leading to a total of 32 (four multiplied by eight) readings. Genotyping was performed using Illumina HumanHap300 duo. We restricted our initial analyses on chromosome 22, and we selected common SNPs (n=5355) between HumanHap300, on which individual genotyping was performed, and HumanHap300 duo. We infer allelic frequency of pools by using correction factors which take into account dye intensities in heterozygotes and homozygotes of individual genotyping (1). Pearsons correlation coefficient within pool replicates was 0.96. The assessment of the correlation coefficient between pools and individual genotyping is on going.
1 Baum et al. Molecular Psichiatry 2007, 1-11.

First results of a genome-wide association using jointly 10k and 500k Affymetrix chips in a Sardinian cohort. *M. Uda[1], S. Sanna[1,2], W-M. Chen[2], G. Albai[1], G. Usala[1], A. Maschio[1], F. Busonero[1], A. Mulas[1], M. Dei[1], S. Lai[1], A. Scuteri[1], M. Orru'[1,4], S. Naitza[1], L. Crisponi[1], M. Masala[1], E. Lakatta[3], P. Costa[3], G.R. Abecasis[2], D. Schlessinger[3], A. Cao[1]* 1) INN, CNR, Monserrato, Cagliari, Italy; 2) Department of Biostatistics, University of Michigan, Ann Arbor, MI; 3) Gerontology Reasearch Center, NIA, Baltimore, MD; 4) INRCA, Rome, Italy.

The ProgeNIA Project aims to identify the genetic components of aging-associated conditions in the Sardinian founder population. This population has been isolated since the last glaciation and developed to 1,500,000 inhabitants without appreciable admixture from in-migration. Thus, Sardinians share much of the same genetic information, which makes it easier to track genetic effects through generations. We recruited and phenotyped 6,148 individuals (aged 14-102) from a cluster of four towns. We considered and analyzed 98 quantitative traits as risk factors for several aging related complex diseases. Using Affymetrix gene chip arrays technology, we genotyped 3,329 and 1,412 individuals with 10K and 500K sets respectively. We took advantage of the relatedness between individuals so that for those genotyped with the 10K SNPs array only, we used a modified version of the Lander-Green algorithm to identify stretches of haplotype shared with close relatives who were genotyped at higher density and probabilistically infer missing genotypes. The validity of this strategy is confirmed by a significant increase in the p-values for most of the traits analyzed. For the 362,129 SNPs that passed quality control tests we performed a family-based genome-wide association analyses in order to evaluate the correspondent additive effects for the levels of 38 blood tests, 5 anthropometric measurements, 35 personality traits and 20 measurements of cardiovascular function. Genome-wide significant associations with genes were found for most traits. We present data for genes associated with levels of bilirubin, red blood cell indices, BMI, uric acid. Our approach revealed previously unmapped loci for several traits, including important regulators of fetal haemoglobin levels.

Noonan Syndrome Associated with Neuroblastoma. *J. Pierre-Louis[1], S. Viero[2], J. Kirsh[2], D. Chitayat[1,2]* 1) Mount Sinai Hosp, Prenatal Diagnosis Medical Genetics Program; 2) Hospital for Sick Children, Divisions of Pathology (SV), Cardiology (JK) and Clinical and Metabolic Genetics (DC), Toronto, Ontario, Canada.

Noonan syndrome (NS) is characterized by distinct facies, short stature, congenital heart defect; broad/webbed neck; unusual chest shape with superior pectus carinatum, inferior pectus excavatum, and low-set nipples, cryptorchidism and variable developmental delay. Associations between NS and an increased risk of some malignancies, notably leukemia and neuroblastoma, have been reported. Recent data indicate that somatic PTPN11 mutations occur in children with sporadic juvenile myelomonocytic leukemia, myelodysplasic syndrome, B-cell acute lymphoblastic leukemia, and acute myelogenous leukemia. We report an additional case of NS associated with a mutation in the PTPN11 gene who developed neuroblastoma. A term male infant born to 38 year old primigravida mother with a birth weight of 3.46kg and Apgar scores were 8 and 9 at 1 and 5 minutes respectively. After birth, he was found to have facial dysmorphism, pulmonary stenosis and supravalvular pulmonary stenosis and had an unsuccessful balloon dilatation at 2 months and thus has a surgical repair. His weight and height were always below 3rd centile despite good appetite and calorie intake. He had mild developmental delay. NS was suspected and DNA analysis for the PTPN11 gene showed that he was heterozygous for a single base change of AG in exon 8 of the PTPN11 gene. This mutation is predicted to change the normal Asparagine residue (AAT) to an Aspartic acid residue (GAT) at position 308 of the SHP-2 protein. An abdominal ultrasound at 16 months showed a paravertebral mass posterior to the left kidney and a biopsy was consistent with nodular ganglioneuroblastoma with favorable histology and intermediate mitotic index and favorable biological features with n-MYC not amplified and chromosome 1p not deleted. This case adds to the growing body of literature suggesting potential link between NS and malignancies including neuroblastoma. The role of Shp2 in Ras activation and the frequent mutations of RAS in human tumors lend support the possibility that PTPN11 mutations play a broader role in carcinogenesis.

Prenatal detection and characterization of supernumerary marker chromosomes by array-CGH. *M.J. Simovich[1], S.H.L. Kang[1], A. Patel[1], A. Pursley[1], A.C. Chinault[1], J.R. Lupski[1], A.L. Beaudet[1], I.B. Van den Veyver[1,2], S.W. Cheung[1]*
1) Dept Mol Hum Genet; 2) Dept Ob-Gyn, Baylor College of Medicine, Houston, TX.

Small supernumerary marker chromosomes (sSMC) occur in about 0.043% of newborns and in 0.076% of prenatal diagnoses. The phenotypes associated with sSMC vary substantially depending on size, gene content and chromosome origin, which cannot easily be determined by karyotype or FISH analysis. Therefore, prediction of the pregnancy outcome is difficult and genetic counseling can be a challenge. We analyzed five prenatal cases referred to our laboratory for chromosome microarray analysis (CMA) by array-CGH after karyotype analysis showed an uncharacterized sSMC. In case 1, CMA detected a gain of DNA copy number in the pericentromeric region of 12q, estimated to be approximately 5Mb in size. Metaphase FISH analysis revealed a minute ring-like sSMC in 16 of 20 cells analyzed. In case 2, array-CGH detected a gain of ~4Mb on chromosome 12p. FISH analysis showed that the marker was present in 2.5% of the cells and corroborated the chromosome 12p origin. In case 3, array-CGH detected an 18 Mb gain in the proximal region of chromosome 21q that was confirmed by interphase FISH analysis on cultured amniocytes in 100% of the cells. Postnatal follow-up by array-CGH also confirmed the results. The sSMCs in case 4 and 5 were shown to have originated from the fusion of the centromeric heterochromatin of one or both chromosomes 14 and 22 by G banded chromosome and FISH analyses. The array-CGH did not detect any abnormalities. Since the array is designed to detect unique sequences in the pericentromeric regions, these results suggest there is no apparent genetically active chromatin material present in the marker. We show that the origin of sSMC cannot be identified by conventional cytogenetic analysis alone. Their precise characterization requires high resolution genome analyses by molecular techniques, of these; array-CGH emerges as the fastest and most precise diagnostic tool to determine the chromosomal origin and approximate size of the sSMC. This improved characterization, is crucial for accurate prenatal genetic counseling.

Interlaboratory validation study of High Resolution Melting Curve Analysis for mutation scanning of BRCA1 using the Idaho LightScanner. *N. van der Stoep[1], C.D.M. Paridon[1], P. Norambuena[2], A. Stambergova[2], M. Macek[2], T. Janssens[3], G. Matthijs[3], E. Bakker[1]* 1) Center of Human and Clinical Genetics (LUMC), Leiden, Netherlands; 2) Institute of Biology and Medical Genetics, Prague, Czech Republic; 3) Center for Human Genetics, Leuven, Belgium.

The current set up for mutation scanning of BRCA1 occurs through sequence analysis, DGGE, PTT and DHPLC. All these techniques are time consuming and expensive. Therefore we have evaluated the High-Resolution Melting Curve Analysis (HR-MCA) as a high-throughput mutation-scanning tool for the BRCA1 gene using the LightScanner from Idaho Technology (IT) and the LCGreen Plus+ mastermix. This study was implemented in the EuroGentest evaluation program for new techniques in genome diagnostics. Therefore the BRCA1 mutation scanning test was first set up at the LUMC in Leiden and subsequently partly re-evaluated by the laboratories in Prague and Leuven. Investigations were carried out using a panel of 189 variants and 327 wt controls. We optimized and evaluated HR-MCA of 48 primer sets that encompass all 24 exons of the BRCA1 gene. All heterozygous variants could be detected using the Call-IT 1.5 software (Idaho) and resulted in a 100% mutation detection sensitivity. These variants also include small DNA deletions and insertions. Out of 327 wts we observed 3,7% false positive curves (FP) resulting in a specificity of 96%. The detection of the homozygous polymorphisms depended on the used primer set, but due to overlapping fragments eventually all 9 homozygous variants could be detected as well. Moreover using unlabeled probes we were able to identify several frequent occurring polymorphisms, omitting unnecessary sequence analysis upon detection of these non-pathogenic variants. Finally we performed blind tests for 22 different BRCA1-amplicons and were able to detect all variants (except 1 homozygous variant) and observed a FP score of 1,8%. Re-evaluation of ten BRCA1-amplicons in the second diagnostic laboratory gave rise to identical results (third lab-study is ongoing). In conclusion, HR-MCA with the LightScanner appears to be a rapid and sensitive method for mutation scanning. More details will be presented at the meeting.

Balancing selection maintains allelic diversity at MBL2 and TLR6 loci. *P. Majumder[1], D. Wagener[2], U.S.A.-India Research Group on Vaccine Response (RTI, Duke, CpG, TCGA, NICED)* 1) Human Genetics Unit, Indian Statistical Inst, Kolkata, India; 2) RTI International, Research Triangle Park, North Carolina, USA.

Because innate immunity (InnImm) genes play a vital role in microbial recognition and activation of the adaptive immune system, natural selection may play a crucial role in shaping the genotype and allele frequencies among individuals inhabiting areas that have a high load of bacterial and other microbial pathogens. We sampled ~175 unrelated individuals from two communities (Muslim and Hindu) inhabiting slums of Kolkata, India, with annual outbreaks of typhoid, cholera and other diarrheal diseases. We resequenced (double-pass) 11 InnImm genes (DEFA4, DEFA5, DEFA6, DEFB1, MBL2, TLR1, TLR2, TLR4, TLR5, TLR6, TLR9). We found many unreported SNPs. Allele and haplotype frequency are similar for both communities. Haplotype diversities are high (0.6-0.9). The correlation coefficient of LD values of adjacent SNPs in all genes between Muslim and Hindu is 0.98, indicating a strong similarity of LD structures in both communities. Analyses of these data revealed (a) Tajimas D, and Fu & Lis D* and F* values are all significant ($p<0.05$) and positive for MBL2 and TLR6, indicating an excess of intermediate frequency variants that is observed under balancing selection, and (b) two or more high-frequency haplotypes are separated by long branches in a median-joining network - a signature of balancing selection - for both genes. For MBL2, 4 of 20 haplotypes and, for TLR6, 3 of 14 haplotypes have high frequencies (>15%). The MBL2 and TLR6 produces proteins at the cell surface that are crucial for recognition of a wide range of pathogens. Thus, our finding that the overall allelic diversity at these loci is maintained by balancing (diversifying) selection is consistent with their function, which is similar to earlier findings for the MHC locus that is also involved in pathogen recognition. Supported by: NIAID, NIH, USA, Contract No.: HHSN200400067C.

Somatic *TP53* mutations associated with microenvironmental genomic alterations and clinicopathological features in sporadic but not *BRCA1/2*-related breast carcinomas. *P. Platzer[1], A. Patocs[1], L. Zhang[2], Y. Xu[2], F. Weber[1], T. Caldes[3], G. Mutter[4], C. Eng[1]* 1) Genomic Medicine Institute; 2) Sect of Statistical Genetics; Cleveland Clinic Foundation, Cleveland, OH; 3) Laboratory of Molecular Oncology, San Carlos University Hospital; 4) Department of Pathology, Brigham and Womens Hospital, Harvard Medical School.

TP53 mutations, occurring in sporadic and *BRCA1/2*-related (HBOC) breast carcinomas, have variably been associated with clinical outcome. The tumor microenvironment (eg tumor stroma) of sporadic and hereditary breast cancers exhibit differences in the frequency and location of genomic alterations, suggesting different pathways for progression. No studies concurrently assess the *TP53* mutation status and its associations with genomic alterations and clinicopathological variables at the tumor microenvironment level, which is known to play an important role in the initiation and progression of sporadic breast cancers. We performed *TP53* mutation analysis and whole-genome loss-of heterozygosity (LOH) analysis on epithelial and stromal DNA from 175 sporadic and 43 archived HBOC-related cancers. We analyzed compartment-specific patterns of LOH and *TP53* mutations and computed associations between *TP53* status, LOH and patient clinicopathological characteristics. We found *TP53* mutation is associated with increased LOH in both HBOC and sporadic breast cancers. The stroma of sporadic breast carcinomas had 67 loci associated with mutated *TP53*, in comparison to only 1 locus (2p25.1) in the HBOC stroma samples. Somatic *TP53* mutations in the stroma, but not epithelium, of sporadic breast cancers were also associated with nodal metastases (pN). No such associations were observed for HBOC-related cancers. Our data indicate that stroma-specifc LOH is associated with somatic *TP53* mutation and an increased likelihood of regional metastases in sporadic breast carcinoma, but not HBOC-related breast cancers. A subset of 5 loci associated with increased LOH in the stroma of sporadic cases also contribute to the association between *TP53* mutation and pN, suggesting they may harbor modifiers which increase stromal p53s effect on sporadic breast cancer progression.

Cytogenetic analysis of 135 myelodysplastic syndrome patients. *E. Pariltay[1], A. Alpman[1], E. Karaca[2], B. Durmaz[2], O. Cogulu[2], F. Ozkinay[2]* 1) Medical Genetics, Ege University Faculty of Medicine, Izmir, Turkey; 2) Department of Pediatrics, Division of Genetics and Teratology, Ege University Faculty of Medicine, Izmir, Turkey.

Myelodisplastic syndromes (MDS) represent heterogeneous group of disorders with a variety of features including peripheral cytopenia, characteristic morphological findings and cytogenetic abnormalities in bone marrow. Clonal chromosomal aberrations may be found in about 40 to 50% of all MDS patients. In this study we retrospectively evaluated the cytogenetic findings in a series of 135 MDS patients that karyotype analysis were performed between 1998 and 2007. Among 124 cases of MDS that were cytogenetically analyzed successfully, abnormal karyotype was found in 33 cases. The abnormal karyotypes were determined to be 20 numerical, 12 structural changes and 1 both numerical and structural. The most common chromosomal aberration was found to be loss of Y chromosome (n=5) which is followed by mosaic trisomy 21 (n=3). The structural findings included deletions (chromosome 5q, 7q, 9q, 12p, 13q, 17p and 22q) and translocations [t(1,3)(p10;q10), t(10;17)(q24.3;q11.2), t(3;11)(p12;p15), t(8;20)(p21;q21), t(7;14)(q10;p10)]. The evaluation of the cytogenetic findings in this relatively large, single-institution study will likely facilitate further studies to characterize and to document rare and primary cytogenetic changes associated with MDS.

Association of the ARLTS1 Gly65Val and Cys148Arg variants with breast and prostate cancer risk. *J. Schleutker[1], S. Siltanen[1], K. Syrjakoski[1], R. Fagerholm[2], T. Ikonen[1], P. Lipman[3], K. Holli[4], T. Tammela[5,6], HJ. Jarvinen[7], JP. Mecklin[8], K. Aittomaki[9], C. Blomqvist[10], JE. Bailey-Wilson[3], H. Nevanlinna[2], LA. Aaltonen[11], P. Vahteristo[11]* 1) Laboratory of Cancer Genetics, Institute of Medical Technology, Univ of Tampere, Tampere, Finland; 2) Dept of Obstetrics and Gynaecology, Helsinki Univ Central Hospital (HUCH), Helsinki, Finland; 3) Inherited Disease Research Branch, National Human Genome Research Institute, NIH, Baltimore, Maryland; 4) Dept of Oncology, UTA and TAUH, Tampere, Finland; 5) Dept of Urology, TAUH, Tampere, Finland; 6) Medical School, UTA, Tampere, Finland; 7) Second Dept of Surgery, HUCH, Helsinki, Finland; 8) Dept of Surgery, Jyväskylä Central Hospital, Jyväskylä, Finland; 9) Dept of Clinical Genetics, HUCH, Helsinki, Finland; 10) Dept of Oncology, HUCH, Helsinki, Finland; 11) Dept of Medical Genetics, Univ of Helsinki, Helsinki, Finland.

ARLTS1 was recently found as a tumor susceptibility gene when a nonsense mutation Trp149Stop was found more frequently in familial cancer cases than in sporadic cancer patients and healthy controls. We screened the ARLTS1 gene for 1242 breast cancer, 541 prostate cancer, and 241 colorectal cancer cases as well as for 809 healthy population controls by direct sequencing. The Trp149Stop was found at frequencies 0.5-1.2% in all cancer patient subgroups, and with the highest frequency among controls. The recessive model of Cys148Arg variant was found to be more common among breast cancer cases (OR=1.48, 95% CI 1.16-1.87, p=0.001) and in prostate cancer patients (OR 1.50, 95% CI 1.13-1.99, p=0.005) when compared to controls. A novel variant that may have an effect on cancer risk is a Gly65Val alteration that was found at higher frequency among familial prostate cancer patients (8/164, 4.9%) when compared to the controls (13/809, 1.6% OR 3.14, 95% CI 1.28-7.70, p=0.016). No association was found with any of the variants and colorectal cancer risk. Our results suggest that Trp149Stop is not a predisposition allele in breast, prostate or colorectal cancer in the Finnish population, whereas the Gly65Val increase the familial prostate cancer risk and the Cys148Arg both prostate and breast cancer risk.

Expression profiles of ependymal tumors correlate with clinical characteristics and help to identify involved oncological pathways. *T. Palm[1], F. Scaravilli[2], I. Salmon[3], J. Mikol[4], D. Figarella-Branger[5], C. Lacroix[6], F. Chapon[7], D. Ellison[8], M. Vikkula[1], C. Godfraind[9]* 1) de Duve Institute, UcLouvain, Belgium; 2) UCLondon, UK; 3) Erasme University Hospital, Belgium; 4) Lariboisière Hospital, France; 5) Hôpital de La Timone, France; 6) Hôpital de Bicêtre, France; 7) CHU de Caen, France; 8) Oregon Health & Science University, USA; 9) Laboratory of Neuropathology, UcLouvain, Belgium.

Ependymal tumors are primary tumors of the central nervous system. The tumorigenesis of the ependymal tumors is not well understood and current histoprognostic markers only imperfectly predict the clinical evolution of the WHO grade II and III tumors. For several cancers, novel specific treatments have been developed, but for ependymal tumors we have not even characterized and understood their tumorigenesis pathways. In this study, we used a series of 38 ependymal tumors to perform an array-based expression study with the aim to identify tumor sub-type specific gene expression profiles and to characterise pathways leading to tumor development. By a non-supervised bio-informatic analysis, the ependymal tumors first clustered depending on tumor grade and secondly depending on tumor localisation. By a supervised analysis, opposing the expression profiles of grade II and grade III tumors, a series of differently expressed genes was isolated. The expression level of these genes could become molecular markers to be used to help to determine tumor grade and to improve quality of diagnostics. Furthermore, by analysing specific pathways known to be important in cancer, we identified alterations in expression levels of specific genes which confer one, or another, tumor-inducing characteristic to the ependymal cells. Although, these characteristics were prominent, they were not exclusive to one single tumor group. In conclusion, we show that each ependymal tumor has a specific expression profile, depending firstly on tumor grade and secondly on tumor localisation. However, expression profiles also differ regarding suggested tumor-inducing pathways, demonstrating different profiles even for tumors of the same grade and localisation. (Catherine.Godfraind@anpg.ucl.ac.be).

Molecular spectrum of Hunter syndrome in Taiwan. *S.P. Lin[1,2,3], J.H. Chang[4], C.K. Chuang[2], G.J. Lee-Chen[4]* 1) Department of Pediatrics, Mackay Memorial Hospital, Taipei 104, Taiwan; 2) Department of Medical Research, Mackay Memorial Hospital, Taipei 251, Taiwan; 3) Department of Early Childhood Care and Education, Mackay Medicine, Nursing and Management College, Taipei 251, Taiwan; 4) Department of Life Science, National Taiwan Normal University, Taipei 117, Taiwan.

Hunter syndrome (MPS II) is a very important rare inherited disorder in East Asia. It is an X-linked recessive lysosomal storage disease caused by a defect of the iduronate-2-sulfatase (IDS) gene, and it counts for more 65% of our MPS population. Various mutations underlying Hunter syndrome have been reported worldwide. To investigate the molecular spectrum of Taiwanese MPS II to help with clinical management, probands and families were recruited and screened for IDS mutations. Expression study was also performed by transfection of COS-7 cells with the mutated cDNA. Together a total of 22 mutations, including 12 missense mutations, 4 splicing defects, 2 nonsense mutations, and 4 deletions, were characterized from 34 families. Missense single nucleotide substitutions A85T, W267C, S305P, and splicing defects G374sp, 1006+5g>c were found from 5 mild MPS II patients. P228L was identified from an intermediate form patient. Carrier detection confirmed a 3:2 ratio of inherited and de novo mutations. In transfected COS-7 cells, mutations from mild form MPS II showed 2.0-3.9% of normal IDS activity. Although they did not cause an apparent reduction in the level of IDS mRNA, the expressed IDS precursor did not show normal maturation. The characterization of gene mutations may delineate their functional consequence on IDS activity and processing, and may enable future studies of genotype-phenotype correlation to estimate prognosis and lead to better selection of MPS II patients for therapeutic intervention.

Pinpointing candidate genes for non-syndromic core autism by high resolution SNP array based segmental aneuploidy screening. *B. van der Zwaag[1], W.G. Staal[2], M. Poot[3], R. Hochstenbach[3], N. Verbeek[3], H.A. Spierenburg[1], R. van 't Slot[4], M.V. de Jonge[2], M.R. Nelen[3], E. van Daalen[2], H.K. Ploos van Amstel[3], H. van Engeland[2], J.P.H. Burbach[1]* 1) Rudolf Maguns Institute of Neuroscience, Dept. of Pharmacology and Anatomy, UMC Utrecht, Utrecht, Netherlands; 2) Dept. of Child and Adolescent Psychiatry, UMC Utrecht, Utrecht, Netherlands; 3) Dept. of Medical Genetics, UMC Utrecht, Utrecht, Netherlands; 4) Dept. of Biomedical Genetics, UMC Utrecht, Utrecht, Netherlands.

Autism spectrum disorders (ASD) are common neurodevelopmental disorders characterized by impaired reciprocal social interaction, communicative deficits, and restricted and repetitive interests and patterns of behavior. The risk for ASD is highly determined by genetic factors, but only a few genes have been unambiguously linked to the disorder (e.g. MeCP2, FMR1, TSC1/2, and SHANK3), and the pathways involved have remained elusive. Whole genome copy number analysis has shown that inherited and de novo copy number variations (CNVs) contribute significantly to ASD etiology. However, most of these CNVs contain many genes, in part explaining the presence of diverse and often severe clinical features in these patients in addition to ASD. Based on the hypothesis that autism patients with only a limited clinical co-morbidity are likely to carry relatively small pathogenic chromosomal aberrations, we have screened 54 patients with core autism without additional clinical features for segmental aneuploidies on the Infinium HumanHap300 SNP platform. In total we identified 81 regions with copy number changes that did not occur in healthy controls (n=266), ranging in size from 4.3 Kb to 6.21 Mb. There was little to no overlap between individual patients, suggesting significant heterogeneity in ASD. Nineteen of the aberrant regions overlapped with CNVs previously reported in ASD (Vorstman, Mol.Psych. 2006), and 11 contained one or more genes that could contribute to ASD. This has allowed us to pinpoint several candidate genes for ASD, including SHANK3. Selected candidate genes, which have been implicated in synaptogenesis and actin dynamics, were all expressed in the developing murine brain cortex.

Apoptosis in nonsyndromic cleft lip with or without palate. *K.S. Weymouth[1], S. Stal[2], J.B. Mulliken[3], D. Ma[4], S.H. Blanton[4], J.T. Hecht[1]* 1) University of Texas Medical School at Houston; 2) Texas Children's Hospital, Houston, TX; 3) Boston Children's Hospital, MA; 4) University of Miami Miller School of Medicine, Miami, FL.

Nonsyndromic cleft lip with or without palate (NSCLP) is a common birth defect affecting 1/700 livebirths and 4,000/yr in the United States. NSCLP is a complex disease involving multiple genes and environmental factors. Development of the lip and palate is a multifaceted process in which program cell death plays a vital role in craniofacial development. Fusion of the palatine shelves requires apoptosis of the epithelial edge, exposing the basal epithelial cells and allowing the midline seam of the palate to form. Failure of program cell death to occur in the epithelial edge could contribute to the development of NSCLP. Genetic variation in key genes of the mitochondrial-mediated apoptotic pathway may play an etiological role in NSCLP. To test this hypothesis, genes in the apoptotic pathway, CASP3, CASP8, CASP9, CASP10, Apaf-1, Bid (pro-apoptotic genes), Bcl-2 and CFLAR (anti-apoptotic genes), were interrogated. Fifty-four SNPs spanning these apoptotic genes were genotyped in 127 multiplex families and 348 simplex trios of Caucasian and Hispanic ethnicity. All SNPs were in Hardy-Weinberg equilibrium. Analysis with PDT was stratified by population because the allele frequencies differed between Caucasian and Hispanic populations. CASP3 (three SNPs), CFLAR (2 SNPs) and Bcl-2 (1 SNP) were associated with NSCLP in the Caucasian cohort. CASP3 showed association with NSCLP in the Hispanic cohort. One CASP3 SNP (rs4647602) genotyped showed association with NSCLP in both the Caucasian (p=.03) and Hispanic (p=0.006) cohorts. CASP3 is expressed during palatal fusion, thus variation in CASP3 expression could affect the initiation of program cell death. CFLAR and Bcl-2 are both anti-apoptotic genes and variation in these genes would affect their ability to inhibit the apoptotic pathway. Gene-gene interaction studies are underway. These results suggest an association of CASP3, CFLAR and Bcl-2 with NSCLP indicating that variation in apoptotic genes may play a role in NSCLP.

The GLUT9 gene is associated with serum uric acid levels in Sardinia and Chianti cohorts. *S. Li[1], S. Sanna[2, 3], M. Dei[2], S. Lai[2], G. Usala[2], A. Maschio[2], F. Busonero[2], A. Mulas[2], M. Orrù[2], G. Albai[2], S. Bandinelli[4], D. Schlessinger[1], A. Scuteri[1,5], S. Najjar[1], A. Cao[2], G. Abecasis[3], L. Ferrucci[1], M. Uda[2], WM. Chen[3], R. Nagaraja[1]* 1) Gerontology Research Center, National Institute on Aging, Baltimore, MD; 2) Istituto di Neurogenetica e Neurofarmacologia, Consiglio Nazionale delle Ricerche, Cagliari, Italy; 3) Center for Statistical Genetics, Department of Biostatistics, University of Michigan, Ann Arbor, Michigan, United States of America; 4) Geriatric Rehabilitation Unit, Azienda Sanitaria Firenze (ASF), Florence, Italy; 5) Unita Operativa Geriatria, Istituto Nazionale Ricovero e Cura Anziani, Rome, Italy.

High serum uric acid levels are associated with higher risk of cardiovascular events and metabolic syndrome; they are also likely accompanied by activation of inflammation cascade. We executed a genome-wide association scan in the genetically isolated population of Sardinia to identify genetic variants associated with levels of uric acid as a quantitative trait. Specifically, 3329 individuals were genotyped with the Affymetrix 10K SNP Mapping Array and 1,412 individuals with the Affymetrix 500K Mapping Array set. With the latter data, and using modified Lander-Green algorithm, full genotype on the 2,893 individuals typed with 10K panel was derived. Using the 362,129 SNPs that passed quality control checks, we found associated SNPs on chromosome 4 in the GLUT9 gene, a class II glucose transporter predominantly expressed in liver and kidney. Within the gene, rs6855911 showed the strongest association with uric acid levels (p = 1.84*10-16) along with 8 other SNPs (p-values 7.75*10-16 to 6.05*10-11), all in the 5 portion of the gene. In Sardinia, homozygotes for the rare allele of this SNP (minor allele frequency = 0.26) had 0.9 mg/dl less uric acid than homozygotes for the common allele; the results were replicated in an unrelated cohort from the Tuscany region (InCHIANTI study). GLUT9 polymorphisms could lead to differential glucose assimilation and indirectly, affect uric acid levels.

Association study of five human genes involved in melatonin signaling pathway and photoentrainment (AANAT, MTNR1A, MTNR1B, OPN3, OPN4) in mood disorders. *V. Soria[1], M. Gratacos[2], J.R. Gonzalez[2], J. Valero[3], E. Martinez-Amoros[1], M. Bayes[2], A. Gutierrez[3], R. de Cid[2], J.M. Crespo[1,4], L. Martorell[3], E. Vilella[3], A. Labad[3], J.M. Menchon[1], J. Vallejo[1], X. Estivill[2,5], M. Hospital Universitari Institut Pere Mata, Rovira i Virgili University. Reus. Tarragona, Catalonia, Spain; 4) Department of Psychiatry, Barcelona University. Barcelona, Catalonia, Spain; 5) Pompeu Fabra University, Barcelona, Catalonia, Spain.

Disruption of circadian rhythms including abnormalities of circadian phase position and melatonin secretion, have been described in mood disorders (MD). We performed a genetic case-control study for the following candidates genes: Arylalkylamine N-acetyltransferase (AANAT), opsin 3 (OPN3), opsin 4 (OPN4), melatonin receptor 1A (MTNR1A) and melatonin receptor 1B (MTNR1B). The sample consisted of 365 unrelated patients (218 Unipolar Major Depressive Disorder, 147 Bipolar Disorder) diagnosed according to DSM-IV criteria and 419 screened control subjects. We genotyped a set of 29 TagSNPs representative of the patterns of common variation identified in European population selected from HapMap project dataset covering the entire genomic region of OPN3, OPN4, MTNR1A, MTNR1B and validated variants in AANAT. The SNPlex Genotyping System was used. Single SNP case-control association analysis considering the MD phenotype identified a positive association in MTNR1B which did not remain significant after Bonferroni correction, and a significant association in a SNP located in the promoter region of AANAT which remained significant after multiple testing correction. Subjects carrying the AANAT rare allele had almost two-fold probabilities of suffering from MD (OR = 1.84; CI95% = 1.32-2.56; p = 0.0003). Our results support the hypothesis that the circadian clock mechanisms could contribute to the pathophysiology of MD.

Spectrum of NPHP6 (CEP290) Mutations in Leber Congenital Amaurosis and Delineation of the Associated Phenotype. *I. Perrault[1], N. Delphin[1], S. Hanein[1], S. Gerber[1], J.-L. Dufier[2], O. Roche[2], H. Dollfus[3], A. Munnich[1], J. Kaplan[1], J.-M. Rozet[1]* 1) Genetics Dpt & Research Unit INSERM U781, Hopital Necker, Paris, France; 2) Ophthalmology Dpt, Hopital Necker, Paris, France; 3) Ophthalmology Clinic, Hopitaux Universitaires de Strasbourg, France.

Purpose: Mutations in the NPHP6(CEP290)gene account for Joubert and Senior-Loken syndromes and Leber congenital amaurosis (LCA). LCA patients were reported to carry an intronic mutation resulting in an aberrantly spliced transcript and low levels of wild-type transcript believed to explain the absence of cerebellar and renal involvement in LCA patients. The aim of the present study was to give the survey of NPHP6 mutations in our series. Methods: 192 unrelated LCA cases were screened for the frequent intron 26 mutation(c.2991+1655A>G)as well as the 53 coding NPHP6 exons. Results: Mutations were identified in 38/192 LCA families (38/38 of European descent). All mutations but two were either non-sense, frameshift or splice-site changes. The common NPHP6 intronic mutation accounted for 33/76 of all disease alleles. Twelve unrelated LCA cases did not carry this common intronic mutation, ten of which, at least, harboured two mutations expected to truncate the protein. Whatever their genotype, all patients but three had a visual acuity <1/20, salt and pepper aspect of the retina with macular degeneration in the first decade progressing to a typical aspect of RP at the end of the second decade onwards, a severe hyperopia (+6D or more) and a slight photoaversion. Conclusions: We confirm the high frequency of NPHP6 mutations in LCA (19.8%) as well as that of the c.2991+1655A>G mutation (43% of disease alleles). We suggest that a significant fraction of LCA families segregate two null alleles questioning the relevance of the assumption according to which the retinal-restricted phenotype in LCA could be due to a residual NPHP6 activity. Indeed, Joubert syndrome was excluded by cerebral MRI in all patients presenting with developmental delay. Finally, we show that all patients of our series are affected with the cone-rod subtype of the disease whatever their NPHP6 genotype.

A population-based WGAS approach to identify genes associated with plasma levels of GGT levels, as a marker for liver disease in Metabolic Syndrome. *H.A. Stirnadel[1], X. Yuan[2], P. Vollenweider[3], D. Waterworth[2], K.S. Song[2], B. Koshy[2], G. Waeber[3], V. Mooser[2]* 1) GlaxoSmithKline, R&D, London UK; 2) GlaxoSmithKline, R&D, King of Prussia PA, RTP NC; 3) CHUV University Hospital Lausanne, Switzerland.

BACKGROUND : Non-alcoholic fatty liver disease, a condition associated with metabolic syndrome (MS), is usually accompanied by an elevation in plasma levels of Gamma Glutamyl Transferase (GGT). Susceptibility to this condition may have an underlying genetic component. We hypothesized that genes determining GGT levels have a more profound effect on this trait in the presence of stressors like MS, alcohol and certain drugs. The primary goal of the present study was to identify such susceptibility genes for liver diseases, using plasma GGT levels as proxy. METHOD : We performed a four-step WGAS on the Lausanne CoLaus population-based study with 5641 participants, 35-75 years of age, genotyped with the Affymetrix 500K SNP chip. Linear regression analysis was performed on GGT levels as quantitative trait. RESULTS : In the overall study population 797 subjects were classified with having MS according to the ATP-III criteria, and 1764 subjects reported to drink at least 10 alcoholic beverages per week (alcohol group). The serum GGT levels (MeanSD) were significantly higher in the MS (52 66 IU/L; $p<0.0001$) and alcohol group (42 53 IU/L; $p<0.0001$) compared to the general population (3240 IU/L). Out of 21,522 SNPs associated with GGT levels in the general population, 2900 were specific to MS patients. From this pool, 495 SNPs (130 genes), were also associated with GGT levels in alcohol drinkers. Eighty-eight of these genes are expressed in human liver. CONCLUSION : Our preliminary results indicate that 88 liver-related genes are associated with plasma GGT levels. Replication of these genetic associations may help identify genes that predispose susceptibility to metabolic syndrome-associated and/or drug-induced liver disease.

Genetic evaluation of CNDP1 and CNDP2 polymorphisms in Diabetic Nephropathy. *C.W. McDonough[1], P.J. Hicks[2], B.I. Freedman[3], D.W. Bowden[1-3]* 1) Molecular Medicine, Wake Forest University School of Medicine, Winston-Salem, NC; 2) Biochemistry, Wake Forest University School of Medicine, Winston-Salem, NC; 3) Internal Medicine, Wake Forest University School of Medicine, Winston-Salem, NC.

The 5L allele of an SSTR marker in the carnosinase 1 gene (CNDP1) on chromosome 18q22.3 is associated with protection from diabetic End-stage renal disease (ESRD) in Europeans and European Americans (EA). CNDP1 encodes a secreted serum carnosinase which degrades carnosine; potentially predisposing to ESRD via oxidative injury and advanced glycation end-product formation. We identified 55 SNPs by sequencing the exons, promoter and 3 UTR of CNDP1 and the adjacent CNDP2 gene in DNAs from 6 African Americans (AAs) and 6 EAs. 46 SNPs were genotyped in 300 EA subjects with type 2 diabetes mellitus (T2DM)-ESRD) and 310 controls, and in 380 AA subjects with T2DM-ESRD and 364 controls. Three SNPs in CNDP1; two intronic: rs4892247, rs11659237, and one in the 3 UTR: rs2887; were significantly associated in multiple genotypic models in both populations. In EAs the 3 SNPs were associated with risk of T2DM-ESRD in a recessive model: odds ratios OR (p value) 1.95(0.023), 2.03(0.015) and 2.22(0.007) respectively. In AAs, rs4892247 was protective in an additive model: OR (p value) 0.73(0.002); and rs11659237 and rs2887 were associated with risk in an additive model: OR (p value) 1.37(0.003) and 1.33(0.007) respectively. If the EA population was stratified by 5L status, no risk association was seen in 5L/5L homozygotes, but the 3 SNPs were still significantly associated with risk in those with one or no copies of the 5L allele in a recessive model: OR (p value) 2.1(0.022), 2.05(0.024) and 2.27(0.01) respectively. When AAs were stratified by 5L status, rs11659237 and rs2887 showed significant association in 5L homozygotes in an additive model: OR (p value) 1.49(0.027) and 1.45(0.032) respectively; and rs4892247 and rs11659237 were significantly associated in those with one or no copies of 5L allele: OR (p value) 0.72(0.012) and 1.32(0.04) respectively. The 3 SNPs are in high LD These results suggest additional genetic variants in CNDP1 influence susceptibility to T2DM-ESRD.

Functional characterisation of 3 novel missense mutations in the ferroportin 1 gene (Hemochromatosis type 4). *E. Létocart[1], G. Le Gac[1], C. Ka[1], C. Férec[1], H. Fierens[2], W. Wuyts[2], S. Majore[3]* 1) Inserm U 613, BREST, France; 2) Univ Hospital, Antwerp, Belgium; 3) Camillo-Forlanini Hospital, Rome, Italy.

Background: Hemochromatosis (HC) refers to 5 inherited disorders of iron metabolism. HC type 4 can be distinguished from the other forms as it is transmitted through a dominant mode and that it can predominantly affect Kupffer cells rather than hepatocytes. Ferroportin 1 (FPN1) is the only known membrane protein that can export iron from enterocytes, macrophages and hepatocytes. Upon an iron overload condition, FPN 1 is down-regulated by hepcidin. The FPN1 mutants fall into two functional categories: loss-of-function mutants, which are not able to export iron into the blood circulation, and gain-of-function mutants, which resist to hepcidin. Goal of the study: To demonstrate an association of 3 novel missense mutations with the disease through the development of functional experiments. Patients and methods: The 3 studied mutations were identified in single pedigrees. The patients originated from Belgium, Italy and Ivory Coast. Our functional tests allowed cellular localisation studies (using cell fragmentation and Western-Blottings), iron export measurements (by directly assessing radioactive iron release or indirectly by quantifying the intracellular ferritin levels) and resistance to hepcidin evaluations (using a synthetic 25 aa peptide and subsequently quantifying the intracellular ferritin levels). Results: We have achieved the functional experiments proving that the three tested protein mutants are efficiently addressed onto the cell surface and are able to export iron. We are currently testing resistance to hepcidin to evidence a gain-of-function. Conclusion: All the reported SLC40A1 mutations are rare or private and most of them are missense. This situation excludes the classical genotype/phenotype strategy and clearly requests the development of functional approaches. Moreover, the description of three novel amino-acid changes could give new opportunities to better understand the structure/function relationship between hepcidin, which is a key regulator of the iron homeostasis, and its cell target, namely the ferroportin 1 protein.éé.

Polymorphisms in the interleukin-12 and interleukin-23R genes are associated with psoriasis of early onset in a UK cohort. *Rh.Ll. Smith[1,2], R.B. Warren[1,2], S. Eyre[1], P. Ho[1], X. Ke[1], H.S. Young[2], C.E.M. Griffiths[2], J. Worthington[1]*
1) ARC-EU, The University of Manchester, UK; 2) Dermatological Sciences, The University of Manchester, UK.

Psoriasis is a chronic inflammatory skin disease that affects approximately 2% of the population worldwide. A recent genome-wide association scan (GWAS) focussing on gene-centric single nucleotide polymorphisms (SNPs) identified four non-Human Leucocyte Antigen (HLA) SNPs associated with psoriasis in a North American population (Cargill, *et al.* 2007), one of which (rs3212227) had previously been associated with psoriasis in a study of Japanese patients. These polymorphisms were found within the interleukin (*IL*)-*12* and *IL-23R* genes located on chromosomes 5 and 1 respectively. The purpose of this study was to investigate these associations in a UK cohort of Type I psoriasis patients (onset of disease 40 yrs of age). Each marker was investigated independently in a case-control setting. The four SNPs, 2 in *IL-12* and 2 in *IL-23R*, were genotyped in 597 UK Type I psoriasis patients (53.6% male; mean age of onset 19.8 years) using the Sequenom iPLEX genotyping platform. Genotype frequencies were compared against healthy volunteers (data made available by the Welcome Trust Case Control Consortium, ~2700; and 1958 Birth Cohort, ~4700). All four SNPs: rs3212227, rs6887695, rs11209026 and rs7530511 were significantly associated with Type I psoriasis ($p = 0.003$, 0.001, 0.001 and 0.001 respectively). In *IL-12*, SNP rs3212227 conferred risk by carriage of two copies of the major allele with an odds ratio (OR) = 1.38 (95% CI 1.14 - 1.68, $p = 0.0004$); and rs6887695 conferred risk on the basis of a dominant model of inheritance for the major allele OR = 1.72 (95% CI 1.18 - 2.56, $p = 0.0016$). The *IL-23R* polymorphism rs11209026 also conferred risk by a dominant model of inheritance for the major allele OR = 1.67 (95% CI 1.20 - 2.37, $p = 0.0008$) with rs7530511 conferring risk by carriage of two copies of the major allele OR = 1.98 (95% CI 1.51 - 2.63, $p < 0.0001$). These results confirm the association of both *IL-12* and *IL-23R* in a UK population of patients with early-onset psoriasis.

A Bayesian Hierarchical Mixture Model for Genotype Calling in a Multi-Cohort study. *C. Spencer, J. Marchini, Y.Y. Teo, P. Donnelly* Dept Statistics, Univ Oxford, Oxford, United Kingdom.

It is becoming well understood that artifacts from genotype-calling algorithms can lead to elevated false-positive rates in genome-wide association studies. This problem is as serious as the well-known confounding effect of unknown population structure but has received far less attention in the literature. We have developed a new genotype calling algorithm, CHIAMO, implemented in a Bayesian statistical framework. The model underlying the algorithm is hierarchical, allowing the pooling of information across different collections and from external sources or other studies, with a prior structure that favours plausible configurations of the positions and shapes of intensity clusters. CHIAMO was used to call genotypes for the Wellcome Trust Case-Control Consortium multi-disease study. Using genotypes assayed on both Illumina and Affymetrix platforms we assessed performance of the algorithm in comparison to the widely used BRLMM algorithm. We found that CHIAMO approximately halved both the error rate (0.60% to 0.37%) and percentage of missing data (0.63% to 0.33%). A detailed analysis of calls at individual SNPs shows that BRLMM, CHIAMO and the Illumina platform are prone to different kinds of errors. We show how to adapt the algorithm for the next-generation genotyping chips.

Genotyping error detection in unrelated samples. *N. Liu[1], D. Zhang[2], H. Zhao[3,4]* 1) Dept of Biostatistics, Univ of Alabama at Birmingham, Birmingham, AL; 2) Dept of Statistics, Purdue Univ, West Lafayette, IN; 3) Dept of Epidemiology and Public Health, Yale Univ, New Haven, CT; 4) Dept of Genetics, Yale Univ, New Haven, CT.

Even with the advancement of modern technology, data with genotyping errors are still common in genetic studies. Besides the possibility of causing genotyping errors from equipment, such as any damage or loss of performance of some probes of the multiplexed platforms used for genotyping, there are other situations where genotyping errors can also be induced, such as variation in DNA quality/quantity or molecular effects. Many studies have shown that genotyping errors can cause severe problems in genetic studies. To date, however, almost all analytic methods assume that the inputs of the genotype data are without errors. The identification of genotyping errors still remains neglected. The majority of existing genotyping error detection methods is for pedigree data, such as checking for Mendelian consistency and/or Hardy-Weinberg equilibrium (HWE). For unrelated population data, very few methods have been developed for this purpose, besides HWE checking. They mainly rely on external "validation" study, or replicates to get the estimates of error rates, with very few exceptions. We evaluate several models for genotyping error detection in unrelated samples with SNP data. We show that the parameters of these models are not identifiable. However, we also show that with some restrictions on the parameter spaces, the parameters of some of the models are identifiable. Simulation study shows that one of the models performs well, with appropriate coverage probabilities for the estimates and decent power. We also apply that model on HapMap data and another real data to show its usability in practice. The results show that even for high quality HapMap data, there are still SNPs which would have been overlooked by deviations from HWE but are suspicious to genotyping errors. Our work may help researchers to estimate genotyping error rates of their data, and use the estimates of errors in their analysis to increase power and decrease bias, without the extra work to genotype family members or replicates.

Cryptic Xq duplications in *ETV6/RUNX1*-positive acute lymphoblastic leukemia. *H. Lilljebjörn[1], M. Heidenblad[1], B. Nilsson[1], C. Lassen[1], A. Horvat[1], J. Heldrup[2], M. Behrendtz[3], B. Johansson[1], A. Andersson[1], T. Fioretos[1]* 1) Department of Clinical Genetics, Lund University Hospital, Lund, Sweden; 2) Department of Pediatrics, Lund University Hospital, Lund, Sweden; 3) Department of Pediatrics, Linköping University Hospital, Linköping, Sweden.

Seventeen *ETV6/RUNX1*-positive pediatric acute lymphoblastic leukemias (ALLs) were investigated by high resolution array-based comparative genomic hybridization (array CGH), gene expression profiling, and fluorescence in situ hybridization (FISH). Comparing the array CGH and gene expression patterns revealed that genomic imbalances conferred a great impact on the expression of genes in the affected regions. The array CGH analyses identified a high frequency of cytogenetically cryptic genetic changes, e.g., del(9p) and del(12p). Interestingly, a duplication of Xq material, varying between 30 and 60 Mb in size, was found in 6 of 11 males (55%). Genes on Xq were found to have a high expression level in cases with dup(Xq); a similar overexpression was confirmed in t(12;21)-positive cases in an external gene expression data set. By studying the expression profile and proposed function of genes in the minimally gained region, several candidate target genes (*SPANXB, HMGB3, FAM50A, HTATSF1, RAP2C*) were identified. Among them, the testis-specific *SPANXB* gene was the only one showing a high and uniform overexpression, irrespective of gender and presence of Xq duplication, suggesting that this gene plays an important pathogenetic role in t(12;21)-positive leukemia.

Screening for melanocortin-4 receptor mutations in a cohort of Dutch obese children. *L. van den Berg[1,2], H. Delemarre-van de Waal[2,3], P. Heutink[1,3]* 1) Section of Medical Genomics and Center for Neurogenomics and Cognitive Research, VU medical center, Amsterdam, Netherlands; 2) department of Paediatrics, VUmc, Amsterdam, Netherlands; 3) Institute for Clinical and Experimental Neurosciences, VUmc, Amsterdam, Netherlands.

The most common monogenic form of obesity is caused by mutations in the gene encoding the melanocortin 4 receptor (MC4R). This receptor integrates orexigenic and anorexigenic signals in the hypothalamus to regulate food intake and energy expenditure. Several aspects of the role of MC4R mutations in obesity remain unclear. For instance, it is unclear which phenotypic characteristics accompany MC4R mutations. We have established a centre for childhood and adolescent obesity. More than 500 obese children have already visited this centre.

We have screened the coding sequence and the minimal promoter region of MC4R of 119 random patients from our cohort. We found 15 variants, two of which were not described previously (-1101C>T and -705A>T). The -705A>T variant may influence gene expression because it is located in a regulatory element (Lubrano-Berthelier et al. 2003 *Diabetes* 52:2996-3000). It was found in a 3-year-old girl with a body mass index standard deviation score (BMI-SDS) of 3.4. We found a Tyr35STOP mutation in a 12-year-old boy with a BMI-SDS of 2.5. This mutation leads to a truncated non-functional receptor. We detected a G231S mutation in a 15-year-old girl with a BMI-SDS of 3.3. This mutation has been shown to reduce the basal activity of the receptor (Govaerts et al. 2005 *Peptides* 26:1909-1919). Three variants remain to be tested functionally (F202L and two variants in the 3UTR). All other variants that we detected are not expected to be pathogenic because they have failed to show MC4R impairment in *in vitro* studies (Asp37Val, V103I, and I251L) or because they have been found at the same frequency in lean people (-1042C>T, -1005C>T, -896C>T, -178A>C). We will extend our research by screening additional patients, studying co-segregation of mutations and obesity in families, studying phenotypic characteristics of MC4R mutation carriers, and functional studies of mutations.

Various Activating TIE2 Tyrosine Kinase Domain Mutations, Including the Recurrent R849W Substitution, Cause Cutaneomucosal Venous Malformation (VMCM) in a Paradominant Fashion. *N. Limaye[1], V. Wouters[1], M. Uebelhoer[1], A. Irrthum[1], L.M. Boon[1,2], J.B. Mulliken[3], J. Murphy[4], P. Rieu[5], L. Kangesu[6], A. Pennington[7], Y. Lacassie[8], J. Berg[9], S.A. Ivarsson[10], O. Enjolras[11], A. Dompmartin[12], E. Baselga[13], M. Vikkula[1]* 1) de Duve Institute, U.C. Louvain, Belgium; 2) Cliniques Universitaires St-Luc, Belgium; 3) Childrens Hospital, Boston, USA; 4) Hospital for Sick Children, Canada; 5) Kinderchirugie, U. Nijmegen, Holland; 6) Essex Hospital, UK; 7) St-Vincents Hospital, U. Melbourne, Australia; 8) Childrens Hospital, LSU Health Sciences Center, USA; 9) Guys Hospital, UK; 10) Universitetssjukhuset, Sweden; 11) Hôpital Lariboisière, France; 12) C.H.U-Department of Dermatology, France; 13) Hospital de la Santa Creu I Sant Pau, Spain.

Venous malformations, characterized by localized bluish lesions in the skin and mucosae, are predominantly sporadic, but 1-2% occur as an autosomal dominantly inherited trait, cutaneomucosal venous malformation (VMCM). Two causative kinase-domain mutations (R849W and Y897S) have thus far been identified, in the Ang receptor TIE2. We studied the TIE2 gene in twelve VMCM families: six bear the R849W change, five have novel tyrosine kinase domain mutations, and one has a carboxy-terminal end mutation. As with the known mutations, in vitro overexpression of these novel mutants results in ligand-independent TIE2 hyperphosphorylation. Interestingly, we also discovered a somatic deletion in VM tissue from a patient carrying the inherited R849W allele, which occurs in trans and partially deletes the TIE2 ligand binding domain. This is the first report of a somatic double-hit mutation in VMCM. Moreover, we show that the deletion-mutant is not hyper-phosphorylated, nor does it increase phosphorylation of the R849W allele. It may instead represent a local loss of wild-type TIE2, which would otherwise rescue the deleterious effects of the mutant, inherited allele. The focal development of VMCM is likely due to such combinations of predisposing hyper-phosphorylating germline mutations, with somatic second-hits, hallmarks of paradominant inheritance. (miikka.vikkula@uclouvain.be).

A simplified single-step SNP genotyping assay - application to multiple ATP-binding cassette transporter SNPs.

C.G. Lee[1,2,3], Z. Wang[1], P.H. Sew[1], S.S. Chong[4] 1) Biochemistry, Natl Univ Singapore; 2) DUKE-NUS Graduate Medical School; 3) National Cancer Centre; 4) Pediatrics, Natl Univ Singapore.

Several different methods have been developed for the simultaneous genotyping of multiple single nucleotide polymorphisms (SNPs). However, most of these techniques either require costly reagents or involve several steps. Here, we describe the development of a low cost, simple, rapid and sensitive SNP genotyping assay that involves a modified real-time allele-specific PCR. In this assay, only standard reagents for real-time PCR with SYBR Green dye are used except for 2 modifications. Instead of regular Taq DNA polymerase, a high fidelity DNA polymerase with 3-5 exonuclease proofreading activity is used. Secondly, one of the amplification primers is allele-specific and modified with a 3-phosphothioate end. With this modification, the 3-5 proofreading activity of the polymerase is blocked when a 3 mismatch between primer and template occurs preventing the polymerase from extending from the mismatched primer. Thus, primer extension, and ultimately DNA amplification, will only occur when there is a perfect match between 3-phosphothioate modified allele-specific primer and DNA template. Amplified product is readily detected in real-time via SYBR Green fluorescence emission. Through threshold cycle (C_t) analyses, the genotype of the DNA target can be readily determined. The entire genotyping process takes <2.5 hours in a standard real-time thermocycler and <1 hour in a Fast Real-Time PCR System. We evaluated the feasibility of this method in a pilot validation analysis of SNPs within several ATP-Binding Cassette (ABC) transporter genes displaying evidence of recent positive selection with potentially functional importance (Wang et al, 2007 HMG 16(11):1367-1380). For each SNP, >20 different genomic DNA samples were genotyped using this method in parallel with minisequencing and/or sequencing. Of 16 different SNPs examined in >400 DNA samples thus far, a genotype concordance rate of >97% was achieved. We conclude that this simple single-step genotyping assay is reliable and potentially amenable to high-throughput simultaneous analyses of multiple SNPs and mutations.

Demographics in FOS - the Fabry Outcome Survey. *A. Mehta[1], M. Beck[2], J. Clarke[3], A. Linhart[4], G. Sunder-Plassmann[5]* 1) Dept Haematology, Royal Free Hosp, London, UK; 2) Childrens Hosp, Univ Mainz, Germany; 3) The Hosp for Sick Children, Toronto, Ontario, Canada; 4) Charles Univ, Prague, Czech Republic; 5) Div Nephrology & Dialysis, Dept of Medicine III, Medical Univ Vienna, Austria.

Background: Fabry disease (FD) is a progressive multisystemic X-linked lysosomal storage disease caused by deficiency of the enzyme -galactosidase A. FOS - the Fabry Outcome Survey - is an international, multicentre database established to monitor patients with FD and their response to enzyme replacement therapy (ERT) with agalsidase alfa. Aims: To examine changes in the characteristics of a large group of patients at enrolment in FOS over a 2-year period. Methods: Data from patients enrolled in FOS were analysed in terms of demography and clinical manifestations of FD. Results and discussion: As of February 2007, FOS contains data from 1329 patients with FD (41% men; 42% women; 8% boys; 9% girls). More females than males have been enrolled since 2005 (82 females v 32 males in 2006/7). A total of 220 children are enrolled in FOS, 54% of whom are girls. These data may reflect increased understanding that women and children with FD can be symptomatic. FOS contains treatment data for 882 patients (51% men, 36% women, 13% children); 66% of the patient population. A larger proportion of women is receiving ERT than reported in 2005 (57% v 47%, respectively). Since 2001, the age at start of ERT has remained relatively stable overall; however, in children, the mean age at start of ERT has decreased (mean age in boys, 12.2 years in 2006/7 v 13.8 years in 2001/2; mean age in girls, 12.8 years in 2006/7 v 15.5 years in 2001/2). Furthermore, the mean severity of signs and symptoms of FD at the start of treatment, as measured by the FOS adaptation of the Mainz Severity Score Index, has decreased in both male and females since 2001. This may indicate that physicians are becoming more aware of the early manifestations of FD and the importance of prompt therapeutic intervention with ERT. Conclusion: These data suggest that heightened awareness in the medical community may have decreased the delay between the onset of symptoms and diagnosis of FD, resulting in the earlier initiation of ERT.

Neuronal ceroidlipofuscinoses (NCLs) in Czech and Slovak patients: Two novel mutations in CLN2 gene and high amount of unexplained NCL6-like cases. *H. Vlaskova, L. Dvorakova, M. Hrebicek, L. Stolnaja, H. Myskova, M. Elleder* Institute of Inherited Metabolic Disorders, 1st Faculty of Medicine and University Hospital, Charles University, Prague.

Ninety one cases of NCLs from 77 families have been diagnosed in our Institute that serves as a diagnostic center for the Czech Republic and Slovakia (15 mil. inhabitants). The diagnosis was carried out using histology, electron microscopy, histochemistry, biochemistry and recently mutation analysis. NCL1 and NCL4 proved to be extremely rare (2 cases of NCL1, one case of NCL4 - the dominant Parry type). NCL2 was diagnosed in 35 patients. The cases corresponded to the classical clinical phenotype, neuropathology, and electron microscopy. In postmortem samples there was a uniform generalized SCMAS (subunit c of mitochondrial ATP synthase) storage. The diagnosis of NCL2 was proved by enzyme assay in 8 patients. Mutation analysis, performed in 11 patients, showed a high prevalence of p.R208X (16/22). Other identified mutations were IVS5-1G>C (3/22), p.S475L (1/22) and two novel substitutions, c.1439T>G (p.V480G) and c.1642T>C (p.W548R). DNA of one patient was not available, analysis of the parental samples revealed a probable patients genotype (p.R208X/p.V480G). This patient presented with an atypical onset (at 6 years) and course of the disease (prolonged span of life until 15 years), which suggests p.V480G to be a mild mutation. NCL3 was diagnosed in 2 patients, both homozygous for the prevalent deletion of 996bp. The rest of the series represented by 34 families with high incidence in the Gipsy population (about 50% of cases) is classified as NCL6 - like. The current DNA analysis carried out in 8 unrelated patients did not reveal any mutations neither in CLN6 nor in CLN5 and CLN8 genes. The diagnosis of NCL6 is thus made per exclusionem and open for further investigation. Our laboratory is a member of The Rare NCL Gene Consortium (www.ucl.ac.uk/ncl/RNGC.shtml). Support: IGA MZ CR NR/8351-3, VZ MSM CR 0021620806, VZ MZ CR 64165.

Miglustat in Niemann-Pick type C disease (NP-C): results of 24 months treatment. *M. Patterson[1], D. Vecchio[1], H. Prady[2], L. Abel[3], J.E. Wraith[2]* 1) Dept Neurology, Columbia Univ, New York, NY, USA; 2) Royal Manchester Childrens Hospital, Biochemical Genetic Unit, Manchester, UK; 3) Department of Optometry and Vision Sciences, University of Melbourne, Australia.

NP-C is an inherited neurodegenerative disorder characterized by an intracellular lipid-trafficking defect and pathological storage of glycosphingolipids. Miglustat, a small iminosugar molecule, prevents accumulation of GSLs by reversibly inhibiting glucosylceramide synthase. Due to its ability to cross the blood-brain barrier, miglustat has the potential to treat NP-C. Adults and juveniles (n=29, age 12 years) were randomized to either miglustat 200 mg t.i.d. (n=20) or standard of care (n=9) for 12 months. In addition, 12 children (age 4-12 years) received miglustat at a dose adjusted for body surface area. All patients were then given miglustat for a second year. Horizontal saccadic eye movement (HSEM) velocity was the primary endpoint. Juveniles/adults receiving miglustat for 12 and 24 months were compared by ANCOVA using baseline and center as covariates. 19 adults/juveniles (meanSD age 24.69.1 years) and 10 children (7.22.5 years) completed the 24-month study. Although an increase (worsening) from baseline in HSEM- was seen at last value in adults/juveniles treated for 12 or 24 months, the increase was smaller in the 24-month group (treatment difference, -0.594; 95%CI -2.078, 0.889). The pattern in children was comparable with the adult/juvenile 24-month group. A higher proportion of patients had stable or improved swallowing capacity in the 24-month than in the 12-month group, and patients in the 24-month group showed a more favorable change on the Standard Ambulatory Index. The most common AEs were diarrhea (64%), weight loss (68%), tremor or aggravated intention tremor (57%), and abdominal pain (54%). The safety profile was similar in both treatment groups. In conclusion, miglustat may slow disease progression in NP-C. A collaborative project on NP-C natural history will help to further understand interventional trial outcomes. The safety/tolerability of miglustat 200 mg t.i.d. in NP-C was consistent with that seen in type 1 Gaucher disease, where half this dose was administered.

Mammal-specific domain in BRN-2 associated with maternal behavior. *M. Nasu[1], Y. Kataoka[2], M. Sato[2], H. Ichise[2], N. Yoshida[2], S. Ueda[1]* 1) Department of Biological Sciences, The University of Tokyo, Tokyo, JAPAN; 2) The Institute of Medical Science, The University of Tokyo, Tokyo, JAPAN.

Brn-2 is a neuronal transcription factor, expressed in the neocortex, the hypothalamus, the cerebellum, etc. and known to regulate the expression of some neuronal factors and proliferation, differentiation and migration of neuronal cells. BRN-2 protein has three stretches of homopolymeric amino acids, polyG, polyQ and polyP, in its transactivation domain. These are conserved among mammals but lacked in fishes and amphibians, meaning that these are mammal-specific sequences. Mammal-specific domain could be associated with mammal-specific function, but there is no verification of that. To investigate the function of mammal-specific domain of BRN-2, we generated mutant mice lacked all of three stretches of homopolymeric amino acids in BRN-2, namely BRN-2GQP.

We found that mutant mice appeared normally to develop, grow and mate, but they were more prone to fail to nurture their pups. Not all but larger number of pups delivered from mutant dams could not survive to be weaned. The decline of pups viability depended not on the genotype of pups but on that of dams. These results suggest that BRN-2GQP retains basal functions for life in spite of the lack of the mammal-specific domain, but BRN-2GQP fails to motivate particular functions. The mammal-specific domain in BRN-2, namely three stretches of homopolymeric amino acids, might contribute to establish maternal behavior including nursing, which was characteristic of and essential to mammals.

Knowledge on heredity and genetics among Japanese. *A. Sakurai, Y. Yamanouchi, Y. Mori, R. Kawamura, T. Kosho, K. Wakui, T. Wada, Y. Sekijima, Y. Fukushima* Dept Med Genet, Shinshu Univ, Matsumoto, Japan.

Thanks to our improvement of understanding on human genome, genome-based personalized (tailor-made) medicine, which provides idealized treatment and drug choice for each patient, is becoming realistic. In order to appropriately utilize such new medical technology, it is required that a meaning of genetic information is correctly recognized and handled by both medical professionals and general public. However, in Japan, education of human genetics has been pointed out to be insufficient both qualitatively and quantitatively. Even in a medical school, education of human genetics is not fully established. We performed questionnaire-based surveys to evaluate knowledge and impression of heredity and genetics among various population and professional groups such as general physicians, nurses, community health nurses, medical students, non-medical college students and elderly (mostly over 60 yrs) citizens who are not engaged in medical services. When asked knowledge of genetics-related terms such as DNA, gene and chromosome, percentage who answered understand and can explain what it is or roughly understand what it is were, ~50% among nurses, ~60-70% among newly-enrolled medical students, ~40-50% among newly-enrolled non-medical students, and ~30% among elderly citizens. The term genome was not well recognized and only 10% of nurses, 10% of non-medical students and 6% of elderly citizens answered that they understand what this word stands for. Terms related genetic medicine such as genetic test and gene therapy were further less recognized; 60-70% of non-medical college students and 60-80% of elderly citizens answered have not heard such word or have heard but do not know what it means. Medical students well recognized those words but their conception was not always correct. For instance, about half of medical students thought gene therapy can prevent transmission of mutant gene from affected parent to offspring. In general, knowledge on human genetics is apparently insufficient among Japanese population even in medical professionals. It is urgently asked to establish standardized education of human genetics and improve genome literacy.

Heritability of female reproductive characteristics in a population exposed to polybrominated biphenyls. *K.C. Taylor[1], C.M. Small[1], M.P. Epstein[2], M.L. Terrell[1], M. Marcus[1]* 1) Epidemiology, Emory University, Atlanta, GA; 2) Human Genetics, Emory University, Atlanta, GA.

We investigated whether exposure to polybrominated biphenyls (PBBs), which are hormonally active environmental contaminants, affected the heritability of reproductive characteristics in an exposed population. Using a cohort comprised of 373 families with variable PBB exposure, we estimated the heritability of self-reported age at menarche and menstrual cycle length using the software package MENDEL and further assessed whether such heritability estimates differed among high-exposed and low-exposed families. We limited the menarche analysis to those who reported age at menarche between 9 and 16 years inclusive (N=1045 of 1057 women who reported an age at menarche). Consistent with other studies, age at menarche was heritable in our population (heritability=0.530.05). We found evidence of additive genetic effects only (dominance effects were not significant). After stratifying by PBB exposure, heritability was somewhat higher in the low-exposed group than in the high-exposed group (0.630.08 vs. 0.460.07). For menstrual cycle length, we limited the analysis to premenopausal women who were not using hormonal contraceptives (N=544), and reported having a standard menstrual cycle length (17-43 days) in the past year (N=521 of 544). After controlling for age at interview, we found menstrual cycle length to have an estimated heritability of 0.26 (0.11). Again, we found evidence of only additive genetic effects and no dominance effects. Heritability of menstrual cycle length was similar in the low-exposed and the high-exposed groups (0.200.16 vs. 0.300.15). To our knowledge, no other studies have examined heritability of menstrual cycle characteristics. In conclusion, age at menarche was more heritable than menstrual cycle length in this population. PBB exposure may modify the effects of genetic factors on these reproductive outcomes.

Public opinion for Direct-to-consumer (DTC) genetic testing in Japan. *T. Ohata, A. Tsuchiya, M. Watanabe, F. Takada* Dept of Medical Genetics, Graduate school of Medical Science, Kitasato Univ, Sagamihara, Japan.

In recent years, DTC genetic testing has gradually become popular. In this situation, consumers are buying tests by their own choices, collecting information from the internet or magazines. In clinical scene, medical professionals require to provide instruction and counseling for genetic testing, following some guidelines. On the other hand, the organization of testing companies, Council for Protection of Individual Genetic Information, made their own guideline voluntarily. But there is no comprehensive regulation system for these testing in Japan.

On February 2007, we performed the inquiry survey based on 3,000-people scale, to hear their opinion on DTC genetic testing. Their ages were ranged from 20 to 69 years old. Twenty seven point five percent of the people answered I have used it, or I know it, and 46.6% answered Genetic testing, provided at any place other than a hospital is convenient. Although the visibility of DTC genetic testing was not so high, the expectation for doing it at any place other than a hospital was high.

About the regulation in this questionnaires, we provided 5 choices which were Our government should regulate it by law, Academic societies should make guidelines which virtually regulate it, Some organization of companies should control it voluntarily, Each company should make a decision voluntarily, and No particular regulation is necessary, and the 66.8% of them expected the regulation by the government.

These results will serve as a basis for initial trials when the regulation for DTC genetic testing will be considered near future.

Genotype-phenotype correlation in adenylosuccinate lyase (ADSL) deficiency. *M. Zikanova, K. Mullerova, J. Krijt, S. Kmoch* Institute for Inherited Metabolic Disorders, Prague, Czech Republic.

ADSL is enzyme acting in two pathways of purine nucleotide metabolism. Mutations in ADSL gene compromising the enzyme activity lead to hypotonia, seizures, psychomotor retardation and behavioral changes. Although spectrum and severity of clinical symptoms overlaps, three forms of ADSL deficiency - severe neonatal, severe childhood and mild myopathic - can be distinguished clinically based on onset and symptoms severity, and biochemically as severity of symptoms decrease with increased ratios of accumulating succinylpurines concentration in body fluids(SAdo/SAICAr ratio). Pathogenetic mechanisms underlying the phenotypic and biochemical heterogeneity remain unknown. We introduced a complex diagnostic system for ADSL deficiency based on metabolite profiling, enzyme activity measurement, mutation analysis and recombinant mutant protein characterization. So far we have analyzed 22 patients from 18 families (8 Czech, 7 Poland, 5 Germany and 2 US). We identified 16 ADSL mutations and cloned, expressed, purified and characterized catalytic properties of corresponding recombinant wild type and mutant ADSL proteins. We observed that residual enzyme activity, calculated as a mean of genotype corresponding homoallelic activities, correlates with severity of phenotype. However, all the active mutant enzymes displayed proportional decrease in activity towards both substrates and no ground for the varied SAdo/SAICAr ratio was found. As all the experiments have been performed on single isolated proteins, the situation does not reflected compound heterozygosity status found in most patients and thus the fact that two different mutant enzymes may form structurally and functionally unique tetrameric structures. This limitation may be partly overcome in complementation experiments. From the literature we therefore collected data on 57 ADSL patients and chose 17 patients with clinically different forms (4 severe neonatal, 6 severe childhood and 7 mild myopathic phenotypes) associated with extreme SAdo/SAICAr ratios. We cloned all 21 ADSL mutations involved in the selected cases and expressed mutant proteins which are currently being characterized.

Hyperacusis in persons with Smith Magenis syndrome: Expanding the SMS phenotype. *A.C.M. Smith[1,2], J. Bentley[3], C. Zalewski[3], R. Morse[1], W. Introne[1], C. Brewer[3]* 1) NHGRI/NIH, Bethesda,MD; 2) Georgetown Univ., Washington,DC; 3) NIDCD/NIH, Bethesda,MD.

Otolaryngologic abnormalities are documented in as many as 94% of individuals with SMS. Oversensitivity to loud sounds is an expressed parental concern. This study seeks to quantify the occurrence and severity of hyperacusis in persons with SMS and document the types of responses, triggers and palliative techniques. Hyperacusis is an oversensitivity to sounds that are tolerable to listeners with normal hearing. A 2-page questionnaire used to evaluate the severity of hyperacusis in William syndrome (WS)(Cohen et al., 2006) was mailed to parents of children with SMS participating in our IRB-approved protocol at NIH (SMS-US) & Australian families at Camp-Breakaway (SMS-AUS). Healthy SMS siblings (n=20) serve as controls. Completed questionnaires (n=63) include 47 SMS-US (mean age 12y) and 16 SMS-AUS (mean age 12.7y). No significant differences were found between SMS-US and SMS-AUS with respect to sensitivity to loud sounds (74% vs 87%) or mean hyperacusis severity score (3.9 vs 4.1), respectively, permitting the data to be combined (SMS-GP). Sensitivity to loud sounds was present in 78% compared to 10% of controls. Mean SMS-GP severity score (3.96, SD 2.92) was significantly higher than controls (0.90, SD 1.52) ($p<0.001$). Intolerance for loud sounds remained unchanged over time for 59%, and 33% improved with time. No significant relationship to degree or type of hearing loss was observed. Major triggers for distress were tiredness (47%) and mood (29%); tiredness was the most cited reason for heightened reaction in 50%. Common behavioral responses to distressing sounds were covering the ears with hands (88%), becoming upset (58%), or displaying anxiety/tension (52%). Self-injurious behaviors were triggered by loud sounds in 28%. Palliative measures or techniques for sound reduction varied with less distress reported when prepared or warned of impending sound. Thus, hyperacusis is pervasive in SMS; however, the SMS mean severity rating is less than reported in WS (mean 5.78,SD2.6)(Cohen et al., 2006), which shares some commonalities in physical and behavioral features.

Autosomal dominant distal myopathy associated with a recurrent missense mutation in the gene encoding the nuclear matrix component, matrin 3. *A. Roos[1], J. Senderek[1], S.M. Garvey[2], I. Tournev[3], C. Stendel[1], A. Urtizberea[4], V. Guergueltcheva[3], V. Mihailova[3], H. Feit[5], J.J. Tramonte[6], P. Hedera[7], J. Weis[8], J.S. Beckmann[9], E. Seboun[10], M.A. Hauser[2], C.E. Jackson[6]* 1) Institute of Human Genetics, Aachen University of Technology, Aachen, Germany; 2) Duke Center for Human Genetics, Duke University, Durham, USA; 3) Department of Neurology, Sofia Medical University, Sofia, Bulgaria; 4) Hôpital Marin, Hendaye, France; 5) Department of Neurology, Henry Ford Hospital, Detroit, USA; 6) Scott & White Memorial Hospital, Temple, USA; 7) Department of Neurology, Vanderbilt University Medical Center, Nashville, USA; 8) Institute of Neuropathogy, Aachen University of Technology, Aachen, Germany; 9) Service of Medical Genetics, CHUV, Lausanne, Switzerland; 10) Division de Génétique et de Microbiologie, Université Pierre et Marie Curie, Paris, France.

Distal myopathies represent a heterogeneous group of inherited skeletal muscle disorders. One type of adult-onset, progressive autosomal dominant distal myopathy, frequently associated with dysphonia and dysphagia, has been mapped to chromosome 5q31 in a North American pedigree (vocal cord and pharyngeal weakness with distal myopathy; VCPDM). Here we report identification of a second VCPDM family of Bulgarian descent and fine mapping of the critical interval. The refined candidate region includes the MAT3 gene that encodes a protein of the nuclear matrix, a filamentous protein network in vertebrate nuclei. MAT3 is a candidate for VCPDM as mutations in the genes for the nuclear envelope proteins lamin A/C and emerin cause muscular dystrophies. Screening of MAT3 for mutations led to the identification of a non-conservative missense mutation affecting a highly conserved serine residue (S85C) in both pedigrees. Different disease related haplotype signatures were observed in the two families, providing evidence that two independent mutational events at the same position in MAT3 cause VCPDM. Our data provide evidence that the nuclear matrix is crucial for normal skeletal muscle structure and function and put VCPDM on the growing list of monogenic disorders associated with the nuclear proteome.

GENOME WIDE SCAN, IDENTIFICATION OF A COMMON HAPLOTYPE CONTAINING A NON-SYNONYMOUS SNP ASSOCIATED TO SYMPTOMATIC OSTEOARTHRITIS. *I. Meulenbelt[1], J.L. Min[1], S. Bos[1], N. Riyazi[2], J.J. Houwing-Duistermaat[3], H-J. van Wijk[3], H.M. Kroon[4], A.G. Uitterlinden[5,6], J.B.J. van Meurs[5], W.M. van der Deure[5], T.J. Visser[5], A.B. Seymour[7], N. Lakenberg[1], R. ter Breggen[1], D. Kremer[1], C.M. van Duijn[6], G. Kloppenburg[2,8], J. Loughlin[9], P.E. Slagboom[1]* 1) Dept. Molecular Epidemiology, Leiden University Medical Center, Leiden, Z-H, Netherlands; 2) Dept. Rheumatology, Leiden University Medical Center, Leiden, Z-H, Netherlands; 3) Dept. Medical Statistics and Bio-informatics, Leiden University Medical Center, Leiden, Z-H, Netherlands; 4) Dept. Osteoarthritis (OA) is a prevalent late-onset disabling joint disease with complex inheritance for which no drug exist which is able reverse or slow down the disease process. Genome-wide nonparametric linkage in 183 sibships from the GARP-study with a generalised OA phenotype, suggested evidence for linkage on chromosome 14q32.11 (LOD = 3.03, $P = 1.9 \times 10^{-4}$). The location of the linkage peak revealed three candidate genes. Genotyping and joint modelling of linkage and association of tagging SNPs capturing the genetic variation of these genes revealed a non synonymous common variant in one of the genes that explained part of the linkage (P = 0.006). In our attempt to replicate this result in two additional independent studies we identified a common haplotype, exclusively containing the minor allele of this SNP, with a significant recessive association (OR = 1.71, 95% CI 1.33-2.19, $P = 2.6 \times 10^{-5}$) in females with symptomatic hip OA. Our findings underscore the importance of a new gene and pathway in the etiology of symptomatic OA.

Identification of abnormalities in subtelomeric regions by microarray analysis: A study of 5380 cases. *L. Shao, C.A. Shaw, X. Lu, A. Patel, T. Sahoo, C.A. Bacino, S. Lalani, P. Stankiewicz, A.C. Chinault, A.L. Beaudet, J.R. Lupski, S.W. Cheung* Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Subtelomeric imbalances are a major cause of congenital disorders. Screening for these abnormalities has utilized GTG-banding analysis and subtelomeric FISH assays. Array CGH is a relatively new technology that can identify microscopic and submicroscopic chromosomal imbalances. Chromosome Microarray Verison 5 (CMA V5) has 853 BAC clones (www.bcm.edu/cma/table.htm, Chip Map V5.0), of which subtelomeric clones constitute a significant fraction (481/853) with an average coverage of 12 clones /10 Mb /region. CMA Version 6 (CMA V6) has 1475 BAC clones and has similar coverage at subtelomeric regions as V5 (www.bcm.edu/cma/table.htm, Chip Map V6.0). We screened 4493 consecutive clinical cases using CMA V5 and 887 cases using CMA V6 and found copy number changes in 591 patients (detection rate of 10.99%), among which pathogenic rearrangements were observed in 238 patients (4.4% of total). Among these patients, 94 had a deletion and 55 had a duplication with a size 9 Mb, 11 had a deletion and 5 had a duplication 9 Mb, 44 had unbalanced translocations, and 19 had complex rearrangements. Almost half of the deletions (45/94) and the majority of the duplications (48/55) were 3 Mb in size. Interstitial rearrangements that would be missed by subtelomeric FISH occurred in 37/94 deletions and 44/55 duplications. In patients with known karyotype or FISH results, 37 deletions out of 70 and 31 duplications out of 35 evaded detection by karyotype and/or FISH. Deletions of 1p36.3, 22q13.3, 4p16.3, and duplications of Xq28 were the most common submicroscopic alterations. In conclusion, subtelomeric genomic imbalances contribute significantly to congenital disorders and array CGH enables greater detection rates when compared to subtelomeric FISH (4.4% versus 2.6% in Ravnans study of 11,688 patients). Targeted array CGH with dense coverage on subtelomeric region is a vital diagnostic tool for identifying subtelomeric imbalances, especially for submicroscopic and interstitial imbalances.

SOLiD™ Sequencing and 2-Base Encoding. *H.E. Peckham[1], S.F. McLaughlin[1], M.D. Rhodes[2], J.A. Malek[1], K.J. McKernan[1], A.P. Blanchard[1]* 1) Applied Biosystems, Beverly, MA; 2) Applied Biosystems, Foster City, CA.

The next generation of DNA sequencing platforms produces sequencing reads with increased depth of coverage but reduced read length and lower per-base accuracy than data from Sanger-based DNA sequencing. New approaches are needed to overcome these issues and provide accurate mutation discovery and consensus sequences. 2-Base encoding is uniquely enabled by the ligation-based sequencing protocol used in the SOLiD™ system (a massively parallel sequencing technology based on ligation of oligonucleotides). Sequencing is carried out via sequential rounds of ligation with high fidelity and high read quality. In this system there are 16 dinucleotide combinations with 4 fluorescent dyes, each dye corresponding to a probe pool of 4 dinucleotides per pool. Using this dinucleotide, 4-dye encoding scheme in conjunction with a sequencing assay that samples every base, each base is effectively probed in two different reactions. The double interrogation of each base causes a SNP to result in a two-color change while a measurement error results in a single color change. In addition, only one-third of all possible two-color combinations are considered valid and result in a base change. 2-Base encoding rules (a single mismatch is a measurement error, only one-third of adjacent mismatches are valid) significantly reduce the raw error rate (30 bp reads have a 45x reduction in raw measurement errors) and this benefit increases 3/2 as the read length is increased. The reduction in raw error rate enabled by 2-base encoding translates into more accurate alignment of short reads, polymorphism discovery and consensus calling.

THE RNA SPLICER GENE SRRM2 IS STRONGLY ASSOCIATED WITH PARKINSON DISEASE. *L.A. Shehadeh[1], N.F. Tsinoremas[4], J.M. Vance[3], N. Adi[2], S. Papapetropoulos[2]* 1) Mol and Cell Pharmacology, University of Miami Miller School of Medicine, Miami, FL; 2) Neurology,UM; 3) Human Genetics, UM; 4) Informatics, Scripps Florida Research Institute.

OBJECTIVES: Parkinsons disease (PD) is a complex neurodegenerative disorder with both genetic and non-genetic factors involved in its etiopathogenesis. Our hypothesis is that by interrogating transcriptome-wide expression data from different PD tissue sources we can discover susceptibility genes that may have sizeable public health benefits. METHODS: We performed extensive analysis on 3 microarray experiments. A total of 148 raw Affymetrix data (cel) files available through GEO were utilized: (A) 22 genechips from substantia nigra (SN) in postmortem brain of PD and controls, (B) 21 from rotenone-treated neuroblasoma cells (an in vitro model of PD), and (C) 105 from blood of PD versus healthy and neurological disease controls. Raw expression files were normalized using GC-RMA processor and analyzed using GeneSpring software. RESULTS: There were 174 transcripts corresponding to 160 genes that were overlapping in at least 2 out of the 3 experiments with only one gene overlapping among all the three PD experiments: the RNA splicing gene SRRM2 (or SRm300), (sereine/arginine repetitive matrix 2. It has been previously reported in two other PD expression studies as significantly upregulated in postmortem substantia nigra of PD patients versus controls. SRRM2 transcript was upregulated by 80% ($p<0.01$) in the substantia nigra of PDs versus controls and by 40% in the 4 wk rotenone treated cells versus the controls. Interestingly, while SRRM2 transcript was upregulated by 20% in the blood of female PDs versus female healthy controls, and 30% in the blood of male PDs versus male healthy controls, it was not changed in the blood of neurological diseased female or males versus the healthy controls. CONCLUSION: The consistent upregulation of the RNA splicer gene SRRM2 in two different PD neuronal sources and in PD blood but not in blood of neurologically diseased patients makes SRRM2 a strong candidate gene for Parkinson disease and draws attention to the role of RNA splicing in the disease.

The Whole-genome Association Study Pipeline (WASP): A Comprehensive Tool for Large-Scale Association Studies. *D.P. Sexton, J.L. McCauley, J.T. Giles, W.S. Bush, Y. Bradford, J.L. Haines* Center Human Genetics Research, Vanderbilt University, Nashville, TN, USA.

Whole genome association studies generate vast amounts of genotypic data produced by rapidly evolving technologies. Studies of complex diseases contain ever increasing sample sizes and phenotypic measures. Genotype quality assurance is nothing novel, these checks were once trivial to perform given the constraints of small datasets with few markers. However, data management can be a very time consuming task if not automated in large complex datasets. We have explored the difficulties of managing these data for ongoing family-based and case-control studies and have subsequently developed the Whole-genome Association Study Pipeline (WASP) software tool. The principle goal of this tool is to aid in storing, evaluating, formatting, and analyzing genotypic and clinical data from the latest large-scale genotyping studies. The WASP application implements a battery of quality control procedures to assess and analyze these data. The currently available procedures are the examination of marker and sample genotyping efficiency, allele frequency calculations, checks of Mendelian error and gender discrepancies (based on available chromosome X or Y genotypes), and tests of Hardy-Weinberg Equilibrium. Additionally, the application can retrieve and format data for other software programs such as the Graphical Representation of Relationships (GRR) program, STRUCTURE and EIGENSTRAT. Beyond the quality control aspect of this application, WASP can perform standard tests of association using the TDT, for family-based datasets and the chi-square test of association for case-control datasets. Additional analyses currently include the Cochran-Mantel-Haenszel test, and the Armitage Trend test, with additional analytic extensions in development. In addition to the command line procedures used in WASP, we have created a graphical user interface (GUI) data plotter (WASP Plotter) that allows the user to visually examine the data in a rapid and interactive manner. As datasets reach and exceed billions of datapoints, such tools will become a necessity for virtually all large-scale genotyping studies.

Diaphragmatic hernia, renal cysts and cardiac abnormalities: A new X-linked condition? *M. Thompson[1,4], S. Keating[1,4], P. Shannon[1,4], G. Seaward[2,4], J. Pierre-Louis[3,4], H. Sroka[3,4], D. Shaw[1,4], A. Wolff[1,4], D. Chitayat[3,4]* 1) Dept Pathology & Lab Medicine, Mount Sinai Hosp, Toronto, ON, Canada; 2) Dept of Obstetrics and Gynecology, Mount Sinai Hosp, Toronto, ON; 3) The Prenatal Diagnosis and Medical Genetics Program, Mount Sinai Hosp, Toronto, ON; 4) University of Toronto, Toronto, ON.

Congenital diaphragmatic hernia (CDH) occurs in 1:4,000 live births. In most cases, it is isolated and has a multifactorial mode of inheritance. Familial CDH makes up 0.9-2% of all cases, and of these, 8-10% have bilateral CDH. We report a hitherto new familial condition with CDH, cardiac, renal and other abnormalities with an apparent X-linked mode of inheritance. The parents of two affected siblings were Caucasian and non-consanguineous. The mother's brother died of diaphragmatic hernia soon after birth, further information unavailable. Case 1: A male infant with karyotype 46, XY, was born at 39.6 weeks gestation with coarse facial features, left CDH, tapering fingers, hypoplastic lungs, a small heart with dysplasia of all 4 valves, dextrocardia, dilatation of ascending aorta, tubular hypoplasia of the isthmus, fenestrated foramen ovale, elongated main PA, large kidneys, a small placenta and a 2 vessel cord. The infant died at 3 hours. Case 2: A stillborn male, brother of case 1, with karyotype 46, XY, was born at 36 weeks gestation with coarse facial features, bilateral CDH, tapering fingers, hypoplastic lungs, cardiovascular anomalies including dysplasia/thickening of all 4 valves, aneurysmal dilatation of ascending aorta, persistent left SVC, elongated ductus arteriosus; malrotated bowel, hepatomegaly, enlarged cystic kidneys, thymus and spleen, large placenta and rare CNS white matter calcifications. The long bones showed long standing growth disturbance and the metacarpals were short. To the best of our knowledge, only 4 X-linked conditions have been reported with CDH: Simpson-Golabi-Behmel, thoracoabdominal, craniofrontonasal and MIDAS syndromes. The clinical manifestations in our cases are not consistent with any of these conditions and point toward a new, likely X-linked condition.

Further support for involvement of *Reelin* gene variation in working memory performance. *J. Wedenoja[1,3], A. Tuulio-Henriksson[2], T. Paunio[1,2,4], J. Suvisaari[2], A. Loukola[1], J. Ekelund[1,2,4], T. Partonen[2], J. Lönnqvist[2,3,4], H. Stefansson[5], L. Peltonen[1,3,6]* 1) Dept of Molecular Medicine, National Public Health Institute, Helsinki, Finland; 2) Dept of Mental Health and Alcohol Research, National Public Health Institute, Helsinki, Finland; 3) Dept of Medical Genetics, University of Helsinki, Finland; 4) Dept of Psychiatry, Helsinki University Central Hospital, Finland; 5) deCODE genetics, Reykjavik, Iceland; 6) Broad Institute of Harvard and MIT, Cambridge, MA, USA.

Shortage of true positive results in gene identification for mental disorders has increased interest towards quantitative traits, which provide more power in analysis and may thus help in the susceptibility gene search.
We have demonstrated replication of schizophrenia (SZ) linkage to chromosome 7q21-32 in 352 Finnish families (n=1626). A regional *Reelin* (*RELN*) gene on 7q22, encoding glycoprotein involved in neuronal migration regulation during brain development, and contributing to synapse remodelling, crucial for cognitive abilities, showed robust association with an intragenic microsatellite marker in a subsample of 186 neuropsychologically tested families (n=618) to traits measuring visual (p=.003) and verbal (p=.000006) working memory, memory (p=.002), and executive functioning (p=.002). Also animal studies have supported the role of *RELN* variation in cognitive processes.
We utilized an independent Finnish sample of neuropsychologically tested 67 SZ patients and 121 healthy controls, genotyped with Illumina 317K SNP array as part of the SGENE consortium, and analyzed 105 *RELN* intragenic SNPs. Among patients, multiple SNPs associated to verbal attention (p=.006) and working memory (p=.005), learning (p=.001), and memory (p=.006). Among controls, multiple SNPs associated to verbal attention (p=.002), visual attention (p=.00003) and working memory (p=.000003), memory (p=.002), and processing speed (p=.0007). The strongest signals emerged from the high LD region where the previously associated microsatellite is located. Our results provide further evidence for involvement of *RELN* variation in cognitive functions.

The common inversion of the Williams-Beuren syndrome region does not cause clinical symptoms. *E.J. Tam[1], E.J. Young[1], C.A. Morris[2], C.R. Marshall[3], S.W. Scherer[3], C.B. Mervis[4], L.R. Osborne[1]* 1) Medicine, University of Toronto, Toronto, Ontario, Canada; 2) Pediatrics, University of Nevada School of Medicine, Las Vegas, NV; 3) Genetics & Genomic Biology, SickKids, Toronto, Ontario, Canada; 4) Psychological and Brain Sciences, University of Louisville, Louisville, KY.

The 1.55 Mb Williams-Beuren syndrome (WBS) deletion is caused by meiotic recombination between highly similar flanking DNA segments. A common inversion of the region, WBSinv-1, also occurs through recombination between flanking repeats in opposite orientation to each other and exists as a polymorphism in the general population. WBSinv-1 was also found in individuals with general features associated with WBS (eg. mental retardation, ADHD, friendly personality) but no deletion, suggesting it could cause clinical symptoms. In order to investigate the possible role of WBSinv-1 in WBS symptoms, we performed a full clinical, developmental and genetic assessment of two previously reported atypical WBS patients with WBSinv-1. The phenotypes of these atypical patients did not show significant clinical or psychological overlap with those of individuals with WBS, suggesting that the presence of the WBS inv-1 chromosome and clinical symptoms in these patients is coincidental. In addition, a 1.3 Mb duplication of part of the velocardiofacial syndrome region on chromosome 22q11.2 was found in one patient, which may account for her symptoms. We also examined the expression of genes within the WBS region at 7q11.23 in unaffected carriers of WBSinv-1, but found no evidence of significantly altered expression of any of the genes tested, even in an individual who was homozygous for WBSinv-1. These results suggest that WBSinv-1 does not cause clinical symptoms. Caution should be taken when diagnosing patients with atypical presentation of rare syndromes and diagnosis should be carried out by health professionals with extensive experience in the specific syndrome, wherever possible. Whole genome analysis, which is becoming more routine in the clinical setting, may reveal previously unidentified copy number variants that could contribute to syndromic features.

Interaction between Estrogen Receptor Alpha Genotypes and Human Herpesvirus 8 Infection Resulting in an Increased Risk of Prostate Cancer. *P.R. Shea[1], C.H. Bunker[2], P.V. Benos[1], D.L. Corcoran[1], A.L. Patrick[3], F.J. Jenkins[4], R.E. Ferrell[1]* 1) Dept of Human Genetics, University Pittsburgh, Pittsburgh, PA; 2) Dept of Epidemiology, University of Pittsburgh, Pittsburgh, PA; 3) Tobago Regional Health Authority, Scarborough, Trinidad and Tobago; 4) Dept of Pathology, University of Pittsburgh, Pittsburgh, PA.

The role of interaction between viral infection and host genetic susceptibility has increasing become recognized as an important factor in the etiology of human cancer. Several epidemiologic studies have suggested that prostate cancer is a complex disease involving host genetic factors and environmental exposures that modify risk. Here we report a novel interaction between infection with human herpesvirus 8 (HHV8) and the human estrogen receptor alpha XbaI polymorphism which is associated with an increased risk of prostate cancer (p=0.032; OR=3.11 95%CI (1.42-6.77)) in an Afrocaribbean population from Tobago. Further, we have identified estrogen response elements in the promoter regions of genes in the HHV8 genome, suggesting a direct form of interaction. Using gel shift and luciferase reporter assays we have shown these sequences are capable of binding human estrogen receptor proteins and are responsive to estrogen induction. Our results suggest that direct interaction between the estrogen receptor and HHV8 gene transcription may play a role in the etiology of prostate cancer and that common polymorphisms in the estrogen receptor alpha gene may increase risk.

Deletion of CFHL1 and CFHL3 Genes in Age-related Macular Degeneration. *L.M. Olson[1], K. Spencer[1], Y. Chen[2], P. Gallins[3], M.A. Hauser[2], S. Schmidt[2], W.K. Scott[3], N. Schnetz-Boutaud[1], A. Agarwal[1], E.A. Postel[2], M.A. Pericak-Vance[3], J.L. Haines[1]* 1) Dept Molec Phys & Biophysics, Vanderbilt Univ Medical Ctr, Nashville, TN; 2) Ctr for Human Genetics, Duke University, Durham, NC; 3) Institute for Human Genomics, University of Miami, Miami, FL.

Age-related macular degeneration (AMD) distorts central vision and is the primary cause of blindness in the elderly in developed nations. Genetic risk factors for AMD include both susceptibility variants and protective haplotypes in the complement factor H (CFH) gene on chromosome (chr) 1, variants in the HTRA1/LOC387715 locus on chr 10, and the R32W polymorphism in complement factor B on chr. 6. Recently, deletion of the CFH-like genes CFHL1 and CFHL3 was found within a protective CFH haplotype, suggesting that these deletions may be protective for AMD (Hughes et al. 2006). We genotyped the deletion in 780 cases and 265 controls by PCR amplification with primers that amplify both a 325 bp product of CFH and a 381 bp product of CFHL1. We identified the deletion in 16 individuals, but the deletion does not segregate perfectly with the A allele of rs6677604, as suggested by Hughes et al. 2006. However, haplotype H4 (Hageman et al. 2005, 2007) had a frequency of ~47% in the deletion individuals, and the majority of these people are homozygous for the T allele of Y402H (14 TT Y402H homozygotes of 16 total deletion homozygotes). Overall, deletion homozygosity was significantly more frequent in controls than cases (2.6% controls, 0.8% cases, Fishers exact p=0.025, OR=0.29, 95% CI 0.10-0.86). After controlling for age, Y402H, smoking, and A69S in LOC387715, the protective effect of the deletion was no longer statistically significant (OR=0.45, 95% CI 0.11-1.83, p=0.27). This may be caused by decreased power in a reduced sample of 469 cases and 190 controls with complete covariate data. Deletion of CFHL1 and CFHL3 may account for a small portion of the protection from AMD associated with particular haplotypes in CFH. The presence of protective haplotypes in CFH that do not carry the deletion (Hageman et al. 2005, 2007 and Spencer et al. 2007), suggest that other protective variants in this region have yet to be discovered.

SGK expression is increased by an ancestral allele showing a latitudinal cline in human populations. *F. Luca[1], M. Zou[2], S. Kashyap[2], S. Conzen[2], A. Di Rienzo[1]* 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) Department of Medicine, University of Chicago, Chicago, IL.

Serum and Glucocorticoid regulated-Kinase (*SGK*) encodes a glucocorticoid-induced anti-apoptotic protein required for cell survival in breast epithelium. In triple negative breast cancer, *SGK*overexpression may contribute to tumor growth. *SGK* is also an important mineralocorticoid receptor (MR) target in the kidney, leading to increased salt and water reabsorption. Glucocorticoid receptor (GR) and MR can use the same hormone responsive elements (HREs), thus genetic variation in HREs is expected to affect both GR- and MR-mediated transcriptional efficiency. We tested the hypothesis that variations in the regulatory sequences of *SGK* exist and were selected in human populations based on their ancestral requirements for salt/water retention. Such variants could account for some of the differences observed between people of African vs European ancestry in the prevalence of hypertension and triple negative breast cancer.

We identified 3 conserved sequence elements upstream of *SGK* that contain: 1) 6 SNPs with large allele frequency differences between Africans and Europeans and 2) predicted HREs. These elements were a) resequenced in 14 Europeans and 14 African samples and b) tested for enhancer activity by reporter gene assays. In order to test for a correlation between allele frequency and climate, the 6 SNPs were genotyped in 52 human populations worldwide.

By combining population genetics and a molecular approach, we identified a genetic variant upstream of *SGK* in which the ancestral allele increases *SGK* expression in response to glucocorticoid. The frequency of this allele is highest in Sub-Saharan African populations and is strongly correlated with latitude and temperature variables in worldwide samples. Because of the critical role of *SGK* in sodium homeostasis, this variant is likely to have evolved under a spatially-varying selective pressure related to climate.

Filaggrin mutations confer susceptibility to atopic dermatitis but not to asthma. *A.J. Rogers[1,2,4], J.C. Celedón[1,2,4], J.A. Lasky-Su[1,3], B.J. Klanderman[1], E.T. Bevilacqua[1], L.M. Catalano[1], S.T. Weiss[1,2,4], B.A. Raby[1,2,4]* 1) Channing Laboratory, Department of Medicine, Brigham and Women's Hospital, Boston, MA; 2) Harvard Medical School, Boston, MA; 3) Harvard School of Public Health, Boston, MA; 4) Pulmonary Division, Brigham and Women's Hospital, Boston, MA.

Background: Loss-of-function mutations in the filaggrin gene (FLG) have been strongly associated with atopic dermatitis and allergic phenotypes in multiple populations. The role of these mutations in relation to the development of asthma is less clear, particularly in patients who do not have coincident atopic dermatitis.
Objective: To determine whether FLG mutations are associated with asthma and/or asthma-related intermediate phenotypes.
Methods: We genotyped two loss-of-function FLG mutations (R501X and 2282del4) in white children (ages 5-12 years) with mild to moderate asthma who participated in the Childhood Asthma Management Program (CAMP). We assessed the relationship of these mutations to asthma and allergy-related phenotypes in children with and without atopic dermatitis using both population-based and family-based tests of association.
Results: One third (174/611) of the participating children had concurrent atopic dermatitis. Although strong associations were observed between FLG mutations and atopic dermatitis (OR 2.39, $p = 7 \times 10^{-5}$ for combined mutation) and total serum Immunoglobulin E levels (p=.006 in the atopic dermatitis cohort), these mutations were associated with neither asthma nor asthma-related phenotypes (p >0.1 for all tests).
Conclusion: Although FLG loss-of-function mutations are consistently associated with atopic dermatitis and other allergic phenotypes, these mutations do not appear to influence susceptibility to asthma, nor do they influence asthma severity phenotypes.

No association between OPA1 polymorphisms and primary open-angle glaucoma (POAG) in three different populations. *Y. Liu[1], D. Munro[1], X. Qin[1], S. Schmidt[1], J. Wiggs[3], MA. Hauser[1,2], RR. Allingham[1,2]* 1) Center for Human Genetics, Duke Univ Medical Center, Durham, NC; 2) Department of Ophthalmology, Duke University Eye Center, Duke University Medical Center, Durham, NC; 3) Harvard Medical School, Boston, MA.

Mutations in the optic atrophy 1 (OPA1) gene have been associated with optic atrophy type 1, which is a dominantly inherited optic neuropathy resulting in progressive loss of visual acuity. SNPs rs10451941 and rs166850 of OPA1 have been associated with normal tension glaucoma (NTG) in the Caucasian and Japanese populations, as well as high tension glaucoma (HTG) in the Japanese population. No such association was found with NTG in the Korean or the African-Caribbean population of Barbados in West Indies, or with HTG in Caucasian population. We investigated the association between these SNPs and POAG with elevated intraocular pressure in the Caucasian (279 cases, 227 controls), African American (193 cases, 97 controls), and Ghanaian (West African) (170 cases, 138 controls) populations. We found no significant differences in OPA1 allele or genotype frequencies between POAG cases and controls at the rs10451941 and rs166850 SNPs in either dataset. In conclusion we report no association between two previously implicated OPA1 polymorphisms and a POAG phenotype that includes elevated IOP. This represents the first association analysis of OPA1 in high tension glaucoma in the African American and Ghanaian populations. OPA1 association with POAG may be limited to patients with normal tension glaucoma in these populations.

Maternal Cigarette Smoking, Metabolic Gene Polymorphisms, and Preterm Delivery: New Insights on GxE Interactions and Pathogenic Pathways. *H.-J. Tsai[1], X. Liu[1], K. Mestan[1], X. Yu[1], S. Zhang[1], C. Pearson[2], K. Ortiz[2], B. Zuckerman[2], H. Bauchner[2], S. Cerda[2], P. Stubblefield[2], X. Xu[3], X. Wang[1]* 1) Childrens Memorial Hospital and Children's Memorial Research Center; Department of Pediatrics, Feinberg School of Medicine, Northwestern University, Chicago, IL; 2) Boston University School of Medicine and Boston Medical Center, Boston, MA; 3) Center for Population Genetics, University of Illinois at Chicago School of Public Health, Chicago, IL.

Background: While we have investigated previously genetic susceptibility and gene-environment interaction in low birth weight and gestational age, this paper extends this work to preterm term delivery (PTD) which is largely unexplored. Such data may help elucidate pathogenic pathways for PTD. **Methods:** This report included 1,749 multi-ethnic mothers (571 with PTD and 1,178 controls) enrolled at Boston Medical Center. Regression analyses were performed to detect individual and joint associations of maternal smoking, two functional variants of CYP1A1 and GSTT1 with PTD and with preterm subgroups after adjusting for important covariates. False discovery rates were applied to correct for multiple testing. **Results:** We observed a moderate effect of maternal smoking on PTD (OR: 1.6; 95% CI: 1.1-2.2). Consistent with our earlier report, we found that compared to non-smoking mothers with low-risk genotypes, there was a significant joint association of maternal smoking, CYP1A1 (Aa/aa) and GSTT1 (absent) genotypes with gestational age (: -3.37; SE: 0.86; $P = 9x10^{-5}$). With a larger sample size, we further demonstrated the joint association with PTD (OR: 5.8; 95%CI: 2.0-21.1). Such joint association was particularly strong in certain preterm subgroups, including spontaneous PTD (OR: 8.3; 95%CI: 2.7-30.6), PTD < 33 weeks (OR: 10.3; 95%CI: 2.9-42.4), and PTD accompanied by histologic chorioamnionitis (OR: 15.6; 95%CI: 4.1-76.7). We also showed similar patterns across ethnic groups. **Conclusions:** Maternal smoking significantly increased the risk of PTD among women with high-risk CYP1A1 and GSTT1 genotypes. Such joint associations were strongest among PTD accompanied by histologic chorioamnionitis.

Dose-related effect of sapropterin dihydrochloride (sapropterin) on blood phenylalanine (Phe) in patients with phenylketonuria (PKU). *M. Wasserstein[1], B. Burton[2], D. Grange[3], C. Harding[4], M. Lipson[5], N. Longo[6], L. Waber[7], C. Whitely[8], J. Wolff[9], J. Bebchuk[10], A. Dorenbaum[11], G. Vockley[12]* 1) Mount Sinai Schl Med,New York,NY; 2) Child Mem Hosp,Chicago,IL; 3) St Louis Child Hosp,St Louis,MO; 4) Oregon Health & Sci U,Portland,OR; 5) Kaiser Permanente,Sacramento,CA; 6) U Utah,Salt Lake City,UT; 7) Child Med Ctr,Dallas,TX; 8) U Minnesota Med Ctr,Minneapolis,MN; 9) U Wisconsin,Madison,WI; 10) Statistics Collaborative Inc.,Washington,DC; 11) BioMarin Pharmaceutical Inc.,Novato,CA; 12) Child Hosp,Pittsburgh,PA.

Intro:Sapropterin, an oral formulation of tetrahydrobiopterin, can decrease blood Phe levels in patients with PKU. We report the effects of 3 sapropterin dose levels on blood Phe in PKU patients who previously responded to sapropterin. Methods:80 patients(8yrs) with PKU and elevated blood Phe(600mol/L), who had relaxed/abandoned a Phe-restricted diet entered the forced-dose titration phase of an open-label study and received 3 consecutive 2-wk courses of sapropterin, 5,20 and 10mg/kg/day (od). Mean(SD) change from Wk 0 in blood Phe level was calculated at Wks 2, 4 and 6 after 5,20 and 10mg/kg/day respectively, and analyzed using a longitudinal model (subjects served as their own controls). Results:Subjects were 98% Caucasian, 59% male, with mean(SD) age of 20.4(9.6)yrs. Mean(SD) decreases in blood Phe from Wk 0 at Wks 2, 4 and 6 after treatment with 5,20 and 10mg/kg/day were -100(295), -263(318) and -204(303)mol/L respectively. Mean change in blood Phe was related to dose, shown by a statistically significant difference in effect when comparing doses ($p<0.01$ for all pairwise comparisons). Proportion of subjects with 30% decrease from Wk 0 in blood Phe was 25%, 55% and 46%, for 5,20 and 10mg/kg/day respectively. All dose levels were well tolerated (Randolph et al.) with no apparent relationship between dose and safety profile. Concl:In this forced-dose titration phase, sapropterin (5,10 and 20mg/kg/day) effectively reduced blood Phe in subjects with PKU in a dose-related manner with an acceptable safety profile. 20 mg/kg/day produced significantly greater decreases in blood Phe than lower doses.

Safety and efficacy of sapropterin dihydrochloride (sapropterin) treatment over 22 weeks in patients with phenylketonuria (PKU). *L. Randolph[1], J. Baker[2], J. Bergoffen[3], P. Harmatz[4], A. Morris[5], E. Crombez[6], M. Seashore[7], H. Christ-Schmidt[8], A. Dorenbaum[9]* 1) Child Hosp,Los Angeles,CA; 2) Kaiser Permanente Med Ctr,Oakland,CA; 3) Kaiser Permanente Genetics Dept,San Jose,CA; 4) Child Hosp,Oakland,CA; 5) Royal Manchester Child Hosp,Manchester,UK; 6) David Geffen Scl Med UCLA,Los Angeles,CA; 7) Yale,New Haven,CT; 8) Statistics Collaborative Inc.,Washington,DC; 9) BioMarin Pharmaceutical Inc.,Novato,CA.

Intro:Sapropterin, an oral formulation of tetrahydrobiopterin, can decrease blood phenylalanine (Phe) levels in some patients with PKU. We report 22-week efficacy and safety data from an open-label Ph 3 extension study of sapropterin in PKU patients who previously responded to sapropterin. Methods:80 patients (8yrs) with PKU, elevated blood Phe (600mol/L) and who had relaxed or abandoned a Phe-restricted diet were enrolled. Design: 6-wk forced-dose titration phase (all patients received 3 consecutive 2-wk courses of sapropterin at 5, 20 and finally 10mg/kg/day), followed by a 4-wk dose-analysis phase (sapropterin maintained at 10mg/kg/day) and 12-wk fixed-dose phase (patients received 5, 10 or 20mg/kg/day based on their blood Phe level at Wk 2 and 6 visits). Results:Mean(SD) age was 20.4(9.6)yrs; 59%37; patients were male; 79 patients completed the study. Mean(SD) blood Phe concentration decreased from 844(398)mol/L (14.1[6.6]mg/dL) at Wk 0 to 645(393)mol/L (10.8[6.6]mg/dL) at Wk 10 and 652(383)mol/L (10.9[6.4]mg/dL) at Wk 22 (end of fixed-dose phase). At Wk 22, 46%(36/79) patients had a 30% reduction in blood Phe compared with Wk 0. Adverse events (AEs) were reported by 68/80 patients (85%); all but one (tooth abscess considered to be unrelated to study drug) were mild/moderate in severity, no patient withdrew due to AEs, and 31 (39%) patients reported an AE considered possibly/probably related to study drug. Most commonly reported AEs during the study were headache (20% patients), pharyngolaryngeal pain (15%), nasopharyngitis (14% vomiting (13%), diarrhea (10%) and upper respiratory tract infections (10%). Concl:Sapropterin (5, 10 and 20mg/kg/day) reduces blood Phe levels in PKU patients through 22 weeks of treatment with an acceptable safety profile.

Post genome-wide association challenges at the complex-disease associated locus *CD25* on chromosome 10p15.
C.E. Lowe, J.D. Cooper, J.A. Todd Juvenile Diabetes Research Foundation/Wellcome Trust Diabetes and Inflammation Laboratory, University of Cambridge, UK.

Large-scale, genome-wide association studies of complex traits have led recently to the identification and confirmation of several new disease loci, a turning point in the genetic analysis of multifactorial disease. However, the next steps in the investigation of these loci are more challenging and uncertain. The aim is to correlate the most disease-associated variant(s) in the disease-associated region with phenotypes relating to the expression and/or function of genes in the region. However, as much as 30% of the common variation is unknown, any of which could be the causal variant(s). In order to evaluate the association of the interleukin-2 receptor gene (*IL2RA* or *CD25*) region on chromosome 10p15 with type 1 diabetes (T1D), we resequenced the entire 180 kb region (total 5.7 Mb), identified 737 polymorphisms, including 468 SNPs at MAF 0.05, of which 95 were novel. We genotyped 307 SNPs in 2,965 cases and 2,548 controls, and followed up 12 SNPs in 5,312 cases and 6,855 controls. Logistic regression identified two overlapping regions, covering 40 kb of intron 1 and the 5' of *CD25*, that were independently associated with T1D. The combined OR for the most associated SNPs, rs41295061 (susceptibility allele frequency, SAF=0.90) and rs11594656 (SAF=0.75), from these two regions was 2.04 (95% CI=1.70-2.45; P=1.92x10^{-28}). Multiallelic and copy number polymorphisms have yet to be investigated. Nevertheless, we tested the two current best SNPs for association with the plasma concentration of the immune activation marker soluble CD25 in 1,357 T1D cases. Both rs41295061 and rs11594656 were associated with this biomarker (P = 1.88x10^{-8} and 2.15x10^{-23}, respectively), indicating that the association of chromosome 10p15 with T1D involves the function of *CD25*. None of the 11 SNPs from the two T1D-associated regions alter coding sequence or any known regulatory element in or near *CD25*, highlighting the complexity that disease-associated variants could have obscure roles in the regulation of gene expression.

Sydenham's Chorea: a study of the Ser9Gly polymorphism in the *DRD3gene*. *D.M. Miranda[1], L.A. De Marco[2], H. Correa[1], A.L. Teixeira[3], F. Cardoso[3], W. Boson[2], M.A. Romano-Silva[1]* 1) Mental Heathy, UFMG, Belo Horizonte, Minas Gerais, Brazil; 2) Pharmacology Department, UFMG, Belo Horizonte, Minas Gerais, Brazil; 3) Internal Medicine Department, UFMG, Belo Horizonte, Minas Gerais, Brazil.

Sydenhams Chorea is a neuropsychiatric presentation of rheumatic fever, it is characterized by weakness, uncoordinated movements and emotional lability. Rheumatic fever usually occurs in children between 5 and 15 years old and follows an infection by Streptococcus beta-haemolyticus, but a familiar susceptibility seems to determine who will or will not develop Rheumatic Fever and Sydenhams Chorea. Few studies have investigated some polymorphisms and genes associated with Sydenhams Chorea. Actually Sydenham Chorea is a self-limited disorder but, when necessary a pharmacological treatment with good results is the use of dopaminergic antagonists. The pharmacological response and findings of association between the Ser9Gly polymorphism of DRD3 gene and tardive diskinesia - another movement disorder - motivated our study. It consisted on clinical evaluation and study of Ser9Gly polymorphism in DRD3 gene of 45 patients from the Rheumatic Fever Clinic of Universidade Federal de Minas Gerais and 46 healthy controls. The genotyping was performed as described by Segman et al. (1999). The genotype findings were statistically analyzed by the Chi-square test. We did not find association between Ser9Gly polymorphism and Sydenhams Chorea. This was a pilot study with a small number of patients investigated, however, even considering the limitations Ser9Gly does not seem to be a polymorphism associated with Sydenhams Chorea. References: Segman R, Neeman T, Heresco-Levy U, Finkel B, Karagichev L, Schlafman M, Dorevitch A, Yakir A, Lerner A, Shelevoy A, Lerer B. Genotypic association between the dopamine D3 receptor and tardive dyskinesia in chronic schizophrenia. Mol Psychiatry. 1999;4(3):247-53.

Sporadic Venous Malformation is Caused by Somatic Mutations in TIE2. *V. Wouters[1], N. Limaye[1], M. Uebelhoer[1], J.B. Mulliken[3], L.M. Boon[1,2], M. Vikkula[1]* 1) Human Molecular Genetics, Christian de Duve Inst, Brussels, Belgium; 2) 2Center for Vascular Anomalies, Cliniques Universitaires St-Luc, Université catholique de Louvain, Brussels, Belgium; 3) Vascular Anomalies Center, Childrens Hospital, Boston, USA.

Venous malformations (VM) are the most frequent vascular malformations referred to vascular anomaly centers. An autosomal dominant familial trait, glomuvenous malformation (GVM), representing about 5% of venous lesions, is caused by premature truncation mutations in the glomulin gene, whereas another autosomal dominant form, termed cutaneomucosal venous malformation (VMCM), representing about 1% of venous lesions, is caused by gain-of-function mutations in the TIE2 gene. Recently, we identified several novel mutations in the TIE2 gene in VMCM patients, as well as, for the first time, a somatic second-hit deletion (see abstract N. Limaye et al.). The aetiology of sporadic VM, which represents more than 95% of venous lesions, has however remained unknown. Here we show that sporadic VMs are caused by somatic mutations in TIE2. We identified seven missense mutations in VM tissue DNA, which were however absent in blood DNA from these patients, and in tissue DNA from 89 controls. All the mutations, which were predicted by bioinformatic analysis to have deleterious effects of varying severity, were found to result in a strong in vitro ligand-independent increase in phosphorylation of TIE2. In some patients, we observed two mutations acting in cis. Such combinations on the same allele induced even higher phosphorylation levels of the receptor. Furthermore, we identified additional non-synonymous changes in TIE2 at the cDNA level, suggesting a somatic second-hit hypothesis to explain the localized nature of these lesions, as well as the presence of mechanisms that perhaps attempt to repair the dysfunctional allele. In conclusion, these data identify the etiopathogenic cause of sporadic VMs, thereby pinpointing the TIE2 signaling pathway for the development of novel therapeutic strategies, such as small molecule inhibitors. (miikka.vikkula@uclouvain.be).

Gamma-hydroxybutyric aciduria and severe lactic acidosis in a young Chihuahua dog. *D.P. O'Brien[1], E. Kelmer[1], G.D. Shelton[2], B.A. Barshop[3], G.S. Johnson[4], S. Kahn[4], E.A. Struys[5], C. Jacobs[6]* 1) Veterinary Medicine & Surgery, University of Missouri, Columbia, MO; 2) Department of Pathology, University of California San Diego, La Jolla, CA; 3) Department of Pediatics, University of California San Diego, La Jolla, CA; 4) Department of Pathology, University of Missouri, Columbia, MO; 5) Department of Pediatrics, University of Pittsburg, Pittsburg, PA; 6) VU University Medical Center, Amsterdam, The Netherlands.

Succinic semialdehyde dehydrogenase (SSADH) deficiency is a rare, autosomal recessive disorder of children characterized by neurological impairment and gamma-hydroxybutyric acid (GHB) in the urine. We report a 5 month old Chihuahua that presented with a history of waxing and waning ataxia and altered mental status. The dog was severely acidotic (pH 6.938) with elevated serum lactate (18.27 mmol/L). Urine organic acid analysis showed dramatic elevations in lactic acid (>30,000), pyruvic acid (>2,000), and GHB (812 mmol/mol creatinine). SSADH activity in leukocytes was 30% of parallel controls (n=2 dogs). Activity of hydroxyacid-oxoacid transhydrogenase (HOT), an enzyme metabolizing GHB, was comparable to control (n=4 dogs) in autopsied liver from the proband. The *SSADH* coding region was sequenced and no pathological mutations were identified. Severe lactic acidosis seen in this dog is atypical in children with SSADH deficiency. Similarly, although the SSADH activity was decreased, it was not to the extent typically seen in children with SSADH deficiency. We speculate that the decrease could reflect a mutation in the non-coding region affecting gene expression, or a secondary effect on the enzyme perhaps linked to overwhelming lactic acidosis and/or oxidant stress.

SNPs in SCN5A for risk of arrhythmias in the context of myocardial infarction. *Q. Xi, L. Li, Q.K. Wang* Molecular Cardiology, Lerner Research Institute / Cleveland Clinic/, Cleveland, OH.

Introduction: The cardiac sodium channel gene SCN5A is critical for generating the cardiac action potential and for conduction of electrical pulse in the heart. Many mutations in SCN5A have been found in patients with ventricular arrhythmias (VT) and sudden cardiac death due to long QT syndrome, Brugada syndrome and cardiac conduction disease. Coronary artery disease (CAD) and myocardial infarction (MI) causes >70% of sudden cardiac death. In the present study, we tested the hypothesis that single nucleotide polymorphisms (SNPs) in SCN5A may confer the risk of arrhythmias in CAD/MI patients. Methods: We carried out a case/control association study using 143 MI patients with VT and 360 control MI patients without VT. Four SNPs, one non-synonymous SNP, one intronic SNP and two SNPs in the promoter region of SCN5A were studied. SNP allelic frequencies were compared between cases and controls by a Chi-square test. Allelic specific risks were estimated as odds ratios (ORs). Bonferroni correction was used for P-value adjustment for multiple testing. Results: The allelic frequency of one SCN5A SNP showed nominal significance for association with VT in MI patients (P=0.03) with an odds ratio of 1.43. The significance of association diminished after Bonferroni correction (P=0.12). Conclusions: One SNP in SCN5A may be potentially associated with risk of developing VT in the MI population. However, the association was marginal and became non-significant after Bonferoni correction.

Association of GIRK channel gene polymorphism *GIRK2* A1032G with postoperative analgesia. *D. Nishizawa[1], M. Hayashida[2], Y. Ogai[1], S. Kasai[1], J. Hasegawa[1], M. Tagami[3], M. Nagashima[4], K. Ikeda[1]* 1) Molecular Psychiatry, Tokyo Institute of Psychiatry, Tokyo, Japan; 2) Anesthesiology, Saitama Medical University International Medical Center, Saitama, Japan; 3) Anesthesiology, Toho University Sakura Medical Center, Chiba, Japan; 4) Surgery, Toho University Sakura Medical Center, Chiba, Japan.

Objectives: Opiates are commonly used as analgesics for the treatment of acute and chronic pain in the clinical scene today. However, it has been increasingly well recognized that there is considerable inter-subject difference in the sensitivity to opiate analgesics, which hampers satisfactory pain control. To explore polymorphisms responsible for the inter-subject difference in the opiate sensitivity, we performed an association analysis focusing on the SNPs in *GIRK2*, which is the gene encoding a subtype of G protein-activated inwardly rectifying potassium (GIRK) channel, known to play a key role in transmitting the analgesic effects of opioids. **Materials and Methods**: In the initial screening for polymorphisms in *GIRK2* gene and putative promoter regions, nine SNPs were identified. Among them, two SNPs of G-1250A and A1032G were selected for the following association study examining the relationships between the SNPs and requirement of postoperative analgesics. The subjects in the association study were a total of 129 patients who underwent surgical operation in hospitals and were treated with analgesics including opioids after surgery. **Results and Discussion**: During the first 24 postoperative hours, patients with the genotype A/A in the A1032G required analgesics more frequently than those with A/G and G/G in the SNP ($p=0.011$ and $p=0.018$, respectively), while no such associations were detected for the G-1250A. Although the molecular mechanism underlying the difference in the analgesic requirements remains to be elucidated, our data indicate that the SNP *GIRK2* A1032G could serve as a marker for predicting the analgesic requirements in patients. Our findings will lead to satisfactory pain control for patients suffering intolerable pain and open a path for personalized pain treatment in the future.

HLA Genetics of multiple sclerosis in Israeli Arab populations. *T. Paperna[1], G. Benedek[2], A. Miller[1], I. Lejbkowicz[1], C. Brautbar[2], J.R. Oksenberg[3], S. Israel[2], Israeli MS Genetics Group* 1) Medicine, Technion, Haifa, Israel; 2) Hadassah Med. Ctr. Jerusalem, Israel; 3) University of California, San Francisco, CA.

Genetic studies of multiple sclerosis (MS) highlighted the HLA region as associated with disease risk, although specific genes have not yet been identified. Expanding analyses to previously under-studied populations, specifically, populations with high genetic homogeneity may reveal and strengthen associations with specific genes. Israeli Arabs, including Christians, Druzes and Muslims, have maintained endogamy over generations, suggesting their possible advantage for genetic studies. The aim of this study was to examine the association of HLA genes with MS in Israeli Arab populations, and characterize disease phenotypes. DNA samples from 96 Arab MS patients and 114 unrelated, ethnicity matched healthy individuals were genotyped for HLA class I (HLA A and B) and II (DRB1 and DQB1). Case control analyses to compare allele distribution were done. Disease characteristics including age of onset, disease type, severity, and rate of progression were compared between the different sub-ethnicities. DRB1 allele frequencies differed significantly between Muslims, Druzes, and Christians. Global testing of cases versus controls revealed a significant difference only in Christians (p=0.027), likely due to DRB1*03. However, in contrast to previous reports, here DRB1*03 was negatively associated with disease (17.7% in controls vs. 2.6% in MS, p=0.003) with a clear dose effect (p for trend= 0.014). In Muslims and Druzes, the pattern for DRB1*03 is reversed, consistent with data from other populations. We were not able to detect association with DRB1*15 previously reported as a susceptibility allele. For DQB1, HLA A and HLA B, we currently could not identify allele associations. Differences in disease characteristics between the sub-ethnicities were observed, suggesting genetic heterogeneity may underlie the phenotypes. In conclusion, genetic studies in Israeli Arab populations suggest new allele associations with MS risk compared to other populations. Further research in these populations is ongoing.

BCHE genotype and clinical phenotype in patients following the muscle relaxant succinylcholine. *S. Levano, E. Schobinger, A. Matter, M. Singer, A. Urwyler, T. Girard* Departments of Anesthesia and Research, University Hospital Basel, Switzerland.

Butyrylcholinesterase (BCHE) quickly hydrolyzes drugs containing ester bonds such as succinylcholine (SCh) and mivacurium widely used in anesthesia. However a delayed hydrolysis of these short acting neuromuscular blocking drugs is observed in patients with acquired or inherited reduced BCHE activity. The aim of this study was to compare the detected mutations in BCHE gene with the clinical phenotype. In those patients receiving a standard dose of SCh (1mg/kg) the time of recovery of neuromuscular function was recorded. In addition 20 patients with a normal duration of neuromuscular blockade (< 10 min) were included. The patient physical status was classified according to the American society of anesthesiology (ASA) grading system. The BCHE gene was analysed by dHPLC and sequencing. Prolonged muscle relaxation (10 min) was found in 221 out of 1480 patients (14.9%) with a median duration of 13.35 min (10.2 to 44 minutes). Most of the patients were classified as ASA II (n=768) and ASA III (n=542). The average age of the patients was 64.3 years (18 to 97 years). Performing genetic analysis in 176 out of 221 patients the most frequently mutations in heterozygous forms were A209G (A-variant, 12.5%), G1615A (K-variant, 36.4%) and G1169T (F2-variant, 2.3%). The K-variant in homozygous form was detected in 18 cases. Double carriers of A- and K-variants were found in 19 patients. In addition single patients have shown recurrent and novel BCHE mutations. Multivariate linear regression analysis revealed a significant influence of ASA status ($p<0.001$) and genotype ($p<0.001$) but not age. The influence of the different genotypes compared to wild type was significant for the A-variant ($p<0.001$) and the F-variant ($p<0.05$) but not for the K-variant. In summary, prolonged neuromuscular blockade was measured in 15% of patients. About 50% of these patients were carriers of BCHE mutations. ASA physical status and BCHE genotype had a significant influence on the duration of action of SCh. The K-variant had no significant influence, neither in the heterozygous, nor in the homozygous state.

A 2-D graphic clustering model for reconstructing migration routes of human populations. *F. Xue*[1,2], *L. Jin*[1,3] 1) Center for Anthropological Studies, School of Life Sciences, Fudan University, Shanghai, China; 2) School of Public Health, Shandong University, Shandong, China; 3) CAS-MPG Partner Institute for Computational Biology, SIBS, CAS, Shanghai, China.

The classical clustering methods are less appropriate in reflecting spatial or geographic information including physical distance and spatial connectivity of the populations. We present a novel clustering approach, 2-D graphic clustering model (2-D GCM) which is based on three matrices of populations: genetics distance *Fst* matrix, spatial location matrix, and spatial adjoining matrix. Using different genetic markers (Y-chromosome haplogroups, mtDNA haplogroups, microsatellites and HLA-A), we will show a general spatial pattern of East Asian populations and their migration routes which are in accordance with the historical records. The results demonstrate that 2-D GCM can be used to reveal spatial genetic structure of populations, spatial genetic relationship between populations, and their migration routes.

Two adjacent loci on rat chromosome 1 regulate LPS-induced TNF and IL-6 production, experimental encephalomyelitis and arthritis. *R. Nohra[1], A. Beyeen[1], J. Ping Guo[2], O. Isacsson[1], T. Olsson[1], J. Lorentzen[2], M. Jagodic[1], E. Wallström[1]* 1) Karolinska Institutet,Department of Clinical Neuroscience, Neuroimmunology Unit, CMM L8:04, Stockholm, Sweden; 2) Karolinska Institutet,Department of Medicine, CMM L8:04, Stockholm, Sweden.

A genome-wide linkage analysis previously performed in an F2 cross between the experimental autoimmune encephalomyelitis (EAE)-susceptible LEW.AV1 and the MHC identical but EAE-resistant PVG.AV1 rat strains identified a quantitative trait locus(QTL) on rat chromosome 1 regulating LPS-induced production of proinflammatory cytokines. Using a congenic line between these two rat strains, we confirmed a role of this locus in EAE and in the production of proinflammatory cytokines. Further mapping was performed in a G10 advanced intercross line between the EAE-susceptible DA (AV1) strain and the PVG.AV1 strain. The same region was also analyzed in pristane-induced arthritis (PIA) and LPS-induced IL-6 and TNF production in G12(DAxPVG.AV1) rats. The initial QTL was resolved into two loci. The first locus regulates EAE and overlaps a QTL that regulates IL-6 production. This locus harbours approximately 8 genes, including genes playing a role in neuronal development, axonal growth and spinal cord injury. The second locus regulates EAE and overlaps a QTL that regulates PIA and TNF production. We were thus able to define two adjacent QTLs in the rat that regulate encephalomyelitis, arthritis and proinflammatory cytokine production. Sequencing and expression analysis of candidate genes are ongoing.

Heritability of metabolic syndrome and its phenotypic components in Chinese female twins aged 20 to 60 years.

S.C. Zhang, X. Liu, Y.X. Yu, H.J. Tsai, X.B. Wang Mary Ann and J. Milburn Smith Child Health Research Program, Childrens Memorial Hospital, Northwestern University Feinberg School of Medicine, Chicago, IL.

Introduction: Metabolic syndrome (MS) is defined as a cluster of metabolic abnormalities including central obesity, dyslipidemia, hypertension and hyperglycemia. The prevalence of MS has increased rapidly worldwide in the past decades. However, the role of genetic and environmental influence on MS remains unclear. This study investigates the heritability of MS and its five phenotypic components using a twin design. **Methods:** A total of 1,606 female twin pairs, 1,108 monozygotic (MZ) and 498 dizygotic (DZ) twin pairs, aged 20 to 60 years, were recruited from a rural area in China. Zygosity was determined using 10 polymorphic microsatellite markers, with an accuracy exceeding 99.5%. MS is defined as follow: central obesity (waist circumference 80 cm), plus any two of the following factors: triglyceride (TG)1.7m mMol, high density lipid (HDL) 1.1m mMol, systolic blood pressure (SBP) 130 or diastolic blood pressure (DBP) 85 mmHg, fasting plasma glucose (FPG) 5.6m mMol (ref). Heritability was estimated using structure equation modeling (Mx software). We fitted an ACE model that estimates additive genetic (a^2), common (c^2) and specific (e^2) environmental components of MS and its five components. **Results:** The prevalence of MS in this study population is 3.2%. The correlation coefficients of MS and its five components among MZ (ranging from 0.54 to 0.79) are higher than those among DZ (ranging from 0.19 to 0.58). Consistently, heritability (95%CI) estimates of MS, central obesity, high TG, low HDL, high BP and high FPG are 0.79 (0.17-0.88), 0.52 (0.19-0.79), 0.53 (0.04-0.65), 0.66 (0.32-0.76), 0.46 (0.10-0.84) and 0.13 (0.00-0.52), respectively. **Conclusions:** This large twin study demonstrated strong genetic influence on MS and its components, except for high FPG. It underscores that further investigation of MS should consider both genetic predisposition, environmental factors, and GxE interactions. Ref: Bayoumi A et al.Obesity, 2007;15(3):551-556.

Analysis of a de novo balanced translocation [46,XY,t(2;9)(p13;p24)] in a patient with autism spectrum disorder reveals direct interruption of RAB11FIP5. *J. Roohi[1], D.H. Tegay[1], J.C. Pomeroy[1], G. Stone[2], R. Stanyon[2,3], S. Christian[4]* 1) Stony Brook University Medical Center, Stony Brook, NY; 2) Comparative Molecular Cytogenetics Core, National Cancer Institute, Fort Detrick, Frederick, MD; 3) Department of Animal Biology and Genetics, University of Florence, Florence, Italy; 4) Department of Human Genetics, The University of Chicago, Chicago, Illinois.

An apparently balanced de novo translocation between chromosomes 2 and 9 [46,XY,t(2;9)(p13;p24)] in a patient with pervasive developmental disorder not otherwise specified (PDD-NOS), significant fifth finger clinodactyly, slight hypotonia, and slight microcephaly was mapped using flow sorted chromosomes generated from Epstein-Barr Virus immortalized peripheral white blood cells. Chromosomes 2 and 9 isolated from a normal individual and the patients derivative chromosome 9 were amplified with Phi29 DNA polymerase and the normal material hybridized against the patients onto a tiling path BAC array. The translocation breakpoints were identified to within approximately 200kb and PCR used to map them in finer detail. RAB11 family interacting protein 5 (RAB11FIP5) on chromosome 2p13.2 was found to be directly interrupted by the translocation; no gene on chromosome 9 was involved. RAB11FIP5 is a Rab11 effector associated with the mitochondria and recycling endosomes. It regulates the recycling of plasma membrane receptors and is expressed at low levels in several organs, including the brain. Mutations that affect Rab11, a GTPase that regulates vesicle targeting and fusion, have been associated with autism and mental retardation. Given the potential importance of RAB11FIP5 in autism pathogenesis, we used Hi-Res melt analysis to investigate this gene in 607 autistic individuals and have identified several undescribed changes.

Single-nucleotide polymorphisms in the *CYP2D6* gene are correlated with iloperidone drug exposure levels, impacting the degree of QTc prolongation associated with iloperidone treatment. *C. Wolfgang, M. Polymeropoulous* Vanda Pharmaceuticals, Inc. Rockville, MD.

QT interval prolongation has been associated with numerous drugs, including antipsychotics. Genetic variants altering drug metabolism can result in higher than normal drug concentrations that may result in QT interval prolongation. Iloperidone, an investigational mixed D_2/5-HT_2 antagonist antipsychotic developed for the treatment of schizophrenia, is primarily metabolized by CYP2D6. The objective of this study was to identify and confirm genetic polymorphisms in *CYP2D6* that are associated with QT interval prolongation after iloperidone treatment. Seventy-four patients receiving iloperidone 16-24 mg/d in an open-label safety study (S1) and 300 patients receiving iloperidone 24 mg/d and 147 patients receiving placebo in a double-blind, efficacy/safety study (S2) were genotyped for two specific *CYP2D6* polymorphisms. Genotype/phenotype associations were characterized using iloperidone and metabolite concentration ratios in S1 to classify patients as either extensive metabolizers (EMs), intermediate metabolizers (IMs), or poor metabolizers (PMs). ECG was performed at protocol-specified intervals in each study. Maximum and mean QT interval changes from baseline (QTc) were calculated for each polymorphism. Mean and maximum QTc were significantly greater in IMs and PMs than in EMs among iloperidone-treated patients. Patients receiving placebo showed no change in mean QTc interval and a slight decrease in mean maximum change in QTc interval. *CYP2D6* polymorphisms were associated with higher levels of iloperidone exposure, resulting in larger QTc interval prolongations. These associations were characterized and then prospectively confirmed. Identifying patients genetically at risk for QT prolongation when treated with iloperidone before treatment initiation provides an opportunity to individualize therapy, balancing optimal tolerability and symptom relief.

Ion channel genes associated with migraine with aura. *K.S. LaForge[1,2], D.R. Nyholt[3], M. Kallela[1,2], P. Tikka-Kleemola[1,2], M.A. Kaunisto[1,2], P. Lahermo[1], K.R.J. Vanmolkot[4], G.M. Terwindt[4], S. Purcell[5], M.J. Daly[5], C. Kubisch[6], M. Dichgans[7], D.R. Cox[8], J. Kaprio[2], A.M.J.M. van den Maagdenberg[4], L. Peltonen[2,5], M. Wessman[1,2], A. Palotie[1,2,5]*
1) Finnish Genome Center, Univ. of Helsinki, Helsinki, Finland; 2) Research Program for Molecular Medicine, Univ. of Helsinki, Helsinki, Finland; 3) Genetic Epidemiology Laboratory, Queensland Institute of Medical Research Brisbane, QLD, Australia; 4) Dept. of Human Genetics, Leiden Univ. Medical Centre, Leiden, the Netherlands; 5) The Broad Institute of MIT and Harvard, Cambridge, MA; 6) Institute of Human Genetics, University of Cologne, Cologne, Germany; 7) Dept. of Neurology, Klinikum Grosshadern, Munich, Germany; 8) Perlegen Sciences Inc., Mountain View, CA.

Twin studies have firmly established the heritability of common forms of migraine. Mutations in three ion-transporting genes cause a rare Mendelian form, familial hemiplegic migraine, yet identification of genes involved in non-Mendelian migraine has proved elusive. We hypothesize that common variants of ion channel genes may also underlie common forms of migraine with aura (MA). We performed a saturation candidate gene study of 155 ion channel genes in a Finnish migraine study sample. Tagging SNPs with MAF0.10 and LD of $r^2$0.80 were selected for each gene. Allelic association tests were performed for 5269 markers in 841 cases and 884 controls. Twenty-four SNPs distributed in 15 genes had (uncorrected) significance values of p0.005. We selected SNPs in these genes for further validation in two population-based cohorts and two clinic-based cohorts. In a population-based Australian sample of 1127 migraine cases and 1129 controls, evidence for allelic association was detected with the intracellular chloride channel gene *CLIC5*. A second population sample of 800 cases and 946 controls from the Netherlands did not yield any significant allelic associations when all cases were analyzed; however, when MA cases (n=258) were compared to controls, we found suggestive evidence for association with the potassium channel gene *KCNB2*. These findings are currently being followed up in clinic-based cohorts from Cologne and Munich.

Prevalence of polyneuropathy in adult type 1 Gaucher disease (GD1): a multinational prospective observational study. *L. Marodi[1], M. Biegstraaten[2], I.N. Van Schaik[2], E. Mengel[3], M. Petakov[4], C. Niederau[5], P. Giraldo[6], D. Hughes[7], M. Mrsic[8], A. Mehta[7], C.E.M. Hollak[2], and the 018 Study Group* 1) Department of Pediatrics, University of Debrecen, Debrecen, Hungary; 2) Academic Medical Centre, Amsterdam, The Netherlands; 3) Universitaets Kinderklinik, Mainz, Germany; 4) Institute of Endocrinology, Clinical Center of Serbia, Belgrade, Serbia; 5) Klinik fur Innere Medizin, Universitat Essen, Duesseldorf, Germany; 6) Miguel Servet University Hospital, Zaragoza, Spain; 7) Royal Free Hospital, London, UK; 8) University Hospital Centre, Department of Hematology, Zagreb, Croatia.

GD1 has traditionally been categorized as non-neuronopathic. However, some cases of polyneuropathy (PNP) have been reported and also in patients exposed to miglustat. Since there is no definite explanation, a multinational (7 countries, 8 centres) prospective, observational study has been set up to establish the prevalence and incidence of PNP in GD1. This study was set up under the auspices of the European Working Group on Gaucher Disease. Diagnosis of PNP was based on compatible neurological signs and/or symptoms and abnormal electrodiagnostic studies. A standardised protocol was used in all centres. An independent central assessor adjudicated PNP diagnosis. Secondary endpoints included the 2-year incidence of PNP and other parameters (neuropsychological status, organ involvement, skeletal manifestations, laboratory measurements and quality of life). 103 GD1 patients were enrolled; either untreated (n=17) or treated with enzyme replacement therapy (n=86). Mean ageSD was 42.614.5 years (53% female). Eleven patients were diagnosed with sensory or sensory/motor axonal PNP (10.7%, 95%CI, 5.5-18.3%). This prevalence is significantly higher than in the general population (0.12 to 3.6%). Patients with PNP were older than those without PNP (meanSD, 61.110.3 vs. 40.413.4, respectively). Further investigations will focus on the relation with disease severity, and other factors associated with PNP. These findings prompt awareness of this new co-morbidity in GD1, and suggest that careful questioning and, in case of suspected PNP, further examination by an experienced neurologist is needed.

Fine mapping of the chromosome 14 primary open angle glaucoma (POAG) region. *J.L. Wiggs[1], M.A. Hauser[2], R.R. Allingham[3], M.A. Pericak-Vance[4], J.L. Haines[5]* 1) Dept Ophthalmology, Harvard Medical Sch, MEEI, Boston, MA; 2) Center for Human Genetics, Duke University School of Medicine, Durham, NC; 3) Department of Ophthalmology, Duke University School of Medicine, Durham, NC; 4) University of Miami Miller School of Medicine, Miami, FL; 5) Center for Human Genetic Research, Vanderbilt Medical School, Nashville, TN.

Primary open angle glaucoma (POAG) is a genetically and phenotypically heterogeneous disorder that causes irreversible damage to the optic nerve and is a leading cause of blindness worldwide. Using a collection of 195 affected sibling pairs, we have previously completed a genome scan that provided evidence for POAG loci on chromosomes 2, 4, 14, 15, 17 and 19 (Wiggs et al., 2000). Model dependent and model free linkage analysis gave highest values for markers D14S264 and D15S165. Haplotype analysis performed with additional markers in the areas of peak linkage identified a 50 cM interval on chromosome 14q11-q22 extending from marker D14S72 to D14S274 shared by affected individuals in 53% of the pedigrees (n=86) included in the analysis. SNP genotype data from a SNP-based genome scan (Illumina) using the same families was analyzed to further refine the region defined by the microsatellite haplotypes. 44 families had a shared haplotype among affected individuals that corresponded to the regions shared by the microsatellite markers. Of these families, the affected members of 23 families shared a portion of a single haplotype with the shared segment extending from rs1951085 to rs7160965, a region of 4.2 Mb that includes microsatellite marker D14S264. Candidate genes located within this reduced region will be evaluated for association with POAG using a case control cohort. These results suggest that a POAG susceptibility gene(s) located in this region is responsible for a significant portion of the genetic contribution to POAG in this population.

The National Ophthalmic Disease Genotyping Network: eyeGENE™. *S.J. Tumminia[1], A. Nezhuvingal[1], D. Scheim[2], N. Smaoui[1], D. Blain[1], H. Chin[1], B.P. Brooks[1]* 1) NEI/NIH, Bethesda, MD; 2) Private Systems Specialist, Blacksburg, VA.

Purpose: Create a National Ophthalmic Disease Genotyping Network (eyeGENE™) to facilitate inherited ophthalmic disease research. **Methods:** Individuals are recruited into eyeGENE™ from academic centers and private clinical practices. Clinicians complete a registration process, obtain informed consent and assure that genetic counseling is provided. Blood and DNA are processed in a CLIA-certified fashion for molecular diagnostic testing. Remaining DNA is stored at the eyeGENE™ Repository. The clinician submits phenotypic information via a secure eyeGENE™ database which also contains genotype results. Upon approval, investigators may access the database, DNA samples for research or recruit individuals for participation in a clinical study. **Results:** We created eyeGENE™ which includes a Network of CLIA labs, a DNA repository and a database that couples anonymous genotype-phenotype data. An external Steering Committee provides opinions regarding scientific, ethical, and management issues. CLIA laboratories provide testing for over 40 disease genes including macular diseases (e.g., Best disease, Stargardt disease), other retinal diseases (e.g., retinitis pigmentosa, choroideremia), strabismus (e.g., congenital fibrosis of the extra-ocular muscles), glaucoma (e.g., dominant juvenile glaucoma, Axenfeld-Rieger syndrome), and corneal dystrophies (e.g., Reis Bucklers, granular dystrophies). Minimal phenotypic criteria have been established for each disease tested. On September 20, 2006 the first patient sample was received through eyeGENE™. At the time of abstract submission, 90 samples are being analyzed. **Conclusions:** A National Ophthalmic Disease Network was created to manage molecular diagnosis and clinical data for use in research. eyeGENE™ also provides CLIA-certified molecular diagnosis to patients. eyeGENE™ will eventually facilitate the discovery of new ophthalmic disease genes, identify genetic modifiers of disease; aid in the analysis of genotype:phenotype correlations and enhance recruitment for clinical trials. eyeGENE™ will be a resource for the vision community and benefit medical care for a broad patient population with inherited eye disease.

Optimized criteria for using interphase FISH in the prenatal diagnosis of common aneuploidies. *S. LECLERCQ[1], A. LEBBAR[1], V. TSATSARIS[2], D. LETESSIER[1], G. GRANGE[2], JM. DUPONT[1]* 1) Unite de Cytogénétique, GROUPE HOSPITALIER COCHIN SAINT VINCENT DE PAUL, PARIS, France; 2) Service de gynécologie obstétrique,GROUPE HOSPITALIER COCHIN SAINT VINCENT DE PAUL, PARIS, France.

Interphase FISH is commonly used in addition to karyotype for rapid detection of selected aneuploidies with a result usually available in 24 to 48 hours. This test offers an obvious benefit for the management of women presenting a high risk of fetal chromosomal anomaly giving them, in most cases, early reassurance. However, this test is time consuming and labour intensive increasing the cost of the prenatal diagnosis procedure. In order to evaluate medical and economic performances of different strategies selecting patients eligible for interphase FISH, we compare three different protocols used in our last 6 years activity. The three strategies differs in terms of probes selection according to the reason for referral and technical modification of the procedure. In this time frame, 2707 women were referred to our laboratory for prenatal diagnosis either because of maternal age over 38 (48%), abnormal maternal serum screening with a calculated risk over 1/250 (35%) or abnormal ultrasound (17%). A grand total of 4.8% chromosomal anomalies were diagnosed after karyotyping. Theoretically, interphase FISH would detect 79.4% of the unbalanced anomalies. The last protocol adopted, which offers a rapid test to 57% of women undergoing amniocentesis, allows the best aneuploidies detection rate (68% of total aneuploidies,87%of trisomy 21). Aneuploidies not selected for FISH testing were mostly observed in samples referred for maternal age under the protocol cut-off level. Selecting probes according to the patient risk evaluation combined to technical procedure modification allows medico economic improvement of interphase FISH in general practice.Thus, number of eligible patients is increased for a same reagent cost leading to better pregnancy management. However,analysis time increases,limiting the number of tests to perform. Although we improve the use of interphasic FISH in prenatal diagnosis, its generalization will need further technical improvements such as automated spot counting to become reality.

Towards a pathway definition of Parkinson's disease. *L.B. Moran, M.B. Graeber* University Department of Neuropathology, Imperial College London and Hammersmith Hospitals Trust, London, UK.

We have used brain tissue from well characterised cases of sporadic Parkinsons disease (PD) and established a first whole genome transcriptomic profile of the medial and lateral substantia nigra as well as frontal cortex (1). 570 highly significantly ($p<0.001$) deregulated sequences were initially identified. By focusing on the most comparable PD cases and controls in our cohort we have refined our analysis and established an extended list of 892 deregulated genes which we expect to form the core of the 'disease pathway'; underlying PD. In addition, our dataset was reanalysed using a new software package and a database of eukaryotic molecular interactions, Resnet 5.0 (PathwayStudio, Ariadne). Back-mapping to brain tissue of mRNAs of interest has already resulted in two new Lewy body markers (2). The validated dataset (1) will be deposited in the GEO database. The complete gene regulatory network now under scrutiny contains more than 100 genes whose association with PD is known from the literature. Of those more than 40 genes belong to the highly significantly deregulated group. Further tissue back-mapping of all deregulated gene products by means of antibodies and in situ hybridisation is necessary to 'stratify'; the current tentative pathway signature for the different cell types present in the human substantia nigra, i.e. neuronal subtypes, astrocytes, microglia, oligodendrocytes and vascular and perivascular cellular elements. SNCA appears to have a central role in PD pathogenesis as it forms part of several of the deregulated regulatory networks so far investigated (3). However, a number of heat shock proteins including HSPA1A, metallothioneins and various synaptic proteins also figure prominently. A list of all components of the current PD pathway definition will be presented at the meeting. New genes not previously associated with PD include FGF13, NRXN1, RELN, SDC1 and SYT1. 1. Moran et al. Neurogenetics 2006;7:1-11; 2. Moran et al., ABN meeting abstract, Cambridge, UK, 12 Apr 2007, J Neurol Neurosurg Psychiatr, in press; 3. Moran et al. Acta Neuropathol 2007;113:253-63. Funding from the UK Parkinsons Disease Society is gratefully acknowledged.

Phenotypic variability in the CDAGS syndrome: Report of an additional family. *R.L. Sparkes, A.M. Innes, D.R. McLeod* Department of Medical Genetics, Alberta Children's Hospital, Calgary, AB, Canada.

A distinct, autosomal recessive genetic syndrome was recently characterized and genetically mapped to 22q12-q13[1]. The name CDAGS was suggested for its commonly associated features: **c**raniosynostosis and **c**lavicular hypoplasia; **d**elayed fontanel closure, cranial **d**efects and **d**eafness; **a**nal anomalies; **g**enitourinary malformations; and **s**kin eruption. Seven patients from four families with diverse ethnic backgrounds were described. The most consistent clinical features included coronal synostosis, wide open fontanels with parietal foramina, sparse brows and lashes, imperforate anus and hyperkeratotic skin eruptions.

We report the eighth and ninth individuals with the CDAGS phenotype: a brother and sister born to consanguineous Pakistani parents. Our patients lack coronal synostosis, genitourinary malformations and anal anomalies. Features shared with the published cases include sagittal and lambdoidal craniosynostosis, cranial defects, facial dysmorphism, dental anomalies, deafness, developmental delay, hypoplastic clavicles and skin eruptions, the latter being mild. Unreported features seen in one or both of our siblings include bilateral paresis of the ocular depressor muscles, Chiari I malformation, occult spinal dysraphism and chronic pancreatitis.

Although the genetic defect in CDAGS is not known, because of overlapping features with other genetically characterized conditions including cleidocranial dysplasia (*RUNX2* gene), it was suggested that the molecular pathogenesis involves disruption of multiple signaling pathways important for osteoblast differentiation, chondrocyte maturation and craniofacial morphogenesis, thereby explaining the paradoxical occurrence of both delayed ossification and accelerated suture closure. Identification of the gene for CDAGS and phenotypic characterization of additional families will facilitate further understanding of these developmental mechanisms in this interesting and variable genetic condition.

[1]Mendoza-Londono et al. *Am J Hum Genet* 77:161-168,2005.

The four and a half LIM domain protein 2 (FHL2) interacts with CALM and is highly expressed in AML with complex aberrant karyotypes. *Z. Pasalic, B. Tizazu, M. Mulaw, L. Fröhlich-Archangelo, A. Krause, P. Greif, S. Bohlander* GSF- MEDIII, KKG-Leukemia, Munich, Germany.

The CALM/AF10 translocation t(10;11)(p13;q14) is found in acute myeloid leukemia (AML), T-cell acute lymphoblastic leukemia (T-ALL) and malignant lymphoma. The CALM/AF10 fusion gene has been shown to cause aggressive biphenotypic leukemia in a murine bone marrow transplant model. The CALM (Clathrin Assembly Lymphoid Myeloid leukemia gene) gene product is a clathrin assembly protein which plays a role in clathrin-mediated endocytosis and trans Golgi network trafficking. AF10 is a putative transcription factor likely involved in processes related to chromatin organization. To learn about the function of the CALM/AF10 fusion protein, we searched for protein interaction partners of CALM using a yeast-two-hybrid (Y2H) assay and identified FHL2 as a putative CALM interacting partner. The CALM FHL2 interaction was confirmed by GST pull-down and CoIP experiments. In co-localization studies a translocation from cytoplasm to the nucleus is seen. Expression analysis (Affymetrix based) in different AML subtypes showed a significantly higher expression of FHL2 in AML with complex aberrant karyotypes compared to AML with normal karyotypes or balanced chromosomal translocations like the t(8;21), inv(16) or t(15;17). FHL2 is a TP53 responsive gene known to interact with proteins in both nucleus and cytoplasm and it can function as a transcriptional cofactor. Known FHL2 interactors include TP53, BRCA1, PLZF (promyelocytic leukemia zinc finger protein), the proto oncogene SKI1 and beta-catenin. High expression of FHL2 in breast cancer has recently been shown to be associated with an adverse prognosis. Reporter gene assays using a GAL4-DNA binding domain FHL2 fusion protein and a GAL4 responsive luciferase reporter were able to demonstrate a transcriptional activation function of FHL2. In independent experiments with CALM and CALM/AF10, a synergism occurred implying that it is conceivable that FHL2 is playing an important role in CALM/AF10-mediated leukemogenesis by tethering the CALM/AF10 fusion protein to various nuclear transcription factor complexes.

The Type 2 Diabetes Gene CDKAL1 is Expressed in Beta Cells and Modulated by Glucose Concentration. *V. Steinthorsdottir[1], I. Reynisdottir[1], G. Thorleifsson[1], S. Ghosh[1], R. Benediktsson[2], G. Sigurdsson[2], A. Kong[1], M. Gurney[1], J.R. Gulcher[1], U. Thorsteinsdottir[1], K. Stefansson[1]* 1) deCode Genetics, Reykjavik, Iceland; 2) Landspitali University Hospital, Reykjavik, Iceland.

The CDKAL1 gene, identified through genome-wide association study, was found to be associated to increased risk of T2D in nearly a recessive manner, with genotype odds ratio for the homozygous carrier 1.45 and 1.55 for individuals of European and Asian ancestry, respectively. The function of the CDKAL1 gene product is unknown but it is similar to another protein, CDK5RAP1, an inhibitor of the CDK5/p35 complex in neuronal tissue. This complex is also expressed in pancreatic beta cells and, in the presence of its active form, insulin expression is decreased under glucotoxic conditions. This led to the hypothesis that CDKAL1 might be an inhibitor of the CDK5/p35 complex in pancreatic beta cells. Furthermore, we have shown that the risk variant of CDKAL1 is associated with reduced insulin secretion and this effect is mostly seen for the homozygote where a 24% reduction in insulin response is observed compared to the heterozygous carriers or non-carriers. This is in line with the nearly recessive mode of inheritance observed for this variant with respect to disease risk. The aim of this study was to gain further insight into the role of CDKAL1 using the rat pancreatic beta cell line INS-1. The rat pancreatic beta cell line INS-1 was cultured in the presence of variable glucose concentration, ranging from 2.5-30 mM, to evaluate whether CDKAL1 expression is regulated by glucose concentration. We demonstrated that the expression of CDKAL1 in rat INS-1 cells varied according to glucose concentration in the culture medium with reduced expression detected under glucotoxic conditions compared to normal glucose concentration. This indicates that CDKAL1 expression in pancreatic beta cells is sensitive to glucose concentration. It is possible that this response to glucose may be affected in individuals carrying the variant of CDKAL1 that is associated to T2D. This could explain the reduced insulin secretion observed by these individuals in response to an oral glucose challenge.

The role of opioid receptor genes in heroin-induced subjective responses. *D. Zhang[1], L. Jin[1,2]* 1) Center for Anthropological Studies, School of Life Sciences, Fudan University, Shanghai, China; 2) CAS-MPG Partner Institute for Computational Biology, Shanghai, China.

We reported earlier that *OPRM1* was associated with self-reported positive responses on first use of heroin. To further evaluate the role of opioid receptor genes (, and receptor gene: *OPRM1*, *OPRD1*, *OPRK1*, respectively) and their interaction underlying heroin-induced subjective responses, we conducted association analyses of tagging SNPs (tSNPs) in *OPRD1* and *OPRK1* with subjective responses, respectively. Multinomial non-conditional logistic analysis revealed that the genotype CT at rs12404612 (located within *OPRD1*) and the C allele of rs1691808 (in *OPRK1*) were associated with heroin-induced subjective responses, respectively, but the association vanished after adjusting for multiple testing. However, strong interactions were detected between *OPRM1*-*OPRD1* and between *OPRM1*-*OPRK1* in subjective responses on first heroin use. The findings suggest that *OPRM1* play the most important role in self-reported positive responses on first use of heroin among three opioid receptor genes.

Whole-genome Resequencing with Short Reads: Accurate Mutation Discovery with Mate Pairs and Quality Values. *S.F. McLaughlin[1], H.E. Peckham[1], Z.H. Zhang[2], J.A. Malek[1], J.M. Sorenson[2]* 1) Applied Biosystems, 500 Cummings Center, Beverly, MA 01915; 2) Applied Biosystems, 850 Lincoln Centre Dr, Foster City, CA 94404.

The next generation of DNA sequencing platforms produces sequencing reads with different qualities from the familiar data characteristics of Sanger-based automated DNA sequencing. Reduced read lengths and lower per-base accuracy have been compensated by significant increases in the available depth of coverage. The use of such reads for whole-genome resequencing requires a re-examination of previously solved algorithmic issues such as optimal alignment, consensus calling and the incorporation of quality metrics into raw and finished results. The Applied Biosystems SOLiD system (a massively parallel sequencing technology based on ligation of oligonucleotides) is the only next-generation system capable of utilizing 2-base encoding to significantly reduce the raw error rate. We have developed algorithms for the SOLiD system that utilize 2-base encoding as well as quality values and systematic error to improve upon the raw resequencing ability of short unpaired (<50bp) reads. By incorporating per-base quality values into the consensus calling we are able to successfully discriminate between false positives and true polymorphisms and provide predictions for where false negatives might occur. These algorithms have been tested on several bacterial genomes using a variety of data sets from the SOLiD system. In addition, we show that the availability of highly parallel mate-paired reads allows increased mappability resulting in more accurate characterization of single-base changes as well as the detection of large-scale rearrangements and indels.

Microarray-based Direct Genomic Selection for High Throughput Resequencing. *M.E. Zwick[1], K. Meltz-Steinberg[1], C. Middle[2], T. Albert[2], D. Okou[1]* 1) Dept Human Genetics, Emory Univ Sch Medicine, Atlanta, GA; 2) 2Nimblegen Systems, Inc. Madison, WI.

Comprehensive resequencing can identify all genetic variants, whether they be rare or common, that contribute to disease susceptibility. This vision has fueled the development of a number of highly efficient sequencing technologies (Resequencing Arrays - RAs, 454, Solexa). Similar progress, however, has not been forthcoming in methods of target DNA preparation. Template DNA preparation in complex eukaryotic genomes is currently based upon multiple PCR fragments or other clone-based methodologies that remain arduous, inefficient and expensive. Here we report our results using a novel strategy, Microarray-based Direct Genome Selection (MGS) that offers revolutionary improvements in speed, efficiency and cost of template DNA preparation for resequencing. MGS isolates user-specified genomic fragments that can be generically amplified and sequenced by any of the next-generation sequencing technologies.

Using MGS and RAs, we have resequenced in replicate 300kb of unique sequence in 10 HapMap samples (5 CEPH/5 Yoruban) and a sample with a known mutation (TR91) from a 1.3 MB sized region on the human X chromosome that contains the FMR1/FM2 genes. The observed replication rate is 99.99%; in the 4.8MB of genomic sequence. An accuracy rate of 99.8%; (10 discrepancies / 4812 identical) is observed as compared to HapMap Genotype calls. Using a single MGS array design, we are selecting and resequencing all the unique exons on the X chromosome in the same 10 HapMap samples. Initial results demonstrate a call rate of more than 80%; with an accuracy rate of greater than 99%; as compared to the HapMap. MGS offers an inexpensive (~ $300 per sample) and rapid (~ 3 days from sample to sequence ready DNA) protocol that can enable the comprehensive resequencing of genomic regions, chromosomes, linkage peaks or collections of genes identified in systems biology analyses from complex eukaryotic genomes with next-generation sequencing technologies.

Beyond maleness: The Y-chromosome as a risk factor for ADHD and autism. *J.R. ten Bosch[1,2], B. Merriman[1], R.M. Cantor[1], P.K. Gregersen[3], D.H. Geschwind[1], J.J. McGough[1], S.L. Smalley[1], S.F. Nelson[1]* 1) David Geffen School of Medicine, University of California, Los Angeles, Los Angeles, CA; 2) Medical Genetics Institute, Cedars-Sinai Medical Center, Los Angeles, CA; 3) Feinstein Institute for Medical Research, North Shore-Long Island Jewish Health System, Manhasset, NY.

ADHD and autism are complex neurobehavioral disorders with a strong male bias. Both disorders are approximately four-times more prevalent in males than females. For idiopathic autism, at least a portion of this bias appears to be attributed to risk factors present on chromosome 17 in affected males (Stone et al. 2004; Cantor et al. 2005). To further clarify the underlying etiology that gives rise to this sex bias in autism and ADHD, we examined Y-chromosome copy number and haplotype in affected and control individuals. We found XYY individuals were much more common among male probands, particularly those affected with ADHD (*P*-value < 0.00001), than among control subjects. In addition, we identified Y-chromosome haplogroups that were significantly associated with both these disorders, thus demonstrating that the Y-chromosome contribution to the acquisition of ADHD and autism is of greater significance than previously appreciated.

Enzyme replacement therapy in children with Fabry disease: current practice as reported in FOS the Fabry Outcome Survey. *U. Ramaswami[1], G. Pintos-Morell[2], G. Kalkum[3], R. Parini[4], M. Beck on behalf of the FOS investigators[3]* 1) Paediatric Metabolic Unit, Addenbrooke's Hospital, University of Cambridge, UK; 2) Department of Paediatrics, German Trias i Pujol Hospital, Badalona, Spain; 3) Department of Paediatrics, University Children's Hospital, Mainz, Germany; 4) Clinica Pediatrica, Università Milano Bicocca, Monza, Italy.

Fabry disease (FD) is an X-linked lysosomal storage disorder characterized by deficient activity of the enzyme -galactosidase A. Signs and symptoms of this condition are already present in childhood and include neuropathic pain, gastrointestinal disturbances and hypohidrosis, which can severely impact upon quality of life. Data from FOS, an international database of patients with FD, were analyzed to compare disease severity - as assessed using a modified version of the Mainz Severity Score Index (FOS-MSSI) - and the proportion of children and adults receiving treatment. In February 2007, 1329 patients were registered with FOS, comprising 551 men, 558 women and 220 children (102 boys, 118 girls). In total, 80.9% of men and 57.3% of women had received enzyme replacement therapy (ERT). ERT was administered to 45.9% of boys under 10 years of age and 72.3% of boys aged 10 years or older. Similarly, 34.1% of girls under 10 years of age and 49.4% of girls aged 10 years or older had received ERT. Prior to receiving ERT, median FOS-MSSI scores were 16.5 (10-90th percentile, 6.0-33.5; n = 498) and 9.5 (0.0-24.0; n = 503) in adult males and females, respectively. In boys and girls under 10 years of age, median FOS-MSSI scores were 5.0 (0.0-12.5; n = 33) and 2.5 (1.0-16.5; n = 36), respectively. Boys and girls aged 10 years or older had median FOS-MSSI scores of 8.0 (1.0-16.5; n = 57) and 7.5 (0.0-17.0; n = 72), respectively. These data indicate that, while a significant number of adults with FD are receiving ERT, young patients (< 10 years old) are less likely to be on treatment, despite exhibiting signs and symptoms of FD. This may be due to the false perception that the symptoms of FD do not represent a significant disease burden in these patients, as FOS-MSSI scores are often lower in children than in adults.

Detecting deletions in candidate genes for cleft lip and palate. *M. Shi[1], A. Jugessur[2], H. Gjessing[3], A.J. Wilcox[1], R.T. Lie[2], C.R. Weinberg[1], T.N. Trung[2], K. Christensen[4], J.C. Murray[5]* 1) Biostatistics Br, NIEHS, Res Triangle Park, NC; 2) University of Bergen, Bergen, Norway; 3) Norwegian Institute of Public Health, Oslo, Norway; 4) University of Southern Denmark, Odense, Denmark; 5) Department of Pediatrics, University of Iowa, Iowa City, IA.

Apparent deviations in family genotypes from Mendelian inheritance have routinely resulted in these datapoints being discarded as errors. With the realization of the importance and wide distribution of copy number variants in the human genome, methods have been developed to detect deletion events based on patterns of Mendelian inconsistencies in data collected from high-density SNP surveys. In this study, we analyzed genotype data from a large scale candidate gene study of isolated cleft lip and palate using a multi-national collection of samples to detect deletions as one component of an association study. Genotyping was performed by CIDR for over 1,200 SNPs in 340 candidate genes using 1,535 Norwegian and 1,397 Danish samples consisting mostly of caseparent triads. This dataset has a high duplicate reproducibility rate (99.98%) and low rates of missing data (0.55%), which provided a powerful opportunity for deletion detection. We detected ten potential deletion regions based on patterns of Mendelian failures. Four are located in the cleft candidate genes SUMO1, TGFBR2, FGF10, AP2, EDN1, and PVRL2, previously suggested to play a role in facial development. Overall 1.6% of families in this study had a suggested deletion suggesting a significant impact on genetic etiology by this mechanism. We are performing denser SNP genotyping, direct sequencing and quantitative analysis to confirm and characterize the size of these potential deletions.

Pharmacogenomic study of iloperidone treatment in patients with schizophrenia identifies markers associated with efficacy. *L. Licamele, S. Volpi, C. Heaton, K. Mack, R. Lannan, J. Hamilton, I. Holt, C. Wolfgang, M. Polymeropoulos, C. Lavedan* Vanda Pharmaceuticals, Inc., Rockville, MD.

In the practice of medicine, it is widely appreciated that the same dose of a medication given to patients with the same disease will result in many different outcomes relative to efficacy, tolerability, and safety. Practitioners frequently use a trial-and-error approach to identify the best treatment for each patient. Unfortunately, patients may experience weeks or months of suboptimal management of their illness. This inefficient approach is particularly evident in the treatment of schizophrenia. No single antipsychotic agent offers optimal efficacy and tolerability for every patient with schizophrenia. Pharmacogenomics (PG) provides the opportunity to discover genetic markers predictive of response. Knowing how a patient with schizophrenia will respond to a particular therapy based on his or her genetic makeup will allow clinicians to select the most optimal drug and dosage with less trial and error. We report the results of a whole-genome association study conducted to discover genetic markers of efficacy response to a novel atypical antipsychotic, iloperidone, in patients with schizophrenia. Three analyses of the change in the PANSS total score (PANSS-T) between baseline and Day 28 were performed: (1) 2-stage approach by which DNA samples were separated into 2 groups50% of the samples for a discovery phase in which only the top and bottom 30% of the change in PANSS-T were used and the other 50% as a hold-out group for a confirmatory phase; (2) ANOVA of last-observation-carried-forward data of all iloperidone-treated patients; (3) mixed-effects model repeated-measures analysis of all patients using the parsimonious genetic model of each SNP. We identified 6 SNPs associated with iloperidone efficacy, including 3 located in genes or regions previously associated with schizophrenia. Odds ratio, sensitivity, specificity, and predictive values were calculated. Results of this PG study provide new insight into markers of response to the novel antipsychotic iloperidone, developed with the ultimate goal of directing iloperidone therapy to those patients most likely to respond.

Methylation of the promoter of the gene responsible for the *cblC* type of combined methylmalonic aciduria and homocystinuria (*MMACHC*) decreases its gene expression and is associated with a malignant phenotype in a human cancer cell line. *A.D. Loewy, K.M. Niles, D. Watkins, J.P. Lerner-Ellis, J.M. Trasler, D.S. Rosenblatt*
Department of Human Genetics, McGill University, Montreal QC.

A highly metastatic variant (MeWo-LC1) of the poorly malignant MeWo human melanoma cell line cannot grow on tissue culture medium in which homocysteine replaces methionine. MeWo-LC1 is a cellular phenocopy of the *cblC* disorder, characterized by decreased synthesis of adenosylcobalamin and methylcobalamin, decreased incorporation of label from [^{14}C]propionate and 5-[^{14}C]methyltetrahydrofolate into macromolecules, and failure to correct this after cell fusion with *cblC* fibroblasts. Upon identification of *MMACHC*, the gene responsible for the *cblC* disorder, sequencing gDNA from MeWo-LC1 failed to reveal mutations in the coding sequence. However, no *MMACHC* mRNA transcript was detected by PCR amplification after reverse transcribing cellular RNA with polyd(T) primers. Other genes involved in cobalamin metabolism (*MMAA*, *MMAB*, *MTR*, *MTRR*) were all expressed in MeWo-LC1, as were the control genes *GAPDH* and *ACTB*. All of the genes including *MMACHC* were expressed in MeWo, a human lung carcinoma cell line A549, and a normal fibroblast cell line. Transfection of wild-type *MMACHC* under control of a constitutive promoter corrected 5-[^{14}C]methyltetrahydrofolate and [^{14}C]propionate incorporation, as well as the synthesis of methylcobalamin and adenosylcobalamin in MeWo-LC1. The transfection also corrected the methionine dependent phenotype in these cells. Bisulfite sequencing showed that the CpG island 5' of *MMACHC* had low methylation in a control fibroblast cell line (0-14%, n = 15), MeWo had intermediate methylation (5-76%, n = 18) and MeWo-LC1 had high methylation (90-100%, n = 21). Similar methylation results were found by quantitative analysis of DNA methylation using real-time PCR (qAMP). Gene silencing by promoter hypermethylation is a phenomenon known in tumor-suppressor genes, and also appears to be associated with the malignant phenotype in MeWo-LC1 cells.

Preparing for treatment of familial dysautonomia with kinetin: improved mRNA splicing in FD carriers. *M. Leyne[1], G. Gold-von Simson[3], J. Mull[1], L.M. Rolnitzky[4], D. Berlin[3], Y.T. Chen[1,2], L. Liu[1], R.S. Shetty[1,2], F.B. Axelrod[3], S.A. Slaugenhaupt[1,2]* 1) Center for Human Genetics Research, Massachusetts General Hospital, Boston, MA; 2) Harvard Medical School, Boston, MA; 3) Department of Pediatrics, New York University School of Medicine, New York NY; 4) Division of Biostatistics, New York University School of Medicine, New York NY.

Familial dysautonomia (FD) is caused by mutations in *IKBKAP*. The most common mutation disrupts mRNA splicing and reduces IKAP protein expression below the threshold required for proper development of the sensory and autonomic nervous systems. As part of an NINDS sponsored drug screen, kinetin was found to promote normal splicing and increase expression of normal mRNA and protein in FD cells, suggesting it as a potential therapeutic agent. Prior to initiating clinical trials of kinetin in FD patients, we evaluated *IKBKAP* expression in peripheral blood samples obtained from 45 FD patients, 26 FD carriers, and 24 non-carriers. Estimated mean *IKBKAP* mRNA levels, expressed as amount relative to the non-carrier average, were 0.23 in FD patients and 0.58 in carriers. Interestingly, comparison of *IKBKAP* mRNA levels of the 22 FD patients with related carriers enrolled in the study showed a strong correlation, suggesting genetic influence on splicing efficiency. Next, kinetin was given orally to 29 FD carriers who were divided into 5 cohorts. Cohort doses were determined from the modified Fibonacci dose escalation scheme (e.g., x, 2x, 3.3x, 5x, 7x; x = 3.14 mg/kg/d). After the first single dose, serum kinetin levels were determined at 30 min, 1 hr, 2 hr, 6 hr, 12 hr, and 24 hr. Each volunteer took the same daily dose for a one-week period. Blood was sampled prior to the first kinetin dose and after the last dose for measurement of *IKBKAP* mRNA levels. Maximum serum concentration was achieved in 1-2 hours. In cohort 5 concentrations remained at therapeutic levels (> 10 M) for 6 hours. After 7 days of a single daily dose, expression of wild-type to mutant mRNA ratios increased and the percent positive change of *IKBKAP* mRNA correlated with serum kinetin levels. These exciting results support initiation of trials in FD patients.

Balloon Occlusion Catheter-Based Delivery of HDAd into the Nonhuman Primate Liver Results in Stable, High Level Transgene Expression with Minimal Toxicity. *P. Ng[1], G. Stapleton[2], M. Law[2], D. Palmer[1], Y. Zuo[1], M. Finegold[3], A. Beaudet[1], C. Mullins[2], N. Brunetti-Pierri[1]* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Pediatric Cardiology, Baylor College of Medicine, Houston, TX; 3) Department of Pathology, Baylor College of Medicine, Houston, TX.

Helper-dependent adenoviral vectors (HDAds) hold tremendous potential for liver-directed gene therapy because they can mediate long-term transgene expression without chronic toxicity. Due to a nonlinear dose-response, high doses are required to achieve hepatic transduction resulting in dose-dependent acute toxicity. To overcome this obstacle, we have developed in baboons a method to achieve efficient hepatic transduction with low dose of HDAd. A sausage-shaped balloon occlusion catheter was percutaneously positioned in the inferior vena cava of baboon 1 to occlude hepatic venous outflow. $1x10^{11}$ vp/kg of HDAd expressing the baboon a-fetoprotein (bAFP) marker was injected via a percutaneously placed hepatic artery (HA) catheter and left to dwell within the liver for 15 min before balloon deflation. As controls, $1x10^{11}$ vp/kg were administered to baboon 2 and 3 by peripheral intravenous and HA injection respectively without balloon occlusion. All procedures were well tolerated. Mild and transient transaminitis was observed for all animals. Importantly, a high level of AFP was achieved in baboon 1 that was 10-fold greater than baboons 2 and 3 and this high level has been sustained to date (at least 420 days). To distinguish between procedure-related versus vector-mediated toxicity, baboon 4 underwent the balloon procedure but was mock injected with saline and similar mild transaminitis was observed suggesting that the mild hepatotoxicity was procedure and not vector related. Reduction of the occlusion time from 15 to 7.5 min did not affect the level or duration of AFP. Therefore, the therapeutic index of HDAd can be significantly improved by delivering the vector preferentially into the liver using a minimally invasive balloon catheter technique and this may be a first step towards clinical application of HDAd for liver-directed gene therapy.

Association of proopiomelanocortin gene variation with cocaine or opioid dependence: evidence from both family and population-based studies. *H. Zhang[1,2], H.R. Kranzler[3], R.D. Weiss[4], K.T. Brady[5], R.F. Anton[5], L.A. Farrer[6], J. Gelernter[1,2]* 1) Department of Psychiatry, Yale University School of Medicine, New Haven, CT; 2) VA Connecticut Healthcare System, West Haven, CT; 3) Department of Psychiatry, University of Connecticut School of Medicine, Farmington, CT; 4) Alcohol and Drug Abuse Treatment Program, McLean Hospital, Belmont, MA; 5) Department of Psychiatry and Behavioral Sciences, Medical University of South Carolina, Charleston, SC; 6) Department of Medicine (Genetics Program), Boston University Schools of Medicine and Public Health, Boston, MA.

The proopiomelanocortin gene (*POMC*) encodes several biologically active peptides including the adrenocorticotropic hormone and the -endorphin. In this study, we examined the association of *POMC* variants with cocaine dependence (CD) or opioid dependence (OD). Four *POMC* tag single nucleotide polymorphisms (tag SNPs) (SNP1 and SNP2 in the promoter region, SNP3 in intron 1, and SNP4 in intron 2) were genotyped by Illumina array methodology in 1,344 subjects in 612 families [363 African-American (AA) and 249 European-American (EA)] with sibling pairs affected with CD or OD. Family-based association tests demonstrated an association of SNP1 and SNP4 with OD in AA families (P = 0.002 and 0.012, respectively) and SNP4 with CD in EA families (P = 0.039). Moreover, haplotype-based association tests showed a risk effect of a specific haplotype on CD (P = 0.021) in AA families. To confirm the findings, we performed a replication study using two sets of case-control samples (196 AA and 492 EA controls, and 432 AA and 304 EA cases, also affected with CD or OD). A marginally significant association between two *POMC* SNPs (SNP1 and SNP2) and OD was found in AAs. Additionally, a strong association between SNP4 and CD was observed in EAs (allele-wise P = 0.007, genotype-wise P = 0.032). Interestingly, the risk haplotype identified in AA families was significantly more frequent in CD cases than in controls in both AA and EA populations (AAs: P = 0.025; EAs: P = 0.031). In summary, our data from both family and population-based studies indicate that genetic variation in *POMC* may confer vulnerability to CD or OD.

Pharmacogenomic analysis shows differences between markers associated with responses of two atypical antipsychotics, iloperidone and ziprasidone, in the treatment of patients with schizophrenia. *S. Volpi, C. Heaton, K. Mack, L. Licamele, I. Holt, J. Hamilton, R. Lannan, C. Wolfgang, M. Polymeropoulos, C. Lavedan* Vanda Pharmaceuticals, Inc., Rockville, MD.

Schizophrenia is a chronic, severe, and disabling disorder that affects about 1% of the US population. Symptoms include hallucinations, delusions, social withdrawal, and cognitive deficits. There is much evidence that schizophrenia is not caused by a single gene but, rather, by several interacting susceptibility loci and enviromental risk factors. Perhaps because of the heterogeneity of the underlying disease process, the etiology of schizophrenia has not yet been identified. Genetic factors are also expected to play a role in drug response, which is highly variable between individuals. Through a whole-genome association study conducted in a randomized, double-blind, placebo- and ziprasidone-controlled trial of iloperidone for the treatment of patients with schizophrenia, we identified several SNPs strongly associated with iloperidone efficacy, measured by change in the PANSS total score after 4 weeks of treatment. We report here on the analysis of 6 of these SNPs in 98 ziprasidone-treated patients. Allele and genotype frequencies were not statistically different between the iloperidone- and ziprasidone-treated patients. However, we showed that none of these SNPs were statistically significantly associated with ziprasidone efficacy response. Indeed, the genotype of an SNP associated with iloperidone best responders was more common among ziprasidone worse responders. Similarly, we observed that SNPs in the *CERKL* gene, associated with QT prolongation in iloperidone-treated patients, did not correlate with QT prolongation seen in ziprasidone-treated patients. Although some SNPs show a similar trend in association with response to each drug, our results suggest that the genetic signature of response is not identical for all drugs of the same class (here, atypical antipsychotics) but that it reflects the specificity of each drug, which may be mediated by its unique complex-binding profile, its individual interactions with other molecules, and its particular metabolism.

Portability of HapMap tagSNPs in 70 Asian Populations. *S. Xu*[1,2], *L. Jin*[1,2] 1) CAS-MPG Partner Institute of Computational Biology, SIBS, CAS, Shanghai 200031, China; 2) MOE Key Laboratory of Contemporary Anthropology and Laboratory of Theoretical Systems Biology, Institute of Genetics, School of Life Science, Fudan University, Shanghai 200433, China.

The International HapMap Project provides a database of SNP genotypes in four populations from which tag SNPs could be hopefully chosen to apply for linkage disequilibrium-based association studies in other populations. In PanAsian SNP Project, we generated genotype data in more than 70 Asian populations for 58,960 SNPs which distribute on 22 autosomes and X chromosome. We selected 180 regions where inter-marker distance are less than 6 kb/SNP and evaluated the portability of tag SNPs picked from HapMap samples to 70 Asian populations. In East Asian populations, the portability of common SNPs (MAF >0.05) selected from CHB and JPT (r^2>0.8) is generally more than 82%, but it can be as small as 70% in some of Southeast Asian populations. For Indian populations, the portability of common SNPs selected from CHB and JPT is less than 80%, but it can be increased to 85% or larger by using the tags from CEU. Our results indicate that HapMap data of CHB and JPT samples can be used to select tags for genome-wide association studies in many East Asian populations, but for some Southeast Asian populations, this strategy may not be sufficient.

Haplotypes in the promoter of KIF5B affect promoter activity in a cell type specific manner. *A.M. Stütz[1], T. Rice[2], D.C. Rao[2], C. Bouchard[1], T. Rankinen[1]* 1) Pennington Biomedical Research Center, Baton Rouge, LA; 2) Washington University School of Medicine, St Louis, MO.

KIF5B was identified as a candidate gene for the training response in submaximal exercise stroke volume in the HERITAGE Family Study. Significant associations were found for several KIF5B SNPs, one of them in the putative promoter. A 2 kb region surrounding the KIF5B promoter was sequenced in 95 White individuals, revealing 10 SNPs of which four are novel. Haplotype analysis revealed seven major haplotypes that were all cloned as 1,794 bp promoter fragments into a luciferase reporter vector. Strong promoter activity was found in the three tested cell lines HEK293, C2C12 and RH-30, at 103, 598 and 773 times higher than the empty vector, respectively (four experiments per cell line, each in triplicate). For all cell lines, a significant difference in promoter activity between haplotype constructs was observed ($p<0.0001$ for HEK and C2C12, $p=0.011$ for RH-30). In comparison to the haplotype containing all the common alleles, all three haplotypes that contained the rare allele at rs211302 and rs211300 showed greater promoter activity in HEK cells ($p<0.0001$, $p=0.0003$ and $p<0.0001$). The haplotype that was defined by a unique rare allele at -444 showed higher promoter activity than all other haplotype constructs ($p<0.0001$) and a 25.0 % increase compared to the common haplotype. In C2C12 cells, three haplotype constructs again showed different activity compared to the common haplotype ($p=0.02$, $p=0.005$ and $p<0.0001$ respectively). However, unlike the HEK cells, the activity was consistently lower in the C2C12 cells. A similar trend, although less pronounced, was observed in the second muscle-like cell line RH-30. Changes in the transcription factor binding profile between haplotypes (predicted using Alibaba, Match and Consite programs) may explain the differences in promoter activity. Additionally, changes in GC content and creation of CpG dinucleotides in the very GC rich, TATA-box less KIF5B promoter may also contribute. In summary, KIF5B promoter haplotypes showed cell type specific differences in promoter activity and may thus alter the function of the gene in tissue-specific manner.

Genomic analysis of mouse inner ear organogenesis. *S.A. Sajan[1], M. Lovett[1], M. Warchol[2]* 1) Division of Human Genetics and Department of Genetics, Washington University School of Medicine, St. Louis, MO; 2) Department of Otolaryngology, Washington University School of Medicine, St. Louis, MO.

Mammalian organogenesis is a complex process demanding the activity of thousands of genes. To identify novel genes, networks of genes, and pathways active during inner ear (IE) development, we expression profiled mouse IE and non-IE (NIE) tissues beginning at E9, progressing at half-day intervals, up to E15. Various sub-structures of the IE were profiled separately as they became distinguishable during development, resulting in 29 IE samples being collected. Particular attention was paid to micro-dissection and data quality control. More than 5,000 genes varied in expression temporally, spatially, or both, and these defined 28 distinct patterns. Of these genes, 8% currently lack biological annotations, thus representing novel candidates required during IE development. Pathway analysis identified 53 significant signaling cascades enriched in at least one of the 28 expression patterns. Known pathways, including *Notch*, *Wnt*, and *TGF-beta*, and pathways as yet not implicated in IE development such as *Amyloid processing*, *Circadian rhythm*, and numerous immune-related cascades, were identified. Also observed was a down-regulation at E14 of ribosomal protein genes and of those involved in mitochondrial energy production. Whole mount RNA in-situs confirmed the differential expression of selected genes, and also delineated distinct spatial patterns of expression. Moreover, 54 human genomic intervals linked to uncloned non-syndromic deafness were identified that contained genes whose mouse orthologs were expressed and/or differentially expressed in our dataset. These serve as candidates for mutational analysis. Our study contributes significantly towards a comprehensive mouse IE gene expression database, and creates additional opportunities for computational and genomic approaches in understanding IE development.

Genome-wide association study identified a locus on 3p21 for cross-sectional geometry at the femoral neck. *L.J. Zhao[1], X. G. Liu[1,3], L. Wang[1,3], J.F. Liu[1], Y.F. Pei[1,3], H. Yan[1,3], D.H. Xiong[4], F. Yang[2], H.W. Deng[1,2,3]* 1) Departments of Orthopedic Surgery and Basic Medical Sciences, University of Missouri - Kansas City, Kansas City, MO 64108,USA; 2) Laboratory of Molecular and Statistical Genetics, College of Life Sciences, Hunan Normal University, Changsha, Hunan 410081, P R China; 3) The Key Laboratory of Biomedical Information Engineering of Ministry of Education and Institute of Molecular Genetics, School of Life Science and Technology, Xi'an Jiaotong University, Xi'an 710049, P R China; 4) Osteoporosis Research Center and Department of Biomedical Sciences, Creighton University, Omaha, NE 68131, USA.

Bone geometry is an important determinant of bone strength and osteoporotic fractures. Femoral neck cross-sectional (FNCS) geometry is significantly associated with the risk of hip fracture. We first conducted a genome-wide linkage study in 3,998 individuals from 434 pedigrees for FNCS phenotypes CT (cortical thickness) and BR (buckling ratio) with 410 microsatellite markers. Strong evidence of linkage was found for CT at 3p21 (LOD=2.19, P=0.0006). This locus is established in previous independent linkage studies and plausible causative genes (CCR2, PTHR1 COL7A1) are located on this region. To further replicate the finding and identify susceptible variants for FNCS, we conducted a genome-wide association (WGA) study for CT and BR. We examined ~500,000 markers in 1000 unrelated white subjects. Helixtree was used for the data analysis. The WGA study indicated that one SNP (rs7430431) in the receptor-transporting protein 3 located at 3p21.31 was associated with BR (P=4.8 X 10-7) and CT (P=9.8 X 10-5). Additional test using Engisoft confirmed the association (P=7.6 X 10-8 for BR and P=3.8 X 10-6 for CT). The results for BR remained significant after conservative Bonferroni correction. Genotype analysis revealed that the subjects with genotype CC at the rs7430431 had, on average, 8.6% lower BR than TT (P=4.01 X 10-5). This is the first GWA study for FNCS. The observations, combined with compelling evidence from other groups and our functional genomic study, strongly indicate that the locus at 3p21.31 is important for FNCS.

Beyond major locus: looking for modifiers in RLS. *I. Pichler[1], F. Marroni[1], C. Beu Volpato[1], S. Pedrotti[1], D. Grazio[1], A. De Grandi[1], C. Klein[2,3], P.P. Pramstaller[1,2,4]* 1) Institute of Genetic Medicine, European Academy, Bolzano, Italy; 2) Department of Neurology, University of Lübeck, Germany; 3) Department of Human Genetics, University of Lübeck, Germany; 4) Department of Neurology, General Regional Hospital, Bolzano, Italy.

Restless legs syndrome (RLS [MIM 102300]) is a common, yet under-diagnosed, and frequently inadequately treated neurological disorder. Estimated prevalence rates vary widely from 2% to 15% of the general population. Epidemiologic and linkage studies demonstrate that genetic factors contribute consistently to RLS. We systematically assessed three population microisolates (n=1,167) in the western Alps of South Tyrol (Italy) for the presence of RLS and a novel locus on chromosome 2q (RLS-4) was identified. Since a co-occurence of RLS and Parkin mutations has been reported recently, 126 RLS patients were tested for Parkin mutations by gene dosage studies. In a total of 10 individuals with RLS a Parkin mutation (heterozygous deletion of exon 7) was detected. It occurred with RLS in six out of 16 patients (37.5%) of one family, which is linked to the chromosome 2q locus. The mutation was absent in a group of 145 healthy controls. Based on recent studies suggesting that heterozygous mutation carrier status in familial Parkinson Disease influences age at onset, the effect of the Parkin-mutation and the haplotype on chromosome 2q on the age at onset was investigated. An association test showed a significant effect for the chromosome 2q haplotype (p=0.009) and the effect of the Parkin-genotype resulted in a p-value of 0.07. A deeper investigation of the role of this mutation in RLS is underway. The discovery of major and modifier genes for RLS will not only provide new insights in the pathophysiology of this disorder, but will presumably also increase our understanding of other movement disorders and how they interact.

A simple approach for assessing the strength of evidence for association at the level of the whole gene. *A.E. Vine*[1], *D. Curtis*[1], *J. Knight*[2] 1) Centre for Psychiatry, Queen Marys School of Medicine and Dentistry, London E1 1BB, UK; 2) Social Genetic & Developmental Psychiatry Centre, Institute of Psychiatry, De Crespigny Park, London SE5 8AF, UK.

Introduction It is expected that different markers may show different patterns of association with different pathogenic variants within a given gene. It would be helpful to combine the evidence implicating association at the level of the whole gene rather than just for individual markers or haplotypes. Doing this is complicated by the fact that different markers do not represent independent sources of information. **Method** We propose combining the *p* values from single locus and/or multilocus analyses of different markers according to the formula of Fisher, $X=(-2\ln(p_i))$, and then assessing the empirical significance of this statistic using permutation testing. We present an example application to 19 markers around the HTRA2 gene in a case-control study of Parkinsons disease. **Results** Applying our approach shows that, although some individual markers produce low p values, overall association at the level of the gene is not supported. **Discussion** Approaches such as this could be useful in assimilating the overall evidence supporting involvement of a gene in a particular disease. Information can be combined from biallelic and multiallelic markers and from single markers along with multimarker analyses. Single genes can be tested or results from groups of genes involved in the same pathway can be combined in order to test biologically relevant hypotheses.

Community Centered Family Health History. *J. O'Leary[1], N. Bonhomme[1], J. Williams[2], M. Williams[2], P. Kyler[3], S. Terry[1]* 1) Genetic Alliance, Washington, DC; 2) Clinical Genetics Institute, Intermountain Healthcare, Salt Lake City, UT; 3) Genetic Services Branch, MCHB, HRSA/DHHS, Bethesda, MD.

Family health history is an accessible tool which captures heredity, diet, and environment; allows a health care provider to diagnose conditions and understand risk; increases health and genetics knowledge for the individual and the family; and promotes conversations about health in the family and community. It is impossible to create a one-size-fits-all family health history tool, given the diversity of individuals, families, and communities. In the community context, a flexible approach is required, best articulated by the organizations and individuals that are directly involved with them. Genetic Alliance is partnering with a diverse group of communities to create customized family health history tools. We hypothesize that accessible tools produced by the community, for the community, will promote conversations about health within the family and translate knowledge of family health history into healthy choices. Each community involved in the project adapts the "Does It Run In the Family?" family health history toolkit, disseminates it to community members, and evaluates its usefulness through baseline and follow-up surveys. Evaluation of the project serves the dual purpose of measuring the utility of family health history in promoting healthy choices and determining necessary modifications of the toolkit for the creation of an online customizable version. The current "Does It Run In the Family?" template was created using feedback from all partners and the National Advisory Committee. Partner organizations and their Community Advisory Boards customized that template to create their community-specific toolkits. The online version will streamline this process by allowing users to choose photos, personal health stories, and quotations from an online file library. In addition, Genetic Alliance will be releasing an RFP for national and community organizations to beta test the customizable online toolkit. The honorariums available will include costs for developing a tailored family health history tool and printing.

Neural crest migration defects underlie craniofacial dysmorphology in Bardet-Biedl syndrome. *J.L. Tobin[1], M. Franco[2], E. Eichers[3], H. May-Simera[1], M. Garcia[3], J. Yan[3], M. Justice[3], J. Briscoe[4], R. Mayor[5], R. Lupski[3], P. Hammond[1]* 1) Molecular Medicine Unit, UCL Institute Child Health, London, United Kingdom; 2) Biomedical Informatics Unit, UCL Eastman Dental Institute for Oral Health Care Sciences, 256 Gray's Inn Road, London, WC1X 8LD, UK; 3) Dept of Molecular and Human Genetics, Baylor College of Medicine, One Baylor Plaza, Houston, Texas 77030, USA; 4) Developmental Neurobiology, National Institute for Medical Research, London, NW7 1AA, UK; 5) Department of Anatomy and Developmental Biology, University College London, WC1E 6BT, UK.

Facial recognition is central to the diagnosis of many syndromes and key craniofacial patterns may reflect common pathway etiologies. In the pleiotropic Bardet Biedl syndrome (BBS), a primary ciliopathy with intraflagellar transport dysfunction, patients have a characteristic facial gestalt that dysmorphologists have found difficult to characterize. Here, we use dense surface modeling to show BBS patients and mouse models both have midfacial flattening. Zebrafish morphants have defects of homologous facial structures and display hallmarks of disrupted Sonic Hedgehog (Shh) signaling. Fish epistasis experiments in concert with cell-based assays indicated the importance of Bbs proteins for Shh pathway transduction by mediating Gli3 processing. Furthermore, we discovered that Bbs proteins are required for neural crest cell (NCC) migration through their involvement with the planar cell polarity pathway. We propose a model whereby Bbs proteins mediate NCC migration and then modulate their responsiveness to Shh essential for normal patterning of the midline structures of the face. Finally, we observed for the first time, ciliated NCCs, supporting evidence for novel roles for Bbs proteins in NCC migration and Shh transduction. This is the first study to derive molecular pathomechanisms from characterization of facial dysmorphology which should provide the basis for investigation into other dysmorphic syndromes.

EXPANDED VERSION OF TARGETED CHROMOSOMAL MICROARRAY ANALYSIS IMPROVES DIAGNOSTIC POTENTIAL. *C. Soler-Alfonso, C.A. Shaw, A. Patel, T. Sahoo, S. Lalani, C.A. Bacino, S.H.L. Kang, A.C. Chinault, A.L. Beaudet, J.R. Lupski, S. Neill, A.N. Pursley, P.A. Ward, S.W. Cheung.* Deparment Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Chromosomal Microarray Analysis (CMA) using array comparative genomic hybridization (array-CGH) increases diagnostic capability and efficiency in detection of genomic imbalances. Previously, we reported our experience in 2513 postnatal cases using two consecutive versions, CMA V4 and CMA V5 which showed improved detection rates of 7.6% and 8.9%, respectively. Here, we report our experience with the clinical use of an expanded array, CMA V6, containing 1475 BAC clones covering greater than 150 known genomic disorders and all clinically relevant pericentromeric and subtelomeric regions. CMA V6 studies were performed in 1923 postnatal samples with a range of indications including mental retardation, autism, seizures, multiple congenital anomalies and dysmorphic features. CMA V6 identified clinically relevant genomic imbalances in 12.7% (245/1923) of cases. In cases with previous normal chromosome analysis, 11% (53/479) had abnormalities detected by CMA V6, highlighting the improved resolution of this technology. Copy number variations (CNVs) of unknown clinical significance were identified in 13.3% (256/1923) of the cases. To date, parental studies have been performed for 126 families; contributing to define 73.8% (93/126) as familial variants, and 26.2% (33/126) as de novo events. The clinical significance of these de novo changes awaits further investigation. Our findings demonstrate that array-CGH using CMA V6 has a higher sensitivity and detection rate for genomic imbalances in comparison to routine cytogenetic techniques as well as our previous clinical arrays. We have recently transitioned from using the BAC array platform to a custom oligonucleotide array referred to as CMA V6 OLIGO. This array contains an average of 30 oligonucleotides spanning each of the BAC clones on CMA V6 providing comparable genomic coverage at a higher resolution level. Our clinical experience with these two versions (CMA V6 and CMA V6 OLIGO) will be presented.

Variance components analysis provide indirect proof of environmental homogeneity in an isolated population. *F. Marroni[1], D. Grazio[1], C. Pattaro[1], M. Devoto[2], P.P. Pramstaller[1,3,4]* 1) Institute of Genetic Medicine, European Academy, Bolzano, Italy; 2) The Childrens Hospital of Philadelphia, Division of Human Genetics, and CCEB, University of Pennsylvania School of Medicine, Philadelphia, PA, USA; Dipartimento di Medicina Sperimentale, Universita La Sapienza, Roma, Italy; 3) Department of Neurology, University of Lübeck, Lübeck, Germany; 4) Department of Neurology, General Regional Hospital, Bolzano, Italy.

We measured 43 quantitative traits in 1,138 subjects living in three isolated villages in South Tyrol (Italy). We used variance components (VCs) to estimate narrow-sense heritability, individual-specific environmental effects, and shared environmental effects. Estimates of narrow-sense heritability were in good agreement with previous findings. Household effects (Vh/V) were significant for only a few traits, and after correcting for multiple testing no trait showed significant household effect. When a VC (in our case, Vh/V) has a very low value this could be due to the fact that: a) the variance of the studied traits is not influenced by the considered component; or b) the variability of the component in the study sample is reduced, thus the VC is estimated to be low as well. Previous studies have shown that shared environment can significantly affect QTs. This was not confirmed by other studies performed subjects who shared the same environment in the most comprehensive terms (i.e., neighbourhood, lifestyle and habits). It is thus possible that the low estimates of the effects of shared environment in our population are not due to a real lack of its contribution to the studied traits, but rather to its limited variability, which is caused by reduced inter-individual differences in environmental factors. This could explain why our heritability estimates are in good agreement with previous studies, while the estimates of shared environment effects are sensibly lower. We suggest that the low shared environment contribution is indeed an indirect proof of the reduction of environmental heterogeneity in the studied villages.

Use of haplotype analysis to locate Breast Cancer Susceptibility Loci in a genome-wide association study. *P. Smith[1], K. Pooley[2], P.D.P. Pharoah[2], A.M. Dunning[2], D.R. Cox[3], D. Ballinger[3], D. Thompson[1], D.G. Evans[4], D. Eccles[5], N. Rahman[6], M.R. Stratton[6], J. Peto[7], O. Fletcher[8], B.A.J. Ponder[2], D.F. Easton[1]* 1) Public Health and Primary Care, University of Cambridge, UK; 2) Department of Oncology, University of Cambridge, UK; 3) Perlegen Sciences, Inc., USA; 4) Regional Genetic Service, St. Marys Hospital, UK; 5) Wessex Clinical Genetics Service, Princess Ann Hospital, UK; 6) Institute of Cancer Research, UK; 7) London School of Hygiene and Tropical Medicine and Institute of Cancer Research, UK; 8) Breakthrough Breast Cancer Research Centre, UK.

Multi-marker haplotype analysis provides an alternative to single SNP analysis in association studies. Haplotype analyses are more powerful if either a rare variant has recently arisen, or if there is a cis-interaction between alleles.

We applied three methods of analysing haplotype data to a genome-wide study of breast cancer[1] 195,479 genotyped SNPs with a minor allele frequency >5%;, genotyped on 408 high-risk breast cancer cases and 400 controls from the UK in the stage I of this study, were analysed. The median distance between SNPs was 6.1kb. The main analysis used a sliding window approach, using all possible windows of two to eight SNPs, implemented in the Haplostats programs.

Strong evidence for two additional loci was found: a 2-SNP haplotype, p-value=$3x10^{-10}$, and a 3-SNP haplotype, p-value=$7x10^{-8}$.

Further follow-up in additional case-control studies will be required to determine whether these associations can be replicated, and whether the association is due to linkage disequilibrium with an untyped allele or a true haplotype effect.

[1]Easton *et al*, Nature, 2007.

Two polymorphisms in ugt1a1 5-flanking region: their transcriptional regulation and association with coronary heart disease. *J. Zhang[1], Y. Wang[2], J. Dai[1], L. Zhang[1], M. He[1], J. Zhang[2], W. Sun[2], W. Huang[2], J. Jin[1], L. Jin[1,3]* 1) MOE Key Laboratory of Contemporary Anthropology, School of Life Sciences and Institutes of Biomedical Sciences, Fudan University, Shanghai, China; 2) Chinese National Human Genome Center at Shanghai, Shanghai, China; 3) CAS-MPG Partner Institute of Computational Biology, Shanghai Institutes of Biology Sciences, Chinese Academy of Sciences, Shanghai, China.

The antioxidant ability enables bilirubin to protect against coronary heart disease (CHD). UGT1A1 is the main and speed-limiting gene catalyzing bilirubin metabolism. The transcriptional regulation of ugt1a1 plays a key role in controlling UGT1A1 expression. Hence, we investigated the transcriptional effects of two polymorphisms, $(TA)_n$ short tandem repeat (STR) polymorphism and a single nucleotide polymorphism (SNP) at -3,264 site in the 5-flanking region of ugt1a1 by dual-luciferase reporter assay. We found that both polymorphisms significantly affect the transcription of the gene but only (TA)n polymorphism had significant effect on bilirubin level. We further studied such transcriptional effects on serum total bilirubin level and CHD occurrence in a Chinese population. Although bilirubin level is an important factor in CHD occurrence, (TA)n showed no association with CHD. The observed disruption of causative relationship indicates the complexity of the etiology of complex diseases.

Characterization of SOX10 deletions in WS2 highlights the molecular complexity of Waardenburg syndrome. *L. Stanchina[1], F. Dastot-Le Moal[1, 2], N. Collot[1, 2], V. Baral[1], S. Marlin[3], A. Toutain[4], W. Reardon[5], M. Lackmy-Port-Lis[6], R. Touraine[7], T. Attie-Bitach[8], M. Goossens[1, 2], V. Pingault[1, 2], N. Bondurand[1]* 1) Genetic Department, INSERM U841, IMRB, Creteil, France; 2) AP-HP, Groupe Henri Mondor-Albert Chenevier, Service de biochimie et génétique, Créteil, France; 3) Service de Génétique, INSERM U587, Hôpital Armand Trousseau, APHP; 4) Centre Hospitalo-Universitaire, Service de Génétique, Tours, France; 5) Ladys Hospital for Sick Children, Dublin, Ireland; 6) Service de Pédiatrie, CHU de Pointe à Pitre, France; 7) CHU-Hôpital Nord Service de Génétique, Saint Etienne, France; 8) Département de Génétique et INSERM U781, Hôpital Necker, Paris, France.

Waardenburg syndrome (WS) is an auditory-pigmentary disorder that exhibits varying combinations of sensorineural hearing loss and abnormal pigmentation of the hair and skin. Depending on additional symptoms, WS is classified into four subtypes, WS1 to 4. Absence of additional features characterizes WS2 whereas association with Hirschsprung disease characterizes WS4, also called Waardenburg-Hirschsprung disease. Mutations within the genes encoding MITF and SNAI2 have been identified in WS2, whereas mutations of EDN3, EDNRB and SOX10 have been observed in WS4. However, not all cases are explained at the molecular level, raising the possibility that other genes are involved or that some mutations within the known genes are not detected by commonly used genotyping methods. The crucial role of SOX10 during melanocyte development and the phenotypic variability observed among patients with mutations of this gene prompted us to search for SOX10 mutations in 30 unexplained cases of WS2. In particular, we used semi-quantitative fluorescent multiplex PCR and Fluorescent in situ hybridization to search for SOX10 deletions. We identified 5 heterozygous deletions, making SOX10 a new gene of WS2. Full characterization of the deletions revealed different events ranging from the deletion of a single exon to that of up to 5Mb. This study further characterizes the molecular complexity and the close relationship that links the different subtypes of Waardenburg syndrome, and has direct consequences in terms of molecular diagnostic.

The Role of *FOXE1* in the Etiology of Cleft Lip. *J. Machida[1], L.M. Moreno[1], M.A. Mansilla[1], S.B. Bullard[1], T.D. Busch[1], M.K. Johnson[1], T. McHenry[3], M.E. Cooper[3], C. Valencia-Ramirez[4], M. Arcos-Burgos[2], A. Hing[5], E.J. Lammer[6], M. Jones[7], K. Christensen[8], J.C. Murray[1], M.L. Marazita[3], A.C. Lidral[1]* 1) U.Iowa,Iowa City,IA; 2) NIH,Bethesda,MD; 3) U.Pittsburgh,PA; 4) U de Antioquia,Colombia; 5) U.Washington,Seattle,WA; 6) Children's Hosp.Oakland,CA; 7) Children's Hosp.San Diego,CA; 8) U. Southern Denmark, Odense.

Cleft lip with or without cleft palate (CL/P) is a common birth defect of complex etiology. A series of genome wide studies have identified significant linkage to 9q21-q33. Our subsequent studies of candidate genes (*ROR2, BARX1, PTCH, FOXE1, TGFBR1 and ZNF189*) indicated that a 160Kb region around *FOXE1* is associated with CL/P. The **purpose** of this study is to fine map the *FOXE1* region and identify disease causing mutations. **Methods:** Families from Colombia, USA, Denmark, and the Philippines (77 extended, 481 trios; 34 extended, 256 trios; 571 trios; 307 trios respectively) were genotyped for 24 SNPs in the 160 Kb region. FBAT was used to test for association. UNPHASED was used to construct and test haplotypes for association. *FOXE1* and 7 conserved regions within 40kb 5 of *FOXE1* were sequenced on 92 and 24 affected individuals respectively. Bioinformatic tools were used to identify potential regulatory elements. **Results:** Significant association was found for 17/24 SNPs (lowest pvalue=0.000020) and haplotypes (pvalue=1.15e-07) in the *FOXE1* region in the Colombian families. Similar, but not as significant results were observed in the US, Danish and Filipino families. Sequencing identified 2 missense mutations out of 92 individuals. In addition, 4 of 9 newly detected conserved region variants are predicted to affect the transcription factor binding sites for Evi-1, Cap, CdxA, PBF, Dof1, E74A and Hb. However, all of these variants had MAFs12% and occurred in both cases and controls. **Conclusions:** The present data supports the hypothesis that *FOXE1* has an important role in orofacial clefting. However, the lack of a common coding mutation suggests that nearby regulatory elements may be mutated in affected individuals having the common associated haplotype. NIH grants: R01-DE014667, K02-DE015291, P50-DE016215.

No association of *SORL1* SNPs with Alzheimers disease. *R.L. Minster[1], S.T. DeKosky[2], M.I. Kamboh[1]* 1) Department of Human Genetics; 2) Department of Neurology, University of Pittsburgh, Pittsburgh, PA.

A recent study has reported significant association of multiple variants within the SORL1 (sortilin-related receptor, also known as SORLA or LR11) gene and Alzheimers disease (AD) in several population samples (Nat Genet 2007;39:168-77). However, no individual single-nucleotide polymorphism (SNP) or haplotype was associated with AD risk in all samples, raising the possibility that the associations are spurious. We hypothesized that if these associations are real then they should be replicated in a large and independent case-control cohort. We examined four SNPs in the gene that showed significant associations in the reported discovery and replication North European family and case-control samples: *rs668387* (c.939+163C>T), *rs689021* (c.939+3362G>A), *rs2070045* (c.3561T>G) and *rs3824968* (c.4752T>A). The four SNPs were genotyped in up to 1,023 Caucasian Americans with late-onset Alzheimers disease (LOAD) and up to 876 age-matched healthy Caucasian Americans. All four variants were genotyped using fluorogenic 5' nuclease assays. We observed no statistically significant association of these SNPs with the risk of AD either individually or in combination (haplotype) or stratified by *APOE*. Although *SORL1* is an excellent biological candidate gene because of its role in the amyloid precursor protein (APP) recycling pathways, our data suggest that the role of *SORL1* variation in relation to AD risk, if any, is modest at best.

Analysis of four susceptibility SNPs on chromosome 9p21 between Italian MI patients and controls. *G.-Q. Shen[1], L. Lin[1], D. Girelli[2], O. Olivieri[2], R. Corrocher[2], Q.K. Wang[1]* 1) Cleveland Clinic, Cleveland, OH; 2) University of Verona, Italy.

Very recently, two independent genome-wide SNP association studies identified four SNP variants on chromosome 9p21 that were associate with coronary artery disease (CAD: rs10757274, rs2383206) and myocardial infarction (MI: rs2383207, rs10757278). However, it remains to be determined whether these SNPs are associated with CAD and MI in the Italian population. The purpose of this study was to investigate the association between the four SNPs and MI in an Italian Caucasian population. A total of 416 MI patients and 308 controls from Italy were carried out. SNP genotyping was performed using the 5' nuclease allelic discrimination assay with an ABI Prism 7900HT Sequence Detection System. Haplotypes were estimated using the Haploview software. The associations of SNPs or SNP haplotypes were evaluated using the Pearsons Chi-square test. Empirical P-values were calculated using 100,000 Monte Carlo simulations by the CLUMP program. Allelic frequencies of all four SNPs were significantly different between cases and controls (P-obs=0.014-0.037, OR=1.25-1.31). The association remained significant after adjusting for age, gender, smoking, total cholesterol, LDL and triglyceride (P-adj=0.005-0.021), and after permutation testing (P-emp=0.016-0.04). Association analysis of the SNPs using recessive, additive and dominant models were then carried out. All SNPs showed significant association with MI assuming an additive model (P=0.016-0.038) or a recessive model (P-obs=0.004-0.034; P-emp=0.004-0.041). The GGGG haplotype was significantly associated with MI (P-obs=0.028, P-emp=0.028, OR=0.79). These results indicate that four SNPs on chromosome 9p21 also confer risk of MI in an Italian Caucasian population.

-opioid receptor binding affinity to fentanyl is affected by sex but not by 304A/G polymorphism. *R. Landau[1], I. Charvet[1], J.-L. Blouin[2]* 1) Anesthesia, University Hospital of Geneva, Switzerland; 2) Genetic Medicine, University Hospital of Geneva, Switzerland.

Opioids are widely used for pain management even though large inter-individual variability in efficacy exists. A number of sequence variability in -opioid receptor gene (OPRM1) including non synonymous SNPs could explain some differences in analgesic response. The rs1799971 (c.304A/G, p.102Asn/Asp) is the most frequent non-synonymous variant since minor allele frequency is up to 49% (Hapmap-JPT). In vitro the G allele increases binding affinity of -endorphin; women with the G allele have reduced spinal fentanyl requirements during labor analgesia. We tested whether Asn102Asp of OPRM1 increases binding affinity to fentanyl. In this IRB-approved study, 24 volunteers were genotyped for 102Asn/Asp of OPRM1. The ability of fentanyl to displace 3[H]-naloxone bound to freshly isolated lymphocytes was determined with radioligand assays (GraphPad software). A binding affinity constant (Ki) was also calculated in 4 selected subjects. While Asn102Asp of OPRM1 did not affect OR binding affinity, we found a significant difference between ♂ and ♀.

Relative 'naloxone displacement ability' of fentanyl (%, *p<0.0001)

Men	%	Women	%
Total (n=12)	41 +/- 3	Total (n=12)	75 +/- 5 *
A/A (n=9)	40 +/-4	A/A (n=8)	73 +/- 4
A/G (n=3)	44 +/-2	A/G (n=3), G/G (n=1)	77 +/- 6

This is congruent with known sex differences in opioid analgesia and may explain why ♀ require less opioids for pain management. However other pathways such as expression, transduction or receptor trafficking rather than OR binding should be explored to investigate mechanisms by which Asn102Asp of OPRM1 affects the clinical response to opioid therapy.

Balancing gene dosage and ventricular outflowcontrasting cardiac malformations in deletion 17p11.2 syndrome (SMS) vs duplication 17p11.2 syndrome (PLS). *L. Potocki[1,3], J.A. Towbin[2,3], D. Dang[1,3], J.W. Belmont[1,3], J.R. Lupski[1,3]* 1) Molecular/Human Genetics, Baylor Col Medicine, Houston, TX; 2) Pediatrics/Cardiology, Baylor Col Medicine, Houston, TX; 3) Texas Children's Hospital, Houston.

Congenital heart defects (CHD) affect 8-10/1,000 live births and are a leading cause of infant mortality. While both environmental and genetic factors have been implicated in the pathogenesis of CHD, the increased incidence of CHD in chromosomal abnormalities, multiple malformation syndromes, mendelian disorders, and the increased risk of CHD in first degree relatives, strongly support that genetic factors are the major cause of these anomalies. Left ventricular outflow tract (LVOT) malformations comprise a spectrum of defects that include aortic valve stenosis (AVS), bicuspid aortic valve (BAV), coarctation of the aorta (CoA) and hypoplastic left heart syndrome (HLHS). Multiple lines of evidence support a genetic etiology in the pathogenesis of these anomalies. Right ventricular outflow tract (RVOT) malformations comprise a distinct group of anomalies which include tetralogy of Fallot (TOF) and pulmonary valve atresia. The Potocki-Lupski syndrome (PLS)the homologous recombination reciprocal of the Smith-Magenis syndrome (SMS) microdeletionis a newly characterized microduplication syndrome and is the first predicted reciprocal microduplication syndrome described. The key clinical features of PLS include infantile hypotonia and failure to thrive, speech and language impairment, mental retardation, and autism. Greater than 50% of individuals have cardiovascular abnormalities including BAV, dilated aortic root, and septal defects. SMS is a distinct clinical entity. Interestingly the structural cardiac defects in SMS tend to involve the right side of the heart and include tetralogy of Fallot and anomalous pulmonary venous return. Herein we report an individual with the common (3.7Mb) PLS duplication who is status-post cardiac transplant in infancy due to HLHS, analyze the specific cardiovascular anomalies in our cohort of 58 SMS patients and 13 PLS patients, and review the literature regarding ventricular outflow tract anomalies in these reciprocal genomic disorders.

Progress towards the genetic characterization of psoriasis and atopic dermatitis susceptibility within the EDC. *C. Sinibaldi[1], N. Paolillo[1], E. Giardina[1], C. Peconi[1], T. Lepre[1], S. Nisticò[2], G. Novelli[1,3]* 1) Department of Biopathology,Tor Vergata University of Rome,Italy; 2) Department of Dermatology, Tor Vergata University, Rome, Italy; 3) Department of Cardiovascular Medicine, University of Arkansas for Medical Sciences, Little Rock, AR,USA.

Atopic dermatitis (ATOD) and psoriasis (PS) represent common chronic inflammatory skin diseases triggered by both genetic and environmental factors. Linkage studies performed in PS/ATOD families revealed a significant linkage to the epidermal differentiation complex (EDC)locus on chromosome 1q21.We refined the susceptibility region for PS (PSORS4) and ATOD (ATOD2) to a 42 kb interval. Recently, it has been reported that loss-of-function mutations of an independent gene (FLG) located in the EDC are associated with ATOD in many populations. On the basis of these findings we performed an association study both to identify the susceptibility variant/haplotype in PSORS4/ATOD2 locus and in order to disclose a potential contribution of FLG mutations to genetic susceptibility of PS and ATOD in Italian populations. Data generated in two cohorts of 100 PS and 80 ATOD Italian trios, revealed three distinct associated haplotypes within the PSORS4-ATOD region: Hap1 region (9.7 kb),generated significant association in both the diseases (PS p=0.0229; ATOD p=0.0077), the second, Hap2 (8.8 kb) showed association in the ATOD cohort (p=0.0257); the third, Hap3 (38.5 kb) generated significant p-value in the PS cohort (p=0.0270). On the basis of these findings we selected an additional panel of 15 SNPs spanning the three associated regions and typed a newly recruited cohort of 310 PS patients, 210 healthy controls and 130 ATOD trios. Preliminary data confirm the association observed in our first run of genotyping and suggest the existence of a master susceptibility locus for both the diseases. Genotyping of FLG mutations (R501X and 2281del4) failed to reveal evidence of association in ATOD and PS patients. These results support the independence of PSORS4 and ATOD2 genetic susceptibility from known FLG mutations in Italian patients. This work was supported by A.DI.PSO (Italian Association for the Defense of Psoriatic Patients).

A genotype calling algorithm base on Dual Gaussian Mixture Modeling and Hardy-Weinberg Law. *Y. Wang[1], W. Fu[1], L. Jin[1,2]* 1) Center for Anthropological Studies, School of Life Sciences, Fudan University, Shanghai, China; 2) CAS-MPG Partner Institute for Computational Biology, SIBS, CAS, Shanghai, China.

Automated genotype calling is important in high-through genotyping. Though different genotyping system generate different types of raw data, it is possible to transform these raw data to one informative classification variable respectively. We show that Gaussian distribution which is used by many current algorithms for automated genotype calling does not work well enough. We develop an EM algorithm for genotype calling using Dual Gaussian Mixture Model for estimating probability density. Our algorithm also integrates Hardy-Weinberg Law which is useful for fine tuning the classification. We apply our algorithm on 5 problematic datasets from most-used genotyping platforms using sequencing data as the gold standard. Our result is approximately consistent with the sequencing result and outperforms the calls using the software provided by the venders of these genotyping platforms.

A Whole Genome Association Study in Parkinson's Disease Using the Rosetta Syllego System and Publicly Available Genotype Data. *M.A. Peters, A.Q. Chen, C. Davis, E.S. Paegle* Rosetta Biosoftware, Seattle, WA.

Our goal is to identify genetic variation associated with Parkinson's disease (PD) and to identify potential biomarker targets. Using publicly available genotype data, we performed a genome-wide association (GWA) study in a case control cohort to further analyze previous work (Fung et al. Lancet Neurology 2006). The study comprised 271 Parkinson's disease patients and 270 neurologically normal patients. The 408,803 markers genotyped include a combination of Illumina Human-1 and HumanHap 300 arrays. The genotype data were obtained from the National Institute of Neurological Disorders and Stroke (NINDS) repository at the Coriell Institute (https://queue.coriell.org/Q/snp_index.asp). The analyses were carried out using the Syllego Genetic Data Management and Analysis system and PLINK, an open source whole genome association analysis toolset (http://pngu.mgh.harvard.edu/purcell/plink/). An initial analysis using PLINK identified 39 significant SNPs (P-value 0.0001, maximum permutation) which confirmed 23 of 26 markers associated with PD identified by Fung et al. Examination of 800 kb regions surrounding the 39 significant SNPs identified 404 genes located on or near the SNPs. Five of these genes (GSTT1, MIF, CXCL12, UCHL1, and PHOX2B1) are reported in the Genetic Association Database (GAD) to be associated with neurological disorders and will be characterized further. A linear regression analysis on age of onset for the 271 PD patients and 39 significant markers found four significant markers (P-value 0.05) in complete LD on GLT25D2 on chromosome 1. A logistic regression analysis on the same data set (271 PD and 39 markers) identified 2 significant markers (P-value 0.05) associated with family history of PD. One of these is located on chromosome 13 in a gene poor region and the other is located on chromosome 4 near UCHL1 and NSUN7. UCHL1 is reported in the GAD to be associated with neurological disorders. We have confirmed previous potential associations with PD and have identified additional markers that merit further analysis. We have shown that genotype and phenotype data can be combined in the Syllego system to identify biomarker targets.

Sex-specific effects of GPRK haplotypes on metoprolol response. *E. Richard[1], M.S. Lipkowitz[2], D.T. O'Connor[1], N.J. Schork[1,3], R. Salem[1], V. Bhatnagar[1,4], AASK Study Committe* 1) University of California San Diego, La Jolla, CA; 2) Mount Sinai School of Medicine, New York, NY; 3) Scirpps Institute for Genomic Medicine, La Jolla, CA; 4) VA San Diego, San Diego, CA.

Purpose: The objective of the study is to analyze sex-specific differences between genetic variants in the G protein-coupled receptor kinase 4 (GRK4) gene and blood pressure response to metoprolol among African Americans with early hypertensive nephrosclerosis. Methods: 197 men and 131 women randomized to treatment with metoprolol from the African American Study of Kidney Disease and Hypertension were genotyped at Ala142Val and Ala486Val. Of these, 161 were randomized to an aggressive treatment group and 167 to a usual treatment group. Mean arterial pressure (MAP) averages were determined over several time points within the first 200 days after randomization. MAP differences among GRK4 haplotypes were examined using repeated-measures ANOVA within a 45-day time frame and a 200-day time frame, adjusting for baseline MAP and other medications; analyses were carried out stratified by sex and treatment group. Results: Men and women were of similar ages, mean of 55 (standard deviation 10) years; men and women had similar baseline MAPs, mean of 113 (13) mmHg. Men had higher baseline glomerlular filtration rates, 48 (12) versus 45 (13) ml/min (p=.02); men had a lower body mass index, 31 (6) versus 32 (7) kg/m2 (p=.05). Genotype distributions were in Hardy-Weinberg Equilibrium. Among women only, those with Val142/Ala486 homozygous haplotypes responded significantly faster than Val142/Ala486 heterozygous haplotypes (p=0.045 for haplotype by time interaction). This effect was more significant among women randomized to usual treatment (p= 0.012). Although women randomized to the aggressive treatment group with homozygous Val142/Ala486 haplotypes had significantly lower MAP values (p=0.033), the interaction between time and haplotype was not significant. Conclusions: African-American women randomized to usual treatment goals with homozygous Val142/Ala486 haplotypes responded faster to metoprolol. Genotyping may help identify women may need to be treated more aggressively with beta-blockers.

Association of novel FTO variants with BMI in the isolated population of Sorbs in Germany. *A. Tonjes[1], E. Zeggini[2], P. Kovacs[1], Y. Bottcher[1], W. Rayner[2], M.I. McCarthy[2], M. Stumvoll[1]* 1) University of Leipzig, Germany; 2) WTCHG, University of Oxford, UK.

Recently the association of common variants of the FTO gene (FTO) with obesity was described and has been replicated in large cohorts in adults as well as in children. The implicated 47-kb intron region is assumed to contain the predisposing variant but the causal variant and the underlying mechanism of altered gene function remain unknown. Since the impact of isolated populations in the genetics of complex traits has been extensively documented, we performed a genome wide association study using 500K Affymetrix chips in a recently recruited and extensivly phenotyped isolate from the eastern part of Germany. Sorbs are of Slavonic origin and have lived in ethnic isolation among the Germanic majority for the past 1000 years. We used linear regression analyses to calculate the effects of genetic polymorphisms on BMI in 50 individuals with type 2 diabetes and 150 controls with normal glucose tolerance taken from a population based sample (age 61.6 10.2 years, BMI 29.8 4.98 kgm^{-2}). Despite the relatively small sample size, we found 6 FTO-SNPs (in high mutual LD, r2 0.5-1.0) significantly associated with BMI (eg rs8053740: ratio of geometric means per every additional C-allele is 1.06 (95% CI 1.03-1.09), -adjusted p-value $3.93x10^{-5}$). These SNPs map in an intron about 60 kb away from the previously described SNPs which show moderate p-values (0.002-0.06) in our analysis. The LD structure of FTO in the Sorbs is similar to that observed in the European (UK) sample, where the association was initially described. We are extending these findings to a larger sample (N=1000). If confirmed, these findings will provide important clues to the allelic architecture of the FTO-variation effect on weight, potentially indicating alternative functional elements. Our data at this stage of the analysis provide further evidence that variation in FTO is associated with obesity. Our signal localises the effect in intron 3 and thus indicates that either different polymorphisms in FTO may influence obesity in various ethnic groups or that the causal SNP has not been discovered yet.

Glycogen Storage Disease Type 1b and Myasthenia Gravis: casual or causal association? *D. Melis[1], F. Balivo[1], R. Della Casa[1], A. Romano[1], M. Sibilio[1], F. Fontana[1], B. Capaldo[2], A. Imbroinise[2], G. Parenti[1], G. Andria[1]* 1) Dept Pediatrics, Federico II Univ, Naples, Italy; 2) Dept Internal Medicine, Federico II Univ, Naples, Italy.

We describe a patient affected by Glycogen Storage Disease type 1b (GSD1b) and myasthenia gravis (MG). The diagnosis of GSD1b was suspected when she was 8 months old on the basis of the phenotype including growth retardation, hepatomegaly, fasting hypoglycemia, hyperlactic acidemia; the diagnosis was confirmed by enzyme studies and by mutation analysis of the glucose-6-phosphate transporter gene, showing the C911T and 1211-1212 delCT mutations. The patient developed a multi-systemic disease, typical of GSD1b; in particular, she showed neutropenia (treated with Granulocyte-Colony Stimulating Factor -G-CSF), hyperuricemia (treated with allopurinol), nephropathy (treated with ACE-inhibitors) and inflammatory bowel disease (treated with metronidazole). When she was 26 years old, a diagnosis of MG was performed, on the basis of the clinical picture, characterized by dropped lid, diplopia, dysarthria, dysphagia and easy tiredness. The biochemical, imaging and electrophysiological studies showed: no antibodies blocking a receptor of acetylcholine, small thymic gland at chest TC, signs of exhaustion of neuromuscular transmission at electromyography. Different therapeutic approaches were used including pyridostigmine, intravenous immunoglobulins, steroids, plasmapheresis and azhathioprine; however symptomatology exclusively improved with plasmapheresis. The association of GSD1b and MG has never been reported in the literature. We hypothesize that metabolic derangement, and/or G-CSF treatment are risk factor for MG in GSD1b patients. To support the last hypothesis we underline that sporadic occurrence of autoantibodies to GM-CSF has been reported in patients affected by MG, in particular with 'seronegative' MG.

Identification and characterization of a new locus responsible for a recessive congenital muscular dystrophy. *M. Tetreault[1], J. Allyson[1], I. Thiffault[1], L. Loisel[1], JP. Bouchard[2], B. Brais[1,3,4]* 1) Laboratoire de neurogenetique et de la mobilite, Center for the Study of Brain Diseases, Centre de recherche du CHUM-Notre-Dame, Montreal, QC, Canada; 2) Service de neurologie, Hopital de l'Enfant-Jesus, Universite Laval, QC, Canada; 3) Clinique des maladies neuromusculaires, Centre de readaptation Marie-Enfant, Hopital Ste-Justine, Montreal, QC, Canada; 4) Clinique des maladies neuromosculaires, Carrefour de Sante de Jonquiere, Saguenay, QC, Canada.

Congenital muscular dystrophies are a heterogeneous group of disorders characterized by hypotonia and muscle weakness and divided in five different groups. We have recruited a cohort of five affected individuals and their non-affected family members. All the affected individuals from five different families from the same little village on the Madeleine Islands in the province of Quebec are known to be related. The small population of Madeleine Island (13 thousands) from an Acadian ancestry make this region of Quebec a suitable population for linkage analysis on recessive diseases. We have sent the five affected individuals and a parent for a SNP Genome Wide Scan (GWS) using the Illumina HumanHap300 chip. The analysis of the GWS results by homozygosity mapping with the hypothesis that all affected individuals shared a common ancestor chromosome uncovered the locus for this new CMD. There is no neuromuscular phenotype described to date on the locus we have identified. The affected individuals share a 0.9Mb candidate interval. With this study, we have shown that we can uncover new recessive disease by using regional cluster such as the Madeleine Island.

Multiple genes regulating macrophage activation and responses contribute to an immunogenetic phenotype underlying Kawasaki Disease. *V. Wright[1], S. Davila[2], D. Burgner[3], T. W. Kuijpers[4], S. B. Ng[3], W. Breunis[4], J. C. Burns & US KD Genetics Consortium[5], M. L. Hibberd[2], UK KD Genetics Consortium[1], M. Levin[1]* 1) Imperial College London, UK; 2) Genome Institute of Singapore, Singapore; 3) School of Paediatrics & Child Health, UWA, Australia; 4) Emma Children's Hospital, Netherlands; 5) Paediatrics, UCSD School of Medicine, La Jolla, CA, USA.

Background: Kawasaki disease (KD) is a common inflammatory disorder of unknown aetiology affecting young children, which may lead to permanent coronary artery damage in a significant proportion of those affected. KD may arise from an excessive or uncontrolled inflammatory response to one or more infectious stimuli occurring in genetically predisposed individuals. We postulated that functional polymorphic variation in any of the genes regulating the IL12/IFN pathway of macrophage activation would contribute to the immunological phenotype underlying the disorder. **Methods**: We studied 104 SNPs in 13 genes of the IL12/IFN pathway of macrophage activation in 1,903 members of 583 KD families from Australia, UK & US, including 498 trios in a custom Illumina Oligo Pool Assay that successfully typed another 1,391 SNPs in unrelated pathways. We then compared the allelic transmission to affected children of variants in the 13 genes in the IL12/IFN activation pathway with a similar number of variants in randomly selected genes not linked within a single biological pathway. **Results**: Significant associations for individual variants within this pathway were identified within IFNR2, IL12RB1, IL12A and weaker associations for IL12, TGF. Using a novel-linked pathway analysis, 13 genes were found to contribute to the overall genetic effect. The combined genetic effect was significantly different from 3 sets of randomly selected SNPs from both known and unknown genes ($P<0.0001$). **Discussion**: The immunological phenotype underlying the excessive inflammation in KD appears to result from a complex interaction of several genes within the same inflammatory pathway. The method we have used to assess the interaction of genes within a linked functional pathway may be relevant to other complex gene interactions.

Molecular cytogenetic investigation of two patients with Y chromosome rearrangements and intellectual disability. *C. Tyson[1], A.J. Dawson[2, 3, 4], S. Bal[2], M. Tomiuk[2], T. Anderson[2], D. Tucker[2], D. Riordan[2], I. Chudoba[5], B. Morash[2, 3, 4], A. Mhanni[3, 4], A.E. Chudley[3, 4], B. McGillivray[6], M. Parslow[8], G. Rappold[7], R. Roeth[7], C. Fawcett[1], Y. Qiao[1], C. Harvard[1], E. Rajcan-Separovic[1]* 1) Dept Pathology, University of British Columbia, Vancouver, Canada; 2) Div Lab Medicine and Pathology, Health Sciences Centre, Winnipeg, Canada; 3) Dept Pediatrics and Child Health, Health Sciences Centre, Winnipeg, Canada; 4) Dept of Biochemistry and Medical Genetics, Univ Manitoba, Winnipeg, Canada; 5) Metasystems, Germany; 6) Dept of Medical Genetics, Univ BC, Vancouver, Canada; 7) Dept Human Molecular Genetics, Univ Heidelberg, Heidelberg, Germany; 8) Cytogenetics Lab, Victoria General Hospital, Victoria, Canada.

The human Y chromosome has been extensively studied because of its primary function in sex determination and male fertility. Although structural abnormalities of the Y chromosome can explain conditions such as loss of fertility or short stature, the significance of Y chromosome rearrangements in some patients with intellectual disability (ID) is hard to establish, due to a lack of correlated genes identified on the Y. Here we describe two patients with ID and facial dysmorphism, both of whom have non-mosaic Y chromosome rearrangements resulting in deletions of large portions of the Y chromosome. Patient A, who also presented with speech delay, developmental delay, Duanes anomaly of the eye, hypermetropia and mild conductive hearing loss, has 2 derivative Y chromosomes, both of which have p and q arm terminal deletions. Patient B, also with speech and language delay, developmental delay and short stature, has an interstitial deletion of Yq11.21-11.23. The deleted regions for both patients include many genes involved in spermatogenesis and fertility, although the presence of genes involved in physical and intellectual development is questionable. As there were no other imbalances in the genomes of our patients, as investigated by 1 Mb resolution array-CGH, which could be responsible for their clinical picture, then a review of similar cases in the literature was performed, and the significance of Y chromosome rearrangements in ID is discussed.

Identification and characterization of a new locus responsible for recessive late-onset cerebellar ataxia (LOCA).

I. Thiffault[1,2], M. Tetreault[1,2], J. Allyson[1,2], I. Gosselin[1,2], L. Loiselle[1], J. Mathieu[3], JP. Bouchard[4], J. Lessage[5], B. Brais[1,2,3] 1) Laboratoire de Neurogenetique et de la Mobilite, Research Centre CHUM-Notre-Dame, Montreal, PQ, Canada; 2) Centre for the study of brain diseases (CEMC), Research Centre CHUM-Notre-Dame, Montreal, QC, Canada; 3) Carrefour de la Sante de Jonquière, Saguenay, QC, Canada; 4) Department of Neurology, CHUL, Quebec City, QC, Canada; 5) Department of Radiology, CHUM-Notre-Dame, Montreal, QC, Canada.

Recessive ataxias are a heterogeneous group of neurodegenerative diseases. Late-onset ataxias have largely been considered as either milder forms of dominant ataxias or sporadic diseases seemingly not caused by genetic factors. Their prevalence is unknown, but together they are poorly recognized cause of decreased mobility in aging. The unique population structure of the aging Quebec population, with its numerous large elderly living sib ships, provides an exceptional setting to explore the recessive bases of late-onset neurodegenerative diseases that interfere with mobility. We have uncovered two French-Canadian regional clusters of recessive cases of late-onset cerebellar ataxia. One cluster of three families originating within a 20km region of the Eastern Townships and one of 5 families from the Saguenay-Lac-Saint-Jean, a region well known for its founder effects. Recruitment to date has led to our present 34 families cohort which includes 58 affected cases and their 125 sibs. The major clinical feature is the onset during the six and seventh decades (mean: 61.3) of gait ataxia. In all cases the ataxia progresses and may lead to the loss of walking. In some cases further evolution leads to pyramidal, extrapyramidal and autonomic manifestations suggesting a progression in a multiple system atrophy cerebellar subtype (MSA-C). All MRI show some degree of cerebellar atrophy. A genome-wide scan uncovered linkage to a region not previously associated with an ataxia locus or any other neurodegenerative disorders (LOD 5.18). Two major haplotypes explained 55% and 22% of the carrier chromosomes suggesting that they are more than two common mutations.

A complex evolutionary pattern of haplotypes at *RET*. *N. Mukherjee, J.R. Kidd, W.C. Speed, A.J. Pakstis, K.K. Kidd*
Dept Genetics, Yale Univ Sch Medicine, New Haven, CT.

RET is involved in the etiology of complex disorder Hirschprung disease (HSCR) and the Mendelian disorder Multiple Endocrine Neoplasia2 (MEN2). We have studied the genomic region around the *RET* protooncogene on chromosome 10q11.2 in order to understand its pattern of haplotype diversity across global populations. We have genotyped 92 single nucleotide polymorphisms (SNPs) spanning 339 kb in 38 global populations. We identified a 134 kb region including the 3 half of the *RET* gene and extending to 5 of the *RASGEF1A* gene, in which 17 SNPs, interspersed among 20 other SNPs, have almost perfectly correlated (0.98) allele frequencies in all the populations of non-African ancestry, i.e. have nearly identical allele frequencies in each population of non-African ancestry. Analyzing all the SNPs across this region shows that two distinct haplotype lineages have formed independent of each other by mutations of different sets of SNPs. The most common haplotypes do not show evidence of recombination. In the populations of African ancestry derivatives of only one haplotype lineage predominate while in the populations of non-African ancestry derivatives of both the haplotype lineages comprise 80% or more chromosomes. Though LD exists between SNPs within this region and those flanking, LD is much lower at either end of the 134 kb region indicating greater historical recombination. The primary MEN2 mutations lie in exon 11, only 180 nucleotides from the first of these SNPs. The SNP thought most strongly associated with HSCR lies in intron 1, 28.3 kb from this downstream region but show significant LD with the common 17 SNP haplotypes. The HSCR-associated allele is predominantly associated with the haplotype that is essentially non-African, consisting of mostly derived alleles, and the most common haplotype in East Asia. The increased frequency of the non-African haplotype seems to be an effect of random genetic drift. However, maintenance of the HSCR associated allele in high frequency in some popualtions is intriguing and reamins open for further investigation. Supported by NIH grant GM057672 to KKK.

Transcriptome plasticity through mammalian RNA editing. *S. Maas, W. Gommans, N. Tatalias, D. Dupuis*
Biological Sciences, Lehigh University, Bethlehem, PA.

An important mechanism for the generation of molecular diversity in mammals is pre-mRNA editing by A-to-I modification. It increases RNA and protein diversity and regulates key functional properties of neurotransmitter receptors in the central nervous system by changing single codons in pre-mRNA. The deficiency or misregulation of editing has been implicated in the etiology of neurological diseases, such as epilepsy, amyotrophic lateral sclerosis (ALS), depression, and tumor progression.

We have recently identified Alu repeat elements in the human genome as a major target for A-to-I RNA editing. These findings suggest additional roles for RNA editing and links it to other RNA processing phenomena, such as alternative pre-mRNA splicing as well as siRNA mediated gene silencing and miRNA function. We and others have further mapped RNA editing events to micro RNA precursor sequences that suggest changes for the processing of miRNAs and miRNA target specificity.

In all known and characterized cases of recoding by A-to-I editing the ensuing amino acid substitutions have been linked to alterations in protein function. A few additional cases recently identified involved edited nucleotides that had previously been annotated as a single nucleotide polymorphism (SNP) according to the NCBI dbSNP database. In each case the validation for the SNP was solely based on expressed sequence data. This observation raises the possibility that the pool of A/G SNPs that have not been genomically validated might contain more cases of A-to-I RNA editing.

Here we present the results of a bioinformatics approach to delineate A-to-I RNA editing events in the human genome that lead to non-synonymous amino acid changes based on the subset of non-genomically validated SNPs. Out of several hundred potential targets we experimentally confirmed the occurrence of RNA editing in vivo for high scoring candidate genes and predict additional targets.

Oligo array-CGH analysis as a tool for discovering disease mechanisms, atypical phenotype in known syndromes and novel deletion syndromes. *F. Mari, R. Caselli, F.T. Papa, M.A. Mencarelli, V. Uliana, E. Katzaki, K. Sampieri, M. Pollazzon, F. Ariani, I. Meloni, I. Longo, A. Renieri* Medical Genetics, University of Siena, Siena, Italy.

A group of 70 MCA/MR pts has been analyzed by 44K Agilent oligo array-CGH. A first group (45) was selected for having MCA/MR not recognizable on clinical ground and normal karyotype. In this group we have identified 4 novel de novo del in 2q24, 2q32, 6q25, 7q36, 5 known del in atypical cases (4p16[2Mb], 15q11, 17p11, 22q11), 2 known rearrangements difficult to recognize on clinical ground (22q13del, 17p11dup) and 3 novel inherited rearrangements (7q11del, 17q12dup, Xq25del). Excluding the last 3, the mutation detection rate was 24%(11/45). A recognizable phenotype for the novel del could be traced: long and broad alluces, untreatable seizures for 2q24; sleep disturbance, behavioural problems, bifid nasal tip, micrognatia for 2q32; septal heart defect, Williams-like upper face, dysmorphic ears, short stature for 6q25; fetal phenytoin like-face, renal hypoplasia, long QT for 7q36. The inherited 17q12dup (reciprocal of renal cyst-diabetes del syndrome) was identified in a sex reversal male with MR-Peters anomaly and in his healthy father. Since the dup includes TCF2 and it is located 4Mb apart to HSD17B1 low penetrance may be considered. A second group (25) was selected for having defined clinical diagnosis and array-CGH was used to clarify disease mechanism. Deletion mapping in 3 retinoblastoma pts with or without MR pinpointed the MR critical region on 13q14. Analysis of 10 Rett pts ruled out a 16p11 dup polymorphism, probably responsible for the modulation phenotype. Analysis of a pt with Alport and leiomyomatosis (ATS-DL) and Xq23del allowed to confirm the mechanism that only smaller del cause DL in ATS. Analysis of a family including ichthyosis pts with or without MR revealed that pts with MR have a smaller deletion (Xp22[1Mb]) than those without (Xp22[2.8Mb]) pinpointing to ATS-DL similar mechanism. Among the above 70 pts, 24 were analyzed by 105K oligo array and 39 known polymorphisms, 1 novel polymorphism in 1q21 and 4 putative pathogenic variants in 1q44, 7q31, 10q24, Xq21 were identified.

Interaction of blood pressure and LOC387715 SNP for risk of age-related macular degeneration. *K.E. Lee[1], R. Klein[1], B.E.K. Klein[1], C.L. Thompson[2], J. Capriotti[2], T. Joshi[2], S.K. Iyengar[2]* 1) Dept of Ophthalmology & Visual Science, Univ of WI Medical School, Madison, WI; 2) Dept of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH.

Two genes, CFH and LOC387715, are known to cause age-related macular degeneration (AMD). High blood pressure (BP) independently increases risk for AMD. We examined a potential gene-environment interaction between BP and the A69S (GT) variant of the LOC387715 SNP (LOC) for risk of incident late AMD and of incident retinal pigment epithelium depigmentation (RPEdepig), an early lesion of AMD. Family members within the population-based Beaver Dam Eye Study had 8 SNPs, including LOC, in the 10q26 region genotyped using a TaqMan assay (N=2230). Assessment of AMD was done using the Wisconsin ARM grading system. The mean of the two systolic BP measures from a random-zero sphygmomanometer (according to the Hypertension Detection and Follow-up Program protocol) will be used for this report. Discrete linear logistic regression was used to asses the 15-year cumulative incidence associated with a 20 mmHg increase in systolic blood pressure (SBP) from the baseline examination. Results are reported as odds ratio (95% confidence interval) from age-adjusted models. Ignoring genotype, the SBP20 risk for the incidence of late AMD is 1.21 (1.01, 1.46) and for the incidence of RPEdepig is 1.19 (1.04, 1.37). These associations are higher among those with the high risk genotype (T/T) for LOC. Risk of late AMD for SBP20 is 1.34 (0.75,2.40) among the 1012 with the nonrisk genotype (G/G), 1.35 (0.95,1.91) among the 601 heterozygote (G/T) and 2.74 (1.28,5.86) among the 81 T/T variants. The p-value for interaction is 0.20. Risk of RPEdepig for SBP20 is 0.83 (0.61,1.15) among those with G/G, 1.34 (1.00,1.81) among those with G/T and 2.94 (1.37,6.30) among those with T/T variants. The p-value for interaction is 0.005. These results remain after adjustment for smoking and body mass index. These data suggest that blood pressure control may have a larger benefit for reducing the risk of incident AMD among persons with theA69S (GT) variant of the LOC387715 SNP.

Mapping a new candidate locus for autosomal dominant partial epilepsy with auditory features. *F.R. Torres[1], E. Bilevicius[2], R. Secolin[1], N.F. Santos[1], E. Kobayashi[2], L.A.C. Sardinha[2], F. Cendes[2], I. Lopes-Cendes[1]* 1) Depatment of Medical Genetics, UNICAMP, Campinas, São Paulo, Brazil; 2) Department of Neurology, UNICAMP, Campinas, São Paulo, Brazil.

Mutations in the leucine-rich glioma inactivated 1 gene (*LGI1*) have been indentifed in only 50% of the families with autosomal dominant partial epilepsy with auditory features (ADPEAF). The objective of this study was to search for the alternative locus for ADPEAF in a family with no mutations in *LGI1*. We studied one large family with 23 affected individuals. Clinical evaluation with neurological exam, electroencephalogram (EEG) and magnetic resonance imaging (MRI) studies were performed. We genotyped 45 individuals of this for 350 microsatellites markers from the ABI PRISMLinkage Mapping Sets v2.5 kit. We assumed an autosomal dominant inheritance with 80% penetrance for the parametric linkage analysis. Characteristic auditory auras were observed in 18/23 (78%) patients. *Déjà-vu* phenomena was identified in 13/18 (72%) patients. Isolated *déjà-vu* episodes were detected in three individuals and generalized tonic-clonic seizures were reported by two subjects. No MRI abnormalities were found in this family. Genome scan yield a maximum two-point lod score for a microsatellite marker localized on chromosome 1p36. There is an over-representation of the *déjà-vu* phenomena in this family, a clinical characteristic unusual in families with LGI1 mutation. The description of a new locus for ADPEAF confirms genetic and phenotypic heterogeneity in this syndrome.

Human neural crest cells share a complex molecular signature with embryonic stem cells. *S. Thomas[1], M. Thomas[2], P.T. Xu[4], J. Poulain[3], C. Golzio[1], P. Wincker[3], M.C. Speer[4], A. Munnich[1], S. Lyonnet[1], M. Vekemans[1], H.C. Etchevers[1]* 1) INSERM U781 Hôpital Necker, Paris, France; 2) L'Oreal Recherche, Aulnay, France; 3) Genoscope, Evry, France; 4) Center for Human Genetics, Duke Univ, Durham, NC.

A fundamental question of developmental biology is how a wide variety of functionally different mature cell types arises from a unique cell population. Human neural crest cells (hNCC) form in the embryo during the third to fifth weeks of pregnancy. While partially competent progenitors continue to reside in some adult tissues in animal models, most NCC differentiate into all components of the peripheral nervous system, melanocytes, some types of endocrine cells as well as connective and structural tissues in the head. Abnormal development of hNCC leads to malformations and tissue dysplasias known collectively as neurocristopathies. To identify new candidate genes for neurocristopathies, we made a Long-SAGE library from hNCC derived from a normal embryo at Carnegie stage 13. Data analysis showed expression of multiple Gene Ontology functional classes that were anticipated based on animal studies and/or human disease. Hierarchical clustering was performed. A high degree of similarity was found between hNCC and human embryonic stem cells (hESC) compared to 14 other tissues or cell types, including more tissue-restricted stem cells, such as mesenchymal stem cells. Functional annotation of hNCC and hESC SAGE libraries shows that the same molecular cascades are statistically enriched in both cell types, such as transcription regulation, cellular proliferation and growth factor pathways. Furthermore, TPE analysis (Moreno et al., 2001) identified about 400 genes specific to either hNCC or hESC relative to 14 other tissues. Interestingly, half of the genes found preferentially expressed in hNCC were common to hESC and vice versa, with a number of molecules implicated in pluripotency. In addition to highlighting myriad candidate disease genes, this study demonstrates that premigratory hNCC present hallmarks of stem cells, paving the way for further studies of hNCC cell biology and therapeutic potential.

Design of primers, Comparative Sequence Analysis, Structure Prediction of ApolipoproteinE protein in Alzheimers disease. *K.R. Rupesh[1], M. Khosroheydari[2]* 1) Laboratoire de Microbiologie des Environnements Extrêmes, CNRS UMR 6197, IFREMER-Centre de Brest, BP 70, 29280 PLOUZANE, France; 2) Medical Genetic Department, Special Medical Center, P.O. Box 15815/3333, Tehran, Iran.

Background & Objective: Alzheimer's disease (AD), a neurodegenerative disease, is the most common cause of dementia and characterized clinically by progressive intellectual deterioration together with declining activities of daily living and neuropsychiatric symptoms or behavioral changes. Researchers have identified an increased risk of developing late-onset AD related to the apolipoprotein E (apoE) gene found on chromosome 19. In this study we have compared the ApoE gene its protein in different organisms to understand the mechanism of expression of ApoE. Results: Multiple sequence alignment (MSA) of the apoE gene of Human revealed that it is analogous to all the other 16 organisms whereas the apoE protein is found to be 66% homologous. On detailed analysis of the nucleotide sequence of apoE (NM_000041), it was found that the ORF region was present from 84-1034 position. Specific primers for the apoE coding region in the AD were designed and its specificity was checked using computational tools which resulted in a PCR product size of 1109 bp. The nucleotide and protein sequence of the apoE in AD was studied in detail using the computational tools. The analysis of the apoE protein showed that it was hydrophilic and its pI was predicted. 13 antigenic determinants were found when the apoE protein was analysed for Antigenic prediction sites which could be used as targets for other proteins or drugs to interact with. The positions of the alpha helix and b-sheets in the secondary structure of the proteins were predicted along with 3D structure prediction of apoE. Conclusion: The degenerate primers designed could be used as a diagnostic tool for identifying apoE protein expression in AD patients specifically and sensitively. The predicted antigenic sites on the apoE proteins could be used as an effective target for interaction with candidate drugs for the control of the expression of the apoE in AD patients, this has to be further evaluated using in vitro and in vivo methods.

The Cancer Genetics Telephone Clinic Model. *K. Myhill[1], S. Shanley[1], R. Doherty[1], A. Ardern-Jones[1], S. Hall[1], C. Vince[1], S. Thomas[1], P. Aspinall[2], R. Eeles[1]* 1) Genetics, The Royal Marsden NHS Foundation Trust, London, United Kingdom; 2) Univeristy of Kent, Kent, United Kingdom.

The Royal Marsden Genetics Unit conducted a pilot project to evaluate a telephone counselling service as opposed to face to face counselling which is the standard model of care in the UK. The study commenced in March 2004 and evaluation of the clinic was conducted over 17 months from March 2005 to the end of July 2006. A total of 612 patients had telephone consultations during this time, 228 of whom were referred from primary care with a median of 30 patients counselled per month (range of 19-63, depending on staff availability with average of two staff per clinic). Waiting times were measured for GP referrals and all 228 were counselled within the national target-stipulated 13 weeks (median 6 weeks, range 1-12). An additional 132 patients who were sent appointment letters after receipt of their family history questionnaires did not attend their appointments (18% of all potential referrals) and required re-contacting by letter. After telephone counselling, 42% of patients were able to be discharged from the telephone clinic without a subsequent face to face appointment, thereby saving resources. The telephone clinic also had a short set-up time with flexibility on timing and day of administration which would be an advantage in centres where outreach clinic facilities are scarce. The telelink telephone counselling model is highly efficient in triaging high risk individuals for face-to-face counselling as per the Kenilworth model, in effecting concentration of resources and in providing a flexible individual-centred approach to cancer genetic counselling delivery.

Complex genetic approaches to monogenic disease: Cystinosis as an example. *E.K. Moses, J.E. Curran, M.P. Johnson, J. Charlesworth, T.D. Dyer, S.A. Cole, H.H. Goring, J. Blangero* Dept Genetics, SFBR, San Antonio, TX.

Cystinosis is a rare, autosomal recessive disorder characterized by defective transport and accumulation of cystine. Mutations in the *CTNS* gene account for all known causes of cystinosis. However, little is known about the function of CTNS. In this study, we describe a novel approach for elucidating the biological functions of a monogenic disease locus via the application of complex genetic analysis to normal variation in gene expression. To examine the potential functions of the *CTNS* gene, we utilized a unique dataset of whole-genome lymphocyte transcriptional profiles from 1,240 individuals in large extended Mexican American families. Quantitative expression levels of the *CTNS* transcript were significantly heritable ($h^2 = 0.33$, $p = 1.3 \times 10^{-16}$). Resequencing of the *CTNS* gene in 182 normal individuals identified over 180 variants. Association analysis in the sequenced subset revealed strong evidence for *cis*-regulation (with p-values as low as 1.0×10^{-10}). When we genotyped these variants in all 1,240 individuals, evidence for *cis*-regulation dramatically increased (with p-values as low as 2.4×10^{-39}). Using the most highly associated SNPs, we then performed association analysis on the transcriptional profiles to identify genes that are causally downstream of *CTNS*. Preliminary analyses revealed multiple potential downstream genes related to the mediation of polyglutamine tracts and the unfolded protein response that are influenced by *CTNS* sequence variation. Using a genome-wide scan to search for potential upstream *trans*-acting regulatory genes influencing *CTNS*, we identified the *VPS13A* gene (known to be involved in protein sorting) on chromosome 9 as a plausible positional and functional candidate for a *trans*-acting regulator of *CTNS* expression. This was further supported by the identification of genetic variation in *VPS13A* showing strong evidence for association with *VPS13A* expression (i.e., *cis*-effect; $p = 1.9 \times 10^{-7}$) and with *CTNS* expression (i.e., *trans*-effect; $p = 0.029$). Overall, our results suggest that the *CTNS* gene may be important for general cellular maintenance via a role in the elimination of potentially toxic cellular waste.

Serum levels of the KL-6 epitope of MUC1 correlate with pulmonary fibrosis in Hermansky-Pudlak syndrome.

T.C. Markello[1,2], M. Anahtar[2], I. Bernardini[2], B.B. Gochuico[2], K. OBrien[2], G.A. Golas[2], W.A. Gahl[2] 1) 1 Department of Genetics & Metabolism, Children's National Medical Center, Washington, DC; 2) 2Section on Human Biochemical Genetics, Medical Genetics Branch, NHGRI, NIH, Bethesda MD.

Elevated serum levels of the KL-6 epitope of MUC1 have previously been correlated with the presence of interstitial lung diseases, including Idiopathic pulmonary fibrosis (IPF). Little is known about serum levels of KL-6 prior to the onset of clinical symptoms, since patients with IPF typically present after significant fibrosis has occurred, prompting medical attention for the resulting respiratory compromise. Type 1 Hermansky-Pudlak Syndrome (HPS) has a frequency of pulmonary fibrosis that approaches 100% in the 4th through 6th decades of life. Because patients with HPS are first ascertained by their oculocutaneous albinism and their bleeding diathesis, it is possible to analyze serum samples in HPS patients prior to the onset of clinically significant pulmonary fibrosis. We tested archival serum samples from patients with Hermansky Pudlak syndrome who were seen at the NIH Clinical Center between 1998 and 2007. These samples include HPS types 1 and 3, i.e., subtypes with and without pulmonary fibrosis. Compared to normal controls, both HPS type 1 and type 3 patients have a 2.2 fold elevation in KL-6/MUC1 levels prior to onset of clinical pulmonary fibrosis (N=14, range 1.12 to 3.14 fold vs normal controls). HPS type 1 patients have a 12 fold elevation in serum KL-6/MUC1 levels after the onset of clinical pulmonary fibrosis (n=13, range 4.7 to 42.0 fold vs normal controls). These results suggest a potential relationship between a genetic disorder of intracellular vesicle trafficking (i.e., HPS) and a protein that requires intracellular trafficking for proper glycosylation and apical targeting. Further characterization of KL-6/MUC1 and other pneumoproteins in HPS may be useful for early diagnosis and prognosis of pulmonary fibrosis. Serum levels of pneumoproteins, including KL-6/MUC1, may also serve as outcome parameters for future therapeutic interventions in HPS patients with pulmonary fibrosis.

Genes regulated by MECP2 as candidate genes for autism. *N. Nakashima, T. Yamagata, Z. Yu, K. Suwa, M. Mori, M.Y. Momoi* Pediatrics, Jichi Medical University, Shimotsuke, Tochigi, Japan.

Several genes were identified to be regulated by MECP2, a gene for Rett syndrome (RTT). Some downstream genes of MECP2 may contribute for autistic phenotype of RTT, and such genes are candidate genes for autistic disorder (AD). The alternation of imprinting status or the defect of some transcriptional mechanisms on these genes, or gene substitutions on them may relate to AD. To detect the responsible genes for AD, we analyzed the expression level of the genes regulated by MECP2 on lymphoblasts of AD, RTT and controls. And, these genes were analyzed for mutations on AD patients. Among the genes regulated by MECP2, some were imprinted only in the brain. But several genes were confirmed to be imprinted in lymphocytes addition to the brain. Therefore, it is reasonable to analyze the expression level of such genes on lymphoblasts. Patients diagnosed as AD according to the criteria of DSM-IV were enrolled in this study after the informed consents by their parents. The genes studied included DLX5, PEG10, BDNF, SGK, IGFBP3 and IGF2. And also, DLX6 that belonged to the same family with DLX5 and localized next to DLX5 was analyzed. Expression level of each gene was detected in 12 AD patients, three RTT patients and eight control individuals by Real time PCR method, respectively. For mutation analysis, up to one hundred Japanese AD patients were enrolled. All exons and introns nearby of these genes were amplified by PCR, the fragment was analyzed by DHPLC, and finally confirmed by direct sequencing. The expression level of DLX5 and SGK were high in RTT patients and some of AD patients. Instead, the expression level of other genes were not different among the lymphoblasts analyzed. No causative mutation was detected in the genes regulated by MECP2. One missense mutation was detected in DLX6 on one siblings with AD. Although no causative mutation was detected in DLX5 and DLX6 on AD patients in the previous reports, DLX6 might relate for AD. From our results, it is considered that AD and RTT share common pathway after MECP2 through some of the genes. It is required to analyze another genes regulated by MECP2 further to clarify the contribution to autism.

Non-random telomere length changes associated with specific chromosome ends in chronic myeloid leukemia (CML). *J. Yan[1], O. Samassekou[1], A. Ntwari[2]* 1) Dept Pediatrics, Univ de Sherbrooke, Sherbrooke, PQ, Canada; 2) Dept Mathématique, Univ de Sherbrooke, Sherbrooke, PQ, Canada.

Critically shortened telomeres can lead to chromosome instability and thereby promote tumor development. However, most conclusions regarding the telomere shortening were from studies on general or average telomere length. It remains unknown if there are any chromosome-specific telomere length changes associated with the diseases and which chromosome-specific telomere changes play a role in chromosomal instability and rearrangement in cancer. Using quantitative FISH (Q-FISH), we recently demonstrated that the telomere lengths at some specific chromosome ends altered more frequently than others. Particularly, our results showed that the telomere at short arm of the X chromosome (Xp) was significantly lengthened in cells from chronic myeloid leukemia (CML) cases that carry a chromosome 9 and 22 translocation [t(9;22)(q34;q11.2)] as the sole detectable abnormality. The longest telomere on Xp reached about 300 kb that was detected by fiber FISH. This finding of a dramatically lengthened telomere at a specific chromosome from leukemia cells has not yet been reported in the literature. Therefore, the precise measurement of the telomere length would greatly increase the study value in the chromosomal stability. Based on our recent findings, we hypothesize that chromosome-specific telomere lengthening in cancer cells may be the one of the earliest events that will facilitate cell proliferation and thus can be used as a marker to monitor and evaluate the evolution of a cancer at different clinical stages.

Genetic determinants of hair, eye and skin pigmentation in Europeans. *P. Sulem[1], D. Gudbjartsson[1], S. Stacey[1], A. Helgason[1], T. Rafnar[1], K.P. Magnusson[1], F. Jonasson[2], B. Sigurgeirsson[3], K. Thorisdottir[3], R. Ragnarsson[3], K.R. Benediktsson[3], K.K. Aben[4], L.A. Kiemeney[5], J.H. Olafsson[3], J. Gulcher[1], A. Kong[1], U. Thorsteinsdottir[1], K. Stefansson[1]*
1) deCODE Genetics, Reykjavik, Iceland; 2) Department of Ophthalmology, Landspitali-University Hospital, Reykjavik, Iceland; 3) Department of Dermatology and Department of Anatomopathology, Landspitali-University Hospital, Reykjavik, Iceland; 4) Comprehensive Cancer Center East and Department of Epidemiology and Biostatistics, Radboud University Nijmegen Medical Center, Nijmegen, The Netherlands; 5) Department of Epidemiology and Biostatistics and Department of Urology, Radboud University Nijmegen Medical Center, The Netherlands.

The color of hair, skin and eyes are highly heritable and visible phenotypic traits in humans. However, relatively few common sequence variants that account for variation of normal human pigmentation have been identified to date. Here we present results from a genome-wide association scan for variants associated to hair, eye and skin pigmentation among 2,986 Icelanders. The most significantly associated SNPs located in six regions were tested and their association replicated in a second sample of 2,718 Icelandic individuals and a sample of 1,214 Dutch individuals. Genome-wide significance was detected for single nucleotide polymorphisms (SNPs) in the six different regions. Association signals to four of these regions are reported here for the first time, linking a variant on 14q to eye and hair color, a variant on 12q to hair color, two coding variants in a gene on 11q to eye color and freckles and finally a variant on 6p to freckles. We observe the reported effect of MC1R variants on hair and skin types and of variants near OCA2 on eye and hair color. We note that the two new variants associating to freckling did not associate to red hair, unlike the MC1R variants. The two new eye color genes predispose to blue versus green eyes but do not affect brown eye color, unlike the OCA2 variants.

Bifurcated femur with absent tibia: case report and expansion of the phenotype of Wolfgang-Gollop syndrome.

W.V. Wurm[1], C.A. Friedrich[2] 1) Dept Pediatrics, University Mississippi Medical Center, Jackson, MS; 2) Dept Preventive Med, Div Med Genet, UMMC.

A premature neonate (25 wks GA) was evaluated because of bronchopulmonary dysplasia and left leg anomalies. Her mother received no prenatal care. A sibling was healthy. Examination revealed expected findings for gestational age, no coloboma, no cleft lip or palate, a small skin tag over the right clavicle, and no ectrodactyly or upper limb or right leg abnormalities. The left lower extremity showed a medial protuberance of the distal left femur, left talipes equinovarus with the foot rotated almost 180 degrees (pointing posteriorly), and broad great toes. X-rays revealed a bifurcation of the femur with an absent tibia. No spine or rib anomalies were seen. Head and renal ultrasound examinations showed no abnormalities. A high-resolution karyotype revealed no abnormalities including no deletion at 8(q11.23q13.3). A complete genomic hybridization microarray assay revealed no deletions or duplications (ARUP Laboratories, Constitutional Chip V3 and Spectral Genomics 1 MB Chip). Unilateral bifid femur with absent tibia has been reported rarely with unclear inheritance. In some patients an upper extremity is also affected, and ectrodactyly has been reported commonly. Several families with affected sibs and unaffected consanguineous parents have been reported, but in one family multiple generations were affected. One patient had bilateral affected lower limbs. One patient with multiple other congenital anomalies had a deletion of 8q. Congenital heart defects, lissencephaly, cleft palate and palate, and tracheoesophageal fistula have been reported. Despite her extensive localized malformation she did not have any of the associated findings described in previous patients. The etiology of Gollop-Wolfgang Complex (OMIM 228250) remains unknown.

Acidic amino acid tag enhances response to enzyme replacement in mucopolysaccharidosis type VII mice. *S. Tomatsu[1], A.M. Montaño[1], T. Nishioka[1], M. Gutierrez[1], C. Vogler[2], W.S. Sly[3], T. Oguma[4]* 1) Dept Pediatrics, Ped Res Inst, St Louis Univ, St Louis, MO; 2) Department of Pathology, Saint Louis University School of Medicine, St. Louis, MO, USA; 3) 4Department of Biochemistry and Molecular Biology, Saint Louis University School of Medicine, St. Louis, MO, USA; 4) Daiichi Pharmaceutical CO., Tokyo R&D Center, Tokyo, Japan.

Enzyme-replacement therapy is an established means of treating lysosomal storage diseases (LSD). Infused therapeutic enzymes are targeted to lysosomes of affected cells by interactions with cell-surface receptors that recognize carbohydrate moieties, such as mannose and mannose 6-phosphate, on the enzymes. We have tested an alternative, acidic oligopeptide-based targeting system for delivery of enzymes to tissues, especially bone and brain, in a murine mucopolysaccharidosis type VII (MPS VII) model. This strategy is based upon tagging a short peptide consisting of acidic amino acids (AAA) to N terminus of human -glucuronidase (GUS). The pharmacokinetics, biodistribution and the pathological effect on MPS VII mouse after 12 weekly infusions were determined for recombinant human untagged and tagged GUS. The tagged GUS was taken up by MPS VII fibroblasts in a mannose 6-phosphate receptor-dependent manner. Furthermore, the AAA-tagged enzyme had five times more prolonged blood clearance compared with the untagged enzyme. The tagged enzyme was delivered effectively to bone, bone marrow, and brain in MPS VII mice and was effective in reversing the storage pathology. The storage in osteoblasts was cleared similarly with both enzyme types. The tagged enzyme reduced storage in cortical neurons, hippocampus, and glia cells. A highly sensitive method of tandem mass spectrometry on serum, first reported here, indicated that the concentration of serum dermatan sulfate and heparan sulfate in mice treated with the tagged enzyme decreased more than that in mice treated with the untagged enzyme and were nearly normalized. These preclinical studies suggest that this AAA-based targeting system may enhance enzyme-replacement therapy for certain human LSDs.

High altitude selection pressure on Angiotensin-I converting enzyme (*ACE*), Insertion(I)/Deletion(D) polymorphism. *T. Stobdan[1,2], A. Nejatizadeh[1,3], T. Norboo[4], G. Mohammad[5], G. Hemashree[6], T. Thinles[5], M.A.Q. Pasha[1]* 1) Functional Genomics Unit, Institute of Genomics and Integrative Biology, Delhi, India; 2) Dept of Biotechnology, Pune University, Pune, India; 3) Dept of Biochemistry, Jamia Hamdard University, Delhi, India; 4) Ladakh Inst of Prevention, Leh, J&K, India; 5) SNM Hospital, Leh, J&K, India; 6) High Alt Med Research Centre, 153 General Hospital, Leh, J&K, India.

The northern Himalaya, divides population of Indo-European(IE) linguistic groups to west and Tibeto-Burman(TB) to east. While most of the IE resides at an altitude of <800m, the TB occupies the Tibetan plateau (altitude >3500), depicting the fundamental model of human adaptation to high altitude (HA). One unique population i.e. Brokpa, an early branch of IE pastoral tribe, believed Aryan descent from IE linguistic family reside at this confluence (alt ~3000m) from time unknown. To investigate the genetic relatedness of Brokpa with its surrounding populations i.e. Ladakhi & Changpa(TB), Punjabi (IE) and one population from other ethnicity, Santhali (Austro-Asiatic), six *Alu* I/D polymorphisms were analysed. The genetic information was obtained by means of genetic distances (DA), PCA and AMOVA. We campared our findings with 32 different populations distributed worldwide. Since the role of *ACE* I/D polymorphism is implicated in various disease susceptibility, including HA adaptation and disorders, its importance in HA selection pressure was also investigated. Our findings suggest that when *ACE Alu* was included, the genetic distance between closely related populations i.e. Brokpas and Punjabi, with Brokpa subjected to HA selection pressure, was more than average. The PCA and phylogenetic analysis were consistent with linguistic pattern when *ACE* was excluded. We showed that Santhali, is a distinct ethnic group. In conclusion we demonstrated that the Ladakhi and Changpa share a common TB gene pool, clustering with the rest of East-Asian populations. Given the importance of the I allele in HA endurance, its over-representation in the geographically isolated Brokpa population in our study, advocates its association with adaptation to HA hypoxic environment.

The gene-trapped allele of mouse Fkbp8 gene represents another null mutation that has human spina bifida phenotype and is not embryo-lethal. *L. Wong[1], B. Wlodarczyk[1], M. Scott[1], S. Kartiko[1], M. Yen[1], M. Merriweather[1], R.H. Finnell[1,2]* 1) CEGM, IBT, Texas A&M HSC, Houston, TX; 2) TIGM, Houston, TX.

Neural tube defects (NTDs) are disabling birth defects and they are second only to cardiac defects among major congenital malformations. Spina bifida (SB) is a NTD that has a defect at the lumbosacral region where the spinal cord is dysplastic and the overlying spinal column is absent. In the US, the prevalence rate of SB is about 1 in 1000. Up till now, researchers have relied upon mouse NTD models to understand the mechanism of NTD development but many models suffer from partial penetrance of the phenotype or poor recapitulation of either the complex genetics or the phenotype in human NTDs. In our search for models with a SB, we identified a mouse mutant that has a severely dilated posterior neural tube (NT) and more importantly, it exemplifies many features of human SB. The mutant was generated via gene trapping and the trapped gene was Fkbp8, which belongs to the immunophilin family functioning in immunoregulation, protein folding, and trafficking. The gene trapped allele has a complete SB penetrance and is not embryo-lethal. The dilated posterior NT is evident at E10.5 and the NT is closed; however, cross-sectioned NT revealed that the thickness is only 25-30% of that in controls. These mutants have NT patterning defects and increased cell death at the ventral NT. Examination of sectioned spinal cord in mid-gestation fetuses revealed differentiation and DRG defects. At late-gestation fetuses, the skin-covered lesion contains protruded neural tissue and possibly spinal fluid. Alizarin staining of E18.5 nullizygotes revealed vertebrae abnormalities mostly in the thoracic-lumbar region. These mice are identical in size to their control littermates at birth and they survive many weeks post-partum though they develop lower body paralysis. Folate or inositol treatment did not rescue the SB phenotype in the nullizygotes. We are analyzing the phenotype at the cellular and molecular levels, and identifying FKBP8 interactors which might function to pattern the NT. This mouse represents an excellent SB model which will provide further insight into the etiology of human NTDs.

***PDE11A* Global Haplotype Is Associated With Major Depression.** *H.R. Luo, L. Ribeiro, J. Licinio, M.L. Wong*
Center for Pharmacogenomics, Psychiatry & Behavioral Sci, Univ Miami Miller Sch Med, Miami, FL.

Cyclic nucleotide phosphodiesterases (PDEs) hydrolyze the intracellular second messengers cAMP and cGMP to their corresponding monophosphates and play an important role in signal transduction by regulating the intracellular concentration of cyclic nucleotides. Previously, we showed that one individual haplotype, which includes five SNPs in the *PDE11A* gene, is associated with major depressed disorder (MDD) based on block-by-block analysis. There are three PDE genes, namely *PDE11A*, *PDE1A*, and *PDE6D*, located in chromosome 2q31-q35. In this study, we have further explored whether the whole region 2q31-q35 contribute to MDD, we have analyzed the global haplotype by examining 23 SNPs in the *PDE11A*, *PDE1A* and *PDE6D* genes using PHASE software. Only one haplotype has been found to be associated with MDD. This haplotype is different from the most common haplotype at SNPs in *PDE11A* and *PDE1A*. There is no difference between the depressed and control groups when analyzing the global haplotype including six SNPs in the *PDE1A* gene. When including 16 SNPs across 440kb in the *PDE11A* gene, 18 common haplotypes (with frequency higher than 1.4%) have been found in the studied population. The results from both linkage disequilibrium analysis and phylogenetic network for the 16 SNPs showed that several historic recombinations have happened in the *PDE11A* gene. Combined with the genotype distribution between the two groups, the frequencies of three and seven haplotypes are significantly higher and lower in the depressed group than that of the controls, respectively. The frequency of one haplotype is significantly lower in the remitter than that of nonremitter group for the depressed participants treated with either desipramine or fluoxetine. Thus, our data indicate that the *PDE11A* global haplotype is associated with both MDD and antidepressant treatment response. Further experiment such as deep sequencing the whole *PDE11A* gene in the case-control populations is needed to confirm our findings.

Family-Based Association of FKBP5 in Bipolar Disorder. *V.L. Willour[1], H. Chen[2], J. Toolan[1], P. Belmonte[1], D.J. Cutler[3], F.S. Goes[1], P.P. Zandi[4], D.F. MacKinnon[1], F.M. Mondimore[1], B. Schweizer[1], J.R. DePaulo, Jr.[1], E.S. Gershon[5], F.J. McMahon[6], J.B. Potash[1]* 1) Dept Psychiatry, Johns Hopkins Univ, Baltimore, MD; 2) Dept Psychiatry, Univ of Michigan, Ann Arbor, MI; 3) Institute of Genetic Medicine, Johns Hopkins Univ, Baltimore, MD; 4) Dept Mental Health, Johns Hopkins Univ, Baltimore, MD; 5) Dept of Psychiatry, Univ of Chicago, Chicago, IL; 6) Mood and Anxiety Program, NIMH, Bethesda, MD.

The FKBP5 gene product forms part of a complex with the glucocorticoid receptor and can modulate cortisol-binding affinity. Variations in the gene have been associated with increased recurrence of depression and with rapid response to antidepressant treatment. We sought to determine whether common FKBP5 variants confer risk for bipolar disorder. We genotyped seven tag SNPs in FKBP5, plus two SNPs previously associated with illness, in 317 families with 554 bipolar offspring, derived primarily from two studies. Single marker and haplotypic analyses were carried out with FBAT and EATDT employing the standard bipolar phenotype. Association analyses were also conducted using eleven disease-related variables as covariates. Under an additive genetic model, rs4713902 showed significant over-transmission of the major allele ($P = 0.0001$) which was consistent across the two sample sets ($P = 0.004$ and $P = 0.006$). rs7757037 showed evidence of association that was strongest under the dominant model ($P = 0.001$). This result was consistent across the two datasets ($P = 0.017$ and $P = 0.019$). The dominant model yielded modest evidence for association ($P < 0.05$) for three additional markers. Covariate-based analyses suggested that genetic variation within FKBP5 may influence attempted suicide and number of depressive episodes in bipolar subjects. Our results are consistent with the well-established relationship between the hypothalamic-pituitary-adrenal (HPA) axis, which mediates the stress response through regulation of cortisol, and mood disorders. Ongoing whole genome association studies in bipolar disorder and major depression should further clarify the role of FKBP5 and other HPA genes in these illnesses.

Oculo-Facio-Cardio-Dental (OFCD) syndrome : Somatic mosaicism of a large BCOR gene deletion in 2 monozygotic twins and three novel mutations. *S. Whalen[1], S. Manouvrier[2], O. Boute[2], F. Fellmann[3], F. Dastot-Le Moal[1], P. Bitoun[4], M-P. Cordier[5], I. Bailleul-Forrestier[6], M. Goossens[1], A. Verloes[6], I. Giurgea[1]* 1) Genetique & INSERM U841,Hosp H.Mondor, Creteil, France; 2) Dpt génétique clinique, CHRU de Lille, France; 3) Dpt génétique médicale, CHU Vaudois, Lausanne, Switzerland; 4) Dpt génétique, Hosp J.Verdier, Bondy, France; 5) Dpt génétique médicale, Hosp E.Herriot, Lyon, France; 6) Dpt de génétique médicale, Hosp R.Debré, Paris, France.

Oculo-Facio-Cardio-Dental (OFCD) syndrome is a rare disorder associating congenital cataract, microphthalmia, characteristic dysmorphia, congenital heart defects, oligodontia, and radiculomegaly. OFCD syndrome results from mutations in the BCOR gene, located on Xp11.4, encoding a key transcriptional regulator during early embryogenesis. X-linked dominant inheritance is suggested, although a singular BCOR missense mutation, whose relevance remains controversial, was described in a male presenting with Lenz microphtalmia (microphtalmia, mental retardation, and other malformations). To further delineate the clinical spectrum of these disorders, we studied 7 females with OFCD syndrome and 4 males with Lenz microphtalmia, from 6 unrelated families. BCOR mutations were screened by direct sequencing, and deletions by QM-PSF and FISH analysis. Somatic mosaicism for a large deletion of BCOR (50% in peripheral leukocytes) was identified in 2 monozygotic twins presenting with typical OFCD syndrome. One twin transmitted this large deletion homogeneously to her daughter. In addition, 3 novel mutations were identified in 3 unrelated females: 2 frameshift (p.Pro288ArgfsX90 and p.Pro190ProfsX26), and one nonsense (p.Arg1480X) mutation. No mutation of BCOR was found in the patients with Lenz microphtalmia. In conclusion, we report 4 novel BCOR mutations in females with OFCD syndrome. These results broaden the clinical spectrum of OFCD syndrome, as 3 patients did not present heart defects, and one patient had mild mental retardation, thus suggesting that the condition is underdiagnosed. The first description of somatic mosaicism in OFCD syndrome is of particular relevance to genetic counselling.

Dentinogenesis Imperfecta type II: Report of a Mexican Family. *M. PADILLA-ROSAS[1,2,3,4,5], J.A. VELAZQUEZ-RODRIGUEZ[3], O.A. AGUILAR-RAMIREZ[4], L.E. FIGUERA[1,6]* 1) CIBO-IMSS, Guadalajara, Jalisco, Mexico; 2) Doctorado en Genética Humana; 3) Escuela de Odontología, CUCS-UdeG; 4) Escuela de odontología Universidad Guadalajara LAMAR; 5) Division de Medicina Molecular; 6) Division de Genética.

Dentinogenesis Imperfecta type II (DGI-II) (OMIM 125490) is an autosomal dominant disorder in which both the primary and the permanent teeth are affected. It occurs with an incidence of 1:8,000 live birth. The teeth are amber and opalescent, the pulp chamber is obliterated by abnormal dentin. The enamel, although unaffected, tends to get fractured, it makes dentin undergo rapid attrition, leading to a marked shortening of the teeth. DGI-II has been linked to mutations in the dentin sialophosphoprotein (DSPP) gene (locus 4q21), the gene product is cleaved into two dentin-specific matrix proteins, dentin sialoprotein (DSP) and dentin phosphoprotein. Even though its incidence, there are only few reports on familial cases. Here we present a Mexican family with DGI-II, and special attention on clinical description is done. Along four generations have been reported teeth affectation, 5 males and 7 females with male-male inheritance; evaluated individuals show the characteristic changes in color, pulp chamber, fractured enamel and dentin attrition in occlusal and incisal surfaces. The objective this report is to aware on an early diagnosis and genetic counseling.

A Nanofluidic System for Rapid and Reliable Genotyping. *R. Ramakrishnan[1], M. Pieprzyk[1], R. Welch[2], A. Crenshaw[2], B. Hicks[2], M. Yeager[2], S. Berndt[3], W-Y. Huang[3], R.B. Hayes[3], S.J. Chanock[3,4]* 1) Fluidigm Corp, S.San Francisco, CA; 2) Core Genotyping Facility, National Cancer Institute, Gaithersburg, MD USASAIC Frederick, Advanced Technology Program, NCI-FCRDC, Frederick, MD; 3) Division of Cancer Epidemiology and Genetics, NCI, Bethesda, MD; 4) Core Genotyping Facility, NCI, Bethesda, MD.

Although remarkable advances have been made in low- and high-throughput genotyping platforms, there is a need for systems allowing medium multiplexing (30-300 SNPs) platforms with high throughput, excellent call rates, high concordance and low cost. In the current study we demonstrate the use of a unique nanofluidic genotyping system which is simple to use and exhibits these characteristics.

Fluidigm Corporation has developed Integrated Fluidic Circuits (IFCs) which reduce the amount of sample and reagents required for chemical reactions to nanoliter volumes.We demonstrate the use of specific IFCs called dynamic arrays, in a study to genotype 1000 unique human DNA samples on 48 different SNP assays, using nanoliter volumes of reagents. The DNA samples screened included 910 DNA case control samples extracted from blood from an incident adenoma project, and 90 HapMap samples extracted from cell lines. Each dynamic array IFC systematically combines samples and assays into 2,304 reactions. Each chip was thermocycled, imaged and analyzed using a BioMark^{TM} system. Call rates of greater than 99.5% and high concordance values were achieved. Calls from the incident adenoma samples were validated by selected genotyping of the same samples on the ABI 7900, while calls from the HapMap samples were validated by concordance with results obtained by the HapMap project.

The excellent call rates and high concordance, combined with the massively parallel fabrication of valves in nanofluidic chips, provides a formidable genotyping tool. The development of this system profoundly impacts the ability to screen mid-range numbers of genotypes across multiple samples.

Towards a Molecular Classification of Psychiatric Illness. *A.K. Malhotra[1], P. DeRosse[1], T. Lencz[1], K.E. Burdick[1], T.V. Morgan[2], J.M. Kane[1], R. Kucherlapati[2]* 1) Psychiatry Research, Zucker Hillside Hospital, Glen Oaks, NY; 2) Harvard Partners, Center for Genetics and Genomics, Boston, MA.

Schizophrenia (SCZ) is a complex neuropsychiatric disorder characterized by a range of clinical manifestations, including positive, negative, and disorganized symptoms, yet relatively limited work has been conducted to parse out the specific clinical phenomena associated with risk genotypes. Thus, a major goal of our research group is to not only identify candidate genes that predispose to SCZ but also to assess the relation between genotype and refined phenotypes that include symptom domains and neurocognitive function. Using this approach, our group identified a risk haplotype within the gene encoding for dysbindin (DTNBP1) that was not only associated with SCZ but was more specifically associated to a form of the disorder that is characterized by prominent negative symptoms and generalized cognitive impairment. Further, our group also found a relation between variation in DISC1 and risk for SCZ with additional analyses revealing associations to severity of positive symptoms as well as specific deficits in cognitive function (working memory). Candidate gene studies, however, are inherently limited in their scope and fail to adequately address the complexity of SCZ. Therefore, we have recently utilized more comprehensive approaches to identify disease-associated genes. Using the Affymetrix 500k array we conducted the first case-control whole genome association study of SCZ and were successful in identifying a novel risk locus. Using data obtained from the WGA analyses we have also begun to fine map regions of the genome which have previously been associated through linkage analyses with phenotypic variation within SCZ. These analyses have also identified novel loci that may contribute to the heterogeneity of SCZ. Combined with our previous work, these data represent the initial steps towards the molecular classification of psychiatric illness.

Fragile X: Risks of unstable transmissions in females with intermediate and small premutation alleles. *S.L. Nolin, A. Glicksman, T. Sukontasup, G.E. Houck, X. Ding, S.Y. Li, W.T. Brown, C. Dobkin* Human Genetics Dept, NYS Institute for Basic Research in Developmental Disabilities, Staten Island, NY.

Fragile X screening of pregnant women to identify premutation carriers (56-200 repeats) at risk for affected offspring has become routine in many prenatal settings. While 59 repeats is the smallest allele in fragile X families to expand to full mutation in one transmission, the risks of instability for newly identified intermediate (40-55 repeats) and small premutation (56-79 repeats) alleles are not well characterized. We have performed 199 prenatal studies for mothers with 40-79 repeats and observed transmission of the larger alleles in 58% (116/199) of pregnancies. Unstable transmissions were observed in 4/21 with 40-49 repeats (19%), 6/20 with 50-54 repeats (30%), 11/29 with 55-59 repeats (38%), 12/20 with 60-69 repeats (60%) and 26/26 with 70-79 repeats (100%). Among the 59 unstable transmissions, 56 expansions and 3 contractions were observed. For expansions of 40-59 repeat alleles, most increased by 1 to 4 repeats with a range 1 to 12 repeats. In contrast, most alleles from 60 to 79, exhibited much greater size increases. Expansions to full mutations were observed in 11/26 alleles between 70-79 repeats (42%). No expansions to full mutation were observed in alleles <70 repeats. These studies indicate that while unstable transmissions with small repeats expansions are often observed in alleles <60 repeats, most expansions to full mutations occur in alleles >70 repeats.

An Evolving Model for Malignant Hyperthermia Genetic Testing. *D. Steele[1], B.W. Brandom[2], E.E. Smith[1], J.A. Kant[3]* 1) Center for Medical Genetics, Magee-Womens Hosp, Pittsburgh, PA; 2) Dept of Anesthesiology, Univ of Pittsburgh, Pittsburgh, PA; 3) Dept of Pathology, Univ of Pittsburgh, Pittsburgh, PA.

Background and Methods: Malignant hyperthermia (MH) is an autosomal dominant disorder associated with mutations in the RYR1 gene which predispose patients to often fatal reactions during anesthesia. The validated test that confirms MH susceptibility is an expensive bioassay of viable muscle. Associated with the introduction of an *RYR1* screening panel, we designated a genetic counselor to provide information and support to patients and physicians with medical backup from an experienced anesthesiologist. Goals included education that only 50% of patients with clinically proven MH (positive muscle biopsy) have mutations in the *RYR1* gene, the percentage is even lower in patients with a family history or possible MH episodes, the screening panel would not detect all mutations in this 106 exon gene and thus negative genetic testing does not exclude MH susceptibility. We also developed a form for use by a healthcare professional to collect data for transmission to the MHAUS Patient Registry from patients seeking genetic testing. **Results**: 74 patients have been referred for MH testing. 45 spoke with the genetic counselor and 20 of those underwent genetic testing. 25 additional samples were submitted directly to the laboratory. Of 6 patients with *RYR1* gene mutations, only one did not have contact with the counselor. One positive patient had targeted testing following discovery of a novel mutation in a family member. Samples have been submitted from medical examiners and institutions for medicolegal issues. The counseling framework facilitates testing of appropriate family members, the avoidance of unnecessary testing and its costs, and referral for confirmatory muscle testing, if needed. The coordination of laboratory results with the MHAUS Registry facilitates the identification of new disease-associated mutations as well as genotype/phenotype correlations. **Conclusions**: Integration of genetic counseling and data collection from patients seeking genetic testing for malignant hyperthermia (MH) facilitates test utilization. The counselor is a valuable resource for patient and physician.

Genetic association of insulin degrading enzyme (*IDE*) variants with type 2 diabetes in Hong Kong Chinese.

V.K.L. LAM, M.C.Y. NG, J.C.N. CHAN Department of Medicine and Therapeutics, The Chinese University of Hong Kong, Hong Kong, nil, China.

Introduction: Type 2 diabetes (T2D) is a complex disease caused by the progressive loss of beta cell function. It is associated with elevation of islet amyloid polypeptide (IAPP) level which may result partly from the deficiency of IAPP clearance. Insulin-degrading enzyme (IDE) is a ubiquitous short peptidase responsible for IAPP degradation. Inactivations of IDE by drug and knockout mouse are associated with apoptosis and impaired glucose metabolism respectively. Genetic studies including recent genome-wide association studies have demonstrated significant association of variants at or adjacent to *IDE* gene region with T2D. This study aimed to investigate the possible association of *IDE* genetic variations with the pathogenesis of T2D.

Material and Methods: We genotyped eight tag SNPs flanking 2kb upstream and downstream of *IDE* gene using Sequenoms MassARRAY System. We tested their associations with T2D in a case-control samples consisting of 461 unrelated Chinese young onset (age at diagnosis 40 years) familial T2D patients and 419 healthy controls.

Results and Conclusion: The eight tag SNPs captured 77% of common SNPs (minor allele frequency 5%) in HapMap Chinese database at r^2 0.8. All SNPs did not show departure from Hardy-Weinberg equilibrium in control subjects, p 0.05. Case-control analysis discovered that rs6583813 was significantly associated with T2D [OR (95% CI) for C allele = 1.24 (1.01-1.51), p = 0.04] under an allelic model. Further haplotype analysis did not reveal more significant results. In conclusion, the present study suggests that genetic variants at *IDE* gene may contribute to susceptibility for developing T2D.

60-Plex Genotyping Reactions of Single Nucleotide Polymorphisms Using Single Base Primer Extension Coupled with Matrix-Assisted Laser Desorption/Ionization Time-of-Flight Mass Spectrometry. *P. Oeth, G. del Mistro, G. Marnellos, T. Becker, S. Berkenkamp, C. Jurinke, S. Sur, D. van den Boom* Research & Development, Sequenom, Inc., San Diego, CA.

We report the first example a of multiplexed genotyping reaction, greater than 40-plex, to be accurately resolved and typed using Matrix Assisted Laser Desorption/Ionization Time-of-Flight Mass Spectrometry (MALDI-TOF MS). Our results are an extension of the number of genotypes achieved per reaction using the iPLEX genotyping reaction on the MassARRAY system with several important implementations to deal with assay design and the density of peaks per mass spectrum. Assay designs were created using proprietary software (MassARRAY Assay Designer) for homogeneous multiplexed PCR and primer extension reactions. Prior to assay design SNP sequences were screened for proximal SNPs against dbSNP (MassARRAY ProxSNP) and candidate assay primer triplets were screened against the human genome to establish uniqueness for assay hybridization (MassARRAY PreXTEND). Products were resolved on a linear mode MALDI-TOF MS within a mass window of 4500-9500 Da. In order to prevent any potentially confounding effects by salt adducts from parental allelic peaks, which might interfere with peak detection, an adduct reduction reagent was introduced prior to cation exchange desalting. Genotypes were called using a post acquisition clustering algorithm rather than in real-time (TYPER Analyzer 4.0). Preliminary studies using HapMap SNPs with a minor allele frequency of 40% or greater in the CEPH population of western European ancestry have established that 60-plex reactions provide a median assay coverage of 90-93%. Assay and genotype quality filters based on criteria for reproducibility, Hardy-Weinberg Equilibrium and Mendelian Error reduced assay coverage by approximately 5-10% resulting in a conversion rate of 80-88% per 60-plex with a HapMap genotype concordance of greater than 99.5%. Our data to date suggests that each designed 60-plex will yield a working 48-52 plexed reaction for large cohort typing of candidate gene regions during the fine mapping phase of association studies.

Neurotrophins and their receptors: mRNA expression in ischemic rat brain under the treatment with neuropeptide Semax and its C-terminal tripeptide PGP. *V.V. Stavchansky[1], L.V. Dergunova[1,2], A.B. Botsina[2], T.V. Tvorogova[2], V.I. Skvortsova[2], S.A. Limborska[2]* 1) Human Molecular Genetics Dept, Institute of Molecular Genetics RAS, Moscow, Russian Federation; 2) Institute of Stroke RSMU, Moscow, Russian Federation.

To elucidate the effect of neuroprotective polypeptide Semax containing the fragment of adrenocorticotropic hormone - ACTH(4-10) and its C-terminal fragment Pro-Gly-Pro (PGP) on expression of neurotrophins Bdnf, Nt-3 and its receptors TrkB, TrkC and p75 after global cerebral ischemia the profile of its mRNA expression in rat cerebellum and forebrain cortex were analyzed. The study was carried out on 2-3-month-old male Wistar rats (n=85). After 15 minutes of irreversible bilateral common carotid artery occlusion the animals were exposed to intraperitoneal injection of either Semax, PGP or saline 1 hour, 4 hours and 8 hours after the occlusion. Animals were decapitated 30minutes, 1hour, 2, 4, 8, 12 and 24 hours after operation. Intact and sham-operated animals were used as control groups. The mRNA expression of neurotrophins and its receptors was assessed by relative quantification in real-time RT-PCR. Gapdh was used as the reference gene. The most appreciable effect of Semax was revealed in the analysis of p75 mRNA expression in forebrain cortex; the level of p75 transcripts was decreased at 8 h and 24 h after operation compare to animals with ischemia treated with saline. Some considerable effects of the PGP treatment were observed. The level of TrkB transcripts was increased 30 minutes and 1 hour after occlusion while the increase of Nt-3 and TrkC mRNA expression was observed 24 hours after operation. It could be suggested that neuroprotective effect of Semax and PGP is possibly mediated by neurotrophins and its receptors.

COMPUTATIONAL ANALYSIS OF STRUCTURAL AND NON-STRUCTURAL PROTEIN SYNTHESIZED BY CHIKUNGUNYA VIRUS - MOSQUITO BORNE DISEASE AS POTENTIAL TARGET MOLECULES FOR VACCINE. *Mahdieh. Khosroheydari*[1], *K.R. Rupesh*[2] 1) Medical Genetic Department, Special Medical Center, P.O. Box 15815/3333, Tehran, Iran; 2) Laboratoire de Microbiologie des Environnements Extrêmes, CNRS UMR 6197, IFREMER-Centre de Brest, BP 70, 29280 PLOUZANE, France.

Background & Objective: Chikungunya virus (CHIK) is an alphavirus borne by Aedes mosquitoes that produces a dengue-like illness in humans, characterized by fever, rash, painful arthralgia and arthritis throughout sub-Saharan Africa, Southeast Asia, and the Western Pacific. The recent widespread geographic distribution, recurrent epidemics, and infection of military personnel, travelers, and laboratory staff working with CHIK have indicated the need for more understanding and to have a efficacious vaccine. Results: In our present study we have analyzed the characteristics of structural and non-structural proteins synthesized by CHIK using computational tools and predicted the effective possible candidates for use as potential vaccine. The computational analysis of the non-structural protein revealed that it is 275.65 kDa hydrophilic protein, whose pI is 6.841 while that of the structural protein revealed a 138.88 kDa hydrophilic protein of pI 8.88. The antigenic prediction sites on the non-structural and structural proteins predicted were examined for their use in as vaccine candidates for effective control of the disease. The positions of the alpha helix and b-sheets in the secondary structure of the proteins were predicted which laid the path for 3D structural characterization of the target proteins. On analyzing the hydropathy plot, the structural protein and the non-structural protein was found to be hydrophilic. Using the nucleotide sequence of the proteins, degenerate primers were designed for its use in PCR based diagnostic identification of the CHIK. Conclusion: The primers designed could find its use as a diagnostic tool for identifying CHIK infected patients specifically and sensitively. The predicted antigenic sites on the non-structural and structural proteins could be used as effective vaccine candidate which will be further evaluated for its effectiveness by in vitro and in vivo methods.

Obstructive uropathy in cystinuria knockout mice. *A. Sahota[1], E. Cui[1], H.J. Vernon[2], M. Yang[1], S. Ridgely[3], D. Reimer[3], S. Bledsoe[4], A.P. Evan[4]* 1) Dept Genetics, Rutgers Univ, Piscataway, NJ; 2) Dept Pediatrics, Johns Hopkins Univ Sch Med, Baltimore, MD; 3) Laboratory Animal Services, Rutgers Univ, Piscataway, NJ; 4) Dept Anat and Cell Biol, Indiana Univ Sch Med, Indianapolis, IN.

Introduction: Obstructive uropathy is a major cause of renal failure in children. Unilateral ureteral ligation in animals has provided valuable insight into the pathophysiology of urinary tract obstruction, but this is an acute injury model. It provides little information on the development of chronic obstruction as may occur in patients with bladder or ureter stones. Cystinuria, an inherited disorder of dibasic amino acid transport, is the most common cause of urinary tract stones in children. Cystinuria is classified as type I or non-type I, and these are caused by mutations in *SLC3A1* and *SLC7A9* genes, respectively. We created *SLC3A1* knockout mice to investigate the molecular basis of stone disease in cystinuria. **Methods:** Gross pathology was carried at age 12 months, and perfused kidneys, ureters, and bladder was examined by micro computed tomography (micro CT). In previous studies, perfusion and gross pathology were done at ages 4 and 8 months. **Results:** Bladders of *SLC3A1* male knockout mice at age 12 months were distended and filled with numerous uroliths up 4 mm in diameter, and the mucosal lining was thickened. Kidneys from these animals were enlarged and showed regional thinning of the cortex and dilation of the medulla and pelvis. A nephrolith was present in the medulla in a few mice. Ureters were grossly enlarged, but there was no evidence for large stone obstruction. Micro CT demonstrated extensive stone deposition in the bladder, and one animal also showed stones in the kidney and ureter. Bladder stones were also present in 4- and 8-months-old male mice, and there was hydronephrosis. Knockout female mice at any age group showed no gross lesions. **Conclusions:** These studies indicate that the bladder is the major site of stone deposition in cystinuria mice. The progressive accumulation of cystine stones and the subsequent hydronephrosis and hydroureter suggest that these mice may be more relevant models for studying obstructive uropathy compared with ureteral ligation.

Characterization of glycosylation defects in muscular dystrophy. *S.E. Sparks[1, 2], E.P. Hoffman[2]* 1) Genetics & Metabolism, Children's Natl Med Ctr, Washington, DC; 2) Center for Genetic Medicine, Children's Research Institute, CNMC, Washington, DC.

Abnormal glycosylation of -dystroglycan underlies the pathology of a group of muscular dystrophies known as the dystroglycanopathies. The clinical phenotype ranges from congenital onset of muscular dystrophy with CNS and eye involvement, to a later onset form of limb girdle muscular dystrophy, without any CNS or eye involvement. Deficiency of the dystroglycan protein is thought to be incompatible with life, as shown by dystroglycan knock out mice. There is no known disorder that is associated with dystroglycan deficiency. To date, six genes have been identified which alter the glycosylation pattern of -dystroglycan, all of which are known or putative glycosyltransferases. However, with the anticipated 10-15 steps in the glycosylation of -dystroglycan, there are more to be identified. An initial screening of 5000 muscle biopsy samples led to 176 samples from patients under 5 years of age who did not have the diagnosis of Duchenne muscular dystrophy (potential congenital muscular dystrophy patients with a glycosylation defect). Those with normal muscle histology and other confirmed diagnoses were excluded. Of the remaining 121 samples, 113 had clinical findings in 2 out of the following 4 criteria: involvement of the CNS, involvement of the eyes, muscle involvement demonstrated by elevated creatine kinase or EMG consistent with a myopathy, or muscle histology consistent with congenital muscular dystrophy. These 113 samples are being screened for a glycosylation defect. In those with a defect, molecular and biochemical characterization will be pursued. Furthermore, the natural history of these defects will be studied. In addition, the evaluation of clinical end points and biomarkers will be undertaken in hopes of investigating therapeutic options. Eventually, these initial studies on congenital muscular dystrophies will be broadened to include glycosylation analysis in unknown limb girdle muscular dystrophy muscle samples.

Whole-genome association study identifies polymorphisms in the NPAS3 gene associated with super-response to iloperidone treatment in patients with schizophrenia. *C. Lavedan, S. Volpi, K. Mack, C. Heaton, R. Lannan, J. Hamilton, L. Licamele, C. Wolfgang, M. Polymeropoulos* Vanda Pharmaceuticals, Inc, Rockville, MD.

Schizophrenia, a psychotic disorder affecting approximately 1% of the US population, is characterized by the presence of positive symptoms (eg, hallucinations), negative symptoms (eg, social withdrawal), and impaired cognitive functions. Treatment response to typical and atypical antipsychotics is highly variable. No specific, reliable markers predictive of response have been identified. Through a whole-genome association study conducted in a randomized, double-blind, placebo- and ziprasidone-controlled trial of iloperidone for treatment of schizophrenia, we identified several SNPs strongly associated with iloperidone efficacy, measured by change in PANSS total score. Two of these SNPs are located in 14q12-q13 in intron 3 of the *NPAS3* gene. Following 4-weeks iloperidone treatment, patients carrying the non-GG genotype for one SNP (approximately 30%) were 3 times more likely to experience approximately 20% improvement compared with patients with a different genotype. The association of non-GG genotype with better response was observed in both sexes and in all races. A study has described a mother and a daughter with schizophrenia who carried a t(9;14)(q34;q13) chromosome with a breakpoint in intron 3 of the *NPAS3* gene. This breakpoint disrupted the bHLH and PAS domains involved in DNA-binding and dimerization functions of the protein. Studies of mice with disruptions in *NPAS3* and *NPAS1* genes have shown that NPAS3 and NPAS1 transcription factors may control regulatory pathways relevant to schizophrenia. Our data suggest that *NPAS3* may affect response to antipsychotic treatment. More experiments are needed to better understand the function of *NPAS3*, its role in schizophrenia, and patient response to antipsychotic treatment. Additional studies specifically designed to confirm and fully appreciate the clinical value of this finding should provide new insight into response to iloperidone and ultimately may guide the clinician in directing iloperidone therapy to those patients most likely to respond.

Goldsurfer2: A comprehensive tool for the analysis and visualization of whole genome association studies. *F. Pettersson[1], A.P. Morris[1], M.R. Barnes[2], L.R. Cardon[1]* 1) Dept Bioinformatics, Wellcome Trust Centre, Oxford, United Kingdom; 2) Molecular Discovery Informatics, GlaxoSmithKline Pharmaceuticals, Harlow, Essex, United Kingdom.

With recent advances in the efficiency of high-throughput single nucleotide polymorphism (SNP) genotyping technology, genome-wide association studies are now routinely undertaken with the sample sizes necessary to detect the modest genetic effects we expect for complex diseases. There is now a clear demand for efficient analysis tools that can deal with the sheer volume of data generated by these experiments. To meet these demands, we have developed Goldsurfer2, an interactive and user-friendly graphical application to be used in all steps of WGA projects from initial data QC and analysis to biological evaluation and validation of results. The program is implemented in Java and can be used on all platforms. Basic statistical calculations, such as simple tests of SNP association with disease, genotyping failure rates, allele frequencies and Hardy-Weinberg disequilibrium are built in. However, methodology for more complex analysis techniques can be added to the platform. Recently added methods include multivariate statistics such as principal component analysis applied for investigating population stratification and higher-level LD structures. Evaluation of results may involve further statistical analysis, such as reviewing raw genotyping intensities for potential genotyping errors. Finally significant associations need to be prioritised using functional and biological interpretation methods, browsing available biological annotation, pathway information and patterns of linkage disequilibrium. For these tasks there are built in functionalities for importing data, performing calculations and comparative visualisation of results. The interface has been updated for easy switching between a gene centric and SNP centric view of data. For example genes can be selected based on their functional annotation and can be further used for prioritising SNPs and vice versa. For eQTL studies normalized gene expression data can be imported and analysed. The software can be downloaded from www.well.ox.ac.uk/gs2.

Genotype/Phenotype Correlations in Vascular Ehlers-Danlos Syndrome. *J. Yang[1], B.F. Griswold[1], W. Chen[1], C.A. Francomano[2], N.B. McDonnell[1]* 1) LCI, NIA/NIH, Baltimore, MD; 2) GBMC, Baltimore, MD.

Vascular Ehlers-Danlos syndrome is a hereditary disorder of connective tissue caused by mutations in COL3A1, encoding procollagen III. The clinical features include skin fragility, easy bruising and bleeding, joint hypermobility, bowel or uterine rupture, arterial dissections and aneurysms. The life expectancy is significantly reduced. Analysis of phenotype/genotype correlations with COL3A1 mutations can be helpful for anticipatory guidance and counseling for affected families. Thirteen affected families were identified at the National Institutes of Health, and COL3A1 gene was sequenced. The mutations identified included substitution mutations leading to the critical glycine residues in the collagen helix, splice site mutations, small deletions that disrupt the alignment of collagen trimers, as well as premature termination codons that lead to haploinsufficiency. The exon skipping mutations were associated with severe skin features and scarring, while the haploinsufficency mutations were found to lead to a relatively milder phenotype with later age of onset of complications. Glycine substitution mutations were associated with a higher incidence of aneurysms and variable skin features. Maternal death due to uterine rupture had not occurred in the probands or affected family members in our cohort.

A shrinkage regression approach to tackle the HLA region. *C. Vignal[1,2], A. Bansal[2], C. Hoggart[1], D. Balding[1]* 1) Imperial College, London; 2) GlaxoSmithKline, UK.

Many autoimmune diseases have been associated with the HLA region, but the presence of linkage disequilibrium (LD) has meant that finding causal elements has been difficult. Multivariate association analyses can perform better than univariate methods, however, there can be problems when the number of variables exceeds the number of observations or in the presence of correlated predictors.

We adopt a Bayesian-inspired shrinkage regression approach for multilocus analysis of correlated data in which each regression coefficient is assigned a prior distribution that strongly favors zero values. We consider two shrinkage priors, the Laplace or double exponential distribution, and the normal-exponential-gamma distribution. Parameter inference is based on the posterior mode and terms with non-zero posterior modes indicate marker-disease associations.

We applied this approach to a case-control association study on rheumatoid arthritis (RA) using SNPs spanning the HLA region, together with genotypes from the multiallelic HLA-DRB1 locus. The latter is a known RA risk factor that was included in all our models without shrinkage. After controlling for type-I error, we found fewer positive SNP associations than in single-point tests, suggesting that LD might be better-handled. These results were supported by a simulation study. We selected a set of SNPs in various degrees of LD with HLA-DRB1. For each marker, case-control labels were randomised within the HLA-DRB1 allelic classes to simulate causal SNPs, while maintaining LD with HLA-DRB1. Our results showed that the shrinkage approach provides a substantial benefit, both in terms of maintaining statistical power to detect multiple causal variants and in the reduction of false positive associations.

Mental Retardation, Ataxia with Vermis Hypoplasia and Distinctive Facial Appearance, Report of Two Cases. *J. Prieto[1,2], G. Contreras[1], P. M. Hurtado[1]* 1) Inst de Genetica Humana, Univ Javeriana, Bogota Cundinamar, Colombia; 2) Hospital la Victoria, Secretaria Distrital de salud, Bogota, Colombia.

Case report: We decribed two siblings born of consanguineous parents with similar characteristics. Case 1: boy 5.5 years old that comes to our service with a history of global retardation. He is born from a third pregnancy with normal prenatal care. Institutional vaginal childbirth. Weight: 2950 grs, Size: 52 cms, PC: 33 cms. Apgar 8/10 and 10/10. He has had a global retardation and has not achieved the goals for his age. Case 2: older sister of case 1, a girl now 13 years old, has also mental retardation and history of psychomotor developmental delay. No inconvenient is register in her pregnancy. Her weight at birth was 2800 grs and size: 48 cms. Also, for both sibs we described a nonprogressive ataxia, mental retardation, hypertonic in arms and legs and speech delay. At the actual physical examination we found: In the boy short stature, microcephaly, anteverted narins, umbilical hernia, fifth finger both hands shorter; For the girl the positive findings are short stature, microcephaly, prominent helix, sinofris, micrognathia, fifth finger both hands shorter. Paraclinics Vermis hypoplasia documented in both by magnetic resonance imaging (MRI), and also for the girl volume loss in the brain stem at the pons level and cerebellar changes with 4th ventricle enlarged. In our cases, there were no specific clinical signs or positive data in the screening tests with regard to metabolic diseases. For the girl there is karyotype report 46, XX. Discussion Vermis hypoplasia is found in association with a variety of neurologic and systemic disorders. Although the description we found in the literature the vermis hypoplasia is found in patients with different phenotype to the one we described here. We didn't find in the literature a Case report similar to ours, including vermis hypoplasia, mental retardation, nonprogressive ataxia, hypertonic arms and legs, microcephaly, in association with speech delay and motor development impairment. Counting the consanguineous relationship of the parents of this two siblings, we concluded this is an autosomal recessive entity.

A human/bovine comparative approach to identify transcripts related to oocyte maturation: from fertility to aging. *C. Laperuta[1], C. Carbone[1], M. D'Urso[1], B. Lioi[2], M.V. Ursini[1], M.G. Miano[1]* 1) Institute of Genetics and Biophysics "A. Buzzati Traverso", National Research Council, Naples, Italy; 2) Department of Animal Production Sciences - University of Basilicata, Potenza, Italy.

Decline aging-oocyte competence and premature ovarian failure (POF) are common factors in human female infertility. In both conditions, follicular senescence and ovarian dysfunctions occur at different speed. Understanding how an immature oocyte transforms into an egg during oocyte maturation is critical for knowledge of fertility and decline-oocyte aging. This process guides the achievement of the final competence essential to fertilization and zygote division, through evolutionary conserved nuclear and cytoplasmatic events. The maturation of mammalian oocyte requires a co-ordinated programme of gene expression events that itself regulates the development of ovarian follicles. We studied several cases of POF and using microsatellite analysis we narrowed the extension of an interstitial deletion, which resulted to be located between DXS1187 and DXS1073. In this region mmany candidate gene for this disease are present. Therefore, starting from selected genes involved in POF disorders and oocyte aging, we are carrying out a characterization the expression level of bovine ortologous of genes located in the POF locus during oocyte maturation. The rationale for this analysis was that cow constitutes the best surrogate model for studying reproductive human disorders given the great similarity between the two reproductive systems. We assayed systematically the expression level of each transcript in bovine oocytes at different stage of maturation (immature-MI stage and mature-MII stage) coming from young (12 months old) and older animals (13 years old). Oocyte pools (20-100) were collected by puncturing follicles from ovaries of cows and RNA extraction methods were carried out using high recovery rate methods. Our data identified few transcripts specifically expressed during meiosis I and II. We believe that they may represent a good starting point to investigate on the presence of specific mRNAs in the former maturation stages and assay how they vary during decline- competence in aging oocyte.

RNA-based mutation analysis identifies an unusual MSH6 splicing defect and circumvents PMS2 pseudogene interference. *K. Wimmer[1], J. Etzler[1], A. Zatkova[1], A. Peyrl[2], H.-U. Schildhaus[3], A. Ficek[4], C. Kratz[5], L. Messiaen[6], I. Slavc[2], C. Fonatsch[1]* 1) Department for Medical Genetics, Medical University Vienna, Vienna, Austria; 2) Department of Pediatrics and Adolescent Medicine, Medical University Vienna, Vienna, Austria; 3) Institute of Pathology, University Bonn, Bonn, Germany; 4) Department of Molecular Biology,Comenius University, Bratislava, Slovakia; 5) Division of Pediatric Hematology and Oncology, Department of Pediatrics and Adolescent Medicine, University of Freiburg, Germany; 6) Department of Genetics, University of Alabama at Birmingham, AL.

Recent reports provide evidence for a novel recessively inherited cancer syndrome that is characterized by early-onset malignancies and signs of neurofibromatosis type 1 (NF1). Bi-allelic mutations in one of the mismatch-repair- (MMR-) genes MLH1, MSH2, MSH6 and PMS2 were identified as the underlying genetic alteration in almost 30 children of 15 families with brain and/or hematological malignancies presenting also with café-au-lait spots (CLS) or other NF1 symptoms. Blood samples of two families with children suspected to suffer from this syndrome were sent to our laboratory for genetic testing. We established a RNA-based mutation detection assay for the four MMR-genes, since (i) a number of splicing defects may escape detection by the analysis of genomic DNA and (ii) DNA-based mutation detection in the PMS2 gene is severely hampered by the presence of multiple highly similar pseudogenes. Using this assay that is based on direct cDNA sequencing of RT-PCR products we identified a complex MSH6 splicing alteration in the first family and a novel PMS2 mutation in the second family. We demonstrate that RNA-based PMS2 testing effectively avoids pseudogene co-amplification as well as allelic drop-out. With this report we show that reliable and highly sensitive mutation analysis in all four MMR-genes including PMS2 is possible using a RNA-based approach. Secondly, we bring further attention to the accumulating evidence that recessive alleles in the MMR-genes, particularly PMS2, cause early-onset malignancies in children with clinical signs resembling NF1.

The spectrum of mutations in the MMACHC gene in patients with cblC disease. *J.P. Lerner-Ellis[1,2,3], J. Liu[2,3], D. Coelho[1], T. Suormala[1], A.D. Loewy[2,3], D. Watkins[2,3], S. Gurd[2], C. Morel[2,3], T. Pastinen[2], M. Baumgartner[4], D.S. Rosenblatt[2,3], B. Fowler[1]* 1) Metabolic Unit, University Children's Hospital, Basel, Switzerland, CH-4005; 2) Department of Human Genetics, McGill University, Montreal, Quebec, Canada, H3G 1B1; 3) Division of Medical Genetics, McGill University Health Centre, Montreal, Quebec, Canada, H3G 1A4; 4) Division of Metabolism and Molecular Pediatrics, University Children's Hospital, Zurich, Switzerland, CH-8032.

Methylmalonic aciduria and homocystinuria, cblC type (OMIM 277400) is the most common inborn error of vitamin B12 (cobalamin, Cbl) metabolism. The gene for cblC was recently identified. We sequenced MMACHC from the genomic DNA of 119 cblC patients, the second largest cohort of cblC patients in the world. Sixteen novel mutations were identified as well as 17 mutations that were observed previously bringing the total number of identified mutations to 58. Haplotype analysis suggests that several mutations have common founders whereas other mutations occurred more than once in human history. A comparison of mutations was made between 323 patients, 102 diagnosed in Europe, and 221 patients diagnosed in North America. A similar distribution of pathogenic alleles was observed for the most common mutation c.271dupA (p.R91KfsX14) and was observed primarily on one haplotype, while patients with the c.394C>T (p.R132X) mutation were twice as frequent in the European cohort; this mutation was observed on three different haplotype backgrounds. Genotype-phenotype correlations of common mutations were apparent; individuals with the c.394C>T mutation generally had late onset disease whereas patients with the c.331C>T (p.R111X) and c.271dupA mutations presented in infancy. Quantitative RT-PCR of RNA from cell lines homozygous for the c.394C>T mutation had significantly higher levels of MMACHC transcript than cell lines homozygous for c.271dupA and c.331C>T mutations as compared to controls. Clinically, individuals with the c.394C>T mutation have responded to vitamin B12 therapy with complete reversal of neurological manifestations and so these findings provide insight into disease mechanism.

The mutational spectrum of the novel HSP gene REEP1 suggests haploinsufficiency and microRNA target site involvement. *S. Zuchner[1], C. Beetz[2], R. Schüle[3], T. Deconinck[4], J. Beats[4], KN. Trans Viet[5], H. Zhu[6], N. Nagan[6], T. Deufel[2], C. Braastad[6], L. Schöls[3], P. de Jonghe[4], M. Pericak-Vance[1]* 1) Univ. of Miami, MIHG, Miami,FL; 2) Univ. Jena,Germany; 3) Univ. of Tübingen,Germany; 4) Univ. of Antwerp,Belgium; 5) Duke Univ.,NC; 6) Athena Diagnostics,MA.

Hereditary spastic paraplegia (HSP) is a genetically and clinically heterogeneous disease affecting the upper motor neuron. HSP shows clinical and genetic overlap with other diseases of the motor neuron system, such as ALS, dHMN, and axonal neuropathies. The most common forms of HSP are SPG4 and SPG3A that account for about ~40% and ~10%, respectively. Other HSP genes appear to be rarely affected (<1%).Although more than 30 chromosomal loci have been mapped only 15 HSP genes have been identified thus far. We studied two families that showed significant linkage (TP-LOD 4.7) to chromosome 2p12 thereby establishing a new HSP designation, SPG31. Candidate gene sequencing revealed the novel gene REEP1 as the underlying cause for SPG31. Screening of 627 HSP samples from multiple academic centers and a commercial testing laboratory revealed 17 REEP1 mutations in 20 cases/families (3.2%). The majority of mutations (71%) caused frame shifts or splice-site mutations and was predicted to lead to haploinsufficiency. Another 20% of mutations occurred in conserved microRNA target sites suggesting a novel mechanism for HSP and potentially for a wider range of genes involved in neurodegeneration. Detailed genotype/phenotype correlations revealed a pure clinical phenotype and suggested a bimodal distribution of the age of onset. We further designed specific REEP1 antibodies and showed in cell culture and on Western blots that REEP1 localizes to mitochondria and likely resides in the mitochondrial membrane. This fits well into the proposed pathways for HSP and other neurodegenerative disease, where mitochondrial transport, fusion, and oxidative phosphorylation appear to be central molecular themes. Taken together, REEP1 is an important new HSP gene with a considerable frequency that justifies regular testing. The further characterization of its molecular properties, especially the haploinsufficiency and microRNA mechanism, is under way.

Novel linkage for tuberculosis susceptibility: The household contact study in Kampala, Uganda. *C.M. Stein[1,2], S. Zalwango[2,3], D.V. Leontiev[1], W.H. Boom[2], S.K. Iyengar[1], R.C. Elston[1], R.D. Mugerwa[2,3], C.C. Whalen[1,2]* 1) Epidemiology & Biostatistics, Case Western Reserve Univ, Cleveland, OH; 2) Tuberculosis Research Unit, Case Western Reserve Univ, Cleveland, OH; 3) Clinical Epidemiology Unit, Makerere University School of Medicine, Kampala, Uganda.

Tuberculosis (TB), caused by *Mycobacterium tuberculosis* (Mtb), is an enduring public health problem globally and several studies suggest a role of host genetic susceptibility in increased TB risk. As part of a household contact study in Kampala, Uganda, we have taken a unique approach to the study of genetic susceptibility to TB, by studying three phenotypes: culture confirmed TB disease, tumor necrosis factor-alpha (TNF) expression in response to Mtb culture filtrate, and resistance to Mtb infection in the face of continuous exposure as evidenced by a persistently negative tuberculin skin test (PTST). We conducted a full microsatellite genome scan, using genotypes generated by the Center for Medical Genetics at Marshfield. Multipoint model-free linkage analysis was conducted using a recent extension in the implementation of the Haseman-Elston regression model that includes half sibling pairs, and HIV status was included as a covariate in the model. We analyzed individuals from 184 pedigrees, comprising 266 full sibling pairs and 185 half sibling pairs. Preliminary results demonstrate linkage within 15 Mb of a number of candidate gene regions, including IL-6 (TB p=0.0003), SLC11A1 (TNF p=0.05, PTST p=0.02), IL-1 complex (TB p=0.01), IL12BR2 (TNF p=0.05), IL12A (TB p=0.02) and IFNGR2 (TNF p=0.001). We have previously shown association of Mtb-induced TNF expression and TB with IFNGR1, TNFR1 and IL-10 in this sample, therefore other genes in the cascade are logical candidates. In addition, we detected suggestive linkage to three novel regions, one with all three phenotypes, another with only TB as the phenotype, and the third with PTST as the phenotype. These results further illustrate the role of the TNF intermediate phenotype in genetic susceptibility to TB. Further work is needed to identify candidate genes in these novel regions and conduct fine mapping studies.

A novel deletion mutation in *ARG1* gene found in a neonate. *O. Staretz-Chacham[1], N. Goldstein[2], B. Ben-Zeev[2], R. Loewenthal[2], H. Mandel[2], E. Sigalov[2], B. Vilensky[2], Y. Cohen[2], S.D. Cederbaum[2], Y. Anikster[2]* 1) NIH, Bethesda, MD; 2) Safra Children Hospital, Sheba Medical center, Tel Hashomer, Israel.

Argininemia is a rare autosomal recessive disorder caused by deficiency of Arginase I gene (*ARG1*), the final enzyme in the Urea Cycle that catalyzes the breakdown of arginine to ornithine and urea. Arginase I is a cytosolic enzyme expressed predominantly in the liver but also in erythrocytes. Argininemia typically presents as a progressive neurometabolic disorder with spastic paraplegia, developmental retardation, hyperactivity,irritability and episodic vomiting, hyperammonemia and seizures.Basic treatment is dietary protein restriction, and supportive therapy is to prevent and control the hyperammonemia. A 2 weeks old female infant of first cousin Ashkenazi Jewish parents was diagnosed with Argininemia in our clinic. For confirmation of clinical diagnosis, the patient's genomic DNA was PCR amplified for the 8 exons of the *ARG1* gene and analyzed by nucleotide sequencing. PCR amplification yielded PCR products for all exons except exon 2. Since the amplification primers were intronic, results suggested an exon 2 deletion. In order to define the deletion borders, sequence analysis was performed with primers at introns 1 and 2 leading to the identification of a 1337 bp deletion which included exon 2. This results in a reading frame shift after amino acid residue 19 followed by a premature stop codon after 4 amino acids. Examination of the sequence flanking the deletion revealed 5 base repeats at the 5' and 3' breakpoints. The presence of these repeats at the breakpoints might have facilitated the generation of the deletion through a slippage mispairing mechanism. In order to determine the carrier rate of this novel mutation in addition to a second known mutation (D128G) found in several Jewish families of Ashkenazi descent. *ARG1* mutations were genotyped using a chip-based matrix-assisted laser desorption-time-of-flight (MALDI-TOF) mass spectrometer for 760 DNA samples from anonymous Ashkenazi subjects. No carriers were found. These results suggest low carrier frequency for these mutations among Ashkenazi Jews and/or a *de novo* mutation in this neonate.

Genomewide-scan analysis of a multigenerational French Canadian family affected with intracranial aneurysms.
D.J. Verlaan, R. Gillis, J. St-Onge, A. Desjarlais, A. Noreau, G.A. Rouleau Centre de Recherche du CHUM, Universite de Montreal, Montreal, PQ, Canada.

Background: Intracranial aneurysms (IA) are dilations of intracranial arteries that occur most commonly at arterial bifurcations. Unruptured IAs are present in approximately 3-6% of the population aged older than 30 years old. Aneurysms are only rarely symptomatic unless they rupture, which typically results in a subarachnoid haemorrhage that is associated with high morbidity and mortality. The purpose of our study is to map a gene that predisposes to IA.

Methods: A multi-generational French Canadian family containing 11 affected individuals with IA was identified. Six affected cases (2 are reconstructable) and 8 unaffected individuals were sent for an 8 cM genomewide scan at deCODE (Reykjavik, Iceland). The disease segregation within the family was compatible with a Mendelian inheritance pattern, and a parametric LOD score approach was used to test for linkage. Multipoint LOD scores of the autosomes were calculated using GENEHUNTER version 2.1_r5 beta and two-point linkage for the X chromosome was calculated using MLINK from the FASTLINK 3.0P package. An affecteds-only approach was performed, using an autosomal dominant model, a phenocopy frequency of 0.01, a penetrance of 0.8, a disease allele frequency of 0.001 and deCODE allele frequencies.

Results: Preliminary multipoint analyses suggest six possible regions of linkage on chromosomes 3p26.3-1, 4p16.3-1, 5p14.3-q11.2, 7p22.3-21.3, 8p23.1-3, and 18q21.33-22.3. Except for the 5p14.3-q11.2, where an association with the *versican* gene was identified, none of these regions have previously been implicated in the pathogenesis of IA.

Conclusion: Further genotyping and collection of additional individuals will permit us to determine the inclusion or exclusion of these positive regions. Genotyping of additional FC families may also help us determine where this susceptibility locus lies.

Complex telomeric imbalances uncovered by array CGH: Is there a common mechanism for some telomeric rearrangements? *J. Lee, Z. Nawaz, E.J. Wallace, D.H. Ledbetter, C.L. Martin* Dept Human Genetics, Emory Univ, Atlanta, GA.

Several platforms utilizing array-based comparative genomic hybridization (aCGH) have been applied to assess individuals with unexplained mental retardation/developmental delay and have confirmed that telomere imbalances are overrepresented compared to average chromosomal regions. We designed a custom oligonucleotide microarray consisting of high-density coverage for all telomere regions, as well as a whole-genome backbone, to develop a more efficient and comprehensive method for characterizing telomere imbalances. Our custom array has been used to calibrate the size and gene content in 44 samples with cryptic pathogenic subtelomeric imbalances. In five of these cases, three of which were originally detected as pure deletions and two which were structural rearrangements, aCGH detected additional interstitial imbalances adjacent to the telomere imbalance. Two cases, involving the telomeric regions of 2q and 22q, showed duplication juxtaposed immediately adjacent to the breakpoint of a terminal deletion. One case, involving 6q, also showed duplication proximal to the telomeric deletion, however a ~1.5 Mb gap was present between the deletion and duplication. An unbalanced translocation between 9p and 20p, that resulted in partial monosomy 9p and partial trisomy 20p, showed an additional duplication next to the breakpoint of the 9p deletion. Finally, in a case with a ring chromosome 22, duplication was identified adjacent to a terminal deletion. In all of these cases, the duplicated material was derived from the same chromosome as the deletion. Two other recent aCGH studies have also observed inverted duplications adjacent to telomere deletions in cases with a 1p terminal deletion and a ring chromosome 14. The possible mechanism proposed for these rearrangements is pre-meiotic breakage-fusion-bridge cycles after random breakage. Our data provides further evidence for a common mechanism that involves duplication-deletion in cryptic telomeric rearrangements. Further detailed studies, such as FISH and sequence analysis of this breakpoint, will help to interpret this complexity and understand the mechanism underlying some terminal telomere imbalances.

Exhaustive analysis of non-coding DNA around *phox2b* reveals most biologically important sequences are not detected by sequence conservation. *D.M. McGaughey[1], R.M. Vinton[1], J. Huynh[1], A. Al-Saif[1], M.A. Beer[1,3], A.S. McCallion[1,2]* 1) Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 2) Department of Comparative Medicine, Johns Hopkins University School of Medicine, Baltimore, MD 21205, USA; 3) Department of Biomedical Engineering, Johns Hopkins University School of Medicine, Baltimore, MD 21205, USA.

Multi-species sequence conservation is one of the principal tools for the prediction of functional non-coding elements. However, it is unclear whether conservation-based approaches systematically overlook regulatory sequences and, if so, with what frequency. We have addressed this question directly through the construction of a tiling path comprising 33 amplicons across a genomic interval of 40.7 kb, encompassing the *phox2b* neurogenic transcription factor whose exons total 3.1 kb. All sequences therein, excluding the *phox2b* coding region, were functionally evaluated for enhancer activity via zebrafish transgenesis. 20 amplicons could be aligned with other species (Fugu / Tetraodon / Human / Mouse), of which 13 displayed enhancer activity in tissues overlapping endogenous *phox2b* expression. Of significant interest, four of the remaining 13 non-aligned amplicons also demonstrated tissue-specific expression. Analyses of this interval using established and novel algorithms resulted in the following observations. First, the established sequence conservation algorithms detected only 30-53% of the identified functional sequence elements. Second, functional and non-functional sequences in this interval could be discriminated using a de novo motif identification algorithm. Third, we identify functional non-coding sequences conserved between *phox2b* and the non-orthologous human *CART1* locus inferring their common ancestry, a theme we show is iterated at many other loci. Collectively, these data suggest that non-coding conservation between orthologous loci is frequently neither necessary nor sufficient to predict sequence functionality. Consequently efforts to decipher a regulatory vocabulary or search for regulatory variants associated with disease will be significantly impacted.

A targeted *Coch* missense mutation: a knock-in mouse model for DFNA9 late-onset hearing loss and vestibular dysfunction. *N.G. Robertson[1], S.M. Jones[2], T.A. Sivakumaran[1], A.B.S. Giersch[1], S.A. Jurado[1], M.C. Liberman[3], S.F. Maison[3], C.E. Miller[3], C.C. Morton[1]* 1) Dept OB/GYN & Pathology, BWH & Harvard Med School, Boston, MA; 2) Dept Communication Sciences & Disorders, East Carolina Univ, Greenville, NC; 3) Dept Otology & Laryngology, Mass Eye & Ear Infirmary, Eaton-Peobody Lab, Harvard Med School, Boston, MA.

Mutations in *COCH*, expressed at high levels in the inner ear, are etiologic for the late-onset hearing loss and vestibular dysfunction at the DFNA9 locus. To date, 11 mutations (10 missense and one in-frame deletion) have been found in *COCH*. To develop an animal model for DFNA9, we created a *Coch*$^{G88E/G88E}$ knock-in mouse. By RT/PCR and immunohistochemistry, we confirmed successful transcription and translation of the mutated Coch RNA and protein products. Vestibular evoked potential (VsEP) thresholds were analyzed using a two factor ANOVA (Age X Genotype) revealing significant main effects for age and genotype. VsEP thresholds at all ages tested (11-19 months) were elevated compared to wild-type littermates. At 19 months, one of four homozygous *Coch*$^{G88E/G88E}$ mice had no measurable VsEP. Age-related changes were also observed for both wild-type and affected mice; however, the affected homozygotes clearly showed elevated thresholds at every time-point tested. ABR threshold measurements at 11 months were identical at all frequencies for all genotypes. At 19 months, ABR thresholds for the *Coch*$^{G88E/G88E}$ mice were elevated by as much as 15 dB relative to age-matched wild-type; however, a two factor ANOVA was not significant. DPOAE amplitudes at 19 months were slightly reduced compared to controls, which were generally consistent with the elevated ABR thresholds. These results suggest that vestibular function, particularly gravity receptor function, is affected beginning as early as 11 months when cochlear function appears to be normal, and increases with age. Preliminary histological evaluation shows some degeneration of the type IV fibrocytes of the spiral ligament. Initial transcriptional profiling experiments have been performed and will be followed up further using both our own cDNA arrays and Affymetrix arrays.

Large-scale in Silico Mapping of Complex Quantitative Traits in Inbred Mice. *P.Y. Liu, H. Vikis, Y. Lu, D. Wang, M. You* Department of Surgery and the Alvin J. Siteman Cancer Center, Washington University, St Louis, MO.

Understanding the genetic basis of common disease and disease-related quantitative traits will aid in the development of diagnostics and therapeutics. The processs of gene discovery can be sped up by rapid and effective integration of well-defined mouse genome and phenome data resources. We describe here an *in silico* gene-discovery strategy through genome-wide association (GWA) scans in inbred mice with a wide range of genetic variation. We identified 937 quantitative trait loci (QTLs) from a survey of 173 mouse phenotypes, which include models of human disease (atherosclerosis, cardiovascular disease, cancer and obesity) as well as behavioral, hematological, immunological, metabolic, and neurological traits. 67% of QTLs were refined into genomic regions <0.5 Mb with ~40-fold increase in mapping precision as compared with classical linkage analysis. This makes for more efficient identification of the genes that underlie disease. We have identified two QTL genes, Adam12 and Cdh2, as causal genetic variants for atherogenic diet-induced obesity. Our findings demonstrate that GWA analysis in mice has the potential to resolve multiple tightly linked QTLs and achieve single-gene resolution. These high-resolution QTL data can serve as a primary resource for positional cloning and gene identification in the research community.

GENETIC TESTING AND COUNSELING FOR FSHD- THE WOLFSON EXPERIENCE 2000-2006. *M. Yanoov-Sharav[1,2], E. Leshinsky-Silver[2,3], C. Vinkler[1,2], M. Michelson[1,2], S. Cohen[3], T. Lerman-Sagie[2], M. Ginzberg[2], M. Sadeh[4], D. Lev[1,2]* 1) Institue of Medical Genetics, Wolfson Medical Center, Holon, Israel; 2) Metabolic Neurogenetic Clinic Wolfson Medical Center, Holon, Israel; 3) Molecular Genetics Laboratory Wolfson Medical Center, Holon, Israel; 4) Department of Neurology Wolfson Medical Center, Holon, Israel.

FSHD, is a dominantly inherited, late onset, progressive disease. At present, no treatment or prevention of symptoms are available. There is considerable clinical variability, even within families. There is clinical overlap between FSHD and other limb girdle muscular dystrophies. The gene causing FSHD has not been identified, but molecular diagnosis can be made by analyzing the length of the D4Z4 repeat area on chromosome 4q35. Results of DNA analysis can support or rule out the clinical diagnosis of FSHD, but there may also be non- conclusive, gray zone results. Prenatal diagnosis, PGD and pregnancy termination in cases of fetuses with the FSHD genotype are ethically controversial, and are offered only in a few centers in the world. METHODS: 66 individuals were tested for D4Z4 repeat number. 59 patients were referred due to clinical suspicion, 7 were asymptomatic and had a first-degree relative with FSHD. RESULTS: In 77% the results were conclusive. In 23% the results were in the gray zone (1 asymptomatic). 19 individuals (29%) received genetic counseling from our medical geneticists. Cognitive involvement was rare. One family exhibited genetic anticipation - a rare finding in FSHD. CONCLUSIONS: Only 77% of the cases allowed for unequivocal support or ruling out of this diagnosis. Maximal utilization of the existing molecular test for FSHD demands detailed clinical and family pedigree information. We recommend that genetic counseling by medical geneticists be given before and after molecular testing for FSHD, in addition to the neurological follow-up. Presymptomatic testing should only be offered after detailed counseling of the person to be tested and should not be recommended for young adults, still at high risk for becoming symptomatic.

Genome-scan with a quantitative phenotype identifies new genes for the susceptibility to schizophrenia. *F. Macciardi[1], J. Turner[2], D. Keator[2], L. Geronazzo[1], J. Fallon[2], S.G. Potkin[2]* 1) Dept Sci & Biomedical Technol, Univ Milano, Milano, MILANO, Italy; 2) University of California, Irvine, USA.

Introduction: Genome-wide scans are now feasible given new chip technology and genome coverage. Methods: Rather than beginning with a candidate gene and looking for an associated neural phenotype our approach begins with an imaging phenotype (related to left hemisphere DLPFC activation), and then determines the variability in genes that contribute to it. The discovery sample (n=28) was genotyped on the Illumina Human1 (109,365 gene-centered SNPs) and subjects in the verification sample (n=173) on the HumanHap300 (317,503 HapMap tagging SNPs). Results: Two genes, were identified by having at least one SNP whose QT analysis was significant at p < 10-8, with an empirical p-value of 10-6 by permutation. Four of the five top significant SNPs were on one gene (ps 10-8 to 10-6; empirical by permutation 10-6). A circuitry analysis revealed a consistent association between both genes and the prefrontal and dorsal neocortical circuits relevant to schizophrenia deficits. To establish if our method of gene discovery could successfully identify genes related to schizophrenia, we tested these SNP related to these two genes in an independent case-control study collected by the FBIRN consortium (www.nbirn.net). Fifteen SNPs in these genes are significant (< 0.05 to 10-5). Conclusions: Using a novel genome-wide screening strategy with brain activation as the quantitative phenotype we have discovered and verified the association of two genes with schizophrenia. Imaging-derived neural phenotypes are continuous, quantitative, richer than symptom-based diagnoses, and provide considerably more statistical power reflecting the greater penetrance of genetic effects at this more biologically proximate level.

Evidence for autosomal dominant inheritance of absolute pitch modulated by musical training. *E. Theusch[1,2], B. Levinson[2,3], E.A. Athos[2,3], J. Gitschier[1,2,3]* 1) Program in Biomedical Sciences; 2) Institute for Human Genetics; 3) Departments of Medicine and Pediatrics, University of California San Francisco, San Francisco, CA.

The etiology of absolute pitch, the rare ability to instantaneously recognize and label tones with their musical note names without using a reference note for comparison, has been debated for over a century. Familial aggregation and other data have indicated that absolute pitch has a genetic basis, but environmental factors, such as musical training, are also important for the development of absolute pitch. In order to confirm and expand upon these observations, we examined the collection of data from our web-based absolute pitch study on over 3,000 individuals to assemble twin data, to conduct pedigree analysis, and to investigate the associations of musical training initiation age, gender, and absolute pitch possession. In our study, 3 of 4 monozygotic twin pairs exhibited concordance for absolute pitch possession, while one individual in the remaining monozygotic twin pair had no musical training and therefore could not demonstrate any absolute pitch abilities. In comparison, 7 of 13 dizygotic twin pairs were confirmed or reported concordant for absolute pitch possession, while the remaining 6 were discordant. Our collection of pedigree and other family data was consistent with an autosomal-dominant-with-incomplete-penetrance mode of inheritance, and the majority of the instances where absolute pitch possession skipped generations involved individuals who did not receive musical training before the age of 10. Interestingly, the males in our study started musical training later than females on average, though we observed no significant differences in absolute pitch prevalence between genders. Overall, our data indicate that an individuals genetic makeup and musical training history are both important in determining whether or not the individual possesses absolute pitch.

Sequence-based bioinformatic prediction and QUASEP identify genomic imprinting of the KCNK9 potassium channel gene in mouse and human. *U. Zechner[1], S. Bähring[2], D. Galetzka[1], G. Plyushch[1], F.C. Luft[2], P. Nürnberg[3], T. Haaf[1], G. Kelsey[4], N. Ruf[5]* 1) Institute of Human Genetics, Johannes Gutenberg University Mainz, Mainz, Rheinland-Pfalz, Germany; 2) Franz Volhard Clinic, Charité, University Medical School, Berlin, Germany; 3) Cologne Center for Genomics and Institute for Genetics, University of Cologne, Germany; 4) Laboratory of Developmental Genetics and Imprinting, The Babraham Institute, Cambridge CB22 3AT, United Kingdom; 5) Max-Delbrueck-Center for Molecular Medicine, Berlin, Germany.

Genomic imprinting is the epigenetic marking of gene subsets resulting in monoallelic or predominant expression of one of the two parental alleles according to their parental origin. We describe the systematic experimental verification of a prioritized 16 candidate imprinted gene set predicted by sequence-based bioinformatic analyses. We used Quantification of Allele-Specific Expression by Pyrosequencing (QUASEP) and discovered maternal-specific imprinted expression of the Kcnk9 gene as well as strain-dependent preferential expression of the Rarres1 gene in E11.5 (C57BL/6 × Cast/Ei)F1 and informative (C57BL/6 × Cast/Ei) × C57BL/6 backcross mouse embryos. For the remaining 14 candidate imprinted genes, we observed non-imprinted biallelic expression. In adult mouse tissues, we found that Kcnk9 expression was restricted to the brain and also was maternal-specific. QUASEP analysis of informative human fetal brain samples further demonstrated maternal-specific imprinted expression of the human KCNK9 orthologue. The CpG islands associated with the mouse and human Kcnk9/KCNK9 genes were not differentially methylated but strongly hypomethylated. Thus, we speculate that mouse Kcnk9 imprinting may be regulated by the maternal germline differentially methylated region (DMR) in Peg13, an imprinted non-coding RNA gene in close proximity to Kcnk9 on distal mouse chromosome 15. Our data have major implications for the proposed role of Kcnk9 in neurodevelopment, apoptosis, and tumorigenesis, as well as for the efficiency of sequence-based bioinformatic predictions of novel imprinted genes.

Runs of homozygosity reveal highly penetrant recessive loci in schizophrenia. *T. Lencz[1,2,3], C. Lambert[4], P. DeRosse[1], K.E. Burdick[1,2,3], T.V. Morgan[5], J.M. Kane[1,2,3], R. Kucherlapati[5,6], A.K. Malhotra[1,2,3]* 1) Dept. of Psychiatry Research, Zucker Hillside Hosp, Glen Oaks, NY; 2) Dept of Psychiatry, Albert Einstein College of Medicine, Bronx, NY; 3) Feinstein Institute for Medical Research, Manhasset, NY; 4) Golden Helix, Inc., Bozeman, MT; 5) Harvard Partners Center for Genetics and Genomics, Cambridge, MA; 6) Dept. of Genetics, Harvard Medical School, Boston, MA.

Evolutionarily significant selective sweeps may result in long stretches of homozygous polymorphisms in individuals from outbred populations. We developed whole genome homozygosity association (WGHA) methodology to exploit this phenomenon and identify genetic risk loci for schizophrenia (SCZ). Applying WGHA to 178 SCZ cases and 144 healthy controls genotyped at 500,000 markers, we found that runs of homozygosity (ROHs), ranging in size from 200kb to 15MB, were common in unrelated Caucasians. ROHs did not appear to reflect regions of copy number variation, segmental duplication, or low recombination. ROHs appear to reflect regions undergoing positive selection; frequency of each ROH in healthy subjects was significantly correlated with other measures of positive selection, such as iHS ($P<5*10^{-10}$) and Tajima's D ($P<5*10^{-8}$).
ROHs were significantly more common in SCZ, and a set of nine ROHs significantly differentiated cases from controls. Each of these 9 risk ROHs included genes relevant to post-synaptic structure and/or neuronal survival, and four contained or neighbored genes previously associated with SCZ. Using logistic regression, total number of risk ROHs significantly predicted group status ($^2=62.6$, df=1, $P=2.5*10^{-15}$; permuted P=0.00095), with each additional risk ROH imparting an odds ratio of 2.83 (95%CI=2.10-3.81). Results suggest that recessive effects of relatively high penetrance at CNS-relevant loci may explain a proportion of the genetic liability for SCZ.

Identification of novel candidate genes associated with cleft lip and palate using array comparative genomic hybridization. *K. Osoegawa[1], G.M. Vessere[1], K.H. Utami[1], M.A. Mansilla[2], M.K. Johnson[2], B.M. Riley[2], J. L'Heureux[2], R. Pfundt[3], J. Staaf[4], W.A. Van der Vliet[3], A.C. Lidral[2], E.F.P.M. Schoenmakers[3], A. Borg[4], B.C. Schutte[2], E.J. Lammer[1], J.C. Murray[2], P.J. De Jong[1]* 1) Research Inst, Childrens Hosp Oakland, Oakland, CA; 2) Department of Pediatrics, University of Iowa, Iowa City, IA; 3) Department of Human Genetics, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands; 4) Department of Oncology, Lund University, Lund, Sweden.

We analyzed DNA samples isolated from individuals born with cleft lip and cleft palate to identify deletions and duplications of candidate gene loci using array comparative genomic hybridization (array-CGH). Of 83 syndromic cases analyzed we identified one subject with a previously unknown 2.7 Mb deletion at 22q11.21 coinciding with the DiGeorge syndrome region. Eighteen of the syndromic cases had clinical features of Van der Woude syndrome and deletions were identified in 5 of these, all of which encompassed the *interferon regulatory factor 6* (*IRF6*) gene. In a series of 104 nonsyndromic cases we found one subject with a 3.2 Mb deletion at chromosome 6q25.1-25.2 and another with a 2.2 Mb deletion at 10q26.11-26.13. Analyses of parental DNA demonstrated that the two deletion cases at 22q11.21 and 6q25.1-25.2 were de novo, while the deletion of 10q26.11-26.13 was inherited from the mother, who also has cleft lip. These deletions appear likely to be causally associated with the phenotypes of the subjects. *Estrogen receptor 1* (*ESR1*) and *fibroblast growth factor receptor 2* (*FGFR2*) genes from the 6q25.1-25.2 and 10q26.11-26.13, respectively, were identified as likely causative genes using a gene prioritization software. We have shown that array-CGH analysis of DNA samples derived from cleft lip and palate subjects is an efficient and productive method for identifying candidate chromosomal loci and genes, complementing traditional genetic mapping strategies.

Haploview: A computational tool for analysis and visualization of whole genome association data. *JB. Maller[1,2], D. Bender[1,2], J. Barrett[3], S. Purcell[1,2], MJ. Daly[1,2]* 1) Center for Human Genetics Research, Massachusetts General Hospital, Boston MA; 2) Broad Institute of Harvard and MIT, Cambridge MA; 3) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford UK.

Recent advances in technology have resulted in the generation of orders of magnitude more SNP genotype data. This increase has created a need for computational tools which can efficiently analyze and effectively visualize these large data sets. The linkage disequilibrium and haplotype analysis package Haploview has been extended to be a part of a complete set of tools for such whole genome association analysis. Here we describe the new functionality and integration with other tools which enable this type of analysis.

Approximate inheritance reconstruction using high density typing. *H. Yao, K. Markianos* Program in Genomics, Childrens Hospital, Boston, MA.

We present an approximate solution to the estimation of identity by descent probabilities in extended pedigrees and genetic isolates. We rely on the high information content of newer technologies such as high density SNP chips and re-sequencing. Traditionally, simultaneous consideration of hundreds of tightly linked markers requires application of the Lander-Green algorithm or the use of MCMC sampling methods. The approach we present here uses the Lander-Green algorithm only for local inheritance re-construction and error correction (within nuclear families). It relies on pedigree structure and population constraints to estimate sharing among two or more individuals. Estimation of identity by descent coefficients is computationally intensive but grows linearly with the number of individuals and it is well within currently available computer power. Although this is not an optimal approach, the high information content of the new generation of markers makes the results indistinguishable from the exact calculation in several cases of practical interest. We present the advantages and limitations of this approach using simulated as well as real 500k SNP data sets.

Asian mitochondrial DNA (mtDNA) lineages are associated with altered risk of developing type 2 diabetes and metabolic syndrome. *D.C. Wallace[1], L.-M. Chuang[2], P.H. Wang[3], Y.-C. Chang[2], O. Derbeneva[1], D. Mishmar[1, 4], M.L. L'vova[1]* 1) MAMMAG, University of California, Irvine, Irvine, CA; 2) Medicine, National Taiwan University, Taipei; 3) Medicine, University of California, Irvine, Irvine, CA; 4) Biotechnology, Ben-Gurion University, Beer-Sheva, Israel.

Since we first linked mtDNA mutations to Type II diabetes (T2DM) in a family study (Ballinger, S. et al, 1992, Nat. Genet. 1:11-15), increasing evidence has accumulated implicating mtDNA variation in the etiology of T2DM and the metabolic syndrom(MS). Functional mtDNA variation includes both recent inherited mutations but also ancient adaptive polymorphisms encompassed within region-specific mtDNA lineages (haplogroups, hplgrs)(Ruiz-Pesini, E. et al, 2004, Science 303:223-6). To determine if ancient mtDNA hplgrs might also influence risk for T2DM and MS, we studied 488 subjects from Taipei which had been evaluated for T2DM & MS. Taipei was selected because it encompasses a diverse array of Asian hplgrs in a population exposed to a high calorie diet. This analysis revealed that hplgr F4 was strongly associated with obesity including increased waist circumference (wc) and body mass index (BMI) (P0.01), F3 with increased wc; D with elevated systolic bloop pressure (SBP) and D5 with elevated triglycerides (TGs) and SBP (all P0.05). By contrast, N9a was associated with decreased fasting glucose (T2DM protective), in agreement with Fuku, N. et al (2007, AJHG 80:407-15), and low total cholesterol (P0.05), associations that were particularly strong in males (P0.01). Similarly, D5 and D4b were associated with reduced BMI and TG (P0.01) and M10 was associated with reduced TG, SBP & diastolic BP (P0.05). Hence, T2DM and MS risk can be influenced by ancient regional mtDNA polymorphisms, which migth help resolve definitional controversies of MS.

Principal components analysis of signs and symptoms of Schizophrenia: Development of quantitative trait phenotypes for linkage and association analyses. *J.A. McGrath[1], D. Avramopoulos[1, 2], V.K. Lasseter[1], P.S. Wolyniec[1], J.R. Luke[1], M.H. Thornquist[1], M.D. Fallin[3], K.Y. Liang[3], D. Valle[2], G. Nestadt[1], A.E. Pulver[1]* 1) Department of Psychiatry and Behavioral Sciences, Johns Hopkins University School of Medicine, Baltimore, MD; 2) McKusick Nathans Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 3) Bloomberg School of Public Health, Johns Hopkins University, Baltimore, MD.

Subjects with schizophrenia or schizoaffective disorder (SZ) experience a wide range of psychotic and behavioral signs and symptoms that are not pathognomic for these diagnoses. Data reduction techniques offer the possibility of defining a reduced number of dimensions to aid in the classification of more homogeneous groups of patients for linkage and association studies. Establishing the heritability of such dimensional phenotypes is an important first step. Principal components analysis was conducted in a sample of 1199 subjects with SZ (approximately half from European-Caucasian backgrounds and half from Ashkenazi Jewish background) using 73 dichotomous signs and symptoms from consensus diagnostic ratings and the Diagnostic Interview for Genetic Studies. Multiple imputation (Markov Chain Monte Carlo method) was used to impute missing data. Parallel Analyses and Velicer's Minimum Average Partial Correlation test provided statistical support for from 8 to 15 factors: a reasonable 9 factor solution (with varimax rotation) demonstrated basic similarities to a number of earlier studies. Sub-analyses revealed similar solutions for both ethnic groups. Heritability analyses of the 9 sets of factor scores using SAGE ASSOC software demonstrated significant estimates: affective 0.46; child/adolescent sociability 0.352; disorganization 0.582; hallucinations 0.427; impaired / disabled 0.51; negative 0.521; positive 0.365; prodromal 0.421; school / developmental 0.381. These quantitative traits will be used in both linkage and association studies.

The Methylation Status of Transcribed Alu Repeats in Neuroblastoma Cell Lines. *L. Manzella, J. Bischof, M.F. Bonaldo, M.B. Soares* Cancer Biology and Epigenomics, Children's Memorial Research Center, Chicago, IL.

DNA methylation is tightly associated with gene expression. Alterations in DNA methylation are one of several mechanisms involved in cancer development and progression. One epigenetic alteration typically associated with cancer is genome-wide hypomethylation which can de-repress the transcription of oncogenes and retrotransposable elements. It is known that retrotransposition and transcription of retroelements are highly suppressed in somatic and mature germ cells by hypermethylation of those elements, avoiding de novo retrotransposition. Our hypothesis is that the hypomethylation and subsequent transcription of Alu repeats in cancer cells could result in retrotransposition events and thus interfere with gene expression. In order to have a better understanding of the correlation between Alu expression and methylation in somatic cancer cells, we selected transcribed Alu repeats (tAlu) in an aggressive neuroblastoma cell line (LA1-55n). This selection allowed us to identify 136 clones that met strict criteria and gave us a high level of confidence to assign the tAlus localization in the genome. The tAlus identified were mapped to ninety-nine genes, twenty-one in intergenic regions and sixteen in ESTs, including clusters in all categories. The localization in genes included: thirty-four within 3 UTRs, fifty-nine in intronic regions, five in an intron /3UTR, and one in an intron/exon region. We are currently in the process to validate the Pol III transcription by specific RT-PCR. The methylation patterns of fourty-three tAlus have been analyzed using by bisulfite conversion methodology. We intend to concentrate our analysis at first, onto the Alu promoters regions (A and B boxes) of the verified ones. Our further analyses will include compare the methylation patterns of each CG position among the tAlus to identify whether some specific positions play a role in expression.

Molecular characterization of deletion breakpoints in the CREBBP gene. *D. Simon[1], C. Rooryck[1,2], M. Stef[1], D. Lacombe[1,2], I. Coupry[1], B. Arveiler[1,2]* 1) Human Genetics Laboratory, Université Victor Segalen Bordeaux 2, Bordeaux, France; 2) Service de Génétique Médicale, CHU de Bordeaux, Bordeaux, France.

The Rubinstein-Taybi syndrome (RTS) is a rare autosomal-dominant disease caused by mutations in the CREB-binding protein (CREBBP), and more rarely the EP300, genes. RTS is known to be associated with CREBBP deletions in 10-15% of cases. Using array-CGH and quantitative multiplex fluorescent (QMF) PCR analysis we have shown that rearrangements occur in fact in about 20% of patients, and that the deletions sizes range between 1245 bp and 6.5 Mb. We are now aiming to unravelling the mechanisms involved in these rearrangements. The repeated occurrence of breakpoints in some segments of the gene and surrounding region raises the possibility that particular sequences such as segmental duplications or repeated sequences are involved in these rearrangements. In order to investigate this, we have started sequencing the breakpoints of 13 CREBBP intragenic rearrangements. We have so far sequenced the breakpoints of six deletions the sizes of which range between 1245 and 48327 bp. One is a complex rearrangement involving a deletion and the insertion of a 435bp element located about 3 kb away from the deleted segment. No particular sequence was identified at or next to the corresponding breakpoints. In one case, the sequences flanking both breakpoints corresponded to AluSx and AluSc elements sharing 30 bases with 100% identity. In another case the identity was restricted to 5bp in an AluSx and a MIR3-type SINE, and in another one, 7bp were shared between an AluSx element sitting next to one of the breakpoints and an AluSg element located some 250 bp away from the other breakpoint. In the last two cases no homologous sequences could be identified. The other seven rearrangements are currently being characterized. The results obtained so far indicate that Alu sequences are frequently involved in CREBBP intragenic rearrangements. No segmental duplication was identified so far. We shall also characterize the extragenic breakpoints. From a mechanistic point of view, it will be interesting to see whether the large deletions are caused by different mechanisms from the smaller intragenic ones.

Renal carnitine reabsorption in primary and secondary carnitine deficiency. *M.G. Lloyd[1], R. Guymon[2], P. Jungerberg[2], N. Longo[1,2,3], M. Pasquali[1,2,3]* 1) ARUP Inst for Clin and Exp Pathology, Salt Lake City, UT; 2) ARUP Laboratories; 3) Univ Utah, Dept. of Pathology.

Primary carnitine deficiency, a recessive disorder caused by defective OCTN2 carnitine transporters and affecting long-chain fatty acid oxidation, can present with hypoketotic hypoglycemia and/or cardiomyopathy. Affected patients have very low plasma carnitine levels due to increased renal losses. Asymptomatic mothers with primary carnitine deficiency are identified because of low carnitine levels in their infants by newborn screening. Here we evaluate renal carnitine and amino acid reabsorption in adults with primary carnitine deficiency. We analyzed plasma and urine samples from 3 mothers and one child with primary carnitine deficiency, patients with secondary carnitine deficiency due to other metabolic disorders and normal controls. Free and total carnitine concentrations were measured by tandem mass spectrometry. Amino acids were measured by ion-exchange chromatography. Reabsorption of free and total carnitine and individual amino acids for each patient was calculated as percent of filtered load estimated from creatinine clearance. Reabsorption of urinary free and total carnitine was 99.80.4% and 98.61.4%, respectively, in our controls (7 months-43 years of age). By contrast, three asymptomatic mothers with primary carnitine deficiency had free and total carnitine reabsorption reduced to 69.72% and 712.5% ($p<0.01$ vs. controls), respectively. Urinary free and total carnitine reabsorption was <20% in a symptomatic 13 year old patient with primary carnitine deficiency. Carnitine reabsorption was comparable to that of normal controls in patients with secondary carnitine deficiency. The average reabsorption of all amino acids was 93.77.4%, with no significant differences between normal controls and patients with primary or secondary carnitine deficiency. The quantitative study of urine carnitine reabsorption can distinguish primary from secondary carnitine deficiency. Asymptomatic adult mothers with primary carnitine deficiency have higher residual carnitine reabsorption than that classically described in symptomatic children with primary carnitine deficiency.

Searching for recessive alleles in Kosrae, an inbred island population. *J.K. Lowe[1,2,3], J.B. Maller[1,2], I. Pe'er[4], B.M. Neale[1,2], J. Salit[3], E. Kenny[3], M. Noel[3], R. Burkhardt[3], W. Ji[5], J.-N. Foo[5], R. Tewhey[1], P.E. Bonnen[3], N.P. Burtt[1], R.P. Lifton[5], J.L. Breslow[3], M.J. Daly[1,2], M. Stoffel[3], D.M. Altshuler[1,2,6], J.M. Friedman[3,7]* 1) Broad Institute of Harvard and MIT, Cambridge, MA; 2) Massachusetts General Hospital, Boston, MA; 3) The Rockefeller University, New York, NY; 4) Columbia University, New York, NY; 5) Yale University School of Medicine, New Haven, CT; 6) Harvard Medical School, Boston, MA; 7) Howard Hughes Medical Institute.

Geographic isolation and severe population bottlenecks produced an order of magnitude more extensive linkage disequilibrium in natives of the island of Kosrae, Federated States of Micronesia, than that seen in HapMap Asians or Caucasians. In screenings performed in 1994 and 2001, we ascertained 75% of the adult population of Kosrae (n 3200 individuals) for traits related to Metabolic Syndrome, including obesity, dyslipidemia, and hypertension. Subjects were genotyped with the Affymetrix 100k and 500k SNP assays. We developed association methods to analyze this unique cohort in which 98% of genotyped subjects can be joined in a single extended pedigree and performed whole-genome association studies for BMI, plasma lipids, blood pressure, and other traits.

We also note that native Kosraens are dramatically more homozygous than HapMap Asian populations. Homozygous segments of 1 Mb make up an average of 5.2% of the Kosraen genome, compared to 0.6% in HapMap Asians. This unusual degree of homozygosity greatly facilitates the identification of recessive alleles contributing to global trait variation. We observe no correlation between an individuals % homozygosity and quantitative trait value. We attempted homozygosity mapping in the Kosraen cohort and report findings from locus-specific tests of association between homozygous segments and trait variation.

A complex chromosome rearrangement in three generations : reproductive risk, meiotic pairing and phenotype-karyotype correlation. *J. Puechberty, A. Schneider, A.M. Chaze, P. Sarda, G. Lefort, P. Blanchet* Service de génétique médicale, Hôpital Arnaud de Villeneuve CHU Montpellier , Montpellier, France.

Complex chromosome rearrangements (CCRs) are uncommon events generally defined as involving two or more chromosomes and at least three breakpoints. Familial forms are rare and usually associated with a history of infertility, recurrent miscarriage and abnormal phenotype. The advent of multicolor FISH studies and more recently microarray technologies has greatly aided the characterization of CCRs. We report on three generations of relatives with a familial CCR. The rearrangement was ascertained through an unbalanced product during the first pregnancy of a clinically healthy mother. Initial chromosome studies with classical RHG banding techniques suggested that the healthy mother was the carrier of an apparently balanced simple three-way exchange translocation t(7q;12q;17q). This rearrangement was later found to be inherited from her mother. Multicolor FISH studies subsequently identified an additional event : chromosome painting revealed that the interstitial segment between 12q21and 12q22 was translocated onto 7q34, thus modifying the initial karyotype interpretation. The healthy mother has a brother with mental retardation and an unbalanced karyotype. She has a history of 3 pregnancies terminated because of unbalanced karyotypes as well as one spontaneous abortion. She gave birth to a healthy girl with a normal 46,XX karyotype and is presently pregnant for the 6th time. Amniocentesis was performed and the female fetal karyotype shows the apparently balanced maternal rearrangement. We discuss the reproductive risk, pachytene configuration and phenotype-karyotype correlation of this CCR.

CGH microarray analyses in Proteus syndrome. *M.J. Lindhurst[1], J.J. Johnston[1], S.J. Vacha[2], L.G. Biesecker[1]* 1) GDRB, NHGRI/NIH, Bethesda, MD; 2) Agilent Technologies, Inc. Santa Clara, CA.

Proteus syndrome (PS) is a rare sporadic disorder that is characterized by overgrowth of multiple tissues. It is highly variable; patients have a mosaic distribution of lesions that progressively worsen with age. The hypothesis is that a genetic alteration occurs post-zygotically that results in growth dysregulation in tissues derived from the mutant cell. Because the disorder is not inherited, traditional methods for studying genetic diseases are not amenable to studying PS. We hypothesize that a subset of patients has a genomic scale duplication or deletion that causes overgrowth. We have used oligo-based CGH microarray technology to compare genomic DNA extracted from several types of patient tissue. Most comparisons were done using DNA extracted from affected and unaffected areas of the same patient using either cultured cells or DNA extracted directly from affected tissue samples. In addition, three comparisons were done between affected DNA and standard reference DNA. Initially, 14 hybridizations were performed using a CGH microarray platform containing 244K probes. Analyses of these arrays yielded no obvious aberrations, however, there were 529 regions with high LogRatio changes. To confirm these results and further characterize these regions, custom 4 x 44K oligo arrays were designed that zoomed in on each of these areas. Probes that were located within 15 Kb to either side of the probe of interest were chosen for the custom array resulting in 50-80 probes per region. Twelve hybridizations with the DNAs labeled with the opposite fluor were repeated using the custom 44K zoom-in array. Over 185 regions still remain with one or more probes that have an amplification or deletion score of 0.5 or more. Several criteria can be chosen to use for prioritizing follow up studies. However, all have caveats making the choice difficult. The sporadic, mosaic characteristics of PS provide an added challenge in interpreting high-resolution screening technologies, as any single probe outlier could be worthy of further study. We propose to share this data set collaboratively with other investigators to allow a thorough and rational approach to follow-up studies.

A Defect in the Thymidine Kinase 2 Gene without mtDNA Depletion. *C. Vinkler[1,3], E. Leshinsky-Silver[2,3], M. Michelson[1,3], S. Cohen[2], M. Ginzberg[3,4], M. Sadeh[5], V. Barash[6], T. Lerman-Sagie[3,4], D. Lev[1,3]* 1) Institute of Medical Genetics, Wolfson Medical Center, Holon, Israel; 2) Molecular Genetics lab, Wolfson Medical Center, Holon, Israel; 3) Mitochondrial Disease Center, Wolfson Medical Center, Holon, Israel; 4) Pediatric Neurology Unit, Wolfson Medical Center, Holon, Israel; 5) Neurology Department, Wolfson Medical Center, Holon, Israel; 6) Metabolic Unit, Hadassah Medical Center, Jerusalem, Israel.

Isolated mitochondrial myopathies are either due to primary defects in mtDNA, or in nuclear genes that control mtDNA abundance and structure such as Thymidine kinase or due to CoQ deficiency. Defects in the thymidine kinase 2 gene have been found to be associated with mtDNA depletion attributed to a depleted mitochondrial dNTP pool in non-dividing cells. We report an unusual case of isolated mitochondrial myopathy, homozygous for the H90N mutation in the Thymidine kinase2 gene but unlike other cases with the same mutation, does not demonstrate mtDNA depletion. The patient's clinical course is relatively mild and a muscle biopsy showed ragged red muscle fibers with a decrease in complexes I and III and increased Complex IV activities. This report extends the phenotypic expression of TK2 defects and suggests that all patients who present with an isolated mitochondrial myopathy even with normal quantities of mtDNA should be screened for TK2 mutations.

Utility of SNPs within restriction endonuclease sites for improved identification of circulating free fetal DNA in maternal plasma. *J.A. Tynan, M. Ehrich, E. Dragon, D. van den Boom* SEQUENOM, Inc., 3595 John Hopkins Court., San Diego, CA 92121.

Universal methods to confirm the presence of circulating, free fetal DNA in maternal plasma would improve the clinical application of fetal genotyping assays such as those for fetal RHD and gender assessment for X-linked recessive disorders. Previously, we evaluated the detection of paternally inherited SNP alleles as a universally applicable method to detect fetal DNA in maternal plasma. Because fetal DNA constitutes only 3-6% of the DNA in maternal plasma, the utility of detecting paternally inherited fetal SNP alleles is largely dependent on methods enriching for fetal DNA. Here, we incorporate the use of restriction endonucleases (REs) to enhance the detection of specific SNP alleles present at low relative concentrations in DNA mixtures. A panel of SNPs was screened for the presence of RE recognition sites altered by one SNP allele, and for the absence of additional instances of the same RE site within +/- 50 base pairs of the SNP. Primer extension genotyping assays using mass spectrometric analysis were designed for SNPs meeting these criteria. Prior to PCR, DNA was incubated with or without RE in PCR master mix at each REs optimal temperature. DNA was amplified by PCR and genotyped with the TypePLEX assay using the Compact MassArray system. Maximal digestion of heterozygous SNP alleles in genomic DNA could be obtained using 0.25 U RE in PCR buffer with incubation for 15 minutes. Using a model system of DNA mixtures comprising 2, 5, 20, and 50 % DNA heterozygous for a given SNP in a balance of RE cleavable, homozygous DNA, RE digestion allowed detection of the non-cleavable, heterozygous derived SNP allele in all mixtures. Without RE digest, this allele was not detectable in the 2 and 5 % DNA mixtures. These results show the utility of RE enhanced detection of SNP alleles present in low relative concentration in a DNA mixture. Incorporation of this method to detect paternal SNP alleles in maternal plasma will improve confidence in negative genotype calls where the presence of fetal DNA can not otherwise be confirmed.

Association between invasive ovarian cancer and alleles involved with breast cancer and prostate cancer susceptibility. *H. Song[1], S. Ramus[2], S.K. Kjaer[3], R.A. DiCioccio[4], L. Quaye[2], E. Hogdall[3], A.S. Whittemore[5], D.E. Easton[6], C.L. Pearce[7], G. Chenevix-Trench[8], S.A. Gayther[2], P. Pharoah[1]* 1) Department of Oncology, University of Cambridge, UK; 2) Translational Research Laboratories, University College London, London, UK; 3) Danish Cancer Society, Copenhagen, Denmark; 4) Roswell Park Cancer Institute, Buffalo, NY, USA; 5) Stanford University School of Medicine, Stanford, USA; 6) Genetic Epidemiology Unit, University of Cambridge, UK; 7) University of Southern California, Keck School of Medicine, Los Angeles, CA, USA; 8) The Queensland Institute of Medical Research, Post Office Royal Brisbane Hospital, Australia.

Background: Several alleles have recently been identified by genome-wide association study in hormone related cancers (breast and prostate cancer). The aim of this study was to test these alleles for association with invasive ovarian cancer.

Methods: Eleven breast cancer associated SNPs and 2 prostate associated SNPs were genotyped in approximately 2400 invasive ovarian cancer cases and 4100 controls from 6 studies (from Australia, UK, Denmark and USA). Genotype frequencies in cases and controls were compared using a likelihood ratio test in a logistic regression model stratified by studies.

Results: Three of 13 SNPs showed a weak association with ovarian cancer: carriers of the minor allele of rs2107425 (*H19*) were at reduced risk (per-allele odds Ratio (OR)=0.92[0.85-0.99], P-trend=0.03); and the minor allele of rs7313833 (*PTHLH*) was associated with increased risk (per-allele OR=1.09[1.01-1.18], P-trend= 0.02). In analyses restricted to serous ovarian cancer, carriers of the minor allele of rs4954956 (*NXPH2*) were associated with increased risks (per allele OR=1.12[1.01-1.24], P-trend=0.03).

Conclusions: The 5 most significant SNPs from breast cancer study and 2 SNPs from prostate cancer study were not associated with ovarian cancer. However, 3 of the remaining 6 showed association with ovarian cancer which warrant confirmation in independent studies.

Nevo-like phenotype, not associated to lysyl hydroxylase deficiency: a new form of overgrowth syndrome? *G. Scarselli, M. Ottaviani, N. Dayan, A. Zeffiri, E. Lapi, S. Guarducci, M.L. Giovannucci Uzielli* Dept. Paediatrics, Genetics, University of Florence, Firenze, Italy.

We report on three unrelated patients, one female and two males, affected with Nevo syndrome, a rare autosomal recessive disorder, characterized by increased pre- and post-natal length, generalized joint laxity, muscular hypotonia, hyrsutism and moderate mental retardation. In two cases, the parents are consanguineous. For the three cases, pregnancy and delivery were referred at term, with birth weight and length >97th centile. Severe hypotonia was also referred for the three subjects, at birth and during the first 2 years of life. The three patients displayed tall stature, dolicocephaly, kyphosis, large hands and feet, spindle-shaped fingers, hirsutism and hypermobility of the large joints. The psychomotor developmental milestones were delayed: independent walk at the age of 2 years, and delayed cognitive and language development with a progressive, slow improvement. One of the patients was included in a long follow-up programme. At age 28 year, sudden rupture of the left iliac artery occurred, and repaired surgically. The aortic diameter is extremely reduced , especially at the abdominal level, with a manifest dilation at the iliac fork. In 2005, Nevo syndrome was recognized as allelic to the EDS VIA, an inherited connective tissue disorder characterized by a deficiency of lysyl hydroxylase due to mutations in PLOD1 gene. In this patient, the ratio of total urinary lysylpyridinoline (LP) to hydroxylysyl pyridinoline (HP) was normal, excluding mutations in the PLOD1 gene. The same dosage is programmed for the two other subjects, who present a clinical spectrum strictly overlapping to that of the oldest of our patient.

Multiplex Ligation-dependent Probe Amplification analysis identifies ENG and ALK1 deletions in Hereditary Hemorrhagic Telangiectasia. *T.G.W Letteboer[1], M. Tjong-Pon-Fong[1], C.J.J Westermann[2], J.J. Mager[2], R.J. Snijder[2], J.K. Ploos van Amstel[1]* 1) Medical Genetics, University Medical Center Utrecht, Utrecht, Netherlands; 2) St.Antonius Hospital, Nieuwegein, Netherlands.

Hereditary Hemorrhagic Telangiectasia (HHT) is an autosomal dominant disorder characterized by vascular malformations in multiple organs, resulting in mucocutaneous telangiectases and arteriovenous malformations, predominantly in the lungs (PAVM), brain (CAVM) and liver (HAVM). Mutations in the ENG gene and ALK1 (ACVRL1) gene cause HHT1 and HHT2 respectively. In 2004, SMAD4 mutations have been found to cause the combination of HHT and Juvenile Polyposis and recently two possible other loci were associated with HHT. In our laboratory in a population of HHT probands with a diagnosis according to the Curacao criteria(telangiectases, epistaxis, AVM, first degree relative with HHT), mutations in ENG or ALK1 were detected in more than 90% of the HHT families. Here we report on the results of DNA analysis performed in all HHT patients since the start of the DNA analysis in HHT. Analysis was performed in 302, apparently unrelated, probands. Of 42% of these, the presence of HHT symptoms was not well described. Mutation analysis was performed using direct sequencing of both ENG (exons 1-14) and ALK1 (exons 1-10). In probands without a mutation, subsequent Multiplex Ligation-dependent Probe Amplification (MLPA) was performed. In the ENG gene 112 probands showed 69 different pathogenic mutations. Two probands showed deletions identified by MLPA: one deletion of exon 3 and one deletion consisting of exons 3-14. In the ALK1 gene 87 probands showed 50 different pathogenic mutations. One deletion was detected, encompassing exons 2-8. No pathogenic mutations were identified in the remaining probands. These results indicate that large rearrangements are rare in both ENG (2.9%) and ALK1 (2.0%) and do not add significantly to the mutation detection rate. Secondly, when DNA analysis is performed in probands with confirmed diagnosis according to the Curacao criteria, the detection rate is high, whereas, when uncertainty exists on the clinical diagnosis, the mutation detection rate decreases significantly.

Association patterns of 5290 SNPs in the type 2 diabetes 1q linkage region in eight populations. *I. Prokopenko[1], E. Zeggini[1], N.W. Rayner[1], C.J. Groves[1], R. Hanson[2], B. Mitchell[3], J. O'Connell[3], M. Vaxillaire[4], W. Jia[5], M. Ng[6], W. Knowler[2], L. Baier[2], P. Froguel[4], J. Chan[6], P. Deloukas[7], L. Cardon[1], C. Bogardus[2], S. Elbein[8], A. Shuldiner[3], M. McCarthy[1], Type 2 diabetes 1q consortium* 1) WTCHG, Oxford, United Kingdom; 2) Phoenix, AZ; 3) Baltimore, MD; 4) Lille, France; 5) Shanghai, China; 6) Hong Kong; 7) Hinxton, UK; 8) Little Rock, AR.

High density linkage disequilibrium mapping of the 1q linkage region in type 2 diabetes (T2D) was performed in 8 populations (Amish, Utah, UK, French, Hong Kong, Shanghai, African Americans and Pima Indians). 5290 SNPs passed stringent quality control criteria across all datasets in the 22.7Mb candidate region (147.0-169.7Mb, NCBI35, average SNP density ~4.3kb). A total of 1527 T2D cases and 1653 controls were analysed. The proportion of common variation captured on the basis of HapMap was: 80% in CEU, 50% in YRI, 72% in CHB+JPT (pairwise evaluation at r2>=0.8). Population-specific single-point analyses and Mantel-Haenszel-based meta-analyses across 8 populations were performed under the additive and dominant/recessive models. Meta-analysis across all populations identified highly significant associations with T2D for 4 SNPs (combined p<5E-05) from two 1q subregions. Minor allele frequencies (MAF) range from 0.12 to 0.49. The first cluster (3 SNPs) resides in the region of extended LD at 152.0-152.4Mb that includes the *GBA*, *PKLR* and *ASH1L* genes. The strongest association was observed for rs11264372, in the 4th intron of *ASH1L* (OR for allele G 1.39[95%CI1.19-1.62] under the dominant model p=2.5E-05). The second cluster resides within *NOS1AP* (*CAPON*) at ~158.8Mb (allele A of rs7548169, dominant model (OR=1.40[95%CI1.19-1.66] p=4.8E-05). This SNP lies in the 1st intron of NOS1AP, within the same LD block (27kb) as 3 further SNPs associated with p<1E-04. Although MAFs vary between datasets, the direction of the effect was the same in all populations. Association analyses of high-density genotyping in the 1q candidate region for T2D identified several common polymorphisms within two regions of high LD, with the strongest signals residing in the *ASH1L* and *NOS1AP* genes.

Insertion/Deletions as Control Markers for Fetal DNA Detection in Non-Invasive Prenatal Diagnostic Assays. *P. Mahboubi, T. Shi, B. Dragon, D. van den Boom, P. Oeth* Research and Development, Sequenom, San Diego, CA.

The discovery of fetal DNA in maternal plasma has driven development of non-invasive prenatal diagnostic genotyping assays. A technical challenge of this method is to ensure that a negative test result of a disease linked genomic region is truly a negative, not due to insufficient fetal DNA. We have developed a method, using common insertion/deletions (I/D), coupled with allele specific PCR (ASP), to detect fetal DNA, independent of gender, in all samples. To determine how many highly polymorphic I/D assays are needed to detect at least 3 fetal identifier markers in a maternal background, probability calculations were carried out assuming a deletion allele frequency of 0.38 and that only 2 of the 9 possible genotypes of the fetus are informative (I/D where the father is a heterozygote I/D, I/D where father is homozygote I/I). Modeling using these assumptions shows that 90 assays are needed to detect at least 3 fetal identifiers with a confidence greater than 0.99. Based on these calculations 231 I/D polymorphisms, with minor allele frequencies (MAF) greater than 0.30, were obtained. PCR assays were designed into 21-plex reactions using Sequenom Assay Design 3.1 software and genotyped using the TypePLEX reaction on the MassARRAY system (Sequenom). Assays were tested on 23 CEPH DNAs and allele frequencies confirmed on the 90 CEU HapMap DNAs. Robust assays with a MAF of 0.38 or higher were redesigned into 32-plex reactions as ASP assays by overlapping the 3 end of the forward primer with the I/D region (Sequenom QGE Assay Design Software). To mimic detection of fetal DNA against a maternal DNA background, working assays were successfully tested on mixes of an insertion-containing DNA in a deletion DNA background with insertion DNA ranging from 40% to as low as 5% of the total DNA (1000 copies). Our data to date shows that these assays function properly on targets regions composed of 5% of total DNA (50 copies in a background of 950 copies) and establishes the use of common I/Ds as control markers or Fetal Identifiers as a viable and robust method to control for false negative results in the emerging field of non-invasive prenatal diagnostics.

A 46,XX male with bilateral ovotestes and no detectable SRY in peripheral blood or gonadal material. *JJD. Morrissette[1], D. Paduch[2], JP. de Chadarévian[1], F. DeLuca[3], T. Shaikh[4], R. Steckler[5]* 1) Dept Pathology & Lab Medicine, St Christopher's Hospital for Children, Philadelphia, PA; 2) Dept Urology, Weill Medical College of Cornell University, Population Council Center for Biomedical Research, New York, NY; 3) Section Endocrinology, St Christophers Hospital for Children, Philadelphia, PA; 4) Dept Human Genetics, Childrens Hospital of Philadelphia, University of Pennsylvania School of Medicine, Philadelphia, PA; 5) Section Urology, St Christophers Hospital for Children, Philadelphia, PA.

We present a 4 year-old boy with normal male external genitalia, a 46,XX karyotype in peripheral blood, as well as left and right gonad, and left and right scrotal skin. The patient came to medical attention with a history of right testicular pain, intermittent over the past year. Physical examination revealed a red, swollen right scrotum. Ultrasound evaluation seemed consistent with right testicular torsion, with the right scrotum appearing atrophic and fixed. Surgical exploration revealed multiple matted masses adjacent to the right testicle, that grew Stapholococcus aureus. Gross examination identified a small hydrocele, an abnormal appearing right testicle, and an epididymis that looked abnormal and enlarged, which prompted genetic evaluation. Cytogenetic studies revealed a 46,XX karyotype in peripheral blood, which was SRY-negative by fluorescence in situ hybridization (FISH). Biopsy material from both gonads revealed ovotestes bilaterally, with ovarian follicles adjacent to testicular structures consisting of seminiferous tubules with no conspicuous Leydig cells. No primordial germ cells or spermatogonia were identified. Molecular genetic and cytogenetic studies confirmed that both gonads and scrotal skin were 46,XX and SRY negative in over 500 cells studied from each tissue. Nested PCR failed to identify SRY or Y sequences in peripheral blood or tissue from either gonad. Array CGH from gonadal tissue demonstrated an apparently normal female karyotype. This represents a rare case of a true gonadal hermaphrodite with normal male external genitalia, apparently normal female karyotype, and no demonstrable SRY.

The Role of Neuroligin Genes in Autism Spectrum Disorder. *K. Meltz Steinberg, M.E. Zwick* Department of Human Genetics, Emory University, Atlanta, GA.

Neuroligins are cell adhesion molecules important in the post-synaptic density. A number of recent studies identified mutations in the X-linked genes neuroligin 3 (NLGN3) and 4X (NLGN4X) that contribute to autism spectrum disorder (ASD), while other studies have failed to replicate these findings. In order to reconcile these results while identifying all rare and common genetic variation that may contribute to ASD, we are comprehensively resequencing the NLGN3 and NLGN4X genes in individuals from families with two or more affected male sibpairs from the Autism Genetic Resource Exchange (AGRE). Affected male sibpairs were chosen based upon sharing identical markers near NLGN4X (DXS9895 and 9902) with each other as well as with their mother. One male from each sibpair was selected for resequencing. The fathers of the affected males were selected as controls. A total of 314 affected and 314 control males are being resequenced. We designed a high density oligonucleotide resequencing array (RA) containing all of the unique sequences from NLGN3 and NLGN4X. Additionally we included the exon sequences of the neurexin-1beta (NRXN1b) and SHANK3 genes, autosomal genes that encode proteins that bind to neuroligins. Our Microarray-based Genomic Selection (MGS) protocol is being used to isolate target DNA from each patient sample. SNPs identified in our study are partitioned into functional classes (UTR, silent, replacement, intron, intergenic) and compared within and between these classes. Additionally, by using population genetics tests we are able to identify those rare SNPs in replacement sites that are most likely to cause functional changes in the protein. We are also able to identify if changes in conserved non-coding sequences that may be functional using comparative genomics. Data will be presented from the initial 115 affected-control dyads.

A comparison of the fine mapping accuracy of several similarity measures in the framework of Bayesian Partition Models allowing for unphased genotypes. *YQ. Luo[1], SH. Won[1], RC. Elston[1], TS. Park[2]* 1) Epidemiology & Biostatistics, Case Western Reserve Univ, Cleveland, OH; 2) Department of Statistics, Seoul National University, Korea.

Linkage disequilibrium fine mapping can be performed using coalescent-based or haplotype-clustering-based approaches. We have demonstrated, in our previous work, that the current implementation of the latter approach in the Bayesian Partition Models (BPM, Waldron et al. [2006]) is at least as efficient in localization as the coalescent-based approaches, while being much more computationally manageable. The performance of the BPM framework depends on the choice of similarity measures between haplotypes, based on which the haplotypes are clustered. A good similarity measure should be able to capture the evolutionary events well. We compare several similarity measures proposed in the literature in other context, as well as some combinations thereof, in terms of their fine mapping accuracy in the BPM framework. We also extend the BPM framework to handle phase-unknown genotypes via a Metropolized Gibbs algorithm. A non-informative prior is employed so that the estimates are approximately equal to maximum likelihood estimates (MLE). An extensive simulation study shows that our new algorithm improves the accuracy of causal SNP localization.

FISH in Suspension Applied to Interphase Aneuploidy and Metaphase Quantification. *X. Wu[1,2], L.M. Whelchel[1], ZH. Chen[3], J.N. Lucas[1]* 1) ChromoTrax, Inc, Frederick, MD; 2) Union Hospital, Huazhong University of Science and Technology, Wuhan, Hubei, China; 3) University of Utah, Salt Lake City, UT.

The detection sensitivity of classical fluorescence in situ hybridization (FISH) performed on slides is 1 in 100-1000 cells. PCR is very sensitive, but lack of very accurate quantification still is a problem. By contrast, our innovative approach will greatly facilitate accurate and quantitative detection of chromosomal aberrations. It will significantly increase the speed of analysis and number of samples that can be analyzed. Our techniques include a novel approach of hybridizing chromosomes in suspension with fluorescently-labeled DNA probes in combination with flow cytometric analysis, in order to sensitively, precisely and rapidly quantify chromosomal abnormalities. Firstly, we demonstrated the efficacy of our approach for interphase cell analysis by detecting aneuploidy in trisomy 21 human cells with a DNA probe specific for chromosome 21q. For direct comparison, FISH in suspension and FISH on slides were performed simultaneously on cells from four normal controls and four patients with Down syndrome. In the normal group, the average percentages of cells with two signals between FISH in suspension and on slides were 75.4% vs. 74.5%, and in the trisomy 21 group the average percentages of cells with three signals between FISH in suspension and on slides were 73.1% vs. 73.6%. These findings strongly indicate that our interphase FISH in suspension approach is able to generate similar efficacy as standard FISH in detecting numerical chromosome abnormalities. Secondly, we demonstrated that flow cytometry could be used to detect and analyze FISH signals on chromosomes hybridized in suspension. We measured the frequency of chromosome 1 using flow after FISH in suspension and determined the detection sensitivity using serial dilution. The sensitivity was measured to be within one in 10,000. These experiments demonstrate: (1) The hybridized signals are sufficiently bright for flow detection; (2) Chromosome breakage during flow is not a problem. We therefore expect our method will be valuable to flow cytometry in medical genetic.

Genome-wide association scans and replication studies identify multiple loci that influence height. *G. Lettre[1,2], MN. Weedon[3], RM. Freathy[3], CM. Lindgren[3], B. Voight[1], C. Gieger[4], I. Heid[4], T. Tuomi[5], U. Lindblad[5], L. Peltonen[1,6], V. Salomaa[6], G. Davey-Smith[3], AT. Hatterskey[3], MI. McCarthy[3], HE. Wichmann[4], L. Groop[5], TM. Frayling[3], JN. Hirschhorn[1,2], Diabetes Genetics Initiative* 1) The Broad Institute; 2) Children's Hospital Boston, Harvard Medical School; 3) WTCCC Height Team UK; 4) KORA Germany; 5) Botnia/Skara Studies; 6) KTL Finland.

Adult height is a classic complex polygenic trait, as initially proposed by Fisher in 1918. Despite high heritability (70-90%), the genetic factors influencing stature in the general population remain unidentified.

The Diabetes Genetics Initiative (DGI) recently completed a genome-wide association study (GWAS) of type 2 diabetes (T2D) in 3025 cases and controls from Scandinavia. We also analyzed adult height as a quantitative trait in this sample. There was a slight enrichment of SNPs above the null expectations at the tail of the distribution, but no SNPs reached unequivocal levels of significance in the DGI dataset alone. To increase our power, we followed up our top results from the DGI data in additional samples and combined the DGI and WTCCC T2D GWAS height results (N=4921). A SNP in the 3UTR of the *HMGA2* gene achieved a $P=8X10^{-8}$ in the combined data and was strongly replicated in adults (N=20876; $P=2X10^{-13}$) and children (N=6067; $P=1X10^{-6}$). A SNP near the *SH3GL3*/*ADAMTSL3* genes also showed association in both DGI ($P=0.0001$) and FINRISK97 (N=6498, $P=0.0004$). Finally, we combined the DGI height dataset with GWAS data from the KORA study (N=4669), and found 8 loci with $P<1X10^{-5}$ (vs. 3 expected by chance). Replication results for these findings and additional meta-analyses will be presented.

We identified the first robust association to height variation: a common SNP in the 3UTR of the *HMGA2* gene. Meta-analyses and replication of GWAS studies also identified other promising loci, demonstrating the power of large cohorts to identify loci for complex traits. We expect that the identification of novel height genes using GWAS will shed light on the biology of growth and on the architecture of complex traits in humans.

Cerebro-facio-renal-digital-glandular syndrome (CFRDG), a "new" multiple malformation syndrome. *R. Lebel[1], C. Nichols[2], B. DuPont[1], T. Wood[1], J. Avery[1], P. Broome[1], M. Hutchinson[2], C. Shipley[2]* 1) Greenwood Genetic Ctr, Greenwood, SC; 2) Palmetto Richland Hospital, Columbia, SC.

The 37 week infant was born vaginally to a 28 year old G2P1 Rh+ Caucasian without reported exposure to teratogens, no consanguinity. Ultrasound showed hyperechoic cystic kidneys, suspected limb anomalies, Dandy-Walker malformation; oligohydramnios rendering examination incomplete. Prenatal impression favored Meckel-Gruber syndrome as most likely. Amniocentesis revealed karyotype 46,XX (normal for a female). Family history was negative for similar anomalies. Demise followed rapidly after delivery. Anthropometric measurements revealed macrocephaly, telecanthus, small hands and feet. Radiographs revealed hypoplastic facial skeleton, short upper limb tubular bones, normal length femora. Fontanels were large, ears low-set, face flattened. There was a high-arched palate and two large tongue polyps (microscopically: salivary glands). Clitoris was hypoplastic. There was bilateral equinovarus and postaxial polydactyly of all four limbs; both feet had syndactyly 5-6. Dandy-Walker malformation, hypoplastic vermis cerebelli and encephalomegaly were noted. A left-anterior nuchal mass was found (microscopically: mixed thyroid and thymus). Lungs were hypoplastic; there was cardiomegaly, hepatomegaly, and thymomegaly. Kidneys and ovaries had multiple cysts; there was medullary sponge kidney. Fibroblasts confirmed amniocytes: 46,XX. Levels of eight lysosomal enzymes were in the normal ranges (no apparent storage disease). The dysmorphology literature brought us to consider the hydrolethalus syndrome, the Mohr-Majewski syndrome, the Beemer-Langer syndrome, Oral-facial-digital syndrome type II, the Meckel-Gruber syndrome, and the visceroskeletal syndrome of Moerman et al (1985). All but the last (which has very few cases reported) are well established autosomal recessives. All had major overlap of important features, but also significant lack of concordance, so that none appears to accommodate this case. We propose it as a new entity: the cerebro-facio-renal-digital-glandular syndrome (CFRDG).

Association between a haplotype of the GATA3 gene and inflammatory bowel disease. *X. Su[1], KD. Taylor[1], L. Mei[1], SR. Targan[2], JI. Rotter[1]* 1) Medical Genetics, Cedars-Sinai Medical Center, Los Angeles, CA; 2) Inflammatory Bowel Disease Center, Cedars-Sinai Medical Center, Los Angeles, CA.

Background and Aim: The GATA binding protein 3 (GATA3) gene codes for the GATA3 protein which is expressed in the T-lymphocyte lineage and is thought to participate in T-cell receptor gene activation through binding to enhancers. In addition, GATA3 may play an important role in the balance between Th1 and Th2 subsets in the immune response and is thus a candidate for the Th1/Th2 dysregulation characteristic of Crohns disease (CD) and ulcerative colitis (UC). The aim of our study was to test the association of GATA3 variation with CD and UC. Methods: Seven GATA3 SNPs were genotyped in 763 CD, 351 UC and 254 controls; haplotype blocks were constructed by using haploview 3.3; haplotypes were assigned using PHASE 2.0; association tests were performed by using chi-square. Result: Two haplotype blocks with 3 haplotypes per block (freq>0.05) were observed. Block 2, haplotype 1 (H1:1111) was associated with CD (88.7% CD vs 82.3% controls, OR=1.7, 95%CI: 1.14-2.51, p=0.008). H1 was associated with UC with borderline statistical significance (87.7% UC, 82.3% control, p=0.06). This association was strongest in non-Jews (89.5% CD, 79.6% control, p=0.001). Conclusion: The observation of an association between haplotype in GATA3 and CD supports the idea that GATA3 variation contributes to CD pathogenesis through possible effects on Th1/Th2 dysregulation.

Highly parallel bead based DNA analysis. *D.N. Shinde, I. Tiemann-Boege, N. Arnheim* Program in Molecular and Computational Biology, University of Southern California, Los Angeles, CA 90089, USA.

Rare genetic events, such as mutation and recombination, can be measured using PCR based techniques that selectively amplify the molecule of interest from a pool of genomes. This approach involves laborious optimization for each nucleotide examined. Recently, the introduction of emulsion based PCR technology has permitted the amplification of 10^6-10^7 individual molecules in parallel. Amplification occurs in microscopic aqueous compartments of an oil-buffer emulsion in a single reaction tube. PCR products from individual compartments containing a single template molecule and a single magnetic bead are captured by the bead and interrogated using different fluorophore labeled probes. We have modified the method to improve several aspects of the present protocols. First, we increased the proportion of oil/water compartments holding only single template molecules. Second, we increased the length of the product amplified on a bead to more than ~100bp by using alternative polymerases. Finally, we developed a detection method to examine simultaneously two SNPs located on the same molecule of DNA. The four alleles can be distinguished with minimal artifacts using four different fluorophores. These new implementations will allow us to measure rare mutations or recombination events at a high resolution with less effort.

Novel KCNH2 Mutatuion in an Iranian Family with LQTS. *K. Banihashemi[1], S. Saber[3], E. Zaklyazminskaya[2], M. Houshmand[3], M. Eftekharzadeh[4], M. Rostami[3], T. Majidizadeh[3], M. Dehghan[3]* 1) Dept Medicine, Great Persian Encyclopedia Fnd, Tehran, Iran; 2) russian academy for medical sciences; 3) national research institute for genetic engineering and biotechnology; 4) tehran arrhhthmia center.

K Channels made with the KCNH2 protein are active in the heart muscle, where they transport potassium ions out of cells. The gene contains 15 exons spanning approximately 19 kb on chromosome 7q35. A feature of K channelopathy is pronounced prolongation of the QT interval in the supraventricular beat preceding the arrhythmia that can lead to sudden death. The subjects studied included a 6 members family with 3 out of them involved with LQTS. The criteria to identify patients were symptomatic individuals with QTc of 450 ms and asymptomatic individuals with QTc of 470 ms were classified as affected, and symptomatic individuals with QTc of 440 ms . Peripheral blood samples were collected from the patients after obtaining informed consent, and genomic DNA was extracted according to a standard method, and then KCNH2 were PCR-amplified and sequenced for identifying LQTS-causing mutations. We identified intragenic mutations of KCNH2 in the proband as a frameshift in the exon 15 which was present also both in his mother and his elder sister. Bidirectional sequence analyses were carried to be sure that mutations are authentic. The one more mutations included also a novel intronic mutation. All the findings were judged after sequencing the parental DNA to find not to have occurred de novo but inherited from mother to the siblings. The proband a 16 years old boy with a frame shift mutation in exon 15, showed all the features of LQTS and needed an ICD which inserted.There were no such a mutation a other healthy members of the family. Additionally there was an intronic heterozygote mutation which has not been reported although predicted to have no effect on protein truncations. this is the first frameshift mutation in Iranian population and we have provided additional data of KCNH2 mutations in LQTS patients. These findings will contribute to further understanding of the function and structure of KCNH2 and the phenotype-genotype correlation in hereditary LQTS.

A comprehensive association analysis of Alzheimers disease candidate genes reveals a risk haplotype in ACE. *E.S. Torstenson[1], T.L. Edwards[1], M. Pericak-Vance[2], J. Gilbert[3], E.R. Martin[2], M.D. Ritchie[1]* 1) Center for Human Genetics Research, Vanderbilt University Medical Center, Nashville, TN; 2) Center for Genetic Epidemiology and Statistical Genetics, Miami Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL; 3) Center for Genome Technology, Miami Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL.

Alzheimers disease (AD) is the most common form of progressive dementia in the elderly. It is a neurodegenerative disorder characterized by the neuropathologic findings of intracellular neurofibrillary tangles and extracellular amyloid plaques that accumulate in vulnerable brain regions. In this study, we examined single locus and haplotype association with late-onset Alzheimers susceptibility in 738 Caucasian families and an independent case-control dataset exploring 12 candidate genes using traditional analytic approaches. The Multifactor Dimensionality Reduction Pedigree Disequilibrium Test (MDR-PDT) was used to explore single-locus effects as well as 2-locus and 3-locus gene-gene interactions associated with AD in the family data. We observed significant haplotype effects in ACE in both family and case-control samples. ACE also was part of a significant 2-locus and 3-locus MDR-PDT joint effects model with Alpha-2-Macroglobulin (A2M), which mediates the clearance of amyloid beta (A), and Leucine-Rich Repeat Transmembrane 3 (LRRTM3), a nested gene in Alpha-3 Catenin (VR22) which binds Presenilin 1. Significant main effects for these models were confirmed using conditional logistic regression, but no evidence of effect modification was detected. These three genes are all related to A clearance and thus this constellation of effects might constitute an axis of susceptibility for late-onset Alzheimers disease. The consistency of the results between independent datasets, family data and unrelated cases and controls, is strong evidence in favor of the hypothesis asserting ACE as a susceptibility locus for Alzheimers disease.

Co-optimization of Powerplex 16 and restriction analysis for use in the prenatal diagnosis of HSAN4. *C. Oddoux, L. U., K. Hoang, H. Ostrer* Human Genetics Program, NYU School of Medicine, New York, NY.

Maternal cell contamination (MCC) complicates the analysis of prenatal diagnostic cases. The degree of MCC varies greatly from sample to sample, and with specimen type and culture status and the impact of MCC on the interpretation of an assays results is assay dependent. Thus, a reliable means of assessing the likelihood of MCC interference for every prenatal performed is required and it must be tailored for the assay in question. Various combinations of polymorphic markers have been used to assess MCC, but there is little agreement on the number of markers or the best ones to use. The Powerplex 16 panel of markers is a forensic panel of 15 highly polymorphic markers provided in commercially available FDA approved kits with validated reference standards. This represents a highly polymorphic quality controlled marker panel that could be applied to MCC applications. Here, we present our experience with the optimization of Powerplex 16 for MCC assessment in a prenatal diagnosis using a restriction assay for the detection of the GLY571ARG mutation in an HSAN4 family with an affected child in whom whole gene sequencing revealed the presence of two copies of the mutation in NTRK1. We prepared for the prenatal testing by evaluating the informativeness of each marker in the panel for distinguishing the two maternal alleles from each other and from the paternal alleles as well as by performing mixing experiments to calibrate the sensitivity of detection of contamination in both the Powerplex 16 and the restriction assays. We found that it was extremely important to assess the informativeness and the sensitivity to contamination in each prenatal case using both maternal and paternal DNA because the sensitivity varies with the specific alleles competing in the assay. In addition we found that the sensitivity of the Powerplex 16 assay and the restriction assay need to be adjusted to be similar to avoid erroneous conclusions. Thus, assays should not necessarily be optimized to the most sensitive mutation detection, and mixed samples should be run concurrently for the Powerplex 16 assay and the mutation detection assay, for each prenatal performed.

Comparison of high density genotyping results from saliva and blood samples on Affymetrix GeneChip GenomeWide 6.0 arrays. *J.D. Reynolds, I.K. Kuramoto, W.H. Biggs III, C.K. French* Affymetrix Clinical Services Laboratory, Affymetrix, Inc., West Sacramento, CA.

INTRODUCTION: Currently, EDTA-stabilized whole blood is the most common sample type used for high density genotyping in a clinical environment. This experiment involves extracting DNA from paired blood and saliva samples, comparing not only the DNA quality and quantity, but also the microarray call rates (CR) in order to demonstrate saliva's suitability for genetic association studies. Initial feasibility tests on saliva and blood samples have shown comparable results. Saliva samples, as an alternative DNA source for high density genotyping, are easier to collect in remote sites, less invasive, and have more robust storage conditions. METHODS: Collection of paired EDTA anti-coagulated whole blood and DNAGenotek Oragene saliva samples from 90 IRB-approved volunteer donors will be compared using the Affymetrix GeneChip GenomeWide 6.0 arrays. DNA is extracted from both of the sample sets using Agencourt chemistry on a Beckman-Coulter NX^P platform- an automated extraction system using magnetic bead particles for isolation of Nucleic Acids. All samples are analyzed for purity and yield on a NanoDrop ND-1000 spectrophotometer as well as for integrity on a 1% agarose gel. GW6.0 testing will be performed according to the manufacturer's instructions. RESULTS: The Beckman-Coulter NX^P can purify DNA from 96 samples in approximately 3 hours. The blood samples, on average, have an A260/A280 ratio of 1.78 0.05 and a concentration of 90 50.0 ng/l. These averages fall within the tolerance limits defined by Affymetrix for its high density genotyping arrays. Initial feasibility testing on saliva samples demonstrated an average A260/A280 ratio of 1.94 0.05 and a concentration of 90.2 8.0 ng/l. GW6.0 testing on these initial saliva samples indicated that DNA extracted from blood and saliva have comparable results. All samples successfully hybridized to the arrays and produced call rates sufficient for genetic association studies (CR>96%). GW6.0 testing of both blood and saliva samples will proceed after the completion of the DNA extraction from the 90 paired donor samples.

Association Tests for Real-World Studies. *T.M. Teslovich, D.J. Cutler* Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD.

Understanding the role a genetic variant plays in disease is an enormously complicated endeavor. Patient samples are difficult to acquire. Obtaining family members and/or appropriately matched controls may be even harder. After genotyping, data may be missing, and undetected genotyping error is nearly unavoidable. Finally, human populations exhibit variation in allele frequencies. Any of these factors may create false positive results or obscure true genetic effects.

Once these issues are addressed, the complex nature of genetics can frustrate a study. Many diseases exhibit sex-specific effects. Diseases may exhibit some epigenetic component. In the simplest of cases, alleles may be dominant, recessive, over-dominant or semi-dominant. Finally, if one performs enough different tests (at multiple loci, and multiple tests at each locus), sooner or later false positives will arise from the multiple testing problem.

We have created a single unified framework to solve all these challenges: Likelihood Association Tests (LATS). Using a likelihood approach, we explicitly model such things as genotyping error, missing data and population stratification, eliminating false positives due to these complications. Further, when a marker is associated with disease, we estimate the size of genetic effects in both males and females, allowing for parent of origin effects and arbitrary dominance relationships between alleles. Data from multiple trio and/or case-control datasets may be analyzed simultaneously. When many markers are typed, we combine data between SNPs, substantially increasing the power of case-control studies. Finally, we present a method of multiple test correction that can be performed instantaneously and yields p-values equivalent to those obtained by permutation testing.

By utilizing far more of the information inherent within genetic studies, this approach results in genetic tests that yield both fewer false positives and fewer false negatives than any previously described tests. We argue that LATS is the most complete package for analyzing genetic association data and the most powerful approach for real world designs.

Finding indel using short sequencing reads. *Z. Zhang, J. Sorenson, J. Malek* Applied Biosystems, Foster City, CA.

Introduction: In next-generation shotgun resequencing, many short reads (~30bps long) are produced. One challenge is to find indels in the reference genome. Mapping reads to a large genome with indels will result in many false alignments. Some new sequencing technologies include the ability to generate paired reads whose approximate distance can be obtained. For large size indels, the deviation from the average distance can be used to derive the existence and size of an indel. In this work, we address the problem of finding small to medium indels using paired reads. Algorithm: The approach is a two-step algorithm: (1) Map all reads requiring very high similarity (allow at most 1 mismatch); (2) For each pair of reads in which only one tag maps uniquely, we align the other tag allowing 1 indel and/or more mismatches in the small region that is the right distance away from the mapped tag. This distance is determined by the library insert size and its variation. Analysis: For the second step of the algorithm we analyzed the probability that a random sequence can achieve the same alignment. With an independent random sequence model, we find FP is very low so that we can find one deletion of up to 100 bps and insertion of up to 10 bps. For an alignment with an indel, there can be two possible hypotheses: (1) the deletion is real; (2) the read is the result of sequencing errors. We initiated another analysis to test the two hypotheses. Briefly, using a Bayesian approach we estimate the probabilities the read supports either hypotheses, and decide when to accept an indel as real. The analysis tells us that the indel must be relatively in the middle of the read for us to be confident that it is real: e.g., for a deletion, the read must have at least 6 alignable bps at both ends of the deletion. Combining these analysis with other well known results, for a given genome size, coverage rate, read length, and sequencing error rate, we can estimate the chance we find any real indel. Simulation: We did simulation to estimate FP and FN, and the result is similar to the statistical analysis. And in conclusion, under some reasonable assumption, we can find deletion of up to 50 bps long, and deletion up to 8 bps long using only short reads.

Contribution of *SHANK3* mutations to autism spectrum disorder. *C.R. Marshall[1], R. Moessner[1], J.S. Sutcliffe[2], J. Skaug[1], D. Pinto[1], J. Vincent[3], L. Zwaigenbaum[4], B. Fernandez[5], W. Roberts[6], P. Szatmari[7], S.W. Scherer[1]* 1) The Centre for Applied Genomics and Program in Genetics & Genome Biology, Hospital for Sick Children, Toronto, ON, Canada; 2) Center for Molecular Neuroscience and Vanderbilt Kennedy Center, Vanderbilt University, Nashville, TN, USA; 3) Centre for Addiction and Mental Health, Clarke Institute and Department of Psychiatry, University of Toronto, Toronto, ON, Canada; 4) Department of Pediatrics, University of Alberta, Edmonton, AB, Canada; 5) Disciplines of Genetics and Medicine, Memorial University of Newfoundland, St. Johns, NL, Canada; 6) Autism Research Unit, The Hospital for Sick Children, Toronto, ON, Canada; 7) Department of Psychiatry and Behavioural Neurosciences, McMaster University, Hamilton, ON, Canada.

Mutations in *SHANK3* encoding the synaptic scaffolding protein have been described in cases with an autism spectrum disorder (ASD). The *SHANK3* gene (also termed ProSAP2) is preferentially expressed in the cerebral cortex where it functions as a scaffolding protein at the postsynaptic density of excitatory synapses. To assess the quantitative contribution of *SHANK3* to the pathogenesis of autism, we determined the frequency of DNA sequence and copy number variants in this gene in a cohort of 400 ASD cases ascertained in Canada. One *de novo* mutation and two gene deletions were discovered indicating a contribution of 0.75% in this cohort. In one of the deletion families, we also detected a *de novo* duplication in the proband spanning 1.4 Mb at 20q13.33. One additional *SHANK3* deletion was characterized in two ASD sibs from another cohort bringing the total number of published mutations in unrelated ASD families to seven. From these data there are no obvious correlation between phenotype and genotype suggesting all ASD forms are candidates for *SHANK3* testing. The combined data provides support for haploinsufficiency of *SHANK3* causing a monogenic form of autism in sufficient frequency to warrant consideration in clinical diagnostic testing.

Use of the genetic test for Factor V Leiden in practice and impact on patient management. *A.M. Laberge[1], B. Psaty[2], L. Hindorff[2], W. Burke[1,3]* 1) Institute for Public Health Genetics; 2) Cardiovascular Health Research Unit; 3) Dept of Medical History and Ethics; Univ. of Washington, Seattle, WA.

Genetic testing for disease predisposition is perceived as one of the potential benefits of the Human Genome Project. Factor V Leiden (FVL) is a common genetic variant associated with a predisposition for venous thromboembolism (VTE) and adverse pregnancy outcomes. The American College of Medical Genetics (ACMG) and the College of American Pathologists (CAP) have issued recommendations on who should be tested for FVL. This study describes the use of the genetic test for FVL in a large health system (Group Health). The medical charts of all 272 individuals tested for FVL in 2003 were reviewed. Preliminary results on 164 individuals show that the median age of individuals tested for FVL is 49 years (range 17-85 yrs). Male:female ratio is 1:2.6. Heterozygote status was identified in 21% of subjects; no homozygotes were identified. Most (77%) were tested as outpatients, whereas 20% were tested in acute settings. Family practitioners requested the test most frequently (39%), followed by general internists (18%), obstetricians (10%), hematologists (8%), neurologists (7%), and pulmonary specialists (4%). The test was done at the patients request in 7%. Post-test counseling was done for only 2%. Pre-test counseling was not done. Testing was performed in the context of VTE in 42% of subjects, family history of VTE or FVL in 15% respectively, arterial thrombosis in 12%, and pregnancy outcomes (including fetal loss) in 15% of women subjects. When comparing test use in practice to the recommended clinical indications for testing, we observed that practice was in agreement with ACMG recommendations for 65% of subjects and with CAP recommendations for 51%. Patient management was modified after FVL testing in 20% of subjects. Modifications were considered but not implemented in an additional 11%. Modifications included length of treatment, use of prophylaxis, and management of other risk factors. These findings suggest that the uptake of a test for genetic predisposition in practice does not necessarily follow available recommendations or initiate changes in patient management.

Clock Genes may Influence Bipolar Disorder Susceptibility and Dysfunctional Circadian Rhythm. *J. Shi[1], J.K. Wittke-Thompson[1], J.A. Badner[1], E. Hattori[2], E.S. Gershon[1], C. lIU[1]* 1) Dept Psychiatry, Univ Chicago, Chicago, IL; 2) Laboratory for Molecular Psychiatry, RIKEN Brain Science Institute (BSI), Wako, Saitama 351-0198, Japan.

Several previous studies suggest that dysfunction of circadian rhythms may increase liability to bipolar disorder (BP). We conducted a two-phase association study in BP families at 15 circadian genes, including ARNTL, ARNTL2, BHLHB2, BHLHB3, CLOCK, CRY1-2, CSNK1D, CSNK1E, DBP, NR1D1, PER1-3,and TIMELESS. The Sibling-Transmission Disequilibrium Test (sib-tdt) analysis showed nominally significant association of BP with 3 SNPs within or near the CLOCK gene (rs534654, p = 0.0097; rs6850524, p = 0.012; rs4340844, p = 0.015). These 3 SNPs and rs2279665 at TIMELESS, also showed nominally significant association with several circadian phenotypes identified in BP patients, including early insomnia, middle insomnia, late insomnia, insomnia with mania, and rapid cycling. Several haplotypes in the CLOCK gene region were nominally associated with both disease and BP with late insomnia ($p < 0.05$). However, none of these associations reached gene-wide or experiment-wide significance after correction for multiple-testing. We detected a significant multi-locus interaction between rs6442925 in the 5 upstream of BHLHB2, rs1534891 in CSNK1E, and rs534654 near 3 of CLOCK gene in the samples in the second phase of the study ($p = 0.00000172$), which remained significant after correcting for multiple tests using the false discovery rate method. Our results suggest an interaction between three circadian genes in susceptibility to bipolar disorder and weak effects of several circadian genes on dysfunctional rhythms in patients with bipolar.

Analysis of genetic variation in the *SCN5A* sodium channel for association to common forms of arrhythmias. *C. Lefebvre[1,2], E. Lizotte[1,2], P. Goyette[1,2], M.J. Junttila[3], H.V. Huikuri[3], R. Brugada[1,2], J.D. Rioux[1,2,4]* 1) Montreal Heart Institute, Montreal, Quebec, Canada; 2) Department of Medicine, Université de Montréal, Montreal, Quebec, Canada; 3) Department of Internal Medicine, Division of Cardiology, University of Oulu, Finland; 4) The Broad Institute of MIT and Harvard, Cambridge, MA, USA.

The *SCN5A* gene encodes the -subunit of the human cardiac sodium channel and is the main protein responsible for the inward cardiac sodium current (I_{Na}). Several lines of evidence have shown that I_{Na} may modulate the risk for sudden cardiac death (SCD). Genetic defects in SCN5A have been identified in several arrhythmogenic disorders, such as the Brugada syndrome and progressive conduction disturbances where there has been a link with increased risk of SCD. Given the role of *SCN5A* in these monogenic disorders, we speculated that there may be a genetic predisposition to SCD and arrhythmias in the population affected by acute myocardial infarction (AMI). We therefore initiated a study of the genetic variation in *SCN5A* with the aim of examining its potential role in susceptibility to common forms of arrhythmia. Specifically, we conducted an association study of the *SCN5A* gene region on 1200 subjects from the Finnish FinGesture cohort and 550 Finnish healthy controls. This cohort consists of survivors of AMI and SCD victims with an AMI event verified at autopsy. We selected 39 informative SNPs capturing all of the common genetic variation in the *SCN5A* region, as well as the known coding and promoter variants. We observed similar haplotype structure between the FinGesture cohort and the CEU samples from the International HapMap project. Preliminary analyses identified significant association (ChiSq=7.198; p=0.0073) between a common promoter haplotype and the SCD phenotype. We are currently in the process of replicating this finding in two independent cohorts (MSIQue and ICM) and will present the complete results, including genotype-phenotype analyses.

SNP Fine Mapping of Chromosome 8p21 in Schizophrenia. *V.K. Lasseter[1], D. Avramopoulos[1], M.D. Fallin[2], J.A. McGrath[1], P.S. Wolyniec[1], G. Nestadt[1], K.Y. Liang[3], Y. Liu[4], P.-L. Chen[4], D. Valle[4], A.E. Pulver[1]* 1) Department of Psychiatry & Behavioral Sciences, The Johns Hopkins School of Medicine, Baltimore, MD; 2) Department of Epidemiology, The Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 3) Department of Biostatistics, The Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 4) Institute of Genetic Medicine, The Johns Hopkins School of Medicine, Baltimore, MD.

Previously, we reported a schizophrenia susceptibility locus (SSL) on 8p22-p21 with a maximum NPL of 3.64 (p=.0001) at D8S1771 (at ~25.5 Mb) in a linkage scan of 54 European Caucasian (EUC) families (Blouin et al. 1998). Further microsatellite genotyping for these families supported a dominant model (LOD=4.10) peaking at D8S1048 (26.9 Mb)(Pulver, unpublished data) with an estimated 61% of families linked to this SSL. Linkage to an 8p SSL has been replicated in independent samples (Straub et al. 2002; Suarez et al. 2006) and in meta-analyses (Lewis et al. 2003). In a collaborative genome-wide SNP-based linkage scan (Levinson et al., 2006) of 737 EUC pedigrees (including the 54 original and 73 new families from Johns Hopkins), an 8p SSL was confirmed with a peak Zmean of 3.22, p=.0004, at rs9797 (26.6 Mb). We conducted SNP studies in a 4.4 Mb region around rs9797 (1536 SNPs) using a subset of 103 Johns Hopkins 8p-linked families. Linkage analyses with 70 pairwise uncorrelated tag SNPs (r2<.05) found the maximum NPL of 6.95 ($p=2.95 \times 10^{-10}$) at rs11994515 (26.9 Mb). Family-based association analyses (FBAT, additive model) revealed nominal p-values <.001 for two SNPs 5 prime upstream of the adrenergic alpha-1 receptor gene, ADRA1A, at 26.8 Mb, in a relative gene desert. Seven other SNPs were associated at a nominal p<.01 level: 6 SNPs in EBF2 (early B-cell factor 2) and one SNP 14k downstream from the 3 end of EPHX2(epoxide hydrolase 2, cytoplasmic). Finally, modest support (p<.05) was seen for SNPs within 13 of the 32 genes in the region, with a concentration of 5 SNPs in DPYSL2, a gene previously indicated in our studies in the Ashkenazim (Fallin et al., 2005). These analyses help prioritize further genetic studies to characterize a chromosome 8p21 SSL.

Haplotype-based association test for X-linked markers with quantitative trait. *L. Zhang[1,2], E.R. Martin[3], R.W. Morris[4], Y.J. Li[1]* 1) Center for Human Genetics, Dept of Medicine, Duke University, NC; 2) Bioinformatics Research Center, NC State University, NC; 3) Miami Institute of Human Genomics, University of Miami, FL; 4) Dept of Anesthesiology, Duke University, NC.

Haplotype analyses may provide more information than single locus tests in association studies. Many haplotype association methods, family or population-based, have focused on autosomal loci although X-linked genes may be important in some complex diseases. The X-linked loci differ from autosomal loci in their sex-dependent genotypes and mechanism of female X-inactivation. In this study, we develop a family-based haplotype association method of X-linked markers for quantitative traits. We have extended a single locus association method for quantitative trait locus (QTL) on X chromosome to haplotypes. Our haplotype method exhibits three virtues: 1) we have derived solutions for estimating additive genetic value of X-linked QTL and variances of effects through haplotype markers within the likelihood ratio framework. 2) Ambiguous phases of haplotypes and missing parental data can be inferred by EM algorithm conditional on all offspring genotypes and parental mating-type frequencies in the population, which improves computational efficiency and precision of parameter estimation. 3) Dosage compensation (DC) models provide a simple relationship of X-linked additive effects between sexes. Our method has significant power in complete presence or absence of X-inactivation. Properties of our approach are demonstrated by extensive studies using simulated data. The results show that our haplotype-based approach is robust to various biases, including linkage, polygenic effect, and the population admixture, as we vary the sample size (100--2000 families), haplotype frequencies of markers, and allele frequency of X-linked QTL (0.1--0.5). Application of the new method is illustrated by a candidate-gene study of family data with age-at-onset (AAO) of Parkinson Disease (PD) as a quantitative trait. The X chromosome markers RS1800659 and RS979605, located in introns 5 and 12 in MAOA, showed strong evidence of association with patient's AAO of PD($p=0.0075$ in non-DC test and $p<0.0001$ in DC test).

Refinement of the disease locus in Chinese families with TPTPS. *M. Sun, F. Ma, Q. Liu, X. Zhao, F. Wu, W.H.Y. Lo, X. Zhang* Department of Medical Genetics, Peking Union Medical College, Beijing, China.

Triphalangeal thumb-polysyndactyly syndrome (TPTPS, MIM190605) is an autosomal dominant genetic disorder usually shows a duplicated triphalangeal thumb, normal index finger, and cutaneous syndactyly between fingers 3-5. The disease locus was linked to D7S550 on chromosome 7q36, with a maximum LOD score of 6.85 at = 0. The entry of TPTPS in OMIM has been moved to PPD II in 2007 for the reason that they are being considered as the same disease. Preaxial polydactyly type II (PPD II, MIM 174500) is the PPD with opposable triphalangeal thumbs. The candidate locus has been refined to an interval of about 450 kb on chromosome 7q36. In PPD, mutations in the ZPA regulatory sequence (ZRS), a SHH enhancer, have been identified. However, no mutation of this ZRS was found in patients with TPTPS, indicating that TPTPS and PPD might not be the same limb malformation syndrome. We have performed linkage and molecular genetic analyses in four Chinese families with TPTPS. In two large families, we obtained LOD scores of >3 with markers at chromosome 7q36. Haplotype analysis using the same marker set showed haplotype sharing in the other two families. In one large family, we found a recombination event in one affected individual at D9S550. We also found another recombination event at D7S3161 in one individual in the other large family. These results refined the disease locus to the region between D9S550 and D7S3161, overlapping with the PPD locus. We are now sequencing all intergenic conserved elements to identify pathogenic mutations responsible for the TPTPS phenotype.

Intrafamilial Variability in Autosomal Recessive Polycystic Kidney Disease/Congenital Hepatic Fibrosis (ARPKD/CHF). *L. Lukose[1], E. Font-Montgomery[1], D. Adams[1], H. Edwards[1], A. Garcia[1], J. Bryant[1], P. Choyke[3], T. Heller[5], P. Mohan[6], K. Daryanani[7], L. Guay-Woodford[4], W. Gahl[1], M. Gunay-Aygun[1,2]* 1) MGB, NHGRI, NIH, Bethesda, MD; 2) Intramural Office of Rare Diseases, NIH; 3) NCI, NIH; 4) University of Alabama,Birmingham, AL; 5) NIDDK, NIH; 6) CNMC, Washington DC; 7) NIH CC.

ARPKD/CHF is characterized by progressive renal insufficiency and CHF complicated by portal hypertension (PH). It is caused by mutations in PKHD1, which encodes fibrocystin. The majority of ARPKD/CHF patients present early in childhood, mostly perinatally with enlarged microcystic kidneys, oligohydramnios and hypoplastic lungs. A minority present later in childhood or in adulthood with PH. A subset of patients also have macrocysts of the bile ducts (Carolis syndrome) predisposing to cholangitis. Chronic renal insufficiency, hypertension, recurrent cholangitis, esophageal varices and hypersplenism are the major sources of morbidity and mortality. The severity and rate of progression of the kidney and liver disease can be variable even within the same family. As part of an ongoing NIH study on ARPKD/CHF and other ciliopathies (www.clinicaltrials.gov, NCT00068224), we have evaluated 60 ARPKD/CHF patients. In this group, 5 families had 2 and 1 had 4 affected sibs. In one family, one of the sibs was diagnosed prenatally and required kidney transplantation at age 18, whereas the NIH evaluation of her 3 sibs at ages 28, 23 and 21, revealed cysts confined to the renal medulla on high resolution ultrasound; their creatinine clearances were 94, 76, and 122 ml/min/1.73 m2, respectively. In another family, the proband presented at birth with enlarged kidneys, whereas his asymptomatic 12-year old sister, who had normal abdominal ultrasound at age 2, manifested cysts confined to the renal medulla. In another sibship, the 7-year old proband presented with splenomegaly at age 3 and had a severely echogenic liver, marked splenomegaly and grade III esophageal varices. His 9-year old asymptomatic sister had a mildly echogenic liver and borderline splenomegaly. This wide intrafamilial variability suggests the presence of strong genetic modifiers.

Association and gene-gene interaction of SLC6A4 and ITGB3 in autism. *D.Q. Ma[1], H. Mei[3], E.R. Martin[1], R. Rabionet[2], J. Jaworski[1], I. Konidari[1], H.H. Wright[4], R.K. Abramson[4], J.H. Haines[5], M.L. Cuccaro[1], J.R. Gilbert[1], M.A. Pericak-Vance[1]* 1) Univ. of Miami,MIHG,Miami,FL; 2) Univ. Pompeu Fabra,Barcelona,Spain; 3) North Carolina State Univ.,Raleigh, NC; 4) Univ. of South Carolina, Columbia, SC; 5) Vanderbilt Univ.,Nashville, TN.

Autism is a heritable neurodevelopmental disorder with substantial genetic heterogeneity across subphenotypes and subpopulations. One of the most consistent findings, platelet hyperserotonemia, implicates the serotonin pathway. SLC6A4, a serotonin transporter gene; and ITGB3, which encodes for glycoprotein IIIa (GPIIIa) have been implicated. However, the association of SLC6A4 with autism remains inconsistent. Recent studies indicate a sex-specific genetic structure on serotonin levels for both genes and a genetic and expression interaction between them. In addition, a de novo copy number mutation study suggested a different genetic background for sporadic families.This study was conducted in an independent dataset taking into account potential gender and family history as well as gene-gene effect. Family-based association analysis was performed using the functional polymorphisms (5HTTLPR and RS5918) and three additional SNPs within each gene. Gene-gene joint effect was tested by extended multifactor dimensionality reduction (EMDR) and MDR-phenomics using gender of affecteds and family history (Fam+) as covariates. Nominal significant associations were found within SLC6A4 (RS2066713: p=0.0384) and ITGB3 (RS3809865: p=0.0314) with the signal from the Fam+ families, but not from the entire dataset or in families stratified by gender of affecteds [male only (MO) vs.> one female (F1)]. EMDR identified a 2-locus joint effect (RS1042173 and RS3809865) in F1 families and a marginally significant 2-locus joint effect (17P6713SLC6A4 and RS5918) in Fam+ families. MDR-phenomics confirmed these effects while using gender of affecteds (p=0.023) and family-history as covariant (p=0.014). In conclusion, SLC6A4 and ITGB3 might play a role in the etiology of autism independently or interactively. The effect may be modified by the type of families in terms of gender of affected and/or family history.

Depression as a genetic sub-phenotype of Alzheimers disease. *M. Slifer[1], B. Plassman[3], D. Steffens[3], J. Gilbert[2], J. Haines[4], M. Pericak-Vance[2]* 1) Ctr Human Genetics, Duke Univ Medical Ctr, Durham, NC; 2) Miami Institute for Human Genetics Miami, FL; 3) Duke University Medical Center, Durham, NC; 4) Vanderbilt University Medical Center, Nashville, TN.

In 2002 the American Psychiatric Association published diagnostic criteria for the depression of Alzheimer disease (DAD) recognizing the phenomenological distinctiveness and clinical importance of a disorder affecting up to half of those suffering from Alzheimer disease (AD). However, little is known regarding the genetic properties of DAD. In this study, two independent datasets of AD patients (from the Collaborative Alzheimer Project and Duke Twins Study of Memory in Aging) are used to demonstrate a genetic component to DAD. Among non-twin full siblings concordant for AD, we observe significantly elevated sibling recurrence risk for DAD (n=96; Odds Ratio=8.3; $p<0.001$). The DAD recurrence risk effect is even more pronounced among monozygotic twins concordant for AD (n=38; Odds Ratio=25; $p=0.006$). Furthermore, including individuals with depression who had a non-AD etiology for their dementia decreased sibling risk, suggesting that DAD is specific to AD and not simply the consequence of cognitive disorders more generally. Additionally, including individuals with AD who had depressive disorders that were temporally unrelated to their AD also decreased sibling risk, illustrating that DAD does not appear to be the product of reducing the threshold for expression of a conventional depressive disorder.

Hutchinson-Gilford Progeria Syndrome(HGPS): Comprehensive characterization of 15 children. *M.A. Merideth[1,2], W.J. Introne[1], L.B. Gordon[3], M.B. Perry[4], S.B. Clauss[5], V. Sachdev[6], C.K. Zalewski[7], C.C. Brewer[7], J. Kim[7,8], J.C. Graf[4], A.C.M Smith[1,8], L.H. Gerber[9], J.A. Yanovski[10], D.L. Domingo[11], T.C. Hart[11], F.S. Collins[1], E.G. Nabel[6], R.O. Cannon[6], W.A. Gahl[1,2]* 1) NHGRI, NIH, Bethesda, MD; 2) Intramural ORD, NIH, Bethesda, MD; 3) Brown Univ, Providence, RI; 4) CC, NIH, Bethesda, MD; 5) CNMC,Washington, DC; 6) NHLBI, NIH, Bethesda, MD; 7) NIDCD, NIH, Bethesda, MD; 8) Georgetown UMC, Washington, DC; 9) GMU, Fairfax, VA; 10) NICHD, NIH, Bethesda, MD; 11) NIDCR, NIH, Bethesda, MD.

Hutchinson-Gilford Progeria Syndrome(HGPS), a sporadic autosomal dominant premature aging syndrome, has an incidence of 1/4-8 million. The cause is an abnormal lamin A protein(progerin), produced by a cryptic splice donor site activated by a GGC>GGT change in codon 608 of exon 11 of LMNA. HGPS is a multisystemic disease, uniformly fatal at an average age of 13y, with mortality primarily caused by cardiovascular disease. Progerin disrupts the nuclear scaffold and interferes with transcription; it also accumulates with age in normal cells, supporting HGPS as a model for studying the normal aging process. Fifteen children with HGPS, aged 1-17y, were investigated at the NIH between Feb 2005 and May 2006. Our studies confirmed the universal presence of sclerotic skin changes, bone abnormalities, joint contractures, alopecia, growth impairment, and decreased body fat; CV and CNS complications also occurred. New clinical findings included prolonged prothrombin times, elevated platelet counts and serum phosphorus levels, dental and oral soft tissue abnormalities, and a low-frequency conductive hearing loss. Bone density improved with age until 7y; % body fat decreased with age. Growth impairment was not due to inadequate nutrition, impaired insulin action, or growth hormone(GH) deficiency. GH treatment increased height growth by 10% and weight growth by 50%. Increased BP was common, and arterial studies identified diminished arterial distensibility, and increased carotid intima-medial thickness and augmentation indices. This comprehensive evaluation of the HGPS phenotype defines potential outcome parameters for therapeutic interventions, which may also apply to the normal aging process.

Lipodystrophy and multiple congenital anomalies : a new syndrome? *P. Sarda[1], J. Puechberty[1], L. Pinson[1], C. Coubes[1], G. Lefort[1], P. Blanchet[1], L. Van Maldergem[2]* 1) Dept Medical Genetics, Arnaud de Villeneuve Hosp, Montpellier Herault, France; 2) Génétique, Hôpital Henri Mondor Creteil, France.

Lipodystrophies represent a group of diseases characterized by abnormal body fat. Berardinelli-Seip congenital lipodystrophy is a very rare disorder in which congenital generalized lipoatrophy is associated with hepatomegaly, hypertriglyceridemia and acromegaloid features. This disorder follows autosomal recessive inheritance. Two loci have been identified : BSCL1 in 9q34 and BSCL2 in 11q13. At least a third locus must exist. We present what is probably a new syndrome with generalized lipodystrophy in a 14-year-old girl. She was the product of a term pregnancy complicated by intra uterin growth retardation. She presented a small omphalocele (surgically corrected at 6 days), generalized lipoatrophy and dysmorphic traits. Psychomotor development was normal. No cerebral, cardiac, abdominal or skeletal anomalies were noted. At age 6, she underwent surgery for volvulus of the small intestine. Puberty occurred normally. At age 14, the child presented normal weight and height but OFC was at -2.5 SD. Clinically there was severe generalized lipoatrophy. Cardiac examination revealed hyperlaxity of atrio-ventricular valves with mild mitral and pulmonary insufficiency. Skeletal anomalies included arachnodactyly and joint mobility restriction. The child also presented fine skin and cutaneous syndactylies of the fingers. She had dysmorphic traits with brachycephaly, acromegaloid face, dysplastic low-set ears, short philtrum. Intellectual level was normal. Triglyceride serum concentrations were variable. Thoraco-abdomino-pelvic MRI was performed to evaluate fat residue in the event of facial plastic surgery. Images revealed no cutaneous fat in the anterior and lateral planes of the body but a small layer of dorsal fat. Abdominal perivisceral fat was normal. No mutation was found for AGAPT2, BSCL2 and Cav1 genes. Our patient presents a particular lipoatrophic MCA syndrome without mental retardation which is probably a new lipodystrophic syndrome possibly due to a chromosome microanomaly.

Common human cancer genes discovered by integrated gene-expression analysis. *Y. Lu, Y.J. Yi, P.Y. Liu, W.D. Wen, M. James, D.L. Wang* Department of Surgery and the Alvin J. Siteman Cancer Center, Washington University, St Louis, St Louis, MO.

Background: Discovery of genes commonly regulated in cancer may have an important implication in understanding the common molecular mechanism of cancer. Here, we described an integrated gene-expression analysis of 2,074 samples from 36 different studies to identify and validate a cancer type-independent gene signature that can identify cancer patients for a wide variety of human malignancies. **Mehtods:** The commonness of gene expression in 20 types of common cancer was assessed by permutation analysis in training datasets with 1,139 samples from 20 datasets. The discriminative power of a signature defined by these common cancer genes was evaluated by hierarchical clustering in the other 16 independent datasets with 935 samples including novel cancer types. QRT-PCR and tissue microarray were used to validate commonly regulated genes in multiple cancer types and identify a refined list of significantly and consistently regulated genes associated with malignancy. **Resutls:** The integrated analysis identified 187 genes dysregulated in nearly all cancerous tissue samples, regardless of their tissue of origin. The 187-gene signature can robustly predict cancer versus normal status for a wide variety of human malignancies with an overall accuracy of 85%. We further refined our signature to 28 genes that were confirmed by QRT-PCR analysis. The refined signature still achieved about 80% accuracy of classifying samples from mixed cancer types. This signature performs well in the prediction of novel cancer types that were not represented in training datasets. We also identified three biological pathways including glycolysis, cell cycle checkpoint II and plk3 pathways in which most genes are systematically up-regulated in many types of cancer. **Conclusions:** The identified signature is cancer type-independent and has captured essential transcriptional features of neoplastic transformation and progression in general. These findings will help to elucidate the common molecular mechanism of cancer, and provide new insights into cancer diagnostics, prognostics and therapy.

Molecular dissection of NRG1-ERBB4 signaling implicates PTPRZ1 as a potential schizophrenia susceptibility gene. *T. Sakurai[1, 2], L. Georgieva[3], N. Takahashi[1], S. Harroch[4], V. Moskvina[3], N. Norton[3], M.J. Owen[3], M.C. O'Donovan[3], J.D. Buxbaum[1, 5, 6]* 1) Psychiatry, Mount Sinai Sch Medicine, New York, NY; 2) Pharmacology, Mount Sinai Sch Medicine, New York, NY; 3) Psychological Medicine, Sch of Medicine, Cardiff Univ, Cardiff, UK; 4) Neuroscience, Inst Pasteur, Paris, France; 5) Genetics and Genomics, Mount Sinai Sch Medicine, New York, NY; 6) Neuroscience, Mount Sinai Sch Medicine, New York, NY.

Neuregulin and the neuregulin receptor ERBB4 have been genetically and functionally implicated in schizophrenia. We used the yeast two-hybrid system to identify proteins that interact with ERBB4, in order to identify genes and pathways that might contribute to schizophrenia susceptibility. We identified the MAGI scaffolding proteins as ERBB4-binding proteins. After validating the interaction of MAGI proteins with ERBB4 in mammalian cells, we demonstrated that ERBB4 expression, alone or in combination with ERBB2 or ERBB3, led to the tyrosine phosphorylation of MAGI proteins, and that this could be further enhanced with receptor activation by neuregulin. As MAGI proteins were previously shown to interact with receptor phosphotyrosine phosphatase / (RPTP), we postulated that simultaneous binding of MAGI proteins to RPTP and ERBB4 forms a phosphotyrosine kinase/phosphotyrosine phosphatase complex. Studies in cultured cells confirmed both a spatial and functional association between ERBB4, MAGI, and RPTP. Given the evidence for this functional association, we examined the genes coding for MAGI and RPTP for genetic association with schizophrenia in a Caucasian United Kingdom case-control cohort (n = ~1,400). PTPRZ1, which codes for RPTP, showed significant, gene-wide and hypothesis-wide association with schizophrenia in our study (best individual SNP allelic P = 0.0003; gene-wide P = 0.0064; hypothesis-wide P = 0.026). The data provide evidence for a role for PTPRZ1, and for RPTP signalling abnormalities, in the etiology of schizophrenia. Furthermore, the data indicate a role for RPTP in the modulation of ERBB4 signalling which may in turn provide further support for an important role for neuregulin/ERBB4 signalling in the molecular basis of schizophrenia.

Otosclerosis. Family History and Audiological Findings in 103 Mexican Patients. *D.M. Mendoza-Ugalde[1], G. García-Sánchez[1], C.F. Martínez-Cruz[2,3], R. Baez-Reyes[4]* 1) Servicio de Genetica, Direccion de Investigacion.Instituto Nacional de Rehabilitacion, México, D.F; 2) Servicio de Comunicacion Humana.Departamento de Seguimiento Pediatrico.Instituto Nacional de Perinatologia. México D.F; 3) Servicio de Pediatría. Instituto Mexicano del Seguro Social. HGZ 53. México, D.F; 4) Servicio de Genetica,Departamento de Investigacion.Instituto Nacional de Perinatologia. México D.F. email. gsanchezg03@yahoo.com.mx.

INTRODUCTION: Otosclerosis is caused by abnormal bone homeostasis of the otic capsule, resulting in hearing impairment. The etiology of the disease remains unclear and environmental as well as genetic factors have been implicated. The most common age of presentation is among the 2ª and 5ª decade of the life and is rare in the infancy. Is more common in Caucasian and more frequent in women (2:1). To date, seven loci (OTSC1-7) have been reported, but none of the responsible genes have been cloned.The diagnosis is based on the clinic, audiometric and radiological studies.OBJECTIVE:Identify the hereditary patter in 103 Mexican patients with otosclerosis and atudy the audiological findings. MATERIAL AND METHODS:Included 103 Mexican patients with clinical, audiological, radiological and surgical diagnosis of otosclerosis. We carried out to all patients pedigree, wich included at least three generations. RESULTS: The patients had a minimum age of 12 years and maximum of 69 years. 25% men and 75% women. We studied a total of 206 ears: 199 with hearing loss, (100 rights and 99 lefts) and 17 ears with normal hearing. Time of evolution from 1 to 44 years, age of onset between 6 and 59 years old. The type of hearing loss more frequent was mixed with ascending configuration. Vestibular sintomatology was referred in 38.9%. Stapedectomy was performed in 73 patient (67.6%). Hereditary patter was observed in 49 patients (45.4%): Autosomal dominant (28.76%) and autosomal recessive (16.6%). CONCLUSIONS: In this sample the otosclerosis is a genetically heterogeneous disorder, being the autosomal dominant inheritance the most frequent cause.

A Novel missense mutation in the SCN1A gene associated with hepatic coma and brain damage in a child. *D. Lev[1], M. Abu- Rashed[2], L. Blumkin[2], S. Zuberi[3], T. Lerman-Sagie[2]* 1) Institute of Medical Genetics, Wolfson Medical Center, Holon, Israel; 2) Pediatric Neurology Unit,Wolfson Medical Center, Holon, Israel; 3) Fraser of Allander Neurosciences Unit, Royal Hospital for Sick Children, Yorkhill, Glasgow UK.

The spectrum of the infantile encephalopathies related to mutations in alpha-subunit type A of voltage-gated sodium channel (SCN1A) is rapidly expanding and now includes: severe myoclonic epilepsy of infancy (SMEI), SMEI-borderland, vaccine related encephalopathy, severe infantile multifocal epilepsy and even familial hemiplegic migraine. We report a 4 year-old boy with an atypical presentation of a SCN1A mutation. He presented at 7 months with recurrent episodes seizures usually associated with fever.. Myoclonic epilepsy of infancy was suspected and he was put on VPA therapy. At the age of 11 months he developed febrile status epilepticus. His seizure was stopped with phenobarbital. He developed liver and kidney failure with hyperammonemia. The diagnosis of Alpers-Huttenlocher disease was considered because of the myoclonic epilepsy combined with liver failure on valproic acid therapy. A muscle biopsy showed decreased complex II and complexes II +III of the respiratory chain. The skeletal muscle biopsy disclosed minor changes consistent with mitochondrial dysfunction. Sequencing of POLG1 gene did not detect any mutations. MtDNA depletion was ruled out. A liver biopsy at 12 months was normal. Following the acute deterioration, his clinical picture was consistent of a static encephalopathy. He continued to suffer from febrile induced episodes of status epilepticus that were not controlled by anticonvulsants. The unequivocal association between the seizures and fever lead us to suspect severe myoclonic epilepsy of infancy as the primary epileptic syndrome. SCN1A sequence analysis was performed at 3.4 years old. A novel amino acid change p.Val 1637 Glu was detected. This missense mutation changes a neutral amino acid to an acidic amino acid in segment 4 of domain IV of the SCN1A protein. Liver failure in an epileptic child may be the presentation of a SCN1A mutation.

Sequencing of the *CFTR* coding regions is required to optimize molecular diagnosis of cystic fibrosis in patients with clinical features and one identified disease-causing mutation. *M.B. Sheridan, N. Wang, P. Mogayzel, G.R. Cutting* Johns Hopkins University, Baltimore, MD.

Patients with cystic fibrosis (CF) manifest symptoms in the respiratory tract, GI tract, male reproductive tract and sweat gland due to mutations in *CFTR*. Non-classic CF patients have disease in a subset of these organ systems. Most non-classic CF patients have two mutations in *CFTR*. A subset of patients have only one CF-causing mutation after screening for a panel of common CF-causing mutations or following mutation scanning of the coding region of *CFTR*. These patients present a diagnostic dilemma and a challenge for genetic counseling. We evaluated 9 patients with only one CF-causing mutation identified after a screen of 97 *CFTR* mutations (3 patients) or scanning of the coding region of *CFTR* (6 patients). Eight patients, including one set of siblings, have non-classic CF with borderline or elevated sweat [Cl^-] and lung disease. One patient has classic CF. Each of these patients have features that are consistent with CFTR dysfunction including a CF-like nasal potential difference, P. aeruginosa infection, or congenital bilateral absence of the vas deferens, suggesting that they have a 2nd *CFTR* mutation. Mutations that are not detected by screening include insertions or deletions, mutations outside of the *CFTR* coding region that affect RNA splicing or expression, or mutations in the coding region of *CFTR* that were missed by screening. To exclude the 3rd possibility, the 27 exons and flanking introns of *CFTR* were sequenced. A 2nd mutation was identified in the coding region of CFTR in 6 of 9 patients; 3 had screening for 97 known *CFTR* mutations, while the other 3 had comprehensive scanning of the coding region of *CFTR* by modified TGGE. Each of the mutations has been previously described in CF patients and is predicted to cause CFTR dysfunction. These results demonstrate that patients with one *CFTR* mutation and features of CF are likely to have a 2nd mutation in the coding region of *CFTR*. Thus, sequencing of *CFTR* in patients with only one mutation after screening should reduce unnecessary clinical and molecular evaluations in patients being evaluated for a CF diagnosis.

Miglustat improves function and enhances -galactosidase activity in a patient with juvenile GM1 Gangliosidosis: A pharmacologic chaperone effect? *C.P. Morgan[1,2], D.R. Adams[3], C.J. Tifft[1,2]* 1) Children's National Medical Center, Washington, DC; 2) Genetics of Development and Diseases Branch, NIDDK, NIH, Bethesda, MD; 3) Human Genetics Branch, NHGRI, NIH, Bethesda, MD.

GM1 gangliosidosis, caused by a deficiency of lysosomal -galactosidase, is a neurodegenerative disorder with a broad clinical spectrum reflecting the degree of residual enzyme activity. Miglustat, an imino sugar, competitively inhibits glucosylceramide synthase, the first step in glycosphingolipid synthesis, and can reduce the synthesis of GM1 ganglioside. Imino sugars have also been shown to act as molecular chaperones with a number of acid hydrolases, including -galactosidase (Tominaga *et al*, 2001; Yam G. *et al*, 2006). Here we report a patient with juvenile GM1 gangliosidosis who showed rapid clinical improvement following treatment with miglustat. The patient is an 18-year-old male with precocious development until age 5 when he developed deterioration of expressive and receptive language and gait disturbance. After a 7 year diagnostic odyssey, juvenile GM1 gangliosidosis was confirmed. He continued to decline, and by age 16 he had lost all speech skills and was non-ambulatory. After 3 years of miglustat therapy he has regained the ability to speak in sentences and short paragraphs although remains dysarthric, and has gained some tentative ambulatory skills limited by hip dysplasia. The patients fibroblasts were incubated with miglustat for up to 4 days at concentrations of 5, 25, and 50M which is within the range of plasma concentrations in treated patients. We found that under these conditions -galactosidase activity was increased 35-45% in treated versus untreated cell lysates ($p<0.01$). We hypothesize that the increase in enzyme activity may result from a pharmacologic chaperone effect of miglustat. Studies are underway in additional juvenile GM1 patients to further characterize the effects of miglustat.

Fine-mapping of genome-wide breast cancer association study. *M.S. Udler[1], K.A. Pooley[2], A.M. Dunning[2], P.D. Pharoah[2], D.G. Ballinger[3], J.P. Struewing[4], R. Luben[1], S. Ahmed[2], C.S. Healey[2], Search Collaborators[2], C.A. Haiman[5], P. Brennan[6], C.Y. Shen[7], D. Kang[8], D.R. Cox[3], E.A. Ostrander[9], B.A.J. Ponder[10], D.F. Easton[1]* 1) Department of Public Health and Primary Care, University of Cambridge, UK; 2) Department of Oncology, University of Cambridge, UK; 3) Perlegen Sciences, Inc., Mountain View, CA; 4) Laboratory of Population Genetics, NCI, Bethesda, MD; 5) Department of Preventive Medicine, Keck School of Medicine, USC, Los Angeles, CA; 6) International Agency for Research on Cancer, Lyon, France; 7) Institute of Biomedical Sciences, Academia Sinica, Taipeii, Taiwan; 8) Seoul National University College of Medicine, Seoul, Korea; 9) Cancer Genetics Branch, NHGRI, Bethesda, MD; 10) CR-UK Cambridge Research Institute, UK.

Genome-wide association (GWA) studies utilize linkage disequilibrium (LD) between Single Nucleotide Polymorphisms (SNPs) in a population to identify genetic variants that are associated with increased risk of disease. Since SNPs located close to each other on a chromosome may be correlated, it is often difficult to determine which is the causal SNP. We have applied statistical techniques for fine-mapping to susceptibility loci identified in a breast cancer GWA study. The three strongest associations from the study were in *FGFR2*, *TNRC9*, and *MAP3K1*, located in LD blocks on chromosomes 10, 16, and 5, respectively. Here we investigate the use of single and multiple SNP analyses as well as haplotype analyses using data from 8,792 cases and 8,200 controls from five studies of European and Asian descent. For the haplotype analyses, an Ancestral Recombination Graph-based approach (Margarita[1]) and a clustering algorithm (HapCluster[2]) were utilized. Through these approaches, the number of candidate causal SNPs was considerably decreased. In *FGFR2*, of 117 SNPs in the region, all but six were excluded at odds of 100:1 after applying these methods. In this case, logistic regression following genotype imputation provided a straightforward analytical approach, and haplotype-based analysis did not provide additional precision. [1]Minichiello MJ, Durbin R. Am J Hum Genet. 2006;79:910-22. [2]Waldron ERB, et al. Genetic Epidemiology. 2006;30:170-9.

Identifying the Molecular Basis of Morphological Variation in Beaks. *K. Powder[1], S. Brugmann[2], J. Helms[2], M. Lovett[1]* 1) Washington University, St Louis, MO; 2) Stanford University, Stanford, CA.

Both humans and birds exhibit remarkable morphological variation in craniofacial structures. In both species, cranial neural crest (CNC) cells give rise to the facial skeleton. In avians, the neural crest cells contain molecular information that regulate species-specific facial variation. However, the identity of these regulators is unknown. We measured changes in gene expression between microdissected CNC cells from the frontonasal prominences of three bird species (chickens, quails, and ducks) during embryonic development. These changes were measured on microarrays that interrogated transcription factor genes plus a wide variety of signaling pathways. Samples were isolated at two developmental stages, before (HH20) and after (HH25) morphological distinctions between the species are evident. Our data indicate that by HH20, CNC cells have established a species-specific expression profile that is maintained, largely unchanged, until morphological differences are evident. Of the 387 genes found to be differentially expressed (>2-fold with p-values < 0.05) between the three bird species, one third were found to be up-regulated in the duck compared to either the chicken or quail, at either developmental stage. These included developmental regulators, such as *Fgfs*, as well as genes previously implicated in mammalian craniofacial development, such as *Hoxb2, Jagged2, Osr2,* and *Satb2*. The duck also exhibited a dramatic up-regulation of WNT signaling components including *Dkk2, Fzd1, Apc, Lrp5, Wnt1,* and *Wnt10b*. By contrast, members of the TGF-Beta signaling pathway, including *Bmp10, Tgfb2, Tgfb3,* and *Bmpr1a,*were down-regulated in the duck. We also observed a down-regulation of the Calmodulin 2 gene in the duck. This pathway has previously been identified as playing a role in facial variation in Darwins finches. We confirmed differential expression patterns of numerous genes by RNA *in situs,* which also revealed spatial patterns of expression. These data provide a valuable list of candidate genes to investigate human craniofacial abnormalities and variation, and the molecular mechanisms that lead to species-specific craniofacial form.

Reproducibility of pairwise linkage disequilibrium in genome wide association data: Comparisons of HapMap data with 2 large study samples. *R. Lazarus[1], W. Qiu[1], E.K. Silverman[1], B. Raby[1], P. Kraft[2], S. Chanock[3], D. Hunter[2], S.T. Weiss[1]* 1) Channing Laboratory, Boston, MA; 2) Harvard School of Public Health, Boston, MA; 3) CGEMS, NCI and NIH, Bethesda, MD.

Introduction: Small HapMap panels are used to design and evaluate products for efficient linkage disequilibrium (LD) based genome-wide association (GWA) studies. Pairwise LD estimated in small samples is biased upwards. We explored the practical effects of this bias by comparing LD in 550K genotypes in 2 study samples (n=793 and n=1197), with LD from corresponding genotypes for the 60 CEU HapMap founders. **Results:** The MAF distribution from HapMap genotypes was significantly different using the Kolmogorov-Smirnov (KS) test or a paired t-test from the two study samples (eg, KS p<1e-16, t-test p=0.002), but not significantly different between the 2 study samples (KS p= 0.64, t-test p=0.66). Pairwise LD as r^2 was estimated between each distinct pair formed by taking each SNP in turn with the 10 SNPs on each flank. Paired r^2 differences between the 2 study samples (=0.0034) were small but significant by paired t-test (p=0.006), with larger values in the smaller sample. HapMap r^2 values were significantly higher than either of the study samples by paired t-test (eg p2e-16) although less than 1% (=0.009, =0.073) magnitude. 95% of all paired differences between HapMap and either study sample r^2 values were within +/- 0.14. If SNP tags are selected using 60 subjects and an r^2 threshold of 0.8, slightly less than half the pairs will have higher LD in study samples. Of those with lower LD, only a few percent will be below an r^2 of 0.66. r^2 determines effective sample size for LD mapping using a tag SNP, and power varies as the square root of the sample size. Where relative power for LD tagging is 1.0 for r^2=1.0, the lower 95^{th} percentile r^2 value of 0.66 corresponds to a relative power of about 0.81 compared to 0.89 for r^2=0.8. **Conclusion:** Estimates of LD for SNP tagging based on the small HapMap samples are biased upwards, and are subject to substantial sampling variability. In practice the effect of this bias on GWA study power appears to be relatively small.

Impact of DNA Source in the Illumina Golden Gate (GG) Assay. *Y. Tsai, O. Osimokun, I. McMullen, J. Zhang, J. Romm, E. Pugh, K. Doheny, C. Boehm* Center for Inherited Disease Research (CIDR) and Genetic Resources Core Facility SNP Center, IGM, JHUSOM, Baltimore, MD.

We have been providing SNP genotyping services using Illumina GG chemistry since 2004. Here we present performance statistics by DNA source for 53 custom and linkage projects released since summer 2005. The table below shows performance for DNAs from many labs obtained from several commonly-used sources. Samples with lower call rates and lower genotype quality scores are considered failed and data is not returned on them.

DNA source	Number of Samples	Overall Sample Failure	Number of Projects	Range of Failure by Project
Blood	40,110	2.63%	36	0 - 9.4%
Cultured Cells	19,651	1.29%	16	0 - 7.7%
Whole Genome Amplified (WGA)	3,645	5.46%	12	0 - 84.6%
Buccal	3,282	2.80%	5	0 - 16.7%

Blind duplicates supplied by the investigator were used to calculate genotype reproducibility by DNA source. Rates were overall very good (Blood: 99.9968%; Cultured cells: 99.9971%; WGA: 99.9522%; Buccal cells: 99.9937%). However, there is a distinct drop in reproducibility in WGA samples. Within DNA sources samples with higher call rates had higher reproducibility. Conclusion: DNA source made a difference in success of genotyping using the GG chemistry. Sources typically considered high quality (blood, cell lines) yielded higher genotype data quality as measured by reproducibility and call rates. The utility of WGA samples for genotyping was highly variable from project to project, ranging from sample failure rates of 0% to 84%.

Impact of the *BRCA*-genes on the burden of familial breast / ovarian cancer in South Africa. *E.J. van Rensburg[1], N.C. van der Merwe[2], M.D. Sluiter[1], C.M. Schlebusch[1]* 1) Dept Human Genetics, University of Pretoria, Pretoria, South Africa; 2) Division of Human Genetics, University of the Free State and NHLS, Bloemfontein, South Africa.

Breast cancer is the most common form of cancer to afflict women in South Africa (overall lifetime risk of 1 in 27 for all women). Between 5 and 10% of all breast cancer cases display patterns of familial inheritance. It has been estimated that 30 - 50% of familial cases are due to mutations in either of two breast cancer susceptibility genes, *BRCA1* and *BRCA2*. Germ-line mutations within the *BRCA*-genes are responsible for different proportions of inherited susceptibility to breast/ovarian cancer in different populations. Some mutations have frequently been reported in certain population groups, which have been shown to represent founder effects. A study was undertaken in order to determine the proportion of South African Afrikaner families who carry *BRCA* gene mutations. We fully screened 153 Afrikaner breast and/or ovarian cancer families (who had three or more affected individuals) for *BRCA1*/*BRCA2* mutations, using PTT and PCR-SSCP/Heteroduplex analysis. MLPA analysis was carried out to detect large rearrangements in the genes. In total, 103 families (67,3%) had a germ line disease-causing *BRCA*-mutation. Of these, 30 families (19,6%) carry a *BRCA1* mutation and 73 families (~47,7 %) carry a *BRCA2* mutation. Three unique founder mutations (p.E881X and c.1493delC in *BRCA1* and c.8162delG in *BRCA2*) were identified in the Afrikaner population. Collectively these three founder mutations account for 94% of mutation positive Afrikaner families with a history of 3 affected individuals. Genealogical studies have identified the founding couples. In conclusion: the *BRCA*-genes thus account for ~67% of South African Afrikaner breast/ovarian cancer families. The results obtained for *BRCA1* is similar to that found in populations from western Europe and America. The large contribution of *BRCA2* mutations to the burden of breast cancer susceptibility in Afrikaner families is however striking. These results now allow for better testing strategies and risk management of Afrikaner breast cancer families.

A genome-wide association study in 5,402 individuals identifies several susceptibility variants for body mass index. *R.J.F. Loos[1], S. Li[1], J.H. Zhao[1], E. Wheeler[2], S. Debbenham[3], D. Strachan[4], D. Hadley[4], K. Papadakis[4], W. McArdle[5], P. Deloukas[2], M. Inouye[2], R. McGinnis[2], M. Sandhu[3], I. Barroso[2], N.J. Wareham[1]* 1) MRC Epidemiology Unit, Cambridge, UK; 2) The Wellcome Trust Sanger Institute, Hinxton, UK; 3) Institute of Public Health, University of Cambridge, UK; 4) St George's, University of London, UK; 5) University of Bristol, UK.

It is well recognized that genes contribute to the development of obesity. However, the identification of genetic variants for BMI and obesity has been largely unsuccessful.

We applied genomewide association (GWA) to identify variants that contribute to BMI in 5402 men and women. Using inverse variance weighted meta-analysis, we combined 3 GWA studies (Affymetrix 500K GeneChip). The studies included two population-based cohorts; [1] EPIC-Obesity (n=2,418) and [2] the British Birth Cohort 1958 (WTCCC)(n=1,480). The 3rd study comprised the control samples of the Diabetes Genetics Initiative (n=1,504). After QC (SNP call rate 0.90, HWE $p>10^{-6}$ and MAF5%), 352,700 SNPs were considered for analyses. All analyses were based on an additive model. BMI was log-transformed and standardised by sex and age.

We identified 51 SNPs that showed consistent and significant association with BMI ($p<10^{-4}$). A total of 21 SNPs clustered in 9 loci, which included novel loci and FTO ($p=1.4x10^{-5}$). Notably, the strongest association ($p=3.4x10^{-6}$) was observed for a cluster of 9 intronic SNPs (MAF=15%) at chr 17p with a 0.13 z-score (or 0.56 kg/m^2) increase per minor allele. A FOX gene variant (MAF=20%) showed a protective association ($p=1.9x10^{-5}$, =-0.08 z-score/allele) and similar associations were observed for 3 intronic SNPs (MAF=31%) at chr 12p ($p=1.5x10^{-5}$, =-0.09 z-score/allele). Several other SNPs showed highly significant associations and will be discussed.

Our study has identified previously unknown gene variants that contribute to variation in BMI in Caucasians. Further replication is sought in a 4th population-based cohort (n=6,205) that is currently being analysed.

Creation of a humanized *IKBKAP* mouse that models a tissue-specific human splicing defect. *R.S. Shetty[1, 2], M.M. Hims[1, 2], Y.T. Chen[1, 2], J. Mull[1, 2], M. Leyne[1, 2], L. Liu[1, 2], J. Pickel[3], S.A. Slaugenhaupt[1, 2]* 1) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA; 2) Harvard Medical School, Boston, MA; 3) National Institute of Mental Health, National Institutes of Health, Bethesda, MD.

The importance of proper mRNA splicing is evidenced by the fact that 20-30% of all disease-causing genetic mutations result in splicing defects. It has been demonstrated that the plasticity of the splicing reaction can be exploited for the development of therapeutics that modify mRNA splicing efficiency. In familial dysautonomia (FD), a severe neurodegenerative disorder, all patients have an intronic splice site mutation in the *IKBKAP* gene, which results in tissue-specific skipping of exon 20. Although FD is a recessive disease, homozygous mutant cells express wild-type *IKBKAP* transcripts, and are therefore capable of producing normal IKAP protein. The relative amount of wild-type and mutant *IKBKAP* mRNAs varies between tissues, with the lowest levels of wild-type *IKBKAP* production in tissues from the nervous system. These observations suggest that the cellular level of IKAP protein in neurons falls below the threshold level required for normal development and maintenance. In order to study the tissue-specificity of the splicing defect, as well as to test potential therapeutic agents targeted at mRNA splicing, we created several transgenic mouse lines expressing either human wildtype *IKBKAP* or FD (IVS20+6T>C) *IKBKAP* from a human BAC. We show that the presence of the FD mutation in the BAC causes mis-splicing of human *IKBKAP* in mice, and that the efficiency of exon inclusion varies in a tissue-specific manner that closely models that seen in FD patients. The splicing defect is most pronounced in neuronal tissues, proving that the cellular mechanism governing the observed tissue-specific splicing is conserved. These transgenic mice provide the perfect model for pre-clinical testing of therapeutic agents that have been previously shown to improve normal *IKBKAP* splicing *in vitro*. Further, it provides a unique model for unraveling the complexities of tissue-specific alternative splicing.

On the identification of causal genetic effects in family-based association studies. *C. Lange[1], S. Goetgeluk[1], I. Waldman[2], S.T. Weiss[3], S. VanSteelandt[2,3]* 1) Department of Applied Mathematics and Computer Sciences, Ghent University, Ghent, Belgium; 2) Dept Biostatistics, Harvard Sch Public Health, Boston, MA; 3) Harvard Medical School, Channing Laboratory, 181 Longwood Avenue, Boston, MA 02115, USA} altaffiltext{2}{Harvard Medical School, Channing Laboratory, 181 Longwood Avenue, Boston, MA 02115, USA.

In genetic association analysis of complex traits, endophenotypes for different diseases are often associated with the same candidate gene. To understand the biological disease pathways, statistical methodology is needed that is able to distinguish whether such an association with two endophenotypes is purely attributable to environmental factors or whether it is has genetic causes. Here we propose a weighted family-based tests to infer whether a candidate gene has a direct biological influence on a given quantitative trait other than through its influence on another endo-phenotype. The proposed tests allow for incomplete parental mating types and are robust against unmeasured confounding due to population admixture and stratification. We illustrate the practical relevance of our approach by an application to an asthma study in which SNPs in the IL10 gene are associated with both BMI and FEV. Simulation studies show that the proposed methodology performs well with realistic sample sizes and in the presence of admixture and stratification.

Implications of the Property Approach in a Biobanking Context. *J.E. LeGrandeur, T. Caulfield, N. Ries* University of Alberta, Edmonton, Alberta, Canada.

The status and ownership of tissue samples in biobanks continues to be a controversial issue subject to much debate. For example, to what degree do research participants have continuing control over tissue samples that were previously collected? Do researchers need to re-consent for each new research project? Can participants withdraw their consent and request destruction of the sample? In examining these issues, many biobank policy documents focus on traditional consent norms, for example a right to withdraw consent at any time, so long as the samples remain identifiable. Some commentators have suggested that property principles ought to be given more consideration. Indeed, years after the landmark decision in *Moore v. Regents of the University of California*, which debates the ownership of extracted genetic material, the *Washington University v. Catalona* case has, again, raised a number of serious questions regarding the issue of whether patients have a property interest in their tissue.

In this presentation, we will explore: 1) the role of property principles in existing biobank policy documents (i.e., to what degree is property law considered?); 2) existing literature recommending a heightened role of property law in this context; and 3) the possible ramifications of emphasizing property law as compared to other legal/ethical principles (e.g., autonomy based consent law and confidentiality/privacy principles). This analysis will include such considerations as whether tissue donation to biobanks can/should be considered a gift, and the impact of a property perspective on commodification and policy concerns.

The Role of Natural Selection in Shaping Genetic Variation at the N-acetyltransferase (NAT) Genes in African and Global Populations. *H.M. Mortensen[1], P. Awadalla[2], S.A. Tishkoff[1]* 1) Department of Biology, University of Maryland, College Park, College Park, MD; 2) North Carolina State University, Raleigh, NC.

Currently, studies of the possible role of natural selection in shaping the observed variation at drug metabolizing enzyme (DME) loci remain limited. Functional variability at the arylamine N-acetyltransferase (*NAT*) genes is associated with adverse drug reactions and cancer susceptibility in humans. The purpose of this study is: 1) to characterize nucleotide variation at the *NAT* drug-metabolizing genes (*NAT1*, *NAT2*) and the pseudo-gene (*NATP1*) in global human populations, including many previously underrepresented African populations and 2) to understand the role that natural selection has played in shaping variation at *NAT1* and *NAT2* in human populations living in different environmental settings. We resequenced ~3000 bp for each of the *NAT1*, *NATP1* and *NAT2* gene regions, in ~200 ethnically diverse African individuals and ~150 individuals from a representative global panel (HGDP-CEPH). We have identified Single Nucleotide Polymorphisms (SNPs) at each locus (*NAT1* (38), *NATP1* (42) and *NAT2* (40)), and have characterized long-range linkage disequilibrium for the entire ~175 kb region. We are currently testing several models of neutrality under a range of demographic scenarios. This work will contribute to our understanding of how variation at the *NAT* loci may have been adaptive in dealing with changes in diet and exposure to toxins during human evolution. H.M.M. is supported by an NSF grant IGERT-9987590 to S.A.T. Additional funding was provided by US-NSF grants BSC-0196183 and BSC-0552486, US-NIH grant R01GM076637, and David and Lucile Packard Career Award to S.A.T. .

An international collaborative SNP-based whole genome linkage screen for high myopia. *Y-J. Li[1], A. Bulusu[1], R. Metlapally[1], F. Malecaze[2], P. Calvas[2], J.A. Guggenheim[3], D. Mackey[4], T. Nat'l Eye Clinic, Hellerup, Denmark.

Introduction: Myopia (nearsightedness) is a common complex disorder, and severe forms have implications for blindness due to increased risk of premature cataracts, glaucoma, retinal detachment, and chorioretinal degeneration. Multiple studies support a strong genetic component for myopic development. Several non-syndromic high-grade myopia loci have been mapped. The purpose of this study was to map new loci, refine existing locus intervals, and to identify associated genes for high myopia. **Methods:** A total of 6008 SNPs distributed genome-wide from the Illumina Linkage Panel IVb were genotyped. After screening for Mendelian and family relationship errors by PEDCHECK, RELPAIR and PREST programs, a collaborative 5-site international dataset of 249 multiplex high myopia families and 5880 SNPs was compiled. FASTLINK and MERLIN were used for 2-point and multipoint linkage analysis, respectively, for high myopia. Overall and center-specific datasets were evaluated. **Results:** FASTLINK revealed 15 SNPs on chromosomes 2, 5, and 12, with 2-point LOD scores 2.0. The highest 2-point LOD score was 3.18 for rs581642 on chromosome 12. Parametric multipoint analysis showed a 23.5cM linkage region on chromosome 12 with all marker HLOD scores 2 (peak HLOD=3.48). This interval was also supported by center-specific analysis. Other significant multipoint linkage regions were found on chromosome 2 (with a peak HLOD=2.25), and chromosomes 5, 9, and X with HLOD scores 1.0. **Conclusion:** The present results confirmed previously reported high myopia mapped loci on chromosomes 2 (MYP12), 12 (MYP3), and X (MYP1), with potential new linkage regions found on chromosomes 5 and 9. Linkage analyses for refractive error and other stratified datasets are underway. This is the largest linkage screen to date for mapping risk loci for high myopia.

A Whole Genome Scan For Polymorphisms Influencing Warfarin Dosing. *M.J. Rieder[1], G.M. Cooper[1], J.D. Smith[1], M.H. Wong[1], E.A. Johanson[1], D.L. Veenstra[2], A.E. Rettie[3]* 1) Genome Sciences; 2) Pharmacy; 3) and Medicinal Chemistry, University of Washington, Seattle, WA.

Warfarin is the most commonly prescribed oral anticoagulant and has a narrow therapeutic range which determines the stabilized warfarin dose for individual patients. Warfarin dosing is affected by both clinical and genetic factors, with the vitamin K epoxide reductase complex 1 (*VKORC1*) and cytochrome P450 2C9 (*CYP2C9*) genes having the largest known overall effect. To identify potentially novel associations with moderate to large genetic effect sizes (> 5% of stabilized dosage variance), we genotyped 190 warfarin stabilized patients of European-descent using the Illumina 550K BeadChip. Genotyping call rates for 561,466 SNPs averaged >98% across all samples. Regression analyses were used to identify novel, significant SNP/dose associations under three different base models: 1) independent SNP effects 2) adjusted for clinical covariates (i.e. age, sex, and medication use) 3) combined clinical and genetic (i.e. *VKORC1* and *CYP2C9*) factors. While the overall distribution of correlation measures revealed no systematic biases in our analysis, we find evidence for associations at a small minority of loci with uncorrected p-values below 10^{-4}. Under the clinical covariate model, polymorphisms within or in linkage disequilibrium with *VKORC1* and *CYP2C9* SNPs had p-values of $6x10^{-15}$ and 10^{-5}, explaining 25-30% and 10% of the variance in stabilized dose, respectively. *VKORC1* SNPs showed the strongest signal of association, suggesting that no other candidate gene has a greater contribution to stabilized warfarin dose in this dataset. SNPs below a p-value threshold of 10^{-4} were further explored for associations with warfarin dose, and may explain an additional 10-20% of variance in stabilized dose. Lastly, we tested all genotyped SNPs for significant statistical interactions with a highly predictive *VKORC1* polymorphism(rs10871454). In this analysis one polymorphism showed a significant interaction term (p-value < $8.0x10^{-7}$) despite having no independent effect on dose. Replication studies to confirm these findings have been initiated.

Machado-Joseph Disease enhances genetic fitness: a comparison between affected and unaffected women between MJD and the general population. *P.R. Prestes[1,3], M.L.S. Pereira[1,2], I. Silveira[3], J. Sequeiros[3], R. Giugliani[1,4], L.B. Jardim[1,5]* 1) Medical Genetics Service, Hospital de Clinicas, Porto Alegre, RS, Brazil; 2) Department of Biochemistry, UFRGS, Porto Alegre, RS, Brazil; 3) Instituto de Biologia Molecular e Celular, Universidade do Porto, Portugal; 4) Department of Genetics, UFRGS, Porto Alegre, RS, Brazil; 5) Departmento of Internal Medicine, UFRGS, Porto Alegre, RS, Brazil.

Background: Machado-Joseph disease (MJD-SCA3), a spinocerebellar ataxia related to an expansion of a CAG tract, has already been related to anticipation and meiotic drift. However, fitness of MJD carriers has been little studied. Objective: To analyze genetic fitness of MJD patients, comparing them to their unaffected relatives and to the general population (GP) of origin. Subjects and methods: 182 informants, belonging to 82 MJD families, agreed to participate in the study. Informants supplied data about 828 MJD patients. Number of children (NC), gender, age, school attainment, menarche and menopause were compared between general and emeritus (older than 45 years of age or deceased) groups. Results: Mean NC of the GP and of MJD patients were respectively 1.90 and 2.93 2.3 ($p = 0.0037$). Comparisons within families also showed differences: the mean NC of unaffected and affected emeritus MJD women were respectively 2.68 and 3.89 ($p = 0.0037$). Affected MJD women had earlier mean ages at the delivery of their first child and menopauses ($p < 0.011$ and 0.07, respectively). Among affected women, those who did not have children had larger CAG tract than those who had children ($p<0.05$). Conclusion: MJD enhances the fitness of its carriers, and this phenomenon seems to have a biological basis.

Failure to detect a DM1 expansion using triplet repeat-primed PCR. *J.S. Parboosingh, R.J. Klock, P.J. Bridge* Dept Medical Genetics, Alberta Children's Hosp, Calgary, AB, Canada.

Recently, the CTG repeat expansion in the DMPK gene causing myotonic dystrophy failed to be detected in two patients by triplet repeat-primed PCR (tpPCR) using frequently cited primers. In recent years, this method has been applied to a number of trinucleotide repeat disorders as it has several advantages over the traditional Southern blot analysis. Triplet-primed PCR allows for a rapid turnaround time on a small amount of DNA particularly important for diagnostic confirmation in hypotonic babies and prenatal cases; however, it does not allow one to estimate the size.

TpPCR has been the method of choice in the Molecular Diagnostic lab for 20 months. During this time 40 screens have been performed for a variety of reasons including: confirmation of diagnosis, and prenatal testing. A two step approach is taken: 1) primers flanking the repeat are used to determine the number of repeats within the normal range and up to approximately 100 repeats; and 2) tpPCR is performed on all samples with a single repeat from step 1 to exclude the presence of a large expansion and thus confirm homozygosity. We have designed tpPCR assays utilizing both DNA strands (using both a CTG and CAG repeat primer) allowing for bidirectional tpPCR. We have detected 17 patients with expansions. Two of the 17 expansions were not detectable using the frequently cited P1 primer with the CTG repeat primer but were detectable using the complementary CAG repeat primer and the opposite flanking primer (other strand). Utilization of tpPCR in only one direction would have led to a false negative result for these patients. This has led to the identification in the SNP database of a C>T substitution within the P1 primer binding site. We will present these findings as well as a frequency for this polymorphism.

The Inheritance of Resistance Alleles in Multiple Sclerosis. *S.V. Ramagopalan[1,2], D.A. Dyment[1,2], B.M. Herrera[1,2], G.C. DeLuca[1,2], M.R. Lincoln[1,2], S.M. Orton[1,2], M.J. Chao[1,2], A.D. Sadovnick[3], G.C. Ebers[1,2]* 1) Department of Clinical Neurology, Oxford University, Oxford, United Kingdom; 2) Wellcome Trust Centre for Human Genetics, Oxford University, Oxford, United Kingdom; 3) Departments of Medical Genetics and Neurology, University of British Columbia, Vancouver, Canada.

Multiple sclerosis (MS) is a complex trait in which alleles at or near the class II loci HLA-DRB1 and HLA-DQB1 contribute significantly to genetic risk. HLA-DRB1*15 and HLA-DRB1*17 bearing haplotypes and interactions at the HLA-DRB1 locus increase risk of MS but it has taken large samples to identify resistance HLA-DRB1 alleles. In this investigation of 7093 individuals from 1432 MS families, we have assessed the validity, mode of inheritance, associated genotypes and the interactions of HLA-DRB1 resistance alleles. HLA-DRB1*14, DRB1*11, DRB1*01 and DRB1*10 bearing haplotypes are protective overall but they appear to operate by different mechanisms. There are major practical implications for risk and for the exploration of mechanisms in animal models. Restriction of antigen presentation by HLA-DRB1*15 seems an improbably simple mechanism of MHC associated susceptibility.

Association of Tagging SNPs in *MLH1* with Prostate Cancer Susceptibility in Men of European Ancestry. *P. Pal[1], H. Xi[1], S. Guha[1], G. Sun[1], S. Indugula[1], J. Meeks[2], S. Thaxton[2], J. Mallik[1], H. Cheng[1], B.K. Suarez[3], W.J. Catalona[2], R. Deka[1]* 1) Center for Genome Information, Univ Cincinnati, Cincinnati, OH; 2) Department of Urology, Northwestern University Feinberg School of Medicine, Chicago, IL; 3) Department of Psychiatry, Washington University School of Medicine, St. Louis, MO.

Prostate cancer (PCa) is the most commonly diagnosed visceral malignancy and the second leading cause of cancer deaths in men in the United States. There is strong evidence that genetic factors are involved in PCa susceptibility. Mismatch repair genes play a major role in maintaining DNA integrity and are implicated in the etiology of various cancers including PCa. We have tested association of tagging SNPs (tagSNP) in *MLH1*, a known tumor suppressor and member of mismatch repair gene-family, with PCa susceptibility in men of European descent. Seven tagging SNPs were selected from the HapMap database and analyzed in a sample of 596 histologically diagnosed PCa cases and 567 ethnicity matched controls. All of the typed SNPs conform to Hardy-Weinberg expectations. We found significant allelic frequency differences between cases and controls in four of the tagSNPs ($P \sim 0.046$ to <0.0001). Haplotype analysis revealed the second most common haplotype encompassing all 7 tagSNPs to be significantly associated with PCa susceptibility (18% in cases vs 23% in controls; $P = 0.018$). Structure analyses negate the evidence of population stratification which could have confounded the association. These results indicate a primary role of *MLH1* variants in prostate carcinogenesis in men of European descent.

Genome-wide Scan for Association to Schizophrenia. *J.L. Stone[2,7], Intl. Schizophrenia Consortium[1,3,4,5,6,8,9,10]* 1) Inst. of Med. Sci., Univ. of Aberdeen, Aberdeen, UK; 2) Psych. Genet. Initiative, The Broad Inst. of Harvard and MIT, Cambridge, MA; 3) Dep. of Psychol. Med., Cardiff Univ., Cardiff, UK; 4) Windeyer Inst. of Med. Sci., UCL, London, UK; 5) Div. of Psych., Univ. of Edinburgh, Edinburgh, UK; 6) Dep. of Med. Epidemiology and Biostat., Karolinska Inst., Stockholm, Sweden; 7) Psych. and Neurodev. Genet. Unit, MGH, Boston, MA, USA; 8) Dep. of Psych., UNC, Chapel Hill, NC; 9) Dep. of Psych. and Behavioral Sci., USC, Los Angeles, CA; 10) Inst. of Molec. Med., TCD, Dublin, Ireland.

Despite evidence of a strong inherited genetic component in the etiology of schizophrenia, research suggests that each variant may have a small to modest contribution to overall genetic susceptibility. To obtain the number of samples necessary to have sufficient power to identify susceptibility loci of modest effect, researchers from institutions across Europe and the US have created a consortium to perform a case-control whole genome association study. Participating institutions are: Univ. of Aberdeen, The Broad Inst., Cardiff Univ., Univ. College London (UCL), Univ. of Edinburgh, Karolinska Inst., Massachusetts General Hospital (MGH), Univ. of North Carolina (UNC), Univ. of Southern California (USC), and Trinity College Dublin (TCD). Samples were collected at sites representing six countries. Schizophrenic cases, diagnosed using comparable semi-structured interviews, and an approximately equal number of population-based controls were contributed by seven of the above listed institutions (excluding the Broad Institute, MGH and UNC). Samples were genotyped on either the 500K (5.0 SNP Chip) or 1 million (6.0 SNP Chip) Affymetrix SNP genotyping platform. Data were cleaned and analyzed using the genetic analysis package, Plink. Approximately 3800 cases and 4200 controls have been genotyped in two waves at The Broad Institute of Harvard and MIT. The first wave of samples (n ~ 3300) was genotyped on 500,000 SNPs while the second wave of samples was genotyped on 1 million SNPs, reflecting the current rapid evolution of genotyping technologies. Here we present genotyping performance, quality control steps and preliminary association analysis.

Social attitudes toward genetic testing and social image of "gene" in Japan. *A. Tsuchiya, T. Ohata, M. Watanabe, F. Takada* Medical Science, Kitasato University, Sagamihara, Kanagawa, Japan.

A purpose of this presentation is to analyze social attitudes toward genetic testing, especially about polygenic disease, in Japan. This analysis includes correlation between image of gene, an extent of genetic determinism, and the other basic properties like age, gender and the other ones. I used 3000 Samples which were collected by random sampling through out Japan. The ratio of basic properties - age, gender, marriage and region - is distributed according with the one of national census in 2005.

The output below is multiple regression analysis that dependent variable is the degree of needs to genetic testing about life-style related disease and independent variables are an extent of genetic determinism(12-48),image of gene(bad/good 1-4)and the other basic properties(gender,marriage).

	Coef	Std	Err	p>|t|
women (dummy)	.187	.039	4.79	0.000
married (dummy)	-.038	.040	-0.96	0.335
genetic determination	.020	.003	6.83	0.000
image of gene	.134	.019	6.92	0.000
cons	1.485	.188	7.91	0.000

One output of this analysis is that the needs of genetic testing about life-style related disease is affected especially by an extent of genetic determinism and image of gene, controlling the other variables(gender, marriage)..

HTRA1 variant increases risk to neovascular age-related macular degeneration in Chinese population. *Z. Yang[1, 2], F. Lu[2], J. Hu[2], Q. Zhao[3], Y. Lin[2], Y. Yang[2], X. Liu[2], Y. Fan[2], B. Chen[2], S. Liao[2], C. Lei[2], D. Cameron[1], K. Zhang[1]* 1) Ophthalmology Research, Univ Utah, Salt Lake City, UT; 2) Sichuan Academy of Medical Sciences & Sichuan Provincial People's Hospital, Chengdu, Sichuan, China; 3) Xing Hua Hospital, Shanghai Jiao Tong University, Shanghai, China.

Purpose: Age-related macular degeneration (AMD) is a leading cause of irreversible visual impairment in the world. The two forms of advanced AMD, geographic atrophy (GA) and choroidal neovascularization (wet AMD), represent two types of degenerative processes in the macula that lead to loss of central vision. Drusen are characterized by deposits in macula without visual loss and are considered a precursor of advanced AMD. Recently rs11200638 in the promoter of HTRA1 has been shown to increases the risk for wet AMD in Caucaian and Hong Kong Chinese population. We investigated association between rs11200638 and wet AMD and drusen in a Mainland Chinese cohort. Methods: We genotyped rs11200638 for 128 Chinese patients (64 wet AMD and 64 drusen) and 106 normal controls. We performed chi square analysis for an additive allelic model. Results: rs11200638 was significantly associated with wet AMD (P=1.9X10-9). However, it is not associated with drusen in Chinese population . Conclusions: rs11200638 in HTRA1 is significantly associated with wet AMD in Mainland Chinese. These findings confirmed the role of HTRA1 in wet AMD. Understanding the underlying molecular mechanism will provide an important insight in pathogenesis of AMD. **Purpose**.

Ethnicity, gender and the incidence of congenital heart defects: a report from the National Down Syndrome Project. *A.E. Locke[1], L.H. Bean[1], E.G. Allen[1], S.W. Tinker[1], C. Druschel[2], C.A. Hobbs[3], L.A. O'Leary[4], P.A. Romitti[5], M.H. Royle[6], C.P. Torfs[7], K.J. Dooley[8], S.L. Sherman[1], S.B. Freeman[1]* 1) Dept. of Human Genetics, Emory University, Atlanta, GA; 2) New York State Department of Health, Troy, NY; 3) College of Medicine, Dept. of Pediatrics, University of Arkansas for Medical Sciences, Little Rock, AR; 4) National Center on Birth Defects and Developmental Disabilities, Centers for Disease Control and Prevention, Atlanta, GA; 5) Dept. of Epidemiology, College of Public Health, University of Iowa, Iowa City, IA; 6) New Jersey Department of Health and Senior Services, Trenton, NJ; 7) Public Health Institute, Birth Defects Studies, Emeryville, CA; 8) Sibley Heart Center Cardiology, Childrens Healthcare of Atlanta, Atlanta, GA.

The population-based National Down Syndrome Project used a combination of epidemiological and molecular methods to study congenital heart defects (CHDs) in infants with Down syndrome (DS). Between 2000 and 2004, six sites, representing approximately 11% of annual DS births in the US, identified 1469 eligible infants with DS. 44.2% had a major cardiac defect including atrioventricular septal defect (AVSD, 17.2%), secundum ASD (ASDII, 18.6%), ventricular septal defect (VSD, 19.2%), and/or tetralogy of Fallot (TOF, 2.7%). Infants with AVSD showed significant gender and ethnicity differences. There were twice as many affected females as males (OR: 2.19 (95% CI 1.48-3.24)). Compared to whites, black infants were twice as likely to have an AVSD (adj. OR 2.09 (95% CI 1.20-3.64)) while Hispanics were half as likely (adj. OR 0.50 (95% CI 0.28-0.92)). The increased AVSD risk among black infants and the decreased risk among Hispanics were more evident among those whose mothers were born outside the US. These findings suggested that black infants with AVSD would have a higher proportion of African-derived alleles than those without AVSD. Using ancestry informative markers (AIMs), we confirmed a higher proportion of Sub-Saharan Africa-derived alleles in those affected with AVSD ($p = .029$). We conclude that gender and ethnic differences exist for AVSD and, at least among blacks, the ethnic differences could be due to genetic risk factors.

Loss of maternal alleles on chromosome 11 is associated with aggressive prostatic rhabdomyosarcoma in two patients with Costello Syndrome. *K. Sol-Church[1], D. L. Stabley[1], K. Conard[2], L. Nicholson[3], J. Sanford Biggerstaff[4], W. Liu[4], J. Campbell[5], W.H. Meyer[5], K.W. Gripp[3]* 1) Center for Pediatric Research; 2) Department of Pathology and; 3) Medical Genetics, AI duPont Hospital for Children, Wilmington, DE; 4) Sacred Heart Medical Center Cytogenetics Lab, Spokane, WA; 5) OU Health Sciences Center Oklahoma City, OK.

Costello syndrome (CS) is a rare autosomal dominant, multiple congenital anomaly syndrome comprising failure to thrive, short stature, mental retardation, congenital heart disease, and a predisposition for embryonal rhabdomyosarcoma (ERMS). We report on the molecular evaluation of two CS pts with ERMS exhibiting LOH for chromosome 11. **Case 1**: A male with polyhydramnios, prematurity, feeding difficulties and short stature received growth hormone from age 5 to 12 years. A pelvic ERMS involving the prostate and bladder occurred at age 16 years. While the pt had been previously diagnosed with Noonan syndrome, molecular analysis revealed a heterozygous *HRAS* G12S mutation diagnostic of CS. **Case 2**: A male with a history of polyhydramnios, severe feeding difficulties, developmental delay and typical facial features for CS had a germline *HRAS* G12S mutation. He presented at age 18 months with abdominal distension and bilateral hydronephrosis due to outflow tract obstruction. CT scan revealed a large pelvic ERMS, later confirmed by needle biopsy. While normal cells derived from these two pts display biallelic *HRAS* expression, tumor cells show loss of maternal markers located on both arms of chromosome 11 and monoallelic expression of the mutated *HRAS* gene. Besides LOH for chromosome 11 the tumor biopsies display allelic imbalance for markers vWA (12p), FGA (4q), Amelogenin, D5S818, D7S820, D8S1179, D13S317 D18S51, and D21S11. **Conclusion**: LOH for 11p13-15 resulting in overexpression of the paternal allele has been suggested as an initiating event for ERMS. This implies a decreased ERMS risk for CS pts carrying a maternally derived mutation. While our cohort study currently contains too few pts with maternally derived mutations to address this issue, determination of parental *HRAS* mutation origin may further define the risk for ERMS in CS.

Genome-Wide Association Studies for Complex Diseases Using the Quebec Founder Population. *B. Paquin, H. Fournier, J. Raelson, P. Van Eerdewegh, P. Croteau, Q. Nguyen, J. Segal, S. Briand, N. Paquin, B. Stojkovic, V. Bruat, S. Debrus, S. Kebache, R. Little, J. Hooper, A. Belouchi, T. Keith* Genizon BioSciences, St-Laurent, QC, Canada.

To date we have completed 10 GWAS for complex diseases using the Quebec founder population (QFP). Based on permutation studies, we have evidence for genome-wide significance for many association signals across the various studies, indicating that we have achieved well-powered GWAS with relatively small sample sizes (~500 cases and 500 controls). Key to success was the use of the QFP coupled with high quality genotyping and efficient, automated pipelines for genetic analyses. The QFP is an ideal population for genetic studies, characterized by an initial bottleneck of 2,600 effective French founders in the 17th century followed by rapid population expansion in genetic isolation, resulting in a relatively homogeneous population of 6 M individuals. Using an Illumina-based genotyping platform, we generated over 2 B genotypes with call rates 99% and reproducibility and accuracy 99.7%. High-quality genotyping data are crucial for the reliable identification of association signals (simulation studies show signals may be missed by degrading data quality). To efficiently process and analyze the vast amount of data, we have built an automated genetic analysis pipeline, GeneSys, which consists of a suite of optimized genetic analysis components including data cleaning, haplotype estimation, association analyses (both haplotype and single marker), and data visualization using a customized version of GBrowse. We show that some loci were detected in the genome scan exclusively from haplotypes and that haplotype analyses increase power for gene detection in some regions. Using our pipeline, a complete GWAS including genome-wide significance based on 500 permutations can be completed within one week. We perform sub-phenotype and gender-specific analyses and conditional analyses for the detection of gene-gene interactions. The identified genes are used to infer a GeneMap that consists of networks of interacting disease genes and their biological pathways. Our process is shown using examples from various studies.

Replication and fine-mapping of association of FTO SNPs with obesity. *H. Lyon[1,2], G. Lettre[1,2], E. Speliotes and[1,2], J.N. Hirchhorn for the Diabetes Genetics Initiative (DG[1,2], J. Butler[1,2], Z. Gajdos[1,2], L. Peltonen-Palotie[2,3], M. KuokKanen[2,3], V. Salomaa[3], R. Cooper[4], X.F. Zhu[5], G. Dedoussis[6], C. Papoutsakis[6], N. Vidra[6], K. Ardlie[2], K. DeLellis[7], B. Henderson[7], L. Kolonel[8], M. Palmert[5]* 1) Div Genetics, Boston Children's Hosp & Harvard Med Sch, Boston, MA; 2) Broad Inst, Cambridge, MA; 3) National Public Health Inst, Helsinki, Finland; 4) Loyola U Med Cen, Maywood, IL; 5) Case Western Reserve U, Cleveland, Ohio; 6) Harokopio U, Athens, Greece; 7) USC, Los Angeles, CA; 8) U of Hawaii, Honolulu, HI.

Background: Two groups (Frayling 2007, Dina 2007) recently reported an association of SNPs in the *FTO* (fat mass obesity associated) gene with body mass index (BMI) and fat mass in adults and children. We sought to replicate this association in population-based and case-control cohorts, to examine the affect on obesity in children, and to extend this finding into African-American cohorts. Results: We genotyped rs9939609 and 15 SNPs selected on the basis of LD patterns in the HapMap CEU and YRI samples. The association with rs9939609 replicated in 2 adult cohorts, a population based cohort from Finland (FINRISK97, N=6488, p=1x10-6) and a case control cohort from US and Poland (N=2873, p=0.053), as well as in a pediatric cohort (GENDAI, N=790, p=0.04). The association with BMI was less evident in a Scandinavian case-control study of diabetes(DGI, N=3048, p values in cases, controls, and combined =0.055, 0.538 and 0.082 respectively). In a case-control study for age at menarche (Multiethnic Cohort, N=1801), the association appeared stronger in women of Caucasian and Hispanic ancestries with early menarche (p=0.001) rather than late menarche (p=0.81). We have not yet found convincing evidence of association between *FTO* SNPs and BMI in African-Americans (N=835 related people, p=0.382 and N=893 unrelated, p=0.99) or stronger associations with nearby *FTO* SNPs. Conclusion: The intronic variants in *FTO* seem to affect obesity in adults and children of European ancestry, and this effect may be stronger in women with early menarche. Fine-mapping is underway to define the causal risk alleles in African-Americans.

Abnormal karyotype at relapse of Acute Myeloid Leukemia (AML) patients with normal primary diagnostic karyotype. *S.N.J. Sait[1], E.S. Wang[2], M. Barcos[3], A.W. Block[1], M. Wetzler[2], G. Deeb[3]* 1) Clinical Cytogenetics Laboratory, Roswell Park Cancer Institute, Buffalo, NY; 2) Department of Medicine, Roswell Park Cancer Institute, Buffalo, NY; 3) Department of Pathology, Roswell Park Cancer Institute, Buffalo, NY.

Karyotypic abnormalities are the most important independent prognostic factor in acute myeloid leukemia (AML) and predict for treatment response and overall survival following chemotherapy and stem cell transplantation. At Roswell Park Cancer Institute, we examined a cohort of 12 de novo AML patients with an apparently normal karyotype at diagnosis and abnormal karyotype at relapse. According to FAB morphological classifications, five cases were M2, five M1, one M4, and one M5a. The patients median age was 63 years (range 21 to 81 years); 6 were males and 6 females. Chromosomal abnormalities included 3 with unbalanced structural rearrangements; 3 with balanced rearrangements; 5 with complex karyotypes and 1 with numerical changes. Rearrangements observed at relapse did not include those commonly observed in patients with AML at initial diagnosis, except for one patient with trisomy 8. Aberrations commonly associated with secondary AML i.e. -5/5q-, -7/7q- and 11q23 abnormalities were also not observed. FLT3 mutation analysis performed on seven patients in relapse was positive in six cases. Patients had a median overall survival time of 15 months with the median time to relapse being 12 months and median survival after relapse of 4 months. All patients died of refractory disease. The longest overall survival time observed (49 months) was seen in the patient with trisomy 8. Thus, karyotypic instability may play a role in the development of refractory disease in AML. Defining the karyotypic abnormalities at relapse may contribute to the risk stratification of AML patients with a normal karyotype at diagnosis.

Newborn screening for cystic fibrosis in the Czech Republic: systematic utilization of prenatal diagnosis since 1990 has decreased incidence of the disease. *M. Macek[1], M. Balascakova[1], A. Holubova[1], V. Skalicka[2], V. Vavrova[2], D. Zemkova[2], P. Kracmar[3], J. Camajova[1], T. Piskackova[1], F. Votava[3]* 1) Department of Medical Genetics, Charles University -UH Motol, Prague, Czech Republic; 2) Department of Pediatrics, Charles University - UH Motol, Prague, Czech Republic; 3) Department of Pediatrics, Charles University - UH Kral. Vinohrady, Prague, Czech Republic.

An early diagnosis of cystic fibrois (CF) is a favorable prognostic factor. Unless meconium ileus is present at birth, CF can be misdiagnosed by practitioners. Increase of the age at dg. (ADG; before 1998 /median 0.58 years/; 1999-2005 /1.2 years/; p = 0.036), due to the devolution of healthcare since 1993, led us to initiate a pilot CF newborn screening project (NBS; IRT/DNA/IRT; II/2005-XI/2006), covering ~62% of all newborns. Concentrations of immunoreactive trypsinogen (IRT) were measured in 76,438 Guthrie cards and their levels above the arbitrary cut off (75ng/ml) were found in 799 cases (1.05%). Positives were subjected to DNA testing using population specific *CFTR* panel with a ~84% detection rate. In total, 12 CF cases were identified and the median ADG was 37 days (range 26-54). Interestingly, we also diagnosed previously unrecognised CF in 3 older sibs. Fifty three IRT positive newborns with only 1 *CFTR* allele, were subjected to follow-up sweat testing. Thus far, 45 cases were negative (ie. unaffected heterozygotes), while in one instance a borderline result requires long-term monitoring. When using NBS data alone the incidence of CF was rather low (1: 6,369), compared to the previously (from early sixties) epidemiologically established value of 1:2,700. However, when prenatal diagnosis data from within the study period were taken into account incidence of CF has increased to 1:3,900. Overall, our study proved that NBS is a feasible and efficacious tool for uniform and early diagnosis of CF. The current lower incidence of the disease reflects systematic, population wide application of prenatal diagnosis (via compulsory ultrasound screening for fetal hyperechogenic bowel) since 1990.

Polymrophisms In The NPPA Gene Associate With Asthma. *J. Wang[1], S. Mohapatra[2], H. Feng[3], J. Marks[1], L. Chepenik[1], M. Castro[4], C.G. Irvin[4], J.A. Johnson[3], J.E. Sylveste[1], J.J. Lima[1]* 1) Pharmacogenetics Center, Nemours Childrens Clinic, Jacksonville, FL; 2) University of South Florida, Tampa, FL; 3) Pharmacy Practice, University of Florida, Gainesville, FL; 4) Wake Forest University, Winston-Salem, NC.

Asthma is a common chronic complex disease characterized by inflammation, constriction of the airways and bronchial hyperresponsiveness to external stimuli. Susceptibility loci for asthma have been mapped to regions in many chromosomes including Chromosome 1p36 where the *NPPA* (natriuretic peptide precursor A) gene is located. *NPPA* gene encodes for atrial natriuretic peptide (ANP). ANP is produced mainly in the atria and ventricles and distributed in most tissues of the body, playing an important role in vasodilation, bronchorelaxation, pulmonary permeability, and in augmenting allergic inflammation and asthma. We hypothesized that *NPPA* polymorphisms are associated with asthma. Participants with well-characterized asthma (Cases, 297 Whites and 114 Blacks) were selected from clinical trials sponsored by the American Lung Association (NEJM 2001;345:1529; Am J Respir Crit Care Med 2007;175:235). Healthy subjects (Controls, 114 Whites and 73 Blacks) were recruited from a recent study (Metabolism 2007;56L757). Three *NPPA* SNPs were analyzed by a LightTyper instrument using a case-control approach: A/G (rs5063) in Exon 1 resulting in Met32 to Val substitution; C/T (rs5065) in Exon 3 resulting in a change of Arg152 to Ter and A/G (rs5067) in the 3UT region. All 3 SNPs were in HWE for both ethnic groups, except rs5063 in Blacks. Minor allele frequencies for rs5063 A, rs5065 C and rs5067 A were significantly higher in Blacks compared to Whites: 0.074, 0.369, and 0.381 vs. 0.045, 0.160, and 0.100, respectively (p 0.002). In both ethnic groups, significant associations were found between asthma and rs5065 (p 0.003) and rs5067 (p 0.009), with a trend for rs5063 (p 0.02). The frequencies of the minor allele carriers for rs5063, rs5065 and rs5067 in Controls vs. Cases combined from the 2 ethnic groups were 15.8% vs. 7.1%, 52.3% vs. 31.6%, 40.5% vs. 23.3% respectively. We conclude that *NPPA* is an asthma susceptibility gene.

Identification and characterization of a *NUP98-PHF23* fusion gene in acute myeloid leukemia. *J.C. Reader[1], J.S. Meekins[2], I. Gojo[3,4], Y. Ning[1,2]* 1) Program in Human Genetics; 2) Dept. of Pathology; 3) Dept. of Hematology-Oncology, Univ of MD School of Medicine, Baltimore, MD; 4) Marlene and Stewart Greenebaum Cancer Center, Baltimore, MD.

NUP98 is a promiscuous fusion partner gene linked to hematological malignancies. We have recently identified a cryptic 11;17 translocation in an acute myeloid leukemia (AML) patient creating a novel in-frame fusion between *NUP98* exon 13 with *PHF23* exon 4. *NUP98*, which encodes a nucleoporin, has been involved in more than 20 different fusions. *PHF23* is an uncharacterized gene encoding a protein containing a plant homeodomain (PHD) which is found in proteins that mediate chromatin remodeling. The fusion partners of *NUP98* form two distinct groups: homeobox (*HOX*) genes and non-homeobox (non-*HOX*) genes. The non-*HOX* fusion partner genes, which include *NUP98-PHF23*, are diverse in function and are only related by having the capacity to form coiled-coil domain(s). Since the majority of the research has focused on the mechanism of *NUP98-HOX* genes in leukemogenesis, we are interested in further characterizing this novel fusion gene in the non-*HOX* group. In order to test if *NUP98-PHF23* is able to induce oncogenic transformation we have cloned the full length (FL) fusion gene and two mutant constructs into expression vectors. The mutant constructs, which have the PHD domain (PHD) or the PHD and coiled-coil domains (Coil) removed, will be used to determine which domains, if any, are important for transformation. The FL and PHD constructs were used in an anchorage independent growth assay with preliminary results suggesting that the FL and PHD constructs are both capable of inducing anchorage independent growth in NIH3T3 cells; however, the results of this experiment and the Coil construct remain to be confirmed. The constructs will also be used to test their oncogenic potential in blocking differentiation in myeloid cells. Future directions include localization studies, identifying potential interacting co-factors, and determining whether *NUP98-HOX* and *NUP98*-non-*HOX* have a shared mechanism in leukemogenesis which, in turn, could lead to new potential therapeutic targets.

Systematic evaluation of genetic defects in 220 patients with Tetralogy of Fallot. *A. Rauch[1], R. Rauch[2], S. Zink[3], C. Zweier[1], C. Purmann[1], J. Hoyer[1], P. Nürnberg[4], A. Reis[1], H. Singer[3], M. Hofbeck[2]* 1) Institute of Human Genetics, Friedrich-Alexander University Erlangen-Nuremberg, Erlangen, Germany; 2) Pediatric Cardiology, University of Tuebingen, Tuebingen, Germany; 3) Pediatric Cardiology, Friedrich-Alexander University Erlangen-Nuremberg, Erlangen, Germany; 4) Cologne Center for Genomics (CCG), University of Cologne,Cologne, Germany.

Tetralogy of Fallot (TOF) is the most common complex congenital heart defect accounting for about 5-6% of patients. Various chromosomal anomalies, microdeletion 22q11.2 and mutations in NKX2.5 have been described as recurrent causes. In order to address the question about the incidence of these known causes in a larger cohort and to prove the role of JAG1 and TBX1 mutations as candidate genes known to cause isolated TOF in single families and the 22q11.2 microdeletion phenotype, respectively, we performed chromosomal analysis, 22q11.2 microdeletion testing and sequencing of NKX2.5, JAG1 and TBX1 in a cohort of 220 unselected patients with TOF. 80 randomly selected patients were also analysed for chromosomal microaberrations with molecular karyotyping using 100 K SNP arrays. 17 patients (7.7%) showed the common 3 Mb microdeletion 22q11.2, 6 patients (2.7 %) had trisomy 21, 3 (1.2%) had other chromosomal aneusomies. Two patients (1%) each had known mutations in NKX2.5 and JAG1. Two patients showed rare variants in TBX1, one of which did not show any functional alteration in a transcriptional reporter assay while results in the second are pending. Surprisingly, 4 of 80 patients tested (5%) showed causative microaberrations detected by molecular karyotyping. These 4 patients had mental retardation in addition to TOF. Another 4 patients had small microdeletions containing candidate genes for heart development, which are under further investigation. Our results confirm that microdeletion 22q11.2 and trisomy 21 are the most common causes of TOF, while NKX2.5 and JAG1 are only rare causes of TOF. TBX1 apparently does not significantly contribute to the aetiology of TOF. In contrast, microaberrations detectable by molecular karyotyping seem to play a major role in congenital heart defects.

Significant epistasis among susceptibility genes confers increased asthma risk in farmers. *M. Zucchelli[1], A. Dixon[3], E. Melen[2], M. Kronqvist[4], M. Moffatt[3], W.O. Cookson[3], M. van Hage[4]* 1) Centre for Biotechnology at Novum, Karolinska Inst, Stockholm, Sweden; 2) Institute of Environmental Medicine, Karolinska Institutet, Stockholm, Sweden; 3) National Heart and Lung Institute, Molecular Genetics Division, Imperial College, London, UK; 4) Department of Allergy and Clinical Immunology, Institute of Medicine, Karolinska Institutet, Stockholm, Sweden.

Studies of the molecular genetics of asthma and IgE-mediated allergy have pointed out the complexities of these diseases. Multiple chromosomal regions of genetic linkage have been observed and a number of candidate genes for allergy and asthma have been described. Gene-gene interactions, the effect of one locus being altered by effects at another locus/loci, have previously been reported between several candidate genes, especially those involved in the inflammatory response such as the TH2 cytokines. We have genotyped 56 SNPs in 12 common asthma and allergy susceptibility genes in 461 farmers of European descent. Individuals were tested for asthma, allergic disease, atopy and sensitisation to a number of common inhalant allergens. At the SNP level we could replicate, although with modest effect size, that the recently cloned asthma susceptibility gene PHF11, is also associated with asthma and allergy in this specific population. When exploring epistatic effects, we found significant interactions between TNF-? (TNF), FCER1B (MS4A2) and TLR9 with regard to asthma and atopy. Other biologically interesting effects were observed between other genotyped genes but the p-values were not significant after correction for multiple testing. Our results confirm that gene-gene interaction is a common phenomenon in complex diseases such as asthma and allergy and that epistatic analyses should be evaluated when conducting genetics studies of these diseases.

Investigating CAG repeat instability in Huntington's disease. *M. Swami, E. Dragileva, A. Teed, T. Gillis, E. Lopez, M.E. MacDonald, V.C. Wheeler* CHGR, MGH, Boston, MA.

Huntingtons disease (HD) is a progressive neurodegenerative disease caused by the expansion of a polymorphic CAG repeat in exon 1 of the *HD* gene over 35 repeats. Mutant expanded CAG repeats are unstable both in the germline and somatic tissues of HD patients. The highest levels of somatic instability are observed in the striatum and cortex, which are the tissues most susceptible to HD pathogenesis. We are investigating the mechanisms underlying *HD* CAG repeat instability and the role of somatic instability in HD pathogenesis. Genetic modifiers of instability are being investigated in *Hdh*^{Q111} mice, an accurate genetic knock-in mouse model of the disease, previously shown to recapitulate both the germline and tissue-specific somatic repeat instability observed in HD patients. *Hdh*^{Q111} mice have been crossed to various lines of mice deficient in DNA repair proteins and analysed for germline and somatic repeat instability and for the nuclear localization of mutant huntingtin, an early striatal-specific phenotype. Crosses with mice deficient in mismatch repair protein Msh2 and its binding partners Msh3 and Msh6 reveal that Msh2 and Msh3, but not Msh6, are needed for expansions in the male germline and in the striatum. This suggests that germline and somatic instability are mediated via Msh2-Msh3 complexes rather than Msh2-Msh6 complexes. Loss of Msh2 or Msh3 slows the nuclear accumulation of mutant huntingtin. Crosses with mice deficient in Xpc, a component of the nucleotide excision repair pathway, indicate that this pathway is not a major player in *HD* CAG repeat instability. The delayed nuclear huntingtin accumulation in the absence of Msh2 or Msh3 suggests that somatic expansion contributes to the disease process. We are investigating this hypothesis in HD patient brain samples. Using a sensitive small-pool PCR analysis we are quantifying the degree of somatic repeat instability in the cortex of HD patients that exhibit extreme early or extreme late age of onset as predicted by their mutant CAG repeat length in order to test whether patients with higher levels of somatic expansion have earlier ages of disease onset.

Simulation and visualization tools for gene discovery studies of complex human diseases. *S. Schmidt[1], R.-H. Chung[1], X. Qin[1], X. Lou[1], M. Schmidt[2], E.R. Martin[2], E.R. Hauser[1]* 1) Ctr Human Genetics, Duke Univ Medical Ctr, Durham, NC; 2) Inst Human Genomics, Univ of Miami, FL.

We have integrated two software packages that facilitate simulation studies for complex human diseases: an enhanced version of our previously distributed SIMLA package (Schmidt et al. 2005) that is now available with a Graphical User Interface (GUI) for generating the control file, and our recently developed visualization tool SIMLAPLOT (Qin et al. 2007). Specifically, we have implemented the following features: simulation of unrelated case-control datasets; simulation of up to three modifier loci, each of which can generate a categorical phenotypic feature, such as disease severity; simulation of a biallelic quantitative trait locus (QTL) that may influence the distribution of a continuous disease risk factor and/or generate a disease-unrelated trait for QTL analysis; simulation of X-linked disease loci and sex-specific relative risks; simulation of up to four blocks of markers in linkage disequilibrium (LD), which may be in LD with one or two distinct susceptibility variants; LD calculation tool for generating founder haplotype frequencies given user-specified values of D or r^2; and a sibling recurrence risk ($_s$) calculation tool for several complex disease models. SIMLAPLOT graphically illustrates different models by which continuous environmental or clinical covariates may influence the risk of complex diseases, in concert with genetic susceptibility. Examples for such models include gene-environment interaction, the QTL mechanisms described above, and genetic main effects with covariate-based heterogeneity. SIMLAPLOT may be used to better understand the role of various model parameters in a SIMLA control file by graphically displaying the relationship between disease locus (or QTL) genotypes and covariate values. When applied to real datasets, plots produced by SIMLAPLOT may assist in the interpretation of statistical analysis results and the exploration of plausible disease models.

Comprehensive genetic analysis of Caucasian patients with oculocutaneous albinism and autosomal recessive ocular albinism. *R. Spritz, S. Hutton* Hum Med Gen Prog , Univ Colorado Hlth Sci Ctr, Aurora, CO.

Oculocutaneous albinism (OCA) is a group of congenital hypopigmentary disorders that can result from mutations in at least 16 different genes, four of which are associated with classical OCA. Autosomal recessive ocular albinism (AROA) is a clinically mild variant of OCA1 and OCA2. Of the four genes associated with classical OCA, at least 211 different pathologic mutations have been reported in *TYR* (OCA1), 70 in *OCA2*, 5 in *TYRP1* (OCA3), and 26 in *SLC45A2* (OCA4). Furthermore, some patients with clinical OCA have mutations in a Hermanksy-Pudlak syndrome (HPS) gene, *HPS1*, and others thought clinically to have HPS have mutations in *OCA2*. Thus, molecular analysis is essential for accurate diagnosis.

To establish relative prevalence of different OCA types and different gene mutations in one large group of patients, we carried out DNA sequence analysis of the *TYR*, *OCA2*, *TYRP1*, *SLC45A2*, *HPS1*, and *HPS4* genes, and *SILV* (a candidate OCA gene) in 155 unselected, unrelated non-Hispanic Caucasian patients; 118 with classical OCA and 37 with AROA. Of the OCA patients, 84 (71%) proved to have OCA1, 22 (19%) had OCA2, none had OCA3, and 7 (6%) had OCA4; 5 (4%) had no apparent pathological mutations in any of the genes studied. Of the AROA patients, 20 (54%) had pathological mutations in *TYR*, 3 (8%) had mutations in *OCA2*, 2 (5%) had novel variants in *TYRP1* (OCA3) (although these were not definitively pathological), 2 (5%) had pathological mutations in both *TYR* and *OCA2*, and 10 (27%) had no apparent pathological mutations in any of the genes studied. Overall, we found 61 different *TYR* mutations, 11 different *OCA2* mutations, 2 possible *TYRP1* mutations, and 12 different *SLC45A2* mutations. Among OCA patients, no gene mutations were common. However, of the 22 AROA patients with mutations in *TYR*, 21(95%) were compound heterozygotes for a severe OCA1 mutation and the common R402Q variant that is associated with reduced tyrosinase activity.

Our findings thus show that, among both patients with OCA and AROA, OCA1 is most frequent, with a specific type of high-risk genotype common among patients with AROA.

Dissecting clinical heterogeneity relevant to early development in autism by copy number variations. *P.I. Lin[1,2,3], S. Yoon[1], K. Ye[4], M. Wigler[1], J. Sebat[1]* 1) Cold Spring Harbor Laboratory, Cold Spring Harbor, NY; 2) Department of Medicine, University of Maryland, Baltimore, MD; 3) Department of Psychiatry, University of Maryland, Baltimore, MD; 4) Department of Epidemiology and Population Health, Albert Einstein College of Medicine, Bronx, NY.

Autism spectrum disorder (ASD) is a severe neurodevelopmental disorder. Despite the high estimated heritability of ASD, no risk gene has been conclusively identified yet, which may be partly due to heterogeneous phenotype-genotype relationships. Previous evidence indicates that developmental milestones may be modulated by genetic components. Therefore, we proposed to study the association between gene copy number variations (CNVs) and quantitative traits relevant to early development in ASD. We analyzed DNAs collected from 1,485 subjects by using representational oligonucleotide microarray analysis (ROMA) that consisted of 85K probes. The probe intensity ratio of tested DNA to reference DNA corresponds to gain or loss of the DNA. Genotypes were inferred from intensity ratio distributions by clustering analysis (i.e., partition around medoids algorithm). We performed factor analysis to identify four sub-domains of clinical correlates related to early development such as age-at-onset (AAO), head circumference (HC), age-at-first-sitting (AFS), age-at-first-word (AFW), which represented four distinct sub-domains, respectively. We then performed ANOVA to test whether copy number variations were associated with these traits. We found that the duplication within the COL5A1 gene on 9q34 was significantly associated with AAO ($p = 0.00002$), the deletion within the MGAM gene on 7q34 was significantly associated with HC ($p = 0.0001$), the deletion within the NTRK3 gene on 15q25.3 was significantly associated with AFS ($p = 0.0002$), and the duplication within the STARD13 gene on 13q13 ($p = 0.0003$) was significantly associated with AFW. These results suggest that CNVs may play a role in clinical heterogeneity relevant to early development in ASD.

Characterization of splicing variants in NRG3, a positional candidate for schizophrenia. *L. Zhang[1], N. Feng[1], R. Wang[2], N. Cheng[2], S. Almashanu[1], A. Pulver[1,2], D. Valle[1], D. Avramopoulos[1,2]* 1) IGM, JHMI; 2) Psychiatry, JHMI, Baltimore, MD.

The neuregulins (NRGs) are a protein family containing an epidermal growth factor (EGF)-like motif that activates ErbB receptors. Neuregulin 1 (NRG1) performs a wide range of functions in the developing nervous system and has been implicated in schizophrenia (SZ). NRG3 has structural similarity with NRG1 but its expression is more specific to the CNS. Additionally NRG3, maps to10q22, a region suggested to harbor a SZ susceptibility gene by our previous linkage study in Ashkenazi Jewish families and an independent study in a Han Chinese population. NRG1 has been reported to undergo extensive alternative splicing giving rise to multiple isoforms, however very few studies have examined NRG3 for alternative splicing. We have systematically screened NRG3 for alternative transcripts using RT-PCR, cloning and sequencing methods. We found that NRG3, like NRG1, has more than 10 alternative exons and 20 splicing forms as well as multiple transcription start sites producing different N-terminal sequences. Splicing variants lacking the EGF domain were identified in human and confirmed in mouse brain. A novel start site of NRG3 transcription was identified, that leads several brain transcripts encoding a very short extracellular N-terminal sequence of 10 amino acids without an EGF domain. Interestingly we found that this start site is included in a small deletion that occurs with a frequency of 1.5%. Using quantitative PCR we determined that the abundance of the identified alternative transcripts is relatively low in total RNA, each being 20 to 100 fold less abundant than the annotated 9-exon transcript. We conclude that NRG3 undergoes extensive alternative splicing but in total RNA from adult brain the annotated transcript is markedly more abundant than others. The importance and relevance to disease of an identified small deletion that interferes with at least one of these transcripts remains is currently the subject of further study.

Spectrum of *PORCN* mutations in Focal Dermal Hypoplasia. *V.R. Sutton[1], X. Wang[2], J.O. Peraza-Llanes[3], Z. Yu[2], R. Rosetta[4], Y.C. Kou[2], T.N. Eble[1], A. Patel[1], C. Thaller[5], P. Fang[1], P.H. Fernandes[1], I.B. Van den Veyver[1,2]* 1) Molecular & Human Genetics; 2) Obstetrics & Gynecology, Baylor College of Medicine, Houston, TX; 3) Pediatrics, IMSS, Merida, Mexico; 4) Pediatrics; 5) Biochemistry & Molecular Biology, Baylor College of Medicine, Houston, TX.

Focal dermal hypoplasia (FDH), also known as Goltz syndrome (OMIM 305600), is a genetic disorder that affects multiple organ systems early in development. Features of FDH include skin abnormalities, (hypoplasia, atrophy, linear pigmentation and herniation of fat through dermal defects); papillomas of the mucous membranes; patterning defects of the hands and feet, including syndactyly, polydactyly, camptodactyly and oligodactyly; osteopathia striata; colobomas and other ocular abnormalities; and hypodontia/oligodontia. FDH displays X-linked dominant inheritance; 95% of cases are sporadic and only 10% of cases are males. Using array-based comparative genomic hybridization, we identified a 219-kb heterozygous deletion in Xp11.23 in two girls with FDH. The deleted region contained seven known genes, *SLC38A5*, *FTSJ1*, *EBP*, *PORCN*, *OATL1*, *RBM3* and *WDR13*. Sequencing of genes in the deleted region revealed heterozygous mutations in *PORCN* in eleven additional females and mosaic mutations in all four males analyzed. Seven of thirteen mutations result in stop codons, all of which suggests that FDH is due to loss of function of PORCN. The two females with deletions were found to have 100% skewing of X-inactivation (XCI) while 3 of 7 with point mutations had skewed XCI. We have also screened individuals with Aicardi syndrome and have found no mutations in *PORCN*. This proves that FDH, Aicardi syndrome and Microphthalmia with linear skin defects are not allelic. *PORCN* encodes the human homolog of Drosophila porcupine. Drosophila and murine Porcupine are transmembrane endoplasmic reticulum proteins required for post-translational modification and secretion of Wnt proteins. In situ hybridization of E12.5 mouse embryos was performed and revealed expression in axial and appendicular cartilage, retina, tooth buds, and dorsal skin, which suggests that the pleiotropic features of FDH can be explained by defective Wnt signaling.

The novel mitochondrial DNA A4401G mutation is involved in left ventricular hypertrophy in one Han Chinese pedigree. *S. Wang[1], H. Zhu[1,2], R. Li[2], L. Yang[2], Y. Liu[1], Z. Li[1], M.X. Guan[2]* 1) Dept Geriatric Cardiology, Chinese PLA General Hosp, Beijing, China; 2) 1Division of Human Genetics, Cincinnati Childrens Hospital Medical Center, Cincinnati, Ohio.

Left ventricular hypertrophy (LVH) is one of the most important target organ damages in hypertension. Despite the involvement of multiple factors, the genetic factors including mitochondrial genomes have been implicated to play an important role in the pathogenesis of LVH. Recently, a systematic and extended mutational screening of mitochondrial genome has been initiated in a large cohort of Chinese clinical population of Geriatric Cardiology Clinic at the Chinese PLA General Hospital, Beijing. Further genetic evaluation suggested that several Chinese families with LVH appeared to be transmitted maternally. Sequence analysis of mitochondrial DNA in one Chinese pedigree identified a novel A-G transition at position 4401 (A4401G) at the junction of tRNAMet and tRNAGlu. In fact, this mutation was absent in 272 Chinese control subjects. This mutation appears to affect the processing of precursors in these mitochondrial tRNAs. Functional significance of this mutation was supported that the marked decreases in the steady-state levels of tRNAMet and tRNAGln were detected in the cells carrying this mutation. The resultant defects in mitochondrial protein synthesis may contribute to the reduction in the rate of respiration in cells carrying this mutation. These genetic and biochemical data imply that the novel A4401G mutation is involved in the pathogenesis of left ventricular hypertrophy.

A novel deletion in ROR2 causes combined brachydactyly type B and syndactyly type I in a Chinese family. *X. Zhang[1], D. Lv[1], Y. Luo[2]* 1) Departmen of Medical Genetics, Peking Union Medical College, Beijing, China; 2) China Medical University, Shenyang, China.

Brachydactyly type B (BDB, MIM 113000) is a dominantly inherited limb malformation with complete penetrance and variable expressivity. It is characterized by shortening or absence of distal phalanges of fingers/toes 2-5. Thumbs are less severely affected and often show broad and bifid distal phalanges. BDB can be caused by mutations in the ROR2 gene encoding a receptor tyrosine kinase. Syndactyly type I (SD1, MIM 185900) has complete or partial soft tissue syndactyly between fingers 3 and 4 and/or between toes 4 and 5. The SD1 locus has been mapped to chromosome 2q34-q36. We found a three-generation Han Chinese family with combined BDB and SD1. All the 12 affected individuals in the family showed typical BDB limb phenotypes and most of them also displayed complete webbing of fingers 3-4 and toes 2-3. Two-point linkage analysis was first performed using 3 microsatellite markers selected from the genomic region close to the ROR2 gene at chromosome 9q22 and 12 markers from the chromosome 2q34-q36 region. A maximum LOD score of 2.71 was obtained with the markers D9S1815 and D9S1841, suggesting a genetic linkage. Direct DNA sequencing of the PCR-amplified fragments revealed in the proband a heterozygous 1bp deletion in exon 9 of the ROR2 gene. This mutation showed perfect cosegregation with the disease phenotype in the family but not detected in 50 unrelated healthy controls. In summary, we have confirmed the link between the ROR2 gene and the combined BDB and SD1 in a Chinese family.

The Spectrum of Deletions in Kearns Sayre Syndrome. *T. Prior, R.E. Pyatt* Pathology, 125 Hamilton Hall, Ohio State Univ, Columbus, OH.

The common features of Kearns Sayre Syndrome (KSS) include progressive external opthalmoplegia (PEO), pigmentary degeneration of the retina, and defects of cardiac conduction. The typical affected patient presents before the age of 20 with PEO, and pitosis. This is followed by the pigmentary retinal degeneration and heart block. Other features of the disorder may include ataxia, deafness, dementia, and diabetes mellitus. The most common type of mutation found in KSS is a deletion of mtDNA, and almost of all these deletions occur sporadically. About one-third of the cases of KSS are due to a common 4,977 bp deletion which is associated with direct repeats at the deletion junction. The severity of KSS depends on the extent of heteroplasmy and the tissue distribution of structurally altered mitochondrial genomes. An extreme form of KSS phenotype occurs when the frequency of deleted mtDNA in muscle cells is greater than 85%. Whereas, when lower levels of heteroplasmy for the deletion is observed, PEO is the only symptom. We present here the cumulative results from deletion analysis in KSS/PEO patients over a 3 year period. Thirty-five mutation positive cases from unrelated individuals were identified in muscle biopsy specimens. In addition to determining the approximate size of each deletion, the degree of heteroplasmy was also examined using scanning densitometry. These results describe one of the largest sets of mitochondrial deletions in KSS/PEO and illustrate the variability observed in the genetic analysis of this disorder.

DETECTION OF PHILADELPHIA CHROMOSOME IN PATIENTS WITH CHRONIC MYELOID LEUKEMIA (CML) AND ACUTE LYMPHOBLASTIC LEUKEMIA (ALL) BY CONVENTIONAL AND MOLECULAR TECHNIQUES. *G.C. Ramirez-Gaviria[1], C. Aya[1], M. Diosa[1], J.L. Ramírez-Castro[1], F. Quintero-Rivera[2], G. Vásquez-Palacio[1]* 1) Medical Genetics Unit, Antioquia Univ, Antioquia, Colombia; 2) Department of Pathology & Laboratory Medicine, The David Geffen School of Medicine at UCLA, Los Angeles, CA, USA.

CML and ALL are myeloid and lymphoproliferative disorders associated to the Philadelphia chromosome (Ph+),which plays an important role in their pathogenesis. The gold standard for its detection is conventional cytogenetics (CC) on bone marrow or peripheral blood. However interphase D-FISH and RT-PCR are molecular techniques that offer specific alternatives mainly in patients on chemotherapy or bone marrow transplantation (BMT). 23 patients with CML and ALL were study by CC , D-FISH and RT-PCR in order to determine the diagnosis and monitoring the response to Glivec therapy (GT) or BMT. Samples were processed using standard protocols. Of the 17 patients with CML, 9/17 were Ph(+) at diagnosis 62% with three techniques, and 38% only by RT-PCR. 1/17 was Ph(-) by CC and RT-PCR. 44% of patients showed other chromosomal abnormalities by CC (clonal evolution). Of the 4/17 patients evaluated for monitoring of GT: 25% were Ph(+) with all techniques and 75% only by FISH and RT-PCR (b2a2 transcript). In 2/4 patients 9q34 deletion and an extra Ph+ was observed by CC and FISH respectively. Finally, of the 3/17 patients post-BMT: 67% showed transcripts p210 by RT-PCR but negative BCR-ABL fusion by FISH and only 1/3 was Ph(-) by both techniques. Of the 6 patient with ALL: 86% were Ph(+) by RT-PCR but Ph(-) by FISH and CC, however, CC revealed aneuploidy. 14% were Ph(-) by all tecqniques. Only one patient on Glivec exhibited a complex karyotype without Ph+,but showed e1a2 transcript by RT-PCR. In this study we observed a good association (62%) among the results obtained with three different techniques. CC and D-FISH are less sensitive compared to RT-PCR, but important to reveal other chromosomal aberrations which can determine the prognosis in patients with CML and ALL. These results support the fact that all three techniques are an excellent complement for determining diagnosis and monitoring in those patients.

Domain-specific mutations in FBN1 cause a congenital form of scleroderma: Stiff Skin Syndrome. *B. Loeys[1], D. Riegert-Johnson[2], P. Whiteman[3], V. McDonnell[4], P.J. Coucke[1], A. De Paepe[1], D. Judge[6], P. Handford[3], L. Sakai[5], H.C. Dietz[6]* 1) Ctr for Medical Genetics, Ghent University, Belgium; 2) Mayo Clinic, Rochester; 3) St Catherine's College, Oxford; 4) Regional Genetics Center, Belfast, Ireland; 5) Shriner's Hospital, Portland; 6) Johns Hopkins Univ, Baltimore.

Stiff skin syndrome (SSS) is characterized by generalized indurated skin and limited joint mobility. In contrast to classic scleroderma, SSS is congenital and has no visceral involvement. Because the tight skin(Tsk) mouse is heterozygous for an in-frame Fbn1 duplication a role for FBN1 mutations in SSS was hypothesized. In humans, FBN1 deficiency causes Marfan syndrome and related disorders. We studied one sporadic patient and three autosomal dominant families with SSS. All lacked the skeletal, ocular and cardiovascular findings of MFS. Each family demonstrated a missense mutation in FBN1, either substituting or creating a cysteine residue in the TB4 motif of fibrillin-1. These cysteines are essential for proper TB folding and unique to TB4 is the presence of an RGD sequence, mediating matrix cell interactions via integrin binding. In contrast to MFS, pulse-chase analysis of SSS dermal fibroblasts showed preserved fibrillin-1 secretion and matrix deposition. Structural analysis of mutant recombinant peptides encompassing TB4 showed little effect on domain folding and the RGD-motif remained exposed. Immunohistochemistry of SSS skin revealed abnormal keratinocyte morphology with intense accumulation of fibrillin-1 and elastin at the dermal-epidermal junction and gross architectural matrix disturbance throughout the dermis. EM showed increased collagen expression and densely packed collagen bundles with little intervening proteoglycans. Immunogold EM of showed dense, thick and branched microfibrils that lacked the normal periodic staining of microfibrillar lattices. These data suggest that in SSS, a loss of longitudinal growth and increased lateral growth of microfibrillar aggregates occurs; both events are plausibly informed by integrin-mediated matrix-cell attachments. The relevance of this pathogenetic mechanism to classic scleroderma warrants further investigation.

Evaluation of association tests under models including multiple disease susceptibility variants. *X. Lou[1,2], S.S. Schmidt[1], E.R. Hauser[1]* 1) Center for Human Genetics, Duke University Medical Center, Durham, NC; 2) Bioinformatics Research Center, North Carolina State University, Raleigh, NC.

Gene mapping of complex human diseases often results in the identification of several potential risk variants within a gene and/or in the identification of several genes within a linkage peak. These findings are at odds with the hypothesis that a single allele is responsible for a linkage peak. We are interested in understanding the behavior of several association analysis tests under single variant and multiple variant models within a wide linkage region. We have used two association methods that incorporate evidence for linkage in a family based association setting, APL and LAMP. Both tests work well for single marker analysis, but here we compare their performance under models with multiple susceptibility variants. We used the simulation program, SIMLA, to generate family data sets for use in linkage and association studies. SIMLA can generate two haplotypes associated with two distinct susceptibility variants (possibly with different disease risks) with up to 6 markers included in each haplotype. The disease model may also include an interaction between the two variants. We simulated a common disease with prevalence of 0.20 with two haplotypes independently associated with two recessively acting susceptibility variants, each with risk allele frequency of 0.15. We varied the variant-specific odds ratios from 2 to 4 and simulated complex LD structures. The power of APL to detect one or more associated marker allele(s) decreases as the effect size decreases, but APL maintains the nominal type I error rate under all situations. The type I error rate of both LAMP association tests is at the nominal level for single marker models. However, both LAMP-LE and LAMP-LD have high type I error rates (20%) when there are multiple disease-associated marker alleles. The LAMP-LE test maintains relatively high power even with lower effect sizes, while the power of the LAMP-LD test is at its type I error rate in the presence of multiple disease-associated marker alleles. The LAMP-LD test is difficult to interpret when there are multiple disease-associated markers in the linkage region.

Genome-wide array-based comparative genomic hybridization (array-CGH) analysis in Aicardi Syndrome. *X. Wang[1], V.R. Sutton[2], T. Eble[1], C. O'Neill[2], R.A. Lewis[2,3], I.B. Van den Veyver[1,2]* 1) Dept of Obstetrics and Gynecology; 2) Dept of Molecular and Human Genetics; 3) Dept of Ophthalmology, Baylor College of Medicine, Houston, Texas 77030, USA.

Aicardi syndrome is characterized by agenesis of the corpus callosum, chorioretinal lacunae, severe seizures (starting as infantile spasms), neuronal migration defects, mental retardation, costovertebral defects, and typical facial features. Because Aicardi syndrome is sporadic and affects only females or rarely 47,XXY males, it is thought to be caused by *de novo* dominant mutations in an X-linked gene, but an autosomal mutation with sex-limited effects cannot be excluded. Because genetic linkage approaches to map the gene for Aicardi syndrome cannot be used, we performed high-resolution array-CGH analysis with DNA samples of subjects with Aicardi syndrome to search for segments of copy number loss or gain that may contain the mutated gene. Genomic DNA of female subjects with Aicardi syndrome and reference female DNA were labeled differentially with Cy5 and Cy3, and co-hybridized onto human whole-genome 185k or 244k oligonucleotide DNA arrays (Agilent Technologies). After slides were scanned and feature extraction performed, results were visualized and analyzed with Agilents CGH analytics software and displayed as log2 ratios with these settings: 1-fold cut-off, ADM-2 aberration algorithm with threshold 10.0.
To date, we have tested 16 DNA samples from well-characterized females with Aicardi syndrome on the 185K array and 28 on the 244K array. We found between 7-21 copy number gains or losses per subject. There were a total of 146 unique copy number changes across the entire genome in the 44 studied samples. Of these, 124 were previously annotated copy number variants, 6 were also found in unrelated array-CGH hybridizations for other conditions or controls, and 16 (15 autosomal and 1 X chromosomal) have not been seen before. These are currently being confirmed and studied on parental DNAs, as they may represent candidate regions for the Aicardi syndrome genes.

DNA Methylation as an Epigenetic Modifier in Li-Fraumeni Syndrome. *C.D. Wilson[1,2], B. Zhang[1], L.L. Bachinski[1], L.C. Strong[1,2], R. Krahe[1,2]* 1) Cancer Genetics; 2) Human Molecular Genetics Grad Prog, Univ Texas MD Anderson Cancer Ctr, Houston, TX.

Li-Fraumeni syndrome (LFS) is a genetically heterogeneous cancer syndrome. Most cases (~70%) are associated with dominant germline mutations in the tumor suppressor TP53 (p53). We have shown genetic heterogeneity in LFS kindreds at loci other than p53. LFS is characterized by early tumor onset, multiple tumors in individuals and multiple affected family members. There is evidence for significant heterogeneity in p53 and non-p53 LFS, suggesting additional risk modifiers. Tumorigenesis is a multistep process, in which germline mutations alone are not sufficient for tumor development. Epigenetics has been recognized as important in sporadic cancers. While gene-specific hypermethylation is an important mechanism for silencing tumor suppressor genes, global hypomethylation has been identified as an important epigenetic factor in the remodeling of chromatin structure. To test whether DNA methylation plays a role in an inherited cancer syndrome such as LFS, we studied genome-wide and gene-specific hypo- and hyper-methylation using Pyrosequencing Methylation Analysis (PMA) in 10 LFS tumors. We determined the methylation status of 12 tumor suppressor genes hypermethylated in sporadic cancers that are part of the LFS tumor spectrum. Six genes showed significant hypermethylation (BRCA1, ESR1, HIN1, RASSF1, TCF21, TP73). In 10-50% of LFS tumors, BRCA1, ESR1, HIN1 and TP73 were hypermethylated compared to normal PBL samples. RASSF1, which is hypermethylated in sporadic soft tissue sarcomas (STS), was hypermethylated in all STS but no other LFS tumors. TCF21, which encodes a transcription factor involved in epithelial-mesenchymal transition, was hypermethylated in 100% of LFS tumors. Using PMA of SINE and LINE elements as surrogate markers, we determined genome-wide levels of hypomethylation to be intermediate between those of control tumor cell lines and normal PBL samples. The identification of tumor hyper- and hypo-methylation in LFS indicates that, similar to sporadic tumors, epigenetic alterations also play an important role in the genesis of inherited tumors.

Genome-wide association analysis of Attention Deficit Hyperactivity Disorder (ADHD). *J. Lasky-Su[1], K. Zhou[4], C. Lange[14], B. Neale[4], N. Laird[14], M. Daly[7], R. Ebstein[6], J. Buitelaar[3], M. Gill[8], A. Miranda[9], F. Mulas[9], R. Oades[10], H. Roeyers[11], A. Rothenberger[2], J. Sergeant[12], H-C. Steinhausen[13], E. Sonuga-Barke[5], B. Franke[3], P. Asherson[4], S.V. Faraone[1], IMAGE Consortium* 1) SUNY Upstate Medical University, Syracuse, NY; 2) University of Göttingen, Göttingen, Germany; 3) Radboud University, Nijmegen Medical Center, Nijmegen, The Netherlands; 4) Institute of Psychiatry, London, UK; 5) University of Southampton, Highfield, Southampton, UK; 6) S Herzog Memorial Hospital, Jerusalem, Israel; 7) Broad Institute, Cambridge, MA; 8) St James's Hospital, Dublin, Ireland; 9) University of Valencia, Valencia, Spain; 10) University Clinic for Child and Adolescent Psychiatry, Essen, Germany; 11) Ghent University, Ghent, Belgium; 12) Vrije Universiteit, De Boelelaan, Amsterdam, Holland; 13) University of Zurich, Zurich, Switzerland; 14) Harvard School of Public Health, Boston, MA.

Although psychiatric geneticists have begun to produce replicated findings implicating specific genes or chromosomal loci in the etiology of ADHD, most of the genes underlying these disorders have remained elusive. One obstacle to gene discovery for ADHD has been the lack of a tool for screening the genome for genes of small effect. We used 958 parent-child trios with offspring meeting the DSM-IV combined-type criteria for ADHD from the IMAGE project. Families were collected in the Netherlands, Ireland, the UK, Germany, Belgium, Switzerland, Spain and Israel. Probands were European Caucasians aged 5 to 15 years. Genotyping of >550,000 SNPs was recently completed at Perlegen Sciences. In addition to an affection status analysis, we develop a quantitative phenotype at each SNP by weighting 9 inattentive and 9 hyperactive-impulsive symptoms. The weights are selected to maximize the heritability at each SNP and FBAT association tests are performed. For the significant SNPs, corrected for multiple testing using rankings based on conditional power, the correlation between each of the ADHD symptoms and the quantitative phenotype is used to determine what symptoms are driving the association.

Inheritance patterns of pectus excavatum based upon pedigree analysis. *V. Proud[1], L. Horth[2], K. Segna[3], E. Maple[2], R. Kelly[4], D. Nuss[4], M. Stacey[3]* 1) Medical Genetics, CHKD,EVMS, Norfolk, VA; 2) Dept. Biological Sciences, Old Dominion University, Norfolk, VA; 3) Center for Pediatric Research, Eastern Virginia Medical School, Norfolk, VA; 4) Dept Surgery, Children's Hospital of the King's Daughters, Norfolk, VA.

Pectus excavatum (PE) is the most common congenital chest wall malformation, affecting 1/400 children. A chest cavity depression manifests as a result of displacement of the sternum. Additional traits are often associated with PE, including cardiac, musculoskeletal, neural, ocular, skin, and pulmonary-related traits. Thus far, only familial tendency has been reported for PE, based upon clinical observations. Here, we report on the genetic inheritance patterns of PE, based upon pedigree analysis of families harboring PE. We address the presence of secondary traits as they relate to the inheritance of PE. About half of the PE cases demonstrate evidence of sex-linkage, with the majority of these being X-linked recessive inheritance patterns. At least one sixth of the PE cases appear to be a result of a homozygous recessive, autosomal genotype. The remaining cases of PE may be explained by polygenic inheritance or spontaneous mutation, or are cases where we cannot definitively predict one inheritance pattern over another. Secondary traits were evaluated as evidence for a semi-dominant, autosomal PE-associated allele(s), so individuals expressing secondary traits, but not PE, were considered heterozygous for one or more PE-related allele(s). Pedigree data supports the theory that an individual expressing secondary traits, but not PE, may be heterozygous for one or more PE-associated autosomal allele(s). Mutations in Ch10q and in the Col2A1 gene have been associated with PE in other studies, thus the potential for polygenic effects exists.

Uncovering Cln3 interacting partners with the Ubiquitin-based Split-System gives new clues on the pathogenesis of the juvenile neuronal ceroid lipofuscinosis (Battens Disease). *A. Lloret, J. E. Janice, V. C. Wheeler, M. E. MacDonald, S. L. Cotman* CHGR. 185 Cambridge Street. 5th Floor. Rm. 5300. Mass. General Hospital. Havard Medical School. Boston MA, 02114.

Juvenile neuronal ceroid lipofuscinosis is caused by mutation of Battenin, a novel endosomal/lysosomal membrane protein encoded by CLN3. Patients bearing a recessive mutation in this gene display severe widespread neuronal degeneration resulting in retinal atrophy and in massive loss of brain substance and massive autofluorescent lysosomal accumulations. The storage material consists of hydrophobic aggregates containing proteolipids, a predominant component of which in most NCLs is the mitochondrial ATP synthase subunit c. Despite all information provided by several models of the disease the function of battenin is still unknown. Until now, some attempts had been done to establish the protein interactors of Cln3. using the Y2H as the methods of choice, but the reported results are either negative or restricted to a very small fragment of the protein used as bait. Therefore, with the aim of uncover Cln3 protein interacting partners, we decided to apply a method that has proven extremely useful to monitor protein-protein interactions; the Ubiquitin-based Split-protein System (UBPS). This system allows detection of protein-protein interactions in vivo using fusions with two fragments of ubiquitin. We generated an CLN3-Ubiquitin (N-terminal part) fusion comprising the whole sequence of the CLN3 wild type human gene. This bait construct is also in frame with a sequence that encodes for a hybrid transcriptional factor, comprised by the LexA DNA binding domain and the transcriptional activator VP16. With it, we performed a screening using an adult brain cDNA library (fused to the C terminal part of ubiquitin) as our preys. As a result, we obtained 32 positive independent clones for the interaction, 10 of which correspond to the neuronal membrane glycoprotein M6-b (Gpm6B). Taken all together, results derived form this study will help to point out the pathways in which Cln3p is involved, and also will lead to a better understanding of the pathogenesis of the disease.*CLN3*.

Mitochondrial Dysfunction and Glutathione Depletion in a Murine Model of muto Methylmalonic Acidemia. *C. Venditti[1], R. Chandler[1], S. Shanske[2], P. Zerfas[3], T. Cowan[4], G. Enns[4], V. Hoffman[3], S. DiMauro[2]* 1) NHGRI/NIH, Bethesda, MD; 2) Columbia U, NY, NY; 3) DVM/NIH, Bethesda, MD; 4) Stanford U, Palo Alto, CA.

Methylmalonic acidemia (MMA) is commonly caused by defective activity of the enzyme methylmalonyl-CoA mutase (MUT). Patients with severe forms of MMA display a clinical phenotype of intermittent metabolic instability and multi-systemic secondary complications of unclear etiology. Mitochondrial dysfunction and oxidative stress have not been studied as pathogenetic causes. A methylmalonyl-CoA mutase (Mut) mouse model, generated by targeted deletion, was modified by outcrossing (C57BL6x129SvEV) carriers to other strains of inbred mice, followed by intercrossing to generate affected mice. Some Mut -/- G2 animals, which escaped the uniform neonatal lethality of the parental strain, were further studied. Mitochondrial function was assessed by electron microscopy and electron respiratory chain (RC) enzyme assays. Glutathione was measured in tissue extracts by a direct recycling assay or in whole blood using an LC-MS/MS technique. Protein markers of oxidative stress were examined by Western analysis. The G2 Mut -/- survivor mice had massive elevations of pathometabolites as well as poor growth and fragility but survived past weaning. Target tissues from these mice displayed a reproducible electron microscopic mitochondrial phenotype. Liver extracts showed RC dysfunction with a severe decrease in cytochrome c oxidase activity in affected mice. Glutathione pools were reduced in liver and whole blood of mutants. Western analysis suggested that Mn-SOD was up-regulated in the liver of some Mut-/- survivors. This new murine model of severe but stable muto MMA, developed by background modification of an existing null allele, strongly demonstrates that modifier(s) of the lethal phenotype of MMA exist and might partly explain the clinical heterogeneity of the disorder. Furthermore, these studies document that RC dysfunction and glutathione depletion are inherent features of methylmalonic acidemia. Our results suggest treatment strategies, in mice and patients, directed towards improving mitochondrial function, repleting glutathione pools and protecting from oxidative stress.

Multiple Imputation to Correct for Measurement Error in Genetic Structured Association Testing. *M.A. Padilla[1], J. Divers[2], L.K. Vaughan[1], D.B. Allison[1], H.K. Tiwari[1]* 1) Section on Statistical Genetics, Dept of Biostatistics, University Alabama at Birmingham, Birmingham, AL; 2) Section on Statistical Genetics and Bioinformatics, Dept of Biostatistics, Wake Forest University, Winston-Salem, NC.

Structured association testing (SAT) is association testing that takes into account population substructure. Within this framework, a SAT model was developed in the form of a linear model using admixture estimates as covariates to control for population substructure. However, like any statistical model, it assumes that all variables are measured without error. Measurement error can cause biased parameter estimates and confound residual variance in linear models. Its been shown that admixture estimates can be contaminated with measurement error causing SAT models to suffer from the same afflictions. Multiple imputation is presented as a viable tool for correcting measurement error problems in linear models with emphasis on correcting measurement error contaminated admixture estimates in the context of a SAT linear model. Several multiple imputation methods are presented and compared, via simulation, in terms of controlling Type I error (false positives). In addition, both non additive and additive genotype coding were also investigated. Results indicate that multiple imputation can be used to correct for measurement error in admixture estimates in SAT linear models. However, the data should be of reasonable quality, in terms of marker informativeness, because the method uses the existing data to borrow more information in which to make the measurement error corrections. If the data are of poor quality then there is little information to borrow in order to make measurement error corrections.

Severe mutations of ARX are associated with an abnormal phenotype in most heterozygous females but not in mothers of affected children. *J. Sudi[1], M. Kato[2], G. Mancini[4], A. Toutain[3], S. Das[1], S. Christian[1], W. Dobyns[1]* 1) Dept. of Human Genetics, The University of Chicago, Chicago, IL; 2) Dept. of Pediatrics, Yamagata University School of Medicine, Yamagata, Japan; 3) Service de Génétique et Service de Neuropédiatrie, Centre Hospitalier Universitaire de Tours, Tours, France; 4) Dept. of Clinical Genetics, Erasmus University Medical Center, Rotterdam, The Netherlands.

ARX (Aristaless-related homeobox) is a homeobox-containing gene involved in CNS, islet cell and testes development. In males, mutations in ARX have been associated with X-linked lissencephaly with abnormal genitalia (XLAG), infantile spasms and X-linked mental retardation with dyskinesia and epilepsy. We have identified 30 families with severe mutations of ARX including 26 reported (Kato et al., 2004) and 4 novel mutations, and here we present data on 22 heterozygous females including 12 ascertained as mothers of affected genotypic males. All affected males in these families had XLAG. Among the mothers, we found normal intelligence in 12/12, seizures in 0/8, and agenesis of the corpus callosum (ACC) in 3/6. Among the 10 other heterozygous females including 3 probands, we found normal development in 3/10 and variable mental retardation in 7/10. Seizures occurred in 5/7 females including infantile spasms, generalized convulsive and absence seizures. MRI demonstrated ACC in 7/9. We performed X inactivation (Xi) studies by methylation-specific PCR (Kubota et al., 1999) to assess the contribution of Xi to phenotypic variability. Xi was normal in 4 mothers and 3 other females, and skewed in one girl (89:11) with further studies underway. However, we found high normal Xi ratios above 70:30 in 3 mothers and 2 other females. Interestingly, one normal mother and her abnormal daughter were skewed in opposite directions (77:23 and 24:76), supporting the hypothesis that mild skewing may also influence the phenotype. We also detected post-zygotic mosaicism in 3 mothers but none of the other females. These data will significantly alter genetic counseling for ARX-associated disorders, and have broad implications for other X-linked diseases.

Screening Program for Connexin 26 and Connexin 30 Genes in 648 Institutionalized Deafness Population in Colombia. *M. Olarte[1,2], M. Gómez[1], N. Gelvez[1], S. Flórez[2], D. Medina[2], C. Varón[3], N. Garcia[1], L. Morales[1], I. del Castillo[4], F. Moreno[4], M.L. Tamayo[1,2]* 1) Inst de Genetica Humana, Univ Javeriana, Bogota 1, Colombia; 2) Fundación Oftalmológica Nacional, Bogotá DC, Colombia; 3) Fundación Oftalmológica de Santander, Clínica Ardila Lulle (FOSCAL). Bucaramanga, Santander. Colombia; 4) Unidad de Genética Molecular, Hospital Ramon y Cajal, Madrid, España.

Hearing loss affects one of 1000 children. In developed countries, half of the hearing loss is due to genetic causes. The screening program was performed in order to establish the frequency of mutations in Connexin 26 (Cx26) and Connexin 30 (Cx30) genes. We visited institutions for deafness in 11 cities of Colombia. A total of 648 individuals with non-syndromic deafness were selected. The population was classified in two groups: 39.2% (254/648) as recessive nonsyndromic hearing loss (RNSHL) and the remaining 60.8% (394/648) as sporadic cases with unknown cause. The molecular studies including the PCR-RFLP for the 35delG mutation in Cx26 gene; a specific multiplex PCR for the deletions (del(D13S1830) and del(D13S1854)) in Cx30 gene and automatic sequencing of Cx26 gene. We identified in total, 22 mutations in the Cx26 gene, corresponding to 16,2% of cases (105/648). Among these, 5 were new mutations. The most frequent mutations were S199F (42,3%) and 35delG (41%). In Connexin 30 gene, we identified the two studied deletions in 6 cases (0.9%); among these, 5 were compound heterozygotes Cx26/Cx30. Interestingly, the frequency of S199F mutation in our nonsyndromic deaf population is higher than reported in other studies, being the most frequent in our population. The 35delG mutation was found in similar frequency to other reports.

Mapping complex traits in the domestic dog. *E.A. Ostrander[1], H.G. Parker[1], B. Hoopes[1], K. Bryc[3], B. vonHoldt[4], N.B. Sutter[1], K. Chase[2], K.G. Lark[2], P. Quignon[1], D.S. Mosher[1], C. Bustamante[4], R.K. Wayne[3]* 1) Cancer Genetics Branch, NHGRI/NIH, Bethesda, MD; 2) Dept. of Biology, University of Utah, SLC, UT; 3) Dept. Biological Statistics and Computational Biology, Cornell University, Ithaca, NY; 4) Dept. of Ecology and Evolution, UCLA, Los Angeles, CA.

The availability of a high quality draft sequence of the dog genome has changed the way geneticists studying companion animals are tackling the problem of finding genes that control complex traits. Of particular interest are genes controlling the morphologic differences which define different domestic dog breeds, genes regulating behavior, and those that increase disease susceptibility. Central to our ability to use the newly available resources is an understanding of dog breed structure and we herein present a detailed discussion of a new cluster analysis involving 135 U.S. breeds. Also important is an understanding of the strengths and limitations of the current molecular resources, and consideration of the traits which are likely to lend themselves to mapping using available approaches and resources. We describe our recent efforts to localize genes important in controlling body size. Our initial studies suggest a primary role for the IGF-1 gene in making small dogs small. But studies with Portuguese Water Dogs strongly suggest the existence of other loci in controlling overall body size in the dog. Building upon those findings, and using a large number of samples collected from small and large dog breeds we describe other genes and loci which potentially play a role in regulating canine morphology, particularly body size and leg length. Finally we discuss the problem of breed substructure in the context of candidate gene approaches. By way of example we discuss efforts to find genes for behavior traits in the dog, including racing speed among whippet dogs. Extending from our most recent work, we demonstrate that candidate gene analysis can work if special consideration is paid the likely occurrence of population substructure.

ANEUPLOIDY OF CHROMOSOME 17 AND TP53 GENE DELETION IN GASTROINTESTINAL TUMORS OF A COLOMBIAN COHORT. *C.M. Muñetón-Peña[1], G.C. Ramírez-Gaviria[1], J.C. Herrera-Patiño[1], L.F. Isaza-Jimenez[2], F. Quintero-Rivera[3], G. Vásquez-Palacio[1]* 1) Unidad de Genetic Medica, Facultad Medicina Universidad Antioquia, Medellin, Antioquia, Colombia; 2) Departamento de Cirugía, Facultad de Medicina, Universidad de Antioquia, HUSVP, Medellín, Colombia; 3) Department of Pathology & Laboratory Medicine, The David Geffen School of Medicine at UCLA, Los Angeles, CA, USA.

Gastrointestinal cancer is one of the most common malignancies in Colombia. The development and progression of gastrointestinal tumors is generally driven by an accumulation of genetic alterations. Among the alterations, mutations in the TP53 gene or deletion on chromosome 17p13.1 seem to be the key factors in the development of gastrointestinal cancer. Our aim was to evaluate aneuploidy of chromosome 17 and TP53 gene deletions in primary gastrointestinal tumors samples by dual-color FISH. 15 primary gastrointestinal tumor samples were analyzed from different tissues: stomach n=5; esophagus n=2; colon n=6; and rectum and duodenum n=1, respectively. Samples were minced and enzymatically disaggregated with 0.2% collagenase to obtain tumor cells suspension. Dual-color FISH assays were performed using direct fluorescent labeling probes for the centromere (CEP) of chromosome 17 and LSI TP53 gene. Hybridization signals were counted in 100 interphase nuclei. Aneuploidy (monosomy) of chromosome 17 was found in 33.3% (5/15) of the samples. Most of tumor samples exhibited heterogeneous clones that were monosomic, disomic, trisomic and occasionally tetrasomic. The TP53 gene deletion was found in 93.3 % (14/15) of the analyzed samples. Only 1 sample was normal for copy number of chromosome 17 and TP53 gene. 14 out of 15 tumors samples showed an advanced stage of tumorigenesis. These findings demonstrate a low frequency of aneuploidy of chromosome 17; however, we found a high frequency of TP53 deletion in the group of samples with advanced stages and confirmed that deletion in 17p13.1 region is common in gastrointestinal cancer, especially in advanced adenocarcinoma, and that it might play an important role in tumor progression. FISH analysis is a useful tool to simultaneously detect numerical and structural chromosome abnormalities in tumor cells.

Molecular alteration in exon 28 of VWF gene from Patients with von Willebrand Disease. *R. Peñaloza[1], H. Benitez[2], V. Rojas[1], F. Salamanca[1]* 1) UIM Genetica Humana, Instituto Mexicano del Seguro Social, Mexico City; 2) Servicio de Genética, Hospital de Pediatría, CMN SXXI, IMSS.

von Willebrand disease (VWD) is the most frequent inherited coagulopathy in humans, it is expressed as mucocutaneous bleeding of variable intensity. The origin is due an alteration in VWF gene (mutations), that produces changes in the multimerizable protein. It normal function is to induce platelet adhesion to vascular endothelium when tissue damage is present, and carry and protect factor VIII in serum. The aim of the present work was to analyze the molecular alterations in exon 28 of VWF gene from ten families with VWD. METHODS: DNA from peripheral blood was obtained by standard methods, previous informed consent. Exon 28 of VWF was amplified by PCR method, purified and directly sequenced, after labeled by Big Dye (Applied Biosystem, USA). RESULTS. We found alterations in five families, four mutations have been previously informed in other populations, and a new mutation (insT3706) was found in a patient and her mother. This alteration produces a modified protein, shorter than normal. CONCLUSION. It is important to realize the molecular study in order to establish a correct diagnosis, treatment and rightful genetic counseling.

Family-based association method for incorporating half-sib data. *Y.W. Li[1,2], Y.J. Li[2]* 1) Center for Human Genetics, Duke University Medical Center, Durham, NC; 2) Dept Statistics, North Carolina State Univ, Raleigh, NC.

The current family-based association tests are based on pedigree structures with parent-offspring triads, parents and multiple affected full siblings, discordant full sibpairs of large size, or extended pedigrees including related nuclear families and sibships. Therefore, full siblings or parents have been the target of ascertainment in genetic research. In this study, we aimed in developing a family-based association method that can incorporate half-siblings as well. This method will benefit to understudied populations, especially when recruitment is difficult. The new method is based on the same framework of the pedigree disequilibrium test (PDT), in which we used inverse kinship coefficient to weight each marker transmission or sharing score obtained from each pair of samples. The type I error and statistical power were evaluated by extensive simulation studies. We evaluated scenarios for pedigrees containing concordant half sibpairs with parents, discordant half sibpairs without parents, and combination of full and half sibpairs without parents. Two existing methods, PDT and FBAT, were used for comparison. The simulation results demonstrated that our extended PDT (EPDT) method has correct type I error rates (0.045 to 0.052). For the data of 200 concordant half sibpairs with parents, our proposed EPDT method showed comparable statistical power to the PDT and FBAT method (79.8% in EPDT, 69.5% in PDT, and 75.2% in FBAT). We noted that PDT and FBAT cannot analyze certain types of data structure with half siblings such as the discordant half sibpairs without parents. The EPDT method is the only method to handle these types of family data. Thus, EPDT provides a valid test of linkage disequilibrium for family data including half siblings. This method can be extended further to distant related individuals in the future.

Genomic Characterization of Schizophrenia Candidate Gene Regions. *A.Q. Nato, X. Kong, F. Chen, C. He, C. Chiu, L.M. Brzustowicz, T.C. Matise* Department of Genetics, Rutgers University, Piscataway, NJ 08854.

Schizophrenia (SZ) affects 1% of the worldwide population and is considered the most devastating mental disorder. Family, twin and adoption studies have revealed that SZ has a complex genetic aetiology. At present, a handful of genetic factors are strongly implicated in SZ but it is likely that many more remain to be identified. In this study we analyzed data from 43 genome-wide scans and 2 meta-analyses for linkage to SZ and partitioned the genome into eleven genomic regions (designated as SCRs) that show either significant evidence of linkage in 1 or more scans or suggestive evidence in at least 4 scans where the peak lod scores lie within 25 cM of each other. Detailed descriptive web-pages for each of the SCRs are provided on our website. We characterize each SCR by identifying the known and predicted genes within these regions and categorize them based on whether they are linked to phenotypes, GO terms, diseases, or pathways, and on whether they are linked or associated with SZ in published linkage scans, meta-analyses, microarray studies, and association studies. Additionally, within each SCR, we identify copy-number variants, segmental duplications, defined regulatory regions, putative miRNA binding sites, rearrangement hotspots, and evolutionarily conserved sequence motifs that are candidate regulatory elements. We provide object-specific web links to existing large databases, thereby facilitating access to relevant subsets of data. We also compare the sequences of our SCRs with each other to identify homologous stretches of DNA that may include important regulatory elements. The total SCR coverage is 236 cM with SCR sizes ranging from 15.88 cM to 29.81 cM. As new genome scans are published, our SCRs are re-evaluated and refined. Our approach provides a novel method to identify and prioritize SZ susceptibility regions and genomic elements that could be applied to other complex diseases.

Comparative molecular and functional studies of proline and hydroxyproline oxidases. *A.S. Willis[1], C.-A.A Hu[2], G. Steel[1], W.-W. Lin[3], C. Obie[1], H. Levy[4], D. Valle[1]* 1) Inst Genetic Medicine, Johns Hopkins Univ Sch Med, Baltimore, MD; 2) Dept Biochem and Mol Biol, Univ New Mexico Sch Med, Albuquerque, NM; 3) Dept Psychiatry, Tri-Service General Hospital and National Defense Medical Sch, Taipei, Taiwan; 4) Dept Pediatrics, Harvard Medical Sch, Boston, MA.

PRODH (22q11) encodes proline oxidase (POX) and is of interest as the gene responsible for hyperprolinemia type 1 (HP1) and is also involved in schizophrenia and cancer. A similar gene, *PRODH2*, located at 19q13.1 is a candidate structural gene for hydroxyproline oxidase (OHPOX). We utilized RT-PCR, 5 RACE, and expression studies to refine the exon-intron structure of *PRODH2* and determine the function of its protein product. We found the *PRODH2* transcript to be shorter that the cDNA sequence in the public databases (NM_021232) lacking 157 bases at the 5 end, corresponding to the curated exon 1, in either liver or kidney, tissues where this gene is highly expressed. The ORF begins in the curated exon 2 and encodes a 461 amino acid protein with predicted molecular weight of 51 kDa. We expressed this cDNA in CHO cells and found that the *PRODH2* enzyme catalyzes the oxidation of hydroxyproline rather than proline. In addition, we studied a patient with hyperhydroxyprolinemia and found her to be a compound heterozygote for two mutations in *PRODH2* (a slice site change and a 1 bp deletion in the coding sequence). To ask what determines the substrate specificity of POX and OHPOX, we used comparative genomics. We found that all but 2 of 18 active site residues of POX that are conserved to *E. coli* are identical in OHPOX. To investigate the significance of these 2 residues, we designed a residue switching experiment where the residues in OHPOX were changed to those found in POX and vice versa and expressed these recombinant proteins in stably transfected CHO cells. In initial assays, we find that C279Y and S409Y in OHPOX confer low but detectable POX activity. The converse experiment is in progress. We conclude that *PRODH2* (19q13.1) encodes OHPOX and is responsible for hyperhydroxyprolinemia and are defining active site residues that determine the substrate specificities for these 2 closely related imino acid oxidases.

Further Fine-Mapping of 11 Candidate Genes for Schizophrenia in the Ashkenazim. *A.E. Pulver[1], V.K. Lasseter[1], M.D. Fallin[2], D. Avramopoulos[1], J.A. McGrath[1], P.S. Wolyniec[1], G. Nestadt[1], K.Y. Liang[3], P.-L. Chen[4], Y. Liu[4], D. Valle[4]* 1) Department of Psychiatry & Behavioral Sciences, The Johns Hopkins School of Medicine, Baltimore, MD; 2) Department of Epidemiology, the Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 3) Department of Biostatistics, the Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 4) Institute of Genetic Medicine, The Johns Hopkins School of Medicine, Baltimore, MD.

Previously,we reported family-based association analyses of 64 candidate genes for schizophrenia (SZ) and/or bipolar disorder (BPI) using Ashkenazi Jewish (AJ) parent/child triads (Fallin et al. 2005). With an average intermarker density of 11.9 Kb, 274 parent/child triads revealed 6 genes (RGS4, SCA1, GRM4, DPYSL2, NOS1, GRID1) with genotype relative risks significant at the p<.01 for SZ and 6 genes(DPYSL2, DTNBP1, G30/G72, GRID1, GRM4, NOS1) with overlapping suggestive evidence (p<.05) in both SZ and BPI triads. We report here follow-up SNP genotyping in a subset of 11 of the original 64 genes (CABIN1, DAOA, DPYSL2, DTNBP1, GFRA1, GRM4, KIF13A, NOS1, PNOC, RGS4, and SCA1) using an expanded sample of 409 AJ SZ cases and 395 screened AJ controls. We genotyped 1044 SNPs covering 2.2 Mb of sequence at an intermarker density of 2.1 Kb (5.6 times the original SNP density). Statistical comparisons of allelic and genotypic frequencies between cases and controls revealed nominal p<.01 for DPYSL2, SCA1, KIF13A, GRM4, GFRA1, and NOS1. The most significant findings are for the dihydropyrimidinase-related protein 2 gene (DPYSL2) on chromosome 8p21. Haplotype-based analyses using both LD-block-based haplotypes (p<.002) and sliding windows of 2-6 contiguous SNPs (p<.001) across the gene further characterize this susceptibility locus. These studies contribute to our understanding of genetic suceptibility for schizophrenia in the AJ population.

Conditioning on risk and protective alleles for Crohn disease identifies novel gene interactions. *R. Little[1], P. Van Eerdewegh[1], J. Segal[1], J. Raelson[1], P. Croteau[1], Q. Nguyen[1], S. Debrus[1], J. Hooper[1], H. Clark[2], T. Keith[1]* 1) Genizon BioSciences, St Laurent, PQ, Canada; 2) Genentech, Inc. South San Francisco, CA, USA.

While recent genome wide association studies have successfully identified a number of replicated susceptibility genes for complex diseases, much remains to be done to tease apart the underlying gene-gene interactions contributing to risk. For example, the creation of more homogeneous subsets of patients by conditioning on risk and protective haplotypes in known disease genes has the promise of uncovering genetic heterogeneity as well as epistatic interactions. We performed a GWAS for Crohns disease (CD) in the Quebec Founder Population and identified the well established CD genes, CARD15 and IL23R, among the top signals. These regions were used for conditional analysis by identifying sets of risk and protective alleles, genotypes, haplotypes and/or haplo-genotypes. Each case was classified as a carrier or non-carrier of the risk and/or protective factors and controls were kept matched to the cases. Association analysis across the entire genome was then performed with these sample subsets, followed by an assessment of genome-wide significance using permutation analyses. Conditioning on cases lacking a specific risk haplotype in IL23R identified the CARD15 region, suggesting that IL23R and CARD15 are independent CD risk factors. Conditioning on cases with a specific risk haplotype in IL23R identified a novel associated locus, indicating an epistatic interaction. Conditioning on cases with a specific protective haplotype in CARD15 enhanced the significance of the IBD5 region, suggesting that IBD5 and CARD15 are independent risk factors. These types of subsetting studies will be useful in dissection of the genetic contribution of highly associated disease genes, but will also yield additional susceptibility loci due to enrichment for a more homogeneous population sample.

QRAT: A novel robust and powerful QTL association test for nuclear families. *X. Qin, E.R. Hauser, S. Silke* Center for Human Genetics, Duke University, Durham, NC.

Risk models for complex human diseases often include traditional disease-associated covariates, such as body mass index or cholesterol levels, along with genetic susceptibility. It is a challenge to incorporate these types of covariates into gene discovery studies. Models for the relationship between covariates and genetic variants may include QTL models, GXE interaction models, or heterogeneity models. In addition, the models may be confounded by population structure in covariate distributions. Some test statistics for examining these models depend heavily on assuming a normal distribution of the covariate. Departures from normality can inflate the type I error and reduce the power. Here, we propose several flavors of a new nonparametric method called the quantitative rank association test (QRAT). In the absence of population stratification, a rank-based case-only test applied to marker and covariate data of a single sibling selected from each family (1sib_QRAT) may be applied. To protect against population stratification, a modified test (2sibs_QRAT) is proposed. Both tests are derived from the linkage disequilibrium (LD) coefficient between QTL and marker alleles and genotype-specific covariate distributions. We propose test statistics that are based on alleles or genotypes, similar to the PDT and geno-PDT statistics for a binary affection status. Their respective power depends on the true underlying genetic model, which is typically unknown. A staged design may be used in order to evaluate on part of the sample which test statistic is likely more powerful for the dataset at hand. Here, we present extensive simulation studies with the SIMLA software to evaluate the performance of our proposed tests. Type I error and power were compared to the Monks-Kaplan method implemented in the QTDT package and a newly developed likelihood ratio test for two siblings (2sib_LRT) that relies on the assumption of normality. Our results show that 1sib_QRAT is very powerful in the absence of any form of population stratification or covariate heterogeneity. Under some models, the 2sibs_QRAT is more powerful than QTDT and more robust to deviations from normality.

Late-onset Krabbe disease due to loss of expression of the maternal allele and a novel paternal missense mutation in the galactocerebrosidase gene. *I. Warshawsky[1], B. Tsao[2], J.F. O'Brien[3], M.R. Natowicz[1,4]* 1) Dept. of Clinical Pathology, Cleveland Clinic, Cleveland, OH; 2) Dept. of Neurology, Loma Linda University, Loma Linda, CA; 3) Dept. of Laboratory Medicine, Mayo Clinic, Rochester, MN; 4) Genomic Medicine Institue, Cleveland Clinic, Cleveland, OH.

Krabbe disease is a rare autosomal recessive neurodegenerative disorder with diverse clinical presentations and is characterized by CNS myelin loss and peripheral nerve involvement. Mutations of the lysosomal enzyme galactocerebrosidase (GALC) gene and the resulting enzyme deficiency cause the various forms of Krabbe disease. We describe a 37 year old wheelchair-bound man with a 17 year history of progressive leg stiffness/weakness, bladder urgency, decreased erectile function, and difficulty with fine motor function. GALC enzyme activity was variably low in two clinical laboratories. GALC DNA sequence analysis showed: (1) heterozygosity for a paternally-derived novel missense mutation (p.I368T, c.1103T>C); (2) heterozygosity for a paternally-derived synonymous SNP (p.S434S, c.1302C>T); (3) heterozygosity for a maternally-derived non-coding region variant (g.-335G>A); (4) heterozygosity for a maternally-derived synonymous SNP (p.D94D, c.282C>T); (5) homozygosity for a common low enzyme activity polymorphism (p.I546T, c.1637T>C). The probands 31 year old sister with similarly low enzyme activity and an identical genotype denied symptoms but has pes cavus, mild gait abnormality, and lower extremity hyperreflexia. RNA analyses showed loss of expression of the maternal allele in the proband and his more mildly affected sister; allelic loss was seen in the mother's RNA. In conclusion, studies of this kindred reveal: (1) marked intrafamilial clinical heterogeneity in siblings with late-onset Krabbe disease and identical GALC mutations; (2) the complex combination of mutant alleles in the context of homozygosity for a low enzyme activity polymorphism and variably low GALC activity; (3) the unusual occurrence of loss of expression of one of the two mutant alleles in causing a lysosomal storage disease; and (4) the challenges this case poses for clinical biochemical genetic and molecular diagnostic laboratories.

An Improved Dried Blood Spot Screening Method for Gaucher Disease. *M. Titlow, H. Kallwass, J. Barranger, J. Keutzer* Therapeutic Protein Research, Genzyme Corporation, Framingham, MA.

Gaucher disease is caused by a deficiency of the lysosomal enzyme glucocerebrosidase. Many patients are misdiagnosed or remain undiagnosed. A simple screening method could increase diagnosis rate and allow for early implementation of therapy when needed to prevent the serious complications of Gaucher disease. We developed a rapid and reliable screening assay for measuring glucocerebrosidase activity in dried blood spots (DBS) based on the method of Chamoles et al. [Clin. Chim. 317:191(2002)]. A fluorescent assay was developed using the substrate 4-methylumbelliferyl-alpha-D-glucopyranoside and conduritol B epoxide (CBE), an irreversible inhibitor of glucocerebrosidase. The difference in activity in the presence and absence of CBE is used to distinguish glucocerebrosidase activity from that of other -glucosidase isoenzymes. We measured glucocerebrosidase activity in DBS samples from 43 untreated Gaucher disease patients and 153 normal adults. Activity in the Gaucher disease samples ranged from below the limit of detection to 4.4 pmol/(punch*h). Activity in the normal samples ranged from 5.6 to 34.7 pmol/(punch*h) with a mean of 10.9 pmol/(punch*h). The assay was sensitive enough to differentiate DBS from patients with Gaucher disease from normal controls. The DBS assays speed, throughput, and low cost make it an ideal method to screen for Gaucher disease. The applicability of this method for diagnosing Gaucher disease remains to be determined.

Genome Wide Significance and Locus Identification in Genome Wide Association Studies. *P. Van Eerdewegh, J. Segal, P. Croteau, T. Keith* Genizon BioSciences, St-Laurent, QC, Canada.

GWAS have provided a paradigm shift in the identification of disease susceptibility loci for complex traits. Common genetic factors with moderate relative risks have now been identified in several GWAS. Although often only the top signal across the genome meets significance after conservative Bonferroni correction for multiple testing, many other true signals are present in the datasets. Identifying these additional loci is a critical challenge if we want to maximize the usefulness and fulfill the promises of GWAS. We have developed an iterative evaluation of genome wide significance that combines permutations and conditional inference and allows the identification of the number of significant signals at specified levels of genome wide significance. The approach does not require a-priori knowledge of the number of true signals or the specification of prior probabilities for a signal to be real. In contrast to other methods such as False Discovery Rate (FDR), the method is applicable to haplotype analyses as well as single SNPs. Since real signals will not necessarily always be among the top hits, we construct the null distributions of various order statistics by permutation of case and control status. The genome wide significance of the ranked nominal p-values is evaluated by comparing each p-value to its respective null order statistic. The conditional inference starts by identifying the highest p-value that meets genome wide significance and, assuming it is under the alternative, removing it from the list of observed values. The remaining observed p-values have their rank reduced by one and are compared again to the various order statistics for significance. The process terminates when no new p-value meets genome wide significance. The number of peels provides an estimate of the number of true signals and although order statistics are cumulative, localization of the real signals in the genome is obtained from the rank where the peel occurs. This conditional inference by peeling genome wide significant hits will be illustrated from one of Genizons GWAS in the Quebec Founder Population and contrasted with FDR and Bonferroni correction.

The Dlx1and Dlx2 genes and Susceptibility to Autism Spectrum Disorders. *X. Liu[1,5,6], N. Novosedlik[5], A. Wang[5], M. Hudson[1,5,6], I.L. Cohen[3,6], M.E.S. Lewis[4,6], J.J.A. Holden[1,2,5,6]* 1) Dept of Psychiatry , Queen's University, Kingston, ON, Canada; 2) Departments of Physiology, Queens University, Kingston, K7L 3N6; 3) Department of Psychology, New York State Institute for Basic Research in Developmental Disabilities, Columbia, Island, NY 10314; 4) Department of Pathology and Medical Genetics, University of British Vancouver, BC, V6H 3N1; 5) Autism Research Program, Ongwanada, Kingston, ON, Canada, K7M 8A6; 6) www.autismresearch.ca.

An imbalance between excitation and inhibition in the cortex, which could be caused by altered regulation of the growth of specific populations of neurons, has been suggested as a possible aetiological factor for autism. The Dlx genes encode homeobox transcription factors that have been implicated in the development of the GABAergic system. The Dlx1 and Dlx2 genes lie head to head in 2q32, a region implicated in genome scans and cytogenetic studies as harbouring genes associated with autism susceptibility. We investigated 6 Tag SNPs in the region covering Dlx1 and Dlx2 genes in two cohorts of multiplex (MPX) families and a comparison group of 384 samples for association with autism. While no significant differences in allele, genotype, and haplotype frequencies between affected cases and the comparison group were observed, the family-based tests showed strong association for two of the SNPs. We found association of the common G allele at rs788172 (P=0.02) and the common G allele at rs813720 (P=0.015) in the first 178 MPX families. The allelic associations at Dlx1-Dlx2 variants were confirmed in a replication sample of 134 MPX families (P=0.008 and 0.002 respectively) and in the combined 312 MPX families (P=0.0007 and P=0.0002 respectively). Haplotype analysis also revealed significantly excessive transmission of haplotype rs788172_G-rs813720_G from parents to affected children in the two cohorts and the combined samples (P=0.01, 0.0007 and 0.00008 respectively). Further testing of the two SNPs in 290 Simplex families did not replicate these findings, suggesting that genetic variants in Dlx1/Dlx2 genes may affect susceptibility or cause autism in a large subset of familial cases.

Quantifying and correcting for the winner's curse effect in genetic association studies. *R. Xiao, M. Boehnke* Dept Biostatistics, Univ Michigan, Ann Arbor, MI.

Genetic association mapping is a powerful method to detect genetic variants that predispose to human disease. Investigators are also interested in estimating the genetic effect on disease risk of each identified variant. Estimates of genetic effect based on initial positive findings tend to be upwardly biased, a phenomenon known as the winners curse. Overestimation of genetic effect size in initial studies may cause follow-up studies to be underpowered and so to fail. In this paper, we quantify the impact of the winners curse on the uncorrected maximum likelihood estimator (MLE) of the allele frequency difference and odds ratio between cases and controls in association studies. We then propose an ascertainment-corrected maximum likelihood method (see also Zoellner and Pritchard 2007) and an ad hoc bias-correction method to improve the estimate of the allele frequency difference. We extend these calculations to two-stage association studies. We show that the overestimation of the genetic effect by the uncorrected MLE decreases as the power of the study increases for both one- and two-stage studies. Simulation results demonstrate that the ascertainment-corrected maximum likelihood estimator reduces overestimation by different degrees, depending on the sample size, true genetic effect size, and the chosen significance level, while the bias-correction method further improves the estimator performance. We recommend using the ascertainment-corrected maximum likelihood estimator or the bias-corrected estimator unless study power is expected to be high.

Inferring carrier of copy number variation in Bipolar linkage region with novel Expectation-Maximization algorithm. *S. Zollner[1,2], Y. Chen[1], G. Su[3], M.G. McInnis[2], M. Burmeister[2,3]* 1) Dept Biostatistics, Univ Michigan, Ann Arbor, MI; 2) Dept Psychiatry, Univ Michigan, Ann Arbor, MI; 3) Program of Bioinformatics,Univ Michigan, Ann Arbor, MI.

Copy Number variations (CNVs) are polymorphic features of the human genome that provide exciting candidates for risk variants of complex trait phenotypes. Efforts are underway to generate a CNV-map by collecting all common CNVs in the human genome. To assess the phenotypic impact of these polymorphisms, case-control designs will be a useful aproach. Testing for association of CNV carrier status and diseases status in such studies will require scoring such common CNVs in all individuals in the sample by evaluating the signal intensity of SNP genotyping assays. However, such analyses are hampered by a lack of appropriate statistical tools. Here we present a novel statistical method that is designed to perform such inference and apply this method to a known CNV in a Bipolar linkage region. Using an Expectation-Maximization algorithm we infer the carrier status of a CNV in each individual of a sample by modeling the signal intensity as a mixture of multiple normal distributions allowing for locus-specific and allele-specific distributions. Thus we generate a maximum-likelihood estimate for the carrier status of each individual in the sample. We applied the method in a sample of 3512 individuals to a known deletion on 8q24, a region implicated in the etiology of Bipolar Disorder. We unambiguously inferred 172 heterozygous and 1 homozygous deletion carrier among 3512 individuals from 737 families. We confirmed several inferred carriers by PCR amplification and detected no inconsistencies in Mendelian transmission of the deletion. However, we observed no significant association between bipolar disorder and carrier status. Finally, we assessed to power of this EM-algorithm to detect CNVs by sub-sampling from the SNPs covered by this deletion. We demonstrated that our EM algorithm produces precise estimates for CNVs covering 6 or more SNPs.

***PTEN* gene mutation causes megalencephaly with prominent Virchow-Robin spaces without cognitive delays or autism: New PTHS phenotype.** *L. Medne[1], A. Waldman[2], C. Bonnemann[2]* 1) Div of Hum Genetics & Neurology, Children's Hosp Philadelphia, Philadelphia, PA; 2) Div of Neurology, Children's Hosp of Philadelphia, Philadelphia, PA.

We report two patients with a pathogenic *PTEN* gene mutation as the cause of megalencephaly with prominent Virchow-Robin spaces who both demonstrated normal cognitive development for age. Patient 1 presented to neuromuscular clinic at 19 months of age for evaluation of hypotonia, motor skill delay and megalencephaly. Macrocephaly was noted shortly after birth. He had a febrile seizure at 18 mo of age. Repeat MRI showed prominent Virchow-Robin spaces, which lead to an extensive diagnostic work-up with normal results. At 19 months, his length was at -0.8 SD but his head circumference was +4 SD. He had hypotonia and ligamentous laxity but did not have PTHS stigmata. *PTEN* sequencing showed a de novo I101T missense mutation that has been previously reported in Cowden syndrome. At both his19 mo and at 4 yr evaluations, he had normal speech and cognitive development with delays limited to gross motor skills due to hypotonia. Patient 2 presented at 11 months for evaluation of post-natal macrocephaly. The head circumference was normal at birth but was above the 98% by 5 months of age. Brain MRI 14 months revealed prominence of Virchow-Robin spaces. Her length was at -1 SD with head circumference at +2.5 SD. She did not have lipomas or hypotonia and her development was age appropriate. *PTEN* sequencing revealed a novel nonsense mutation E285X that was not present in her mother. The occurrence of megalencephaly with prominent Virchow-Robin spaces is a known association that has been previously reported in patients with or without associated cognitive delays and mental retardation. The underlying genetic etiology is felt to be heterogeneous. We suggest that *PTEN* gene mutations should be considered in patients with apparently isolated megalencephaly and prominent Virchow-Robin spaces as well as those with additional previouly associated PTHS stigmata. Establishing the diagnosis would avoid extensive metabolic work-up, guide further management, and allow for appropriate genetic counseling.

Whole Transcriptome Amplification from Degraded Transcripts. *B. Ward, K. Heuermann* Research and Development, Sigma-Aldrich Corporation, St. Louis, MO.

The possibility of obtaining gene expression profiles from fixed samples of diseased tissues is an extraordinary opportunity for the medical research community. Due to the methods used for tissue fixation and questionable care for nucleic acid stabilization, such samples often have insufficient quantities of intact transcripts to allow for expression analysis. The TransPlex whole transcriptome amplification (WTA) system provides a means to amplify damaged and intact RNAs from limited quantities of total RNA. The method comprises preparation of a reverse transcription-mediated cDNA library absent of 3 bias, followed by limited PCR amplification. The method produces microgram quantities of amplification product that is representative of the pre-amplification transcriptome. Quantitative PCR and dual-color microarray analysis of amplified versus unamplified RNA reveals that representation of differential gene expression between RNA sources are maintained during amplification. Studies using degraded RNA have demonstrated that WTA with TransPlex enables PCR detection of template molecules that could not be detected in the original, unamplified samples. In conclusion, TransPlex WTA is able to provide microgram quantities of amplified cDNAs from samples containing limited quantity and/or quality RNA.

Genome-Wide Association study of Treatment Emergent Suicidal Ideation in the STAR*D Sample. *G. Laje[1], N. Akula[1], A.S. Allen[2], S. Paddock[3], H.K. Manji[4], A.J. Rush[5], D. Charney[6], F.J. McMahon[1]* 1) Genetic Basis of Mood and Anxiety Disorders, Mood and Anxiety Program, National Institute of Mental Health, National Institutes of Health, USDHHS, Bethesda, MD; 2) Dept of Biostatistics and Bioinformatics at Duke University, Durham, NC; 3) Karolinska Institutet, Stockholm, Sweden; 4) Laboratory of Molecular Pathophysiology, Mood & Anxiety Program, National Institute of Mental Health, National Institutes of Health, Dept. of Health & Human Services, Bethesda, MD; 5) Depts. of Clinical Sciences and Psychiatry, University of Texas Southwestern Medical Center, Dallas, TX; 6) Mount Sinai School of Medicine, New York, NY.

Background: Suicidal ideation is an uncommon but potentially dangerous symptom than can emerge during antidepressant treatment. We have previously described association between treatment emergent suicidal ideation (TESI) and markers in GRIK2 and GRIA3. Now we have undertaken a genome-wide association study to search for additional genetic markers that may shed light on the causes of TESI and help identify individuals at high-risk who may benefit from closer monitoring, alternative treatments, and/or specialty care. Methods: A clinically-representative cohort of outpatients with nonpsychotic major depressive disorder who enrolled in the STAR*D trial were treated with citalopram under a standard protocol for up to 14 weeks. DNA samples from 90 white participants who developed TESI and equal number of treated participants who denied suicidal ideas were genotyped with 109,000 single nucleotide polymorphisms on the Illumina Infinium I chip. Findings: Two additional markers were significantly associated with TESI in this sample (marker rs10903034, allelic p =2.77 x 10-6, OR = 2.7; marker rs11628713, allelic p= 2.75 x 10-7, OR = 4.7). These markers reside within the genes IL28R and PAPLN, respectively. Conclusion: IL28R encodes an interleukin receptor and PAPLN encodes papilin, a protoglycan-like sulfated glycoprotein. Together with our previous report, these findings may shed light on the biological basis of TESI and may help identify patients at increased risk of this potentially dangerous adverse event.

***LRRK2* Screening in a Canadian Parkinsons Disease Cohort.** *L. Racacho[1,2], D.A. Grimes[2,3], F. Han[1,2], M. Panisset[4], D.E. Bulman[1,2,3]* 1) Department of Biochemistry, Microbiology & Immunology, University of Ottawa, Ottawa, Canada; 2) Centre for Neuromuscular Disease, Ottawa Health Research Institute - University of Ottawa, Ottawa, Canada; 3) Department of Medicine, Division of Neurology, The Ottawa Hospital, Ottawa, Canada; 4) Unité des Troubles du Mouvement André Barbeau, CHUM Hôtel-Dieu, Montréal, Canada.

Mutations in the leucine-rich repeat kinase 2 (*LRRK2*) gene have become the most common known cause for developing Parkinsons disease. The frequency of mutations described in the literature varies widely depending on the population studied with most reports focusing only on screening for the most common p.Gly2019Ser mutation. In this study seven exons (19, 24, 25, 31, 35, 38, and 41) in *LRRK2* where mutations have been reported were screened in 230 unselected Parkinsons disease patients using denaturing high-performance liquid chromatography. The sequencing of samples with heteroduplex profiles revealed five novel and two known intronic sequence variants. In our cohort, we were unable to detect any of the known mutations in these exons or identify novel mutations within *LRRK2*. Therefore, despite the availability of diagnostic *LRRK2* genetic testing it is unlikely to yield a positive result in this population.

A Supervised Principal Component Approach for Modeling Gene-Gene Interaction. *T. Wang, R.C. Elston*
Department of Epidemiology & Biostatistics, Case Western Reserve University, Cleveland, OH.

Multiple genetic and non-genetic factors are usually involved in the etiology of complex human diseases. The effect of a genetic variant often depends in an epistatic manner on the presence of other genetic variants, rather than simply acting additively, and this complicates efforts in mapping these genetic variants. Although modeling interactions in the analysis may be of limited value for establishing biological mechanisms, it can potentially improve power to identify disease variants that have relatively modest marginal effects. However, modeling all possible interactions involves a severe penalty owing to the greatly increased number of tests or degrees of freedom in an association analysis, which has been called the curse of dimensionality. A more desirable strategy to maximize power should have the ability to allow for interactions while at the same time avoiding a considerable penalty arising because of a large number of interactions being possible. Recently, various approaches have been adopted to reduce dimensionality in detecting interactions. Here, we consider a semi principal component approach that compresses information from multiple correlated SNPs in a local genomic region in order to model gene-gene interactions. Our approach combines a supervised approach for SNP selection with an unsupervised approach for data compression, which provides a parsimonious way to detect gene-gene interaction. We perform a simulation study that demonstrates the validity and superior power of this method over those of several other approaches.

Pure Trisomy 3q29 Presenting as VATER Association. *M.W. Lee[1], A.R. Brothman[2], O.A. Abdul-Rahman[3]* 1) Pediatrics, University of Mississippi Medical Center, Jackson, MS; 2) Department of Human Genetics, University of Utah, Salt Lake City, UT; 3) Division of Medical Genetics, Department of Preventive Medicine, University of Mississippi Medical Center, Jackson, MS.

There are several cases of 3q duplications reported in the medical literature. The typical phenotype involves mental retardation, growth retardation, congenital heart defects, renal anomalies, and characteristic facial features. We report a case of a 9 year-old Caucasian female who initially presented with a diagnosis of VATER association that was later discovered to have a 3q29 duplication on microarray analysis. At birth, she was noted to have multiple gastrointestinal anomalies including a tracheoesophageal fistula, esophageal atresia, Meckels diverticulum, malrotation, and imperforate anus. She was also noted to have vertebral anomalies, but no cardiac or renal defects. A karyotype was performed and did not identify any abnormalities. The patient was diagnosed with VATER until she presented for a follow-up evaluation at 9 years of age. At the follow-up visit, she was noted to have generalized growth deficiency, learning problems, and a history of developmental delay. A microarray analysis was performed using the Spectal 1MB Chip and demonstrated a duplication of chromosome 3q29. The duplicated region was estimated to be about 1.3 to 2.7 megabases and was confirmed by FISH. A review of the medical literature revealed no previously reported cases of a pure 3q29 duplication. Our patient showed very mild characteristics of patients with a larger 3q duplication. Although our patient had significant gastrointestinal and vertebral malformations typically seen in VATER association, none of the previously reported cases had similar findings. Therefore, we suspect that the duplication may have breakpoints within a gene critical for development of the gastrointestinal and skeletal systems. Such a gene may represent a candidate gene underlying at least some cases of VATER association. Based on our findings, we recommend that all patients with a diagnosis for VATER association who present with developmental delay or growth deficiency should undergo microarray analysis.

Identification of loci for body height by genome-wide association (GWA): a comparison of microarray platforms.

F. Rivadeneira[1,2], M.J. Moorhouse[1,2], J.M. van Meurs[1], P. Arp[1], M. Jhamai[1], A. Hofman[2], H.A. Pols[1,2], M.H. Kayser[3], A.G. Uitterlinden[1,2] 1) Internal Medicine; 2) Epidemiology & Biostatistics; 3) Forensic Medicine, Erasmus MC Rotterdam, Netherlands.

Introduction: Body height is a highly heritable complex trait. GWA is a hypothesis-free design we used to identify loci influencing height variation.
Methods: 490 non-diseased Dutch Caucasian women (age 65-75 years) were selected for a pilot-study using the Affymetrix(AFFY) Mapping500K dual array. Of these, 433 were also genotyped for the Illumina (ILLU) HumanHap550 array as part of a large GWA effort in a population-based cohort (n=10,000). 393 women were analysed after excluding 15 missing one AFFY array and 26 with X-ray diagnosed vertebral fractures. Height was measured with stadometer. Allele calling inclusion thresholds were 95%(AFFY-BRLMM) and 98%(ILLU). PLINK was used for QC (*IBS clustering, HWE<0.001, and MAF<0.01 filtering*) and association testing. Loci were ranked based on significance in the total set, effect-consistency across 2 random sets (n=196 each) and after adaptive permutation of selected SNPs.
Results: Average call-rates were 0.985 for the remaining 417,464 AFFY SNPs and 0.995 for the 532,202 ILLU SNPs. P_{unadj} ranged between $9x10^{-7}$ to $9x10^{-4}$ for 299 SNPs/142 loci(L) still significant after permutation (all $p_{emp}<0.002$) : *AFFY*: 146/75L, *ILLU*: 153/102L and *BOTH*: 9/35L. The top five hits included loci on:
Chr20: 4 SNPs(3 AFFY/ 1 ILLU), MAF=0.04, =5.0 cm, gene region YES;
Chr02: 2 SNPs(0 AFFY/ 2 ILLU), MAF=0.47, =1.9 cm, gene region YES;
Chr06: 1 SNP (0 AFFY/ 1 ILLU), MAF=0.44, =-2.0cm, gene region NO;
Chr05: 1 SNP (1 AFFY/ 0 ILLU), MAF=0.12, =-3.1cm, gene region NO;
Chr11: 1 SNP (1 AFFY/ 0 ILLU), MAF=0.12, =3.1 cm, gene region NO.
Ignoring presence of vertebral fractures diluted most associations.
Conclusion: In this pilot study we identified multiple loci influencing height that warrant replication in different cohorts to establish consistency and true effect size. Both genotyping platforms have modest overlap in the loci identified (25%) thus, seem complementary.

Haplotype analysis of prostate cancer susceptibility loci at 8q24. *N. Orr[1], M. Yeager[2,3], K. Jacobs[4], R. Hayes[3], P. Kraft[5], S. Wacholder[3], R. Welch[2,3], H. Spencer Feigelson[6], D. Albanes[7], D. Gerhard[8], R. Hoover[3], D. Hunter[5], G. Thomas[3], S. Chanock[1,3], The CGEMS group* 1) Pediatric Oncology Branch, NCI, Bethesda, MD; 2) SAIC-Frederick, Frederick, MD; 3) Division of Cancer Epidemiology and Genetics, NCI, NIH, Rockville, MD; 4) Bioinformed Consulting Services, Gaithersburg, MD; 5) Department of Epidemiology, Harvard School of Public Health, Boston, MA; 6) Department of Epidemiology and Surveillance Research, American Cancer Society, Atlanta, GA; 7) Department of Health Promotion and Chronic Disease Prevention, National Public Health Institute, Finland; 8) Office of Cancer Genomics, NCI, NIH, Bethesda, MD.

The genetic bases for sporadic prostate cancer have been unknown until recently. Following a genome-wide association scan for prostate cancer risk variants, we identified two independent susceptibility loci at 8q24 separated by a hotspot of recombination (Yeager M, et al. Nat Genet 2007). Here we present haplotype analysis conducted at each locus using the novel approach of variable sized sliding window regularized regression (Li Y, et al. Am J Hum Genet 2007) with the aim of refining the nature of these associations.

In our initial study, the risk loci centromeric and telomeric of the recombination hotspot were defined by associations at rs6983267 and rs1447295 respectively. We genotyped a total of 34 tag-SNPs (15 centromeric and 19 telomeric) in 4137 cases and 4081 controls, drawn from 4 independent prostate cancer cohorts. The centromeric and telomeric region tag-SNPs spanned approximately 63 kb and 116 kb. We found that the most significant haplotype in the centromeric region spanned 15 kb, comprised five SNPs delineated by rs10808555 and rs7014346 ($p=1.17x10^{-11}$) and incorporated rs6983267. The most significant haplotype in the telomeric region spanned 12 kb, contained 6 SNPs and was bounded by rs4871809 and rs7837688 ($p=3.47x10^{-13}$). Interestingly, this haplotype did not include rs1447295, suggesting that it is unlikely to be the causative allele at the telomeric locus. We believe this analysis will be of great value for further fine mapping studies of prostate cancer risk at 8q24.

Identification of novel genes for early age-related macular degeneration (AMD): genome-wide association results from the Los Angeles Latino eye study (LALES). *C. Shtir[1, 2], H. Volk[3], P. Marjoram[3], T. Triche[4, 6, 7], D. Hinton[2, 4, 5], R. Varma[1, 2]* 1) Doheny Eye Institute, University of Southern California, Los Angeles, CA; 2) Ophthalmology, University of Southern California, Los Angeles, CA; 3) Preventive Medicine,University of Southern California, Los Angeles, CA; 4) Pathology, University of Southern California, Los Angeles, CA; 5) Neurosurgery, University of Southern California, Los Angeles, CA; 6) Cancer Biology, University of Southern California, Los Angeles, CA; 7) Pediatrics, Keck School of Medicine, University of Southern California, Los Angeles, CA.

Many genetic and environmental risk factors have been strongly associated with the development of both early and advanced AMD (Klein et al., 2005). Advanced AMD is a leading cause of blindness and its prevalence is significantly higher in Caucasians compared to Latinos (Varma et al., 2004). However, early AMD remains very common among Latinos (Varma, 2004). This study seeks to identify new genes associated with early AMD among Latinos through the use of a genome wide association study based on a 500K Affymetrix chip data set. Prevalent early AMD cases (n=101) and control subjects (n=202) were ascertained from the Los Angeles Latino Eye Study (LALES). Early AMD cases were identified by the presence of intermediate to large soft drusen in both eyes by masked grading of fundus photographs. Using single allelic tests, we identify 26 significant SNPs distributed among 14 chromosomes, all of which survive Bonferroni correction for multiple genome-wide comparisons, 19 of which are intragenic while 7 are intergenic. We then use haplotype association and haplotype trend regression analyses to further explore the disequilibrium structures neighboring these SNPs and to detect situations when single marker effects do not carry enough information to describe the underlying genetic variation. Our results suggest that different genetic factors play a role in AMD etiology among Latinos, which may uniquely protect Latinos from progressing to advanced AMD and its associated blindness.

A newly recognized overgrowth syndrome distinct from Proteus syndrome. *J.C. Sapp[1], R.D. Clark[2], J.T. Turner[1], J. van de Kamp[3], F. van Dijk[3], R.B. Lowry[4], L.G. Biesecker[1]* 1) National Human Genome Research Institute, Bethesda, MD; 2) Loma Linda University Medical Center, Loma Linda, CA; 3) VU Medisch Centrum, Amsterdam, Netherlands; 4) Alberta Children's Hospital, Calgary, Canada.

Syndromes with overgrowth as a major manifestation are clinically and phenotypically heterogeneous and incompletely defined. Proper clinical delineation of these syndromes is important both for research and for clinical care. We present here a series of eight patients who were previously diagnosed with Proteus syndrome but who do not meet published diagnostic criteria for this disorder and whose natural history is distinct. This newly delineated phenotype comprises progressive, complex, and mixed truncal vascular malformations, dysregulated adipose tissue, varying degrees of scoliosis, and enlarged, yet not distorted, bony structures without progressive bony overgrowth. Similarities between these patients' phenotype and that of Proteus syndrome include vascular malformations (low flow blood vessels and lymphatics), linear pigmented nevi, and excess fat deposition or lipomas. Differences between this newly described entity and Proteus syndrome are that the former includes non-progressive, non-distorting overgrowth that is generally congenital and of the ballooning type, and a stereotypical distribution of lesions that includes complex truncal vascular malformations, bilateral foot overgrowth, and lack of cerebriform connective tissue nevi. We conclude that the patients presented here have a phenotype that is both recognizable and distinct from Proteus syndrome and other overgrowth conditions.

Genetic links between maternal diabetes/obesity and neural tube defects. *H. Zhu[1], W. Lu[1], L. Suarez[2], M. Canfield[2], G.M. Shaw[3], R.H. Finnell[1]* 1) Center for Environmental and Genetic Medicine, Institute of Biosciences and Technology, TAMU-HSC, Houston, TX; 2) Department of State Health Services, Austin, TX; 3) California Birth Defects Monitoring Program, Berkeley, CA.

BACKGROUND: Neural tube defects (NTD) are common, costly, and deadly human congenital anomalies. One of the most promising clues to the causes of NTDs is that women who use multivitamins containing folic acid during early pregnancy are at reduced risk for NTD, however, the etiologies and mechanisms remain largely unknown. Maternal diabetes is an established risk factor for NTD. Pre-pregnancy obesity also increases the risk of NTD. A possible explanation for the association between maternal obesity and NTD risk is that obese women have alterations in glucose tolerance. There are many studies of the genetic variants that increase susceptibility to type 2 diabetes and obesity. We hypothesized that these variations may also increase the womens risks for having NTD-affected pregnancies. Under the condition of maternal hyperglycemia, the fetal genes regulating glucose transportation may also have impact on NTD risk. METHODS: We conducted a candidate gene association study to test the aforementioned hypotheses. DNA samples were derived from a population-based case-control study from a Texas-Mexico border Hispanic population. Variants in several candidate genes (TCF7L2, ENPP1, UCP2, LEP and SLC2A2) were interrogated using TaqMan SNP assays. Odds ratios and 95% confidence intervals were used to estimate the risk effect of the variants. RESULTS: A diabetes-associated allele in SNP rs7903146 in TCF7L2 gene is associated with increased risk of NTD-affected pregnancy among this Hispanic population (OR=4.0, 95% CI: 1.1~14.9, P=0.02). This SNP has been consistently reported as a strong predictor for type 2 diabetes and obesity in multiple populations. In addition, a mild protective effect was observed when the minor allele was present in a nonsynonymous SNP in infant SLC2A2 gene. CONCLUSION: Our observations provided preliminary evidence supporting the hypotheses that genetic variations associated with maternal diabetes/obesity and embryonic glucose transportation may increase the NTD risk.

A Robust, Scaleable Solution for High Throughput Data Generation Using Affymetrix Genome-wide 5.0 and 6.0 SNP Arrays. *M. Parkin, C. Gates, B. Blumenstiel, M. DeFelice, D. Gage, W. Winslow, P. Lin, F. Kuruvilla, J. Korn, M. Nizzari, M. Daly, D. Altshuler, S. Gabriel* Broad Institute of MIT and Harvard, Cambridge, MA.

Resources and technologies required to systematically and efficiently scan the human genome for association between common genetic variations and disease have become available over the past year. To conduct Genome-Wide Association Scans (GWAS), it is necessary to create laboratory capabilities with appropriate scale, quality control and integration to advanced bioinformatics capability. To meet this need, we have developed an automated lab process for target prep, data management, and custom tracking systems to support GWAS using Affymetrix SNP arrays. The process has been used for early versions of the SNP arrays (the 100K and 500K), with which we generated genome scan data for over 16,000 samples. A collaborative effort between our group and Affymetrix has resulted in the development of new single-chip products, the SNP 5.0 (470,000 SNPs) and more recently the SNP 6.0 array which interrogates 906,600 SNPs and 920,000 copy number sites. Initially at a scale of 384 samples per week in January 2007, the pipeline scaled to 1152 samples within 4 weeks and reached full scale in June 2007 generating 1536 samples per week. In total over 29,904 arrays have been scanned, with quality and accuracy of data maintained throughout the scale up. Overall call rates using the Birdseed algorithm across five different datasets average 99.6% and accuracy as assessed by segregation tests in family samples and comparison to the Hap Map is 99.7%. To ensure sample integrity we have implemented a fingerprinting panel using the Sequenom Iplex technology in conjunction with the FQC SNPs on these arrays. We also present these and other quality control tests implemented to take advantage of the product content and the dense genotype data.

Branchiootic syndrome-3 and Oculoauriculovertebral spectrum features in a family with a duplication including *SIX1* and *SIX6*. *Z. Ou[1], D.M. Martin[2], M.L. Cooper[1], A.C. Chinault[1], P. Stankiewicz[1], S.W. Cheung[1]* 1) Dept Molecular & Human Genetics, Baylor Colloge Medicine, Houston, TX; 2) Dept Pediatrics and Human Genetics, University Michigan Medical School, Ann Arbor, MI.

Chromosomal insertions are rare structural aberrations with an estimated frequency of 1 in 5,000 infants. We present a 7-month-old boy with developmental delay and multiple congenital anomalies, including multiple preauricular and facial skin tags, right optic nerve hypoplasia, occipital encephalocele with large fontanels, poorly ossified and irregular skull shape, posteriorly sloping prominent forehead, prominence of the maxilla, severe hypoplasia of the mandible, low set ears with abnormally formed antihelix and ear lobe, highly arched palate, broad nasal bridge, small kidneys, small genitalia with cryptorchidism, and bilateral talipes equinovarus. These features suggested branchiootic syndrome-3 (MIM 608389, BOS3) and oculoauriculovertebral spectrum (MIM 164210, OAVS). His father had mental retardation, short stature, hypernasal speech, minor craniofacial dysmorphisms, including tall forehead and crowded dentition. Chromosomal microarray analysis revealed a copy number gain detected by a single BAC clone RP11-79M1 at band 14q23.1. FISH analysis using this clone as a probe showed the third copy of this sequence inserted into the mid long arm of one chromosome 13. The same insertion duplication was also present in the father. To delineate the chromosome breakpoints, array CGH with 244K oligonucleotide probes was used. It revealed an ~11.69 Mb gain of chromosome 14q22.3-q23.3 and a loss of an ~4.38 Mb chromosome fragment in 13q21.31-q21.32 in both the proband and his father. The deleted region on 13q is extremely gene poor and harbors only one gene, *PCDH9*, which encodes protocadherin-9 and has not been related to any disease. Chromosome region 14q22.3-q23.3 contains 51 genes, including *SIX1* and *SIX6*. Interestingly, mutations in *SIX1* have been reported in patients with BOS3 and mutations in *SIX6* cause microphthalmia, cataract, and nystagmus (MIM 212550). We propose that duplication of *SIX1* and *SIX6* causes BOS3 and OAVS-like features in our patients, respectively.

PCAtag: Software for Selecting Tagging-SNPs using Principal Component Analysis. *N. Naiman[1], G.B. Christensen[1], J. Wong[1], C. Teerlink[1], A. Thomas[1], B.D. Horne[1,2], N.J. Camp[1]* 1) Genetic Epidemiology Division, Department of Biomedical Informatics, University of Utah, Salt Lake City, UT; 2) Cardiovascular Department, LDS Hospital, Salt Lake City, UT.

To be able to comprehensively test the role of candidate genes in association studies the selection of informative SNPs is paramount. Specifically, it is important to select tagging-SNPs (tSNPs) that represent a large portion (>90%) of the genetic variation of a gene. Here we describe a new software tool, PCAtag, that performs tSNP selection using principal component analysis (PCA) as described in Horne and Camp (2004). The Horne-Camp method has two steps. In step 1, linkage disequilibrium (LD) groups are identified. In step 2, tSNPs are selected. The advantage of PCA analysis for tSNP selection is that LD groups do not need to be contiguous and can be overlapping. This flexible framework does not impose over-simplified assumptions on the genetic architecture structure, and likely fits reality much better. PCAtag is written in JAVA and is freely available. The input is genotype, and, optionally phenotype, data. The tagging process can be performed using the genotype data (assuming an additive model for alleles) or haplotype data. For the haplotype option, phases are estimated from the genotype data using expectation-maximization (EM), and haplotypes are then used in the tagging process. The software GCHAP (Thomas 2003) is used to perform the EM procedure. The PCA procedures within PCAtag are performed in R. If phenotype data are entered, the user can opt that the tagging is performed in the cases and controls separately, as well as together. This is an important and novel feature. If the genomic structure in diseased individuals is significantly different to the general population -as is likely the case for some underlying modes of inheritance- tSNPs chosen from cases and controls may differ substantially. This must be known at the selection stage to select appropriate SNPs. The output from PCAtag includes both the LD groups and the tSNPs suggested, with additional tabulated data, such as factor loadings. The accuracy of PCAtag was compared to PCA analyses performed by-hand using SAS and SPSS.

Linkage of cross-sectional and longitudinal measures of cystic fibrosis lung disease severity to chromosome 5q.

L.L. Vanscoy[1], S.M. Blackman[1], J.M. Collaco[1], L. Bremer[1], R. Dorfman[2], P. Durie[2], J. Zielenski[2], K. Naughton[1], A. Bowers[1], G.R. Cutting[1] 1) Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 2) Hospital for Sick Children, Toronto, Canada.

Affected twins and siblings demonstrate that modifier genes are major contributors to variation in lung disease severity in cystic fibrosis (CF). To identify regions encompassing these modifiers, we performed genome wide linkage analysis on 683 siblings with CF (360 families). Lung disease severity was defined using forced expiratory volume in 1 second (FEV1), a quantitative measure highly correlated with survival. To facilitate comparison of patients, lung function measures were converted to disease-specific percentiles. The best CF-specific %ile for FEV1 within the last year of available data (MaxFEV1CF%ile) was used as a cross-sectional measure. The lifetime average CF-specific %ile for FEV1 (AvgFEV1CF%ile) and the estimated percent-predicted FEV1 at age 20 (EstFEV1%pred@20yrs) were used as longitudinal measures. Short tandem repeat markers were typed in all affected individuals and their parents (Marshfield Genotyping Center: 402 markers or DeCode: 1030 markers). Two-point and multipoint linkage analyses using Sequential Oligogenic Linkage Analysis Routines (SOLAR) revealed linkage of all 3 lung phenotypes to chromosome 5. Peak multipoint LOD scores on chromosome 5 occurred at 196 cM for MaxFEV1CF%ile and AvgFEV1CF%ile (LOD 3.0 and LOD 3.4, respectively) and at 191 cM for EstFEV1%pred@20yrs (LOD 2.8). Single point LOD scores on chromosome 5 peaked at marker AAT072 (3.3 for MaxFEV1CF%, 3.4 for AvgFEV1CF%, and 1.88 for EstFEV1%pred@20yrs). The region of linkage encompasses approximately 6 megabases near the telomere of chromosome 5q. Linkage to one or two lung phenotypes was observed on chromosome 1 (GATA12A07N, LOD 4.5 for EstFEV1%pred@20yrs) and chromosome 14 (GGAA30H04ZP, LOD 2.33 and GGAA4A12, LOD 2.13 for MaxFEV1CF% and EstFEV1%pred@20yrs, respectively). Linkage of the 3 quantitative pulmonary traits to chromosome 5 suggests that this region encompasses genetic modifiers of CF lung disease severity.

Computational efficiency of Logistic regression trees algorithm as a tool for initial screening in Genome-Wide Association Studies. *V.B. Milanov, R.Z. Nickolov* Department of Mathematics and Computer Science, Fayetteville State University, Fayetteville, NC.

Nowadays genetic epidemiology faces the challenge of dealing with immense number of genetic markers - Genome-Wide Association Studies. Finding a small number of interesting markers for further investigation can greatly facilitate genetic studies. Recently, we have shown that Logistic Regression Tree Algorithms provides an efficient tool for reduction of an initial large pool of markers to a small set of interesting markers with high probability. In this paper we compare the computational capabilities of Logistic Tree with Unbiased Selection (LOTUS) and Random Forest methods to detect an interesting genetic factors involved in disease etiology. Using the simulated data provided for Genetic Analysis Workshop 15 for rheumatoid arthritis (RA), we show how these algorithms perform under different scenarios. Our results indicate that LOTUS is computationally efficient tool for initial screening of large number of candidate markers.

Leveraging community resources through a repository. *K. White, K. Puchir, L. Wise, S.F. Terry* Genetic Alliance, Washington, DC.

High quality, well-vetted resources are valuable to advocates, professionals, policymakers and federal agency officials. Finding useful resources in a timely manner and centralizing them for open access can be a difficult endeavor. Genetic Alliance launched a robust document repository service (www.resourcerepository.org) in 2007 that aggregates the combined resources of advocates, healthcare professionals, government agencies, think tanks, and other contributors. These resources cover a wide range of topics such as fundraising, FDA genetic testing guidances, advocacy at the state and federal level, media strategies, and clinical trials. The Repository contains all of the common file formats, including PowerPoint presentations, Word documents, and PDFs. Examples of shared resources include meeting presentations, how-to-guides, case studies, monographs, white papers, and position papers. The Repository allows visitors to browse collections in categories such as genetics services; ethical, legal, and social issues; organization development; public policy; and communications. Visitors can also track new content tailored to specific interests on a daily, weekly, or monthly basis; view the newest resource added to the Repository, and access the most frequently downloaded resources. The software allows individuals to contribute documents in a few simple steps. Documents are held and reviewed by an editorial team consisting of experts in genetics, electronic document storage, education and information archiving and retrieval. Documents are published, tagged with keywords, and a succinct abstract. Metrics are available for download.

Accommodating longitudinal unstructured clinical information in genetics studies. *R.M. Salem[1,2], N.J. Schork[1,3]* 1) Dept Family and Preventive Medicine, UCSD, La Jolla, CA; 2) Graduate School of Public Health, SDSU, San Diego, CA; 3) Scripps Genomic Medicine, TSRI, La Jolla, CA.

Dynamic complex traits, quantitative phenotypes measured over time, are influenced by the interplay of multiple genetic and environmental factors. Analysis of such traits offers insights into disease processes, progression, and temporality, in contrast to the single dichotomous outcome in the more commonly utilized case-control design. The case-control study design is problematic in that it suffers from bias, uses limited data, and provides no such insights. Unfortunately, many of the existing statistical methods perform poorly or do not fully utilized available data. We introduce a novel statistical framework to model and analyze dynamic complex traits. The first step, involves modeling the dynamic trait using non-parametric functions (curves) fitted to all available data. The dissimilarity (or distance) between a set of individuals functions is calculated and related to genetic and environmental factors via a Multivariate distance matrix regression (MDMR) method. This approach accounts for uncertainty of fitted functions, can accommodate weighting factors, and is easily extended to a multivaraite analysis settings. We compare our approach with standard quantitative longitudinal statistical methods with data from three clinical studies. Across the studies, measurement of blood pressure (BP) varies from highly structured clinical studies to unstructured medical care data. One study, containing medical records represents a valuable and unique perspective for studying BP in a clinical setting. Use of medical data in research poses considerable challenges and has been labeled the Longitudinal Unstructured Clinical Information (LUCI) Problem. Advancement on these problems has direct applications to the study of disease occurrence, progression, and drug response. The proposed method is very flexible, accommodates a wide range of complex and high-dimensional longitudinal clinical datasets, and utilizes all available data. In conclusion, our method anticipates a shift from use of case-control to longitudinal cohort study designs in genetics research.

Myocilin interacting proteins: Screening of a human retina yeast two hybrid cDNA library. *M. Ohtsubo[1], K. Hosono[1], C.X. Wang[1,2], Y. Hotta[2], S. Minoshima[1]* 1) Photon Med Res Ctr,; 2) Dept Ophthalmol, Hamamatsu Univ Sch Med, Japan.

At present, 3 causative genes (myocilin, optineurin, WDR36) have been identified for primary open-angle glaucoma (POAG). However, these genes account for only small fraction of inherited glaucoma. At least 11 more chromosomal regions (GLC1B - D, F, H-N) have been described as candidate loci for POAG. We are attempting to identify new causative genes using extended candidate gene (ECG) approach which we designed. In this approach, novel proteins interacting with a known causative gene product are identified by yeast two-hybrid (Y2H) screening. If the gene of the novel protein is located to candidate chromosomal regions, it is extensively analyzed for mutation in patients.

MYOC (Myocilin) protein functions in the extracellular environment and mutations in the gene lead to a perturbed outflow of aqueous humor in the trabecular meshwork (TM). However, it was reported that myocilin protein is expressed also in retina. Thus, it is not clear whether myocilin functions intracellularly and what is the meaning of the expression in non-TM tissues. We chose MYOC for our ECG approach.

A Y2H cDNA library was constructed with total RNA from human retina by homologous recombination using prey vector pGADT7-Rec (invitrogen) containing GAL4 DNA activation domain. A full-length MYOC cDNA was cloned with pGBKT7 vector containing GAL4 DNA binding domain for a bait. As a result of Y2H screening, we have obtained tens of clones. Further confirmation for the interaction of isolated gene products with MYOC by co-immunoprecipitation and pull-down assay as well as characterization of each protein such as intraocular localization are in progress. These genes include 9 of them localized to candidate chromosomal regions (see above), cathepsin D, opticin, fibulin 5, lamin A/C, Fas-activated S/T kinase, transthyretin and myocilin itself. This study will help to understand the composition of protein functional complex surrounding MYOC and its normal function as well as to discover the novel glaucoma causative genes.

Triple X Syndrome Accompanied by Aortic Coarctation. *L. Murrain[1], A.L. Shanske[2]* 1) Montefiore Medical Center/Albert Einstein College of Medicine, Bronx, NY; 2) Center for Craniofacial Disorders, Children's Hospital at Montefiore, Albert Einstein College of Medicine, Bronx, NY.

Triple X syndrome (47, XXX) is one of the most common sex chromosome abnormalities in females, with an incidence rate of approximately 1 per 1,000 female births. Triple X Syndrome is usually the result of non-disjunction in maternal meiosis I. We evaluated a 4-year-old Jamaican-American female referred to our pediatric genetic clinic for abnormal chromosome analysis, abnormal gait, and aortic coarctation. On exam she was noted to have a short broad neck, synophrys, and a well-healed left thoracotomy scar. She was the full-term product of a pregnancy complicated by advanced maternal age, thalassemia minor, and well-controlled gestational diabetes class A1. She was born via uncomplicated vaginal delivery with a birth weight of 3856 g. In the nursery she was diagnosed with aortic coarctation, and underwent surgical repair at 3 months. At three years of age she was noted to have an abnormal gait. Chromosome analysis revealed a 47, XXX karyotype. While triple X syndrome is associated with considerable phenotypic variability, the vast majority of patients will express a normal phenotype. Affected individuals may display tall stature, premature ovarian failure, developmental delays, learning disabilities, and behavior problems. More recently it has been suggested that genitourinary, gastrointestinal malformations, congenital adrenal hyperplasia, and pituitary tumor be added to the phenotypic spectrum. Several case reports in the literature have described triple X syndrome with Turner stigmata. Although our case lacks stigmata, she has the second most common congenital heart defect associated with Turner syndrome. Our case suggests that cardiac defects be considered as part of the clinical spectrum of 47, XXX, and cardiac assessment be included in the management of affected individuals.

Autosomal dominant disorder involving deafness, ear pits and hypertelorism: A novel syndrome? *S. Sampath*[1], *Y. Lacassie*[2], *B. Keats*[1] 1) Department of Genetics, LSU Health Sciences Center, New Orleans, LA; 2) Department of Pediatrics, LSUHSC, Children's Hospital, New Orleans, LA.

We present an apparent novel autosomal dominant disorder affecting at least three generations of an African-American family. The major features involve deafness, preauricular pits and hypertelorism. The proband is a one-month-old male referred for the evaluation of congenital hearing loss. On physical examination, preauricular pits, hypertelorism, penoscrotal inversion, punctal pits with lacrimal-duct obstruction, and abnormal palmar flexion creases were detected. The family history revealed the presence of multiple affected members; the deaf-mute father has similar features to the proband and even more striking hypertelorism. So far, we have performed detailed phenotypic evaluations and obtained DNA samples for 17 family members of whom 10 are affected. The large pedigree spans five generations and includes 14 other possible affected members from a total of 29. While the deafness is always bilateral, the preauricular pits are either unilateral or bilateral. Some affected members have deafness, preauricular pits and hypertelorism, while others manifest only hypertelorism. Abnormal palmar flexion creases and vertical creases in the 4th interdigital areas are present in two affected individuals; only the proband has punctual pits. Because the phenotype resembles BOR syndrome, the EYA1, SIX1 and SIX5 genes were screened for mutations. No mutations were found in either the coding sequences or in the intron-exon boundaries of these three genes, suggesting that this family may have a novel syndrome with hypertelorism being an important characteristic. We are currently undertaking a SNP-based whole-genome linkage scan to map the disease locus, and identify the gene associated with this disorder.

Disruption of CTNND2 by a de novo t(3;5) is associated with borderline intelligence and avoidant personality disorder. *E.A. Swanson[1], L. Margari[2], P. Ventura[2], A. Presicci[2], M. Gentile[3], F. Margari[4], R. De Blasi[5], M. Buttiglione[2], S.L. Christian[1], W.B. Dobyns[1]* 1) Human Genetics, Univ of Chicago, Chicago, IL; 2) Child Neurological and Psychiatric Service, Department of Neurological and Psychiatric Sciences, Univ of Bari, Italy; 3) Medical Genetic Unit, Hospital Di Venere, ASL BA/04, Bari, Italy; 4) Psychiatric Service, Department of Neurological and Psychiatric Sciences, Univ of Bari, Italy; 5) Neuroradiology Service, Department of Neurological and Psychiatric Sciences, Univ of Bari, Italy.

The genetic basis of subtle developmental and especially behavioral disorders is complex, making gene identification challenging. We ascertained a family segregating the reciprocal translocation t(3;5)(q24;p15.2) that implicate the brain specific gene CTNND2 in brain development and function. A boy with the der (3) had parietal bone foramina, cleft palate and enlarged and lucent right lung associated with pulmonary ectasia, which led to cardiac failure and death. The father and sister were both carriers of the balanced translocation, which was de novo in the father. Both had borderline scores on cognitive testing and an avoidant personality disorder based on history of deficient reciprocal social interactions and communication, as well as anxiety, depression, and poor attention. Brain imaging showed herniation of the mesial parietal lobes through an enlarged tentorial notch (previously associated with parietal foramina) and mild cerebellar vermis hypoplasia (CVH). We used FISH to identify the two breakpoints. The 3q breakpoint was localized to a region ~300 kb telomeric to the ZIC1 and ZIC4 genes that we previously associated with cerebellar hypoplasia and Dandy-Walker malformation (Grinberg et al., 2004). The 5p breakpoint was fine mapped between the first and second exons of the brain-specific gene, CTNND2, using the fosmid G248P87103D2. The gene, located ~11 Mb from the 5p telomere, is deleted in some patients with cri-du-chat syndrome. We hypothesize that altered expression of ZIC1 and ZIC4 are responsible for the mild CVH, while disruption of CTNND2 is responsible for the unusual cognitive and behavioural profile. The cause of the meningeal deficiency is not clear.

Population Stratification in the Quebec Founder Population. *J. Raelson, V. Pinchuk, E. Hardy, L. Nadeau, T.V. Nguyen, B. Stojkovic, V. Perepetchai, P. Croteau, A. Belouchi, P. Van Eerdewegh, T. Keith* Genizon BioSciences, St-Laurent, QC, Canada.

The Quebec Founder Population (QFP) is a population isolate with demographic characteristics that make it a valuable resource for genome wide association studies (GWAS) of complex diseases. During the course of our GWAS we have observed stratification between distinct regional sub-populations of Quebec. Using a 374K chip data (Human Hap300 from Illumina supplemented with 57K SNPs based on LD in the QFP) for a sample of about 1300 QFP control subjects, we have observed differences in allele frequency for tens of thousands of SNPs and relatively high values of lambda for Genomic Control when comparing regional sub-samples. Such regional differences can seriously confound case-control studies where regional mismatch exists between cases and controls producing many false positives. Accordingly, we have developed algorithms to detect the presence of stratification and to build data sets in which cases and controls are closely matched for geographic origin. One approach is genealogical, based upon the use of grandparental birth location. We have developed an algorithm that weights both quality of available information and extent of grandparental region matching that routinely produces optimally matched sets of cases and controls with corresponding lambda values reduced to 1.00 from 1.3-1.4 in input data sets. A second algorithm matches case and control samples using genotype information. Existing methods such as Genomic Control and EIGENSTRAT correct single marker p-values. These methods are not adapted to genome-wide haplotype analyses which we routinely use. Our algorithm, based upon multivariate correspondence analysis, matches cases to controls according to chi-squared distances computed over all markers. Paired individuals are then sorted by this statistic in increasing order and a cut-off is applied at a matching distance corresponding to a lambda value close to 1.00. Both algorithms successfully remove the problem of population stratification. The usefulness of the methodologies will be illustrated with data from GWAS in the QFP.

Genetic Association Between Alzheimers disease and Neuroglobin, a positional and functional candidate gene.

M.M. Szymanski[1], R.H. Wang[2], M.D. Fallin[3], S.S. Bassett[2], D. Avramopoulos[1,2] 1) Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 2) Psychiatry, Johns Hopkins University, Baltimore, MD; 3) Bloomberg School of Public Health, Johns Hopkins University, Baltimore MD.

Neuroglobin (NGB) is a member of the vertebrate globin family involved in cellular oxygen homeostasis, increasing oxygen availability to the brain tissue and providing protection under hypoxic or ischemic conditions, potentially limiting brain damage. It is located on chromosome 14, in a region that we have previously shown significant linkage for late onset Alzheimers disease (AD) when using the presence of psychotic symptoms as a covariate. In a follow up study of our linkage results we have explored NGB as well as four additional positional candidate genes for association with the risk for developing AD, with or without psychotic symptoms. We found that both psychotic AD and non-psychotic AD patients showed association with different but overlapping NGB single nucleotide polymorphisms (SNPs). We further investigated this association by genotyping a total of 37 SNPs within NGB. We found 2 SNPs showing strong association with AD (p=0.0012 and 0.009). In an unrelated family based sample, the same trend was observed, although not statistically significant, possibly due to the low power of that sample. NGB transcript level analysis in 31 AD brains and 29 control brains showed that NGB is downregulated with increasing age, it is higher in males and it is upregulated in AD patients. However the associated SNPs did not show effects on expression. We conclude that NGB is an interesting functional and positional candidate for AD, however further study is needed to replicate the observed association and point to possible mechanisms of involvement.

Novel Sequence Variants in the HLX Gene in Patients with Isolated Congenital Diaphragmatic Hernia. *A. Slavotinek[1], A. Moshrefi[1], A. Mendell[2], GM. Shaw[3], L. Pennacchio[4], MD. Bates[2]* 1) Dept Pediatrics, U585P, Univ California, San Francisco, San Francisco, CA; 2) Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 3) California Birth Defects Monitoring Program, Berkeley, CA; 4) U.S. Department of Energy Joint Genome Institute, Walnut Creek, CA.

Congenital diaphragmatic hernia (CDH) is a common, life threatening birth defect. The genes that cause isolated CDH are largely unknown and only one mutation and two sequence variants of unknown significance have been reported in the FOG2 gene in isolated CDH. The Hlx gene is a divergent member of the homeobox transcription factor family with homology to the Drosophila homeobox gene H2.0. Hlx is highly expressed in intestinal mesenchyme and is detectable in the murine diaphragm at the time of diaphragm closure. Homozygous null mice for Hlx have had extremely small livers, reduced intestinal length and herniation of the diaphragm. In addition, HLX is located at 1q41-1q42 in humans, a chromosome region known to harbor a gene required for normal diaphragm development. We therefore re-sequenced this gene in 122 CDH patients. We identified four novel sequence alterations (3.2%) - c.C35T, predicting p.S12F, c.C53T predicting p.S18L and c.G517T predicting p.D173Y in three patients with isolated, right-sided CDH and c.C1161T, predicting p.A235V, in a patient with left sided-CDH, an atrial septal defect and a patent ductus arteriosus. These sequence alterations affect highly conserved amino acids outside the DNA-binding homeodomain. The alterations were absent in more than 186 ethnically matched control chromosomes. Parental samples were unavailable for all but the mother of the last patient, who was normal. Functional studies showed that only p.S18L resulted in a protein of reduced activity in regulating a smooth muscle actin promoter. The mouse model of CDH in the Hlx null mouse involved two null alleles, whereas these patients had single sequence variants. We have detected four novel, non-synonymous sequence variants in HLX in CDH patients. Our data suggests a minor role for HLX sequence variants in the pathogenesis of isolated CDH in humans, and further functional evaluations are in progress.

Cadherin 13, addiction, alternative splicing, and aging. *Q. Liu[1], D. Walther[1], A. Hishimoto[1], T. Drgon[1], C. Johnson[1], E. Roach[1], O. Pletnikova[2], J.C. Troncoso[2], G.R. Uhl[1]* 1) Molecular Neurobiology Branch, NIDA/NIH, Baltimore, MD; 2) Department of Pathology (Neuropathology), Johns Hopkins School of Medicine Baltimore, MD.

Genome-wide association studies comparing substance-dependent vs control and successful vs unsuccessful abstainers from smoking have each identified SNPs in the 3 region of the cadherin 13 (CDH13) gene. CDH13 is a cell adhesion molecule that anchors to plasma membranes through a glycosyl-phosphatidyl-inositol (GPI) anchor, is well positioned to play roles in regulation of synaptic connectivities that are of interest for brain disorders that include addictions and neurodegenerations. Analysis of the 1.2 Mb human CDH13 gene revealed novel human-specific CDH13 splicing isoforms that include GPI-anchored- and soluble isoforms with five and single cadherin motifs, respectively. The CDH13 splice sites that are involved in these differentially-spliced gene products near the addiction-associated SNPs. We thus sought relationships between CDH13 SNPs and the expression of mRNAs encoding CDH13 isoforms in mRNAs prepared from 135 frontal cortical specimens from individuals who died at ages ranging from 13 to 98. Substantial individual differences in expression of soluble isoforms were identified among these brains. Some individuals appeared to express two soluble isoforms, some expressed one soluble isoform, and some expressed none. We were not able to identify significant reproducible relationships between these expression patterns and addiction-associated SNPs. However, more of the individuals who died at younger ages displayed two soluble isoforms, while more of the individuals who died at older ages expressed no detectable mRNA encoding a soluble isoform. Membrane bound isoforms were expressed universally in samples from each age group tested. While we continue to seek other reproducible molecular correlates of the haplotypes associated with addiction, the differential age-related expression of CDH13 isoforms that we report here might contribute to the brains age-related vulnerabilities to disorders of synaptic function. (Support: NIH IRP (NIDA)).

Variation in Insulin-Like Growth Factor 2 mRNA Binding Protein 2 (*IMP-2*) is Associated with Adiposity in Mexican Americans (MA). *X. Li[1], H. Wijsesuriya[1,2], A.H. Xiang[1], E. Trigo[3], M. Perez-Ospina[1,2], H. Allayee[1,2], J.M. Lawrence[4], T.A. Buchanan[3], R.M. Watanabe[1]* 1) Dept of Preventive Med, Division of Biostatistics, Keck Schl of Med of USC, LA, CA; 2) Institute for Genetic Med, Keck Schl of Med of USC, LA, CA; 3) Dept of Med, Division of Diabetes and Endocrinology, Keck Schl of Med of USC, LA, CA; 4) Research and Evaluation, Kaiser Permanente, Pasadena, CA.

Recent genome-wide association (GWA) studies identified *IMP-2* as a susceptibility gene for type 2 diabetes (T2D). Based on stage 1 GWA results from the FUSION study, we examined whether *IMP-2* was associated with T2D-related quantitative traits (QTs) in the BetaGene study, a family-based study to identify genes associated with T2D-related QTs. A proband with prior gestational diabetes, her siblings and first cousins were phenotyped by oral glucose tolerance test (OGTT), intravenous glucose tolerance tests with minimal model analysis, and DEXA scan for percent body fat (PBF). Our study included 716 subjects in 143 families with mean age of 34.58.4 years, and mean PBF of 33.58.5%. We genotyped 13 SNPs in a 20 Kb region around rs1470579 in *IMP-2*. Three tag SNPs (rs13060777, rs6444082, rs11705701) were identified and tested for association with T2D-related QTs. We report Bonferroni corrected P-values, adjusting for age and sex. PBF was significantly associated with rs6444082 under additive, dominant and recessive genetic models ($p<0.036$) and rs11705701 under additive and dominant genetic models ($p<0.004$). For rs6444082, PBF decreased by 1.0% with addition of one T allele and 1.3% with addition of the second T allele. The magnitude in PBF change was similar for rs11705701. rs11705701 was also associated with T2D-related QTs (30 minute and 2-hour OGTT insulin) under an additive genetic model ($p=0.039$ and 0.034, respectively). However, these associations became non-significant with adjustment for PBF. In conclusion, variation in *IMP-2* is associated with adiposity in MAs. The variation in *IMP-2*, which regulates insulin-like growth factor-2 mRNA, may alter insulin-like growth factor 2 levels which are known to be associated with adiposity.

***LRRK2* R1441G: evidence of a common founding event in the 9th century in northern Spain.** *I.F. Mata[1, 2], C.M. Hutter[3], C. Huerta[4], M. Blazquez[5], R. Ribacoba[5], L.M. Guisasola[5], C. Salvador[5], J. Infante[6], M.C. Gonzalez-Fernandez[7], M.M. Pancorbo[7], E. Lezcano[8], J. Jankovic[9], H. Deng[9], K.L. Edwards[3], V. Alvarez[4], C.P. Zabetian[1, 2]* 1) GRECC, VA Puget Sound HCS; 2) Neurology Dept, Univ of Washington; 3) Epidemiology Dept, Univ of Washington, Seattle, WA; 4) Genetica Molecular-Instituto de Investigacion Nefrologica, Hospital; 5) Servicio de Neurología, Hospital Univ Central de Asturias, Oviedo; 6) Neurology Service, Univ Hospital Marqués de Valdecilla, Univ of Cantabria, Santander; 7) Servicio General de Investigación Genómica: Banco de ADN, Univ of the Basque Country, Vitoria-Gasteiz; 8) Servicio de Neurología, Hospital de Cruces, Barakaldo, Spain; 9) Neurology Dept, Baylor College of Medicine, Houston, TX.

The Leucine-Rich Repeat Kinase 2 (*LRRK2*) gene represents the most common genetic determinant of Parkinson's disease (PD) identified to date. The vast majority of patients with *LRRK2*-related PD carry one of three pathogenic mutations: G2019S, R1441C, or R1441G. While G2019S and R1441C are geographically widespread and have each arisen from at least three different founders, R1441G appears to have arisen from a single founder and is largely restricted to northern Spain. We sought to better understand the genetic and demographic processes that have shaped the current distribution of R1441G. We genotyped 10 microsatellites and one SNP spanning a distance of 15.1 Mb across the *LRRK2* region in 29 unrelated PD patients heterozygous for R1441G and 37 wild-type controls. All controls and all but one patient were from northern Spain. We used PHASE v2.1.1 to infer haplotypes and a maximum-likelihood method to estimate the age of the most recent common founder. Significant allele sharing was observed over a region approximately 9.0 Mb in length bounded by markers D12S2080 and D12S1301. A single, rare background haplotype was seen in all patients indicative of a common ancestor. We estimate that the founding event occurred 1,170 (95% CI, 900-1,530) years ago in approximately the 9th century. This, coupled with limited migration might explain the restricted distribution and relatively high frequency of R1441G in northern Spain.

Molecular characterization of 31 patients with pyridoxine-dependent-epilepsy (PDE). *B. Plecko[1, 2], K. Paul[2], E. Struys[3], C. Jakobs[3], S. Stoeckler-Ipsiroglu[1], W. Erwa[4], M. Baethmann[5], A. Gatta[6], I. Gyoergy[7], G. Horvath[1], G. Kluger[8], B. Neubauer[9], A. Panzer[10], T. Scheffner[11], R. Van Coster[12], S. Vlaho[13], E. PDE (MIM #266100) is caused by mutations of the ALDH7 A1 gene, located on chromosome 5q31. We report on biochemical and molecular findings in 31 Caucasian PDE patients with neonatal seizure onset, 13 of whom have not been reported so far. In all patients with ALDH7 A1 mutations urinary -AASA and plasma PA were elevated 1.6 to 62-fold and 1.5 to 38 - fold, respectively. -AASA and PA concentrations were higher in the 3 patients with pre-treatment sampling. Within 60 of the 62 alleles a total of 16 different mutations were identified. Several mutations had increased prevalence, as p.Glu399Gln (exon 14; 34%), c.1482-1G>T acceptor splice site mutation (intron 17, 12%), Arg82X (exon 4; 10%) and a silent mutation, p.V250V (exon 9; 9%). In 7 patients of 6 unrelated families 6 novel mutations were found: an insertion in exon 1, c.57insA (p.Arg20ThrfsX8), a donor splice site mutation, c.689+2T>C (intron 8), and 4 missense mutations, p.Arg82Gly (exon 4), p.Asn167Ser (exon 6), p.Asn420Lys (exon 15) and p.Gln425Pro (exon 15). All these mutations showed familiar cosegregation and were not present in 120 control alleles.

A comprehensive association study of 106 candidate genes for Attention Deficit Hyperactivity Disorder. *B.S. Maher[1], B. Devlin[2], R.E. Ferrell[2], G.P. Kirillova[2], H. Chilcoat[3], E.L. Murrelle[3], R.E. Tarter[2], M.M. Vanyukov[2]* 1) Dept Psychiatry/MCV, Virginia Inst Psych/Behav Gen, Richmond, VA; 2) University of Pittsburgh, Pittsburgh, PA; 3) GSK, RTP, NC.

Attention deficit hyperactivity disorder (ADHD) is among the most common and heritable psychiatric disorders of childhood. We performed a comprehensive scan of several ADHD liability candidate gene systems, comprising 106 genes, using a 1536 SNP custom Illumina bead array in 313 Caucasian nuclear pedigrees. We used an iterative approach to candidate gene/SNP selection, first identifying SNPs involved in a series of candidate gene systems. Genes were ranked via consensus conference. The next steps focused on inclusion of functional SNPs and LD-coverage of the top ranking genes. All HapMap SNPs were selected in each of the candidate genes and submitted to Illumina for Quality Scoring (QS). SNPs returning a QS < 1 were deleted from the candidate list. The complete list of QS=1 SNPs for the top ranking candidate genes was submitted to the H-Clust algorithm for SNP selection. H-Clust identified 1500 SNPs that provided and average r2 coverage of .615 (based on HapMap) of the 106 highest-ranking candidate genes. In addition, all known non-synonymous common SNPs in each of the genes was selected for genotyping. Family-based association testing, accounting for parental phenotypes, of quantitatively-defined ADHD liability (factor analytically derived inattention (In) and hyperactivity-impulsiveness(HI)) was performed in PLINK. Multiple test correction was performed using FDR. Several genes yielded multiple significant results. Most notably SLC6A2, contained three SNPs (rs1948773: p = 0.0003; rs36009: p=0.0007; rs192303: p=.0.008) and COMT contained 2 SNPs (rs174675: p=0.0002; rs4485648: p=0.0002) that were significant for the HI and In phenotypes respectively.

High-throughput parallel re-sequencing of conserved genomic elements on chromosome 9 in Alzheimer disease.

P. Whitehead[1], J. Gilbert[1], E. Martin[1], J. Haines[2], M. Pericak-Vance[1], S. Züchner[1] 1) Miami Inst. for Human Genomics, University of Miami, Miami, FL; 2) CHR, Vanderbilt University, Nashville, TN.

Alzheimers disease (AD) is the most common form of dementia in the elderly and is characterized by an irreversible loss of neurons. AD is a complex disorder with genetic and environmental risk factors contributing to the onset of disease. We have previously identified a 19Mb (18.6-37.8 Mb) region on chromosome 9p21.3 with a peak heterogeneity LOD of 4.95 at D9S741 (24.5 Mb) in a dominant model. Analyses of a dense array of SNPs across the region showed strong evidence for linkage, but only limited support for association in a subset of 199 families with at least one autopsy-confirmed AD case. We hypothesized that the LOD score was driven by a number of independent and possibly rare sequence variations in a subset of our families in the vicinity of a transcriptional unit or in a conserved genomic element at 9p21.3. We thus set out to explore whether massive parallel re-sequencing is feasable and could yield further insight into the molecular genetic basis of this AD locus. We selected 12 individuals from the families with the highest LOD scores for re-sequencing. By in-silico analyses we ranked genomic elements under the linkage peak by their conservation across 17 different species. The 92 most conserved regions were subjected to a novel high-throughput sequencing platform, 454 Life Sciences. We sequenced a total of 391,284 fragments with an average size of 252 bp amounting to 98.7 Mb with an average coverage of the targeted conserved sequences of 82%. We identified a total of 1420 sequence variations including substitutions, insertions, and deletions. 251 of those variations fulfilled our quality requirements with 112 being novel. Some of those variations clustered around conserved sequence elements; however, further analysis is currently under way to clarify their potential functional role in the context of this AD study. We conclude that massive high-throughput parallel re-sequencing presents a powerful and potentially effective tool, but the sheer amount of data challenges traditional methods of genetic data-mining.

Phenotypic features associated with TGFBR1 and TGFBR2 mutations in familial thoracic aortic aneurysms and dissections. *H. Pannu[1], V. Tran-Fadulu[1], M.C. Willing[2], A. Muilenberg[2], C. Ahn[1], D.M. Milewicz[1]* 1) Department of Internal Medicine, The University of Texas Medical School at Houston, Houston, TX; 2) Department of Pediatrics, University of Iowa, Iowa City, IA.

Mutations in the transforming growth factor receptor type I and II genes (TGFBR1 and TGFBR2) cause thoracic aortic aneurysms and dissections (TAAD), but the full spectrum of the clinical disease is not fully delineated. Mutations in these genes may present as severe aortic disease in children with associated syndromic features, as in Loeys-Dietz syndrome (LDS), or as adult onset TAAD with an absence of syndromic features (FTAAD). Although there are large families reported with TGFBR2 mutations, no multigeneration families with TGFBR1 mutations have been reported. We report 4 multigeneration families with FTAAD due to TGFBR1 mutations (G312S, H315R, L486S, and R487W). To define the extent and progression of vascular disease associated with TGFBR1 and TGFBR2 mutations, we compared the clinical features of 29 affected individuals from 4 families with TGFBR1 mutations to 79 affected individuals from 5 families with TGFBR2 mutations (R460C, R460H). TGFBR1 mutation carriers presented with vascular disease at a younger age (30 years) than those with TGFBR2 mutations (44.8 years, p=0.0002). An effect of gender on vascular disease presentation and survival was evident with TGFBR1 but not TGFBR2 mutations. Women with TGFBR1 mutations presented more frequently with diffuse vascular disease than women with TGFBR2 mutations (p= 0.002). Men with TGFBR1/TGFBR2 mutations presented primarily with aortic disease. Women with TGFBR1 mutations had later onset and survived longer than men with TGFBR1 mutations, (p=0.006, $p<0.05$, respectively). The gender difference in age of onset in TGFBR2 mutation carriers approached significance (p=0.056), with no difference in survival. Three TGFBR2 mutation carriers had type A dissections at diameter below 5.0 cm (the guideline for repair) while 8 patients with TGFBR1 mutations had type A dissections, none at diameter below 5.0 cm. These data suggest gender based differences in vascular disease presentation, age of onset and survival between TGFBR1 and TGFBR2 mutation carriers.

ARG analysis in the Genome Wide Association Scans of the Cancer Genetic Marker of Susceptibility Initiative.

Z. Wang[1,2], M. Yeager[1,2], K.B. Jacobs[3], M. Minichiello[4], N. Orr[6], R. Hoover[2], D.J. Hunter[2,5], S.J. Chanock[2,6], G. Thomas[2] 1) SAIC-Frederick, MD; 2) DCEG, NCI, Bethesda, MD; 3) Bioinformed LLC, Gaithersburg, MD; 4) Wellcome Trust Sanger Institute, UK; 5) Harvard School of Public Health, Boston, MA; 6) Pediatric Oncology Branch, CCR, NCI, NIH, DHHS.

Although single marker association test is presently the main approach to the initial analysis of genome wide association studies (GWAS), multiple marker tests may better exploit the expected linkage disequilibrium between the typed SNPs and the untyped, but sought, functional polymorphism. We focused on an analytic tool based upon the inference of ancestral recombination graphs (ARGs), initially proposed by Minichiello and Durbin, that accounts for coalescent genealogy, to dissect two regions demonstrating promising association signals in the CGEMS GWAS. In the FGFR2 locus associated with post menopausal breast cancer, this approach revealed a single contiguous 20 Kb DNA segment in which all signals for association were high ($p < 0.003$), contrasting with the flanking regions, extending up to 100 Kb away in each direction, in which the signals were systematically low ($p > 0.1$). Thus is this case, the ARG analysis provided a precise information on the location of the functional polymorphism. In the 8q24 region associated with prostate cancer, two association signals were evidenced. The signals were located in regions separated by a hot spot of recombination suggesting that each region harbored an independent functional polymorphism. The ARG analysis further predicted that the mutational event responsible for the centrometic functional polymorphism may be ancient and possibly gave rise to the protective allele as the centromeric functional polymorphism appeared more recent and created the at-risk allele. We observed that, in regions with low linkage disequilibrium, the computational requirement for the ARG analysis is demanding. However, the computation may be implemented in parallel processing. The ARG analysis provides, for regions with strong association signals, a rapid and systematic approach to fine mapping. Its effectiveness in the analysis of GWAS is presently being assessed. Funded by NCI Contract N01-CO-12400.

STRs Markers DXS7424 and DXS101 are Useful on Carriers Female Disease Fabry in Colombian Families. *A. Lopez[1], S. Ospina[1,2], P. Paez[1], C. Duran[1], J.C. Prieto[1,3]* 1) Instituto de Genetica Humana, Universidad Javeriana, Bogota, Cundinamarca, Colombia; 2) Universidad del Rosario, Bogota, Colombia; 3) Hospital la Victoria, Secretaria Distrital de Salud, Bogota, Colombia.

Fabry disease is an X-linked recessive disorder caused by the deficiency of the lysosomal hydrolase alpha-galactosidase A. Affected males are characterized by the clinic presentation of acroparesthesias, corneal opacities, angiokeratoma, hypohidrosis, renal and cardiac alteration. Its diagnosis is confirmed trough the demonstration of a deficiency of alpha-galactosidase activity in plasma and leukocytes. Carrier females can present some minor symptoms or being asymptomatic and the level of GALA are not correlated with the state of the carrier. The objective of this study was to detect of carriers making a haplotype analysis, applying STR flanking the GALA gene determining allelic frequencies and heterozigosity of the used markers then to compare with other ethnics groups. Methodology: We described 2 Colombian families that have diagnosis of this disease. For the population studied were utilized the markers DXS7424 and DXS101 which flank the GALA gene. Results: There were identified 12 alleles for marker DXS101 with a heterocigocity of 92.16%, PIC 0,884.; meanwhile for marker DXS7424 were identified 9 alleles, with a heterozygosity of 98%, PIC 0,780. Haplotipification of affected males, carriers females and relatives evidenced that affected males share the same haplotype of obligate carrier females. Discusion: Haplotype analyses trough the use of STRs, is a good alternative to identify the carriers where the enzymatic levels are normal. The markers DXS101 and DXS7424 are highly informative markers to the disease, because they present a high polymorphism and heterozygosity in the general population.

Potential Association between DUF1220 Domains and Autism, Autism Spectrum Disorders, and Mental Retardation. *M.C. Popesco[3], L. Dumas[1], M. Cox[1,2,3], J. Hopkins[1,2,3], A. Karimpour-Fard[4], J.M. Sikela[1,2,3]* 1) Human Medical Genetics Program, University of Colorado at Denver & Health Sci Ctr, Aurora, CO; 2) Neuroscience Program; 3) Dept of Pharmacology; 4) Dept of Preventative Medicine and Biometrics.

The 1q21.1 region appears to be one of the most complex and dynamic regions in the human, containing a disproportionately high number of sequence gaps. We have identified 10-12 genes (e.g. NBPF8, NBPF11, NBPF20, and PDE4DIP) in the 1q21.1 region encoding DUF1220 domains, a protein domain of unknown function, which appears to be highly amplified in humans. In previous work, we used Western and immunocytochemical analysis to show strong expression of DUF1220 domains in neurons of the human neocortex, a region potentially involved in higher cognitive abilities. A previously reported genome-wide study of copy number variation in individuals with unexplained cognitive dysfunction identified de novo deletions in a 3-Mb region of 1q21.1, suggesting that this may be a recurrent pathological syndrome. More recently results from a comprehensive search for Autism Spectrum Disorder (ASD)-related genes support the possible involvement of DUF1220 domains in ASDs. Specifically, a 1.1 Mb copy number gain was identified at 1q21 in three ASD individuals. Four independent studies show that a 1.1-2.1 Mb region of 1q21 that contains a number of DUF1220-encoding genes (NBPF family) is deleted or duplicated in individuals with idiopathic mental retardation (IMR) autism or ASD, supporting the potential association of DUF1220 domains with these cognitive disabilities. The most recent human genome assembly predicts that, of 44 genes in this region, 6 are NBPF genes and the region encodes 57 DUF1220 domains. In addition, we have used DUF1220-specific Q-PCR to demonstrate that DUF1220 sequences are deleted (43 copies vs. 62 in a normal control) in an IMR individual with a 1.47 Mb de novo deletion of 1q21.1 sequences. In summary we demonstrate a potential link between DUF1220 domains and diseases of human cognition, a finding that, if substantiated, further supports the involvement of DUF1220 domains in higher cognitive function in humans.

Genome-Wide Association Study for Schizophrenia in the Quebec Founder Population. *N. Paquin[1], P. Van Eerdewegh[1], J. Raelson[1], P. Croteau[1], J. Segal[1], M. Lapalme[1], A. Monette[2], A. Langlais[3], E. Stip[4], H. Fournier[1], B. Paquin[1], J. Hooper[1], A. Belouchi[1], T. Keith[1]* 1) Genizon BioSciences, St-Laurent, QC, Canada; 2) CSSS du Suroît, Valleyfield, QC, Canada; 3) Clinique médicale de lest, Sherbrooke, QC, Canada; 4) Hôpital Louis-H. Lafontaine, Montreal, QC, Canada.

To identify susceptibility genes for schizophrenia, we performed a GWAS using the Quebec founder population (QFP). 516 cases and 516 matched controls were individually genotyped for 374,187 SNPs on the Infinium assay (Illumina). The marker map consisted of the HAP300 chip supplemented by 56,683 SNPs based on LD structure in the QFP. 352,728 SNPs and 343,297,218 genotypes with a call rate of 99% and a minor allele frequency 4% were used in genetic analyses. Genome-wide single-marker and haplotype case-control association analyses were performed, with haplotypes of 1, 3, 5, 7 and 9 markers defined by a sliding window. Based on permutation studies, regions with P values that met the criteria for genome-wide significance were identified for both haplotype and single marker association tests, demonstrating that a well-powered GWAS with the QFP was achieved with a relatively small sample size. Among significant signals, haplotype analyses yielded 3 regions with p 10^{-7}, including 1 region with p 10^{-8}, whereas single-marker association identified 6 regions with p 10^{-5} including 2 with p 10^{-6}. Examples of top candidate loci will be described, including information on the length of the regions and the relevance of the encoded genes in relation to schizophrenia. Additional regions identified from gender-specific and paranoid sub-phenotype analyses will also be presented. Evidence for gene-gene interactions from genome-wide conditional analyses identified both epistatic and independent risk factors within and between biological pathways. Candidate regions are well resolved with many of them containing only one or two genes. The identified genes have been used to infer a GeneMap, consisting of networks of interacting disease genes and their biological pathways. The emerging GeneMap includes both novel and known pathways in neurological development, synaptic plasticity, learning, memory and other neurological disorders.

Genome-Wide Association Study (GWAS) Reveals a Novel Gene for Immunoglobulin E (IgE) Levels and Asthma. *Z. Tan[1], Y. Sun[1], L. Pan[1], R. Nicolae[1], S. Kudaravalli[1], A. Heinzmann[2], T. Kurz[2], J.E. Gern[3], R.F. Lemanske, Jr.[3], K.A. Deichmann[2], J.K. Pritchard[1], D. Nicolae[4], A.I. Sperling[4], C. Ober[1]* 1) Dept. Human Genetics, U Chicago, Chicago, IL; 2) Dept. Pediatrics, U Freiburg, Germany; 3) Dept. Pediatrics, U Wisconsin, Madison; 4) Dept. Medicine, U Chicago, Chicago, IL.

IgE is a major immune mediator of atopic disorders, such as asthma, atopic dermatitis, and allergic rhinitis. We performed a GWAS of total IgE levels in 693 Hutterites using the Affymetrix 500k Array. High quality genotypes for 295,307 SNPs with minor allele frequencies 0.05 were analyzed using the general 2-allele model, developed for association studies of quantitative traits in complex pedigrees (Abney et al. AJHG 2002; 70:920). 10 SNPs with p-values <10-5 in the Hutterites were genotyped in 202 children in a birth cohort study from Madison, Wisconsin; 3 SNPs were associated with IgE levels in those children (p=0.006 to 0.034). We then typed those 3 SNPs in 3 additional replication samples: 215 Caucasian asthma cases and controls from Chicago, 264 African American asthma cases and controls from Chicago, and 707 asthma or atopy cases and controls from Freiburg, Germany. rs4733142, located in an intron of a predicted gene BC034319 on 8p12, was associated with IgE in the Hutterites and the 2 Chicago samples (p-values ranging from 0.01 to 4.42 x 10-6) and with asthma in the Hutterites (p=0.032) and in the Chicago Caucasian samples (p=0.02). We used 5-RACE and RT-PCR to obtain the whole cDNA sequence of the gene, which is either a non-coding RNA or a gene with a small (45 amino acid) open reading frame. We detected BC034319 mRNA in activated T cells and transformed B cells, as well as in spleen, thymus and lung. Moreover, using publicly available expression data in LBLs from CEPH Caucasians, we showed that rs4733142 is a trans eQTL for IL21R (p=0.003), which is involved in regulating IgE synthesis. Our study demonstrates the power of GWAS combined with expression studies to detect novel genes and pathways involved in asthma pathogenesis. Supported by HL56399, HL66533, HL72414, HL70831, HL85197 to C.O. and RR00055 to the U of Chicago GCRC.

Nonallelic variants of neuronal sorlitin-related receptor (SORL1) associated with distinct Alzheimer disease (AD) processes observed by magnetic resonance imaging (MRI). *K.T. Cuenco[1], K.L. Lunetta[1], L.A. Cupples[1], A. McKee[1], H. Chui[2], C. DeCarli[3], P. St.George-Hyslop[4], R.C. Green[1], C. Baldwin[1], L.A. Farrer[1], and MIRAGE Study Group* 1) Boston Univ.,MA; 2) USC,Los Angeles,CA; 3) UC-Davis,CA; 4) U-Toronto,Canada.

AD is hypothesized to involve neurodegenerative and cerebrovascular disease mechanisms.Recently, associations between AD and SORL1 gene variants in two distinct regions were reported in independent samples from diverse ethnic backgrounds.

We evaluated association of 30 SORL1 SNPs with 4 MRI traits in 55 African American (AA) and 266 Caucasian (CA) sibships from the MIRAGE Study.Measures of general cerebral (GA) and hippocampal (HA) atrophy, white matter hyperintensities (WMH) and overall cerebrovascular disease (CVD) were derived from MRI.Family-based association tests were used to perform single- and 3-SNP sliding window haplotype analyses, adjusting for age at MRI and AD status.In CA, SNPs 8, 9, and 10 were associated with WMH and CVD (0.0006p0.02);SNP 20 with GA (p=0.004);and SNP 15 with HA (p=0.003).WMH, CVD, and GA were associated with haplotypes in the SNP 6-10 region (0.0002global p0.05);GA with SNP 3-5 haplotypes (p=0.00006);and HA with the SNP 4-6 haplotypes (p=0.026).In AA, associations were observed for WMH and CVD with haplotypes spanning SNPs 20-24 and for CVD with haplotypes spanning SNPs 1-4, but results were based on few informative families.Of note, AD risk was previously associated with haplotypes of SNPs 8-10 in groups of CA, Hispanics (HS) and Israeli-Arabs, and with haplotypes of SNPs 23-25 in CA and AA.A SNP 4-6 haplotypes were associated with AD risk in a study of HS.

Results suggest that multiple nonallelic functional SORL1 variants influence AD risk through neurodegenerative and cerebrovascular pathways.We are currently evaluating whether these haplotypes are differentially associated with accumulation of amyloid in cerebrovascular and cortical regions in extensively characterized brains of ~200 unrelated AD cases and controls.

Chromosome 22q11 instability: deletion and duplication in the same family. *S.C. Saitta, G.R. Jalali, D.M. McDonald-McGinn, E.H. Zackai, B.S. Emanuel* Childrens Hospital of Philadelphia Philadelphia, PA.

We analyzed the parents of a proband with classical features of DiGeorge syndrome including a VSD, hypocalcemia, submucous cleft palate, and a typical chr22q11 deletion. Both parents were clinically normal, however analysis using MLPA showed that the 3 Mb region deleted in the child was duplicated in the father. Multiple recent reports have described reciprocal duplications of the DGS region,that present with variable mild phenotypes. In order to better define the mechanism(s) of rearrangement in this family, we first determined the parental origin of the probands deletion using multiple polymorphic microsatellite markers from within chr22q11. This haplotype analysis showed that the probands alleles were all of paternal origin, consistent with a deletion on the maternally-derived chr22. These findings suggest a de novo DGS deletion in the proband and an apparently unrelated microduplication in his father. We have previously demonstrated that seemingly recurrent deletions in first cousins were de novo and had occurred independently. Our findings highlight the genomic instability of the 22q11 region as predicted by its genomic structure. While the DGS deletion is the most frequently occurring microdeletion syndrome, increasing reports of the reciprocal microduplication of this region indicate that it may also have significant prevalence. With the advent of improved methods for detecting duplications, it becomes increasingly relevant to better define the associated clinical phenotypes, in order to provide accurate prognostic information and recurrence risk counseling.

Age-specific reference ranges and preanalytical stability of amino acids in plasma and urine. *T. Lynn, D. Salazar, J.A. Neidich, S. Goldman, C.M. Strom* Biochemical Genetics Laboratory, Quest Diagnostics Nichols Institute, San Juan Capistrano, CA.

Quantitative amino acid analysis is important for the diagnosis of a large number of inherited defects of amino acid metabolism and is also used for ongoing therapeutic and dietary monitoring of patients once a diagnosis has been established. Normal amino acid levels can vary significantly depending of the age of the patient. Thus, accurate reference ranges are critical in establishing a diagnosis or assessing compliance with diet or medications. There is limited current published information regarding normal ranges for amino acids in physiological fluids, which may partly be due to the difficulty in obtaining samples from healthy neonates. We analyzed 438 plasma and 248 urine samples from apparently healthy individuals by LCMS to determine age-specific reference ranges for greater than 45 amino acids. Of the samples tested, 304 plasma samples and 137 urine samples were pediatric, thereby strengthening the reference ranges in this crucial population. In addition to the reference range determination we also studied the preanalytical stability of amino acids in both sample types. Data were collected regarding the stability of individual analytes at frozen, refrigerated, and room temperatures. The majority of analytes were found to be stable at refrigerated temperatures for up to a week, and many were also stable at room temperature for several days. Stability information will be extremely useful to clinicians attempting to interpret amino acid results for potentially compromised samples that may have been thawed in transit.

Long-term weekly dosing of idursulfase in the treatment of mucopolysaccharidosis II (MPS II, Hunter syndrome). *J. Muenzer[1], E. Wraith[2], M. Beck[3], R. Giugliani[4], P. Harmatz[5], C.M. Eng[6], A. Vellodi[7], R. Martin[8], U. Ramaswami[9], M. Calikoglu[1], S. Vijayaraghavan[2], A.C. Puga[4], B. Ulbrich[9], M. Shinawi[6], M. Cleary[7], S. Wendt[3]* 1) University of North Carolina, Chapel Hill, NC, US; 2) Royal Manchester Children's Hospital, Manchester, UK; 3) University of Mainz, Mainz, Germany; 4) Medical Genetics Service, HCPA/UFRGS, Brazil; 5) Children's Hospital, Oakland, CA, US; 6) Baylor College of Medicine, Houston, TX, US; 7) Great Ormond Street Hospital, London, UK; 8) St. Louis University, St. Louis, MO, US; 9) Cambridge University Teaching Hospitals, Cambridge, UK.

MPS II is an X-linked lysosomal storage disorder caused by a deficiency in iduronate-2-sulfatase. A recent 1-year, double-blind, placebo-controlled clinical trial of enzyme replacement therapy with idursulfase (Elaprase, Shire HGT, Cambridge, MA, US) showed that both weekly and every other week (EOW) dosing of idursulfase (0.5 mg/kg) significantly improved the primary endpoint (a composite comprising sum of the ranks of changes in percent predicted forced vital capacity (%FVC) and distance walked in 6 minutes (6MWT) compared to placebo, with the magnitude of the clinical benefit being larger in the weekly compared with the EOW group (P = 0.13). This trial has been continued as an open-label extension study designed to evaluate the long-term safety and efficacy of weekly dosing of idursulfase (0.5 mg/kg). All patients who completed the double-blind study (n = 94) enrolled in the extension study and were treated with idursulfase at 0.5 mg/kg weekly. Changes in absolute and %FVC, 6MWT, and organ size were continued to be monitored in the open-label extension study. Safety was assessed continuously during the study by monitoring treatment emergent adverse events and by periodic determination of anti-idursulfase antibodies in blood samples. First year open-label efficacy and safety results will be presented.

Lethal Cardiomyopathy in Child with Partial Trisomy 22q11.23 and Homozygous MYBPC3 mutation. *N. Powell[1], L. Gole[2], U. Surti[2], S. Madan-Khetarpal[1]* 1) Medical Genetics, Childrens Hospital of Pittsburgh, Pittsburgh, PA; 2) Pittsburgh Cytogenetics Laboratory, Magee-Womens Hospital of UPMC, Pittsburgh, PA.

We report an Amish male infant having a lethal cardiomyopathy with two genetic abnormalities: a duplication of 22q11.23 identified by array comparative genomic hybridization, but not seen on a 700 G-band karyotype, and a presumably pathogenic homozygous mutation of the MYBPC3 gene which codes for cardiac myosin binding protein C. The family history includes a brother born three years earlier with hypertrophic cardiomyopathy, who passed away at 17 days of life, and several paternal relatives with similar cardiac history. This brother had a genetic and metabolic evaluation which was non-diagnostic, not including array CGH or hypertrophic cardiomyopathy gene testing. Both parents and his 21 month old brother have been asymptomatic but have not undergone formal cardiology evaluation. Most patients with an MYPBC3 mutation have a mild course and prognosis, with lethality rarely being reported. The duplication 22q11.23 may be clinically significant or a normal variant in the population since it is distal to the DiGeorge Syndrome I/Velocardiofacial Syndrome region and the Cat-Eye Syndrome critical region at 22q11.2. This patient is a unique individual with lethal cardiomyopathy having both partial trisomy 22q11.23 and a MYBPC3 mutation.

Transcriptome Analysis of Genes Involved in Neural Tube Closure during Human Embryonic Development Using Long-SAGE. *P.-T. Xu[1], S. Thomas[2], A. Dellinger[1], H.C. Etchevers[2], M. Vekemans[2], J.R. Gilbert[1], M.C. Speer[1]*
1) Center for Human Genetics, Dept Medicine, Duke Univ Medical Ctr, Durham, NC; 2) INSERM U781, Hôpital Necker - Enfants Malades, Paris, France.

Neural tube defects (NTD) are one of the most common birth defects in humans with an incidence of ~1/1000. Little is known about the human genes that regulate these disease processes. To identify potential new genes and pathways that confer susceptibility to neural tube defects, we have generated and analyzed four Long-SAGE libraries using total RNA isolated from the rostral portion (future brain) and the caudal portion (future spinal cord) of neural tubes from normal human embryos at Carnegie (C) stages 12 (C12, at the time of neural tube closure) and 13 (C13, neural tube closure completed). A total of 269,043 SAGE tags, with an average of 67,260 tags for each library, were extracted from these four libraries. These tags represent 137,486 unique transcripts. Preliminary stage specific comparisons of C13 with C12 tag databases demonstrated that a total of 1,433 tags in the caudal region and 1,131 tags in the rostral region were found to have significant Long-SAGE tag count differences ($p < 0.05$). Of this total, 794 tags were up-regulated over time and 639 tags down-regulated in the comparison of caudal libraries, and 523 tags were up-regulated and 608 tags down-regulated over time in the comparison of rostral libraries. Gene Ontology of molecular functional categories analyzed by the EASE program demonstrates that transcripts of nucleic acid/DNA/RNA binding, structure molecules and ribosomal structure proteins, and transcription regulators are among the most up-regulated gene categories in the C13 libraries compared to C12 libraries in both caudal and rostral regions. The most down-regulated gene categories include transporters, hydrolases, signal transducers, protein and metal ion binding proteins. Many differentially transcribed genes fall within NTD linkage subregions or NTD-associated areas, providing a detailed and quantitative picture of known, novel and/or new genes conferring susceptibility to human neural tube defects and/or associated with normal neural tube closure in humans.

Molecular screening in 45 patients with isolated COX deficiency for mutations in COX10, COX 15 and SCO1 genes. *K. Vesela, H. Hansikova, J. Zeman* Center of Applied Genomics, Fac Med /Pediatric, Charles Univ, Prague, Czech Republic.

Cytochrome c oxidase (COX) deficiency represents a heterogeneous group of disorders which predominantly affect tissues with high energy demand, especially the brain, muscle and heart. COX is composed of 13 protein subunits. Three of them are encoded by mitochondrial DNA and the rest originate from nuclear DNA. In addition, numerous other proteins are required for efficient assembly and maintenance of the COX, these proteins originate in nuclear DNA. Currently, there is no efficient treatment, the therapy is just symptomatic; and the prognosis is unfavorable. Knowledge of the exact molecular background is very important for genetic counseling due to possible dual genomic origin of the disease. During this study, we have optimized methods for mutation screening of assembling genes COX10, COX15 and SCO1. Patients were divided according the clinical course and biochemical results. Methods: All coding regions of studied genes were amplified and sequenced. Found mutations were confirmed by RFLP. COX10 was investigated in 24 patients, COX15 in 15, and SCO1 in 6. Results: We descried a novel mutation 394G>A in SCO1 gene in homozygous form; in the other genes we did not find any new pathological mutation. Summary: There are only two patients, siblings, carrying pathological mutations (c.363_364delGA/ c.520C>T) described so far in literature. Mutation 394G>A leading to G132S was not described yet. We did not find the mutation in 200 controls. Patient, a girl, was born in 39th week of gestation (2200g/46cm); APGAR score in 1st and 5th minute was 9 and 10. During the first days of life she developed progressive central hypotony, hepatopathy and she died due to hypertrophic cardiomyopathy in the age of 6 month. Supported by GACR 303/07/0781.

A NEW CANDIDATE REGION FOR COFFIN-SIRIS SYNDROME? *R.S. Simão[1], C.M. Lourenço[1], L.C. Veiga Castelli[2], L.A.F. Laureano[1], L. Martelli[1,2]* 1) Medical Genetics Division, Faculty of Medicine of Ribeirão Preto, University of São Paulo, Ribeirão Preto, SP, Brazil; 2) Department of Genetics, Faculty of Medicine of Ribeirão Preto, University of São Paulo, Ribeirão Preto, SP, Brazil.

Coffin-Siris Syndrome (CSS) is a rare genetic Mendelian disorder characterized by mental retardation, growth restriction, absent fifth-digit fingernails or hypoplastic fifth-finger terminal phalanx and coarse facies. Since the first description, over 60 cases have been reported. All previous patients with well-documented Coffin-Siris Syndrome were chromosomally normal, and the chromosomal location of the gene is unknown. We report the description of an infant with severe typical findings of Coffin-Siris Syndrome who also presented a large de novo duplication of the long arm of chromosome 3, that was confirmed by spectral karyotype analysis. The parental karyotypes were normal and none of the relatives have any sign of Coffin-Siris Syndrome. The breakpoints 1q21.3 and 7q34 have been suggested as possible locations for a Coffin-Siris gene but, to our knowledge, this report is the first to describe a child with Coffin-Siris Syndrome features and chromosomal aberrations that may indicate another candidate region for genetic mapping of this syndrome.

Genome-wide association of bronchodilator response in asthma. *A.A. Litonjua[1,2], K.G. Tantisira[1,2], J.A. Su-Lasky[3], A. Murphy[1,2], R. Lazarus[1,2], B. Klanderman[1,2], C. Lange[3], E.K. Silverman[1,2], S.T. Weiss[1,2]* 1) Channing Laboratory, Department of Medicine, Brigham and Womens Hospital, Boston, MA; 2) Harvard Medical School, Boston, MA; 3) Department of Biostatistics, Harvard School of Public Health, Boston, MA.

Rationale: Short acting inhaled $_2$ agonists are one of the most widely used classes of drugs for the treatment of asthma. However, a substantial proportion of asthmatics do not have a favorable response to these drugs, and identifying genetic determinants of drug response may aid in tailoring treatment for individual patients. Methods: We conducted a genome-wide association analysis using the Illumina HumanHap550 BeadChip in 209 children (randomized to the beta agonist only arm) and their parents participating in the Childhood Asthma Management Program (CAMP). A total of 534,290 autosomal SNPs met quality thresholds (MAF >0, completion rate >90%, <1% Mendelian inconsistency, <0.1% discordancy among replicates) and were included in the analysis. We screened the association of these SNPs with bronchodilator responsiveness (BDR) over the four years of the trial, in a family-based screening algorithm implemented in PBAT that ranked SNPs in order of statistical power. The algorithm screens using the between family-component of the variance in order to identify candidate SNPs with the greatest power for association. Results: We identified a SNP in chromosome 18q21.32 that met the strict screening criteria for association with BDR in a recessive model. Replication genotyping of this SNP in three additional asthma clinical trials is ongoing and will be presented at the meeting. Conclusions: We have identified a novel SNP that determines BDR in a genome-wide association study. Replication of this finding is currently being performed in three separate asthma clinical trials. This work is supported by U01 HL065899 and PO1 HL083069 from the National Heart, Lung and Blood Institute, NIH.

Development of strategies for efficient use of revolutionary sequencing technology for detecting human sequence variation. *W. McCombie, G. Hannon, R. Lucito, E. Hodges, M. Kramer, V. Balija* Genome Research Ctr, Cold Spring Harbor Lab, Cold Spring Harbor, NY.

The combination of a human reference sequence and the availability of a new generation of DNA sequencers are revolutionizing our ability to detect the sequence variation that causes a wide range of human disorders. We are using the Illumina sequencing platform as a base to study human sequencing variation associated with several disorders. As part of this effort we are exploring ways to target selected large sub-regions of the genome for resequencing. We are also developing methods such as the use of molecular barcodes to pool multiple samples from different individuals. These tools are enabling strategies to be developed to sequence crucial genome regions from hundreds or even thousand of samples. The resulting information from studies such as these will radically change our knowledge of the association of sequence variation and sickness or health.

Genetic Susceptibility in Autism. *S.E. Owens[1], M.L. Summar[2], J.L. Haines[2], M. Aschner[1]* 1) Dept Pediatrics, Vanderbilt Univ Medical Ctr, Nashville, TN; 2) Ctr for Human Genetics Research, Vanderbilt Univ Medical Ctr, Nashville, TN.

Autism is a common neurodevelopmental disorder with both genetic and environmental components. Genetic susceptibility to mercury (Hg) toxicity has been advanced as a plausible explanation for autism in a subset of children. Potentially, even safe Hg levels could be implicated in the etiology of autism due to genetic susceptibility that alters metabolism or intracellular compartmentalization. To identify genetic polymorphisms associated with autism that influence the extent of individual susceptibility to Hg neurotoxicity, we are conducting a thorough search for polymorphisms in four genes (MT1a, DMT1, LAT1 and MTF1) involved in Hg transport and clearance in the general population and in autistic individuals and assessing their frequency and association to the disorder. LAT1 and DMT1 have been invoked in Hg transport and MTF1 and MT1a are inducible by Hg exposure. Using a sample pool of 48 unrelated individuals from both the general and autistic populations we employed Single Strand Conformation Polymorphism analysis to screen all of the exons, 5` and 3` untranslated regions, 1kb upstream of the transcript start, and the exonic bordering regions for genetic variations. We have identified and characterized a number of polymorphisms in MT1a, DMT1, MTF1 and LAT1. Seven of the eleven polymorphisms identified in MTF1 are novel. Two of the seven MT1a polymorphisms identified are nonsynonymous (Thr27Asn, and Lys51Arg). Eight DMT1 polymorphisms identified to date have been previously reported. Thirteen LAT1 variants are currently being characterized. Polymorphisms were evaluated for differences in allele frequencies using Fishers exact test ($p<0.05$). Preliminary findings failed to show association with autism for any of these variants. Further analysis with the TaqMan genotyping system in a larger dataset of 224 autistic samples and 224 controls is underway. This work was supported by grants T32 ES007028 and NIEHS R01 07331.

An unusual marker resulting in partial tetrasomy 12p in a patient with multiple congenital anomalies. *J.F. Turocy[1], U. Surti[1], S. Madan-Khetarpal[2], E. James[2]* 1) Dept Clinical Genetics, Magee-Womens Hosp of University of Pittsburgh, Pittsburgh, PA; 2) Dept Clinical Genetics, Childrens Hospital of Pittsburgh of University of Pittsburgh, Pittsburgh,PA.

A female infant was first seen at age 3 weeks. Prenatal amniocentesis (maternal age 38y) showed a marker chromosome determined to be partial chromosome 12. After birth, she was determined to have partial small bowel malrotation, hydrocephalus with macrocephaly requiring VP shunt, infantile spasms, cortical visual impairment, a nasal dermoid of the forehead, and bifid uvula. At age 3 years, she had hypertelorism, downslanting palpebral fissure, normal hair and eyelashes, short webbed neck, polythelia, 5th digit clinodactyly, hypotonia, and inability to sit up without support. OFC was 25th percentile. She was profoundly developmentally delayed, and had limited use of her hands. Karyotype of peripheral lymphocytes showed 47,XX,+mar in all cells. FISH analysis showed that the marker contained 2 copies of the 12p telomeric region, was positive for 12CEP centromeric probe, and was C-Band positive. Microarray analysis indicated a 2-copy gain of 23 BACS measuring 5.1Mb from 12p. Two previous reports described a marker 12 containing a partial distal 12p including 12pter that had a phenotype similar to or milder than that of Tetrasomy 12p Pallister-Killian Syndrome (PKS). Both of these markers were analphoid, with a neocentromere. This appears to be a first case of a similar marker with the centromeric region containing a chromosome 12 -satellite sequence. In comparison to the other two reported cases our patient has a pericentromeric fragment (containing -satellite DNA in the 12p11.22-p10 region), and a similar phenotype. All three patients have a somewhat milder phenotype than typical isochromosome 12p PKS. Also, unlike PKS, the marker chromosome in our case was present in 100% of the peripheral blood metaphases analyzed. The use of microarray analysis of partial tetrasomy 12p may help narrow the critical PKS region(s) responsible for the phenotype and the well documented loss of the complete isochromosome 12p from peripheral blood cultures in vitro.

Molecular cytogenetic analysis of a der(17)t(10;17)(q24;q25) chromosome in a child, by CGH. *M.J. Macera[1], G. Kupchik[2], S. Kinshpun[2], J. Breshin[1], F. Cohen[1], A. Babu[1]* 1) Div Molec Medicine & Genetics, Dept Medicine, Wyckoff Heights Medical Ctr, Brooklyn, NY; 2) Div Medical Genetics, Dept Pediatrics, Maimonides Medical Ctr, Brooklyn, NY.

Cytogenetic analysis on a peripheral blood specimen from a newborn received at birth, revealed a 46,XX,add(17)(q25).ish add(17)(wcp10+) karyotype. The mother and child were evaluated by us, twenty months later. The child displayed dysmorphic features and failure to thrive. Her physical exam was remarkable for epicanthal folds, depressed nasal bridge, midface hypoplasia, microcephaly, low set ears, full lips, pectus, flat occiput, overlapping toes and ulnar deviation of the fingers. An MRI of her brain showed mega cisterna magna extending in crescentric fashion external to the right and left cerebellum. There were small cortical heterotopia indenting the left occipital horn, with deficient white matter bilaterally and very small corpus callosum.

Chromosomal analysis upon her revisit, showed a 46,XX,der(17)t(10;17)(?q24;q25) karyotype. The mothers chromosomes were normal. The fathers blood was unavailable. Comparative genomic hybridization (CGH) was performed to more precisely delineate the chromosome 10 breakpoint. The additional 10 material was determined to be 10q24.1qter. Loss of chromosome 17q was not detected as the material missing was most likely below the level of detection of the assay. The rough estimate of CGH with a fixed diagnostic threshold is 10-12 Mb. The final karyotype was 46,XX,der(17)t(10;17)(?q24;q25).ish cgh der(17)t(10;17)(q24.1;q25)

Partial trisomy 10q, has been well defined although rare. In this syndrome, the additional chromosome material is usually derived from an unbalanced translocation, and often inherited from the father. The phenotype is comparable to the probands clinical presentation, with the exception of a lack of hydronephrosis.

CGH analysis was extremely useful in cases such as this one where the father was not available for cytogenetic analysis.

Association mapping in admixed populations. *S. Myers[1,2], J. Marchini[2], A. Price[1,3], D. Reich[1,3], N. Patterson[1]* 1) Broad Institute of MIT and Harvard, Cambridge, MA; 2) Department of Statistics, Oxford, UK; 3) Harvard Medical School, Boston, MA.

Genome-wide association studies offer a powerful framework for identifying mutations contributing to human disease. Performing these studies in admixed populations, such as African Americans and Hispanics, should enable researchers to identify many variants affecting disease risk. Differing allele frequencies and linkage disequilibrium structures across human populations imply admixed groups are likely to be especially useful both for the identification of new mutations, and in fine-mapping causal variants. Despite these potential benefits, association mapping has thus far concentrated on examining European populations. One reason for this, and a key issue to address, is the fact that there are a number of methodological challenges specific to performing association studies in admixed populations. For example, it is important to infer information about case and control admixture chunks, to prevent false positive associations and to fully exploit available information. We have developed and implemented an analytical framework to address such factors. Our approach uses dense genotype data to probabilistically infer admixture segments, and impute untyped SNPs, using previous variation surveys, e.g. the HapMap, as a framework. These inferences are integrated into a Bayesian full-likelihood methodology, providing a natural weighting of both broad-scale admixture LD information and fine-scale association information. Applying this method to simulated and real African American datasets demonstrate that typing 500,000 or more markers across the genome provides exquisite information about African American population ancestry (capturing over 95% of available information), and allows highly accurate SNP imputation. Finally, we describe the application of our approach to detect prostate cancer risk variants in 650 African American cases and controls. This revealed SNP rs6983267 as being the most strongly associated with disease status. Further, most of the other top associations are strongly replicated in several additional human populations.

Association of haplotype of the signal transducer and activator of transcription gene (STAT4) with RA in the Korean population - Asian and Caucasian populations share common risk haplotype. *H.S. Lee[1, 3], E.F. Remmers[2], J. M. Le[2], D.L. Kastner[2], D.H. Yoo[3], S.C. Bae[3], P.K. Gregersen[1]* 1) The Feinstein Institute for Medical Research, Manhasset, NY; 2) NIAMS, Bethesda, MD; 3) Hanyang University of College of Medicine and the Hospital for Rheumatic Diseases, Seoul, Republic of Korea.

Recently, a study in North American Caucasians has documented the association of a common STAT4 haplotype with risk for rheumatoid arthritis and systemic lupus erythematosus (Remmers et al., manuscript; 2007 ASHG abstract). In order to replicate this finding in the Korean population, we performed a case-control association study. Sixty seven SNPs within STAT4 were genotyped in 1123 Korean patients with RA and 1008 ethnicity-matched controls. The association of the risk genotype/haplotype with RA, anti-cyclic citrullinated peptide(AntiCCP), earlier-onset age, and radiographic severity were analyzed. Attributable proportions (AP) were also calculated as a means to measure interaction between shared epitopes (SE) of HLA-DRB1 and a STAT4-risk haplotype for RA. The most significant four risk SNPs (rs11889341, rs7574865, rs8179673, and rs10181656 located within the third intron of STAT4) among 67 SNPs are identical with those in the North American Caucasian study. All 4 SNPs have the modest risk for RA susceptibility (odds ratio 1.21 - 1.27). The same haplotype (TTCG) as the Caucasian study shows the significant risk for RA [34% versus 28%, P=0.0027, ORs (95% CI) 1.33 (1.10 - 1.60)]. These significant associations of STAT4 were observed in both antiCCP+ and antiCCP- RA groups. In the analysis for interaction with SE, the risk haplotype showed significantly increased RA risk by interaction with SE alleles (AP=0.227, 95% CI 0.044-0.410). In the logistic regression analysis, this haplotype is an independent risk factor in addition to SE for RA. Unlike several other risk genes such as PTPN22, PADI4, and FCRL3 for RA, a haplotype of the STAT4 gene shows consistent association with RA susceptibility across the Asian and Caucasian racial groups.

Suggestive linkage of Brachydactyly Type A3 to 7q36. *K.D. Williams[1], J. Blangero[2], C.R. Cottom[1], S. Lawrence[1], J. Subedi[3], B. Jha[4], T. Dyer[2], J.L. VandeBerg[2], S. Williams-Blangero[2], B. Towne[1]* 1) Wright State University School of Medicine, Dayton, OH; 2) Southwest Foundation for Biomedical Research, San Antonio, TX; 3) Miami University, Oxford, OH; 4) Tribhuvan University Institute of Medicine, Kathmandu, Nepal.

Brachydactyly Type A3 (BDA3) is characterized by a short and broad middle phalanx of the fifth digit. A high prevalence of BDA3 has been observed among children in the Jiri Growth Study, a genetic epidemiological study of child health conducted in the endogamous Jirel ethnic group of eastern Nepal. A hand-wrist x-ray is taken annually of each child to assess skeletal development. The most recent radiographs of 1,357 Jirel children, adolescents, and young adults (676 boys; 681 girls) aged 3-20 years were examined for the presence or absence of BDA3. The overall prevalence of BDA3 in this sample was 10.5% (12.9% of the males and 8.9% of the females were classified as BDA3 affected). An initial whole genome linkage scan was performed on a subset of 426 individuals who each have been genotyped for ~400 autosomal markers. A variance components-based linkage analysis method was used to analyze these data and obtain multipoint LOD scores. The additive genetic heritability of BDA3 was highly statistically significant in this sample (h^2 SE = 0.87 0.16, $p<0.0001$). Suggestive linkage was found of BDA3 to markers on chromosome 7q at 177 cM between 7q36.2-7q36.3 (LOD score = 2.00). A possible positional candidate gene near this region is Sonic Hedgehog (*SHH*), which has an important role in embryo formation. Mutations of *SHH* in mouse models have produced limb and digit dysmorphologies, and in humans, developmental disorders that include a short and broad middle fifth phalanx of the fifth digit as part of their etiology have been mapped to the 7q36 region. This study is the first to report linkage results for BDA3, and the first to suggest that either *SHH*, or genes near *SHH* working individually or in concert with it (or with other genes in the region), may contribute to this specific skeletal anomaly. Supported by NIH grants F32HD053206, R01HD40377, R01AI37091, R01AI44406, and R37MH59490.

Bardet-Biedl syndrome proteins are required for receptor localization to neuronal cilia. *K. Mykytyn[1,2], N.F. Berbari[1], J.S. Lewis[1], G.A. Bishop[3]* 1) Dept. of Pharmacology, The Ohio State University, Columbus, OH; 2) Dept. of Internal Medicine, Division of Human Genetics, The Ohio State Medical Center, Columbus, OH; 3) Dept. of Neuroscience, The Ohio State University, Columbus, OH.

Primary cilia are solitary appendages that are found on nearly all mammalian cells. They are thought to provide important cellular sensory and signaling functions. The importance of these organelles is highlighted by the fact that primary cilia dysfunction has been implicated in the pathophysiology of a number of human genetic disorders. However, the mechanisms underlying cilia dysfunction and their role in disease pathophysiology remain unclear. We have discovered that mouse models of Bardet-Biedl syndrome (BBS), a pleiotropic human genetic disorder whose etiology has been linked to cilia dysfunction, have defective localization of neuronal ciliary receptors in the brain. We find that neurons cultured from mice lacking the *Bbs4* gene lack ciliary localization of receptors and this localization can be corrected by Bbs4 overexpression. Our results indicate that BBS proteins are required for the localization of receptors to neuronal cilia. We hypothesize that BBS proteins function in the localization of ciliary signaling proteins and, in the absence of BBS proteins, ciliary signaling is disrupted. Importantly, this finding may represent the fundamental mechanism underlying the pathophysiology of the seemingly diverse BBS phenotypes, including obesity, cognitive deficits, renal cystic disease, and retinal degeneration. These results may provide important insights into the roles of ciliary signaling and the basis of disease in BBS and other ciliary disorders.

Identification of *BMPR2* deletion/duplication breakpoints in familial pulmonary arterial hypertension (FPAH).

M. Pauciulo[1], K. Clark[1], L. Wheeler[2], J. Loyd[2], W. Nichols[1,3] 1) Cincinnati Children's Hospital Medical Center; 2) Vanderbilt University Medical Center; 3) University of Cincinnati College of Medicine.

FPAH is an autosomal dominant disorder with reduced penetrance characterized by occlusion and remodeling of the pulmonary arteries leading to sustained elevation of pulmonary vascular resistance, progressive right heart failure, and death. Germline *BMPR2* mutations have been identified in approximately 70% of families. In a recent study of 30 FPAH families, *BMPR2* exonic deletions/duplications accounted for 48% (10/21) of the mutations identified. Nine of the 10 deletions/duplications involved one of the two large *BMPR2* introns, either IVS1 (>87 kb) or IVS3 (>46 kb). As the breakpoints of the dosage mutations were not determined, the origins of apparently similar deletion mutations identified for exons 1, 2, and 3 in each of two unrelated families could not be determined. The aim of this study was to identify the *BMPR2* deletion/duplication breakpoints and determine any common mutational hotspots leading to recurring mutations. Real-time PCR assays, designed in the introns of *BMPR2* surrounding the deletions/duplications, were used to map the extent of the dosage mutations. PCR primers were designed flanking the dosage mutations which enabled amplification, cloning, and sequencing of PCR fragments for determining the sequences at the deletion/duplication breakpoints. Breakpoints have been identified for seven of the 10 *BMPR2* deletions/duplications. Our results show that the two families carrying an exon 3 deletion have the identical 9,768 bp deletion which is flanked by a 42 bp identical sequence in introns 2 and 3. However, the breakpoints of the two exon 1 deletions and the two exon 2 deletions found in each of two families are different and thus represent independent mutational events. Identical sequences ranging from 30 to 47 bp were found flanking five of the seven identified deletion/duplication breakpoints, suggesting uneven crossing over as a common, but not an exclusive, mechanism of *BMPR2* exonic deletions/duplications. Our results also suggest that most *BMPR2* deletions/duplications may be independent mutational events and do not arise from intronic mutational hotspots.

Phenotypic subclassification amongst individuals with cohesin-related Cornelia de Lange Syndrome: *SMC1A*, *SMC3* and *NIPBL* specific features. *D. Yaeger[1], M.A. Deardorff[1], M. Kaur[1], L.G. Jackson[2], I.D. Krantz[1]* 1) Division of Human Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Drexel University School of Medicine, Philadelphia, PA.

The Cornelia de Lange syndrome (CdLS) is a dominantly inherited multisystem developmental disorder with characteristic facial features, hirsutism, abnormalities of the upper extremities, growth and cognitive retardation. Mutations in the cohesin regulator *NIPBL* account for 60% of cases and in the cohesin structural proteins *SMC1A* and *SMC3*, another 5%. Severe CdLS is easily recognized, yet mild cases require an appreciation for the phenotypic variability to make an accurate diagnosis, especially as the spectrum continues to expand when inclusive of individuals with *SMC1A* and *SMC3* mutations. While ascertained as CdLS, most of the *SMC1A* and *SMC3* mutation-positive individuals have a distinct phenotype when compared to the more classic CdLS phenotype associated with *NIPBL* mutations. This bias in ascertainment of our study population suggests that a significant cohort of individuals with *SMC1A*/*SMC3* mutations may be undetected amongst populations of individuals with mental retardation. Here we summarize features of 18 individuals confirmed to have a *SMC1A* or *SMC3* mutation and delineate phenotypic differences that will help in classification and targeted molecular analysis. Unlike *NIPBL*-related individuals, birth weight and length are often in the normal range and several individuals had normal growth as they aged. None of the individuals had severe retardation commonly seen amongst individuals with *NIPBL* mutations. Strikingly, no medically significant structural anomalies were present in the *SMC1A*/*SMC3* cohort. Differences in facial morphology included a nose lacking a depressed nasal bridge and upturned tip, substituted with a more elongated and tubular shape; full eyebrows with prominent synophrys without a typical tented arch shape; and normally shaped ears without helical anomalies. As more individuals are identified with *SMC1A* and *SMC3* mutations, recognition of subtle phenotypic variations within the CdLS spectrum will allow for more efficient screening protocols for those that fall within it.

Haplotype-based association in case-control studies - a latent variable approach. *T. Wang[1,2], H.J. Jacob[2], Z.B. Zeng[3]* 1) Div Biostatistics, Medical Col Wisconsin, Milwaukee, WI; 2) Human Molecular Genetics Center, Medical Col Wisconsin, Milwaukee, WI; 3) Bioinformatics Research Center, North Carolina State University, Raleigh, NC.

There is a growing utilization of high-dense genetic markers such as single nucleotide polymorphisms (SNPs) in genome-wide association studies to identify genetic risk factors of complex diseases. Haplotype-based association is attractive in reducing the data complexity especially for tightly linked SNPS. It may also increase the statistical power of detecting disease susceptible loci comparing with the single marker analysis under certain circumstances. However, haplotype analysis faces potential problems including the uncertainty in haplotype frequency estimates, adjustment for sampling ascertainment and multiple testing. Classical weighted logistic regression based on the prospective likelihood is flawed by the fact that it may no longer provide equivalent parameter estimates as the maximum likelihood estimates from a retrospective likelihood due to a constraint of Hardy-Weinberg equilibrium on the genotypic distribution of markers. A systematic testing procedure may also be required not only for haplotypes of the markers but also for haplotypes from a subset of the markers as well as for all marker alleles, since the status of the disease risk factor is often unknown. In the present study, we describe a latent variable method for association analysis between a disease and multiple closely linked markers with unphased genotype data from case-control studies. Based on a retrospective likelihood, the method can appropriately account for both the uncertainty in haplotype frequency estimates and the case-control sampling ascertainment. By introducing a latent variable into the genetic model to play a flexible role of a potential risk factor that may consists of a single allele or a haplotype from the whole set or a subset of the markers, the method also allows us to build a composite test for genetic association between the disease and the marker genotypes regardless of the composition of the risk factor. Simulation studies have been implemented to assess the performance of the method.

A common polymorphism of STAT4 is associated with severe disease manifestations of systemic lupus erythematosus. *K.E. Taylor[1], W.A. Ortmann[2], A.T. Lee[3], E.F. Remmers[4], R.P. Plenge[5], S. Chung[1], J. Nititham[1], D.L. Kastner[4], M.F. Seldin[6], P.K. Gregersen[3], T.W. Behrens[2], L.A. Criswell[1]* 1) Division of Rheumatology, University of California, San Francisco, San Francisco, CA; 2) Genentech, Inc., South San Francisco, CA; 3) Feinstein Institute for Medical Research, North Shore L.I.J. Health System, Manhasset, NY; 4) National Institute of Arthritis and Musculoskeletal and Skin Diseases, Bethesda, MD; 5) Broad Institute of Harvard and the Massachusetts Institute of Technology, Cambridge, MA; 6) University of California Davis, Davis, CA.

BACKGROUND: Systemic lupus erythematosus (SLE) is a genetically complex disease with heterogeneous clinical manifestations. A polymorphism in the STAT4 gene has recently been established as a risk factor for SLE and rheumatoid arthritis (RA), but the relationship with specific SLE subphenotypes has not been studied. METHODS: We studied 91 SNPs in the STAT4 region from the Illumina HumanHap550 genotyping array and clinical data from 2 independent Caucasian SLE case series (total=1026) and independent sets of controls (total=1373). We determined the most significant SNP for SLE risk and studied this SNP for association with specific SLE subphenotypes. To prevent possible type-I errors from population stratification, we reanalyzed the data using a subset of the combined groups determined to be most homogeneous based on EIGENSTRAT analysis. RESULTS: SNP rs7574865 was most strongly associated with SLE risk (MAF 30% cases, 23% controls), as seen previously for SLE and RA. This SNP is in a 70-kb moderate-high LD block; in conditional analysis rs7574865 explained all of the association within this block. Associations of this SNP with SLE characterized by double-stranded DNA (dsDNA) autoantibodies (OR=1.7, 95% CI [1.4-2.1], p=2.6e-7, MAF=34%) and severe nephritis (OR=2.1, 95% CI [1.3-3.4], p=0.001, MAF=39%) were striking. In contrast, STAT4 was less strongly associated with milder disease manifestations, such as oral ulcers (MAF=25%) and photosensitivity (MAF=28%). CONCLUSION: A common polymorphism of STAT4 contributes to the phenotypic heterogeneity of SLE, predisposing specifically to more severe disease.

The ATRX chromatin remodeling protein regulates the expression of specific imprinted genes in the murine brain. *D.C. Tremblay*[1], *M.A. Levy*[1], *N.G. Bérubé*[1,2,3,4] 1) Biochemistry, University of Western Ontario, London, Ontario, Canada; 2) Paediatrics, University of Western Ontario, London, Ontario, Canada; 3) Children's Health Research Institute, London, Ontario, Canada; 4) Lawson Health Research Institute, London, Ontario, Canada.

X-linked -thalassaemia mental retardation (ATR-X) syndrome is characterized by severe cognitive delay, a broad range of developmental abnormalities, and -thalassaemia. Disease-causing mutations in the *ATRX* gene give rise to a malfunctioning protein and result in aberrant DNA methylation at specific repeat sequences. ATRX is an ATP-dependant chromatin remodeling protein that targets -globin gene expression, leading to -thalassaemia in affected patients. To identify additional genes that are regulated by Atrx, we compared the transcriptional profile of Atrx-null and control mouse forebrain samples. We utilized a mouse model system in which Atrx is conditionally deleted in the developing cortex and hippocampus starting at embryonic day 8.5. This analysis revealed that specific imprinted genes are upregulated in the Atrx-null newborn forebrain. Using quantitative RT-PCR, we established that alterations in imprinted gene expression occurred in a progressive manner, suggesting that Atrx might contribute to the maintenance of imprinting marks, such as DNA methylation. We therefore performed bisulfite mutagenesis to identify potential DNA methylation changes at differentially methylated regions (DMRs). Subtle alterations in methylation patterns at imprinting control regions were identified, and additional studies will be required to clarify whether these methylation changes are related to aberrant gene expression. Taken together, our findings establish for the first time a link between Atrx and the control of imprinted gene expression in the murine brain, providing further evidence that imprinting mechanisms are an important facet of brain development and cognitive functions.

Detecting Associations in the Presence of Extreme Allelic Heterogeneity: Application to the Rare Variant Common Disease Hypothesis. *B. Li, S.M. Leal* Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Association studies are frequently utilized to map variants which are susceptibility loci for common diseases. Critical assumptions of this approach are that the disease is due to a common functional variant which is in strong linkage disequilibrium with genotyped SNP(s) and there is minimal allelic heterogeneity. If the rare variant common disease hypothesis holds, current association based methods will be underpowered due to allelic heterogeneity, low allele frequencies and poor correlation (r^2) with tagSNPs. For common diseases where the underlying etiology is believed to involve extreme allelic heterogeneity, large scale candidate gene sequencing is currently underway to discover multiple causal rare variants. However, which methods are optimal for analyzing this type of data to detect associations is unknown. In this study, we analytically demonstrate that collapsing genotypes and rare variants across multiple loci is more powerful than multi-marker test (Hotellings T^2) and single marker test (Fisher exact test). Collapsing methods are also robust against misclassifications unless the non-causal variants are common. In that case, collapsing only rare variants gained significant robustness with little loss of power. Empirical findings from simulation studies were consistent with analytical results and, additionally, it was shown empirically that for collapsing methods type I error is well controlled.

Analysis of Whole-Genome Data by Homozygosity Mapping and Adjustments for Relatedness. *B.F. Voight[1,2], D. Altshuler[1,2], M.J. Daly[1,2], representing the Diabetes Genetics Initiative* 1) Broad Institute of Harvard and MIT, Cambridge, MA; 2) Massachusetts General Hospital, Boston MA.

Whole-genome association data is well suited to detect unusual tracts of homozygosity over many genetic markers, as well as detecting familial relationships present in the ascertained sample. Typically, this information is obtained from the marker data *in silico* by estimating the number of alleles shared identical by descent (IBD). To date, how empirical estimates of IBD and homozygosity can be utilized in the context of whole genome association studies has not been fully explored.

We describe two approaches with take advantage of this information. First, we conjectured that individuals with extreme quantitative trait values would be enriched for homozygosity at specific genomic locale relative to the background population, and that low-frequency recessive mutations of strong effect might be found in those homozygous regions. We computed tracts of homozygosity in a sample of ~3000 individuals collected from Finland and Sweden as part of the Diabetes Genetics Initiative (DGI) and have genotyped them on the 500K Affymetrix platform. These samples have been characterized for measures of glucose metabolism, lipids, obesity, blood pressure, as well as Type 2 diabetes. We demonstrate statistical support (P 10^{-5}) for regions enriched for homozygosity in trait extremes relative to the background population. Second, we propose a modification to the standard allele-based association testing that, in the variance term, corrects for the estimated IBD state for each pair of individuals at each marker, including both individuals with known and unknown relatedness. We illustrate the features of this testing framework via simulation, and highlight results of a re-analysis of the original DGI scan for Type 2 diabetes.

Propionic acidemia: Mutation analysis of patients. *P.-W. Chiang, J.P. Kraus, S. Kopinsky, E. Spector* Pediatrics, UCDHSC, Aurora, CO.

Propionic acidemia (PA) is an autosomal recessive disorder of organic acid metabolism caused by gene mutations in PCCA or PCCB encoding the and subunits of mitochondrial enzyme propionyl CoA carboxylase (PCC). PCC is a biotin-dependent heterododecamer of both subunits with a MW of ~ 800 kDa. PCC catalyzes beta-oxidation of odd-chain fatty acids and catabolism of branch-chain amino acids. PA patients suffer acute metabolic episodes that can be life-threatening, with poor feeding, vomiting, hypotonia, lethargy, hyperammonemia and ketoacidosis. Treatment aims to prevent metabolic crisis and neurological sequelae. It includes a formula restricting amino acids that feed into propionate pathways, a low protein diet, and frequent hospitalization. Biochemical testing is available for diagnosis but not for carrier testing. With tandem MS newborn screening, PA can now be diagnosed prospectively, with enzymatic or molecular confirmation. Worldwide, 48 and 55 different mutations, respectively, have been reported in PCCA and PCCB, including missense and nonsense mutations, splicing defects, insertions and deletions (www.uchsc.edu/cbs/pcc/pccmain.htm). Ethnic differences exist: in PCCB 1218del14ins12 is more common in Caucasians while p.T428I and p.R410W are more often found in East Asians. We have developed DNA testing in our clinical diagnostic laboratory to sequence the entire coding regions of PCCA and PCCB. We report here on DNA analysis of 14 patients so far, including fibroblast cell lines from patients of all complementation groups (pccA, pccB, pccC, and pccBC) with previously published Northern and Western results. We found known mutations (common and rare) and several novel mutations, including 581A>G: K194R; 996G>T: E332D; 350G>A: G117D; 1495C>T: Q499X and IVS17+1G>C in PCCA and IVS 13+1G>C in PCCB. Our synthesis of knowledge on mutations, biochemical profiles, and clinical phenotypes will make genotype-phenotype correlation studies easier and may help to predict severity of symptoms, to plan therapy, and to assess prevalence of asymptomatic homozygotes in the population. DNA sequencing will help families with reproductive planning and genetic counseling, by allowing definitive diagnosis, carrier detection and prenatal diagnosis.

BRI2 (ITM2B) shows Genetic Association with Late onset Alzheimers Disease. *F. Zou[1], J. Kim[1], V.M. Miller[1], Y. Levites[1], K.J. West[1], C. W. Zwizinski[1], B.D. Moore[1], L. Ma[1], D. Cangemi[1], G.D. Bisceglio[1], S. Younkin[1], V.S. Pankratz[2], R.C. Petersen[3], N. Graff-Radford[4], D. Dickson[1], T. Rosenberry[1], T.E. Golde[1], S.G. Younkin[1]* 1) Dept Neuroscience, Mayo Clinic, Jacksonville, FL; 2) Dept Biostatistics, Mayo Clinic, Rochester, MN; 3) Dept Neurology, Mayo Clinic, Rochester, MN; 4) Dept Neurology, Mayo Clinic, Jacksonville, FL.

The biologic effects of mutations in the BRI2 (ITM2B) and APP genes support the hypothesis that cerebral accumulation of amyloidogenic peptides in familial British and familial Danish dementias and Alzheimers disease (AD) is associated with neurodegeneration. Our recent findings show that wild type BRI2 has a robust inhibitory effect on A aggregation both in vitro and in transgenic mouse models. To evaluate the pathophysiologic significance of these findings, we analyzed 6 SNPs in the ITM2B gene for association with late onset AD. These 6 SNPs formed 8 haplotypes that showed significant global association (p=0.045) in the large series of American Caucasians that we examined (1693 AD, 1891 Control). In subjects with an age at diagnosis/entry of 60-80 years (1050 AD, 1059 Controls), the significance of haplotypic association improved considerably despite the reduced number of subjects (global p = 0.006). In this age group, there were 14 ITM2B genotypes that occurred at least 10 times, each formed by a single haplotype pair with probability over 99%. The H1/H5 (p=0.039), H2/H2 (p=0.05), H1/H6 (p=0.051), and H2/H5 (p=0.14) genotypes showed significant or suggestive association with risky ORs of 2.1, 1.5, 2.7, and 3.0 respectively. To determine if this set of genotypes is associated with altered expression of the ITM2B gene, ITM2B mRNA was analyzed in the cerebellum of 141 AD brains. Consistent with our results in transgenic mouse models, ITM2B mRNA levels were significantly increased by 32% in the 116 subjects with low risk genotypes as compared to the 25 subjects with high risk genotypes (p=0.02 by two sided Mann Whitney test). These results identify BRI2 as a novel factor that influences risk for AD by modulating A aggregation and deposition.

A novel duplication confirms the involvement of chromosome 5q23.2 in autosomal dominant leukodystrophy. *I.A. Meijer[1], A. Simoes Lopes[1], S. Laurent[1], T. Katz[1], D.J. Verlaan[1], S. Verreault[2], J-P. Bouchard[2], G.A. Rouleau[1]* 1) Centre de Recherche du CHUM, Hôpital Notre Dame, Université de Montréal, Montréal, PQ, Canada; 2) Hôpital de l'Enfant-Jésus, Québec City, Québec, Canada.

Leukodystrophies are a group of neurogenetic diseases characterized by demyelinisation of the central and peripheral nervous system. Previously, a locus on chromosome 5q23 was identified in five families with adult-onset autosomal dominant leukodystrophy. The reported critical genetic interval is flanked by markers D5S1495 and CTT/CCT15, which span 0.96 cM or 1.47 Mb (L. Marklund et al 2006). This region contains 13 known and putative candidate genes.

We have identified a large multigenerational French Canadian family with autosomal dominant adult-onset leukodystrophy. Six living affected family members were available for collection and presented with autonomic dysfunction as well as upper motorneuron signs affecting gait. Peripheral blood samples were obtained for DNA extraction and for the generation of lymphoblastoid cell lines. Two point linkage analysis confirmed linkage of this family to chromosome 5q23. In addition, a candidate gene screen of all the 13 genes was completed and no mutation was found.

Therefore a whole chromosome Comparative Genomic Hybridization (Nimblegen) for chromosome 5 was performed. The CGH analysis identified a 280 kb duplication within the chromosomal band 5q23.2 in the two tested affected individuals. The two samples were compared to a reference sample consisting of pooled DNA of 6 healthy individuals. The 280 kb duplication contains 3 genes, namely *LMNB1*, *FLJ36242* and *MARCH3*.

Our study supports the findings of Padiath et al. 2006 implicating duplicated *LMNB1* as the disease causing mutation. Further studies are necessary to elucidate the pathophysiology of lamin B1 in myelination and degenerative disorders such as ADLD and multiple sclerosis.

The Extension and Replication of Prior Nicotine Dependence Associations in the Iowa Adoption Studies. *R. Philibert[1], T. Gunter[1], P. Madden[2], A. Heath[2], S. Orzack[3], A. Todorov[2]* 1) Dept Psychiatry, Univ Iowa, Iowa City, IA; 2) Dept Psychiatry, Washington University, St. Louis, MO; 3) Fresh Pond, Inc., Cambridge, MA.

The Iowa Adoption Studies (IAS) is the largest longitudinal case and control adoption study of complex behavioral disorders in the United States. Because genetic and environmental effects are independent in this randomized adoption paradigm, the IAS cohorts are an ideal setting in which to delineate the role of genetic and gene-environment interactions in the initiation and maintenance of substance use disorders, especially nicotine dependence. In 2007, a consortium of NIDA investigators announced the results of their genome wide and candidate gene SNP analyses of nicotine dependence. As part of the NIDA Genetics Consortium, we have attempted to confirm and extend all the 150 most significant genome wide and candidate gene SNP findings from their studies using the genetic and clinical resources of the IAS. We report the results of our analyses with respect to the most promising candidate SNPs from their initial reports. We conclude that nicotine dependence results from the interactions of a large number of small effect loci with the exact effect size of each variant being dependent on its epistatic, environmental and gene-environmental interaction profile.

A Candidate Gene Association Study Identifies a New Susceptibility Gene for Crohns Disease Involved in IL-1 Processing. *A.C. Villani[1], M. Lemire[2], E. Louis[3], M.S. Silverberg[4], C. Collette[1], G. Fortin[1], C. Libioulle[3], A. Bitton[1], D. Gaudet[5], A. Cohen[1], D. Langelier[6], J.D. Rioux[5], P. Rutgeerts[7], S. Vermeire[7], T.J. Hudson[2, 8], D. Franchimont[1]* 1) McGill University Health Center, Canada; 2) McGill University & Genome Quebec Innovation Centre, Canada; 3) CHU of Liège, Belgium; 4) Mount Sinai Hospital IBD Center, Canada; 5) Université de Montréal, Canada; 6) Centre Hospitalier de Sherbrooke, Canada; 7) University Hospital Gasthuisberg, Belgium; 8) Ontario Institute for Cancer Research, Canada.

We used a candidate association approach to identify novel Crohn's disease (CD) susceptibility loci, and to complement the list of CD candidates recently reported from WGA studies. We focussed on genes involved in IL-1 processing and signalling, a cytokine known to play a pivotal role in inflammation. Methods: 738 CD trios, 239 CD cases and 107 controls were assembled. 55 tagging SNPs were selected within a 72kb interval and genotyped in all samples. Association testing was done using FBAT, UNPHASED and Chi-Square tests. Results: The major allele of three SNPs was significantly associated with CD (p as low as 0.0147) in the Leuven exploratory cohort (356 CD trios). We replicated two of these signals in three independent cohorts: Liege trios (156 CD trios) (p=0.0130), Liege case-controls (239 CD and 107 controls) (p=0.00330) and Canadian trios (226 CD trios) (p=0.0310). Combined analysis of 4 cohorts revealed significant associations as low as p=6.694E-5 (OR:1.497; CI:1.223-1.833). Two haplotypes within our region were also significantly associated with CD and replicated across all 4 cohorts (combined p=3.45E-4), supporting the region as a potential CD risk factor. We selected 24 individuals based on carrier status of risk alleles and sequenced the 9kb associated region. No coding SNP could explain the signals, yet three SNPs in LD with the associated markers are located on putative functional sites, which we are currently evaluating. Conclusion: We have uncovered a novel CD susceptibility gene using a candidate gene approach, emphasizing the importance of IL-1 in the pathogenesis of CD. These results highlight the utility of a hypothesis driven methodology to complement WGA studies.

Mutations in the Na^+/H^+ exchanger gene *SLC9A6* cause an X-linked variant of Angelman Syndrome. *K.K. Selmer[1,2], G.D. Gilfillan[1], C.E. Schwartz[3], R.E. Stevenson[3], A.L. Christianson[4], M. Kyllerman[5], T. Egeland[2], M. Kroken[2], M. Mattingsdal[6], K. Eiklid[2], D.E. Undlien[1,2], P. Strømme[7]* 1) Inst. of Medical Genetics, University of Oslo, Oslo, Norway; 2) Dept. of Medical Genetics, Ullevaal University Hospital, Oslo, Norway; 3) JC Self Research Institute, Center for Molecular Studies, Greenwood Center, Greenwood, South Carolina, USA; 4) Division of Human Genetics, University of the Witwatersrand, Johannesburg, South Africa; 5) Dept. of Neuropediatrics, Queen Silvia Children's Hospital, Göteborg, Sweden; 6) Dept. of Medical Informatics, Rikshospitalet-Radiumhospitalet, Oslo, Norway; 7) Dept. of Pediatrics, Ullevaal University Hospital, Oslo, Norway.

Angelman syndrome (AS) is a severe neurological disorder characterized by developmental delay, ataxia, happy demeanor, speech impairment, microcephaly and seizures. The genetic cause of 85-90% of the patients clinically diagnosed with AS is a loss of function of the maternally imprinted gene *UBE3A* on 15q11-13. Linkage analysis on chromosome X identified a locus Xq24-Xq27.3 in a Norwegian family with an X-linked phenotype resembling AS. This region was reported to be linked to a similar phenotype in a large South African family in 1999. Sequencing of candidate genes led to the identification of deletions in the *SLC9A6* gene in both the Norwegian and the South African family. A further 67 males with genetically unexplained clinical AS were sequenced and a nonsense mutation was found in a Swedish patient. The *SLC9A6* gene encodes the organellar Na^+/H^+ exchanger NHE6, which is ubiquitously expressed and is suggested to take part in regulation of endosomal pH and Na^+ concentration. The complete function of this cation exchanger and how it can cause a AS like phenotype when function is impaired, remains to be explored. Both *UBE3A* and *SLC9A6* are involved in the intracellular protein processing pathway, but if they interact or affect a common pathway is currently unclear. In conclusion: Mutations in the *SLC9A6* gene cause an X-linked mental retardation syndrome similar to AS in two families and one sporadic patient of different geographical origin. Functional studies to address the potential consequences of NHE6 deficiency are ongoing.

Ignoring intermarker linkage disequilibrium induces false-positive evidence of linkage for consanguineous pedigrees when genotype data is missing for any pedigree member. *S.M. Leal, B. Li* Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Missing genotype data can increase false-positive evidence for linkage when either parametric or nonparametric analysis is carried out ignoring intermarker linkage disequilibrium (LD). Previously it was demonstrated by Huang et al (2005) that no bias occurs in this situation for affected sib-pairs with unrelated parents when either both parents are genotyped or genotype data is available for two additional unaffected siblings when parental genotypes are missing. However, this is not the case for consanguineous pedigrees, where missing genotype data for any pedigree member within a consanguinity loop can increase false-positive evidence of linkage. The false-positive evidence for linkage is further increased when cryptic consanguinity is present. The amount of false-positive evidence for linkage and which family members aid in the reduction of false-positive evidence of linkage is highly dependent on which family members are genotyped. When parental genotype data is available, the false-positive evidence for linkage is usually not as strong as when parental genotype data is unavailable. For a pedigree with an affected proband whose first-cousin parents have been genotyped, further reduction in the false-positive evidence of linkage can be obtained by including genotype data from additional affected siblings of the proband or genotype data from the probands sibling-grandparents. For the situation when parental genotypes are unavailable, false-positive evidence for linkage can be reduced by including in the analysis genotype data from either unaffected siblings of the proband or the probands married-in-grandparents.

High Density Association Mapping of IBD6. *C. Labbe[1,2], P. Goyette[1], C. Lefebvre[1], C. Stevens[3], T. Green[3], J. Stempak[4], S. Brant[5], R. Duerr[6], K. Taylor[7], J. Cho[8], H. Steinhart[4], M. Daly[3], M. Sylverberg[4], J.D. Rioux[1,2,3]* 1) Montreal Heart Institute; 2) Université de Montréal; 3) The Broad Institute of MIT and Harvard; 4) Mount Sinai Hospital IBD Center, University of Toronto; 5) Johns Hopkins University School of Medicine; 6) School of Medicine, University of Pittsburgh; 7) Medical Genetics Institute, Cedars-Sinai Medical Center, Los Angeles; 8) Yale University.

Crohns disease and ulcerative colitis are known as the Inflammatory Bowel Disease(IBD). Variants at a few loci have been irrevocably associated with IBD.Additional genes are expected to be involved in disease susceptibility. Two of these loci(CARD15 and IBD5) were identified via association mapping of significant linkage regions. We have performed a genomewide linkage study of IBD families and identified a locus(IBD6) on 19p with genomewide significance(LOD score = 4.6). We were interested in identifying the causal variants located within this linked region. We have embarked upon a two-stage association mapping studies of the IBD6 region. In stage 1, 1530 tag SNPs were selected (using Tagger) from HapMap data phase I that would serve as proxies(r20.7) for all other SNPs with a minimum minor allele frequency of 10%. These SNPs were genotyped on 433 trios and 328 cases/236 controls from Canada and Italy. We excluded individuals and families with low genotyping, excessive mendelian errors, and unexpected relatedness. We also excluded SNPs that had a low call rate. We performed association testing of the post-QC data and observed a higher number of associated SNPs(0.001, 1; 0.005, 11; 0.01, 25; 0.05, 129) than would be predicted to occur at random indicating the presence of genes influencing the susceptibility to IBD. We are currently in a replication stage, where the most associated SNPs are being genotyped in an independent cohort of 4000 DNAs.We expect that this comprehensive approach will lead to the identification of a novel susceptibility locus and we will present our screening and replication results.These results as well as examination of gene-gene and gene-environment interactions will be integrated into a general risk model for susceptibility to IBD.

Fifth female patient with Myhre syndrome. A further delineation. *M.L. Ramirez-Duenas[1,2], L.E. Becerra-Solano[1,2], J.A. Nastasi-Catanese[1,2,3], J.J. Toscano-Flores[1,2], L.E. Figuera[1,2], E. Matute[4]* 1) Division de Genetica, Centro de Investigacion Biomedica de Occidente, Guadalajara, Jalisco, Mexico; 2) Doctorado en Genética Humana, Centro Universitario de Ciencias de la Salud, Universidad de Guadalajara, Guadalajara, Jalisco, México; 3) Universidad de Oriente, Núcleo Bolívar, Unidad de Genética, Ciudad Bolívar, Bolívar, Venezuela; 4) Instituto de Neurociencias C:U.B:A. Universidad de Guadalajara, Guadalajara, Jalisco, México.

Introduction: Myhre syndrome(MS)(OMIM 139210) is characterized by short stature, conductive and sensorial deafness,"muscular hypertrophy", limited joint movement, cryptorchidism, and distinctive facial appearance. To date, 15 cases (11 males and 4 females)have been described. The present case is the 5th. female MS patient. Case report: The 13-year-old patient is the 2nd child born to a unrelated 42 and 43 year-old mother and father. She born after a full term pregnancy by cesarean section because of premature rupture of amnion; birthweight was 2150 g. spontaneous cry were referred. At birth, unilateral cleft lip and palate was noticed. Her developmental milestones were normal; she is attending to a regular school. She had menarche at 9 years of age, her menstrual periods have been regular. Physical examination At 11 years of age, her height was 129 cm (-3pct), weight of 29 kg (3-10 pct), and OFC of 49 cm (-3, -2.75 SD). Her physical appearance was squared, by heavy body habitus, short neck and short stature; microbrachycephaly, wide forehead, flat and wide facies, slant-up palpebral fissures, blepharophimosis, flat nasal bridge with hypoplastic left nare, flat maxilla, upper lip with a left surgical scare, overcrowded teeth, repaired clef palate, prognathism, bilateral microtia type I were observed; shortened upper limbs, limited elbow prono-supination, small hands with clinodactyly of the fifth fingers and a wide space between 4th and 5th finger. Her breast and pubic hair development were on III-IV Tanner stage, X-ray studies showed a thick skull vault, broad ribs, mild hypoplastic iliac bones, and broad and short femoral necks. Chromosomal analysis at 550-600 G-bands resolution was normal. The clinical spectrum in MS patients (males and females)is review.

Sequence variants in two novel genes and two intergenic regions within a QTL on human chromosome 7q36 alter plasma triglyceride levels in the human metabolic syndrome. *E.M. Smith[1], L. Martin[2], J. Charlesworth[3], J. Blangero[3], A.H. Kissebah[1], M. Olivier[1]* 1) HMGC, Medical College of Wisconsin, Milwaukee, WI; 2) Childrens Hospital, Cincinnati, OH; 3) Southwest Foundation for Biomedical Research, San Antonio, TX.

We have previously identified a quantitative trait locus on human chromosome 7 (LOD = 3.7) linked to plasma triglyceride levels in an obese cohort of 2207 individuals of Northern European descent. The QTL interval spans a region of 5 Mb.

Single nucleotide polymorphisms were selected across the region based on the linkage disequilibrium (LD) patterns of the CEPH population of the HapMap. A total of 1,048 SNPs were genotyped using Molecular Inversion Probe technology (Affymetrix).

Of the 1,048 SNPs assayed, 109 (10.4%) displayed nominal significance ($p<0.05$) and nine were significantly associated with triglyceride levels after correction for multiple testing. These SNPs were located in six discrete regions of interest clustered in the center of the QTL, containing two genes (DPP6 and HTR5A) and two additional intergenic regions. Haplotype analysis of these regions suggests that each region of interest independently contributes to the overall effect. Haplotypes in high LD regions around DPP6, which spans 1.1Mb, collectively account for approximately 30% of the initially observed linkage. In addition, a haplotype covering the entire HTR5A gene region, spanning 13.6kb, accounts for 26% of the linkage. The two intergenic regions (46kb in total), both more than 85kb from the nearest gene or hypothetical protein, account for a further 18% of the linkage.

These results clearly prove that the initially observed linkage is caused by multiple causal loci each contributing to the observed effect. In addition to two genes, intergenic regions also significantly affect plasma triglyceride levels. However, the physiological mechanisms underlying the genic and non-genic effects remain to be elucidated.

Stillbirth: A multifactorial problem. *E. McPherson, C. Cold* Marshfield Clinic, Marshfield, WI.

We have reviewed 50 consecutive stillbirths occurring over a 4.5 year period in a community hospital which accepts referrals from the surrounding rural area. In 40 (80%) of cases, a protocol including maternal record review, dysmorphology evaluation, placental pathology, karyotype, autopsy and, when indicated, maternal thrombophilia testing led to identification of at least one cause for fetal death. Since only 2/10 with unknown cause were fully evaluated, it is possible that more complete application of the protocol may have led to more identified causes. Causes of stillbirth are typically classified as fetal, cord/placental, and maternal, but in reality, the welfare of the fetus, placenta and mother are inextricably connected. Overall 16/50 (32%) of stillbirths had more than one causative anomaly. Of the 22 fetuses with major anomalies, 13 also had placental abnormalities contributing to fetal death. Since placental pathology was omitted in 6 cases with known chromosomal abnormalities expected to affect the placenta, the true total may have been greater if complete evaluation was done. Conversely, among the 23 with major placental anomalies, 15 had major fetal anomalies and/or PROM /preterm labor contributing to fetal death. Among 5 cases with well-documented cord constriction, two fetuses had amniotic bands and all 5 cords had preexisting malformations. Of 8 cases in which preterm labor or PROM preceded fetal death, half had cord or placental anomalies, 2 more had borderline small placentas, and 1 had both gastroschisis and placental abruption. The mothers of the stillbirths have a prior history of poor pregnancy outcomes with 38/98 (39%) of previous pregnancies ending in miscarriage or stillbirth. 7/50 mothers have thrombophilia and 4/50 have diabetes. Systematic investigation led to recognition of several families with increased recurrence risk including an inherited chromosome translocation, a family with autosomal dominant partial malrotation predisposing to volvulus, and a family with recurrent extra-long umbilical cord in 3 sibs. In hindsight, the majority of mothers of stillborns have pre-existing risk factors. With more careful prenatal care for high risk women, prevention may become possible.

Downregulation of NEIL1 or NEIL2 induces mutator phenotype in mammalian cells. *A.K. Maiti[1], I. Boldogh[2], S. Mitra[1], T.K. Hazra[1]* 1) Biochemistry and Molecular bio, University of Texas Medical Branch, Galveston, TX.77555; 2) Department of Microbiology and Immunology, University of Texas Medical Branch, galveston, TX, 77555.

Oxidatively induced DNA lesions have been implicated in the etiology of many diseases including cancer and in aging. Repair of oxidatively damaged bases in all organisms occurs primarily via the DNA base excision repair (BER) pathway, initiated with their excision by DNA glycosylases. Among four mammalian oxidized base-specific DNA glycosylases, the recently characterized NEIL1 and NEIL2 are unique because of their preference for excising lesions from a DNA bubble, unlike the previously characterized OGG1 and NTH1, which are active only with duplex DNA. The preference of NEILs for bubble DNA substrates raised the possibility that they function in the repair of base lesions during replication and/or transcription. A lack of phenotype in OGG1/NTH1-null mice, and efficient repair of oxidized bases from the genomes of null mouse cells, suggests a critical role for the NEILs. To investigate the role of NEIL1 and NEIL2 in preventing endogenous mutations, we examined the consequences of their deficiency on the hprt locus in chinese hamster V79 cells. Here we show that antisense-mediated downregulation of NEIL1 and NEIL2 separately induced endogenous mutation by about 4 to 6 fold. The mutation frequency was further enhanced (~25 to 30-fold) under oxidative stress. We have analyzed the mutation spectrum by amplifying and sequencing the hprt locus. NEIL1-downregulated cells accumulated mutations mostly at the AT base pairs, on the other hand NEIL2-downregulated cells accumulated mutations mostly in the CG base pairs. Thus the NEILs appear to play distinct and important roles in maintaining the functional integrity of mammalian genomes. (Research supported by USPHS grants R01 CA102271, CA91063 and P01 ES06676).

A variant form of the signal transducer and activator of transcription gene (*STAT4*) increases genetic susceptibility to rheumatoid arthritis and systemic lupus erythematosus. *E.F. Remmers[1], R.M. Plenge[2], A.T. Lee[3], R.R. Graham[2], G. Hom[4], T.W. Behrens[4], P.I.W. de Bakker[2], J.M. Le[1], H.-S. Lee[3], J.P. Carulli[5], L. Padyukov[6], L. Alfredsson[6], L. Klareskog[6], W.V. Rheumatoid arthritis (RA) is a chronic inflammatory disease with a significant genetic component. Susceptibility to disease has been linked with a region on chromosome 2q. We performed association studies using tag SNPs for 13 candidate genes within this region and fine mapped the *STAT1/STAT4* region with 63 SNPs in a total of 1620 established RA cases and 2635 controls. One of the disease-associated SNPs was also genotyped in 1529 recent onset RA cases and 881 controls from Sweden and three systemic lupus erythematosus (SLE) case-control series totaling 1,036 cases and 1188 independent controls. Four SNPs located in the third intron of *STAT4* were strongly associated with susceptibility to RA, minor allele frequency (MAF)=0.27 in established RA cases compared with 0.22 in controls (for rs7574865, $P=3x10^{-7}$; OR=1.32, 95% CI=1.19-1.46). This association was also seen in the Swedish recent onset RA cohort (P=0.02). The haplotype marked by rs7574865 was even more strongly associated with SLE (MAF=0.31 versus 0.22 in the combined SLE cases and controls, $P=2x10^{-9}$; OR=1.55, 95% CI=1.34-1.79). STAT4 transmits signals from cytokines such as IL-12 and type 1 interferon, thereby regulating gene expression programs that are required for T-cell differentiation and for activation of mature dendritic cells. These data emphasize an important role for these pathways in the pathogenesis of both RA and SLE.

The molecular etiology of Stargardt disease in Newfoundland. *A.K. Sheaves, J.S. Green, T.L. Young* Faculty of Medicine, Human Genetics, Memorial University, Health Sciences Centre, St. John's , NL, Canada.

Stargardt disease is an autosomal recessive genetic disorder causing central vision loss often beginning in the first decade of life and is the most common form of juvenile macular degeneration. Mutations in the *ABCA4* gene cause Stargardt disease, with more than 400 reported mutations worldwide. The *ABCA4* protein is a component of the visual phototransduction cascade and absence or deficiencies in this protein lead to the death of retinal pigment epithelium and photoreceptor cells. Individuals with Stargardt disease are often compound heterozygotes for different disease-causing mutations. Other inherited eye disorders can be caused by *ABCA4* mutations, including cone-rod dystrophy, retinitis pigmentosa, and possibly age-related macular degeneration.

There are 34 families with Stargardt disease in Newfoundland and Labrador (NL). The only known mutation associated with Stargardt disease in this population is a homozygous c.5714+5GA splice site mutation. The primary objective of this study is to identify all mutations in the *ABCA4* gene responsible for causing Stargardt disease in the NL population and to determine the genetic epidemiology and genotype-phenotype correlations of the *ABCA4* mutations in the NL population. Haplotype analysis will be performed to associate demography with particular mutations, which can be used to assess distant genealogical connections between families.

So far, the homozygous c.5714+5GA mutation has been verified in a 3-generation family with 3 affected probands, and also found in the homozygous state in an additional 3 families. Additional SNPs found to date include a nonsense mutation (c.2564GA), four missense mutations (c.3322CT, c.3323GA, c.4139CT, c.4163TC), and several known polymorphisms. While the cause of Stargardt disease has been explained in several of the families, continued sequencing of the *ABCA4* gene is needed to understand the full spectrum of disease-causing mutations in the NL population.

Pharmacogenetic markers for cholinergic effects on smoking cessation. *J. Sarginson[1], J. Killen[2], S. Fortmann[2], L. Lazzeroni[1], A. Schatzberg[1], G. Murphy[1]* 1) Psychiatry and Behavioral Scieces, Stanford University School of Medicine, Stanford, CA; 2) Stanford Prevention Research Center, Stanford University School of Medicine, Stanford, CA.

Breaking the cycle of nicotine addiction is difficult even with treatment. Many patients prescribed pharmacologic treatments for smoking cessation experience side effects that result in treatment discontinuation, or start smoking again soon after completing treatment. We are performing a pharmacogenetic study to identify markers for the efficacy and tolerability of bupropion and transdermal nicotine (TN), two treatments for smoking cessation. We are utilizing clinical data and DNA obtained from two smoking cessation studies. In the first, 276 smokers received bupropion and TN for 8 weeks. In the second, 301 smokers received bupropion plus TN for 11 weeks, followed by 14 weeks of placebo or bupropion. Our genetic analysis focuses on two regions, 15q24 and 8p11.2, which were recently implicated in nicotine dependence in a large scale candidate gene study (Saccone et al., Am J Hum Genet 80:856-66, 2007), and contain a total of 5 nicotinic acetylcholine receptor subunits (alpha-5, alpha-3, beta-4, beta-3, alpha-6) between them. Nicotinic cholinergic receptors are activated directly by TN, and are present on neurons that are affected by bupropion. SNPs were selected for a genetic screen of the two regions if they met one of the following criteria 1) they have demonstrated or predicted functional consequences or 2) they are tagging polymorphisms for haplotypic bins or 3) they have been implicated in the genetics of nicotine addiction based on a literature review. The primary clinical outcome measures for this study are point-prevalence abstinence and time to relapse, but craving, withdrawal symptoms and adverse events due to the study drugs, including changes in weight and mood are also considered. These results will provide a comprehensive analysis of genomic regions linked to smoking that contain a number of excellent candidate genes important in the actions of nicotine and bupropion. (Supported by the NIH and the California Tobacco-Related Disease Research Program).

SSADH deficiency - an underdiagnosed cause of mental retardation and behavioral problems. *L. Mehta[1], S. Ramanathan[1], J. Maytal[2], J.A. Neidich[3], D.Z. Salazar[3], C. Jakobs[4], K.M. Gibson[5], P.L. Pearl[6]* 1) Medical Genetics &; 2) Pediatric Neurology, Schneider Children's Hospital, NY; 3) Biochemical Genetics, Quest Diagnostics Nichols Institute, CA; 4) Clinical Chemistry, VU University Medical Center, Amsterdam; 5) Pediatrics & Pathology, Univ of Pittsburgh School of Medicine, PA; 6) Neurology, Children's Natl Med Center, Washington DC.

A 12 y.o. girl was evaluated for hypotonia, learning disabilities and attention deficit disorder with recent episodes of unresponsiveness in school. Baseline EEG and telemetry were normal. Family history was significant for a sister who died at 20. She had learning disabilities, seizures, self-injurious behavior, hallucinations and a diagnosis of depression. There was cognitive regression and memory loss following seizures. No definitive diagnosis was made and cause of death remained unknown. Parents were consanguineous. Our patient had normal chromosomes, subtelomeric FISH, plasma amino acids and fragile X testing. Urine organic acids showed elevated 4-hydroxybutyrate (-hydroxybutyrate or GHB) suggestive of succinic semialdehyde dehydrogenase deficiency (SSADHD). Measurement of SSADH activity in lymphocytes confirmed the deficiency. The patient developed overt seizures and is treated with oxcarbazepine with good control. SSADHD is a rarely diagnosed cause of developmental delays, particularly in expressive language, and neuropsychiatric abnormalities, including hallucinations and seizures. The pathophysiology is related to accumulation of GHB, an agonist of GABA receptors in the brain. GHB is neuropharmacologically active and acts as a sedative. The non-specific nature of symptoms often leaves SSADHD unsuspected. GHB accumulates in urine, plasma, and CSF. Urine organic acid analysis is a good initial diagnostic test, if done in a lab that reports GHB elevations. Some labs do not do so because GHB, like other sedating drugs, is a restricted substance. Urine organic acids are perceived to have a low diagnostic yield in patients with learning disabilities and MR but testing is appropriate in such situations. Many clinicians are not aware of this diagnosis, hence further elaboration of the natural history and pathophysiology will be helpful.

Positional cloning of genes influencing blood pressure on chromosome 2q31-q36 in the Old Order Amish. *P.F. McArdle[1], Y. Wang[1], S. Rutherford[2], J.R. O'Connell[1], S.H. Ott[1], L.J. Reinhart[1], T.I. Pollin[1], C. Damcott[1], Y.C. Chang[1], B.D. Mitchell[1], A.R. Shuldiner[1,3], N.I. Steinle[1]* 1) Department of Medicine, University of Maryland, Baltimore, MD; 2) Department of Genetics, Southwest Foundation for Biomedical Research, San Antonio, TX; 3) Geriatrics Research and Education Clinical Center, Veterans Administration Hospital Medical Center, Baltimore, MD.

Genome-wide linkage analysis in the Amish Family Diabetes Study revealed a single locus on chromosome 2q that was strongly linked to both diastolic (DBP LOD = 4.23; p=0.00001) and systolic (SBP LOD = 1.64; p=0.003) blood pressure. Peak evidence for linkage occurred between positions 181,883,021 and 220,376,982 (Mar2006 Build). This same region has been shown to be linked to hypertension in several other populations including Caucasians and African Americans. Here, we present the findings from association mapping with 2,831 SNPs placed approximately every 5 kilobases in the 1-LOD linkage interval in 762 Amish individuals. Initial screening efforts identified seven distinct regions containing genes highly associated with blood pressure, including SLC4A3 (p=0.0000002 for DBP and p=0.00004 for SBP), PPIL3 (p=0.000002 for DBP and p=00004 for SBP), FAM126B (p=000006 for DBP and p=0.0001 for SBP), ABCA12 (p=00001 for DBP and p=0.007 for SBP), ERBB4 (p=00003 for DBP and p=0.0001 for SBP), ORC2L (p=00001 for DBP and p=00003 for SBP) and BARD1 (p= 00003 for DBP and p= 0.008 for SBP). We also analyzed SNPs from these genes in a second Amish sample of 861 individuals for which Affymetrix 500K genotypes were available. Strong association between blood pressure levels and SNPs in ABCA12, which belongs to the large family of energy dependent ATP binding cassette proteins, (p=0.003 for SBP) and ERBB4, a member of a threonine protein kinase family involved in fetal cardiac development and in maintaining normal adult blood pressure, (p=0.002 for DBP and p=0.03 for SBP) was further demonstrated. Additional analysis in other populations and elucidating the functional consequences of variation in these genes may provide new insights into the genetic basis of hypertension.

A Large-Scale Rheumatoid Arthritis Genetic Study Identifies TRAF1 Variants on Chr 9q33.2. *S.J. Schrodi[1], M. Chang[1], K.G. Ardlie[2], C.I. Amos[3], L.A. Criswell[4], D.L. Kastner[5], P.K. Gregersen[6], M.F. Seldin[7], R.E.M. Toes[8], T.W.J. Huizinga[8], A.B. Begovich[1]* 1) Celera, Alameda, CA; 2) SeraCare Life Sciences, Cambridge, MA; 3) Univ Texas, Houston, TX; 4) UC San Francisco, CA; 5) N.I.H., Bethesda, MD; 6) North Shore-LIJ Inst, NY; 7) UC Davis, CA; 8) Leiden Univ Med Centre, Netherlands.

To identify rheumatoid arthritis (RA) susceptibility loci, we carried out a multi-tiered, case-control association study by genotyping 26,764 putative functional SNPs in 475 white North American RA patients and 475 matched controls. Significant markers were genotyped in two additional, independent, white case-control data sets (661 cases/1322 controls from North America and 595 cases/705 controls from The Netherlands) identifying a SNP, rs1953126, on 9q33.2 that was significantly associated with RA (Pcomb=2.62E-06, ORcommon 1.34). Through a comprehensive fine-scale-mapping SNP-selection procedure, 137 additional SNPs across 668kb from MEGF9 to STOM on 9q33.2 were genotyped in a staged-approach. Significant single marker results (Pcomb less than 0.001) spanned a large 461kb region from PSMD5 to GSN; however, SNP association patterns surrounding TRAF1 were observed to have a higher degree of consistency across sample sets, heightened statistical significance and reduced variability between control groups when compared to other SNPs. A sliding-window haplotype analysis revealed a 29kb-wide maximum peak of global association in TRAF1 (Pcomb=4.15E-08). Further haplotype analyses demonstrated RA-associated variants extending 60-70kb from PHF19 across TRAF1 and through the region 3 of C5. Conditional analyses indicated that two TRAF1 SNPs exhibit stronger relative effects than other associated SNPs in PHF19, C5 or RAB14. TRAF1 is a member of the TNF receptor associated factor (TRAF) protein family that associates with TRAF2 to form a heterodimeric complex, which is required for TNF-alpha-mediated activation of MAPK8/JNK and NF-kappaB. In combination with the other two known genetic risk factors, HLA-DRB1 and PTPN22, the variants reported here substantially alter the risk of RA.

Haplotype Inference for Tightly Linked Markers from Large Pedigrees in the Presence of Recombinants. *K. Zhang, Y. Yoo* Dept Biostatistics, Univ Alabama at Birmingham, Birmingham, AL.

Haplotype inference plays an important role in association studies because haplotype based analysis can provide additional power for gene mapping and haplotypes of diploid individuals cannot easily be acquired. The availability of a large number of tightly linked markers and the presence of missing data pose daunting challenges for haplotype inference from pedigrees. Many methods have been developed for haplotype inference from pedigrees, but they are not suitable for tightly linked markers in the presence of recombinants. Some likelihood-based methods, such as HAPLORE and ZAPLO, assume that no recombination occurs within a pedigree. The other likelihood-based methods, such as GENEHUNTER, Merlin, and Simwalk2, allow for the recombinants but assume linkage equilibrium between alleles among adjacent loci or blocks, which is inappropriate for tightly linked markers. Several rule-based methods have proposed to identify all compatible haplotype configurations with the minimum number of recombinants but most of them fail to provide reliable estimation of haplotype. We propose an EM algorithm incorporating the rule-based algorithm and the haplotype elimination algorithm for haplotype inference in general pedigrees. The algorithm does not assume the linkage equilibrium among markers and can handle pedigrees with recombinants. It can be outlined as the follows: 1) Apply a set of logic rules to identify compatible haplotypes; 2) Perform the haplotype elimination algorithm and only keep the haplotype configurations with the minimum number of recombinants; and 3) Perform the EM algorithm to estimate the haplotype frequencies based on haplotype configurations identified in step 2; only haplotypes with the frequency greater than a threshold will be retained. The partition-ligation technique is implemented to handle large number of markers. We evaluate its performance and compare it with several available methods for haplotype inference from general pedigrees through simulated haplotypes of tightly linked markers based on real pedigrees. Our results indicate that our method outperforms other methods.

Relational Networks of Differentially Expressed Candidate Genes for Glaucoma in Human Retina and Ciliary Body. *V. Raymond[1,2], P. Belleau[1], E. Deilhes[1], N. Boivin[1], R. Arseneault[1], E. Calvo[2]* 1) Ocular Genetics & Genomics, CREMO, Laval University Hospital (CHUL) Res Ctr, Quebec City, PQ, Canada; 2) Molecular Endocrinology & Oncology (CREMO), CHUL Res Ctr.

Primary open-angle glaucoma (POAG) is characterized by an optic neuropathy and blindness. As of January 2007, 13 POAG loci, named *GLC1A* to *GLC1L*, have been mapped for the disorder. Only 3 of these POAG genes have been characterized: *myocilin* (*MYOC*), *optineurin* (*OPTN*) and *WDR36*. To prioritize the screening of candidate genes for glaucoma within *GLC1* loci, we built relational networks of differentially expressed genes using data obtained from genomic convergence, a multistep approach that combines gene expression with genetic linkage. Affymetrix microarrays (HG U133 plus 2.0) were used to probe the retina and ciliary body obtained from 2 asymptomatic individuals (a 67 year old male & a 75 year old female) and one 76 year old POAG female. Candidate genes to inherited diseases (G2D) was used to identify Gene Ontology (GO) terms associated with glaucoma. Keywords were used with Entrez Programming Utilities to search differentially expressed genes on pubmed. Relational networks, that associated differentially expressed genes with the GO, terms *GLC1* loci and keywords, were drawn using GUESS. In our microarray experiments, 530 and 265 differentially expressed transcripts were identified, respectively, in the retina and ciliary body of the patient versus the controls. These transcripts corresponded to 74 genes mapping to 1 of the *GLC1* loci for unidentified glaucoma genes. Using these data, 795 graphs were generated to overview the global implication of each group of genes. These networks were highly related to apoptosis GO terms. This classification of information on genes highlighted the best candidates for glaucoma. For instance, *BCL2L1* was found to interconnect with 6 keywords and 20 other differentially expressed genes, 4 of them mapping to 1 of the *GLC1* loci. By focusing on pathways and genes cited together, networks of genes differentially expressed in glaucoma were defined to identify the best candidate genes for POAG. These networks will be available at www.sequences.crchul.ulaval.ca.

An Approach to Incorporate Linkage Disequilibrium Structure in Genomic Association Analysis. *F. Zhang*
Research Triangle Institute, Resarch Triangle Park, NC.

Genomic association studies often need to analyze a large number of single nucleotide polymorphisms (SNPs) in a chromosomal region or the whole genome to assess linkage disequilibrium (LD) with disease state. However, current analytic methods have some limitations, such as lack of consensus methods of adjusting for multiple testing, computational limitations, and unknown phase issues for haplotype analysis. In this study, we propose combining principal component and regression to analyze population genomic data for associations. This method not only allows testing multiple SNPs simultaneously (thereby addressing the first limitation), but also has flexibility to control for covariates. An illustrative example is presented using a set of 27 SNPs in a gene (MBL) from a population genomic study. Using genotypic data, five principal components were extracted that explain 97 percent; of the total variation at the 27 SNPs. We found one genomic block, defined by the second principal components, that were associated with outcome of interest (p=0.019). The second principal component is weighted heavily to the mid and distal segments of the gene and spans 3 LD blocks identified by Haploview. Compared with traditional single marker-phenotype association analysis, the second principal component captured all of SNPs that were found to be significantly associated with the outcome, using any of the single marker methods: genotypic association, allelic association or Trend test for association. When multiple testing correction was taken into account, all of single markers became no significant, however, our approach still indicated a significant association of the SNPs in the genomic block with outcome of interest. The power to detect a significant association with single SNPs in the sample, for example with a alpha 0.05 and allele frequencies for 0.28 (cases) and 0.213 (controls), is only 41.26 percent. Power may be increased when principal component score is tested, even if the haplotypes are not known.

Common variation at 8q24 and prostate cancer risk. *M. Yeager-Jeffery[1,2], R. Welch[1,2], R.B. Hayes[2], P. Bouffard[3], N. Xiao[1,2], L. Burdett[1,2], N. Orr[4], A. Crenshaw[1,2], Z. Markovic[3], K.B. Jacobs[5], T.P. Jarvie[3], D. Hunter[2,6], R. Hoover[2], G. Thomas[2], T.T. Harkins[7], S.J. Chanock[2,4]* 1) Core Genotyping Facility, Advanced Technology Program, SAIC-Frederick, Inc., NCI-Frederick, Frederick, MD 21702; 2) Division of Cancer Epidemiology and Genetics, National Cancer Institute, National Institutes of Health, Department of Health and Human Services; 3) 454 Life Sciences, Branford, CT; 4) Pediatric Oncology Branch, Center for Cancer Research, NCI, NIH, DHHS; 5) Bioinformed Consulting Services, Gaithersburg, MD; 6) Program in Molecular and Genetic Epidemiology, Department of Epidemiology, Harvard School of Public Health, Boston, Massachusetts; 7) Roche Applied Science, Indianapolis, IN.

Recently, several groups have reported strong associations between common DNA polymorphisms that span a segment of chromosome 8q24 and the risk of prostate cancer. There is evidence that at least three regions of this segment (chromosome 8: 126501167-128998553) are independently associated with risk and are also dependent on the ethnic origin of prostate cancer cases. As an extension of the Cancer Genetic Markers of Susceptibility project (http://cgems.cancer.gov), preliminary association studies of more than 4000 cases and 4000 controls of European origin have identified haplotypes on which disease-contributory mutations most likely exist. We have extensively characterized common genetic polymorphisms present for two of these regions, totaling > 148kb, using Roche/454 next-generation resequence analysis (chromosome 8: 128470954-128619305) of 40 prostate cancer cases and 40 controls of European origin and seven individuals from a CEPH family in which a common predicted susceptibility haplotype is segregating. The characterization of this region is important to rapidly identify common genetic polymorphisms so that they can be investigated for functional significance. There is growing evidence that these regions are also implicated in other cancer types; these observations underscore the importance of characterizing common genetic variation at 8q24.
Funded by NCI Contract N01-CO-12400.

An efficient computational approach to making inferences in multivariate linkage analysis. *N. Morris, C. Stein, R. Elston, T. Wang* Department of Epidemiology and Biostatistics, Case Western Reserve University.

In a world where complex multiple phenotype linkage data are abundant, there is a corresponding need of a method to analyze such data multivariately. Multivariate approaches can provide an effective way of controlling type I error, increasing power and disentangling pleiotropic effects. However, there is no simple way to characterize the distribution of currently available multivariate linkage statistics where tests are performed under complex one-sided constraints. As a result, ad hoc approximations of degrees of freedom or computationally intensive methods such as permutation tests must be used for making valid inferences. Recently, Wang and Elston proposed a robust score statistic for multivariate linkage analysis. Using a modified version of this statistic for illustration, we present a new Monte Carlo approach to calculating the asymptotic p-value under nonstandard conditions. This approach involves decomposing the parameter space into direction and length components, thus reducing the dimension of the parameter space. Theoretical limits to the computational gains attainable by this method and situations where it is efficient are discussed. A similar numerical integration.approach is also suggested. Type I error, power and run times under various simulated situations are presented.

The Future is Now. Will the Real Disease Gene Please Stand Up? *M. Schmidt, E. Martin* Human Genomics, University of Miami, Miami, FL.

In 1996, Risch and Merikangas touted the transmission/disequilibrium test (TDT) as the future of gene mapping for complex diseases. They suggested a million-marker screen affected sibpair families (ASPs), demonstrating that the TDT was a more powerful test of linkage than traditional linkage tests based on allele-sharing when the marker is also associated with the disease locus. While the future of genotyping has arrived, successes in family-based association studies have been modest. This is often attributed to excessive false positives in candidate gene studies. This problem is only exacerbated by the increasing numbers of whole genome association (WGA) screens. When applied in ASPs, the TDT statistic, which assumes transmissions to siblings are independent, is not expected to have a constant variance in the presence of linkage. This results in more extreme statistics which further aggravates the problem of having high levels of type I error. So an important question is how many positive TDT results will show up on a chromosome containing a disease gene due only to linkage, and will they obfuscate the true disease location. To answer this question we combined theory and computer simulations. Our studies show that in ASPs the normal version of the TDT statistic has a mean of 0 and a variance of 1 in unlinked regions, but has a variance larger than 1 in linked regions. The PDT statistic adjusts for correlation between siblings due to linkage and maintains a constant variance of 1 at unassociated markers irrespective of linkage. The TDT statistic is generally larger than the PDT statistic across linked regions for unassociated as well as associated markers. As fair comparison the scores of both statistics were ranked. TDT did a slightly better job placing the associated marker near the top. Though, strictly speaking, the TDT in ASPs should be interpreted as a test of linkage and not a test of association, there is a good chance that if a marker stands out, the marker is associated as well as linked. In conclusion, our results suggest that TDT is an effective screening tool for WGA, especially in multiplex families.

High heritabilities of novel cardiovascular biomarkers in a large multigenerational family. *S.H. Shah, D. Thompson, H. Chen, T. Stabler, C. Haynes, B. Lambertson, S. Nelson, E. Dowdy, E.R. Hauser, W.E. Kraus, V.B. Kraus*
Dept Medicine, Duke Univ Med Ctr, Durham, NC.

Background: Cardiovascular disease (CVD) has a strong genetic component and is highly heritable. Furthermore, conventional biomarkers for CVD risk (i.e. lipids) are heritable. Recently, several novel biomarkers have been shown to be associated with risk of CVD, but the underlying genetic component of these intermediate biomarkers remains yet to be determined. Therefore, in a large US family, we evaluated the hypothesis that these biomarkers are heritable. **Methods:** A pedigree documenting approximately 3000 family members of a large, multi-generational, multiethnic family was created. Biological samples and clinical data were obtained on 365 of these family members. Commercially available assays were used to measure paraoxonase, d-dimer, high sensitivity C-reactive protein (hsCRP) and glycated albumin from frozen serum. Biomarker levels were log transformed prior to analysis. Sequential Oligogenic Linkage Analysis Routines (SOLAR) was used to estimate heritabilities; polygenic models were constructed and adjusted for age-at-sampling and sex. **Results:** We confirmed previous studies showing high heritability of hsCRP (h2r=0.59 [SD 0.15], p=0.00004). Paraoxonase showed the highest heritability (h2r=0.64 [SD 0.12], p=0.0000001). D-dimer showed moderate heritability (h2r=0.26 [SD 0.16], p=0.04), but glycated albumin was not heritable (h2r=0.12 [SD 0.21], p=0.3). **Conclusions:** We report for the first time heritability of novel CVD biomarkers in a large family with a burden of CVD reflective of the average United States population. Paraoxonase, with the highest heritability, is an esterase associated with HDL, whose activity has been shown to be inversely related to the risk of CVD; therefore, mutations in this enzyme may be important determinants of CVD risk. Further studies to identify the underlying genes for these heritabilites are pending.

Complete Genomic Screen in Familial Parkinson Disease. *G.M. Mayhew[1], Y. Liu[2], M.A. Hauser[2], Y.J. Li[2], R. Jewett[1], J. Stajich[2], E.R. Martin[1], J.M. Vance[1], W.K. Scott[1]* 1) Miami Inst Human Genomics, Miller School of Med, Univ of Miami, Miami, FL; 2) Ctr Human Genetics, Duke Univ Medical Ctr, Durham, NC.

Many whole genome screens (WGS) for loci linked or associated with Parkinson disease (PD) have been performed, with only a small amount of agreement across studies. Despite that, most confirmed gene associations in PD lie within these linkage regions. Therefore, to attempt to further identify genes important to PD, we expanded our initial WGS performed in 2001 (174 families, 356 microsatellite markers) with a second WGS in an augmented dataset of 302 multiplex families (2 or more sampled individuals with PD) using a denser map of 6008 single nucleotide polymorphisms (SNPs; average spacing 0.62 cM). The families contained 1505 sampled members (669 affected), 248 sampled affected sibling pairs and 175 other sampled affected relative pairs. Mean age at onset was 59.713.2 years. Linkage analysis using dominant and recessive affecteds-only models identified two novel regions. In addition to having two-point MLOD scores greater than 2, one of these regions (on chromosome 3) generated a multipoint MLOD score greater than 2, making it the most interesting region in the screen. A second novel region of strong interest (on chromosome 18) had markers with both two-point and multipoint MLOD scores greater than 1.5. These results implicate two additional genomic regions for follow-up studies and extend the picture of genetic heterogeneity that characterizes studies of the late-onset, complex form of PD.

Comparison of haplotype-tagging SNPs from two resequencing projects (HapMap and PopGen) for 70 human genes related to immune responses. *Y. Yoo[1], K. Zhang[1], J. Tang[3], A. Loraine[1], J. Edberg[4], R. Kaslow[2]* 1) Dept Biostatistics; 2) Dept Epidemiology; 3) Dept Medicine; 4) Dept Clinical Immunology & Rheumatology, Univ Alabama at Birmingham, Birmingham, AL.

SNP data from the International HapMap Project are being widely used as a reference panel for selecting SNPs for genotyping in population studies. For many genes, data obtained by re-sequencing serve as an alternative panel for haplotype-tagging SNP (htSNP) selection to provide denser coverage. We have compared the performance of htSNPs selected from HapMap and from the NIH/NIAID Population Genetics Analysis Program (PopGen) for 70 immune response genes independently re-sequenced at the SeattleSNPs facility. For each candidate gene region, we obtained SNPs with minor allele frequency (MAF > 1%); from HapMap and from PopGen and identified those SNPs that were genotyped in both projects. We compared the percent coverage ($r^2 > 0.80$) using all SNPs genotyped for both projects with the percent coverage using the htSNPs selected from all SNPs available from both projects. We also compared the number of htSNPs selected from each project and the number of htSNPs selected from both projects using MultiPop-TagSelect algorithm (Howie et al., 2006). For Caucasians, 789 SNPs were obtained from HapMap only, 2,210 SNPs from PopGen only, and 662 SNPs from both projects. For Africans, 960 SNPs were from HapMap only, 3,513 from PopGen only, and 826 from both sources. For HapMap, 87% and 92% SNPs were covered by SNPs genotyped in both projects for Caucasian and African populations, respectively. For PopGen, 54% and 40% SNPs were covered by SNPs genotyped in both projects for Caucasian and African populations, respectively. Using only htSNPs, 86% and 91% SNPs from HapMap were covered by SNPs genotyped in both projects, and 38% and 30% SNPs from PopGen were covered by SNPs genotyped in both projects, for Caucasian and African populations. These analyses indicate that the SNPs in HapMap do not capture nearly all of the htSNPs of MAF >1% in the 70 selected genes. They suggest that, when feasible, more complete coverage of htSNPs may be achieved by combining data from multiple sources.

Bayesian Model Search and Selection for Association Studies. *M.A. Wilson, M.A. Clyde, E.D. Iversen, Jr.* Dept. of Statistical Science, Duke University, Durham, NC.

Modern genotyping techniques allow vast amounts of data to be collected for genetic association studies. With this volume of data comes an increased need for statistical methods that are able to efficiently sort through the enormous number of models given the available genetic and non-genetic data. In addition, it is increasingly the case that there is prior data on the structure and function of genetic pathways and their interaction with environmental factors. Analyses that ignore this information and focus, instead, on marginal associations will have diminished power. We describe a Bayesian model selection technique utilizing Evolutionary Monte Carlo that searches over models including genetic and environmental main effects and their interactions in a computationally efficient manner. The approach formally incorporates prior data on pathways, thus restricting the model search space. As alternatives, we consider SNP-by-SNP and gene-by-gene approaches in which each SNP (or gene) is analyzed separately and where pathway- or study-wide association is determined by a secondary analysis, e.g., of test statistics or associated p-values derived from the primary analyses.

Using Hapgen, we simulate a set of case-control pathway studies of SNP data that reflect true patterns of linkage disequilibrium and minor allele frequencies. We utilize these data sets to compare the power of the competing analytical strategies described above. We describe how the power of each of these analytical strategies depends upon the true model of association, sample size, and strength and extent of association. As part of this study, we investigate the performance of Evolutionary Monte Carlo as we change the parameters of the tempering scheme, the number of iterations run and the assumed penalty function/prior. Finally, we describe the advantages and disadvantages of each approach in terms of model complexity, computational tractability and analytical simplicity. We have found that SNP-by-SNP methods are surpisingly powerful given their simplicity and that Bayesian model selection techniques, while more computationally demanding, provide a promising alternative.

A genomewide association study of chronic fatigue syndrome. *A.K. Smith, S.D. Vernon, E.R. Unger, M.S. Rajeevan*
Centers for Disease Control, Atlanta, GA.

Chronic fatigue syndrome (CFS) is a complex disorder of unknown etiology. Current hypotheses suggest hypoactivity of the hypothalamic pituitary adrenal (HPA) axis leads to psychoneuroendocrine and immune alterations. While multiple studies support a genetic contribution to CFS, genomewide efforts to identify associated loci remain unexplored. This study addresses the role of genetic variation in CFS by evaluating 116,204 single nucleotide polymorphisms (SNPs) in 40 empirically-defined CFS cases and 40 non-fatigued (NF) controls identified in a population-based study. DNA extracted from peripheral blood mononuclear cells was amplified prior to genotyping. Chi-square tests were used to assess association between a marker and case status, and p-values were estimated using 10,000 Monte Carlo simulations. Case and control subjects did not significantly differ in age, sex, body mass index, or history of major depressive disorder.

Allelic association tests revealed 65 SNPs with p-values ranging from 0.00005-0.001 that were consistent with Hardy-Weinberg proportions in controls. Associated SNPs reside in or near genes related to brain function (*PPFIBP1*, *NPAS2*, *ARHGAP20*), glutamate neurotransmission (*GRIK2* and *GRIN2B*), immunity (*LILRB4*), inflammation (*NLRP13*, *NLRP11*, *PELI1*) and metabolism (*MTAP*) as well as expressed sequence tags identified from HPA axis tissues. To further interrogate the roles of these 65 SNPs with HPA axis function, association with morning serum cortisol levels was examined using analysis of variance adjusted for age, sex, and BMI. SNPs in *NLRP13*, *GRIK2*, and *MTAP* were also associated with cortisol levels (p=0.0015-0.043). Further analysis of *NLRP13*, a gene that activates proinflammatory mediators that influence the neuroendocrine system, identifies a haplotype (33.9%) associated with CFS (p=0.001) and with decreased serum cortisol (p=0.005), consistent with hypoactivity of the HPA axis. This study, though limited by sample size, identifies candidate genes not considered in prior studies and supports psychoneuroendocrine and immune disruption in CFS. Further studies will be required for fine mapping, functional validation and to replicate these findings in additional populations.

Depletion of Bypass DNA polymerases leads to genomic instability after treatment with DNA interstrand crosslinking agents. *K. Riggan, A. Hemphill, M. Al-Dhalimy, S.B. Olson, R.E. Moses* Molecular and Medical Genetics, Oregon Health and Science University, Portland, OR.

DNA interstrand crosslinks (ICLs) are potent forms of DNA damage, inhibiting replication and transcription. Yeast mutants of Rev3, the catalytic subunit of the bypass polymerase Pol , are sensitive to ICL agents. We tested whether depletion of human Rev3 would recapitulate that sensitivity to ICL agents. Depletion of Rev3 produces genome instability as manifested by increased radial formation with ICLs. GM639 immortalized fibroblasts were sensitized to Mitomycin C (MMC) by depletion of Rev3, as shown by decreased survival. Rev1 is an inserter polymerase involved with Pol in translesion synthesis, where Rev3 specifically extends past the nucleotide inserted by Rev1. Depletion of Rev1 in GM639s resulted in increased sensitivity to MMC as indicated by an increase in breaks and radials after ICL formation. Like Rev3, Pol is an extender of mispaired primer termini. For this reason, we were interested in whether the depletion of Pol also resulted in increased sensitivity to ICL agents. The depletion of Pol in HEK293 immortalized fibroblasts led to increased chromosome breakage and radial formation after treatment with MMC. Increased radial formation after ICLs is a phenotype characteristic of Fanconi Anemia (FA). For that reason, we depleted Rev3 in FA-D2 cells, to test the epistatic relationship of Rev3 to the FA pathway. Depletion of Rev3 in these cells increased the sensitivity to MMC, suggesting that Rev3 acts in a distinct ICL repair pathwaythat is, it is non-epistatic to the FA pathway. Rev1 was also tested for epistasis to the FA pathway by depletion in FA-D2. Depletion of Rev1 increased sensitivity to MMC, indicating that Rev1 is additive to the FA pathway. Our results support the conclusion that multiple pathways for ICL repair are present in higher eukaryotes and that bypass DNA polymerases act in the process outside the FA pathway.

MicroRNA Transcriptome Of Mouse Retina & Functional Characterization of a Sensory Organ Specific miRNA Cluster. *S. Xu[1], P. Witmer[2,3], S. Lumayag[1], B. Kovacs[1], D. Valle[3]* 1) Dept of Ophthal/Neurol Sci, Rush U Med Ctr, Chicago, IL; 2) Predoc Training Prog in Human Genet; 3) McKusick-Nathans Inst of Genet Med, Johns Hopkins U. Baltimore, MD.

To begin to understand the functions of miRNAs in retina, we compared miRNA profiles in adult mouse retina, brain and heart by microarray analysis & showed that at least 78 miRNAs are expressed in adult mouse retina, of which 15 are confirmed retina specific or preferentially expressed. Among these, we identified a polycistronic, sensory organ-specific paralogous miRNA cluster including miR-96, miR-182 & miR-183 on mouse chr6qA3 with conservation of synteny to human chr7q32.2. In situ hybridization showed that they are expressed in photoreceptors, bipolar & amacrine cells. qRT-PCR showed they have a similar expression pattern with abundance increasing postnatally & peaking in adult, suggesting that they may play important roles in the differentiation during development & the maintenance of the phenotypes & functions of adult retina. Target prediction & in vitro functional studies showed that MITF, which is required for the establishment & maintenance of retinal pigmented epithelium (RPE), is a direct target of miR-96 & miR-182, suggesting that these miRNAs may contribute to the establishment & maintenance of the neuroretinal identity. We also performed miRNA profiling with retinal RNA of noon (ZT5) & midnight (ZT17) & identified 12 miRNAs, including miR-182 with diurnal expression. Target prediction & in vitro functional studies showed that miR-96 & miR-182 directly downregulate adenyl cyclase VI (ADCY6), an important regulator of AANAT, a key enzyme in melatonin synthesis. qRT-PCR showed that Adcy6 is expressed in retina with a circadian pattern with an apex at ZT9 & a nadir at ZT17, inverse to that of miRs-96/182 with an apex at ZT13 & a nadir at ZT5 but about 4 hours out of register, supporting that these miRNAs may be involved in circadian regulation partly through regulating Adcy6 expression. Additional target prediction suggests that the miR-183/96/182 cluster may play important roles in modulating the circadian clock machinery through multiple genes in the clock network.

Mutations in the 3'-5' DNA exonuclease TREX1 are associated with systemic lupus erythematosus. *M. Lee-Kirsch[1], M. Gong[2], D. Choudhury[3], L. Senenko[1], K. Engel[1], Y. Lee[2,4], U. de Silva[5], T. Witte[6], T.J. Vyse[7], J. Kere[8], C. Pfeiffer[9], S. Harvey[5], S. Koskenmies[10], K. Rohde[2], A.F. Dominiczak[11], M. Gahr[1], T. Hollis[5], F.W. Perrino[5], J. Lieberman[3], N. Hubner[2]* 1) Klinik für Kinder- und Jugendmedizin, Technische Universität Dresden, Dresden, Germany; 2) Max-Delbrück-Centre for Molecular Medicine, Berlin-Buch, Germany; 3) CBR Institute for Biomedical Research, Harvard Medical School, Boston, MAä; 4) Charité, Department of Pediatrics, Berlin, Germany; 5) Department of Biochemistry, Wake Forest University Health Sciences, Winston-Salem, NC; 6) Medizinische Hochschule Hannover, Klinische Immunologie, Hannover, Germany; 7) Imperial College, Section of Rheumatology and Molecular Genetics, London, UK; 8) Karolinska Institute, Department of Biosciences and Nutrition, and Clinical Research Centre, Huddinge, Sweden; 9) Klinik für Dermatologie, Technische Universität Dresden, Germany; 10) University of Helsinki, Department of Medical Genetics and Department of Dermatology, Helsinki, Finland; 11) Department of Medicine and Therapeutics, Glasgow University, Glasgow, UK.

The hallmark of systemic lupus erythematosus (SLE), a complex autoimmune disease, is the elaboration of autoantibodies to nuclear antigens including DNA. Although several genes, which function in processing DNA or immune complexes or lowering the threshold for T cell activation, have been implicated, the genetic and molecular basis of SLE remains ill defined. We show that a mutation in the gene encoding 3'-5'DNA exonuclease (TREX1) leads to familial chilblain lupus, an autosomal dominant monogenic form of cutaneous lupus erythematosus that presents in the first years of life. We extended our findings to SLE by resequencing the entire coding region of TREX1 in SLE patients and controls. We observed monoallelic frameshift or missense mutations and one 3 UTR variant of TREX1 in 9/417 individuals with SLE that were not found in 1712 controls ($P=4.1x10^{-6}$). We functionally tested 3 mutant TREX1 alleles and show impaired enzyme activity, granzyme A-mediated apoptosis or subcellular targeting. Our findings implicate TREX1 in the pathogenesis of SLE.

Paving the Way to Accurate Genotype-Phenotype Predictions Using High Resolution Whole Genome SNP Oligonucleotide Microarray Analysis (SOMA) in the Clinical Cytogenetics Laboratory. *B. Levy[1], V. Jobanputra[1], O. Nahum[1], W. Chung[1], A. Shanske[2], K.A. Yeboa[1], L.G. Shaffer[3], D. Warburton[1]* 1) Columbia University Medical Cntr, New York, NY; 2) Children's Hosp Montefiore, Albert Einstein College of Med, Bronx NY; 3) Signature Genomic Laboratories, Spokane WA.

Constitutional chromosomal abnormalities are often associated with a spectrum of clinical abnormalities. The phenotypic consequences of the anomaly vary considerably and depend on the nature and chromosomal origin of the apparent imbalance, as well as precisely which genes are involved in the aberrant region. In many cases, prognostic information is solely derived empirically by reviewing apparently similar cases in the literature. High resolution SNP oligonucleotide microarray analysis (SOMA) allows for the identification of visible and submicroscopic cytogenetic imbalances by scanning the entire genome in a single step. A major advantage of SOMA is its ability to more precisely define the boundaries and nature of the region of imbalance, especially with respect to the gene content. We have performed studies using the Affymetrix 500K array to study: [1] cases with well characterized cytogenetic aberrations, [2] cases containing a variety of previously uncharacterized chromosomal imbalances and [3] cases containing genomic imbalances involving single gene regions. We also performed a blinded study of coded specimens with cytogenetic aberrations, including cryptic subtelomeric unbalanced rearrangements and diseases caused by single gene abnormalities. In all studies, we reliably detected the various chromosomal imbalances whose sizes ranged from single genes to megabases. In this report we highlight the potential diagnostic scope of SOMA with particular attention to the benefits of characterizing the gene content together with accurate clinical information. In clinical cytogenetics, the precise identification of the origin of the additional or missing chromosomal material is a key factor when considering genotype-phenotype correlations and may ultimately lead to the discovery of the genes that are responsible for the clinical features that present in such patients.

DNA demethylation in breast cancer. *A.H. O'Donnell[1, 2], R.A. Rollins[3], T.H. Bestor[2]* 1) MD/PhD Program; 2) Genetics and Development, Columbia University, New York, NY; 3) Current address: Wyeth Research, Pearl River, NY.

DNA hypomethylation was first identified in primary tumors by Feinberg and Vogelstein in 1983. Demethylation is especially prominent at retrotransposons, pericentric satellite sequences, and cancer-testis genes. No progress in elucidating the mechanism of demethylation in tumors has been made to date, although mutations or dysregulation of the DNA methyltransferases have been ruled out. It is not known whether cancer-specific demethylation is the result of gain-of-function or loss-of-function pathways. In order to address this issue, cell hybrids were generated by fusion of a demethylated and a normally methylated breast cancer cell line. While maintaining relatively stable DNA content over 160 generations, the hybrid cells show persistence of parental methylation patterns and a slow trend towards demethylation of pericentric satellite DNA. Dysfunction of the DNMTs is not responsible for the demethylation phenotype as the DNA methylation machinery of the normally methylated cell line is unable to methylate the demethylated DNA. While DNA demethylation has been shown to increase genomic instability, it may also have an anti-cancer role. Demethylation may activate a demethylation checkpoint mediated by local inflammatory response via the TLR9 innate immunity pathway and through the expression of neoantigens that are attacked by components of the adaptive immune system. In addition, low methylation levels have been shown to induce apoptosis. Identification of the mechanism and genes involved in DNA demethylation will facilitate the development of novel therapeutics in the treatment of breast cancer.

Information Service on Inborn Errors of Metabolism (SIEM): 5-year report from a pioneer Brazilian call-free service. *C.F.M. Souza[1], S. Herber[1], C.D. Lima[1], L. Giugliani[1], L.F. Refosco[2], M.T. Sanseverino[1], C.B.O. Netto[1], C.L. Rafaelli[1], R. Giugliani[1,3]* 1) Medical Genetics Service, Hospital de Clinicas, Porto Alegre, RS, Brazil; 2) Diet & Nutrition Service, Hospital de Clinicas, Porto Alegre, RS, Brazil; 3) Department of Genetics, UFRGS, Porto Alegre, RS, Brazil.

The SIEM is a pioneer toll-free service in Brazil and South America, having a team specialized in IEM available to help health professionals to diagnose, manage and treat suspected and affected patients. Since IEM are poorly recognized by physicians in Brazil, as in most developing countries, improve diagnosis and management is crucial to provide a better prognosis for patients and/or better counseling to families. Between October 2001 and March 2007, 1043 cases were registered at SIEM. From these, 77% were from South and Southeast Brazil and 52% of the contacts were made by pediatricians or neonatologists. The majority of the professionals (85%) called the SIEM for diagnostic support and early management orientation, 8% to obtain information concerning IEM and 7% for suppport in the follow-up as the diagnosis was already established. From the 1043 entries, 629 (60%) had their investigation for IEM concluded, and on 97 (15.4%) of these cases a diagnosis of IEM was confirmed. From these, 22.7% presented organic acidemias, 20.6% amino acid disorders, 15.5% lysosomal diseasesm, 10.3% energy defects, 10.3%carbohydrate metabolism defects, 6.3% peroxisomal diseases and 14.3% other disturbances. We are convinced that SIEM is an extremely important source of information about IEM, specially in a country were such group of disorders is often unrecognized, helping health professionals to obtain a faster and more efficient diagnosis and treatment, reducing morbidity on these patients and families (PROREXT/UFRGS/Fundacao Medica/Support).

Efficacy of whole genome array analysis for detection of chromosome abnormalities: Toward validation of a quantitative SNP array. *A. Murmann, D. Conrad, H. Ho, R. Nicolae, C. Ober, S. Schwartz* Dept Human Genetics, Univ Chicago, Chicago, IL.

Technologies to detect cytogenetic abnormalities have changed over the past three decades and continue to evolve. As new technologies are developed it is important to determine how effectively these technologies will delineate abnormalities. In this study we tested the efficacy of a quantitative SNP array for whole genome analysis of chromosomes by studying 85 patients with confirmed cytogenetic abnormalities (either balanced or unbalanced) and 15 chromosomally normal patients. A new algorithm for the quantitation of the SNP array data and individual patient results were compared with findings of 181 normal individuals. We have been able to confirm all chromosome imbalance previously know for the cases studied and have been able to better define the precise size of the deletion and/or duplication. Twenty four deletions and duplications have been detected with the array analyses that were not seen with high resolution chromosome analysis but could be confirmed by FISH. These abnormalities were as small as 100 kb, although most were between 300 kb and 5 Mb. Results from this study reveal important information including that: (1) the newly developed algorithm allows quantitative analysis of SNP array data that can be utilized to detect unbalanced chromosomal abnormalities not seen in routine chromosome studies; (2) Our new methodology has been introduced to help both in the detection of the abnormalities and in the controlling the background noise associated with these analyses; (3) The majority of these abnormalities would not have been detected by the currently available clinical arrays; (4) These findings are important not only for clinical studies, but for research studies involving both phenotype-karyotype correlations and mechanisms underlying the etiology of structural chromosomal abnormalities; (5) We have been able to identify many new copy number variations based on our studies; (6) While copy number variation is problematic in all array studies, we believe that these studies will allow the routine detection of pathogenic deletions and duplications greater the 500kb.

Distinctive LD and haplotype frequencies in human populations extend beyond ALDH2. *H. Oota[1], A.J. Pakstis[2], M.-Y. Lee[2], J.R. Kidd[2], K.K. Kidd[2]* 1) Dept Integrated Biosciences, U. Tokyo, Kashiwa, Japan; 2) Dept Genetics, Yale U. Sch Med, New Haven, CT USA.

The ALDH2 gene codes for acetaldehyde dehydrogenase 2, a key enzyme in ethanol metabolism. We previously published on normal variation in LD and multi-site haplotype frequencies for 6 SNPs and 1 STRP in 38 human populations. We have expanded our study to include more populations (45-50) and polymorphisms (41 SNPs) at higher density within ALDH2 and extended to include flanking ACAD10 and MAPKAPK5 genes (~193 KB total). Except for a functional site varying only in E.Asia, the avg heterozygosity across 45 population samples for 40 SNPs ranges from .18 to .37. In general, very strong LD (R^2 >.65) prevails in the 193 kb region but LD weakens considerably in several intervals for the African samples and to a lesser extent in E.Asia, Pacific, and the Americas; LD is very strong and more continuous for the European and some SW Asian samples. The unusual pattern of alternating intervals of very high (mostly .23 to .39) and low Fst (.05 to .09) values (compared to a reference distribution where avg Fst[45pops]=~.14) reported in our earlier work is also present in the genes flanking ALDH2. More high Fst values are concentrated in ACAD10 and ALDH2 (including promoter) than in MAPKAPK5 or the intergenic regions. In each of two 12-SNP and one 17-SNP haplotypes constructed (EM algorithm) there are 14-17 haplotypes at common frequencies. Consistent with the strong LD, this is a relatively small number of haplotypes at common frequencies in the 193KB region but this is more complex than the core 31kb of ALDH2 where 2 haplotypes account for 98% of chromosomes with strikingly similar frequencies in all populations studied suggesting balancing selection occurred. By continent, the haplotype frequencies display distinctive patterns across the 193 kb region. African samples show the most haplotype diversity; each continental grouping of populations has one or more haplotypes at distinctively higher frequencies compared to other world regions or has a haplotype essentially unique to the region, e.g. E.Asian haplotype carrying the functional variant. Supported in part by NIH AA09379 to KKK.

Allele Distribution Difference of NOS2 Promoter polymorphisms between Patients With Chronic Rhinosinusitis and Non-sinus Disease Controls. *X. Wang, Y. Di, C. Li* Lab Medicine and Pathology, University of Minnesota, Minneapolis, MN.

Chronic rhinosinusitis (CRS) is one of the most prevalent of the chronic diseases, affecting about 15% of the U.S population. Its etiology is not well understood. CRS is defined as a condition manifested by an inflammatory response involving the mucous membranes of the nasal cavity and paranasal sinuses. Nitric Oxide (NO) exhibits significant immunoregulatory activity. The enzyme NO synthase 2 (NOS2), often called inducible NOS, plays a central role in the inflammatory reactions that follow infection or tissue damage. Several recent studies indicate that genetic polymorphisms at the NOS2 gene are associated with asthma, atropy, malaria, and parasitic diseases. A study of gene expression profiles in nasal polyps and normal epithelial cells revealed that NOS2 mRNA reduced 5.5 fold in polyp tissue. To evaluate possible role of NOS2 gene in CRS, we have analyzed 261 CRS patients and 147 non-sinus problem controls for three NOS2 promoter polymorphisms. It is a pentanucleotide repeats, $(CCTTT)_n$ sequence located approximately 2.5 kb upstream of the main TATA-directed transcription initiation site, a di-allelic TAAA repeat (4 repeats or 5 repeats) and a single nucleotide substitutions: G>C variation, at position -954 (G-954C). We found that allele distribution in CRS patients is different from controls at $(CCTTT)_n$ (^{2}, p=0.03), but not at TAAA and G-954C polymorphisms. Allele $(CCTTT)_{12}$, the most common allele, has a lower frequency in CRS patients than controls (29% vs 38%, p=0.008). Individual bearing at least one $(CCTTT)_{12}$ allele has a lower risk (OR=0.63, 95%CI 0.42-0.95) for CRS. Allele frequency of $(CCTTT)_{10}$ is higher in the CRS patients than controls (13% vs 7%, p=0.003). Individual bearing at least one $(CCTTT)_{10}$ allele has a higher risk (OR=2.06 95%CI 1.19-3.57) for CRS. These results suggest that NOS2 may be one of the predisposing factors to CRS.

Genome-wide association scan for HDL cholesterol, LDL cholesterol and triglyceride levels in 9,000 individuals.

C.J. Willer[1], A. Scuteri[2,3], L.L. Bonnycastle[4], S. Sanna[5], A.U. Jackson[1], A. Maschio[5], W.L. Duren[1], F. Busonero[5], R. Pruim[6], Diabetes Genetics Initiative[7], R.M. Watanabe[8], S.S. Najjar[2], L.J. Scott[1], M. Uda[2], J. Tuomilehto[9], G.R. Abecasis[1], F.S. Collins[4], D. Schlessinger[2], K.L. Mohlke[10], E.G. Lakatta[2] 1) Dept Biostatistics, Univ Michigan; 2) Gerontology Research Center, National Institute on Aging; 3) Unita Operative Geriatrica INRCA, Rome Italy; 4) Genome Technology Branch, National Human Genome Research Institute; 5) Istituto di Neurogenetica e Neurofarmacologia, CNR, Cagliari, Italy; 6) Dept Mathematics & Statistics, Calvin College; 7) Broad Institute of Harvard & MIT, Lund Univ, & Novartis Institutes of BioMedical Research; 8) Dept of Physiology and Biophysics, Keck School of Medicine, Univ Southern California; 9) Dept Epidemiology & Health Promotion, Dept Biochemistry, National Public Health Institute, Helsinki, Finland; 10) Dept Genetics, Univ North Carolina.

Cardiovascular diseases (CVD) are the leading cause of death in industrialized countries. Low density lipoprotein cholesterol (LDL) is a major risk factor for CVD whereas high density lipoprotein cholesterol (HDL) protects against CVD. Triglyceride levels (TG) may also be associated with risk of coronary artery disease. Heritability of these traits is between 30 and 60%. We have combined genome-wide association data from the ProgeNIA study of 4,301 Sardinian individuals from 450 families, the FUSION study of 2,337 Finnish individuals and 2,659 Caucasian individuals from the Diabetes Genetics Initiative (DGI). To allow for meta-analysis with genotyped SNPs from two platforms (Affymetrix 500k and Illumina 300k), we imputed genotypes for untyped SNPs in the FUSION individuals. Meta-analysis provided clear association with several previously reported loci, including *APOC1* (LDL, $p = 1 \times 10^{-18}$), *GCKR* (TG, $p = 3 \times 10^{-16}$), *CETP* (HDL, 6×10^{-16}), *LPL* (TG, $p = 7 \times 10^{-15}$), *APOB* (TG, 9×10^{-10}), and *LIPC* (HDL, 2×10^{-8}). We detected second independent association signals in 5 of these genes ($p < 5 \times 10^{-6}$). We observed 15 new loci with $p < 5 \times 10^{-6}$ that we are in the process of genotyping in 7,300 individuals. The new loci appear to be involved in pathways such as cell adhesion and lipid metabolism.

Detection of balanced translocations by DNA microarrays. *C.C. Lau[1], C. Davis[1], P. Rao[1], R. Selzer[2], P. Eis[2]* 1) Texas Childrens Cancer Center, Baylor College of Medicine, Houston, TX,; 2) NimbleGen Systems, Inc. Madison, WI.

Balanced translocations are hallmarks of many human cancers and some of them are also used as prognostic markers. With pediatric acute lymphoblastic leukemia (ALL), several translocations including t(12;21), t(1;19), t(4:11) and t(9;22) are used as part of a prognostication algorithm to stratify patients to risk-based therapy. These translocations are detected clinically by a combination of G-banding and FISH but the precise location of the breakpoints, which might have further prognostic significance, is not identified by either one of these techniques. We report here preliminary results using long oligonucleotide tiling-path microarrays to simultaneously detect the presence of these translocations and precisely map the breakpoints. Using a 390K feature microarray designed and manufactured by NimbleGen to interrogate specific translocation breakpoints with a median probe spacing of 5 bp, we analyzed 8 bone marrow samples from pediatric ALL patients, including 7 from fresh frozen specimens and 1 matched sample from cell pellet previously fixed in methanol-acetic acid. The 3 samples with t(12;21) all showed microdeletions ranging from 200 bp mapped within intron 5 of the TEL/ETV-6 gene on chr 12p13 to 60 kb of the 3-end of TEL/ETV6 starting from intron 5. Only 1 out of 3 t(12;21) samples showed a 600 bp microdeletion approximately 36 kb 5 of exon 1 of the AML-1 gene on chr 21q22. The four cases of t(1;19) we examined included a matched pair of fresh frozen and fixed samples from the same patient. The matched samples showed identical results with duplication of sequences at both breakpoints of the PBX1 gene on chr 1q23 and the E2A/TCF gene on chr 19p13.3. One sample showed loss of intron 16 in the E2A/TCF3 gene but no change in the PBX1 gene breakpoint. One sample with t(4;11) was also analyzed which showed a microdeletion of 900 bp within intron 3 of the AF-4 gene on chr 4q21 and 200 bp within intron 14 of the MLL gene on chr 11q23. Overall, we identified the correct translocations in 7 out of 8 samples analyzed so far. Finally, we also detected additional changes involving other breakpoints that were missed by G-banding and FISH.

***Caenorhabditis elegans*: a model to further dissect features of Bardet-Biedl Syndrome.** *C. Mok[1,3], M. Zhen[3], E. Héon[1,2]* 1) Program of Genetics & Genome Biol, Sick Kids Hosp, Toronto, ON, Canada; 2) Department of Ophthalmology and Vision Sciences, Hospital for Sick Children, Toronto, ON, Canada; 3) Mount Sinai Hospital Research Institute, Toronto, ON, Canada.

Bardet-Biedl syndrome (BBS) is an autosomal recessive, genetically heterogeneous, pleiotropic disorder. Cardinal features include photoreceptor degeneration, obesity, digit anomalies, kidney anomalies, cognitive impairment and hypogonadism. BBS genes have recently been linked to ciliary proteins and the intraflagellar transport (IFT) system. C. elegans bbs-7 and -8 mutants have decreased ciliary axoneme length and chemotaxis defects (Blacque et al., 2004). Neurosensory defects in C. elegans have been associated with decreased body length (Fujiwara et al., 2002) and increased fat accumulation (Mak et al., 2006). We hypothesize that C. elegans bbs mutants will share specific phenotypes related to various ciliated-neurons. The following strains were used: N2 (Bristol), *bbs-1(ok1111)I*, *bbs-5(gk507)III*, *bbs-7(ok1351)III*, *bbs-7(n1606)III*, *bbs-8(nx77)V*, *bbs-9(gk471)I*, *che-3(ok1574)I*, *che-3(e1124)I*, *sma-1(ru18)V*. Transgenic rescue strains of *bbs-1*, *-7*, and *-8* mutants were created by co-injection of wild type *bbs* genes along with a transcriptional podr-1::GFP fusion. Measurements were completed on all strains listed at the L4 stage as well as 24 and 72 hours post-L4 stages. DiI staining was completed on mixed populations of all strains. Worms were mounted and observed for DiI uptake the following day. Measurements showed a statistically significant loss of 15-20%; in mean body length of *bbs* mutants that was abrogated in transgenic rescue lines. DiI staining identified *bbs* mutants as having a dyf phenotype that was abrogated in transgenic rescue lines. Body length and DiI results indicate that *bbs-5(gk507)III* may be a hypomorphic allele as it did not appear to have severe body length defects and was normal for DiI uptake. Mutations in *C. elegans bbs* orthologs lead to a marked decrease in mean body length for *bbs* knockout mutants and DiI uptake defects. Body length measurements correlate strongly with DiI defects. *C. elegans* can be used to identify possible pathways involved in BBS.

Lack of clinical use, of molecular, enzymatic and cytogenetics diagnostics test, at medical genetics services, in Bogotá, Colombia. *F. Suarez, A. Ordonez, E. Diaz* Inst de Genetica Humana, Univ Javeriana, Bogota, Colombia.

Molecular, enzymatic and cytogenetics diagnostics tests are an essential part of the diagnostic process of the patients attended at the genetics consultation. Objectives: to determine the frequency of use of molecular, enzymatic and cytogenetics diagnostics test in the consultation of medical genetics of three hospitals of the city of Bogota. Methods: revision of 600 clinical histories, of the three hospitals. After the clinical charts were reviewed, a survey to the parents of the patients, was made, asking about their perception about the genetic tests. Results: 600 clinical histories were reviewed; the patients were attended between the 01/9012004 to 01/12/05. A definitive diagnostic was reached in 284 cases (47, 3%); of which 109 cases (38, 4%) were patient with Down syndrome. A definitive diagnostic obtained through molecular tests was accomplished in only just 4 cases (1,4%): 1 case of Cystic Fibrosis and 3 cases of Muscular Dystrophy of Duchenne. The diagnostic through FISH was made in a case of Prader Willi (0,4%). The diagnostic of a metabolic pathology through enzymatic test was carried out in two cases of Morquio syndrome (0,7%) and a case of a homocystinuric child (0,4%). The molecular, enzymatic tests and FISH were asked for in the clinical history in 80% of the cases. The most asked laboratory test was Karyotype, in 66% of the patients, but it was made in less than 50% of the cases. The survey to 264 parents of the patients in which it was not possible to reach a definitive diagnostic showed that: the genetic tests, were not covered by their health policies (81,8%); the genetics consultation was not covered in their health policies (88.3%); the insurers do not know where, of what kind of laboratory companies is able to make that type of laboratory test (62%). Conclusions: the diagnostic genetic tests are not broadly used in the consultation of medical genetics at Bogota city; the main causes are the lack of cover on the part of the insurance health policies and the deficiency of specialized laboratories. The negative consequences of this situation in the context of clinical attention of the affected by genetic diseases, are discussed.

Improved identification of von Hippel-Lindau gene alterations in DNA from clear cell renal tumors reveals a large percentage of mutations that appear to reside in a subpopulation of total tumor cells. *M.L. Nickerson[1], J.A. Durocher[1], S. Mahurkar[1], K.B. Walters[1,2], J.D. Karkera[1]* 1) Genome Research Division, Transgenomic, Gaithersburg, MD; 2) Department of Biological Sciences, The George Washington University, Washington, DC.

Considerable progress has been made in understanding the genetic basis of kidney cancer. Molecular studies examining tumor DNA from sporadic clear cell renal cell carcinoma (ccRCC) have revealed that von Hippel-Lindau (VHL) alterations are a common, early event in the carcinogenic process and may be associated with prognosis and response to therapy. DNA from 205 patient tumors was analyzed for alterations in the VHL protein coding region, splice junctions, and promoter. Endonuclease scanning and Sanger sequencing were applied in parallel to screen for VHL somatic mutations. Using this approach, mutations were identified in 82.4% (169/205) of the cases. Seven tumors (3%) possessed two mutations. Detailed analysis of fluorescent sequencing chromatograms revealed that almost half of the mutations exhibited very low signal compared to wild type. Potentially these findings have implications for genetic progression during tumor formation or metastasis if only a small number of total tumor cells possess the VHL mutations that were identified. Detailed analysis of 11 CpG sites in the VHL promoter identified an additional 8.3% of tumors that were potentially silenced through hypermethylation. Interestingly, hypermethylation was found exclusively in tumors that were VHL mutation negative. Together, a total of 91% of RCCs exhibited apparent alteration of VHL. High throughput, sensitive methods for genetic analysis of tumors will be essential to stratify patients for individualized treatment using targeted therapeutics. Examination of VHL in ccRCC provides validation for combinatorial application of endonuclease scanning and Sanger sequencing and provides a practical, robust means of identifying somatic mutations in other types of cancer. Genetic analysis of VHL is particularly relevant to treatment of RCC given the recent success of several related targeted therapeutics.

36-Months on Treatment: Open-Label Phase I/II Long-Term Study of Enzyme Replacement Therapy (ERT) with Gene-Activated Human Glucocerebrosidase (GA-GCB) in Patients with Type 1 Gaucher Disease. *A. Zimran[1], M. Phillips[1], G. Altarescu[1], K. Bhirangi[2], R. Mensah[2], D. Elstein[1]* 1) Gaucher Clinic, Shaare Zedek Medical Ctr, Jerusalem, Israel; 2) Shire Human Genetic Therapies, Inc., Cambridge, MA.

AIM: To evaluate the long-term safety and clinical activity of Gene-Activated human glucocerebrosidase (GA-GCB), a novel ERT for patients with type 1 Gaucher disease. **BACKGROUND:** GA-GCB is produced in a human cell line using proprietary gene-activation technology, with and has an identical amino acid sequence to the naturally occurring human enzyme. **METHODS:** Ten of 11 patients who completinged the Phase I/II study enrolled in the long-term extension study. One patient discontinued treatment for reasons unrelated to GA-GCB. During the first 12 months of treatment with GA-GCB patients received 60U/kg GA-GCB every other week. At or after Month 12, all patients qualified (Therapeutic Goals; Semin Hematol. 2004) for a step-wise dose reduction from 60U/kg to 45U/kg (13 weeks) and then to 30U/kg. **RESULTS:** Preliminary data up to Month 30 on treatment with GA-GCB are included in this abstract. Month 36 data will be presented. Safety results up to Month 30: GA-GCB was generally well tolerated at all doses administered. To date, no drug-related serious adverse events have been reported. The majority of were mild to moderate. Two patients experienced an infusion-related adverse event during study extension, without interrupting treatment. Notably, no patients developed anti-GA-GCB antibodies up to Month 30. There were statistically significant increases in hemoglobin from baseline (mean increase from baseline = 2.17g/dL; mean percent change of 18.7%; from baseline) and in platelet counts (mean increase from baseline = 85.8 x 103/mm3; mean percent change of 154.0%). At Month 24, MRIs showed statistically significant decreases in the mean percent change of spleen and liver volume from baseline (by 70.9% and 26.9%, respectively). **CONCLUSION:** GA-GCB was generally well tolerated and demonstrated clinical activity in disease parameters in these adult patients with type 1 Gaucher disease. These results have led to the development of Phase III clinical trials that will enroll adults and children.

Association of a *VEGF* functional allele with cardiac atrioventricular septal defects and a possible genetic interaction with *CRELD1* mutations. *C.L. Maslen[1], D. Babcock[1], C.D. Morris[2], S. Sherman[3], L.J.H. Bean[3], K.V. Dooley[4], E. Feingold[5]* 1) Molec/Med Genetics; 2) Medical Informatics, Oregon Health Sci Univ, Portland OR; 3) Genetics; 4) Pediatrics, Emory Univ, Atlanta GA; 5) Human Genetics, Univ. Pittsburgh, Pittsburgh PA.

VEGF is a potent signaling molecule that regulates endothelial cell growth and migration. It plays a key role in heart development in the formation of endocardial cushions, the precursors of atrioventricular (AV) valves and septa. Failure of this process results in the congenital heart defect known as an atrioventricular septal defect (AVSD). Increased expression of VEGF interferes with AV endocardial cushion morphogenesis. A functional *VEGF* polymorphism, +405G/C, is associated with altered VEGF expression. To test the hypothesis that this variant influences risk for AVSD, we compared the allele frequencies between subjects with AVSD and a control population of individuals without a heart defect or family history of congenital heart disease. We analyzed 65 individuals with either complete or partial AVSD (cases) and 34 controls. Among the cases, 33 had Down syndrome (DS) and 32 were non-DS and among controls, 24 had DS and 10 were non-DS. The +405C allele was more prevalent in cases than controls overall ($p<0.025$) and when stratified by DS and non-DS case/control groups ($p=0.04$ and $p=0.04$, respectively). When all cases were stratified by complete versus partial AVSD, there was a highly significant association with the +405C allele compared to controls only among complete AVSD ($p<0.009$), but not among partial cases ($p>0.10$). Overall these results indicate a specific association of the *VEGF* +405C allele with complete AVSD in both the DS and non-DS populations. In previous studies we showed that mutations of *CRELD1* are associated with AVSD. Interestingly, 4/5 AVSD cases with a *CRELD1* mutation also carried at least one *VEGF* +405C allele, and in each case where the *CRELD1* mutation was inherited it came from one unaffected parent while the *VEGF* +405C allele was inherited from the other parent. These preliminary data suggest that there may be an interaction between the *CRELD1* and *VEGF* alleles that increases the risk of AVSD.

Physical activity modifies the genetic effect of common variants in the FTO gene with body mass index (BMI). *E. Rampersaud, B.D. Mitchell, M. Fu, H. Shen, T.I. Pollin, J.L. Ducharme, A.R. Shuldiner, S. Snitker* Department of Medicine, Univ Maryland, Baltimore, MD.

Recently, two groups reported associations with SNPs in intron 1 of the FTO gene on chromosome 16q12.2 with body mass index (BMI) and obesity in multiple large cohorts of Caucasian adults and children. We replicated this association in an Amish population and further assessed whether the genotype effects on BMI were modified by physical activity levels. Our sample included 627 Amish adults (mean BMI = 26.54.5 kg/m2) for whom physical activity was measured with Actical accelerometers worn on the hip for 7 consecutive days. Physical activity was expressed as counts, a raw measure of activity independent of body size. Nine SNPs (r2=0.50-1.0) between rs1861869 and rs9930506 in FTO, including the SNPs previously reported, were associated with sex and age adjusted BMI (P=0.04-0.0002) in an additive genetic model. In further analyses stratified by sex-specific median physical activity, our three most strongly associated SNPs (rs1861869, rs1861868, and rs147796) were associated with BMI in subjects with low ($p < 0.001$), but not high ($p > 0.20$) levels of physical activity (p-values for interaction: 0.015 - 0.012). Since Amish women have less physical activity and higher mean BMI compared with men (27.75.4 and 25.63.2 for BMI respectively, $P< 0.0001$), we evaluated whether sex differences influenced our results by examining the relationship of these SNPs with BMI in men and women separately. We observed significant associations in women with low physical activity levels (p 0.001) and suggestive evidence in the same direction for men with low physical activity ($p = 0.05$). In conclusion, the FTO gene has been identified as a well replicated obesity-related gene, although no functional variant or known mechanism has yet been identified. Our results strongly suggest that the increased risk to obesity due to genetic susceptibility by FTO variants can be modified by physical activity. The efficacy of public health efforts to combat obesity may be increased by targeting genetically susceptible individuals such as those carrying FTO variants.

Design issues related to the generation of a 50,000 SNP array for studying heart, lung, blood and sleep candidate genes. *S. Tischfield[1,2], B. Keating[6], P.I. De Bakker[2], T.R. Bhangale[3], M. Fornage[4], G. Papanicolao[5], S. Gabriel[2], D.A. Nickerson[3], J.N. Hirschhorn[1,2]* 1) Genetics and Endocrinology, Children's Hosp Boston & Harvard Med. School., Boston, MA; 2) Broad Inst of MIT and Harvard, Cambridge, MA; 3) Genome Sciences, U of Washington Seattle; 4) Candidate-gene Association REsource SNP Comm; 5) NHLBI/DPPS,Bethesda, MD; 6) ITMAT, Univ. of Penn., Phil. PA.

Commercial whole genome products are valuable for association studies and cover most common variation in the genome, but coverage varies across genes. To complement these products, we designed an array of 50,000 SNPs to uniformly capture common variation in nearly 2,100 candidate genes related to heart, lung, blood, and sleep phenotypes, in multiple ethnicities. We used the Tagger software package to choose SNPs to capture common variation, individually or in multimarker combinations. We used a cosmopolitan tagging approach to capture common variants in each of the HapMap populations. Some genes were tag hogs (the top 5% required 33% of the tags), only the most compelling candidates among this set were retained. The 400 genes of greatest interest to the group were tagged more intensively. For these genes, we tagged all variants between 5 kb upstream and the 3 end of the gene that had MAF >2% in HapMap, using an r2 threshold of 0.8, requiring an average of 29 SNPS/gene. We supplemented these genes with additional SNPs identified through resequencing efforts (SeattleSNPs) when available. For the remaining genes, variants with MAF >5% were tagged at an r2 threshold of 0.5, requiring an average of 17 SNPs per gene. Several additional strategies were not adopted because of the cost of extra tags. For example, requiring a nonredundant set of variants from commercial genomewide genotyping products required an additional 9 SNPS/gene and tagging a larger flanking region (20 kb 5/10 kb 3) required 10 additional tags per gene. To complete the array of SNPs, we added missense SNPs and SNPs in highly conserved noncoding regions, a set of ancestry informative SNPs and SNPs with prior evidence of association to a phenotype of interest.

A Test for Hardy-Weinberg populations using just two individuals. *N.M. Scott, J. C. Long* Dept. of Human Genetics, Univ. of Michigan, Ann Arbor, MI.

Human Genetic studies often use location, race, or isolate status as a proxy for a population in Hardy Weinberg Equilibrium (HWE). Even so, cryptic population structure is a problem in many samples. Here we provide a multiple locus test to determine if two individuals represent random draws from the same HWE population. Our basic premise is that the proportion of homozygous loci in a single individual is a valid and unbiased estimator for the homozygosity in a HWE population. Therefore, homozygosity should not differ significantly between two individuals from the same HWE population. The comparison of two individuals is strengthened by considering their pseudo-homozygosity, which we define as the probability that, at a locus, a random allele chosen from the genotype of one individual is identical in state with a random allele chosen from the genotype of the other individual. For a pair of individuals from the same HWE population, the expectation of pseudo-homozygosity equals the population homozygosity. Thus, a pair of individuals provides three estimates of population homozygosity.

Here we derive the variances and covariances of these estimates for multiple unlinked SNP loci. We also derive a test statistic for homogeneity of the three estimates and use computer simulation to show that a chi-square distribution with three degrees of freedom fits the distribution of the test statistic. For the case that the homogeneity hypothesis is rejected, we develop linear contrasts to distinguish between two alternative hypotheses: high individual homozygosity between a pair of individuals in comparison to their pseudo-homozygosity, and low individual homozygosity between a pair of individuals in comparison to their pseudo-homozygosity. Biologically, high pseudo-homozygosity is consistent with relatives sampled from the same HWE population, whereas, low pseudo-homozygosity is consistent with sampling individuals from different HWE populations and/or inbreeding. To prove our principles, we apply this method to HapMap population and family trio data sets, and show analytically that it is easy to identify population misplacement and cryptic family structure with genome-wide SNP data. Supported by NIH grant T32-HG00040.

De novo submicroscopic deletion of 20p12.3 involving BMP2 gene in an individual with Wolff-Parkinson-White syndromeIdentifying a new locus for WPW. *SR. Lalani[1], X. Wang[1], W. Bi[1], MS. Bray[1,3], C. Shaw[1], J. Towbin[1, 2], RA. Friedman[2], G. Zapata[1], A. Pursley[1], SW. Cheung[1], JW. Belmont[1], L. Potocki[1]* 1) Dept of Genetics, Baylor Col Medicine, Houston, TX; 2) Dept of Cardiology, Baylor Col Medicine, Houston, TX; 3) Dept of Pediatrics, Baylor Col Medicine, Houston, TX.

Wolff-Parkinson-White (WPW) is a cardiac conduction abnormality that arises from a developmental defect in the atrio-ventricular electrical insulation due to the presence of an accessory pathway. It is known that about 3.4% of the affected individuals (1-3 persons in 1000) have first-degree relatives with pre-excitation, usually inherited as a mendelian autosomal dominant trait. PRKAG2 (7q34-q36) is the only gene, unequivocally known to be associated with familial WPW syndrome. Here, we report an individual with WPW, who bears a de novo submicroscopic deletion of 1.3 Mb on 20p12.3. The deletion, initially detected by clinical BAC array-CGH and fine-mapped with an Illumina HumanHap300 array, involves a single gene, BMP2. This individual was incidentally found to have WPW during the evaluation for suspected seizures and mild respiratory difficulties in the newborn period. Echocardiogram showed an ASD. Although WPW is asymptomatic in this patient, subsequent evaluations revealed pectus deformity, failure to thrive, and mild delay in language expression and comprehension at age 19 months. It is known that Bmp2 is required for myocardial patterning and plays an important role in atrioventricular cushion morphogenesis in mice. We have performed mutation analysis of BMP2 gene in 30 individuals with either isolated, familial, or syndromic WPW and have not found mutations in the coding region of this gene. Quantitative-PCR studies for BMP2 copy number alterations in these individuals are currently being analyzed. Interestingly, another individual with WPW syndrome associated with a larger deletion of 20p12.3 has recently been identified (Thakuria et al., this meeting). We propose that genetic aberrations of BMP2 can cause pre-excitation and deletions involving this gene on 20p12.3 can cause Wolff-Parkinson-White syndrome.

Misregulation of small noncoding regulatory RNAs by the loss of MeCP2 in a mouse model of Rett Syndrome. *K. Szulwach[1], X. Li[2], S. Mathias[3], X. Zhao[2], P. Jin[1]* 1) Dept Human Genetics, Emory Univ, Atlanta, GA; 2) Dept of Neuroscience, University of New Mexico, Albuquerque, NM; 3) Division of Biocomputing, University of New Mexico School of Medicine, Albuquerque, NM.

Rett Syndrome (RTT) is a neurodevelopmental disorder mainly caused by mutations in X-linked gene methyl-CpG-binding protein 2 (MECP2) and primarily affects females. Identification of the genes regulated by MeCP2, particularly in the context of neurodevelopment, is critical for understanding the molecular pathogenesis of RTT. MicroRNAs (miRNAs) are small (18-24nt) noncoding regulatory RNA able to suppress translation from protein coding transcripts without necessarily having an effect on steady state mRNA levels. MeCP2 mediated regulation of miRNA expression, therefore, provides an alternative mechanism by which MeCP2 deficiency could alter expression of proteins without affecting mRNA transcription itself. Toward this end, we have examined the possibility that MeCP2 might regulate a subset of small noncoding regulatory RNAs in neurogenesis. Using TaqMan based miRNA profiling and Solexa 1G sequencing based expression profiling we have assayed expression of small noncoding RNAs in proliferating and differentiated adult neural stem cells (aNSCs) derived from wildtype and MeCP2 knockout mice. We have identified and verified increased expression of at least two miRNAs, mmu-mir-137 and mmu-mir-301, in the absence of MeCP2. Furthermore, we have observed direct binding of MeCP2 to the genomic regions proximal to mmu-mir-137 in wildtype aNSCs using chromatin immunoprecipitation, suggesting that MeCP2 could directly regulate the expression of miRNAs. Furthermore, using Solexa 1G sequencing based expression profiling, we have obtained over 30,000 unique small RNA sequences corresponding to more than 1.5 million individual small RNA derived from both wildtype and MeCP2 KO proliferating aNSCs. We have identified previously unannotated small noncoding RNAs with altered expression in the absence of MeCP2. Our results suggest that MeCP2 could regulate a subset of small noncoding regulatory RNAs and that dysregulation of these small RNAs could contribute to the pathogenesis of RTT.

Impact of diet on the evolution of human amylase gene copy number. *G.H. Perry[1,2], N.J. Dominy[3], K.G. Claw[2], A.S. Lee[1], H. Fiegler[4], R. Redon[4], J. Werner[2], F.A. Villanea[3], J.L. Mountain[5], R. Misra[2], N.P. Carter[4], A.C. Stone[2], C. Lee[1,6]* 1) Brigham & Women's Hospital, Boston, MA; 2) Arizona State University, Tempe, AZ; 3) University of California, Santa Cruz, CA; 4) The Wellcome Trust Sanger Institute, Hinxton, UK; 5) Stanford University, Stanford, CA; 6) Harvard Medical School, Boston, MA.

Recent studies have shown that copy number variation (CNV) among humans is surprisingly common, and there has been intense speculation that CNVs may have played important roles in human evolution. However, few studies have yet directly tested evolutionary hypotheses for CNVs. We performed a detailed evolutionary study of a multi-allelic CNV, the salivary amylase gene (AMY1), which encodes for an enzyme responsible for starch hydrolysis. Specifically, we questioned whether different selective pressures have acted on AMY1 CNV for populations with traditionally high-starch diets (e.g., agricultural societies and hunter-gatherer groups in arid environments) versus populations with traditional diets containing substantially reduced amounts of starch (e.g., rainforest and circum-arctic hunter-gatherers and some pastoralist groups). AMY1 gene copy number was found to correlate positively with salivary amylase protein levels, and individuals from populations with high-starch diets have higher AMY1 copy numbers than those with traditionally low-starch diets. Comparisons with other CNV loci, using data from a whole genome platform, suggested that the observed level of differentiation of AMY1 copy number is highly significant. Our data are consistent with a model of positive or directional selection on AMY1 copy number in high-starch populations, but neutral evolution (i.e., genetic drift) on AMY1 copy number in low-starch populations. This is one of the first examples of positive selection on a human CNV and our study shows that natural selection, in response to behavioral variation, can readily shape the structure of our genomes. Other CNV loci may also be subject to similarly strong pressures of natural selection, related to behavioral or environmental changes.

Functional characterization of a sensory organ-specific miRNA cluster. *P.D. Witmer[1,2], S. Xu[3], J.T. Mendell[1], S. Fisher[1], D. Valle[1]* 1) McKusick-Nathans Institute of Genetic Medicine; 2) Predoctoral Training Program in Human Genetics, Johns Hopkins Univ, School of Medicine, Baltimore, MD; 3) Department of Ophthalmology/Neurological Sciences, Rush Univ Medical Ctr, Chicago, IL.

Using a custom array to profile miRNA expression in adult mouse tissues, we identified a group of miRNAs whose expression is apparently limited to retina. Among these, we identified a polycistronic, paralogous miRNA cluster including *miR-96*, *miR-182* and *miR-183* on mouse chromosome 6qA3 with conservation of synteny to human chr7q32.2. Reported studies and our own results strongly suggest that expression of this cluster is restricted to sensory neurons of the retina, inner ear, olfactory epithelium, taste buds and dorsal root ganglia. Sequence conservation extends to zebrafish, where expression is also detected in the lateral line, a mechanosensory organ. Our hypothesis that members of the *miR-183/96/182* cluster play important roles in sensory neural biology is further supported by analysis of their predicted targets, which includes many genes required for the development and/or function of various sensory organs. We performed *in vitro* functional studies that showed that *MITF*, which is required for the establishment and maintenance of retinal pigmented epithelium, is a direct target of *miR-96* and *miR-182*, suggesting that these miRNAs may contribute to neuroretinal identity. Additionally, we performed *in vivo* functional studies utilizing morpholino-directed knockdown of expression of the *miR-183/96/182* cluster in zebrafish and produced larvae with abnormal balance, swimming abnormalities and an attenuated response to vibrational stimuli. Embryos (5 dpf) treated with DASPEI, a dye that labels sensory hair cells, showed decreased staining or absence of lateral line neuromasts as compared to uninjected controls. Together, our results suggest a phenotype similar to those reported for zebrafish *circler* mutants with known vestibular defects. We conclude that members of the *miR-183/96/182* cluster are important for sensory neuron development and/or function. Additional studies are underway to characterize the nature of the sensory deficits in these fish and relate these observations to human phenotypes.

Genetic associations with ancestral differences in gene expression in the small airway epithelium in response to cigarette smoking. *T.P. O'Connor[1], B-G. Harvey[1], W. Wang[2], A. Clark[2], J. Mezey[2], P. Schweitzer[2], J. Salit[1], I. Dolgalev[1], T. Raman[1], N.R. Hackett[1], R.G. Crystal[1]* 1) Weill Cornell Medical College, New York, NY; 2) Cornell University, Ithaca, NY.

Epidemiologic data suggest that Americans of African ancestry are more susceptible to cigarette smoking than those of European ancestry, with faster rates of lung function decline and increased mortality. In the context that the small airway epithelium (SAE) is the initial site of smoking-associated disease, we hypothesize that: (1) the SAE gene expression profile of individuals of African ancestry responds differently to cigarette smoke compared to individuals of European ancestry; and (2) genome-wide SNP genotyping will reveal *cis*-acting single nucleotide polymorphisms (SNPs) correlated with expression of differentially responsive genes. Gene expression levels in SAE were assessed with Affymetrix HG-U133A Plus 2.0 arrays in 24 healthy smokers (14 of African and 10 of European ancestry) and 18 healthy non-smokers (10 of African and 8 of European ancestry). Smoking-responsive genes in each ancestral group were independently identified as significant with a fold-change >2 and a p value <0.01 in smokers compared to non-smokers. Smokers of European ancestry showed a greater number of smoking-responsive genes (n=356 genes) than smokers of African ancestry (n=188 genes) and, in general, a greater magnitude of differential expression between smokers and non-smokers. For example, xenobiotic metabolism genes were up-regulated in smokers of both groups, but cytochrome P450 1A1 and 1B1 were upregulated 16 and 20-fold, respectively in smokers of African ancestry, while the same genes were upregulated 40 and 150-fold, respectively, in smokers of European ancestry. Genome-wide SNP profiles were obtained on genomic DNA from blood samples from a large cohort of individuals using Affymetrix 5.0 SNP arrays. Significant associations of SNPs within 25,000 base pairs of many of the genes that were differentially responsive to smoking in the two ancestral groups were identified using a likelihood ratio test.

The Angiotensin System Mediates Renal Fibrosis in Glycogen Storage Disease Type Ia Nephropathy. *W.H. Yiu[1], C.J. Pan[1], R.A. Ruef[1], M.F. Starost[2], B.C. Mansfield[3], J.Y. Chou[1]* 1) Section on Cellular Differentiation, Program on Developmental Endocrinology and Genetics, National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, MD 20892; 2) Division of Veterinary Resources, National Institutes of Health, Bethesda, MD 20892; 3) Correlogic Systems, Inc., Rockville, MD 20850.

Glycogen storage disease type Ia (GSD-Ia) patients are deficient in glucose-6-phosphatase- and manifest disturbed glucose homeostasis. While intensive dietary therapies can maintain euglycemia in GSD-Ia, renal disease of unknown etiology remains a long-term complication. In this study we examined whether the angiotensin system mediates renal fibrosis in GSD-Ia mice. The expression of angiotensinogen, the precursor of the multifunctional cytokine angiotensin II, angiotensin type 1 receptor, transforming growth factor-1 (TGF-1) and connective tissue growth factor (CTGF) are elevated in the kidneys of GSD-Ia mice compared to the controls. While the increase in renal angiotensinogen expression was evident in 2-week-old GSD-Ia mice, the increase in renal expression of TGF-1 and CTGF was not observed until the GSD-Ia mice were at least 3 weeks old. This is consistent with the finding that Angiotensin II up-regulates the expression of TGF- and CTGF. In addition, renal expression of genes for the extracellular matrix (ECM) proteins, fibronectin and collagens I, III, and IV were all elevated in GSD-Ia mice, compared to the controls. This was associated with renal fibrosis in the GSD-Ia mice which was characterized by a marked increase in the synthesis and deposition of ECM proteins in the renal cortex and renal histological abnormalities including tubular basement membrane thickening, tubular dilation, and multifocal interstitial fibrosis. Our results suggest that activation of the angiotensin system plays an important role in the pathophysiology of renal disease in GSD-Ia.

Genotype-phenotype analysis in Retinal Vasculopathy with Cerebral Leukodystrophy with 3-truncating mutations in human 3'-5' DNA Exonuclease TREX1. *A.M.J.M. van den Maagdenberg[1,2], A. Richards[3], J.C. Jen[4], D. Kavanagh[3], D. Spitzer[3], M.K. Liszewski[3], M.L. Barilla-LaBarca[3], G.M. Terwindt[2], Y. Kasai[5], M.G. Grand[6], K.R.J. Vanmolkot[1], P.T.V.M. de Jong[7], M. Dichgans[8], K.E. Kotschet[9], T. Hardy[10], S.F. Nelson[11], R.R. Frants[1], R.W. Baloh[4], M.D. Ferrari[2], J.P. Atkinson[3]* 1) Dept Human Genetics, Leiden Univ Medical Ctr, Leiden, Netherlands; 2) Dept Neurology, Leiden Univ Medical Ctr, Leiden, Netherlands; 3) Dept Medicine Rheumatology, Washington Univ, St. Louis, MO; 4) Dept Neurology, UCLA, Los Angeles, CA; 5) Genome Sequencing Ctr, Washington Univ, St. Louis, MO; 6) Dept Opthalmology, Washington Univ, St. Louis, MO; 7) Dept Opthalmology, Academic Medical Ctr, Amsterdam, The Netherlands; 8) Dept Neurology, Klinikum Gross Hadern, Munich, Germany; 9) Dept Neruology, Monasch Medical Ctr, Victoria, Australia; 10) Dept Neurology, Concord Repatriation General Hospital, New South Wales, Australia; 11) Dept Human Genetics, UCLA, Los Angeles, CA.

Our International Consortium set out to identify the molecular defects in patients with Retinal Vasculopathy with Cerebral Leukodystrophy (RVCL,MIM192315), an autosomal dominant microvascular endotheliopathy with middle age onset. The retinal vasculopathy resembles diabetic retinal vasculopathy and delayed post-radiation brain vasculopathy. A large Dutch family and two US families were linked to 3p21. Heterozygous carboxyl-terminal frameshift mutations were identified in TREX1 a ubiquitously expressed 3'-5' repair exonuclease. Frameshift mutations were identified in TREX1 in six additional RVCL families from different parts of the world: in total, five different truncating mutations, including one recurrent mutation present in five unrelated RVCL families. Despite the stereotypic 3-truncating TREX1 mutations, RVCL families show inter- and intra-familial variation with respect to severity and clinical features, including progressive visual loss, migraine, Raynauds phenomenon, liver and kidney dysfunction, stroke, and dementia-like features. TREX1 seems involved in maintenance of vascular integrity.

Polymorphisms in the Tissue Plasminogen Activator gene (*PLAT*) are associated with multiple measures of coronary artery disease. *A.V. Smith[1], T. Aspelund[1], L. Launer[2], T. Harris[2], V. Gudnason[1,3]* 1) Icelandic Heart Association, Kopavogur, Iceland; 2) National Institute on Aging, Bethesda, MD, USA; 3) University of Iceland, Reykjavik, Iceland.

The Tissue Plasminogen Activator gene (*PLAT*) has been implicated in atherothrombotic disease. To investigate the genetic role of *PLAT* into the development and progression of cardiovascular disease, individuals from the Age, Gene/Environment Susceptibility (AGES Reykjavik) Study were typed with polymorphisms from the *PLAT* gene as part of a larger examination of multiple candidate genes. AGES Reykjavik is an extensive and detailed phenotyping of surviving participants (now 67 and older) of the 40 year long Reykjavik study. 2,300 individuals were typed with seven polymorphisms spanning the gene. A single SNP (rs2020919; MAF 0.075) located immediately upstream to the *PLAT* transcript is significantly associated with multiple related phenotypes combined as coronary events (CE) (OR 1.81; p=6.9e-6) consisting of myocardial infarction (MI) (OR 2.04; p=1.1e-5), narrowing of the arterial lumen resulting in bypass surgery (OR 2.32; p=4.2e-7), and percutaneous coronary intervention (1.35; p=0.15). Significant associations are observed in both males and females with similar odds ratios and an overall population attributable risk of 6%. This polymorphism is suggestively associated with coronary artery calcium levels (p=0.01 for top bottom differences), while no association was detected with conventional cardiovascular risk factors currently measured, such as cholesterol levels. These results are consistent with a hypothesis that the polymorphisms in the *PLAT* gene are associated with progression and complications of cardiovascular disease rather than the initiation of disease.

Development of a Low Cost SNP Barcode Panel. *B. Marosy, J.M. Romm, K.N. Hetrick, K.F. Doheny, E.W. Pugh, Y. Tsai* Center for Inherited Disease Research (CIDR) and Genetic Resources Core Facility (GRCF), IGM, JHUSOM, Baltimore, MD.

Advances in SNP genotyping technology have made it possible to produce up to 1 million genotypes for a given sample. These assays are costly; therefore, it is imperative to establish a validation process to pre-test and track samples through the lab and analysis process. CIDR is developing a SNP barcode panel that will uniquely identify individuals and provide pre-testing data to confirm gender, detect Mendelian inconsistencies, cryptic relatedness, mixed/contaminated DNA samples and low concentration samples prior to production genotyping. In order to utilize a SNP barcode, a more cost effective SNP assay is required. The Illumina VeraCode offers low-plex SNP genotyping at a reasonable cost.

Markers were chosen from the 384 Ancestry Informative Markers within all Illumina GWA products. We selected a subset of SNPs based on assay qualities including: location, clustering in both HapMap and experimental samples, allele frequencies in the 3 HapMap populations that minimized the probability that two samples will have identical genotypes even if the two samples are related.

To determine sample performance using SNP pre-testing, without inflating false-pos/neg poor performance rates, we utilized call rates from previous SNP data generated on 5,204 samples from one study that was pre-tested using STRPs. This data was then compared to the actual performance of the samples in production. False pos/neg rates were then calculated based on these comparisons, STRP 0.48%, 3.2% and SNP 0.15% and 2.5%, respectively. To evaluate the VeraCode assay, we performed an Illumina GoldenGate Assay and hybridized product to both a Sentrix Array Matrix and a Veracode Bead Pool. The genotypes generated from VeraCode were 99.988% concordant with GoldenGate and call rates were identical in 93.55% of the samples.

CIDR is beginning to evaluate a production version of the SNPs (OPA) for the SNP Barcode panel. This evaluation will include the ability to uniquely identify samples throughout lab processing and to determine sample quality without inflated false-pos/neg results.

Whole Genome Linkage Disequilibrium Association Mapping of Binary Traits. *P. Scheet*[1], *M. Stephens*[2], *G.R. Abecasis*[1] 1) Dept. Biostatistics, Univ. of Michigan, Ann Arbor, MI; 2) Depts. Human Genetics and Statistics, Univ. of Chicago, Chicago, IL.

Genome wide association (GWA) studies are being used to successfully identify many common alleles that underlie complex disease susceptibility. Most of these studies rely on commercial genotyping panels with 300,000 to 600,000 SNPs. Rarer SNPs, which account for the bulk of genetic variants in human populations, are less well-represented than other variants (directly or through tagging) in these commercial genotyping panels. Haplotype-based approaches may be able to capture the impact of these SNPs on disease susceptibility better than the single marker association tests commonly used in GWA analysis. Unfortunately, traditional haplotype-based methods suffer either from the "curse of high dimensionality" due to the large number of unique haplotypes in a sample, or from reduced power due to considering haplotypes of a small number of SNPs only. Inherent in these approaches is the added complication of first estimating haplotypes. We introduce a method for mapping disease associated variants in case-control studies. Our method may be applied to unphased data directly, summarizing the evidence for association at any position while taking into account the information on all flanking SNPs. The method allows the information from adjacent markers to decrease gradually, mimicking linkage disequilibrium (LD) patterns in the region. To flexibly capture such patterns of LD, we use a hidden Markov model for genetic variation based on clustering the latent haplotypes over short regions. Parameters are estimated with an expectation-maximization algorithm. We then test for association between the trait and each haplotype cluster. On simulated data, our method offers an increase in absolute power of 34% over single-marker tests when the disease allele is rare (< 5%) and typically untyped. A preliminary analysis of a large case-control study of type 2 diabetes (FUSION) using 2,335 individuals identifies promising leads for further analysis. We are currently extending our method, implemented in the software package fastPHASE, to deal with quantitative traits, as well.

GENETIC AND NON-GENETIC SOURCES OF PHENOTYPIC VARIATION IN HUMAN LYMPHOBLASTOID CELL-LINES. *R. Yelensky[1,5,7], E. Choy[1,2,7], S. Bonakdar[1], R.M. Plenge[1], P.L. de Jager[1,3], R. Saxena[1,2], E. McFarland[6], C. Wolfish[1,3], E. Kieff[6], D.A. Hafler[1,3], M. Daly[1,4], D. Altshuler[1,2,4]* 1) Broad Institute, Cambridge, MA; 2) Molecular Biology, MGH, Boston, MA; 3) Neurology, B&W Hospital, Boston, MA; 4) CHGR, MGH, Boston, MA; 5) HS&T, MIT, Cambridge, MA; 6) Channing Lab, B&W Hospital, Boston, MA; 7) equal contributors.

Lymphoblastoid cell lines (EBV-transformed human B-cells) are an exciting new ex-vivo model for population genetics combining advantages of model organisms with benefits of working directly on human biology. Genotyped LCLs have already been successfully used to study gene expression and attempts have been made to identify DNA variants that influence response to radiation and chemotherapy. However, for LCLs to be broadly useful as a generic ex-vivo human model, it is critical to understand the relative contributions of genetic and non-genetic influences to cellular phenotypes. The field has focused on genes with cis-eQTLs, but in fact these make up only a small fraction of expressed RNAs. Pharmacogenetic studies in LCLs, while promising, have thus yielded few replicated results.

We sought to advance our knowledge of this important new model system by elucidating both genetic and, importantly, non-genetic factors influencing LCL phenotypes. We profiled essential cell-line properties - EBV genome, cell surface receptor and cytokine make-up (i.e. the B-cell immuno-phenotype), in vitro growth rates and metabolic state - and assessed their influence on RNA expression and drug response. We find that while a small fraction of phenotypic variation can be consistently related to DNA (~5% of RNAs in current studies), a much greater proportion is explained by these cell-line dependent factors. For instance, 24% of all well-measured, varying genes in LCLs appear to be determined by EBV and the secreted cytokine milieu, while chemotherapeutic response is markedly influenced by baseline growth rate and metabolic state. These findings reveal important, previously uncharacterized, modifiers/confounders of genetic effects in LCLs and will guide both interpretation of prior studies and design of future work.

Association of *NALP1* genotype with immune cell survival and autoimmune disease. *C.M. Mailloux[1], M.G. Netea[2,3], E.C. Lewis[2], Y. Jin[1], C.A. Dinarello[2], R.A. Spritz[1]* 1) Hum Med Genet Prog, Univ Colorado Hlth Sci Ctr, Aurora, CO; 2) Dept Medicine, Univ Colorado Hlth Sci Ctr, Aurora, CO; 3) Dept Medicine, Radboud Univ Nijmegen Med Ctr, Nijmegen, Netherlands.

Generalized vitiligo is a common, multifactorial, polygenic disease in which autoimmune loss of melanocytes results in depigmented spots of skin and overlying hair, often associated with other autoimmune disorders. We recently showed that vitiligo and co-occurring autoimmune diseases are associated with common high-risk genetic variants of *NALP1*. NALP1 is an NLR protein that is a key component of the inflammasome, binds the anti-apoptotic proteins Bcl-2 and Bcl-X_L, and regulates both the caspase-1 mediated inflammatory response and apoptotic pathways in response to pathogen-associated molecular patterns such as muramyl dipeptide. As some autoimmune diseases appear to involve defects of apoptosis, with elevated or prolonged expression of Bcl-2, we hypothesized that *NALP1* variants associated with vitiligo might result in defective apoptosis of immune cells. To test this hypothesis, we assayed survival in culture of unstimulated peripheral blood monocytes from patients with vitiligo-associated multiple autoimmune disease versus healthy controls. Overall, survival of monocytes from patients was significantly prolonged compared to monocytes from controls. Furthermore, this difference was directly related to carriage of high-risk *NALP1* genotypes, rather than to disease state; survival of monocytes from individuals carrying high-risk *NALP1* genotypes was significantly prolonged compared to monocytes from individuals with low-risk *NALP1* genotypes. Our findings provide a direct correlation between *NALP1* genotype and survival of immune cells that may contribute to the development of the autoimmune response.

Therapeutic implications of a differential response to rapamycin in cells from Gorlin Syndrome patients versus unaffected controls. *M.R. Rossi[1], B. Hoffman[1], J. Zhou[1], S. Westman[1], P. Beck[1], S. Mane[1], L.M. Milstone[1], J.A. Crowell[2], L. Kopelovich[2], A.G. Knudson[3], A.E. Bale[1]* 1) Yale University School of Medicine, New Haven, CT; 2) National Cancer Institute, Bethesda, MD; 3) Fox Chase Cancer Center, Philadelphia, PA.

Basal cell nevus syndrome (BCNS), also known as Gorlin Syndrome, is an autosomal dominant disease characterized by palmar pits, jaw cysts, skeletal anomalies, and multiple basal cell carcinomas (BCCs). Although the BCCs associated with BCNS are rarely life threatening, they lead to disfigurement and are a major clinical management challenge in these patients. BCNS is caused by heterozygous mutations of the PTCH1 gene, a regulator of the hedgehog (HH) signaling pathway. Hereditary and sporadic BCCs arise through a two-hit mechanism in which both copies of PTCH1 are inactivated, resulting in aberrant HH signaling mediated through the GLI family of transcription factors.

Rapamycin is an antagonist of cellular transformation by GLI, but this effect is not mediated directly by HH signaling and the mechanism is unknown. In a phase I clinical trial, global gene expression was used as an endpoint to measure the effects of rapamycin on BCNS-derived cells in vitro. Biopsies from normal-appearing skin from a total of 9 BCNS patients (5 male, 4 female) and 8 unaffected controls (4 male, 4 female) were used to generate primary keratinocyte and fibroblast cultures. These cultures were treated with 10 and 50 M of rapamycin, and RNA was extracted and analyzed using the Affymetrix U133 Plus 2.0 expression array. The resulting data showed no statistically significant expression differences between BCNS patients and controls before treatment, but major differences in gene expression were observed following rapamycin treatment for both keratinocytes and fibroblasts. Analysis of the genes accounting for these differences revealed novel transcriptional targets of rapamycin, and also provided insight into the mechanism of action of rapamycin in blocking effects of HH pathway activation. Rapamycin or a derivative is promising as a pharmacologic agent for prevention and treatment of BCCs in vivo.

The Million Minds Approach: Community Annotation and Discovery in A Wiki for Professionals. *B. Mons[1,2,3], P.B. 't Hoen[1], M. Schuemie[2], E. van Mulligen[2,3], C. Chichester[1,3], J. den Dunnen[1], R. Jelier[1,2], H. van Haagen[1], A. Botelho bovo[1], Knewco Inc, Open Progress* 1) Human Genetics , Leiden University Medical Center, Leiden, ZH, Netherlands; 2) Erasmus Medical Center Rotterdam, Netherlands; 3) Knewco Inc. Rockville, MD USA.

The scientific literature contains an exploding number of factual relationships between concepts that are pertinent. A growing subset of these relevant facts, such as the confirmed function of proteins have been curated in databases and these have become indispensable tools for biological research. However, the exponential growth of discovery renders complete annotation of the literature for facts by any central team of experts an unachievable goal. Here we describe a system to use the power of a million minds to counter the information overload. We coin the process with the term Community Annotation, which is an interactive, collaborative process, of immediate added value to the day-to-day core activities of the collaborating Scientists. Web 2.0 technologies have been developed to generate a first version of a Community Annotation System. The approach is based on a relational Wiki-environment, supported by a new way to summarize knowledge about concepts and their interactions in a dynamic ontological structure called Knowlets. Knowlets contain multiple relationships between concepts that are both qualitative and quantitative. A knowlet space can be created based on mining with different technologies and approaches. The beta-system currently contains over 1 million Knowlets of concepts in Medline and a potential number of 1 million Author Knowlets. The system was recently featured in a Nature editorial (Nature 445, 691 (Feb 2007). Recent results provide proof of concept for the discovery of implicit knowledge from the literature using our methods. Scientists that currently struggle with the under representation of their favourite genes and proteins in established central data bases will be able to use the open source system to annotate their own part of the Knowlet space and will generate an interactive in silico discovery environment for themselves in the process.

Copy Number Variation in Individuals with Hypoplastic Left Heart. *J.T.C. Shieh[1,3], G.M. Shaw[4], D. Srivastava[2,3]*
1) Div. Medical Genetics,; 2) Div. Pediatric Cardiology, Dept. Pediatrics, University of California San Francisco; 3) Gladstone Institute of Cardiovascular Disease, San Francisco, CA; 4) California Birth Defects Monitoring Program, Berkeley, CA.

Hypoplastic left heart (HLH) syndrome is a form of congenital heart disease with high morbidity and mortality despite advances in surgical techniques. Although many of the molecular mechanisms underlying normal cardiogenesis are known, it is still unknown why the left ventricle fails to develop in this condition. Furthermore, genes whose expression is specific for the left ventricle are lacking. We have performed genome-wide screening for critical genes that underlie hypoplastic left heart.

To determine susceptibility genes in HLH, we collected blood samples from affected individuals and examined them for unique regions of copy number variation (CNV). We ascertained cases of HLH and parental samples from Cardiology clinic. Of those with normal karyotypes, we determined regions of copy number variation using high-resolution oligonucleotide-based comparative genomic hybridization (CGH). The size of CNV ranged from 20kb to 650kb. Using bioinformatics, we determined unique regions of CNV that have not been reported in normal individuals. By testing parents, we demonstrate that although some of these regions are inherited, some represent unique regions of relative copy number gain or loss. These regions encompass potential candidate genes for disease. To aid in evaluating candidate loci, we reviewed 719 HLH cases from the California Birth Defects Monitoring Program. In this cohort of HLH cases, nearly half of the cases included septal defects or potential laterality defects affecting the heart and blood vessels; 6 percent of cases had chromosome abnormalities such as Trisomy 21, 18, 13 and Turner syndrome. The remainder consisted of 334 cases of classic HLH often associated with outflow tract abnormalities. Some of these cases demonstrate specific chromosome abnormalities that will be correlated with regions of copy number variation. This combined approach has the potential to reveal novel candidates for hypoplastic left heart.

Shades of gray: A comparison of linkage disequilibrium (LD) between the CEPH and Hutterite populations. *E. Thompson[1], Y. Sun[1], D. Nicolae[1,2], C. Ober[1]* 1) Department of Human Genetics, The University of Chicago, Chicago, IL; 2) Departments of Statistics and Medicine, The University of Chicago, Chicago, IL.

Founder or isolated populations have advantages for genetic studies due to the decreased genetic and environmental heterogeneity that characterize these populations. Moreover, longer range LD in many of these populations should facilitate gene localization, but extensive LD may limit the utility of these populations with respect to gene identification. The North American Hutterite population is one of the best characterized young founder populations and this isolate has been the subject of our studies of complex traits, including asthma, allergy, and cardiovascular disease, for >10 years. Here, we assess the patterns and extent of global LD using SNP genotypes with minor allele frequencies (MAFs) >5% from the Affymetrix GeneChip Mapping 500K array in 60 relatively unrelated Hutterites and 60 unrelated CEPH Caucasians (HapMap). We surveyed six 500kb genomic regions representing low recombination (12q), high recombination (22q), gene rich (18q), gene poor (21q), and Xp and Xq, as well as a long (chr 2q) and short (chr 21q) chromosome arm. Median (upper, lower quartiles) r^2 was 0.054 (0.147, 0.015) in Hutterites and 0.033 (0.099, 0.007) in CEPH on chromosome 2q and 0.042 (0.115, 0.011) in Hutterites and 0.023 (0.070, 0.005) in CEPH on chromosome 21q among SNP pairs within 500kb. Although LD among some marker pairs extend further in the Hutterites compared to CEPH, the pattern of LD and MAFs are remarkably similar in the two populations. These results indicate that 1) identifying disease genes should be no more difficult in the Hutterites than in outbred Caucasian populations, and 2) the same common disease alleles should be present in the Hutterites and outbred populations. On the other hand, the homogeneous environment that results from their communal lifestyle may enhance the effects of genes and facilitate gene discovery in the Hutterites.

Integrated genetic and epigenetic studies of breast cancer progression and metastasis using Affymetrix SNP chips. *M. Lee, N. Diaz-Meyer, M. Kadota, H. Yang, W. Lin* Laboratory of Population Genetics, National Cancer Institute, Bethesda, MD 20892 USA.

Breast cancer is one of the most common human cancers. The prognosis for primary breast cancer varies considerably from patient to patient. Lymph node metastases and tumor stage appear to be the most reliable prognostic indicator for primary breast cancer. Breast cancer progression and metastasis depends on the interactions among genetic background, environmental exposures, and somatic genetic/epigenetic alterations. To identify genetic/epigenetic mechanisms that determine cancer progression, we perform genotyping, copy number alteration, and allele-specific DNA methylation analyses using Affymetrix SNP chips (10K and 500K) in 21 pairs of breast cancers that were from ductal carcinoma in situ (DCIS), invasive breast cancer (IBC), and lymph node positive cancers and their matched normal samples. In addition, we performed genomic and epigenomic studies on four MCF10A series of breast cancer cell lines that can give rise to benign tumor, differentiated carcinoma, and poorly differentiated metastatic carcinoma in xenograft. Our studies identified ten genes including SPOCK, GRM7, AQP9, RPS6KA5, AGPS, CRY1, DSCAM, PKHD1L1, PBX1, and LSAMP that showed significant methylation changes between normal and tumor. We also identified 8 genes including GPC6, TIMP2, FBN1, SYTL3, DGKH, KCTD10, SH3GL3, and ARID1B that showed significant methylation difference between node positive and negative tumors. Interestingly, Kaplan-Meier survival analysis showed significant difference when samples are split by the gene expression for five of the 8 genes (GPC6, TIMP2, FBN1, SYTL3, SH3GL3). We also identified a 10-Mb region on 2q14 showing contiguous hypomethylation in tumor samples. Intriguingly, hypermethylation on 2q14 was recently identified as a common global epigenetic marker in colon cancer. We are currently validating our results in a panel of 200 pairs of breast cancer samples. Our goal is to identify genetic/epigenetic signature that can predict breast cancer progression and metastases.

Prevalence of Gastrointestinal Symptoms and Effects of Enzyme Replacement Therapy with Agalsidase alfa in a Cohort of Young Fabry Patients. *R.V. Parini[1], F. Santus[1], P. Desveaux[2], G. Pintos-Morell[3], U. Ramaswami[2]* 1) Metabolic Diseases Unit, Department of Paediatrics, San Gerardo Hospital, Monza, Milano, Italy; 2) Paediatric Metabolic Unit, Addenbrookes Hospital, Cambridge, UK; 3) Dept. of Paediatrics, University Hospital Germans Trias i Pujol, Badalona, Spain.

Gastrointestinal (GI) symptoms are frequent in Fabry Disease. Our aim was to assess the prevalence of GI symptoms and the effect of Enzyme Replacement Therapy (ERT) with agalsidase alfa in a young population with Fabry disease followed in 3 metabolic centers.Number and frequency of GI symptoms were analysed in 41 patients (20 males and 21 females) less than 21 years of age. 17 (13 males and 4 females) are on ERT and have been treated for at least 1 year. 29/41 patients (70%) had GI symptoms more than once a week. Most frequent GI symptoms were abdominal pain (27), diarrhoea (13), constipation (11) nausea (8), bloating (9) and vomiting (5). 2 patients had all 6 symptoms. 19/29 patients (65%) had more than one symptom. No patient had gastritis, haemorrhoids, ulcer or pancreatitis. **Treated subgroup:** At baseline, 12/17 (70%) had GI symptoms and 11/12 (92%) had symptoms more than once a week. Data after 12, and 24 months of ERT show a reduction in frequency of GI symptoms. The number of patients with GI symptoms fell from 12 at baseline to 9 and 5 at 12 and 24 months respectively. Number of patients with GI symptoms more than once per week fell from 11 at baseline to 3 and 1 at 12 and 24 months. **Conclusion** 70% of our young patients with Fabry disease had GI symptoms. They had a clear benefit from ERT with agalsidase alfa. Favourable effects appear early after starting treatment and are sustained.

Direct and indirect mutation analysis for preimplantation genetic diagnosis (PGD) of cystic fibrosis (CF). *B. Tazon-Vega, A. Victor, C. Zhang, O. Davis, S. Spandofer, K. Amoroso, Z. Rosenwaks, KP. Xu* Center for Reproductive Medicine and Infertility, Weill Cornell Medical College, New York, NY.

CF is a common severe autosomal recessive disorder. Misdiagnosis may occur when PGD for CF is performed by mutation detection only due to allele dropout (ADO) from single cells and it is not applicable to couples carrying unknown mutations. Linkage analysis using polymorphic markers can indirectly diagnose the disease while also assessing ADO. Our objective was to provide more reliable and suitable PGD for most CF couples. Linkage analysis for the couple and available relatives is performed prior to PGD with 1 flanking marker and 3 intragenic markers of the *CFTR* gene: *D7S522*, *IVS1CA*, *D7S677*, and *IVS8CA*. This analysis determines the paternal and maternal haplotypes linked to CF. Informative markers are tested by co-amplification (with the mutation if known) from single peripheral blood lymphocytes prior to IVF-PGD treatment. During IVF-PGD, single blastomeres are obtained on day 3 after fertilization, a multiplex PCR reaction of the informative markers and the mutation is carried out followed by individual nested PCR; amplified products are run on a genetic analyzer. This approach has been applied to 3 couples in our center, 2 of which have both members carrying the F508 mutation. The paternal mutation for the third couple was F508 and the maternal unknown. Amplification efficiency for all markers was 90% and ADO was 10% for lymphocytes. Overall 26 embryos were biopsied obtaining a total of 30 blastomeres. Six embryos were diagnosed as non-carriers, 12 carriers, and 7 affected. One embryo had an inconclusive diagnosis due to ADO. Two embryos were transferred for each couple resulting in one ongoing and one biochemical pregnancies. It is worth noting that in the couple with an unknown maternal mutation, of the 11 embryos analyzed 6 would have been considered non-transferable if microsatellite markers had not been used to distinguish the maternal chromosomes. Linkage markers flanking the *CFTR* gene allow for fully informative PGD in most CF couples even if they carry unknown mutations, thus reduce the risk of misdiagnosis.

Atypical pattern of multiple malformations: pseudo-trisomy 13 syndrome with syngnathia? *C.C. Rebelo[1], C.M. Lourenço[1], L.C. Peres[2], J.M. Pina-Neto[1], V.E.F. Ferraz[1]* 1) Department of Genetics, Medical School of Ribeirão Preto, University of São Paulo, Ribeirão Preto, Brazil, MD; 2) Department of Pathology, Medical School of Ribeirão Preto, University of São Paulo, Ribeirão Preto, Brazil, MD.

The pseudo-trisomy 13 syndrome is characterized by variable multiple anomalies including holoprosencephaly, polydactyly, severe facial anomalies and other defects, resembling trisomy 13. Autosomal recessive inheritance is suggested for this disorder due to cases with consanguinity. We report on a fetus who was born with multiple malformations at 34 weeks of gestational age, from a nonconsanguineous couple. Ventilation of the baby was not possible due to choanal atresia and syngnathia. The clinical examination showed microcephaly, exorbitism, microphtalmos, facial asymmetry, microtia, microstomia, preaxial polydactyly, meningocele and abnormal external genitalia. On necropsy it was observed holoprosencephaly, syngnathia, hypoglossia, single umbilical artery, hemivertebrae, uterus bicornis. Heart and kidneys were normal at examination. Skin fibroblast karyotype was 46,XX. The present case may expand the spectrum of the pseudo-trisomy 13 syndrome, including syngnathia as an additional feature.

CHROMOSOMAL DELETIONS WITHOUT PHENOTYPIC EFFECT: GENE DENSITY IN THE HUMAN GENOME. *S. Li, R. Hyde, P. Blackett, J.J. Mulvihill* Dept Ped/Gen, BSEB 224, Univ Oklahoma Hlth Sci Ctr, Oklahoma City, OK.

The infrequent reports of constitutional chromosomal deletions with no phenotypic abnormality beg an explanation. One speculation was that such abnormalities occur in genomic regions of low gene density. With Borgaonkars Chromosomal Variation in Man and PubMed searching, most reports of such deletions in clinically normal individuals were assembled. The distribution of genes on all chromosomes was retrieved from online databases for the human genome and averaged 8.64 genes/Mbp. For all 52 normal individuals reported with cytogenetic deletions, the calculated gene density of each deleted region averaged 4.14 3.20 genes/Mbp. For comparison, in individuals with mild clinical abnormalities, the deleted regions had a calculated average gene density of 7.03 2.14 genes/Mbp (n=41). We therefore conclude that there is a significantly (p=0.002) lower gene density in the deleted regions associated with a normal phenotype. It appears that the severity of the phenotypic outcome is at least partly controlled by the gene density of the deleted region; or, conversely, only regions of sparse gene densities can deleted without clinical phenotypic abnormalities.

A genome-wide association study of autism finds association to a locus on chromosome 1. *L. Weiss[1,2], T. Green[1,2], S. Santangelo[1], P. Sklar[1,2], M. Daly[1,2]* 1) Center for Human Genetic Research, Harvard-MGH, Boston, MA; 2) Broad Institute, Harvard-MIT, Cambridge, MA.

Autism has been estimated to be the most heritable psychiatric disease, yet, to date, linkage and association studies have not explained a substantial proportion of the genetic susceptibility to autism. We have partnered with the Autism Genetics Research Exchange (AGRE) to conduct a large genome-wide association study on over 2500 members from more than 700 multiplex families from the AGRE family database using the Affymetrix 5.0 platform. Employing a new algorithm, Birdseed, to make genotype calls, and PLINK for QC and genome-wide analysis, we have obtained data for more than 400,000 polymorphic SNPs that pass strict QC thresholds. Association was evaluated with a family-based TDT. Preliminary analysis reveals one locus on chromosome 1 in a nongenic region that meets strict criteria for genome-wide significant association by the TDT. This will be followed up by integration of independently genotyped NIMH control samples to increase power and additional genotyping in the chromosome 1 region to finemap the association signal. Several other signals of suggestive significance will also be followed up. In addition, we are performing a high resolution evaluation of de novo copy number abnormalities and testing common copy number polymorphisms for association with autism, using SNP probes as well as an additional 420,000 distinct invariant oligonucleotide probes intended expressly for copy number estimation.

Genomic strategy identifies Stratifin (*SFN*) and WD-Repeat Domain 65 (*WDR65*) as candidate genes for cleft lip and palate. *N. Rorick[1], A. Kinoshita[1], M. Peyrard[2], S.L. Goudy[3], J. Weirather[1], R. Ferreira de Lima[4], D. Moretti-Ferreira[4], H. Koillinen[5], J. Kere[2], J.C. Murray[1], B.C. Schutte[1]* 1) Genetics PhD Program, Univ Iowa, Iowa City, IA; 2) Karolinska Institutet, Huddinge, Sweden; 3) Vanderbilt University, Nashville, TN; 4) UNESP, Botucatu, Brazil; 5) University of Helsinki, Helsinki, Finland.

Genetic variation in the transcription factor Interferon Regulatory Factor 6 (*IRF6*) causes Van der Woude (VWS) and popliteal pterygium syndromes (PPS), two autosomal dominant orofacial clefting disorders, and contributes risk for isolated cleft lip and palate (CLP). We hypothesized that genes regulated by IRF6 might also be involved in orofacial clefting disorders. We used five criteria to identify potential IRF6 target genes; differential gene expression in skin taken from Irf6 wild type and mutant mouse embryos, localization to the VWS2 critical region (1p36-1p32), overlapping expression with *Irf6*, presence of a conserved putative IRF binding site in the promoter region, and a mutant mouse phenotype that is similar to the *Irf6* mutant mouse. Microarray analysis showed altered expression for 573 genes, and 13 of these genes were located in the mouse region syntenic to the VWS2 locus. Two of these genes, *Wdr65* and *Sfn* (14-3-3 sigma), met four of the five possible criteria. *Wdr65* is a novel gene that encodes a predicted protein of 1250 amino acids with two WD domains. *Sfn* encodes a phosphobinding protein, and like *Irf6*, is required for skin, limb and craniofacial development in mice. As potential targets for Irf6 regulation, we hypothesized that disease-causing mutations will be found in both *WDR65* and *SFN* in clefting populations. No mutation was identified in either gene in the proband with VWS2. However, a potentially etiologic missense mutation was found in *WDR65* in a patient with VWS that does not have exonic mutations in IRF6, suggesting that *WDR65* could be a second causative gene for VWS. Additionally, a potentially etiologic mutation in *SFN* was found in a patient with isolated CLP. In sum, this genomic approach identified two new candidate genes for CLP, *WDR65* and *SFN*.

Molecular pathogenesis of isolated multiple cutaneous neurofibromas in segmental NF. *J.B. Williams[1], O. Maertens[2], T. Callens[1], B. Yuan[1], A. Carroll[1], F. Mikhail[1], A. Theos[3], B. Korf[1], L. Messiaen[1]* 1) Genetics, UAB, Birmingham, AL; 2) Medical Genetics, Ghent University Hospital, Belgium; 3) Dermatology, UAB, Birmingham, AL.

The large size of the *NF1* gene and its many pseudogenes, the complex interactions between cell types and the *NF1* haploinsufficient state of all cells in the body complicate the elucidation of the biological framework underlying the development of the wide range of neurofibromatosis type 1 (NF1)-related symptoms and complications. Determining the timing during development and the cell-type disturbed by the constitutive and somatic *NF1* mutations will be critical for understanding the phenotype in NF1 and its alternate forms. We and others have recently shown that a second *NF1* hit in specific cell types within the lesion is associated with CAL-spots, neurofibromas, gastrointestinal tumors, JMML and tibial dysplasia. We studied a 50-yo woman with a segmental phenotype consisting of ~50 cutaneous neurofibromas (diameter 3-7mm) restricted to the R-ear, cheek and neck in the absence of any other signs of disease. No *NF1* mutation was found in her blood lymphocytes. Accurate diagnosis of segmental NF was established through *NF1* comprehensive mutation analysis on various cell types cultured from 8 cutaneous neurofibromas. An identical first hit mutation (*NF1* total gene deletion, type 1) as well as a different second hit mutation was present in all 8 Schwann cell (SC) cultures, selectively cultured in the absence of forskolin ($SC^{-/-}$). Interestingly, the neurofibromas arose within the background of predominantly *NF1* wild-type cells: the total gene deletion was absent in the fibroblasts and only present in ~10% of the Schwann cells from the $SC^{+/-}$ cultures, indicating the abundance of $NF1^{+/+}$ cells in the neurofibroma environment. The data indicate that the clinical phenotype of segmental NF in this patient is due to a post-zygotic first-hit *NF1* mutation in a neural-crest derived SC precursor, followed by different *NF1* second hit mutations at a later point in time/development. The strategy proposed allows a more accurate diagnosis and genetic counseling in patients with segmental and/or mosaic *NF1*.

Public Policy Issues Surrounding Genetic Information and Long-Term Care Insurance. *E.M. Ramos[1], K.L. Edwards[2], E. Ramos[3], W.A. Kukull[2], C.A. Watts[2]* 1) NHGRI, Bethesda, MD; 2) U. of WA, Seattle, WA; 3) ASHG, Bethesda, MD.

Objective: Information gleaned from genetic tests for Late-onset Alzheimers disease (LOAD) may affect access to long-term care (LTC) insurance. We applied a policy framework to dissect this difficult issue. **Background:** LOAD is a prevalent, complex neurodegenerative disease that leads to severe disability and the need for expensive nursing home or at-home care. LTC insurance is one mechanism to cover these costs. It has been difficult to elucidate the genetic and environmental stimuli that influence LOAD onset. Only APOE has been verified as a genetic risk factor. As new research tools are implemented, such as genome-wide association studies, additional genetic variants may be uncovered. **Methods:** A literature search was conducted to inform the elements of the policy framework including outlining relevant background information pertaining to genetic testing, LTC insurance, and adverse selection; identifying the stakeholder groups and analyzing their interests and concerns; generating a list of potential policy options to regulate the use of genetic information in LTC insurance; and evaluating these options to determine the consequences of implementation. **Results:** We identified insurance applicants and their families, insurance companies offering LTC policies, state and federal governments, employers, and genetic testing companies as the primary stakeholders. Each group has distinct interests that define their public policy positions. Policy options range from prohibiting the use of all genetic information in LTC insurance to imposing no regulations and allowing market forces to drive the future of LTC insurance. **Conclusions:** Policymakers must balance complex issues including equity, accessibility, and affordability when instituting legislation that regulates use of genetic information in the LTC insurance market. Many policy options exist and each needs careful evaluation to ensure that appropriate coverage for LTC insurance is available for consumers. **Disclaimer:** This abstract was prepared while Dr. Ramos was employed at the U of WA. The opinions expressed here are the authors own and do not reflect the views of the Dept. of Health and Human Services.

Hypomethylation of the *H19/IGF2* ICR1 in Russell-Silver Syndrome. *M. S. Penaherrera[1], S. Weindler[2], M.I. Van Allen[1], S. Langlois[1], W.P. Robinson[1]* 1) Dept. Medical Genetics, University of British Columbia, Canada; 2) Fac. of Medicine, University of Leipzig, Germany.

Russell-Silver Syndrome (RSS) is characterized by pre- and post-natal growth deficiency, dysmorphic facial features, relative macrocephaly and body asymmetry. Around 10% of RSS cases are associated with maternal uniparental disomy for chromosome 7 (UPD7). Methylation sensitive Southern Blot analysis of the telomeric imprinting center region (ICR1) of *H19/IGF2* has previously shown that 20-55% of RSS cases (n=89) are associated with epimutations at 11p15. To further evaluate this we assessed the methylation status of two CpGs within ICR1 in peripheral blood of 22 RSS patients and 22 unaffected, age-matched controls using Single-Nucleotide Primer Extension (SNuPE). The methylation status at both sites was highly correlated (r^2=0.95; p<0.0001). The mean percent methylation at ICR1 in the patients (29.9%, SD +/-11.21) was significantly lower than that of the controls (37.8%, SD+/-5.69) (p= 0.005; Students t-test). If hypo- and hypermethylation are defined as a value of more than 2 standard deviations (SD) below and above the mean of the controls, then 8 of 22 (36%) patient samples but no control samples in our series showed evidence of hypomethylation. The distribution of the patient methylation values is consistent with at least two distinct etiologies of RSS, in which approximately 1/3 of cases are associated with ICR1 hypomethylation. In this subgroup, the mean methylation value was 15.8% (SD+/-4.93). UPD11p15 was excluded in all cases. Two cases with UPD7 had normal methylation values. Pairwise comparisons between the presence or absence of a series of clinical features between the hypomethylated and normally methylated group showed no statistically significant differences. Methylation analysis is a useful tool to confirm the clinical diagnosis of RSS; however, it is not clear if such errors arise due to some other underlying factor. We are currently extending the methylation analysis of this region to several other CpGs located within the ICR1 using pyrosequencing.

CD36 as a Candidate Gene for the Metabolic Syndrome. *L. Love-Gregory, R. Sherva, L. Sun, J. Wasson, R. Neuman, M.A. Permutt, N.A. Abumrad* Washington University School of Medicine, St. Louis, MO 63110.

A genome scan in African American (AA) families of the Hypertension Genetic Epidemiology study (HyperGEN) identified a QTL for beta cell function and another for insulin sensitivity on chromosome 7q near a 1.2Mb region encompassing the CD36 gene. CD36 is a transmembrane glycoprotein that facilitates fatty acid (FA) uptake into adipose and skeletal muscle tissues. Impairment of FA metabolism is implicated in the etiology of obesity, insulin resistance, and hypertension (central components of the metabolic syndrome, MS). AA have a high incidence of variability at the CD36 locus and this may play a role in the susceptibility to obesity and related diseases in this population. We obtained DNA and clinical parameters from 2300 AA HyperGEN participants. We initiated genotyping of tag SNPs across CD36 and its promoter regions to determine if common variants in this region are associated with MS and how they impact CD36 expression. Of 40 SNPs genotyped in 2020 subjects, 90% have minor allele frequencies (maf) 5%. Preliminary analyses of data adjusted for age, gender, BMI, and recruitment site identified 4 non-coding SNPs that increase risk for MS ($p<0.034$). However, the minor allele (m.a.) of 1 coding SNP (maf 10%; to-date only identified in subjects of African ancestry) associates with decreased odds ratio for MS, OR 0.710 (95% CI 0.52-0.95, p 0.0098), decreased triglycerides ($p=0.0058$), and increased HDL-C ($p=0.0002$) The coding SNP is predicted to cause complete CD36 deficiency in subjects homozygous for the m.a. while heterozygous subjects likely have reduced CD36 levels. Data were analyzed using PROC GENMOD in SAS (regression, Additive Model) in which SE were adjusted to for family relationships. Subsequent analysis with FBAT confirmed findings. Although these data suggest that the m.a. is protective, subjects homozygous for the m.a. (presumably CD36 deficient, n=10) trended metabolically (higher mean TGs and lower HDL) in the opposite direction vs. heterozygotes. These findings suggest that variants in the CD36 gene influence metabolic syndrome susceptibility and that partial vs. complete CD36 deficiency may associate with different phenotypic outcomes.

The genetics of Oculocutaneous Albinism: molecular results in a European and African cohort. *C. Rooryck[1,2], F. Morice[2,3], V. Bubien[2], D. Lacombe[2], A. Taieb[3], B. Arveiler[1,2]* 1) Laboratoire Génétique Humaine, Université Victor Segalen, Bordeaux, France; 2) Service de Génétique Médicale, Hôpital Universitaire Pellegrin-Enfants, Bordeaux, France; 3) Service de Dermatologie Pédiatrique, Hôpital Universitaire Pellegrin-Enfants, Bordeaux, France.

Oculocutaneous albinism (OCA) is an autosomal recessive disorder characterized by skin, hair, iris and retina hypopigmentation. Four genes are involved in the four non syndromic OCA types: TYR at 11q14.3 in OCA1, OCA2 at 15q12 in OCA2, TYRP1 at 9p23 in OCA3, and SLC45A2 (MATP) at 5p13.3 in OCA4. We studied a cohort of 72 OCA patients from several European and African countries. Molecular exploration included deletion search by quantitative PCR and mutation screening by DHPLC and sequencing in the four genes. In the TYR gene, 8 novel point mutations were identified. One heterozygous deletion encompassing the whole gene was identified. OCA2 screening revealed 8 new point mutations. Novel intragenic deletions encompassing one or several exons were identified, and a deletion of the whole gene was found in a patient presenting both OCA and Angelman syndrome. We identified 4 new mutations in the TYRP1 gene, including two mutations in a Caucasian patient. MATP screening revealed a higher frequency of mutations than ever described in the literature, since 5 different mutations were identified, including four new ones, in patients from different countries. This study allowed us to reevaluate the worldwide frequency of mutations in each OCA gene. Among the mutated alleles, mutations in TYR were predominant (44%), then OCA2 (38%) MATP (13%) and TYRP1 (5%). 70% of patients were either compound heterozygotes or homozygotes, 24% presented only one mutation and 6% had no mutation identified. These observations lead to two hypotheses: the missing mutations are in unexplored regions of the genes (such as intronic or regulatory elements) or in other genes that have not been identified so far. Two patients presented three mutations in two different genes suggesting possible triallelic inheritance.

Genetic Components of Variance for Common Latent Components of Obesity-related Traits in African-Americans. *B. Tayo[1], D. Kan[1], R. Harders[1], A. Luke[1], X. Zhu[2], R. Cooper[1]* 1) Department of Preventive Medicine and Epidemiology, Loyola University, Chicago, Maywood, IL; 2) Department of Epidemiology and Biostatistics, Case Western Reserve University,Cleveland, OH.

Objective: To identify significant common latent components or factors which account for observed covariation of obesity-related traits, and to estimate their genetic components of variance in African-Americans. Methods: We used the maximum likelihood factor analysis method to both determine the number of, and extract scores of significant common factors of selected obesity-related measures on 1775 subjects from 599 African-American families. The obesity-related measures include body mass index, body surface area, fat mass, percent body fat mass, resting metabolic rate, waist circumference and hip circumference. Variance-component analysis was performed to estimate the environmental and polygenic variance components of the common latent factors. Results: Two significant common latent factors were identified. The proportions of covariation of the obesity-related traits accounted for by the first and second factors are 0.862 and 0.136, respectively. The estimated sex and age-adjusted genetic components of variance for the two common latent factors are 0.374 and 0.433, with heritability estimates equal to 51.37% and 53.27%, respectively. Conclusions: The results of our analysis provide support for the existence of common genetic influence on obesity-related traits. Linkage or association analysis of common latent components of obesity-related traits can be useful in mapping pleiotropic loci for these traits.

Genome-wide profiling of epigenetic modifications in postmortem brain using microarray based methods: Use of the PWS/AS domain as a proof of feasibility. *R. Person, X. Zhang, Y-H. Jiang, A.L. Beaudet* Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Epigenetics is the study of stable and potentially heritable changes in gene expression that do not entail changes in DNA sequence. The majority of epigenetic studies focus on analysis of DNA methylation and of chromatin modifications using chromatin immunoprecipitation (ChIP). We wish to test the hypothesis that epigenetic abnormalities in brain may cause disorders such as autism and schizophrenia. As a proof of feasibility, we have analyzed DNA methylation using three methods and shown that the DNA abnormalities in Prader Willi syndrome (PWS) and Angelman syndrome (AS) brain can be detected robustly using genome-wide Agilent CpG island arrays. We have found that methods to detect methylated DNA distinguish AS but not PWS well from control brain and that methods to detect unmethylated DNA distinguish PWS but not AS well from controls; this means that searches for DNA methylation differences should utilize at least two methods, one to detect methylated DNA and another to detect unmethylated DNA. Similarly, using ChIP on microarrays (ChIP-chip) with multiple antibodies to histone modifications, we have characterized the PWS/AS domain in depth using a dense array focused on this region, and also shown that the abnormalities in PWS and AS can be detected using genome-wide Agilent promoter arrays. Findings of note are the occurrence of sharp peaks of H3K4 methylation at all active promoters in the PWS/AS domain and the presence of a broad peak of H3K9 trimethylation over the paternal but not the maternal copy of the HBII-85 snoRNA cluster. A modest amount of data comparing autism and control brain is available, and more extensive studies are ongoing, but no definitive abnormalities have been detected in autism brain to date. These results demonstrate the feasibility of detecting epigenetic defects causing autism or schizophrenia using genome-wide methods and postmortem brain, if such abnormalities do occur.

HapMap SNPs in the UCSC Genome Browser. *H. Trumbower* Genome Bioinformatics Group, Univ California, Santa Cruz, Santa Cruz, CA.

The UCSC Genome Browser (http://genome.ucsc.edu) is a web-based interface for displaying full genome data sets. HapMap SNPs are an important new genome-wide resource for the study of human polymorphism. The HapMap SNPs have been added to the Genome Browser with a set of customized visualization features.

For each of the 4 million SNP positions in HapMap Phase II, the display includes a summary of genotype results from each population, as well as orthologous alleles from chimp and macaque. For the four populations, the display uses a color gradient based on minor-allele frequency; the orthologous alleles are shaded based on quality score of the assembly at that position. When zoomed in, the major allele is shown for each population.

Software is provided that dynamically filters the data set. A location can be excluded based on whether the chimp allele is available, and whether it matches the human major allele, human minor allele, or neither human allele. This filter is only valid if an overall major allele exists, which is true for eighty percent of the HapMap SNPs. An independent filter with the same features is also available for macaque.

Another filter will exclude SNPs based on whether the major allele is consistent or mixed across the populations. Heterozygosity (2pq) is calculated over all populations at each position and has its own filter. Other filters include minor allele frequency minimum and maximum, monomorphism, population availability and quality score for orthologous allele.

Evaluating marker-based pairwise relatedness estimators for population-based genome-wide association study.

K.S. Wang[1], L.Y. Wu[2], M. Liu[1] 1) Gen & Genomic Biol/TMDT East, Hosp Sick Children, Toronto, ON, Canada; 2) Dept statistics, Univ Waterloo, Canada.

The knowledge of relatedness between individuals is central to many studies in genetics. However, for natural populations detailed pedigree structure is usually unknown. A large number of SNPs are now available in humans as well as in other model organisms and provide one potential application in determination of pairwise genetic relationships in natural populations. Recently, a unified mixed linear model (MLM) method for association mapping accounting for multiple levels of relatedness was developed (Yu et al. Nature Genetics 2006). However, little is known about the relatedness estimators' ability to detect the relationship among individuals. The objective of our study is to evaluate six relatedness estimators using a large real data set: KL(Loiselle et al. 1995), KR(Ritland 1996), RLR(Lynch & Ritland 1999), RQG(Queller & Goodnight 1989), RW(Wang 2002) and RL(Li et al.1993). The evaluations are conducted using genotypes of 1940 heterogeneous stock mice and their relatives from 81 pedigrees derived from eight inbred strains (Valdar et al. Nature Genetics 2006). These pedigrees include 1470 parent-offspring (PO), 6581 full-sib (FS), 4026 avuncular (AV), 726 grandparent-grandchild (GG), 5104 first-cousin (FC) and 12090 unrelated founder (UR) pairs. The six estimators are calculated using 1099 unlinked SNPs via the program SPAGeDI. The KL estimator has the lowest the mean squared error (MSE) for PO, FS, GG and AV pairs while the KR estimator has the lowest MSE for FC and UR pairs but similar to those of KL. The regression coefficient of estimated relatedness on expected pedigree relatedness () was close to one for the estimators of KL and RQG. The correlation between the estimated and pedigree relatedness () ranged from 0.78 to 0.94, which are highly significant ($p<0.0001$). In conclusion, our results showed that the SNP-based estimators of KL and RQG approximate to the pedigree relatedness, especially the KL estimator also showed lower MSE in most cases, which are promising for population-based genome-wide association study. The KR estimator is another good choice.

***In Silico* Genotyping for Genome-Wide Association Studies.** *Y. Li, C.J. Willer, J. Ding, P. Scheet, G.R. Abecasis*
Center for Statistical Genetics, Department of Biostatistics, School of Public Health, University of Michigan, Ann Arbor, MI.

Large scale genome-wide association (GWA) studies hold the promise of detecting the small genetic effects that underlie genetic susceptibility to complex diseases but pose a range of analytical and computational challenges. We propose a method that can rapidly impute several million SNPs genotyped by the HapMap consortium using genome-wide SNP genotyping data such as that provided by commercial genotyping platforms by Illumina, Affymetrix or Perlegen. The method uses a hidden Markov model to assemble mosaics of haplotypes observed in the appropriate HapMap reference population that match each of the sampled individuals. We illustrate our approach with real data sets studying age-related macular degeneration and type 2 diabetes. We demonstrate the capability of our method (1) to generate highly accurate genotypes along with correspondent measures of imputation uncertainty, (2) to improve coverage and gain power in association mapping, and (3) to facilitate meta-analysis across studies that use different commercial panels for genotyping. Our method is computationally efficient. For example, in our study of type 2 diabetes, we imputed several billion genotypes using genotypes from the Illumina 317K panel as input. The computation took less than two days for the largest chromosome and multiple chromosomes were conveniently run in parallel. The allelic concordance between imputed and true genotypes is ~98.5%, which can be further improved to over 99% by excluding the 5% of SNPs that are estimated to have lower quality imputed genotypes. Our method is implemented in C++, runs on Windows, Mac and Linux and is available at www.sph.umich.edu/csg/abecasis/mach/.

Investigation of genetic susceptibility to Late-onset Alzheimer disease through genomic convergence. *X. Liang[1], M. Slifer[2], E.R. Martin[2], N. Schnetz-Boutaud[1], J. Bartlett[1], B.M. Anderson[1], S. Zuchner[2], J. Gilbert[2], M.A. Pericak-Vance[2], J.H. Haines[1]* 1) Ctr Human Genetics Research, Vanderbilt Univ, Nashville, TN; 2) Miami Institute for Human Genomics, Miami, FL.

With the exception of APOE gene, no universally accepted genetic association has been identified for Late-onset Alzheimer Disease (LOAD). A broad region of chromosome 10 (chr10) has engendered continued interest from both preliminary genetic linkage and candidate gene studies, including VR22/LRRTM3, PLAU and IDE. However, there is a very extensive heterogeneity on chr10. Therefore, we converged linkage analysis and gene expression data using the concept of genomic convergence that suggests that genes showing positive results across multiple different data types are more likely to be involved in AD. We identified and examined 28 genes on chr10 for association with AD in a case-control dataset of 1064 individual Caucasians (506 cases and 558 controls) with substantial clinical information. The cases were all Late-onset Alzheimer disease (minimum age at onset (AAO)60 years). Both single marker and haplotypic associations were tested in the overall dataset and 8 subsets defined by age, gender, ApoE status and clinical status. PTPLA showed allelic, genotypic and haplotypic association in the overall dataset. SORCS1 was significant in the overall data sets (p=0.0025) and most significant in the female subset (p=0.00002). Odds Ratio of SORCS1 in the female subset was 1.7 (p0.0001). SORCS1 encodes sortilin-related VPS10p domain containing type 1 receptor. It is a homologue of SORLA that has been associated with AD by inhibiting the generation of amyloid peptide (A),one of the hallmarks of Alzheimer disease. SORCS1 is also a substrate of -secretase that cuts amyloid precursor protein (APP) and generates A. Genetic variations in PTPLA and SORCS1 may be associated and have modest effect to the risk of AD by affecting A pathway. The replication of the effect of these genes in different study populations and search for susceptible variants and functional studies of these genes are necessary to get a better understanding of the roles of the genes in Alzheimer disease.

Mutations in FHL1 cause a novel X-linked myopathy with specific/unique clinical features. *C. Windpassinger[1,2], B. Schoser[3], S. Hochmeister[4], A. Noor[1], B. Lohberger[4], N. Farra[1], E. Petek[2], T. Schwarzbraun[2], L. Ofner[2], W. Löscher[5], K. Wagner[2], H. Lochmüller[3], J.B. Vincent[1], S. Quasthoff[4]* 1) Neurogenetics Section, Centre for Addiction and Mental Health, 250 College Street, Toronto, Ontario, M5T 1R8, Canada; 2) Institute of Human Genetics, Medical University of Graz, Graz, Austria; 3) Friedrich-Baur Institute, Department of Neurology, Ludwig Maximilians University Munich, Munich, Germany; 4) Department of Neurology, Medical University of Graz, Graz, Austria; 5) Clinical Department of Neurology, Medical University of Innsbruck, Innsbruck, Austria.

We have identified a large multigenerational Austrian family displaying a novel form of X-linked recessive myopathy. Affected individuals develop a late-onset scapulo-axio-peroneal myopathy with bent spine syndrome characterized by specific atrophy of postural muscles along with pseudo-athleticism/hypertrophy, and cardiac involvement. Known X-linked myopathies were excluded by microsatellite analysis and direct gene sequencing. Marker analysis revealed significant linkage at Xq26-q27. Haplotype analysis based on SNP microarray data from selected family members confirmed this linkage region on the distal arm of the X-chromosome (Xq25-q27.1), narrowing down the critical interval to 10 Mb. Sequencing of functional candidate genes led to the identification of a missense mutation within the four-and-a-half LIM domain 1 gene (FHL1), which putatively disrupts the 4th LIM domain. FHL1 on Xq26.3, is highly expressed in skeletal muscle and oxidative fibers in particular, as well as cardiac muscles. Thus, we have characterized a new form of X-linked recessive myopathy, and identified FHL1 as the causative gene.

A two-stage genome-wide association study for type 2 diabetes. *R. Sladek[1,2], L. Shen[2], D. Meyre[3], G. Rocheleau[1], C. Dina[3], J. Rung[2], L. Shen[1], A. Mazur[1], C. Polychronakos[1,4], D.J. Balding[5], P. Froguel[1,6]* 1) Department of Human Genetics, McGill University, Montreal, PQ, Canada; 2) McGill University and Genome Quebec Innovation Centre, Montreal, Canada; 3) 8090-Institute of Biology, Pasteur Institute, Lille, France; 4) Departmnent of Pediatrics, McGill University, Montreal, Canada; 5) Department of Epidemiology and Public Health, Imperial College, London, United Kingdom; 6) Section of Genomic Medicine, Imperial College, London, United Kingdom.

The recent availability of high-density genotyping arrays, which combine the power of association studies with the systematic nature of a genome-wide search, led us to undertake a two-stage, genome-wide association study to identify T2DM susceptibility loci. In the first stage of this study, we obtained genotypes for 392,935 single-nucleotide polymorphisms (SNPs) in 694 T2DM and 669 control subjects. Markers with the most significant differences in genotype frequencies between cases and controls were fast-tracked for testing in a second cohort consisting of 5,511 cases and controls. Our strategy identified 4 novel loci containing variants that confer T2DM risk, in addition to confirming the known association with the TCF7L2 gene. To complete the second stage, we have designed a custom iSelect panel to genotype the 5% most significant associations in the first stage. Based on a joint analysis of the two stages, this strategy will provide 82% power to detect an association conferring a heterozygous relative risk of GRR=1.3 for a minor allele frequency of MAF=0.20 (see table). Relevant methods, including strategies for correcting population stratification using ancestry informative markers and principal component analysis, will be presented.

MAF	GRR 1.2	GRR 1.3	GRR 1.4	GRR 1.5
0.05	0	5	29	65
0.10	3	36	81	95
0.20	21	82	97	100
0.30	40	92	99	100
0.40	51	95	100	100

.

HLA frequencies and genetic distances between Ashkenazi and non-Ashkenazi Israeli Jews. *M. Maiers[1], L. Gragert[1], M. Fernandez-Vina[2], W. Klitz[3], I. Haviv[4], S. Israel[4], C. Brautbar[4]* 1) Bioinformatics, National Marrow Donor Program, Minneapolis, MN; 2) Laboratory Medicine, MD Anderson Cancer Center, Houston, TX; 3) Public Health Institute, Oakland, CA; 4) Hadassah Medical Center, Jerusalem, Israel.

We have analyzed the HLA allele and haplotype frequenices of a cohort of Israeli Jewish individuals in 2 ethnic categories:10,078 Ashkenazi and 5,360 Non-Ashkenazi. 2-digit HLA Haplotype frequency analysis was performed using the EM algorithm on HLA-A, -B and -DRB1 typing results obtained by a combination of serologic and DNA-based methods. A set of 3 US cohorts were analyzed for comparison: 433,901 US_European, 103,382 US_African, 8,753 US_Japanese. Genetic distance computations were performed on equal-sized cohorts of 5,000 individuals selected at random from each group. The similarity index (Renkonen s If) was highest between the Ashkenazi and non-Ashkenazi groups (0.331). The similarity index between US_European and Ashkenazi was 0.291 and between US_European and non-Ashkenazi was 0.282. By way of comparison the similarity index between US_European and US_African was 0.268 and between US_European and US_Japanese was 0.160. Several other genetic distance measures were computed (Fst, Wn, Nei) on the A-B-DRB1 2-digit haplotype frequencies. In all cases, Ashkenazi and non-Ashkenazi were found to be the most similar. Genetic diversity within each group was evaluated based on the sum of the top 3 haplotypes and the non-Ashkenazi group was found to be more diverse with only 0.049 compared to 0.128 for Ashkenazi. We have also performed a sub-analysis by country of origin which includes samples from countries with very little published HLA information (non-Ashkenazi: Morocco, Iraq, Yemen, Iran, Tunisia, Libya, Egypt, Algeria, Syria and India, Ashkenazi: Russia, Romania, and Poland).

Deficiency of Arid4a and Arid4b alters histone modifications, impairs genome stability, and induces acute myelogenous leukemia. *M. Wu[1], K. Eldin[2], A.L. Beaudet[1]* 1) Dept Molec & Human Genetics, Baylor Col Medicine, Houston, TX; 2) Dept Pathology, TEXAS Children Hospital, Houston, TX.

Arid4a and Arid4b are two related Arid (AT-rich interaction domain) family genes, previously known as retinoblastoma-binding protein 1 (Rbbp1) and Rbbp1-like protein 1 (Rbbp1l1), respectively. Recently, we have reported a murine model for Arid4a and Arid4b deficiency. Studies indicated Arid4a and Arid4b function in the regulation of genomic imprinting through controlling epigenetic modifications. Here, using the murine model system, we found that Arid4a-deficient mice displayed ineffective myeloid hematopoiesis. Analysis of histone modifications in Arid4a-/- bone marrow cells characterized the role of Arid4a in controlling H4K20 trimethylation and H3K9 trimethylation at heterochromatic regions. We further combined deficiency of Arid4a and Arid4b in mice and found that the Arid4a-/- Arid4b+/- mice frequently developed acute myelogenous leukemia (AML). Analysis of mouse embryonic fibroblasts (MEFs) demonstrated genomic instability caused by the Arid4a and Arid4b mutations. We also found that Arid4a together with Arid4b serve an unanticipated function for normal development of male germ cells, in which deficiency of these two genes led to spermatogenic failure observed in meiotic spermatocytes and during the maturation of postmeiotic haploid spermatids.. Our findings define molecular mechanisms for the Arid4a and Arid4b genes in myeloid homeostasis, and assign their roles in normal mammalian development.

Variation in novel exons (RACEfrags) and human genetic disorders; the case of Rett syndrome. *P. Makrythanasis[1], P. Kapranov[2], L. Bartoloni[1], A. Raymond[3], S. Deutsch[1], R. Guigo[4], F. Denoeud[4], C. Rossier[1], F. Ariani[5], V. Capra[6], A. Renieri[5], T. Gingeras[2], S.E. Antonarakis[1]* 1) Medical Genetics and Dev., University of Geneva, Switzerland; 2) Affymetrix, Santa Clara, US; 3) University of Lausanne, Switzerland; 4) IMIM, Barcelona, Spain; 5) University of Sienna, Italy; 6) Neurochirurgia, Istituto G.Gaslini, Genova, Italy.

The study of transcription using genomic tiling arrays, strikingly has lead to the identification of numerous additional exons connected to known genes. One example is the MECP2 gene on the X-chromosome; using 5RACE and RT-PCR in numerous human tissues and cell lines, we have found more than 15 novel exons (RACEfrags) connecting to at least one exon of MECP2 gene and map up to 1 Mb telomeric to it. We subsequently asked if variation in the novel exons is causatively associated with Rett syndrome, a monogenic disorder commonly due to pathogenic mutations of MECP2. We sequenced all MECP2-connected exons and flanking sequences in 3 groups: 48 Rett patients without mutations in MECP2 and CDKL5 genes (group 1); 30 Rett patients with mutations in the MECP2 gene (group 2); 100 control individuals from the same geoethnic group (group 3). Approximately 14 kb was sequenced per sample, for a total of 2.6 Mbs of DNA resequencing. We found 75 individuals with rare variants (observed in 1-4 alleles). The individuals with rare variants were 19/48, 11/30, and 45/100 in groups 1 to 3 respectively, i.e. there is not a statistically significant difference among the 3 groups. These results suggest that variants in the newly discovered exons studied do not contribute to Rett syndrome, furthermore if some of these variants are related to a phenotype, this must be different from Rett. Interestingly however, the variants in the novel exons are twice as frequent as those found in flanking sequences (50 vs 24 for approximately 1.3 Mb sequenced for each class of sequences). The significance of this result remains to be elucidated; one hypothesis is that novel exons accumulate variants faster than the rest of the genome (positive selection?) that could underscore the functional importance of these sequences.

Multidisciplinary evaluation in 12 Mucopolysaccharidose type II or Hunter Syndrome patients prior Enzyme Replacement Therapy. *T. Vertemati[1,2], C. Micheletti[1,2], C. Mendes[1,2], E. Fraccaro[1,2], E. Menegatti[1,2], J. Correa[1,2], M. Rant[1,2], T. Pereira[1,2], A. Martins[1,2]* 1) CREIM, UNIFESP, São Paulo, São Paulo, Brazil; 2) Ambulatório de Doenças Metabólicas do Centro de Referência em Erros Inatos do Metabolismo (CREIM), Escola Paulista de Medicina da Universidade Federal de São Paulo (UNIFESP/EPM), São Paulo, São Paulo, Brazil.

BACKGROUND: Mucopolysaccharidose Type II (MPS II) is a Lysossomal Storage Disease (LSD) that results from human lysossomal function defects by inherited enzyme iduronate-2-sulfatase (I2S) deficiency, which is an X-linked disease. OBJECTIVE: The purpose was to evaluate the MPS II patients by our multidisciplinary group and perform clinical and laboratorial evaluations, at baseline and proceed with the control after beginning enzyme replacement therapy (ERT) at 26th and 52th weeks. METHODS AND PROCEDURES: In 2007, 12 MPS II patients, 11 male and 1 female, were evaluate by CREIM's multidisciplinary group. RESULTS: The MPSII patients had ages ranging from 3,7 to 14,3 years old, mean age of 9,3 years old. The age at first signs and symptoms ranging from 3 to 27 months old, mean age of 15,1months; after the first evaluation. At physical examination, all of them presented facial dysmorphisms characteristic of the MPSII, hepatomegaly, short stature, skeletal deformities and joints stiffness. We found macrocephaly in 6 (50%), neurodegeneration leading to profound mental retardation in 11(91,66%), seizures in 4 (33,33%), hyperreflexia or hyporreflexia in 6 (50%), hypotonia or spastic hypertonia in 10 (83,33%), Babinski and Clonus in 3 (25%), agitation and attention deficiency in 6 (50%), hemiparesis or spastic tetraparesis in 6 (50%), past hydrocephalie in 1 (8,33%), abnormal cardiac exam in 9 (75%). DISCUSSION AND CONCLUSION: The possibility of specific treatment of this disease with Idursulfase impose the necessity of evolutive attendance on several clinical and laboratorial aspects of the MPS II patients for better knowledge of the benefits regarding the treatment, irreversible damages prevention and promotion of better quality of life.

Characterization of cis-regulatory elements in the Alpha-synuclein gene. *B. Schuele, L. Sterling, J.W. Langston*
Parkinson's Institute, Sunnyvale, CA.

Purpose: To evaluate evolutionary conserved regions within the Alpha-synuclein (SNCA) gene as cis-acting regulatory elements in vitro. Background: A microsatellite repeat NACP-Rep1, 9.8kb upstream of the SNCA gene, has been shown to modulate the expression of the SNCA gene and two of the five alleles of this repeat have been shown to be associated with Parkinsons disease (PD), one is protective and one is causative. Based on these findings and the observation that SNPs in other regions of the SNCA gene show highly significant p-values in case-control studies of PD, we hypothesized that other cis-regulatory elements in the SNCA genomic region regulate expression of SNCA and can be causative for PD if disrupted or impaired. Methods: Pair-wise comparison of a 206kb genomic region encompassing the SNCA gene including a 44.5kb upstream and 50kb downstream intergenic region revealed 32 conserved DNA sequences between human and mouse. These regions had >75% sequence identity and were at least 100bp in length. All elements were cloned into pGL3 promoter vector (Promega). In dual luciferase reporter assays, constructs were co-transfected with pRL-TK renilla plasmid into SK-N-SH neuroblastoma cell lines. Assays were run in quadruplicates and three independent experiments. All data were normalized to the pGL3 promoter plasmid. Results: Overall 11 of 32 elements exhibited either an enhancement or reduction of the expression of the reporter gene. Three elements upstream of the SNCA gene displayed an approx. 1.5 fold ($p<0.009$) increase in expression. Of the intronic regions, three showed a 1.5 fold increase and two others indicated a 2 and 2.5 fold increase in expression ($p<0.002$). Two elements downstream of the SNCA gene showed 1.5 fold and 2.5 fold increase ($p<0.0009$). One element downstream of SNCA had a reduced expression of the reporter gene of 0.35 fold ($p<0.0009$) of normal activity that was also confirmed in a pGL3 control (containing promoter and enhancer) vector. Conclusion: Our results demonstrate that the SNCA gene contains cis-regulatory regions that might regulate the expression of SNCA. Further studies are ongoing to test that these regions specifically modulate the transcription and expression of the SNCA gene.

Validation of resequencing variants by Pyrosequencing. *M. Maheshwari, S. Scherer, B. Ng, G. Metcalf, K. Blankenburg, F. San Lucas, A. Garcia, D. Wheeler, G. Weinstock, R. Gibbs* Human Genome Sequencing center, Department of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX 77030.

Baylor College of Medicines Human Genome Sequencing Center has sequenced hundreds of candidate genes to identify alleles that may confer risk of various diseases like epilepsy, autism, cardiomyopathies, bipolar disorder and schizophrenia. Medical resequencing has facilitated the detection of thousands of single nucleotide polymorphisms (SNPs) and insertion-deletions (Indels) including coding and non coding variants. Because high throughput software is used to call variants, validation is needed to inform downstream functional analyses, broader population screening and accurate public database submissions. We adopted the PyroMark MD (BIOTAGE) pyrosequencing platform to validate SNPs and Indels discovered by Sanger sequencing based on verification studies demonstrating overall pass rates of 93% and correspondence rates of better than 99% using known HapMap SNPs and a CEPH DNA sample set. Pyrosequencing is sequencing by synthesis method, based on real time pyrophosphate detection. We chose pyrosequencing over alternative platforms as it generates both unambiguous genotyping results and some flanking sequence information beyond the SNP position, which serves as internal control. To date, we have validated hundreds of SNPs discovered primarily from our ion channelopathy and lung adenoma projects across tens of thousands of samples by re-amplifying each locus from the original DNA stocks. Overall concordance rates with Sanger platform/SNP Detector 3 derived SNPs and Indels is currently running between 75 and 80 percent. Further pipeline improvements in throughput, cost and data-tracking are currently under development.

Clinical manifestations and consequences of the P479L mutation of carnitine palmitoyl transferase type 1 deficiency in the Alaskan native population. *M.L. Raff[1,2], C. Trahms[2], S.H. Hahn[1,2], P. Schubert[1], M.A. Parisi[1,2], M. Hannibal[1,2], I.A. Glass[1,2], C. Leblond[3], M.J. Bennett[4]* 1) Div Genetics, Children's Hospital, Seattle, WA; 2) Dept Pediatrics, Univ of Washington, Seattle, WA; 3) State of Alaska Dept of Health, Anchorage, AK; 4) Depts of Pathology and Lab Med, Univ of Penn, Philadelphia, PA.

Carnitine palmitoyl transferase type 1 catalyzes the transport of long-chain fatty acids into the mitochondria where they undergo oxidation of energy production. The P479L mutation in the CPT1A gene exists in high frequency in the native populations of Alaska. The pathogenicity of this mutation has previously been questioned. Physical examination of 50 children with confirmed P479L CPT1A deficiency identified by state newborn screening, testing of siblings of affected children, or investigation of suspicious cases, noted clinical findings in 16 individuals. Clinical findings were found among infants and toddlers who had not followed a regimen of strict avoidance of fasting. Complications included hypoglycemia, elevated liver transaminases, seizures, hypotonia, motor delays, and death. Two cases diagnosed by DNA testing were undetected by newborn screening using tandem mass spectrometry, indicating that an increased level of suspicion of the conditon is necessary to avoid missing a diagnosis of cpt-1 deficiency. Recognition of this disorder in populations at risk followed by swift initiation of measures to avoid fasting, particulary during times of illness, can reduce morbidity and mortality. P479L has been shown elsewhere to cause insensitivity to malonyl-CoA inhibition of fatty acid oxidation, suggesting that there is a low-level constitutive enzyme activity with this mutation. Others have demonstrated that failure to inhibit cpt-1 function in rats is associated with increased feeding behavior. P479L may promote increased caloric intake in times of plenty, perhaps improving survival in times of famine, but conversely may contribute to higher rates of obesity and insulin resistance. The existance of other mild deficiency alleles is under investigation.

Genome-wide association study identifies new susceptibility genes for obesity. *Y.J. Liu[1], X.G. Liu[2], L. Wang[2], J. Liu[1], L.J. Zhao[1], H. Yan[2], D.H. Xiong[3], J.L.. Li[1], R.R. Recker[3], C. Papasian[1], H.W. Deng[1,2,3,4]* 1) Basic Medical Sciences, University of Missouri - Kansa, Kansas city, MO; 2) The Key Laboratory of Biomedical Information Engineering of Ministry of Education and Institute of Molecular Genetics, School of Life Science and Technology, Xi'an Jiaotong University, Xi'an , Shaanxi 710049, P. R. China; 3) Osteoporosis Research Center and Department of Biomedical Sciences, Creighton University, Omaha, NE 68131, USA; 4) Laboratory of Molecular and Statistical Genetics, College of Life Sciences, Hunan Normal University, Changsha, Hunan 410081, P. R. China.

Obesity is a serious health problem that causes or exacerbates several common diseases. Obesity has strong genetic determination. Extensive candidate gene association studies and whole genome linkage scans have been performed but have achieved limited success in identification of obesity susceptibility genes. The recent advance in introduction of technological platforms for whole-genome association (WGA) studies provides an opportunity to identify obesity genes with modest effects. We report results of a WGA study in 1000 unrelated Caucasian subjects using Affymetrix 500K SNP arrays. Quantitative phenotypes used in this study are BMI (body mass index) and body fat mass measured by DXA (dual X-ray absorptometry). We performed association analyses for single SNPs as well as haplotypes with sliding windows of various sizes. For BMI, the most significant association ($P= 9.4 \times 10^{-10}$)was found on locus 10q25 (rs1385092) near the SORCS3 (SORCS RECEPTOR 3) gene. Interestingly, additional 10 SNPs around rs1385092 within the SORCS3 gene achieved P values of less than 2.0×10^{-9}. For fat mass, the most significant association ($P= 2.2 \times 10^{-8}$) was also observed on 10q25. The results of haplotype analyses of different sliding window sizes further confirmed the significant association on 10q25 (P values of ~10^{-9} - 10^{-8}). Notably, linkage of the locus 10q25 to obesity and related phenotypes has been repeatedly reported in earlier studies of various populations (including ours), further supporting the importance of the gene(s) at 10q25 on development of obesity.

Galaxy: bridging the gap between experimental and computational biology. *J. Taylor[1], D. Blankenberg[2], I. Schenck[2], N. Coraor[2], G. Von Kuster[2], R. Lazarus[3], A. Nekrutenko[2]* 1) New York University, New York, NY; 2) Penn State University, University Park, PA; 3) Harvard Medical School and Brigham and Women's Hospital, Boston, MA.

High-throughput data production technologies are revolutionizing modern biology. Translating this experimental data into discoveries of relevance to human health increasingly relies on sophisticated computational tools that can handle large-scale data. Many such tools exist or are currently being developed; however, making computational tools easy-to-use requires significant effort, which tool developers frequently cannot afford. Thus, for an average experimental biologists with limited computer expertise, there is a substantial barrier to taking advantage of these tools. Galaxy (http://g2.bx.psu.edu) removes this barrier by providing easy-to-use interfaces to existing computational tools. Galaxy is unique in two ways. First, in the ease with which it allows complex large-scale analyses to be performed with nothing more than a web browser. Second, in how simple it is for existing computational tools to be integrated into Galaxy, gaining a modern user interface, and substantial added value through connections with other tools and databases. Here we will show how Galaxy bridges the gap between experimental and computational biology, and highlight the exciting new developments in Galaxy including:

1) A new and unique suite of tools for working with large scale multiple genomic alignments in Galaxy, along with powerful phylogenetic tools, together a substantial advance in the accessibility of high-end comparative genomic analyses.

2) The availability of a set of statistical genetics tools, leveraging the Rgenetics (http://rgenetics.org) project, that bring the power, efficiency, and ease-of-use Galaxy has achieved in genomics, to bear challenges such as the analysis of whole-genome SNP chip association data.

3) Advances in the collaborative and workflow features that make Galaxy an ideal platform for sharing reproducible analyses.

Rapid Selection for HLA alleles that Protect against HIV-1 Infection Correlates Significantly to the Declining Incidence of HIV-1 in an East African Sex Worker Population. *M. Luo[1], J. Kimani[1,2], N.J.D. Nagelkerke[3], T. Ball[1], K. MacDonald[4], J. Ndinya-Achola[2], S. Njenga[2], J. Bwayo[1], S. Ramdahin[1], T. Bielawny[5], L. Mendoza[5], J. Tuff[5], S. Thavaneswaran[1], M. Narayansingh[1], J. Rutherford[1], L. Slaney[1], K. Fowke[1], E. Ngugi[2], J. Embree[1], F. Plummer[1,5]* 1) University of Manitoba, Canada; 2) University of Nairobi, Nairobi, Kenya; 3) United Arab Emirates University, UAE; 4) Mount Sinai Hospital, Toronto, Canada; 5) National Microbiology Laboratory, Winnipeg, Canada.

Human Leukocyte Antigens (HLA) present antigens to T cells and are centrally involved in acquired immunity against infectious pathogens. The extreme diversity of HLA system is thought to be the result of selection by infectious pathogens and is a populations ecologic defence mechanisms against epidemics. Like other pandemics in history the selective pressure of current HIV-1 epidemic in sub-Saharan Africa may influence HLA genotype frequencies in the population. We examined the effect of HIV epidemic on HLA genotype frequency of two African research cohorts (n=1345) with very different exposures to HIV-1 over two decades. The frequencies of HLA genotypes associated with resistance to HIV-1 infection increased significantly (p=0.003, odds ratio: 1.42, 95%CI: 1.13-1.79) over time in the sexworker cohort (1985-2001). This change in sexworker cohort is independent of ethnic makeup and country of origin and significantly correlated to the decrease of seroconversion over time (p=0.00003). Multivariate analysis with time-dependent covariates including condom usage, number of partners per day, age at enrolment, duration of prostitution before enrolment and resistant HLA genotype showed that the increase of resistant genotypes in the population is one of the factors significantly correlated with the reduced HIV-1 infection risk in the highly exposed population (p=0.004). This study provides the first insight into host population genetic changes as a result of selection by HIV-1 in Sub-Saharan Africa and shows that natural selection may ultimately play an important role in controlling the HIV-1 epidemic.

Evaluation of whole genome amplification in tumor genome analysis. *W. Winckler[1,2], R. Onofrio[2], N. Burtt[2], C. Guiducci[2], R. Tewhey[2], K. Ardlie[2], M. Meyerson[1,2], S. Gabriel[2]* 1) Dept of Medical Oncology, Dana Farber Cancer Institute, Boston, MA; 2) The Broad Institute of Harvard and MIT, Cambridge, MA.

Large-scale cancer genomics often requires more DNA than can be obtained from a single tumor sample. Many studies on inherited variation have dealt with similar sample limitations by using whole genome amplified (WGA) DNA. It is unclear, however, whether this amplification process performs equally well in tumors, which have added complexities like aneuploidy and stromal contamination. To evaluate WGA for tumor analysis, we compared genomic and phi29 polymerase multiple strand displacement WGA DNA by Affymetrix 250K Sty SNP array and Sanger sequencing.

Unamplified and WGA DNA from 30 tumors and 17 normals were evaluated for copy number using SNP arrays. Amplified samples had consistently poorer copy quality metrics than their unamplified equivalents. Additionally, we detected regions with reduced copy number in all WGA samples but not in unamplified ones, affecting 4% of the SNPs on the 250K Sty chip. This was particularly pronounced at the telomeres. These results indicate that phi29 WGA is inferior for copy number analysis by SNP array.

To address the effect of WGA on sequencing, we sequenced PIK3CA and TP53 in 12 breast and 12 colorectal carcinomas, including the unamplified tumor and two independent WGAs of the tumor. Each of the 8 mutations observed in the unamplified tumor was also seen in WGA DNA, indicating that there is unlikely to be a substantial false negative problem with sequencing WGA DNA in tumors. No new mutations were seen in the amplified material, suggesting that the WGA process is not introducing de novo mutations at a high rate. Also, we found that 13 of the 1,000 genes studied by the Tumor Sequencing Project, which used WGA DNA to sequence 190 lung adenocarcinomas, occur in our identified regions of low WGA copy number. 24 somatic and 34 germline mutations were discovered in these genes, further indicating that mutations can be detected using WGA material-even in the regions that performed poorly on SNP array.

A comprehensive analysis of the HapMap for trans- and long-range cis- associated SNPs - potential inference errors for genome-wide association studies. *R.W. Lawrence, L.R. Cardon, E. Zeggini* WTCHG, Oxford University, UK.

Recent advances in high-throughput genotyping and a better understanding of human genome sequence variation have now made genome-wide association scans (GWAS) possible. However, exhaustive screening of common variation is not yet feasible. Therefore, inferences about the localisation of disease variants have to be made on the basis of GWAS results. Incomplete surveys of local linkage disequilibrium (LD) architecture could conceivably lead to misinterpretation of findings. We have calculated LD between every SNP pair (with MAF5%) from all three HapMap phase II samples (CEU, YRI, and JPT/CHB combined). We observe that a number of SNPs have at least one strongly associated ($r^2$0.7) marker on a different chromosome or at a distance greater than 1Mb on the same chromosome. 1.0% and 1.1% of common SNPs (MAF5%) were found to be strongly correlated ($r^2$0.7) with another variant at a distance greater than 1Mb (CEU and YRI respectively). Although the reason behind these observations in not yet clear, SNPs that have little or no LD with neighbouring markers but display trans-chromosomal and/or long-range (>1Mb) LD could represent mis-mapped variants. SNPs with both local and long-range/trans-chromosomal LD could stem from distal segmental duplications. Although relatively rare (11,770 out of approximately 2 million SNPs from the CEU sample), trans-chromosomal associations could lead to inference errors in the downstream interpretation of GWAS results. Several SNPs displaying long-range/trans-chromosomal associations in the HapMap phase 2 CEU sample (1,492 and 3,010 SNPs with trans-chromosomal and >1Mb associations ($r^2$0.7), respectively) are present in current whole-genome SNP chip arrays (Affymetrix 500k and Illumina 550k) so there is direct relevance to current GWAS. We are developing a resource enabling researchers to quickly retrieve information on these long-range associations for any given common HapMap SNP. This will conceivably help gene-hunters localise strong signals emerging from disease association studies, plan targeted replication strategies and delineate appropriate intervals for fine-mapping and resequencing.

Tay-Sachs Carrier Testing By Hexosaminidase A Assay In Serum And Platelets And By Mutation Analysis. *S. Nakagawa[1,7], J. Zhan[7], W. Sun[7], A.M. Roe[1], A. Schneider[2], D. Finegold[3], J. Charrow[4], K. Aleck[5], S. Minkoff[5], J.D. Hoffman[6], A. Spencer[1], S. Apfelroth[1,7], N. Schreiber-Agus[1], S.J. Gross[1,7]* 1) Albert Einstein College of Medicine, Bronx, NY; 2) Albert Einstein Med Ctr, Philadelphia, PA; 3) Childrens Hospital of Pittsburgh, Pittsburgh, PA; 4) Chicago Center for Jewish Genetic Disorders, Chicago IL; 5) Jewish Genetic Diseases Center of Greater Phoenix, Phoenix, AZ; 6) Tufts-NEMC, Boston, MA; 7) Jacobi Medical Center, Bronx, NY.

BACKGROUND: Different methodologies have been used for Tay-Sachs Disease (TSD) carrier screening in the Jewish population. Serum analysis can be inaccurate due to pregnancy or oral contraceptive use and has a high rate of inconclusive results. Therefore, other biochemical assays that measure Hexosaminidase A (HexA) in cells have been developed to overcome this limitation. **AIM**:To determine the screening characteristics of the HexA isoenzyme platelet assay for carrier testing in the Jewish population. **RESULTS**:Carrier testing of 1036 self-identified Jewish individuals from various communities showed the following results:

Assay Method	Non-Carrier	Carrier(%)	Inconclusive(%)
Platelet	997	35 (3.4)	4 (0.4)
Serum	838	29 (2.8)	169 (16)
DNA	1005	31(3.0)	not applicable

Of the 4 inconclusive platelet assays, 2 had identifiable mutations. No DNA mutations were detected in the 997 platelet assay non-carriers. Of the 4 positive platelet assays that were not confirmed by DNA, all were of unknown or mixed ethnicity. **CONCLUSION**: We have demonstrated that the platelet Hex A assay is an excellent option for TSD carrier screening that is simple, accurate, and has a very low inconclusive rate (0.4%).

Genomic convergence identified CAPG and VAMP8 as candidate genes for coronary artery disease. *L. Wang[1], E.R. Hauser[1], D. Crosslin[1], S. Nelson[1], A.B. Hale[1], S.G. Gregory[1], S.H. Shah[1,2], GENECARD. Investigators[1,3,4,5], D. Seo[6,7], W.E. Kraus[2], P.J. Goldschmidt-Clermont[6], J.M. Vance[7]* 1) CHG, Duke Univ Medical Ctr, Durham, NC; 2) Division of Cardiology, Duke Univ Medical Ctr, Durham, NC; 3) Vanderbilt Univ, Nashville, TN; 4) Univ of Wales College of Medicine,Cardiff, UK; 5) Univ of Sheffield, Sheffield, UK; 6) Miller School of Medicine, Univ of Miami, Miami, FL; 7) MIHG, Univ of Miami, Miami, FL.

By combining evidence from linkage and microarray study, we identified capping protein, gelsolin-like (CAPG) and vesicle-associated membrane protein 8 (VAMP8) as candidate genes for coronary artery disease (CAD). The two genes reside within 200 kb on chromosome 2p11.2, where consistent linkage evidence was found for myocardial infarction (MI). Both genes were upregulated in aortas with atherosclerosis. A SNP rs1010 in VAMP8 was associated with MI in a genome-wide association study. To thoroughly evaluate association in the two genes, we examined all 16 tagging and 11 exonic SNPs. To validate association, multiple datasets were used, including a family-based (N=2954), a White case-control (N=982), and an African-American case-control (N=250) dataset. Stratified analyses on the MI subphenotype and gender were performed. Allele-specific gene expression was evaluated in 92 aortas. VAMP8 SNP rs3731828 was the most significant result, with association in both Whites (p=0.008, OR=1.4) and African-Americans (p=0.007, OR=2.3), and highly significant in the joint analysis of both ethnic groups (p=0.0001, OR=1.6). The risk allele of rs3731828 was correlated with higher VAMP8 expression (p=0.05). One SNP in CAPG and the previously reported rs1010 were also significant ($p<0.05$). However, the association at rs1010 could be accounted for by rs3731828. No MI or gender specific associations were found. In summary, our study supports CAPG and VAMP8 as CAD risk genes. Importantly, our data suggest VAMP8 as a major CAD risk gene as its genetic effect is not constrained by subgroups represented by ethnicity, MI subphenotype, or gender. We are the first to show allele-specific VAMP8 expression, which provides a plausible mechanism for the genetic risk conferred by the gene.

Differential Expression of TGIF1 Homeobox Gene Transcripts Variants in Oral Squamous Cell Carcinoma: A Preliminary Study. *T. N. Liborio[1], M. G. Silva-Valenzuela[2], L..F Matizonkas-Antonio[1], J. Câmara[3], M. R. Tavares[4], F. D. Nunes[1]* 1) Molecular Pathology Laboratory, School of Dentistry, University of São Paulo, Brazil; 2) Biochemist Department, School of Chemistry, University of São Paulo, Brazil; 3) Pathology Department, School of Dentistry, Federal University of Amazonas, Brazil; 4) Hospital das Clínicas, School of Medicine, University of São Paulo, Brazil.

The study of developmental genes, especially in the homeobox family, can provide insights into processes that differ between normal and neoplastic cells. Interestingly some of these genes may do a process called alternative splicing, in which different variants of mRNA are generated from the same gene. Different transcript variants may be associated with distinctive behaviors in the same cancer. TGIF1 homeobox gene transcripts were already found in oral squamous cell carcinoma, a type of cancer that accounts for at least 95% of all types of oral cancer worldwide, although the participation of the different transcripts variants of TGIF1 in this cancer is currently unknown. The aim of this study was to analyze the expression of TGIF1 variants 2, 4, 5, 7 and 8 in oral squamous cell carcinomas (OSCC) and compare to the adjacent non-tumoral margin (NT). Were analyzed 25 samples of OSCC and 16 of NT. Total RNA of each sample was extracted using TRizol solution. A generic pair of primers first amplified each sample and then those showing amplicons were submitted to primers specific for each variant. The generic primer amplified 92% of OSCC samples, and variant 7 (var7) was in 91,3% of those followed by var5 and 8 (52,2%), var4 (39,1%) and var2 (30,4%). For the NT, the generic primer amplified 87,5% of cases, in which, 57,1% presented equally var7 and 8, followed by var2 and 5 (35,7%) and var4 (28,6%). These results shows that all studied TGIF1 variants are expressed in OSCC. However, var7 was significantly more expressed in OSCC when comparing with NT samples. The increase of some variants expression and the loss of others, suggest that different TGIF1 transcripts have diverse roles in oral carcinogenesis.

Differential expression of lipid metabolism and insulin signaling genes in skeletal muscle of glycerol kinase KO mice. *L. Rahib[1], K. M. Dipple[1,2]* 1) Biomedical Engineering, IDP, UCLA, Los Angeles, CA; 2) Departments of Human Genetics and Pediatrics, UCLA, Los Angeles, CA.

Glycerol kinase (GK) is at the interface of fat and carbohydrate metabolism. GK deficiency (GKD) is an X-linked inborn error of metabolism with metabolic crises as well as predisposition to obesity and type 2 diabetes mellitus (T2DM). Individuals with a GK missense mutation, N288D, are at risk for insulin resistance and T2DM (Gaudet et al., Am J Hum Genet 66:1558, 2000). The purpose of this study was to elucidate the role of GK in fat metabolism and insulin signaling in skeletal muscle (an important tissue in T2DM). To accomplish this, we performed microarray analysis (Affymetrix mouse genome 430 2.0) on a glycerol kinase (Gyk) knock out (KO) mouse model. Total RNA was extracted from muscle hindlimb from one day old Gyk KO and wildtype (WT) male mice. Microarray analysis determined that there were 525 genes that were differentially expressed (1.2 fold, p-value <0.05) between KO and WT mice. Of these 215 were up-regulated and 309 were down regulated. EASE analysis revealed that some of the most statistically significant biological groups were protein binding, ion homeostasis, growth factor binding, insulin-like growth factor binding, cell-matrix adhesion, nucleic acid binding, and regulation of cell growth. Of particular interest were the twenty genes that are involved in lipid metabolism and the ten genes involved in the insulin signaling pathway and diabetes that were differentially expressed between the KO and WT mice. Real Time-PCR confirmed the differential regulation of genes including Gyk and phosphatidylinositol 3-kinase, regulatory subunit, polypeptide 1 (p85 alpha) (Pik3r1), insulin-like growth factor 1 (Igf1), and growth factor receptor bound protein 2-associated protein 1 (Gab1). Further investigations of these genes may provide insight into the role of GK in insulin signaling, insulin resistance and type 2 diabetes mellitus in skeletal muscle. These findings support our previous studies performed in brown adipose tissue (Rahib et al., Eur J Human Genet 15:646, 2007) and further supports the role of GK in insulin sensitivity in various tissues.

High resolution long oligo based array CGH for clinical diagnostics: whole genome array versus targeted array.

B. Wu[1,3], Y. Shen[1,2], D. Miller[1,3], V. Lip[1], X. Sheng[1], K. Tomaszewicz[1], H. Shao[1], H. Fang[1], H. Tang[1], M. Irons[1,3], C. Walsh[1,3,4], O. Platt[1,3], J. Gusella[2,3] 1) Lab Med & Path, Children's Hosp, Harvard Medical Sch, Boston, MA; 2) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA, 02114; 3) Harvard Medical School, Boston, MA; 4) Howard Hughes Medical Institute.

Array CGH is now an indispensable clinical diagnostic tool for patients with genetic disorders associated with genomic imbalances. The clinical utility varies depending on the chip platform used for testing. We adopted a commercially available high resolution oligonucleotide array (Agilent 244K aCGH array) for detection of genomic imbalance events in both targeted regions that correspond to commercially available targeted arrays and across the whole genome. Clinical interpretation of arrays with whole genome coverage is complicated by detection of copy number variants (CNVs). We addressed this concern through a combined approach of dataset filtering, size cutoffs, examination of gene content, annotated database search, and general literature search. We offered parental testing free of charge to evaluate previously unreported CNVs. We tested 323 samples on with this comprehensive approach. We found 37 (11.5%) clinically relevant imbalance events in 323 samples. Seventeen of 37 samples are located outside the stated coverage of commercially available targeted arrays (equivalent to Signature v4 and Baylor v6). We detected many imbalance events below 500kb, including novel copy number variants and clinically relevant microdeletions/duplications, that would not be identified by an array based on large insert clones. Due to the redundancy of probe coverage, dye-swap confirmation was often not necessary for large regions of imbalance (>500Kb). Within these large regions, subsequent FISH was 100% concordant with array CGH data. We believe the high resolution nucleotide array transcends the traditional concept of array CGH as an alternative to multiplex FISH. With careful interpretation, the whole genome array is highly valuable in the clinical detection of unsuspected genomic imbalance events among patients with unexplained developmental defect.

What interests and values should guide biobanking? Lessons from two experiments in deliberative public consultation. *H. Walmsley[1], R. Abadie[2], D. Hartell[1], M. Burgess[1], B. Koenig[2]* 1) University of British Columbia, Vancouver, BC, Canada; 2) Mayo Clinic College of Medicine, Rochester, MN.

What interests and values should guide biobanking? Existing governance frameworks were developed for small-scale research projects and are based upon personal autonomy and individual informed consent. Large-scale and networked collections of biological specimens and data pose new problems. These range from the expense and unwieldy nature of the consent process for researchers, to complaints about commercialization and unauthorized use of samples by indigenous groups, to fears of data linkage by privacy advocates, and debates about the relative value of biobanks versus cohorts to public health. Transparent public engagement with biobanking is long overdue. We provide lessons learned from two deliberative public consultations: one conducted in British Columbia (BC), Canada, the second in Olmsted County, Minnesota (MN). A proposal for a BC-wide BioLibrary and Mayo Clinic plans for an institutional biobank provided the opportunity for citizens to shape planning for an actual, as opposed to a hypothetical, biobank. This joint project draws from theories of deliberative democracy and pioneering examples, such as the Citizens Assembly in BC. Our aim: to facilitate a genuinely inclusive public debate. An innovative community engagement structure was developed and implemented in BC and MN. The engagement exercise included two full weekends (4 days) of face-to-face deliberation in large and small groups. Professional moderators facilitated the discussion. Diverse expert and stakeholder presentations, background readings circulated ahead of the event, and physical models of the proposed biobank features provided the stimulus for informed yet open-ended deliberation by 25 demographically-stratified citizens at each site. Recording of all sessions and online discussions and a members-only website facilitated research on the event. The challenge to the deliberants: what interests and values should guide biobanking? The challenge to the research team studying the events: what methods allow for authentic public consultation about complex scientific topics by citizens in a democracy?

A patient with pancreatic neuroendocrine tumors and Von Hippel-Lindau V84L mutation: A new VHL subset?
E.C. Oquendo, H. C. Gaddipati, K.L. Nathanson Division of Medical Genetics, Children's Hospital of Philadelphia, Philadelphia, PA.

Von Hippel-Lindau (VHL) disease is an autosomal dominant tumor susceptibility syndrome caused by germline mutations of the VHL tumor suppressor gene. Patients develop hemangioblastomas of the central nervous system and retina aswell as endolymphatic sac tumors, renal cell carcinomas, cysts and neuroendocrine tumors of the adrenal gland (pheochromocytomas) and the pancreas. The VHL protein plays an important role in angiogenesis as a negative regulator of hypoxia-inducible mRNAs. We present a 43-year-old Caucasian male patient with history of benign bilateral adrenal pheochromocytomas (PCCc) status post adrenalectomy and retroperitoneal paraganglioma status post resection. At the age of 40 he developed symptoms of diarrhea, fatigue and flushing. A 3cm pancreatic mass was detected on abdominal MRI scan. The histopathology of the specimen obtained from pancreatoduodenectomy was consistent with 3 localized benign pancreatic neuroendocrine tumors (PNETs). Brain, spine MRI scans, thyroid ultrasound and retinal exams were all normal. DNA sequencing of the VHL gene detected a heterozygous missense mutation G463T changing a valine for leucine at amino acid position 84 of the protein (V84L). We previously reported the correlation between the V84L mutation and multiple early-onset PCCs in 4 unrelated families with VHL type 2C. None of these patients had PNETs. PCCs and PNETs have been found to occur concurrently in VHL patients principally in the VHL2B subtype. VHL2C is characterized by patients with isolated PCCs and low risk for renal cell cancer. Therefore this novel association between the V84L mutation, PCC and PNET may represent a new variant of VHL2B, VHL2C subtypes or possibly a new subtype VHL2D. This case illustrates the ambiguity sometimes encountered when we make genotype-phenotype correlations based on clinical classification models. Should molecular or clinical criteria predominate in classification and management? Interestingly our patient had hormonally active PNETs which is very unusual in VHL syndrome. In conclusion it is clear that VHL patients with the V84L mutation should be screened for PNETs in addition to early onset PCCs.

Quantitation of Fusion Transcripts Using TaqMan Gene Expression Assays. *K.Y. Lee[1], F. Hu[1], E. Langit[1], C. Preud'Homme[2], J.M. Cayuela[3], B. Cassinat[4], M. de Graaf[1], S. Guenther[1], G. Marcus[1], P. Brzoska[1]* 1) Applied Biosystems, Foster City, CA; 2) Laboratoire dHematologie, Lille, France; 3) Laboratoire Central d'Hématologie, Hôpital Saint-Louis, Paris, France; 4) Unité de Biologie Cellulaire, Hôpital Saint-Louis, Paris, FRance.

Chromosomal aberrations such as translocations are frequently found in human cancer cells. Chromosomal translocations may result in a chimeric gene expressing a fusion transcript which is then translated into a fusion protein that affects normal regulatory pathways and stimulates cancer cell growth. A well known example is the BCR/ABL chimeric mRNA which is the result of a translocation of ABL on chromosome 9 to the BCR breakpoint cluster on chromosome 22. The resulting fusion transcript is the cause for 90% of chronic myelogenous leukemia. Current methods for identifying translocations include FISH and karyotyping, neither of which can be used to quantify the expression level of the fused gene. We have designed TaqMan Gene Expression Assays for a set of known fusion transcripts for quantitative analysis. We collected 214 fusion transcript GenBank mRNA Accessions representing 165 unique translocation events from two data sources (Chimer D:http://genomce.ewha.ac.kr/ChimerDB/ and Hahn et al, PNAS 2004;101;13257-13261. The transcripts were annotated and fusion breakpoint locations were identified or verified. Assays were designed such that the primers and probe spanned the breakpoint region and were not placed directly on the breakpoint. The transcript breakpoint region (~10bp), SNPs and repetitive sequences were masked before the assay was designed using the Applied Biosystems assay design pipeline. As proof of principle, several assay designs were tested against plasmids and patient samples known to contain the translocation variant. Only those samples containing the fusion transcript were amplified indicating the specificity of the assay. From a large number of assay designs, we selected 165 TaqMan Gene Expression Assays targeting each of the 165 translocation variants. These 165 assays for quantitating fusion transcripts are currently published on the Applied Biosystems Website (http://www.appliedbiosystems.com).

Phenotypic characterization of patients with interstitial duplications of 15q11-q13 detected by array based comparative genome hybridization (array CGH). *H. Yonath, C. Bacino, S.R. Lalani, A. Patel, A.L. Beaudet, S.W. Cheung, T. Sahoo* Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX.

Interstitial duplications and isodicentric chromosomes involving the 15q11q13 region are a relatively common cytogenetic abnormality associated with altered behavior, developmental delay/mental retardation (DD/MR), autism, and seizures. This chromosomal region has considerable genomic instability and is subject to imprinting in a parent-of-origin manner. Deletions in this region give rise to Prader-Willi/Angelman syndromes. There is a lack of exhaustive phenotypic data from cases with interstitial duplications of 15q11q13, that involve the Prader-Willi/Angelman syndrome critical region (PWACR). There is evidence that duplications of maternal origin cause autism and ones of paternal origin are generally benign. In order to identify patients with this duplication, we screened 6000 cases that were referred for targeted array CGH. The array CGH was found to provide a more accurate detection and identification of these submicroscopic duplications, most of which could not be identified cytogenetically. We report here the cytogenetic, molecular and phenotypic characterization of 12 patients harboring a duplication of the PWACR. A combination of array CGH, fluorescence in situ hybridization, methylation analysis, and a custom 44K array CGH focused on 15q11-q13 allowed delineation of the size and nature of the duplicated segment; in 6 cases (5 interstitial and 1 inv dup 15) the duplication extended from breakpoints 1 to 3 (class I), in 5 cases from breakpoints 2 to 3 (class II), and one case of inv dup 15 included a more distal breakpoint (breakpoint 4). Detailed patient information was obtained form the referring physician after obtaining informed consent from the patients or their parents. The indications for the array CGH were DD/MR in 6 patients, DD and absent speech in 1, autistic spectrum in 2, seizures in 2 and behavioral problems in one patient. In one case the duplication is de novo and the rest of the cases are awaiting the parental results. A genotype/phenotype correlation including parent of origin effect and size of the duplication will be presented.

Urinary GAG behavior and clinical correlation in three patients with MPS I-Scheie during irregular enzyme replacement therapy. *M.V. Munoz-Rojas, T. Vieira, A. Federhen, L. Pinto, K. Lazzaroni, M. Burin, J. Coelho, R. Giugliani* Medical Genetics Service, Hospital de Clinicas de Porto Alegre, Porto Alegre, RS, Brazil.

Introduction: MPS I is caused by L-iduronidase deficiency and subsequent glycosaminoglycan (GAG) storage in organs and tissues and above normal urinary (u)excretion levels. Clinical trials with laronidase ERT have shown decreased urinary excretion levels in patients with MPS I after laronidase ERT introduction. The standard laronidase dosage is 0.58 mg/ kg, weekly on a regular basis. Purpose: To report the behavior of uGAG concentration during standard dosing, on ERT irregular infusion time intervals, in three MPS I - Scheie patients, with self reported clinical correlation. Methods: uGAG concentration on the first void, was assessed for all patients, prior to laronidase infusion when one or more weekly infusions had been missed, independently of the reason for missing an infusion. Any adverse event, occurred since last infusion, as well as any report on clinical improvement or worsening was captured. Results: All three patients are on ERT for over 2 years and all have several uGAGs analysis showing lower GAGs concentration when compared with pre-treatment levels. Patient 1, who has received standard dose ERT but usually in an every-other-week interval, revealed uGAG levels within normal limits on all occasions and reports no clinical worsening or complains. Patient 2 and 3, have received standard dose ERT on a weekly basis although with infusion gaps of several weeks; Both reveal uGAG levels increase although patient 2 reports only a few mild complains mainly on sleeping and breathing worsening while patient 3 refers important worsening with intercurrent infections, abdominal distension, fatigue and sleep apnea symptoms. Conclusions: ERT seems to play an effective role in decreasing the concentration of uGAGs, which in turn, may correlate at some extent with somatic clinical status. Although Laronidase standard dose and regimen is established, inter individual response may exhibit a substantial difference and it might reflect that individual adjustments may be possible for result optimization.

Molecular genetic analysis of long QT syndrome patients and identification of one novel mutation in KCNH2. *X. Zhang[1,2], S. Chen[2], L. Zhang[3], C. Oberti[1], G.M. Vincent[3], Q. K. Wang[1,2]* 1) Department of Molecular Cardiology, Lerner Research Institute, Cleveland Clinic, Cleveland, Ohio; 2) Center for Human Genome Research, Huazhong University of Science and Technology, Wuhan, P. R. China; 3) LDS Hospital and University of Utah, Salt Lake City, UT.

Long QT syndrome is a cardiac disorder characterized by prolonged QT interval, ventricular arrhythmias and sudden death. To date, eight genes have been found for LQTS, including KCNQ1, KCNH2, SCN5A, Ank2, KCNE1, KCNE2, KCNJ2 and CACNA1C. In the past few years, we have been studying 89 independent families and patients affected with LQTS and ventricular arrhythmias. Ten mutations in KCNQ1, including five novel mutations, were previously reported (Chen S. et al. Clinical Genetics 2003;63:273-282). In this study, we performed linkage and mutation analyses for the rest of known LQTS genes in this population of patients. For two LQTS families, linkage analysis with polymorphic marker that span the LQTS genes linked one family to KCNH2, and the other family to SCN5A. Direct DNA sequence analysis identified two cis-variants, K897T and A490T in KCNH2, that co-segregated with all affected individuals in family 1. In family 2, we found that the E1784K mutation in SCN5A was present in all affected individuals, but some affected individuals also carried a G38S polymorphism in KCNE1. The patients who carried both the SCN5A E1784K mutation and KCNE1 G38S polymorphism had statistically longer QT interval than those with only the SCN5A E1784K mutation. Furthermore, the autopsy report of the proband who died suddenly at age 31 revealed dilated cardiomyopathy-like phenotype and fat infiltration and fibrosis, implicating that some LQTS patients may have the potential risk of developing dilated cardiomyopathy. Six other mutations were also identified and all in the KCNH2 gene. These mutations include one novel mutation 2040insAG, and five known mutations, A561T, D609N, A614V, D629S, and R366X. In summary, we report one novel KCNH2 mutation that causes LQTS. Further, our results suggest that polymorphisms in a known LQTS gene can modify the phenotype of LQTS patients carrying mutations in a different LQTS gene.

Origins of regulatory mutations at the LCT locus in African populations. *A. Ranciaro[1,2], F. Reed[2], J. Hirbo[2], K. Powell[2], O. Sabah[3], M. Osman[4], H. Muntaser[4], S.A. Tishkoff[2]* 1) Dept. of Biology, University of Ferrara-Italy; 2) Dept. of Biology University of Maryland, College Park, MD; 3) Kenya Medical Research Institute, Centre of Biotechnology Research and Development, Nairobi, Kenya; 4) Dept. of Molecular Biology, Institute of Endemic Diseases, University of Khartoum-Sudan.

In most human populations, the ability to digest lactose, the sugar present in milk, declines rapidly after weaning because of decreasing levels of the enzyme lactase (lactase-phlorizine hydrolase, LPH) in the small intestine. However, there are individuals who maintain the ability to digest milk and other dairy products into adulthood due to a genetic adaptation, primarily in populations that herd cattle and have a history of drinking fresh milk. The goal of the current project is to identify new variants that may be associated with Lactase Persistence (LP) in ethnically diverse populations, to characterize nucleotide diversity in a diverse set of African and Middle Eastern populations and to reconstruct the evolutionary history of this region. We collected phenotype data from from Tanzania, Kenya and the Sudan. We resequenced 1.7 kb of intron 9 and 3.3 kb of intron 13 of the MCM6 gene (previously found to be associated with lactase persistence in European populations) and 2.2kb of the promoter region of the LCT gene in 280 Africans with phenotypic data and in 300 African and Middle Eastern individuals without phenotypic data. Four SNPs located in intron 13 (at position -14010, -13915, -13910, -13907 from the start of the LCT gene) showed a significant association with the LP trait. Resequencing of these regions in a panel of great apes indicated that the alleles associated with LP are derived. This result suggests that multiple mutations arose independently in different African populations due to convergent evolution. These results have implications for understanding the origins of pastoralism as well as historic migration events within Africa.

Duplication of chromosome 12q24.11q24.23 identified by array-CGH in a patient with Noonan syndrome. *A. Patel[1], O. Shchelochkov[1], J. Wiszniewska[1], G. Weissenberger[1], P. Fernandes[1], A.C. Chinault[1], M.K. Kukolich[2], C. Eng[1], S.W. Cheung[1], V.R. Sutton[1]* 1) Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX; 2) Clinical Genetics, Cook Children's Hospital, Fort Worth, TX.

Noonan syndrome is an autosomal dominant disorder with an estimated incidence of 1 in 1000 to 2500 live births. It is characterized by short stature, short neck with webbing, cardiac anomalies, developmental delay of variable degree, cryptorchidism in males and characteristic facies. Gain of function mutations in the *PTPN11*, *KRAS* and *SOS1* genes that are components of the RAS-ERK signaling pathway are identified in about 68% of individuals with Noonan syndrome. We report the first case of a duplication of chromosome region 12q24.11q24.23 identified by arrayCGH that includes the *PTPN11* gene in a 3 year old girl with features of Noonan syndrome. The patient presented with postnatal onset failure to thrive, developmental delay, microcephaly, velopalatal incompetence, pectus excavatum, coarctation of aorta, atrial and ventricular septal defects, decreased muscle tone, and facial dysmorphic features consistent with Noonan syndrome, however, sequence analysis of *PTPN11* and *KRAS* did not identify a missense mutation. In addition, at three years of age her speech, gross and fine motor development was at the level of a 12-18 month old child. This degree of developmental delay was atypical for a patient with Noonan syndorme, raising concerns for a chromosomal abnormality. ArrayCGH showed an interstitial duplication of at least 8Mb including the *PTPN11* gene. The increased gene dosage of the *PTPN11* gene in the form of duplication is postulated to be comparable to the gain of function mutations seen in Noonan syndrome. We have shown that increased dosage of *PTPN11* can result in a Noonan syndrome phenotype. We suspect that duplications of one of the RAS-ERK pathway regions/genes may result in a Noonan syndrome phenotype in some of the remaining 30% of patients for whom no missense mutation was detected and should be considered part of a comprehensive evaluation for molecular defects in this pathway.

The genetic architecture of congenital heart disease. *J.B. Winston, J.M. Erlich, P.Y. Jay* Pediatrics, Washington University, St. Louis, MO.

Many genetic mutations have been discovered in the past decade that cause congenital heart defects in man and mouse models, but little is known regarding the genetic pathways that lead to specific defects. Heterozygous mutations of the cardiac transcription factor NKX2-5 cause a broad spectrum of heart defects with incomplete penetrance. Modifier genes may contribute to variable NKX2-5 phenotypes. An unbiased genetic approach to their discovery can offer insight into pathways and phenotypic variability. A large-scale linkage analysis project was conducted to identify modifier genes that have a main or epistatic effect on the Nkx2-5 mutant phenotype by crossing Nkx2-$5^{+/-}$ mice in an isogenic C57Bl/6 background to FVB/N or A/J inbred strains. Nkx2-$5^{+/-}$ animals in the C57Bl/6 background have a 15-20% incidence of ventricular or atrial septal defects (VSD, ASD). Nkx2-$5^{+/-}$ F1 progeny of C57Bl/6 mice crossed to inbred strains FVB/N or A/J have a nil or rare incidence of defects. Defects are recovered in F2 progeny of inter- and parental backcross backgrounds, suggesting an effect of homozygosity of unknown modifier loci. To map loci that modify the Nkx2-5 mutant phenotype, neonatal hearts of 1,426 F2 Nkx2-$5^{+/-}$ mice were serially sectioned to identify congenital heart defects. Thus far, 256 defects have been found with the vast majority being VSD. Genome wide linkage analysis for VSD susceptibility loci was carried out on F2 progeny to localize inbred strain polymorphisms that influence Nkx2-$5^{+/-}$ hearts toward or away from defects. Analysis revealed a suggestive main effect locus on chromosome 10, and 16 significant epistatic QTL involved in 11 epistatic interactions. Four loci representing 2 epistatic interactions were also found to be significant in the C57Bl/6-A/J intercross. Seven epistatic loci form an interaction network suggesting the existence of a complex regulatory pathway associated with Nkx2-5. The results offer a conceptual framework to place genes into genetic pathways. Finally, an appreciation of the role of modifier genes and genetic interactions in disease pathogenesis should suggest novel, unprecedented strategies to prevent or ameliorate serious congenital heart disease, a leading cause of death in children.

Culture creates genetic structure in Daghestan. *E. Marchani[1], W.S. Watkins[2], K. Bulayeva[3], H.C. Harpending[1], L.B. Jorde[2]* 1) Dept Anthropology, Univ Utah; 2) Eccles Inst of Human Genetics, Univ Utah; 3) N.I. Vavilov Inst of General Genetics, Russian Academy of Sciences.

We investigate the effect of mating practices on genetic structure in Daghestan by comparing the frequency of 24 mitochondrial DNA (mtDNA) and 22 Y chromosome (NRY) haplotype-defining single nucleotide polymorphisms in three highland (Avar, Dargin, Kubachi) and two lowland (Kumik, Nogai) populations from Daghestan. AMOVA analysis reveals three times the amount of genetic structure in the NRY data than in the mtDNA data (mtDNA $_{ST}$=10.3%, NRY $_{ST}$=31.5%). The same comparison in a series of European and East Asian populations produces nearly-equal values for both sets of markers (mtDNA $_{ST}$=46.1%; NRY $_{ST}$=42.9%). This is consistent with the ethnographic record of patrilocality among highland Daghestani populations.

AMOVA between highland and lowland pooled populations ($_{ST}$=42.7%, $p<0.001$) reveals NRY genetic structure nearly as great as that between European and East Asian populations posted above. The highland-lowland structure is not nearly as strong in the mtDNA data ($_{ST}$=3.9%, $p<0.01$), and weaker than that observed when all Daghestani populations are considered independently ($_{ST}$=10.3%, $p<0.001$). Reduced NRY haplogroup diversity among highland populations (*h*: 0.00-0.47) when compared to lowland populations (*h*: 0.82-0.93) suggests drift caused by isolation and patrilocality.

The pairwise $_{ST}$ between the Nogai and Europe (21.0%) exceeds that (13.2%) between the Nogai and East Asia, consistent with their Mongolian origin. This unique observation is opposite the relationship observed between the Nogai and Europe and East Asia in the NRY data (Europe $_{ST}$=18.8%; East Asia $_{ST}$=45.1%), even though they are the only Daghestani population to exhibit Asian Y haplogroups D and Z. These results demonstrate that population history, isolation, and patrilocality have all left distinctive signatures on the genetic structure of Daghestans populations. Supported by NIH Grant GM-59290 and NSF Grant BCS-0218370.

Identification of interacting proteins for glaucoma-related optineurin (OPTN) by yeast two-hybrid system. *T. Rezaie[1], L. Huang[2], M. Walter[2], M. Sarfarazi[1]* 1) Molecular Ophthalmic Genetics, University of Connecticut Health Center, Farmington, CT; 2) Medical Genetics, University of Alberta, Edmonton, AB, Canada.

Our original study identified mutations in the *OPTN* gene in adult-onset primary open-angle glaucoma (Science 295, 2002). We hypothesized that altered protein-protein interaction caused by *OPTN* mutations may contribute to the glaucoma. This study aimed to identify novel OPTN interacting proteins (OPTN-IPs) and the pathways through which *OPTN* mutations lead to glaucoma. A cDNA library from human trabecular meshwork (HTM) cells was constructed by cloning of the cDNA in ProQuest prey vector containing GAL4 DNA activation domain. The *OPTN* full-length cDNA was cloned in pDEST32 containing GAL4 DNA binding domain as the bait. Approximately 2.4 X 10^5 colonies were screened from which 7 colonies activated the HIS3, URA3 and lacZ reporter genes. Bait and prey plasmids were recovered from yeast. Sequencing of bait plasmids confirmed the specificity and absence of undesired mutations. Four new potentially OPTN-IPs identified by sequencing of the prey colonies. Further characterization of these colonies with confirmation of interaction by co-immunoprecipitation and pull-down assay and full-length sequencing of prey plasmids is underway. The 4 new candidates consist of an interacting protein to TNF-, an activator for RAB-like small GTPases, a subunit of RNA splicing factor and a kinase protein. The HTM cDNA library is a valuable tool for discovery of the genes related to ocular function. Association of the new OPTN-IPs with TNF- and RAB pathways is in agreement with earlier findings that OPTN is inducible by TNF- and is an interacting partner for RAB. The genes for these 4 new OPTN-IPs are potential candidates for mutation screening of glaucoma patients. Identification of OPTN interacting proteins and their disease-related pathways will provide new opportunities to study mechanism underlying the *OPTN*-linked glaucoma neuropathies. This study may further help to assign functions to uncharacterized proteins, to understand the composition of protein complexes and may lead to identification of novel therapeutic targets. Support: NIH Grant EY-014959 and Canadian Institutes of Health Research.

Fine mapping of a risk gene for multiple sclerosis. *D. Reich[1,2], N. Patterson[2], P.L. De Jager[2,3,4], A. Tandon[1,2], S. McCarroll[2,5], A. Waliszewska[1,2,3], J. Neubauer[1,2], C. Schirmer[1,2], R.R. Lincoln[4], S. Poduslo[6], O. Khan[7], S.L. Hauser[4], J.R. Oksenberg[4], D.A. Hafler[1,2,3]* 1) Harvard Med School, Boston MA; 2) Broad Institute, Cambridge MA; 3) Brigham & Women's Hospital, Boston MA; 4) UCSF, San Francisco CA; 5) Mass General Hospital, Boston MA; 6) Med College of Georgia, Atlanta GA; 7) Wayne State School of Med, Detroit MI.

We recently reported a whole genome admixture scan in African Americans with multiple sclerosis (MS), demonstrating a risk locus in a 28 Mb region of chromosome 1. We have since increased the sample size to 882 cases and 1,056 controls, and the evidence for association is overwhelming (LOD=9.0). We estimate that the rate of MS on average in African Americans is ~48% lower than in those who inherit entirely European ancestry at the locus. This is sufficient to explain the lower incidence of MS in Africans Americans compared with European Americans.

Here we report a saturation fine-mapping study of the peak of MS association, using the same strategy we used in the last year to successfully identify risk variants underlying a prostate cancer admixture peak. We genotyped the African American MS cases and controls at a panel of ~2,350 single nucleotide polymorphisms (SNPs), tagging >95% of common variants in the Human Haplotype Map (HapMap) in both European Americans and West Africans. Among the 1,399 SNPs analyzed so far, none predicts MS risk beyond the admixture association. A whole genome scan in European-derived populations also failed to find a variant in the region explaining the association, suggesting that HapMap may not include the variant(s) responsible for MS risk.

A striking feature of the peak is that it includes the q-arm side of the centromere, which is incompletely assembled because of copy number polymorphisms and repetitive sequence. The coverage of SNPs in HapMap across this region is also thin, perhaps explaining why screens of HapMap SNPs have not identified a causative variant. We describe the discovery and genotyping of copy number polymorphisms in this region, and testing them for association to MS.

Geospatial variation in the Human Leukocyte Antigen (HLA) system in the United States. *E.P. Williams, M. Maiers, L. Gragert* Bioinformatics, National Marrow Donor Program, Minneapolis, MN.

We examined geospatial variation in HLA alleles, haplotypes, and phenotypes in the United States from a sample of 3.8 million volunteer donors in the National Marrow Donor Program (NMDP) registry. Each of the donors was typed for HLA-A, B, and DR at 2-digit resolution and linked with provided zip code and self-identified race and ethnicity (SIRE) information. Within the broad SIRE categories, variation in many HLA alleles and haplotypes is both significant and measurable, indicating a differing ancestral makeup in different US regions. We used the coefficient of variance statistic across regions of the United States to identify the strongest genetic clines in frequency and identify the areas that are the most unique genetically. Combining several genetic clines for a set of alleles and haplotypes can identify US regions of strong genetic similarity. For populations not native to the North America (European-Americans, Hispanics, Asian-Americans, African-Americans), geospatially-variable immigration trends to the US may be derived in the future with the aid of geospatial HLA frequency patterns from their ancestral countries. Signatures of substructure within the indigenous North American population especially can be seen. For example, the HLA-DR14 type has a coefficient of variation of 0.814 across states in Native Americans with a strong negative gradient eastward over the Rocky Mountains, while the coefficient of variation is 0.072 for European-Americans, 0.305 for Hispanics, 0.128 in African-Americans, and 0.138 in Asian-Americans.

Partial trisomy 2q: Report of a de novo inv dup(2)(q35-qter). *Y.F. Li[1], E. Roeder[2], B. Nowakowska[3], M.L. Cooper[1], A. Patel[1], W.W. Cai[1], S.W. Cheung[1]* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Division of Genetics and Metabolic Disorders, Department of Pediatrics, University of Texas Health Science Center at San Antonio, San Antonio, TX; 3) Dept. of Medical Genetics, Institute of Mother and Child, Warsaw, Poland.

The partial trisomy 2q (q35-qter) phenotype has been well described in the literature. Many cases of 2q duplication result from familial translocation, and concomitant monosomy for other chromosome segments obscures the genotype-phenotype correlation of the 2q duplication. Pure duplications of the distal part of chromosome 2q are rare. We describe a female infant with a de novo inverted duplication involving the distal long arm of one chromosome 2. The clinical findings of this patient include congenital heart defect, hypothyroidism , hypotonia, nystagmus, dysmorphic features, and developmental delay. Initial chromosome analysis by GTG-banding analysis revealed an additional chromosome material of unknown origin on the terminal long arm of chromosome 2. To identify the origin of this material, a genome-wide BAC clone array with a set of 21,658 RP11 BAC clones with 7 BAC clones per 1 Mb was used. This set of clones was selected by a computer program with unique sequences at both ends and tightly distributed insert size that completely cover the entire human genome. An interstitial duplication of 21.2 Mb in size between 2q35-qter was identified. This duplication was subsequently confirmed by fluorescence in situ hybridization analysis and was determined that it is an inverted duplication. Thus, the proband's karyotype was interpreted as 46,XX,inv dup(2)(q35-qter). Both parental chromosome studies were normal. These findings provide further evidence for a recognizable facial appearance associated with duplication of 2q35-qter. The phenotype-genotype correlation as compared to other case reports of partial trisomy 2q will be reviewed.

Clinical characterization of three patients with NF1 and suspected glomus tumors. *J.L. Sloan[1], C. Park[1], A. Moshyedi[2], L. Yao[3], C.R. Lee[4], D.R. Stewart[1]* 1) GDRB, NHGRI, Bethesda, MD; 2) NIH Clinical Center, Bethesda, MD; 3) Dept. of Radiology, NIH Clinical Center, Bethesda, MD; 4) Lab. of Pathology, NCI, Bethesda, MD.

Glomus tumors are benign tumors that arise from the glomus body, a ubiquitous contractile neuromyoarterial receptor that controls blood pressure and temperature. They are classically solitary, located in the distal phalanx and present with temperature hypersensitivity and severe, localized, paroxysmal pain. Multi-focal glomus tumors in patients with neurofibromatosis type 1 (NF1) have been reported, suggesting a possible association. Adults with NF1 were recruited to the NIH for a study on disease variability. Of the ~75 participants in our cohort, 3 reported a history of fingertip pain. Patient 1 was a 35-year-old female with classic glomus tumor symptoms. MRI revealed tumors in 3 of 6 symptomatic digits. The tumors in the 3 fingers were extirpated and confirmed histologically to be glomus tumors. She had complete resolution of pain in 2 fingers and partial in the other digit. Patient 2 was a 35-year-old female who reported pain in her left 4th digit and recently developed pain in her right 1st digit. No abnormalities were observed on physical exam or by bilateral hand MRI. Patient 3 was a 50-year-old male with a 15-year history of pain in his left arm with symptoms consistent with reflex sympathetic dystrophy (RSD). MRI of both hands revealed lesions consistent with glomus tumors of the left 2nd and 4th digits and right 1st digit. These tumors were removed and pathology confirmed glomus tumors in all digits. Our experience supports the hypothesis of an association between NF1 and glomus tumors. Three of our 75 patients reported fingertip pain, suggesting that this complication of NF1 may be more common than previously anticipated. In sporadic cases, multi-focal tumors are very rare. In all 3 NF1 patients, glomus tumors were either suspected or confirmed in multiple fingers. There was also variability in the natural history of the probable glomus tumors ranging from mild temperature sensitivity and pain to RSD. The molecular pathogenesis of glomus tumors in NF1 is under investigation.

Postural Orthostatic Tachycardia is an age dependent manifestation of Ehlers-Danlos Syndromes. *C. Slemenda[1], B.F. Griswold[2], L. Sloper[2], C.A. Francomano[3], N.B. McDonnell[2]* 1) LI, NIA/NIH, Baltimore, MD; 2) LCI, NIA/NIH, Baltimore, MD; 3) GBMC, Baltimore, MD.

Postural Orthostatic Tachycardia (POTS), defined as a heart rate increase greater than thirty beats per minute from supine to standing, has been reported to be associated with joint hypermobility. We studied the prevalence of POTS among 61 consecutive patients with hypermobile and classical forms of Ehlers Danlos syndrome seen at the National Institutes of Health. Supine, sitting, and standing heart rate measurements were obtained for each subject with five minutes of rest between each position. Thirty eight percent (23/61) of the subjects met criteria for POTS. The condition was significantly more common ($p<0.001$) in patients under the age of 25, with 72% of such patients being affected, as compared to 13.9% of persons over the age of 25. The presence of POTS was associated with a reduction in quality of life, including inability to maintain gainful employment or attend school. The etiology and natural history of POTS in this cohort is not well understood and merits further investigation.

CDKAL1 and diabetes in Mexican Americans. *J.H. Lieman[1,2], R.J. Leach[2,3], M. Escamilla[2,3], H.H.H. Goring[4], J. Blangero[4], R. Duggirala[4], M.P. Stern[2,3], D.M. Lehman[2,3]* 1) The University of Texas Pan American, Edinburg, TX; 2) South Texas Medical Genetics Group University of Texas Health Science Center San Antonio, Edinburg, TX; 3) The University of Texas Health Science Center, San Antonio, TX; 4) Southwest Foundation for Biomedical Research, San Antonio, TX.

It is now widely established that hereditary factors influence risk for development of type 2 diabetes (T2D), yet few gene variants have been confidently identified through consistent replication. Recently, several genome-wide association studies, conducted primarily in Caucasian populations, have identified and replicated T2D-associated variants in and near novel candidate genes. These data are consistent with the notion that multiple genetic factors affect T2D risk, with each conferring incremental risk. Since the genetic risk factors may vary between ethnic groups, we sought to determine whether these same variants contribute to T2D risk in a Mexican American population, the San Antonio Family Diabetes/Gallbladder Study (SAFDGS) which consists of large pedigrees (n=692 genotyped). The variants tested were rs7756992 and rs10946389 (CDKAL1), rs10811661 (near CDKN2A/CDKN2B), rs4402960 (IGF2BP2), rs1111875 (near HHEX), rs94759 (near CEP55), and rs8050136 (near FTO). All SNPs conformed to HWE expectations. Each SNP was tested for association with the traits diabetes and diabetes age-of-onset using a measured genotype approach, as implemented in SOLAR. We observed nominal association with diabetes for the 2 highly correlated SNPs located in CDKAL1 (rs7756992 p=0.02 RR=1.20 for GG genotype; rs10946398 p=0.01 RR=1.24 for GG genotype). No other associations were detected. Further, accounting for bmi did not affect any of the diabetes association results (average bmi = 31.5). These results provide supportive evidence for a potential role for alterations in the CDKAL1 gene in T2D pathogenesis with comparable risk among Mexican Americans as that reported in Caucasian populations. The risk for the homozygous carriers of the minor alleles at the SNPs in CDKAL1 was much stronger than that for the heterozygotes, consistent with results reported in Steinthorsdottir et al (Nature Genetics, 2007).

Idursulfase Replacement Therapy in 2 Infants with Hunter Syndrome. *D. Viskochil, C. Ashurst, I. Hung, J. Carey, S. Bleyl, N. Longo* Dept Pediatrics, Div Med Gen, Univ Utah, Salt Lake City, UT.

Mucopolysacharidosis II (MPS II) is an X-linked lysosomal storage disorder caused by a deficiency in iduronate-2-sulfatase. Based on the success of a double-blind, placebo-controlled clinical trial (Muenzer J, et al., 2006, Genet Med 8; 465-473), the Federal Drug Administration recently approved the administration of idursulfase (Elaprase^{TM}) for individuals with MPS II. The 2 primary endpoints of the trial were the distance covered in a 6-minute walk and change in predicted forced vital lung capacity, which essentially excluded children less than 5 years of age. We have initiated idursulfase replacement therapy in 2 infants with MPS II. Case 1 presented to our service at 8 months of age with gibbus. Additional findings included macrocephaly, mild facial gestalt, a salmon-colored, pebbly skin patch on his thorax, and intermittent otitis media/upper respiratory infections. He had a prior history of hernia repair at 1 month of age, but did not have hepatosplenomegaly, cardiac defects, or joint contractures. Case 2 presented at 8 months of age with hepatomegaly and hearing loss. He also had macrocephaly, mild facial gestalt, anterior beaking of the 2nd lumbar vertebra, and recurrent otitis media. Idursulfase has been provided for a total of 37 weeks for case 1 with interruption of therapy for 10 weeks due to lack of insurance coverage, and 20 consecutive weeks for case 2. Response to therapy was noted by decreased urinary glycosaminoglycans (GAGs) in both cases. Both developed transient skin rashes during infusion on the 5th week, which resolved by decreasing the infusion rate. Subsequently, over time and with diphenylhydramine pre-treatment, we have increased the rate of infusion to the standard dosing (0.5 mg/kg administered step-wise over 3 hours). Both have tolerated the enzyme infusions with only mild hypersensitivity reactions, without respiratory compromise. We conclude that idursulfase therapy over the short-term is effective and safe in children less than 5 years of age. Long-term studies of infants treated with weekly infusions will be important to evaluate the potential prevention of complications due to an accumulation of GAGs in MPS II.

In vivo radical species quantification in C. elegans mitochondrial mutants. *R. Lightfoot[1], T. Lamitina[2], E.P. Polyak[1], H. Ischiropoulos[1], M.J. Falk[1]* 1) Department of Pediatrics, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Department of Physiology, The University of Pennsylvania, Philadelphia, PA.

The mitochondrial respiratory chain is associated with oxidant production and altered longevity in C. elegans. These associations have been made largely using in vitro markers of oxidant damage. Dysfunction in either complex I or II is associated with shortened lifespan and increased oxidant damage, while impaired coenzyme Q biosynthesis or complex III function lead to increased longevity and resistance to oxidative stress. To better assess the involvement of individual mitochondrial complexes in oxidant species generation, we developed an in vivo method to quantify C. elegans mitochondrial superoxide production using microscopic fluorescence intensity quantification in the mitochondrial-rich pharyngeal bulbs of worms fed Mitosox, a mitochondrial superoxide indicator dye. Synchronous young adult populations of C. elegans were fed standard E. coli on nematode growth media plates spread with Mitosox. C. elegans strains studied included wildtype (N2) animals, as well as single gene missense mitochondrial mutants in complex I (gas-1), complex II (mev-1), complex III (isp-1), and the long-lived insulin receptor mutant (daf-2). No significant variation in fluorescence intensity was detected among these strains following overnight 5 uM Mitosox exposure. However, a significant fluorescence increase was observed in the mitochondrial mutants compared to N2 following overnight exposure to both 5 uM Mitosox and 100 uM methyl viologen, an agent which induces superoxide production. This suggests mitochondrial mutants have either an increased sensitivity to oxidant stress or a decreased capacity to scavenge oxidant species. Among the long-lived mutants compared to N2, fluorescence intensity was significantly lower in the insulin receptor mutant (daf-2) and greater in the complex III mutant (isp-2). This suggests longevity is not always characterized by resistance to oxidative stress, particularly in mitochondrial mutants. Further studies with additional markers, strains, and stressors are currently underway.

Genetic effects on the expression of genes implicated in human T-cell regulation of inflammation in pedigreed baboons. *A. Vinson[1], J.E. Curran[1], M.P. Johnson[1], T.D. Dyer[1], E.K. Moses[1], J. Blangero[1], S.A. Cole[1], L.A. Cox[1,2], J. Rogers[1,2], J.L. VandeBerg[1,2], C. Brugnara[3], O.S. Platt[3], M.C. Mahaney[1,2]* 1) Dept. of Genetics, Southwest Foundation for Biomedical Research, San Antonio, TX; 2) Southwest National Primate Research Center, San Antonio, TX; 3) Department of Laboratory Medicine, Harvard University Medical School, Cambridge, MA.

T-cell regulatory effects in inflammation are implicated in many complex human diseases, including atherosclerosis, osteoporosis, and autoimmune disease. T-cells regulate inflammation in part via activation and differentiation into T-helper cell subsets characterized by largely subset-specific cytokine production. The goal of this study was to evaluate the baboon (*Papio hamadryas*), a species with evolutionary proximity and physiological similarity to humans, as a model organism for studies of the genetics of human T-cell immunity. We addressed this goal by analyzing quantitative expression data measured in baboons for over 100 transcripts coded by genes implicated in human T-cell activation and differentiation. Expression data was generated from mRNA levels measured in lymphocytes from 499 pedigreed baboons using the Illumina Human Sentrix-6 BeadChip microarray system. Using a maximum likelihood variance decomposition approach, our analyses detected significant (p0.05) additive genetic contributions to the variance in expression for 57 of these transcripts (h^2 estimates ranged from 0.09-0.79). Multipoint whole genome linkage screens detected significant evidence for QTLs influencing phenotypic variation in 14 of these 57 heritable transcripts (LOD score range 2.8-14.9, genome-wide P=0.036-9.71x10^{-15}). These results demonstrate that baboons display detectable genetic effects on the expression of multiple genes implicated in human T-cell activation and differentiation, and that QTLs influencing these processes may be localized to orthologous chromosomes in the human genome. Detection and localization of genes affecting quantitative variation in these transcripts to specific regions of the baboon genome suggests that studies dissecting the genetic architecture of T-cell activation and differentiation should be successful in this species.

Inferring the evolutionary history of the Duffy-O mutation. *C.A. Lambert[1], J.M. Akey[1], R. Qiu[2], J. Madeoy[1], D.G. Buckley[2], M.V. Olson[1,2]* 1) University of Washington Department of Genome Sciences, Seattle, WA; 2) University of Washington Genome Center, Seattle, WA.

The Duffy-O mutation, which confers complete resistance to malaria caused by the parasite *Plasmodium vivax*, is a well-accepted example of positive natural selection in African populations. However, many details about the evolutionary history of the Duffy-O mutation remain unknown. To this end, we resequenced 10.5 kb surrounding the site of Duffy-O in 65 geographically-diverse individuals. Our goal was to infer possible evolutionary histories for the Duffy-O mutation by analyzing patterns of DNA variation at the locus. The signature of positive selection we observed is a 6.4-kb region of dramatically reduced diversity among Duffy-O chromosomes; all variation outside this region can be explained by mutation and historical recombination events. Our results are consistent with the Duffy-O mutation arising on a single ancestral chromosome in our sample, which then became fixed in sub-Saharan Africa sometime after the diaspora of modern humans.

To determine how unusual the patterns of variation are surrounding Duffy-O, we also performed a genome-wide scan for positive selection using publicly available data from the HapMap Project. In our scan, we identified SNPs with allele-frequency distributions similar to or more extreme than the Duffy-O mutation. The scan produced an additional 15 loci that have patterns of genetic variation consistent with strong, recent positive selection in the Yoruban population. While only one of the SNPs we identified occurs at a protein-coding site, 12 others occur in introns or just upstream of known genes. Interestingly, 3 of the non-coding SNPs occur in regions of extremely high interspecies conservation, suggesting that regulatory sites may be an important substrate of recent adaptive evolution. All fifteen loci are currently being resequenced in a panel of geographically diverse individuals to facilitate detailed evolutionary analyses. More generally, our data and approaches are providing new insights into the history of the Duffy-O mutation, as well as additional targets of African-specific positive selection.

Machine Learning Methods for Detection of Epistasis under Low Penetrance. *K.K. Nicodemus[1], Y.Y. Shugart[2]* 1) GCAP, CBDB/NIMH/NIH, Bethesda, MD; 2) Johns Hopkins SPH, Baltimore, MD.

Machine learning (ML) algorithms may be useful in the detection of epistasis in large-scale studies. Although the misclassification rate (MR) is one way to evaluate ML methods, in conditions of low penetrance expected in genetic studies, reduction in MR may be modest. Another way to measure performance is using measures of variable importance (VI). We simulated 250 replicates, including 3 genes not associated with case status and 2 genes that participated in a 2-SNP interaction (N SNPs = 199; N cases = N controls = 500). Prevalence = 0.10 and the odds ratio for interaction was 2.5 (baseline penetrance = 0.09, penetrance for double risk homozygotes = 0.24). One causal SNP was in a gene with strong LD; the second causal SNP was in a low LD gene. Null replicates were created by permuting case status. Methods evaluated were random forests (RF), Monte Carlo (MCLR) or logic regression (LR) and generalized boosted regression (GBR). For all 3 ML methods we calculated 1) detection rates (DRs) (% replicates where causal SNPs were ranked in the top 5% important) and permutation based p-values 2) MR for cases and controls using an independent test and 3) training dataset. Algorithms used a classification/logic tree as base learners. We also performed bivariate logistic regression. Under conditions of modest penetrance, all ML methods showed prediction (test set) MR near 0.5; no different from random guessing. Using the training set, both LR and GBR obtained a 10% reduction in MR; RF did not show any reduction. MCLR VI measures detected the correct causal SNPs in 32 and 51% of the replicates (p-values ranged from 0.14-1.8e-4); the DRs using GBR were 26 and 69% (p-values ranged from 0.059-1.0e-4). RF detected the causal SNP in low LD in 100% of the replicates (p-values ranged from 0.048-1.0e-5) but did not detect the causal SNP in high LD. Logistic regression DRs were lower: 24 and 29%. In reduced penetrance conditions, no reduction in MR for predicting case status was observed; reduction in MR using the training set was modest. MCLR and GBR outperformed logistic regression in detecting causal SNPs using VI. Ongoing work is considering complex, multi-SNP pathways.

Clinical testing experience for large genomic rearrangements in the *BRCA1* and *BRCA2* genes for hereditary breast and ovarian cancer. *W. Spence, T. Judkins, J. Schoenberger, S. Rajamani, C. Colvin, S. Chen, M. Frost, J. Trost, R. Wenstrup, B. Roa* Myriad Genetic Laboratories, Inc. Salt Lake City, UT.

Testing for large genomic rearrangements throughout the *BRCA1* and *BRCA2* genes has been performed on high risk breast/ovarian cancer patients referred to our laboratory since August 2006. Our BRC*Analysis* Rearrangement Test (BART) is a multiplexed quantitative endpoint PCR assay for deletions and duplications in the promoter and coding regions of *BRCA1* and *BRCA2*. Analytical software normalizes gene copy number and provides a statistical confidence level for mutation calls. Expert-developed criteria based on family history were used to select patients with ≥30% risk for a mutation. BART complements our panel of 5 common *BRCA1* rearrangements performed on all comprehensive BRC*Analysis* patients. A variety of large rearrangements were identified by BART, wherein ~83% are observed in *BRCA1* and ~17% in *BRCA2*. The profile for *BRCA1* includes private as well as recurrent rearrangements. BART identified a *BRCA1* deletion of exons 9-12 in high risk patients of Latin American ancestry. Another noteworthy rearrangement is the *BRCA1* duplication of exons 18-19, which we found exclusively in unrelated patients of African descent. We also observed recurrent deletions of *BRCA1* exons 1-2, exon 17 and exons 21-24, seen predominately in patients of European descent. One very interesting *BRCA2* rearrangement consists of a triplication of exons 14-24 identified in multiple individuals, mostly traced to a large North American kindred. Recurrent *BRCA2* mutations include deletion of exons 1-2 found in patients of Western European descent, and deletion of exons 14-16. The majority of *BRCA2* rearrangements, however, appear to be private. Expanded large rearrangement testing using BART in addition to sequencing on high risk patients increased the overall *BRCA1/BRCA2* mutation detection rate from ~30% to 33%. Our clinical testing experience with BART provided key information on the *BRCA1* and *BRCA2* large rearrangement profile, and documented apparent founder mutations in specific populations. These data demonstrate the value of testing high risk individuals for large rearrangements in the *BRCA1* and *BRCA2* genes.

A multi-stage evaluation of genetic association with early-onset CAD in MYLK gene. *J. Vance[1], L. Wang[2], E.R. Hauser[2], D. Crosslin[2], S. Nelson[2], A.B. Hale[2], S.G. Gregory[2], S.H. Shah[2,3], GENECARD. Investigators[3,4,5,6], W.E. Kraus[3], P.J. Goldschmidt-Clermont[7]* 1) Miami Inst Human Genomics, Univ Miami Miller Sch Medicine, Miami, FL; 2) CHG, Duke Univ Medical Ctr, Durham, NC; 3) Division of Cardiology, Duke Univ Medical Ctr, Durham, NC; 4) Vanderbilt Univ, Nashville, TN; 5) Univ of Wales College of Medicine, Cardiff, UK; 6) Univ of Sheffield, Sheffield, UK; 7) Univ Miami Miller Sch Medicine, Miami, FL.

We and others have reported linkage evidence for coronary artery disease (CAD) at chromosome 3q13-21. To fine map the region, we previously conducted a peak-wide association survey using SNPs spaced at 100 kb intervals. While strongest association was found at Kalirin gene, multiple genes were associated with early-onset CAD, including the myosin light chain kinase (MYLK) gene. MYLK is a member of the Kalirin-RhoGTPase pathway that we have proposed previously to be important in CAD. To further define association in MYLK, we examined 46 tagging and functional SNPs across the gene in the CATHGEN case-control samples with early-onset CAD (N=750), resulting in an average density of one SNP every 6 kb. Significant results were then validated in GENECARD families with early-onset CAD (N=2954). As a third evaluation, the GENECARD probands (N=560) were compared to the CATHGEN controls (N=291). Finally, validated SNPs were examined for correlation with atherosclerosis in 145 human aortas. Multiple SNPs were significant in the initial screening (p=0.001 to 0.038). However, only three of them were validated in all datasets (p=0.0011 to 0.0014 in CATHGEN, p=0.021 to 0.046 in GENECARD, p=0.0055 to 0.0075 in the comparison of GENECARD probands with CATHGEN controls). The risk alleles of the three validated SNPs were also correlated with higher atherosclerosis burden in aortas (p=0.007 to 0.040). The three SNPs are in linkage disequilibrium with each other (r2>0.9) and span over 50 kb region at the 5 end of the gene. Our multi-stage evaluation strongly supports MYLK as a novel CAD risk gene. MYLK regulates smooth muscle cell contraction and endothelial cell permeability. The known functions of MYLK provide a plausible mechanism for its role in the development of CAD.

Fabry Disease: Normal Renal Ultrastructure Indicates that -Galactosidase A Variant D313Y Causes Plasma Enzyme Pseudodeficiency. *M. Yasuda[1], R.E. Gordon[2], S.H. Dikman[2], R.J. Desnick[1]* 1) Department of Genetics and Genomic Sciences, Mount Sinai Sch Medicine, New York, NY; 2) Department of Pathology, Mount Sinai Sch Medicine, New York, NY.

Fabry disease is an X-linked inborn error of glycosphingolipid catabolism resulting from the deficient activity of the lysosomal enzyme, a-galactosidase A (-Gal A). In affected males, the progressive lysosomal accumulation of globotriosylceramide (GL-3), particularly in the vascular endothelium, results in renal failure, cardiac and cerebrovascular disease, and early demise. While over 400 disease-causing -Gal A mutations have been identified to date, only one pseudodeficiency allele, D313Y, has been described. Males with D313Y have markedly decreased -Gal A activities in plasma or serum. Previous overexpression studies in COS-7 cells demonstrated that the D313Y enzyme has ~60-70% of wild-type intracellular -Gal A activity, but was unstable in plasma at neutral pH (Yasuda et al. Hum Mutat 22:486-492, 2003). In addition, D313Y was present in ~0.45% of Caucasian individuals. However, recent studies screening for Fabry disease detected patients with deficient -Gal A activities with only a D313Y allele in hemodialysis and hypertrophic cardiomyopathy clinics, raising concern that this mutation may cause Fabry disease. A renal biopsy was obtained from a male carrying the D313Y allele, who was being considered as a kidney donor for his nephew, who had Fabry disease (-Gal A mutation, 895del14). The potential donors -Gal A enzyme level in plasma was deficient [1.6 nmol/hr/ml (normal mean SD: 12 4.2)], while his leukocyte activity was within normal range [53 nmol/hr/ml (normal mean SD: 34.6 14.6)]. At age 56, he did not have proteinuria or other symptoms of Fabry disease. On electron microscopy, the glomerular podocytes, mesangial and endothelial cells as well as tubular, arterial medial, endothelial, and interstitial cells all lacked the characteristic electron-dense laminated lysosomal GL-3 inclusions. These studies indicate that D313Y is a rare -Gal A coding region sequence variant that does not cause renal pathology, and therefore, is not a disease-causing -Gal A mutation.

Genomic copy number variations as a basis of genetic susceptibility for Amyotrophic Lateral Sclerosis (ALS).

J.H. Veldink[1], H.B. Blauw[1], M.A. Van Es[1], C. Saris[1], C. Sabatti[2], L.H. Van den Berg[1], R.A. Ophoff[1,2] 1) Department of Neurology, Rudolf Magnus Institute of Neuroscience and Complex Genetics Section, University Medical Center Utrecht, Netherlands; 2) Department of Human Genetics, University of California, Los Angeles, USA.

Genomic copy number variations (CNVs) are abundant source for genetic variation in the human genome and have been associated with genomic disorders as well as complex human traits. ALS is a devastating disease characterized by progressive degeneration of motor neurons in brain and spinal cord leading to muscle weakness. We and others have shown that CNV in the Survival of Motor Neuron gene (SMN) is associated with the severity/susceptibility to ALS. In order to investigate the role of CNVs in ALS genome-wide, we have developed a CNV detection script for high-density SNP data. We genotyped 450 patients with ALS and 450 healthy sex- and age-matched controls using the Illumina HumanHap300 BeadChip. Two observations are relevant to the detection of CNVs: the logR ratio (= SNP intensity), and the B allele frequency (= SNP genotype). Criteria in our script were set based on 1,000 visually scored CNVs. We identified 1144 CNVs in patients with ALS and 1184 in controls (in total 2328) with 36% (n=833) not present in the online database. Duplications outnumbered deletions (1416 versus 868 hemizygous deletions). We identified 382 CNVs that were uniquely observed in controls and 407 that were only present in ALS patients. Although differences were found in a few common CNVs with regard to their frequency between patients and controls, none were statistically significant. To achieve a more comprehensive and objective way of CNV detection, we developed an HMM-based algorithm. Prior probabilities were estimated using an external dataset (HapMap) and 245 true positive CNV findings (HumanHap300 BeadChip). This enabled us to describe the emission and transition probabilities for our HMM. Using this approach we designed an operational algorithm and are currently further optimizing our model. Our efforts will lead to improved detection of CNVs using genome-wide SNP data and enable us to study the impact of CNVs on disease susceptibility.

Autosomal dominant multiple familial trichoepithelioma in a large consanguineous Bedouin family: linkage to chromosome 16q12-13. *H. Romi[1], A. Zvulunov[3], R. Ofir[1], K. Elbedour[2], O.S. Birk[1,2]* 1) The Morris Kahn Laboratory of Human Genetics, National Institute for Biotechnology and Faculty of Health Sciences, Ben-Gurion University of the Negev, Beer-Sheva , Israele; 2) Genetics Institute, Soroka Medical Center, Beer-Sheva, Israel; 3) Schneider Children's Medical Center, Petah Tikva, Israel.

Multiple familial trichoepithelioma (MFT) is an autosomal dominant skin disease characterized by the presence of many small benign epithelial tumors with pilar differentiation predominantly on the face. The appearance of the lesions produces significant cosmetic distortion and causes much discomfort to the patients. A candidate MTF locus has been mapped to chromosome 9p21 in three north American families. Recently, mutations in the disease gene for familial cylindromatosis, the CYLD gene located on chromosome 16q12-13, have been shown to underlie MFT in four Chinese families. In order to identify the genetic defect causing autosomal dominant MFT in a large consanguineous Bedouin family in southern Israel, we initially performed linkage analysis with microsatellite markers from 9p21, ruling out linkage to this locus. Using microsatellite markers spanning the CYLD gene locus at 16q12-13, we genotyped all available individuals. Our results demonstrate linkage association to this region. Sequencing of the CYLD gene in the Bedouin patients is underway. These findings imply that CYLD defects are the cause of MFT in populations other than the Chinese.

Admixture Genome Scan for Loci Involved in Cleft Lip. *L.M. Moreno[1], E.W. Pugh[2], M. Moreno[3], M. Arcos-Burgos[4], C. Valencia-Ramirez[3], M.L. Marazita[5], J.C. Murray[1], A. C. Lidral[1]* 1) Univ of Iowa, Iowa City, IA; 2) CIDR, Baltimore, MD; 3) U. of Antioquia, Medellin, Colombia; 4) NIH,Bethesda, MD; 5) U of Pittsburgh, Pittsburgh, PA.

Introduction: The prevalence of nonsyndromic cleft lip with or without cleft palate (CL/P) varies by ancestry and is highest among Amerindians and Asians followed by Caucasian and African populations. Admixture mapping can identify genomic areas containing disease loci that are linked to ancestry markers. Purpose: We performed the first genome wide admixture mapping to identify disease loci for CL/P. Methods: 162 affected probands and 52 controls from North West Colombia were genotyped by the Center for Inherited Disease Research for 385 STRPs. 86 individuals from the Human Diversity Panel representing the founding populations were genotyped for over 400 markers by the Mammalian Genotyping Service Center. Alleles were aligned for 254 markers by using CEPH controls genotyped in both labs to adjust for allele size differences. The software STRUCTURE was used to compare Amerindian ancestry at each marker to the genome average of Amerindian ancestry in a two-sided hypothesis approach to evaluate for departures above and below the genome average. Results: Areas of excess Amerindian ancestry in cases compared to controls were observed at 1p22-p33 with markers D1S728, (109 cM, Z score 2.0) and D1S551 (114cM, Z score 1.6). On the contrary, an area with a significant excess of Amerindian ancestry was found among the controls at 17q11-q21 with markers spanning a region of 45-67cM (D17S219-D17S975-D17S188-D17S129, Z scores 4.0-7.0). Both 1p22-p33 and 17q11-q21 have been previously identified as susceptibility areas for CL/P. Conclusions: The opposite differences in Amerindian ancestry at these two regions provide further support for the multifactorial etiology of clefting and imply that disease risk in this Colombian population is the result of admixture of susceptibility loci from two different founding populations. The study highlights the utility of admixture mapping in complex traits.

Genome-wide Mapping of Allele-specific Protein-DNA Interactions in Human Cells. *N.D. Maynard[1], T.H. Kim[1], J. Chen[2], J.B. Fan[2], B. Ren[1]* 1) Cellular & Molecular Medicine, LICR - UCSD, La Jolla, CA; 2) Illumina, Inc., San Diego, CA, USA.

Recent investigations have reported differences in allele transcript levels of a large number of human genes. However, little is known about the mechanisms governing the majority of these differentially expressed alleles. Mapping of transcription factors and proteins involved in chromatin architecture to specific alleles should provide insight into the mechanisms involved in allele-specific expression. Here we combine chromatin immunoprecipitation (chIP) with SNP arrays (300K SNPs) to detect protein binding to the different alleles in human fetal fibroblasts (IMR90). We show significant variation in allele-specific binding of RNAP and insulator binding protein CTCF to approximately 4.2% and 7.9% of enriched heterozygous SNPs sampled, respectively. Our results confirmed allele-specific binding of RNAP and CTCF to the IGF2/H19 locus, as well as RNAP binding to other known imprinted loci. The methodology described here provides a window into understanding transcription by looking at binding of transcription machinery or markers to DNA in an allele-specific manner. This new level of information should lead to a greater understanding of the factors that play a role in allele-specific expression.

Copy Number Variation Analysis Using Quantitative TaqMan Copy Number Assays. *K. Li[1], A.J. Broomer[1], Y. Wang[1], C. Xiao[1], C. Barbacioru[1], I.R. Casuga[1], F. Wang[1], A.J. Sharp[2], E.E. Eichler[2], C. Chen[1]* 1) Applied Biosystems, 850 Lincoln Centre Dr., Foster City, CA94404; 2) USA and 2 Department of Genomic Sciences and Howard Hughes Medical Institute, University of Washington School of Medicine,Seattle, WA 98195.

Recent whole-genome studies have identified 1447 CNV regions (CNVRs) that cover about 12% of the human genome. Some of CNVR may contain disease loci/genes, whose copy number changes could impact gene activity and disease susceptibility. Copy number changes are also detected in microdeletion/microduplication syndromes, which are associated with genomic disorders. Although array-based technologies are powerful for large-scale CNV discoveries and microdeletion/microduplication syndrome screening, more quantitative technologies with higher sample throughput are required to validate newly identified CNVs and to detect deletions/duplications for a large sample size in candidate regions/genes. To meet these challenges and demands, Applied Biosystems has developed TaqMan based real-time quantitative copy number assays. Here, we report the development of the TaqMan copy number assay design pipeline and validation of TaqMan copy number assays. We used this proprietary pipeline to design assays targeting the chromosomal regions associated with genomic disorders and CNV-associated OMIM genes. The assays were tested with DNA sets for validation, HAPMAP DNA collection as well as samples with known deletions/duplications. The TaqMan copy number assay is a duplex reaction with a FAM-assay targeting the gene of interest and a VIC-assay targeting the reference gene (two copies per diploid genome) in the same well. The copy number is determined by relative quantification using a reference sample known to have two copies of the gene of interest. Our validation data demonstrate a high success rate of assay design and excellent assay performance. TaqMan copy number assays are quantitative and robust, with high reproducibility, specificity, and sample throughput.

Candidate Gene Selection and Mutation Screening of Adult-Onset Primary Open Angle Glaucoma (POAG) at the GLC1B, GLC1C and GLC1H Loci. *M. Sarfarazi[1], J. Aragon-Martin[1,2], R. Sharafieh[1,2], T. Rezaie[1], A. Child[2]* 1) Molecular Ophthalmic Genetics Laboratory, University of Connecticut Health Center, Farmington, CT; 2) Department of Cardiac and Vascular Sciences, St. Georges University of London, London, U.K.

Glaucoma is a blinding condition that affects millions of people worldwide. Of the 20 loci published so far, only 4 of their defective genes (CYP1B1, MYOC, OPTN, WDR36) have been identified. In this study, we used published information on Linkage Mapping, mRNA expression, Microarray Data, known Biological Function or Predicted Biochemical Pathways of candidate proteins and prioritized a selected group of genes for specific screening at the GLC1B (2cen-q13), GLC1C (3q23) and GLC1H (2p16) loci. The GLC1B region contains over 220 genes, of which we previously excluded 20 of them. Bioinformatic, Genomic Convergence and Proteomic Streamlining methods prioritized 23 of these genes as the most promising candidates. We screened and excluded 7 new genes (TGOLN2, MAT2A, ST3GAL5, BCL2L11, NCK2, UNC50, FHL2) from this region. Only 3 non-synonymous, non-disease causing variations were observed in TGOLN2 (R259W, F453L) and FHL2 (R88K). Likewise, we screened 10 genes (ACPL2, ZBTB38, RASA2, RNF7, GRK7, ATP1B3, TFDP2, GK5, XRN1 and ATR) from the GLC1C locus and identified a total of 90 DNA variations. Seven non-disease causing alterations were observed in ZBTB38 (P300A, S319A, N617D), GRK7 (E443G, P460T) and ATR (M211T, R2606Q). For the GLC1H locus, we previously screened and excluded 29 genes. In this study, a total of 10 new genes were prioritized from a list of over 61 possible candidates. Six of these genes (RPS27A, EFEMP1, USP34, PSME4, PAPLOG and RTN4) were screened and excluded. Altogether, 72 genes were screened from these 3 published POAG regions. Screening of other prioritized genes is currently in progress. The overall linkage data suggest that GLC1B, GLC1C, and GLC1H loci are physically located within regions of 6.66, 1.32 and 10.90 Mb, respectively. The strategy used in this study will facilitate gene selection for detailed mutation screening at these 3 known POAG-linked loci. Supported by EY-009947 and M01RR-06192.

Noncoding sequence variation in human populations. *J.D. Wall[1], M.P. Cox[2], A. Woerner[2], M.F. Hammer[2]* 1) Institute for Human Genetics, UCSF, San Francisco, CA; 2) ARL Division of Biotechnology, University of Arizona, Tucson, AZ.

We conducted a large resequencing study of nuclear noncoding DNA sequence variation in a diverse collection of six human populations. Our study design allows us to obtain a more complete view of human genetic diversity, and only 20% of the SNPs that we found were contained in the HapMap. As in previous studies, non-African populations have less variation, fewer rare variants and more linkage disequilibrium than sub-Saharan African populations. Strikingly, however, levels of differentiation between populations are higher than previously reported, especially on the X chromosome.

The Intermountain Genealogical Registry: Initial Evaluation of a Population Genealogy for an Outbred Continental Population. *J.B. Muhlestein[1,2], J.L. Anderson[1,2], T.L. Bair[1], D.G. Renlund[1,2], A.G. Kfoury[1,2], D.L. Lappe'[1,2], J.F. Carlquist[1,2], R.R. Pearson[1], H.T. May[1], M.S. Hammad[1], B.D. Horne[1,3]* 1) Cardiovasc Dept, LDS Hosp, SLC, UT; 2) Cardiology Div, Univ Utah, SLC, UT; 3) Genet Epidemiol Div, Univ Utah, SLC, UT.

Cardiovascular (CV) genetic studies traditionally evaluated families from inbred isolates, close relatives, or samples of unrelated individuals. Because CV diseases are common and complex, additional approaches are needed. We record-linked publicly-available genealogical records to patient records to create an Intermountain Genealogical Registry (IMGR) for CV genetic research. In an outbred continental Caucasian population previously shown to be genetically similar to the US Caucasian population, electronic pedigree information was extracted from public records in published books and on the internet. Beginning in 2004, CV patients provided 5-generation pedigree charts (name, birthdate, death date) for 3 generations of ancestors, themselves, siblings, and children. A probabilistic matching algorithm, the Phonetic Transducer, eliminated duplicate records and curated pedigree connections, with patient-submitted pedigrees used to validate computerized record-linking. Subsequent record-linking of genealogical and medical data was performed. Pedigrees of 10.1 million individuals were included in IMGR, with 3 life events (birth, marriage, death) per pedigree occurring in Utah and surrounding states after 1846. Most pedigrees covered the 1800s and 1900s, with many extending to the 1500s. Among >14,000 cardiac patients who donated DNA, record-linking found 13% matched exactly to IMGR by name, sex, and birthdate, with 31% more having record-linking scores suggesting a correct match. Among 340 patients who provided pedigree charts, 66% had one or more relative among the 10.1 million in IMGR, including 15% for whom all pedigree data were included. IMGR, a population genealogy among a general, outbred population, was created and found to provide substantial information regarding cardiac patient pedigrees. This resource will provided enhanced ability to identify and study familial cardiac traits.

Finding Genetic Risk Factors for Breast Cancer by Pedigree-Free Identity-By-Descent Mapping. *B.L. Merriman, Z. Chen, S.F. Nelson* Human Genetics, UCLA, Los Angeles, CA.

The most well known genetic risk factors for familial breast cancer are the BRCA1 and BRCA2 genes. However, mutations in these genes explain less than half of all familial breast cancer, and the rest remains largely unexplained, despite extensive searches using standard linkage and association methods. In this study, we apply a new method we have been developing, Pedigree-Free Identity by Descent Mapping, which has novel power to identify risk alleles if there are strong founder effects in the population. This method uses high-density SNP genotyping data to directly infer shared DNA fragments between affected individuals, without relying on any pedigree information. In order to enrich for the necessary founder effects, we carry out the strategy in the Ashkenazi-Jewish population. As proof of principle, we first demonstrate that within this population, as few as 5 carriers of each of the known mutations suffice to localize the BRCA1 and BRCA2 genes. We then go on to apply the approach with 100 cases free from known BRCA mutations, and show that this highlights several regions and specific risk haplotypes, as well as identifying novel BRCA-related risk haplotypes not previously identified in this population. This demonstrates that Pedigree-Free IBB mapping is a powerful technique for identifying risk loci, with strengths that are complementary to those of standard methods for linkage and association analysis.

Maternal transmission effects of the RUNX2 and TCOF1 genes among cleft case-parent trios from Four Populations. *J.W. Sull[1], K.Y. Liang[1], J.B. Hetmanski[1], M.D. Fallin[1], R.G. Ingersoll[1,2], J. Park[3], Y.H. Wu-Chou[4], P.K. Chen[4], S.S. Chong[5], F. Cheah[5], V. Yeow[6], B.Y. Park[7], S.H. Jee[1,7], E.W. Jabs[2], R. Redett[2], A.F. Scott[2], T.H. Beaty[1]* 1) Johns Hopkins School of Public Health, Baltimore, MD; 2) Johns Hopkins School of Medicine, Baltimore, MD; 3) Sungkyunkwan University, Korea; 4) Chang Gung Memorial Hospital, Taiwan; 5) National University of Singapore, Singapore; 6) KK Women and children Hospital, Singapore; 7) Yonsei University, Korea.

Oral clefts (cleft palate or CP; and cleft lip palate or CL/P) are among the most common human birth defects. RUNX2 and TCOF1 have been suggested as candidate genes for oral clefts. This study examines the association between markers in RUNX2 and TCOF1 and isolated, non-syndromic CP and CL/P, considering parent-of-origin effects. Case-parent trios from four populations (386 trios) were genotyped for 35 single nucleotide polymorphisms (SNPs) in the RUNX2 and TCOF1 genes. We performed the transmission disequilibrium test (TDT) and the transmission asymmetry test (TAT) on individual SNPs. Parent-of-origin effects were assessed using the parent-of-origin likelihood ratio test (PO-LRT) for both SNPs and haplotypes. For RUNX2, TAT revealed a block of 11 SNPs showing excess maternal transmission statistically significant at the p=0.01 level when all CL/P trios were combined. For these 11 SNPs, odds ratios (OR) of being transmitted to the case from the mother ranged from 3.0 to 4.0. For TCOF1, when all CP trios were combined, the OR (transmission) was statistically significant for SNP rs15251 (OR=2.88, p=0.007), as well as rs2255796 and rs2569062 (OR=2.08, p=0.03; OR=2.43, p=0.041) when parent-of-origin was not considered. TAT also revealed 1 SNP (rs15251) that showed excess maternal transmission statistically significant at the p=0.005 level (OR=6.50), however, the PO-LRT was only marginally significant for this SNP. Analysis of haplotypes of two SNPs (rs2255796 and rs15251) in TCOF1 also yielded possible evidence of a maternal transmission effect. RUNX2 and TCOF1 genes appear to influence risk of CL/P and CP, respectively, through a parent-of-origin effect.

Building Workflows for the Quality Control of Genome Wide Association Data. *R. Munro[1], E. Pugh[2], C. Zhang[1], W. Newell[1], L. Watkins, Jr.[2], Y. Sun[2], B. Craig[2], D. Kalaitzopoulos[1]* 1) InforSense, London, United Kingdom; 2) Center for Inherited Disease Research (CIDR), Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD.

The Center for Inherited Disease Research is exploring the addition of Affymetrix GWA arrays to an existing Illumina Infinium GWA service. CIDR has developed a series of informatics tools to monitor quality and produce a variety of reports and data files for Infinium. Faced with the desire for a new informatics pipeline at a time when programming resources were committed to other projects, CIDR collaborated with InforSense to explore if InforSense could be used to quickly develop similar tools for Affymetrix SNP chips while minimizing the need for programmer involvement. During this process, the InforSense team customized the InforSense GenSense platform for building the pipeline in response to CIDR feedback.

Nodes within GenSense calculate Mendelian inconsistencies, duplicate errors, completion rate by sample and locus, and test for Hardy Weinberg Equilibrium. CIDR used these nodes to quickly build a workflow that described a small dataset of 88 Affymetrix 5.0 arrays and build a list of problematic SNPs. Nodes within InforSense then filtered the data, and GenSense recalculated statistics on the filtered data.

This initial successful proof of concept has led to a continued collaboration as CIDR is expanding the size of the datasets attempted and the range of problems to address with InforSense workflows.

.

Ethnic adjustment factors for Black women undertaking prenatal screening for Down syndrome in Ontario. *A. Summers, T. Huang* Genetics Program, North York General Hosp, Toronto, ON, Canada.

In prenatal screening for Down syndrome, the measurements of certain serum markers are adjusted for ethnicity as there are differences in the levels of these markers among different racial groups. In Canadian, Black women were mainly Afro-Caribbean, although there are increasing number of African women in our screening population. This study estimated ethnic differences in the levels of the first and second trimester serum markers between Black and Caucasian women in our population and explored ethnic adjustment factors for Black women. The study was based on 7361 Black and 47840 Caucasian women undertaking prenatal screening in North York General Hospital between 12/1999 and 12/2006 using screening software Alpha. Multiple pregnancies, pregnancies associated a known chromosomal anomaly or insulin dependent diabetes were excluded from the study. Black and Caucasian women were identified through screening requisitions. The study quantified the ethnic differences in the levels of serum markers between Black and Caucasian women by comparing median MoMs of serum markers between the two groups prior and after weight correction. Fixed ethnic correction factors for Black women were estimated for AFP, hCG and PAPP-A. Weight correction formulae for Black women were developed for PAPP-A through regression analysis. After allowing for maternal weight, median MoMs of AFP was 15% higher, total hCG 12% higher, uE3 3% higher, PAPP-A 57% higher, and inhibin A 5% lower in Black women. The variations in the levels of serum markers in Black women were different from those reported by the studies in UK and US, suggesting local ethnic adjustment factors may needed for screening programs in different ethno-geographic regions. The differences in the levels of AFP, total hCG and PAPP-A can be corrected by applying Caucasian based weight correction formulae and a fixed ethnic adjustment factor to Black women. The differences in the levels of PAPP-A may also be corrected by applying exponential or quadratic weight correction formulae specific for Black women. A median MoM of 1.0 was obtained for AFP, total hCG and PAPP-A in Black women after the adjustments for ethnicity.

X-linked Bilateral Abductor Vocal Cord Paralysis: A Case Report. *R. Veith[1], A. Khmour[2], D. Beste[1], P. Trapane[2]*
1) Children's Hospital of Wisconsin, Milwaukee, WI; 2) Medical College of Wisconsin, Milwaukee, WI.

Stridor in neonates may often have an underlying cause of vocal cord paralysis; however, familial vocal cord paralysis is much less common. Cases of isolated congenital adductor paralysis and isolated congenital abductor paralysis have both been reported. Families with congenital adductor paralysis have demonstrated autosomal dominant inheritance (OMIM 150270) whereas families with congenital abductor paralysis have demonstrated either autosomal dominant (OMIM 150260) or X-linked inheritance (OMIM 308850). Those with the X-linked form of congenital abductor paralysis are the rarest with only 4 pedigrees reported to date.

We report a family with a phenotype of vocal cord paralysis due to bilateral abductor paralysis that appears to be inherited in an X-linked fashion. The family contains 2 affected males and 1 affected female in two generations. The affected individuals are a male child and a female child of two sisters whose brother is also affected. A third male has a history of breathing difficulties for whom a diagnosis has not yet been confirmed. All affected individuals have had neonatal onset of stridor leading to the placement of a tracheotomy for adequate ventilation. Tracheotomy placement ranges from four days of age to two months of age. Dysmorphic features are not present in affected individuals. We believe that this family has the X-linked form of congenital abductor paralysis (OMIM 308850). X inactivation studies will be performed in addition to chromosome studies and DNA microarray analysis.

High prevalence of Food Allergies in Patients with Ehlers-Danlos Syndromes. *H. Zhang[1], B.F. Griswold[1], L. Sloper[1], M. Lavallee[3], C.A. Francomano[2], N.B. McDonnell[2], A. Gustafson[1]* 1) LCI, NIA/NIH, Baltimore, MD; 2) GBMC, Baltimore, MD; 3) IUSM, South Bend, IN.

Ehlers-Danlos syndromes (EDS) are a heterogeneous group of hereditary disorders of connective tissue that are characterized by joint, skin, and vascular abnormalities. Complete physicals and medical histories were obtained from 95 patients with hypermobile, classical, and vascular EDS enrolled in the National Institutes on Aging Protocol 2003-086, Clinical and Molecular Manifestations of Heredity Disorders of Connective Tissue. We found a high prevalence of food allergies in patients with EDS (14%) when compared with the general population (P<.0001). We also found a significantly higher incidence of gastrointestinal manifestations in our cohort when compared with the general population (P<.0001). The presence of food allergies also seems to correlate with gastrointestinal dysfunction in some patients. Of the patients who reported constipation, irritable bowel syndrome, gastroesophageal reflux disease, and/or chronic abdominal pain, many also reported having a food allergy (40%, 42%, 17%, and 20%, respectively). Collagen abnormalities may cause mucosal lesions, altering tissue integrity and increasing the chance of larger proteins crossing the mucosal barrier and creating an immunogenic response. Multiple studies have correlated eosinophillic gastrointestinal disorders, allergic responses that fall in between IgE and TH2-type responses that are mediated by IL-5 and other eotaxins, with classic mast cell tissue degranulation, producing gastrointestinal disorders similar to those seen in our patients. Understanding the mechanisms associated with food allergies in patients with EDS may aid in development of effective treatments.

Identification of Late-Onset Alzheimers Disease (LOAD) Susceptibility Alleles in the PAI1 Gene. *S. Wilcox[1], M. Carrasquillo[1], S. Younkin[1], M. Li[1], L. Younkin[1], D. Dickson[1], N. Graff-Radford[1], R. Petersen[2], S. Younkin[1]* 1) Dept Neuroscience, Mayo Clinic, Jacksonville, FL; 2) Dept Neurology, Mayo Clinic, Rochester, MN.

Given that the plasmin system has been implicated in A degradation and that accumulation of A in the brain has an important role in AD, genes encoding proteins in the plasmin system are obvious AD functional candidates. In this study we focused on the role of the plasminogen activator inhibitor-1 (PAI1), a protease inhibitor that is believed to be produced in the brain. Previous reports of association of PAI1 with AD are conflicting. To further evaluate PAI1's contribution AD risk, we selected variants within the PAI1 genomic region which met minor allele frequency (MAF) and conservation criteria: MAF 1-45%, and human-mouse identity >70% over 100bp windows. Variants were tested for association with disease status by logistic regression analyses at the level of single variant, haplotypes and multilocus genotypes (MLGs) using gender, age-at-diagnosis and APOE4 dosage as covariates in our LOAD case-control series (1,807 vs. 1,970). All 8 variants that met genotyping criteria fall within a haplotype block that encompasses the entire gene. Seven out of 8 variants tag a haplotype, and were tested individually under allelic dosage, recessive and dominant models. The dominant model yielded the most significant results. One of the 8 variants, rs12673157, showed nominal significance (p=0.04). Five others, including rs1799889 reported in 2006 by Shibata et al. to associate with LOAD, showed suggestive association (0.06p0.25). The haplotypic global p-value did not achieve significance (p=0.15), however, MLGs were highly significant (global p=0.002). Forty-three MLGs account for 94% of all individuals in our case-control series. Two of these MLGs seem to confer significant risk (OR=5.5, p=0.001; OR=3.3, p=0.03) and 12 MLGs showed suggestive evidence (0.05p0.25) of either risk (ORs 1.3-1.7) or protection (ORs 0.3-0.6). Overall, our results strongly suggest that PAI1 plays a role in AD pathogenesis. Additional genetic and functional studies ought to be carried out to further substantiate its involvement.

Generalized arterial calcification of infancy (GACI): two novel ENPP1 mutations in a stillborn fetus. *J. Martinovic[1], A. Bazin[1], O. Catanas[1], F. Briget[1], F. Duchatel[3], Y. Nitschke[2], F. Rutsch[2]* 1) Department of Pathology, Laboratory Pasteur-Cerba, Pontoise, France; 2) General Pediatrics, University Children's Hospital, Muenster, Germany; 3) Department of Gynecology and Obstetrics, Hospital Rene Dubos, Pontoise, France.

GACI is a rare disease not mentioned in current pathology textbooks. We present a male fetus born to a non-consanguineous couple at 39 gestational weeks. The mother was a healthy 28 year-old GI. The pregnancy was uneventful with unremarkable ultrasound scans performed at 13, 22, and 32 weeks of gestation. A stillborn macerated fetus was delivered spontaneously. TORCH, thrombophilia, and Kleihauer screening were negative. The birth weight was 3300g, the length 49cm. External examination was normal. Internal examination revealed pleural and pericardial effusions and moderate splenomegaly. Striking cardiomegaly with calcifications of the great vessels were noted. Radiological examination showed global and bilateral calcifications of the brachial and femoral arterial network. Histology confirmed generalized arterial calcifications (heart, kidneys, lungs, spleen, pancreas, thalami), particularly at the level of the internal elastic lamina. The association of these findings was highly suggestive of GACI (MIM 208000), a recessive disorder linked to the ENPP1 gene. ENPP1 encodes for ectonucleotide pyrophosphatase/phosphodiesterase-1, a cell surface enzyme that generates inorganic pyrophosphate. This solute serves as an essential inhibitor of calcification. Direct sequencing of ENPP1 revealed that the fetus was compound heterozygous for the two novel mutations c.826G/A (p.D276N) in exon 9 and c.1412A/G (p.Y470C) in exon 14. GACI has a recurrence risk of 25% among sibs. Correct diagnosis of the disease is essential for appropriate genetic counselling. Mutation analysis of ENPP1 in the index case is a prerequisite for prenatal diagnostic testing in a subsequent pregnancy.

Marker-marker correlation, population stratification and significance thresholds in genome-wide association studies. *J. Shi[1], A. Whittemore[2], J. Webster[3], D. Stephan[3], D. Levinson[1]* 1) Psychiatry & Behavior Science, Stanford University, Stanford, CA; 2) Health and Research Policy, Stanford University, Stanford, CA; 3) Neurogenomics, Translational Genomics Research Institute, Phoenix, AZ.

Permutation tests are used to obtain empirical significance levels in case-control genome-wide association (GWA) studies. Using gene expression data, Efron demonstrated that correlation among tests can lead to overdispersion or underdispersion of test statistics relative to the expected normal distribution, and suggested correcting for this effect to avoid spurious findings or power loss. We evaluated whether a similar effect could be observed in GWA data. We studied data for ~300,000 SNPs (after QC filtering) from each of two European-ancestry control populations, creating replicate datasets by randomly selecting cases and controls from a population. The uncorrected (unconditional) 5% genome-wide significance threshold (b) was determined across replicates. Then, for each replicate, the conditional genome-wide p-value (GWP) of b was computed, using a novel logistic regression method to adjust for the central proportion of Z-scores (computed based on the theoretical distribution) falling within 1 SD of the mean. For the theoretical 5% significance threshold, the conditional GWP ranged from 2% to 10% depending on the central proportion. The variance of the conditional GWP for a given b is predicted mathematically by the squared average marker-marker genotypic correlation (tau-squared). Population stratification (PS) can cause correlation among unlinked markers. In both datasets, after correcting for PS (Eigenstrat), tau-squared was reduced by 80%, and the central proportion no longer predicted GWP. In these European-ancestry GWA datasets, marker-marker correlations are sufficiently weak that the potential effect of distribution dispersion can be ignored, if an adequate correction for PS is applied.

Robotic microscopy for detection and analysis of circulating tumor cells. *F. Ntouroupi[1], A. Seppo[2], S. Wang[2], Y. Kim[2], P. Tsipouras[2], F. Tafas[2], M.W. Kilpatrick[2], W.F. Bodmer[1]* 1) Cancer Research UK, Oxford, UK; 2) Ikonisys Inc, New Haven, CT.

Identification and analysis of rare circulating tumor cells has great potential; for detection of disease recurrence or minimal residual disease following treatment, or screening for malignancies. The challenge to the utilization of rare tumor cells diagnostically is to be able to accurately detect, quantify and analyse cells present in small numbers in a large, complex cellular background. We used the Ikoniscope robotic microscopy system, developed specifically for cell identification and analysis by automated fluorescence microscopy. Slide analysis is accomplished in a completely unattended manner, allowing analysis of samples for the presence of rare cells, avoiding complex purification procedures which risk loss of the cells being sought and can create unresolvable clusters of normal and cancer cells. Blood samples were collected from 12 colorectal cancer patients, 7 prostate cancer patients and 3 healthy controls. The mononuclear cells were immunostained with Cam5.2 directed against epithelial specific Cytokeratins 7/8 and either AUA1 (directed against EpCam) or anti-PSA, then analyzed on the robotic microscope. Potential tumor cells were identified at 10x and all identified targets verified at 100x magnification. All 12 colorectal cancer patients presented at least one EpCam/cytokeratin-positive cell with the morphological characteristics of tumor cells. On average 26 53 immunoreactive cells were detected per 7.5 ml blood sample. The number of cells detected was different before and after surgical resection. Five out of seven prostate cancer patients presented EpCam/cytokeratin or PSA/cytokeratin-positive cells with the morphological characteristics of tumor cells. The number of cells ranged from 1.2 to 22.5 per ml blood. No immunoreactive cells were detected in the blood samples from healthy volunteers. This data supports the potential clinical utility of circulating cancer cell detection and analysis. By maintaining the integrity of the tumor cells detected, the approach has the added advantage of allowing the further analysis of both cell morphology and phenotype.

Endogamic exogamy in Gujarati Patels. *F-Y. Li[1], T.J. Pemberton[1], N.U. Mehta[1,2], S. Wong[1], J.W. Belmont[3], C. Tyler-Smith[4], N.A. Rosenberg[5], P.I. Patel[1,2]* 1) Inst Genetic Medicine, Univ Southern California, Los Angeles, CA; 2) Dept of Biochem and Mol Biology, Univ of Southern California, Los Angeles, CA; 3) Dept of Mol and Human Genetics, Baylor College of Medicine, Houston, TX; 4) Wellcome Trust Sanger Institute, Hinxton, Cambridge, UK; 5) Dept of Human Genetics, Univ of Michigan, Ann Arbor, MI.

Social stratification in India is evident as social classes that are defined by a number of endogamous groups often termed as jātis or castes. The jātis themselves exist among one of four varnas or classes: Brahmin, Kshatriya, Vaishya and Shudra. Within a jāti, there exist exogamous groups known as gotras, or gols, which refer to the lineage or clan of a person. Societal rules governing marriage are similar in diverse regions of India. There is typically a strict definition of the clan, gol or gotra from within which an individuals mate may be selected and a sanction against marriage to any individual from within his or her own gotra. This practice typically translates into a surname or gotra endogamy. Thus, while consanguinity is strictly avoided and there is some randomness in mate selection, there is likely a degree of gene flow restriction. Patels who originate from the state of Gujarat practice this form of endogamic exogamy. Members of a village do not marry anybody from their own village and may only marry an individual from one of the other villages within a specified group of villages. We have studied one such group, the Chh Gaam Patels. This group, which constitutes the largest gol among Patels, comprises Patels from six villages. In order to determine the genetic structure of this group, we have obtained genotypes at ~800 microsatellites and ~400 indel loci. Y-chromosome and mitochondrial haplogroup analyses have also been conducted. These data are being analyzed to determine if the restricted marital practice within the same geographic region has resulted in limited genetic differentiation and effective genetic isolation. The number of founders and the extent of admixture with neighboring groups will also be investigated.

Novel and small copy number variant regions identified in high resolution microarray screening of healthy French Caucasian males. *A. Tsalenko[1], A. de Smith[2], N. Sampas[1], A. Scheffer-Wong[1], A. Yamada[1], P. Tsang[1], A. Ben-Dor[1], Z. Yakhini[1], L. Bruhn[1], S. Laderman[1], P. Frouguel[2,3], A. Blakemore[2]* 1) Agilent Technologies, Santa Clara, CA; 2) Genomic Medicine, Imperial College London, Hammersmith Hospital, London, UK; 3) CNRS 8090-Institute of Biology, Pasteur Institute, Lille, FR.

Recent studies identified a wide range of copy number variations (CNVs) in the human genome. Current estimates suggest that the CNV map is still quite incomplete, and that a significant number of especially smaller variations remain to be uncovered. Toward this end, we studied CNVs in a population of 50 apparently healthy, Caucasian males of northern French origin using genomic DNA derived from peripheral blood. We used high resolution arrays with 60mer oligonucleotide probes designed to enable detection of both small and large CNVs. Initial screening for putative copy number variant loci using a genome-wide array with 185K probes was followed by a focused measurement using 244K arrays with probes spaced on average 500 bp in 2475 regions of interest identified in the initial screening. In addition, we examined 2,148 regions reported in the TCAG Database of Genomic Variants (http://www.tcag.ca/). We found 1469 copy number variant regions (CNVRs) detected by multiple probes, of which 45% were observed in more than one individual. The majority of multi-probe CNVRs measured in this study were relatively small, with a median size of 4.4Kb, in contrast to the size distribution of variations in the TCAG database. 721 CNVRs did not overlap regions in the TCAG database. Half of the novel variations were smaller than 1.5Kb, however several regions were as big as 1Mb. The novel regions contain 368 genes, which were present in similar proportions in small and large variants, of which 150 genes are represented in the OMIM database. The breakpoints of many of our detected CNVs were highly conserved across the cohort. The coefficient of variation for 83% of variant breakpoints in multi-probe CNVs observed in multiple samples was less than 0.1, suggesting that there might be a higher utility for CNVs in association studies than previously thought.

Copy number variant detection using Illumina BeadChip arrays. *D. Pinto[1, 2], J. Zhang[1, 2], B. Thiruv[1, 2], L. Feuk[1, 2], S.W. Scherer[1, 2]* 1) The Centre for Applied Genomics, Toronto, Canada; 2) Program in Genetics and Genomic Biology, Research Institute, The Hospital for Sick Children, Toronto, Canada.

Understanding common genomic variation associated with disease susceptibility and population diversification is fundamental in human genetics. High-resolution SNP-based microarray technology now permits the simultaneous detection of SNPs and copy number variants (CNVs) on a genome-wide scale in a single experiment. This is achieved by using both the SNP allele calls and intensity of the allele-specific hybridization signals. The increase or decrease in hybridization signal for neighbouring SNPs can be used to identify regional patterns of structural genomic change. Currently, GeneChip (Affymetrix) and BeadChip (Illumina) are the platforms most widely used. Regardless of the platform used, identification of CNV regions is challenging, and the available tools have not been thoroughly tested. Illuminas Hap650Y BeadChip uses the Infinium assay to interrogate more than 655,000 tag SNPs, targeting common variation in four populations. To evaluate the performance of this array for the detection of both CNVs and SNPs, we examined 148 HapMap samples, various X-chromosome copy cell lines and the cancer cell line HL-60, and analyzed the data using various CNV calling algorithms, including BeadStudio, QuantiSNP and dCHIP. We also present a new CNV detection algorithm -iPattern- which uses a pattern recognition approach to analyze probe intensities of a group of samples and sliding windows to search for consecutive outliers. For any region, samples with probe intensities higher or lower than the average intensity of the majority samples are identified as gain or loss respectively. Preliminary results with Illumina Hap650Y were compared to Affymetrix GeneChip 500K data. This indicated that iPattern performs well for both platforms, showing significant concordance with another CNV calling algorithm, GEMCA. Here, we will review the CNV calling algorithms currently available and discuss results in light of previous studies.

Efficient Identification of Novel Developmental Cardiac Genes Through Transcriptional Profiling of Differentiating Mouse Embryonic Stem Cells. *R. Miller[1,2], N. Christoforou[2], J. Gearhart[2,4], A. McCallion[1,3]* 1) Institute of Genetic Medicine; 2) Institute for Cell Engineering; 3) Department of Comparative and Molecular Pathobiology; 4) Department of Obstetrics and Gynecology, Johns Hopkins University, Baltimore, MD, 21205.

The heart is the first organ to form and function in mammalian development. Congenital heart defects (CHD) are the most prevalent birth defects in the general population (~7 in 1000 live births), reflecting its complex and highly regulated genesis. To gain a better understanding of mechanisms involved in cardiac development, we set out to determine the transcriptional profile of mouse embryonic stem cells (mESCs) as they differentiate along a cardiac lineage. Using an Nkx2.5 cardiac specific promoter driving GFP, we marked and isolated differentiating cardiomyocytes (DCMs) at specific time points during the differentiation. By comparing the profile of DCMs with time-matched nonDCMs and undifferentiated mESCs we have identified genes whose expression is enriched in DCMs compared with non-DCM populations. Approximately 50% of these genes already have established roles in cardiac function and development. We will describe our efforts to evaluate the biological relevance of the remainder to cardiac development. To date we have completed RNA *in situ* hybridization of 25 novel candidates identified in this screen, determining the embryonic expression patterns at key points during cardiogenesis (E7.5, E8.5, E9.5). The majority (21/25) have expression in key cardiac structures, such as the cardiac crescent, heart tube, looping heart, inflow and outflow tract, and branchial arches. We will present this data as well as on-going experiments to expand expression analysis of our candidates and to evaluate their pathological relevance.

Long-term Correction of PKU in the *Pah*^{enu2} mouse by mutant and chemically modified forms of Phenylalanine Ammonium Lyase. *P. Laipis[1], J. Embury[1], W. Zeile[1], C. Henschel[2], S. Bell[2], P. Fitzpatrick[2], R. Zori[3], C. O'Neill[2], L. Tsuruda[2]* 1) Dept. Biochemistry and Molecular Biology, Univ. Florida College Medicine, Gainesville, FL; 2) BioMarin Pharmaceutical Inc., Novato, CA; 3) Dept. Pediatrics, Univ. Florida College Medicine, Gainesville, FL.

Phenylketonuria (PKU) is the most frequent disorder of amino acid metabolism (~1 in 10^4 births) in populations of European origin. PKU patients accumulate phenylalanine (Phe) to abnormally high concentrations due to low or absent phenylalanine hydroxylase enzyme (PAH) activity. High Phe exposure results in symptoms ranging from mild cognitive impairment to severe mental retardation. Although deleterious effects can be minimized by a Phe-restricted diet instituted at birth, most adult PKU patients are poorly compliant leading to cognitive and behavioral deficits. Alternate therapies would be valuable, especially for possible treatment of Maternal PKU Syndrome. A recombinant phenylalanine ammonium lyase (rPAL) was modified by addition of multiple polyethylene glycol molecules (PEG) and used as an enzyme substitution therapy for PKU (rAvPAL-PEG). Treatment of BTBR *Pah*^{enu2} mice, an animal model of PKU, with rAvPAL-PEG resulted in long-term correction of Phe levels (~ 6 months). Male PKU mice administered weekly subcutaneous injections of either wild-type or a mutated form of rAvPAL-PEG rapidly reduced serum Phe levels into the physiological range. After 6-8 weekly injections, serum Phe levels stabilized at or near physiological range for the entire week. This pharmacodynamic effect was maintained even when injections ceased for 2-4 weeks. Longer pauses in treatment (~10 weeks) resulted in a loss of the stable weekly physiologic Phe levels; this effect could be re-induced by reinitiating rAvPAL-PEG administrations. Mice were healthy, showed increased body weight and exhibited no adverse effects. We previously reported histological abnormalities in brains of PKU mice and their reversal by a gene therapy vector expressing PAH; similar studies are in progress with rAvPAL-PEG treated mice. These results suggest that rAvPAL-PEG is a viable therapeutic option to reduce blood Phe in PKU patients.

Gene dysregulation in FXTAS. *F. Tassone[1,2], D. Garcia-Arocena[1], C. Iwahashi[1], R. Hagerman[2,3], E. Berry-Kravis[4], P. Hagerman[1,2]* 1) Department of Biochemistry and Molecular Medicine, UC Davis, CA, USA; 2) M.I.N.D. Institute, UC Davis, Medical Center, Sacramento, CA, USA; 3) Department of Pediatrics, UC Davis Medical Center, Sacramento, CA, USA; 4) Departments of Pediatrics, Neurology, and Biochemistry, RUSH University Medical Center; Chicago, IL,USA.

Fragile X-associated tremor/ataxia syndrome (FXTAS) is a late-onset neurodegenerative disorder characterized by action tremor, gait ataxia and other features including autonomic dysfunction,parkinsonism, cognitive decline and peripheral neuropathy. Neuropathological studies of postmortem FXTAS brains have demonstrated significant cerebrum white matter disease, Purkinje cell loss in the cerebellum, and the presence of intranuclear inclusions in neurons and astrocytes throughout brain. Immunocytochemical studies and mass spectrometric analysis have revealed the presence within the inclusions of a number of different proteins, including ubiquitin, lamin A/C, the RNA binding protein hnRNP A2, Hsp70; and two other small heat shock proteins, aB-crystallin and Hsp27. In addition, FMR1 mRNA was found within the inclusion, consistent with the proposed RNA-toxicity model for FXTAS, wherein the expanded RNA itself triggers the pathogenic process. A striking feature of CNS cellular dysfunction in FXTAS, is the disorganization of the lamin A/C nuclear architecture in brain tissue and neural cells from FXTAS cases, in addition to a stress response involving induction of aB crystallin. To determine if the features of the CNS cellular phenotype in FXTAS also extend to transcriptional dysregulation, we studied the pattern of expression of a number of genes, implicated in FXTAS pathogenesis, in FXTAS tissues, including brain and primary fibroblasts, and compared to age matched controls. We identified several genes whose expression is dysregulated in premutation tissues. Indeed, measurements of mRNA levels of LMNA, GLT1 as well as of stress proteins (including aBCry, Hsp27 and Hsp70) indicate significant differences in samples derived FXTAS patients compared to age-matched controls. These observations indicate that abnormal expression of the expanded CGG-repeat FMR1 mRNA leads to gene and cellular dysregulation in FXTAS.

A large extended Newfoundland family with nonsyndromic sensorineural hearing loss is a third family found to be linked to Xp21.2 (DFN4). *N. Merner, K. Richardson, E. Ives, A. Griffin, T.L. Young* Discipline of Genetics, Memorial University, St. John's, NL, Canada.

X-linked deafness is rare accounting for only 1% of all hereditary deafness cases. To date there have been four loci identified, namely DFN2, DFN3, DFN4 and DFN6. Of these, only one gene, POU3F4 in DFN3 has been identified. Two extensive Newfoundland families with nonsyndromic sensorineural hearing loss show an x-linked pattern of inheritance. Affected individuals experience a progressive type of sloping hearing loss that is moderate to profound in severity. Obligate female carriers show variable expression. Both families trace back to an isolated area on the provinces north-east coast and share several surnames, thus we believe that they share a common ancestor. Combined there are 50 affected individuals over 6 generations with several consanguinity loops. The entire X chromosome was genotyped using 18 markers from panel 28 of the ABI Genome Wide Linkage Kit (v2.5). Hearing loss was linked to DXS1214 (Xp21.2), the DFN4 locus. After fine mapping, a deafness-associated haplotype was identified in affected individuals spanning 1.3 Mbp, from markers DXS992-DXS1219. Within this region there were 3 annotated genes, namely TAB3, FTHL17 and DMD. All coding exons and intron-exon boundaries were sequenced using ABI BigDye Terminator v3.1 cycling sequencing kit. The centromeric boundary had a crossover in the middle of DMD between markers DXS997 and DXS1219 therefore only exons 49-79 of the largest DMD isoform and the non-overlapping exons of isoforms Dp71 and Dp116 were sequenced. As well, because intragenic rearrangements account for mutations in the DMD gene, MLPA was performed to detect potential duplications and/or deletions. After analysis no pathogenic variants were found. However, the critical region was narrowed to approximately 800Kb. The most likely candidate is the DMD gene because two other families have been previously reported to be linked to the DMD locus and the mdx mouse model has been shown to have auditory dysfunction.

Novel mutations of DNA polymerase *(POLG1)*. *Q. Zhang, E.S. Schmitt, N. Brunetti-Pierri, P.C. Chou, C. Truong, J. Wang, W.J. Craigen, L-J. Wong* Department of Molecular and Human Genetics, Baylor Colloge of Medicine , Houston, TX 77030.

Human mitochondrial DNA is replicated by the nuclear-encoded DNA polymerase *(POLG1)*. Mutations of *POLG1* are responsible for a variety of mitochondrial diseases including dominant and recessive forms of progressive external ophthalmoplegia (PEO), Alpers syndrome, Parkinsonism, juvenile spinocerebellar ataxia-epilepsy syndrome (SCAE), as well as sensory ataxia, neuropathy, dysarthria and ophthalmoparesis (SANDO). In order to understand the importance of this gene in the molecular etiology of patients with these mitochondrial disorders, we sequenced the coding exons of *POLG1* in approximately 370 patients. A total of 37 different *POLG1* mutations were identified in 44 patients. 27 patients carried two mutated alleles, 17 had only one identified mutation, two patients were homozygous. The mutations include 71 missense (32 unique), 1 nonsense, 2 insertion/deletion frameshift (both unique), and 2 splice site mutations (both unique). Large deletions or duplications were not found. Approximately 54% (20 out of 37 different ones) of molecular alterations were located in the polymerase domain, the remaining were in the exonuclease domain or linker region. A467T is the most common mutation accounting for 20% of mutations (18 alleles in the 44 positive patients). G848S was the second most common mutation (observed 8 times), which resided in the polymerase domain. Significantly, 22 novel mutations were identified in either heterozygous or compound heterozygous type. They are: G11D, Q68X, L83P, H110Y, S305R, L392V, R853Q, V855A, L886P, G888S, R943C, R946C, I1079L, S1095R, R1138C, K1191R, D1196N, G1205A, c.1270delCT, c.2157+5 G>A, c.2480+1G>A, and c.2544_2545insGC. Each novel *POLG1* mutation was specific to an individual family. These findings indicated that *POLG1* is a major nuclear gene responsible for mitochondrial disorders.

Methylation Analysis of the Fmr-1 Promoter Region in Fragile X Patients. *B. López, E. Velasco, M.J. Alonso, M. Durán, J. Tellería, I. Fernández* Human Genetics Lab, IBGM, Valladolid, Spain.

Fragile X syndrome (FRAXA) is the most common cause known of inherited mental retardation. It is origined by an expansion of an unstable CGG-repeat tract in the 5'-untranslated region of the Fmr-1 gene on the X chromosome. According to repeat size, four allele categories have been established: normal (<45 CGG), grey zone (45-54 CGG), premutated (55-200 CGG), and full mutated (>200 CGG). The massively expanded CGG repeat leads to promoter hypermethylation and transcriptional inhibition. We have studied forty male patients classified according to repeat size: 10 X-Fragile full mutated (FM), 10 premutated (PM), 10 grey zone (G) and 10 normal by methylation-specific PCR (MSP) and bisulphite sequencing in order to study Fmr-1 promoter methylation status and specific methylation at CpG sites. Bisulphite sequencing was performed by sodium bisulphite treatment with CpGenome DNA Modification Kit (Chemicon International) followed by PCR reaction using primers similar to that of Weinhäusel et al. described for antisense strand. Purified PCR products were then used for the sequencing reaction and sequenced with an ABI 3100 machine. After bisulphite treatment, all cytosines must be converted to uracil except those that are mehylated (5' methylcytosine).We have observed that C-T conversion performance of non methylated cytosines was total in controls and XF excluding three specific cytosines at 13518, 13551, 13561 positions (GenBank accession number L29074 antisense strand) that remain still partialy not converted for FM patients. Comparative study between N, G and PM alleles and FM alleles shows that this phenomenon is exclusive for methylated promoter, and suggests the possibility that Fmr-1 methylated promoter could have targets for methyl specific transcription factors at this sites. This fact would explain the bisulphite treatment protection of these three cytosines surrounding CpG sites. The finding that all studied FM patients have the same not converted cytosine pattern at three cytosines next to methylated CpG sites opens the possibility of a coordinated transcription inhibition between methylation and methyl-binding protein repressors.

Familial interstitial deletion of Xp11.22 in two brothers with autistic spectrum disorder. *Y. Qiao[1, 2, 6, 7], X. Liu[3, 6, 7], C. Harvard[2, 6], MJ. Hildebrand[1, 6], JJA. Holden[3, 4, 5, 6], E. Rajcan-Separovic[2, 6], MES. Lewis[1, 6]* 1) Dept Medical Genetics, UBC, Vancouver, Canada; 2) Pathology, UBC; 3) Psychiatry, Queens Univ, Kingston, Canada; 4) Physiology, Queens Univ, Kingston; 5) Autism Research Program, Kingston; 6) ASD-Canadian American Research Consortium (www.autismresearch.com); 7) The first two authors contributed equally to this work.

Xp11 is an unstable genomic region that contains numerous candidate genes for X-linked mental retardation (MR). Using array CGH (1 Mb whole genome array), we identified an interstitial deletion of Xp11.22 in a male proband with an autism spectrum disorder (ASD). The deletion, confirmed to be maternal in origin, was also detected in an autistic male sibling by real-time (RT) qPCR, but was not detected in an unaffected female sibling. The affected siblings have identical behavioral and physical phenotypes including ASD, moderate MR, normal growth parameters, facial asymmetry, low-set ears with thickened helices, broad and high nasal root, cleft lip, and coarse facies. The brothers have both had normal routine karyotyping and Fragile X findings as well as negative 22q11 and subtelomeric FISH. The unaffected mother has strongly skewed (90%) X-inactivation, further suggesting this inherited submicroscopic change is causative of the phenotypes seen in the two siblings. RT qPCR characterization of the Xp11.22 del region (53,887,400bp~ 54,359,100bp) shows a 470 kb deletion fully encompassing the PHF8 (OMIM: 300560; midline craniofacial formation and cognitive function) and partially WNK3 (OMIM: 300358; promotes cell survival via procaspase-3 activation) genes; both reported in X-linked MR. PHF8 is also implicated in cleft lip/palate, seen in both brothers. A duplication in this region (~950 kb distal to our deletion), has also been reported in another male with ASD further suggesting that this genomic region is prone to rearrangement and is closely associated with ASD. Further screening of 400 ASD individuals has not identified additional cases carrying this deletion. To the best of our knowledge, this is the first report of an Xp11.22 deletion in ASD and implicates genes PHF8 and WNK3 in the pathogenesis of autistic disorder.

Functional organization of the transcriptome in human cerebral cortex, caudate nucleus, and cerebellum. *M.C. Oldham[1], S. Horvath[2], K. Iwamoto[4], T. Kato[4], D.H. Geschwind[3]* 1) Neurosci. PhD Program; 2) Biostat., Human Genet; 3) Human Genet., Neurology, & Semel Inst., UCLA, Los Angeles, CA; 4) Lab. for Mol. Dynamics of Mental Disorders, Brain Sci. Institute, RIKEN, Saitama, Japan.

Microarrays have emerged as a powerful tool for exploring the functional identities of tissues by enabling comparisons at the level of the transcriptome. In the brain, transcriptional profiling is complicated by significant cellular heterogeneity, which can cloud functional context. New analytic methods that treat microarray data as a holistic system instead of a collection of discrete measurements have shown great promise in illuminating the higher-order structure of biological networks. Here we apply one such method, weighted gene coexpression network analysis, to microarray data derived from human cerebral cortex, caudate nucleus, and cerebellum. Through detailed exploration of gene coexpression relationships we provide an integrated view of the transcriptome in each brain region. We demonstrate that the network structure of gene coexpression in human cerebral cortex is highly reproducible across microarray platforms and individuals, suggesting a fundamental organization to the cortical transcriptome that has not been previously recognized. Through comparisons with cerebellum and caudate nucleus we identify many aspects of network structure that are conserved across brain regions, and some that are not. We characterize modules of co-expressed genes that correspond to each of the major cell classes of the brain: neurons, oligodendrocytes, astrocytes, and microglia. Other modules distinguish additional cell types, organelles, synaptic function, and gender differences. We introduce a quantitative metric that describes how strongly each gene "belongs" to each module in a given gene coexpression network. Our analysis provides a new foundation for neurogenetic inquiries and reveals the existence of a previously unrecognized functional organization to the human brain transcriptome. Support: Postmortem brain tissue was donated by The Stanley Medical Research Institute's brain collection courtesy of Drs. Michael B. Knable, E. Fuller Torrey, Maree J. Webster, Serge Weis, and Robert H. Yolken.

Identification of Mutations in *CLN5* Gene in Neuronal Ceroid Lipofuscinosis (NCL) Patients with Diverse Ethnic Backgrounds and Variant Clinical Presentations. *W. Xin[1, 2], D. Sleat[3, 4], R. Kiely[1], X. Feng[1], L. O'Malley[1], Y. Shen[1], H. Zheng[3], P. Lobel[3, 4], K. Sims[1, 2]* 1) Neurogenetics DNA Diag Lab, Mass Gen Hosp, Boston, MA; 2) Dept of Neurology, Mass Gen Hosp, Boston, MA; 3) Ctr for Adv Biotech & Med, Piscataway, NJ; 4) Dept of Pharm, Robert Wood Johnson Med Sch-UMDNJ, Piscataway, NJ.

Neuronal ceroid-lipofuscinosis (NCL) are a group of autosomal recessive neuro-degenerative disorders. Disease characteristics include progressive cognitive and motor deterioration, visual loss, seizures and early death. Clinical suspicion of specific NCL type is based on the age of onset, clinical symptoms, and pathologic nature of inclusions by EM. Eight subtypes have been described. The Finnish variant late-infantile form of NCL (fLINCL; *CLN5*) has been reported primarily in patients from Finland. To date, 7 mutations have been described in *CLN5* gene in patients with onset of clinical symptoms in late infancy.

We now report mutation identification in 6 patients out of 16 screened who had clinical NCL features but no defect in other CLN genes. These patients had late-infantile, juvenile or adult onset NCL and were not of Finnish extraction. DNA sequencing of *CLN5* gene identified 1 NS mutation (in 2 patients), 2 MS mutations, and 2 out-of-frame deletions. A large deletion of all 4 exons was suspected in 1 patient. We have also identified previously unreported intronic and 3 UTR nucleotide changes and a silent mutation. To assay the functional consequences of these DNA mutations and to confirm pathogenicity, relative quantitation using mass spectrometry has been done. Loss of *CLN5* product has been documented.

The results from our study suggest that mutations in *CLN5* gene are 1) more common in NCL patients than originally reported, 2) are found in NCL patients with diverse ethnic backgrounds, and 3) can be identified in NCL patients with clinical presentations outside of the late-infantile age range. *CLN5* genetic testing is warranted in a wider population with clinical features suggestive of a NCL disorder.

Improved specific activity of random primer DNA-labeling by optimizing the Cy-dCTP/dCTP ratio. *J.W. Ling, B. Tazon-Vega, C. Zhang, K.P. Xu* PGD laboratory, Center for Reproductive Medicine and Infertivity, Weill Cornell Medical College, New York, NY.

To date the random primer labeling method has generally been used for array-CGH with Cy-dCTP incorporated into DNA competing with dCTP. Previous studies suggested that specific activity (SA, defined as [amount of target DNA (ng) x 1000] / [dye incorporated (pmole) x 324.5]) of 1 incorporated dye per 25 to 50 nucleotides was optimal for microarray hybridization. Only a SA of about 70 could be achieved with the commonly used 1:1 ratio of Cy-dCTP/dCTP in our preliminary experiments. We tested whether altering the Cy-dCTP/dCTP ratio could increase the labeling quality to the optimal range. Five different Cy-dCTP/dCTP ratios (1:1, 2:1, 3:1, 5:1 and 10:1) were tested with 10 samples in each group. The total amount of Cy3/5-dCTP and dCTP in every group was equivalent to each of the other three dNTPs in the reaction. For each group 4g of human genomic DNA were labeled by the Bioprime DNA Labeling System using Cy3- or Cy5-dCTP and Exo-Klenow. Unincorporated nucleotides were removed by filtration and the labeling quality was determined by the SA of labeled DNA using a spectrophotometer (ND-1000, NanoDrop Technologies). The average SA of Cy3 labeling for each group was 70.97.8, 70.96.7, 23.61.9, 23.01.6, 18.11.3; and 76.22.1, 74.11.6, 36.80.8, 35.20.5, 33.81.4 for Cy5. For both dyes the labeling efficiency increases with the amount of Cy-dCTP in the reaction but not proportionally. The lower incorporation capacity of Cy-dCTP requires a much higher proportion to increase the labeling efficiency. However when the ratio increases to a certain extent the double strand DNA becomes unstable by the dye, preventing further increase of incorporation. Our data showed that a 3:1 ratio may be optimal for both Cy3- and Cy5- DNA labeling achieving the SA of 23 and 37 respectively. Further investigation should be performed to test the quality of this labeled DNA for arra-CGH.

Molybdenum Cofactor Deficiency: Extension of Phenotype and Neuroradiology. *S. Prasad, S. Sharma, A. Petros, K. Nischal, J. O'Connell, P. Daubeney, A.K. Saggar* Paediatric Intensive Care, Cromwell Hospital, London, SW5 0TU, United Kingdom.

Molybdenum Cofactor Deficiency (MCD) is a rare, autosomal recessive, inborn error of metabolism, characterised by seizures and lens dislocation. Cardiomyopathy has not previously been recognised as an association. We report an 18 month old Arab girl, born of consanguineous parents. Following an unremarkable pregnancy, hypotonia and delayed milestones were observed at 5 months. She was admitted to hospital at the age of 13 months, with a severe respiratory illness requiring ventilation. Her symptoms progressed to include seizures, dystonia and bulbar dysfunction. An MRI demonstrated necrosis in the thalami and lentiform nucleus, and cerebral volume loss; these findings were reported as compatible with hypoxic ischaemic injury. The patient was transferred to the UK for further evaluation. Examination revealed gross developmental delay, microcephaly (0.4th percentile), dystonia and posturing. Ophthalmic examination confirmed bilateral dislocated lenses. She required ventilatory support, and due to persistent tachycardia and intermittent hypertension, an echocardiogram was performed showing significant cardiomyopathy. The combination of lens dislocation and refractory seizures is consistent with sulphite oxidase deficiency. High sulphite, high xanthine and low uric acid levels in the urine suggested MCD. This was confirmed by the finding of a homozygous deletion at the MOCS2 gene. The patient was given a low cystine, low methionine diet which made no difference to her clinical symptoms. The literature suggests that MRI changes in this disorder are similar to hypoxic brain injury; on further review of the MRI films, the appearances were felt to be consistent with metabolic disease. A subsequent MRI confirmed these appearances. This case highlights the unusual clinical features of hypertension and cardiomyopathy in MCD, lack of response to dietary restriction, and MRI findings similar to those found in hypoxic injury. MCD should be considered in cases of refractory seizures and lens dislocation; review of MRI scans by a specialist neuroradiologist is advised.

Sensitive and specific real-time PCR assays to accurately determine gene copy number variations (GCNVs) of human complement *C4A, C4B, C4-long, C4-short* and RCCX modules: elucidation of *C4* GCNVs in 50 consanguineous subjects with defined HLA genotypes. *Y.L. Wu[1], S.L. Savelli[1], Y. Yang[1], B. Zhou[1], B.H. Rovin[2], D.H. Birmingham[2], G.N. Nagaraja[2], L.A. Hebert[2], C.Y. Yu[1]* 1) Center for Molecular and Human Genetics, Columbus Children's Research Institute, Columbus, OH; 2) Department of Internal Medicine, The Ohio State University, Columbus, OH.

Recent comparative genome hybridization studies revealed hundreds to thousands of human genomic loci can have inter-individual copy-number variations (CNVs). One of such CNV loci in the HLA codes for immune effector protein complement component C4. Sensitive, specific and accurate assays to interrogate *C4* CNV and its associated polymorphisms using sub-microgram quantities of DNA are needed for high throughput epidemiologic studies of *C4* CNVs in autoimmune, infectious and neurological diseases. Quantitative real-time PCR (qPCR) assays were developed using TaqMan chemistry and based on sequences specific for *C4A* and *C4B* genes, structural characteristics corresponding to the long and short forms of *C4* genes, and the breakpoint region of *RP-C4-CYP21-TNX* (RCCX) modular duplication. Reliable assignments for gene copy-numbers (GCN) were achieved by relative standard curve method, using cloned *C4* genomic DNA covering six logs of DNA concentrations for calibrations. The accuracies of test results were cross-confirmed internally in each sample, as the sum of *C4A+C4B* equals to the sum of *C4L+C4S*, or the total copy number of RCCX modules. These qPCR assays were applied to determine *C4* CNVs from samples of 50 consanguineous subjects with defined HLA genotypes. The results revealed the presence of 8 haplotypes with single *C4* genes coding for either C4A or C4B in monomodular RCCX that are associated with multiple autoimmune and infectious diseases. There are 33 bimodular, 4 trimodular, and 1 quadrimodular RCCX haplotypes with different combinations of *C4L* and *C4S*, and *C4A* and *C4B*. Two to eight copies of *C4* genes in a diploid genome are firmly established. These *C4* qPCR assays are proven to be robust, sensitive and reliable, as they have contributed to the elucidation of *C4* CNVs in large cohorts of samples with autoimmune and neurological diseases.

Small molecule correction of an inherited learning defect in *Neto1* mutant mice. *D. Ng[1], M. Kanisek[3], G.M. Pitcher[2], R.K. Szilard[3], A. Sertie[1], S.J. Clapcote[3], J.C. Roder[3], M.W. Salter[2], R.R. McInnes[1]* 1) Developmental Biology; 2) Brain & Behaviour, Hosp for Sick Children, Toronto, Canada; 3) Lunenfeld Res Inst, Toronto, Canada.

The NMDA receptor (NMDAR) is a principle ionotropic excitatory glutamate receptor in the brain, where it is crucial for synaptic plasticity, learning and memory. We previously demonstrated that Neto1, a largely neurospecific transmembrane protein with two extracellular CUB domains, associates with NMDARs. Here we report that *Neto1*$^{-/-}$ mice had normal levels of the NR2A and NR2B subunits of the NMDAR in the hippocampus, but reduced post-synaptic localization of NR2A-containing NMDARs and diminished amplitude of basal NMDAR-mediated excitatory postsynaptic currents. Long-term potentiation (LTP) at hippocampal CA3-CA1 synapses, a form of NMDAR-dependant synaptic plasticity, was depressed in acute hippocampal slices from *Neto1*$^{-/-}$ mice by approximately 50% (n = 11, $p < 0.001$), indicating that Neto1 is critical to synaptic plasticity. Consistent with the depressed LTP, *Neto1*$^{-/-}$ mice have impaired spatial learning: in the initial learning phase of the Morris water maze, *Neto1*$^{-/-}$ mice performed normally, but in subsequent learning trials, performance was severely impaired (n = 10; effect of genotype: $F_{1,16} = 5.50$, $p < 0.05$). We next hypothesized that administration of CX546, an ampakine that indirectly enhances NMDAR signaling by modulating AMPA receptors, might correct the NMDAR-dependant abnormalities. Remarkably, both the LTP and spatial learning deficits in *Neto1*$^{-/-}$ mice were completely restored to wild-type levels by CX546 (n = 10; effect of genotype: $F_{1,10} = 13.30$, $p < 0.01$), at doses that in wild-type mice had no effect on LTP and only a modest effect on learning. We conclude that 1) Neto1 is required to establish or maintain the normal abundance of NR2A-containing NMDARs at the postsynaptic density; 2) Neto1 has a role in NMDAR-dependant synaptic plasticity and spatial learning; 3) an inherited defect of synaptic plasticity and spatial cognition can be pharmacologically rescued, a finding with important therapeutic implications for human neurological disease.

Frequency of the Thr399Ile single nucleotide polymorphism of the Toll-like Receptor 4 gene in obese mestizo women of Durango, Mexico. *B. Lazalde[1], M.R. Reyes[2], H. Rodriguez Hernandez[1], M. Rodriguez Moran[1], F. Guerrero Romero[1], G. Zambrano[1]* 1) Biomedical Research Unit, Mexican Institute of Social Security, Durango, Durango, Mexico; 2) Faculty of Medicine U.J.E.D., Durango, Dgo., Mexico.

Background. Obesity is associated to insulin resistance and chronic inflammation. The Toll-like receptor 4 (TLR4) mediates inflammatory events and insulin resistance in peripheral organs. A single nucleotide polymorphism in the TLR4 gene, Thr399Ile, has been associated with hyporesponsiveness for signal transduction, hence the carriers of this polymorphism could have a lower risk for developing obesity and chronic inflammation. The prevalence of this polymorphism in distinct populations is between 6% and 10% according to various reports. Aim. The aim of this work was to determine the allelic and genotypic frequencies of the Thr399Ile TLR4 polymorphism in a sample of obese mestizo women of Durango, Mexico. Methods. Previous informed consent from participant women, a sample of venous blood was obtained for DNA isolation and the Thr399Ile polymorphism was determined by HinfI RFLP after PCR amplification of the polymorphic site using primers and amplification conditions published elsewhere (Biotechniques 31: 22-24, 2001) Amplification products were resolved by electrophoresis in agarose gels stained with Et-Br. Results. The allelic and genotypic frequencies found were as follows: Thr allele, 97.71%; Ile allele, 2.29%; Thr/Thr genotype, 95.42%, Thr/Ile genotype, 4.58%; the Ile/Ile genotype was not found. The sample was in Hardy-Weinberg equilibrium. Conclusions. Our results showed that the wild Thr allele and the Thr/Thr genotype were overrepresented in the women studied; on the contrary, the mutated Ile allele was underrepresented when compared to the frequencies reported for other populations. Whether these findings reflect the frequencies of the general population of Durango remains to be elucidated. Further studies are warranted since the determination of this polymorphism could have implications with preventive aim in individuals at risk for developing obesity and chronic inflammation. (Partially supported by grant DGO-2007-C01-66735 from COCYTED-FOMIX to B. L.).

Family history of chronic diseases in Mexico: genomic tool for the risk establishment in public health. *P.F. Oliva-Sanchez[1], E. Velasco -Mondragon[2], R. Lopez-Ridaura[3], G. Jimenez-Sanchez[1]* 1) National Institute of Genomic Medicine, Mexico; 2) School of Public Health and Policy, Morgan State University,MD; 3) National Institute of Public Health, Mexico.

The objective of this study was to evaluate the association between chronic diseases, like diabetes type 2 (DT2), hypertension (HTA) and metabolic syndrome (SM), with family history (FH) in its different components (antecedents paternal or maternal or both) on Mexican adult population. An analysis of the National Health Survey of 2000 (ENSA 2000) was made. This Survey was implemented by the National Institute of Public Health and the Mexican Ministry of Health, by means of the application of an interview on a random representative sample of adults over 20 years in Mexico. Non - adjustment and adjustment OR was calculated by logistic regression analysis. We evaluate the association between chronic diseases and family history. Sample size of participants adult subjects in the survey was of 45,294. The 7, 5% (3,334) of them had DT2, the 31, 6% (14,004) HTA, the 2, 5% (696) SM. Was observed that those individuals who reports antecedents of DT2 in both parents they have 5, 11 ($p < 0, 0001$) grater possibility to suffering DT2 than those individuals without antecedents of this disease. In the adults who had SM was observed 9, 15 ($p < 0, 0001$) odds ratio on those who had the antecedents of DT2 in both parents in comparison with the individuals without antecedent of this disease. Another important finding is the interaction of HF with the body mass index (BMI). When we performed the stratification by groups of BMI, the OR of DT2 associated to FH in both parents on thin individuals, turned out to be higher in comparison to the same association in people with overweight and obesity. These results suggested that FH represents more the genomic component than the environmental component in causation of DT2.We considered that FH is a tool in genomic medicine and public health that serves to detect groups of greater genomic vulnerability.The HF represents a tool to detect individuals and/or families in risk. This strategy will be applied in better health policies, in terms of the diseases control in Mexico.

E-Selectin Ligand 1 Negatively Regulates TGF in the Golgi during Skeletogenesis. *T. Yang[1], R. Mendoza[1], H. Lu[1,5], K. Li[1], B. Keller[1], M.M. Jiang[1,2], Y. Chen[1,2], T.K. Bertin[1], B. Dabovic[4], D.B. Rifkin[4], J. Hicks[3], A.L. Beaudet[1], B. Lee[1,2]* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Howard Hughes Medical Institute; 3) Department of Pathology, Baylor College of Medicine and Texas Childrens Hospital; 4) Department of Cell Biology, New York University Medical Center; 5) Department of General Internal Medicine, UT MD Anderson Cancer Center.

E-Selectin Ligand-1 (ESL-1), the cysteine rich protein originally isolated as a ligand for E-Selectin, was also found to interact with FGFs and to be co-purified with TGFb1 in a large protein complex. To elucidate its in vivo function, we generated Esl-1-/- KO mice. The newborn Esl-1-/- mice are notably smaller with narrow chests and generalized shortening and thinning of all bony elements. The severe growth retardation was observed from E15.5 to maturity. Histologically, P1 Esl-1-/- mice showed shortening of the growth plates in both the proliferating zone and hypertrophic zone. Moreover, the notable less bone density was also detected in the adult mutant mice. Further molecular assays show that ESL-1 acts as a negative regulator of TGF production by binding TGF precursors via the laternt activation domain (LAP) in the Golgi in a cell autonomous fashion. In vivo, loss of ESL1 function causes increased TGF signaling resulting in decreased cell proliferation and delayed terminal differentiation in the growth plate, independent of effects on BMP and FGF signaling. Moreover, in vivo genetic models of gain vs. loss of TGF signaling in the growth plate confirm this effect. Transforming growth factor (TGF) signaling plays critical roles on regulating the growth and differentiation during development and diseases. Its context dependent action is specified by numerous control mechanisms at the extracellular level and downstream of ligand-receptor interactions, but little is known about the regulation of its post-translational trafficking. Our data not only identified ESL-1 as a critical regulator for skeletogenesis, cartilage and bone homeostasis, but also revealed a novel mechanism for regulating TGF intracellular pool in these processes.

Contrasting patterns of variation in two pigmentation candidate genes: *TYR* and *LYST*. *H. Norton, M. Hammer*
ARL-Biotechnology, Univ Arizona, Tucson, AZ.

Skin pigmentation is a complex trait that has been shaped by natural selection as humans expanded out of Africa and into different UVR environments across the globe. This process of local adaptation is expected to leave identifiable signatures in the DNA sequence of pigmentation genes, such as a reduction in heterozygosity, an excess of high-frequency derived alleles, and strong population differentiation between populations subject to different UVR environments. However, as processes related to changes in population structure, size and distribution can also have similar effects it is important to be able to distinguish between patterns due to selection and those arising from non-neutral demography. Here we compare sequence variation in two pigmentation candidate loci, *TYR* and *LYST*, to variation in 21 neutral autosomal loci sequenced in the same panel of 90 individuals representing 3 African (Biaka, Mandenka, and San) and 3 non-African populations (Han Chinese, French Basque, and Melanesians). *TYR* shows a significantly elevated Tajimas D value in our Melanesian sample ($D = 2.57$, $p < 0.01$), but does not appear to be an outlier for any other statistic in this population or any of the five others studied. On the other hand, *LYST* shows reduced heterozygosity in both the Han Chinese and Melanesian samples relative to the comparison autosomal loci, reduced haplotype diversity in both populations, and a Tajimas D value (-1.73) that falls at the extreme of the empirical distribution in the Han population. *LYST* F_{ST} values between the Han and Melanesians and all other populations are also relatively high (0.19 - 0.45), indicating relatively strong inter-population divergence at this locus. The patterns suggest that polymorphisms in *LYST*, but not *TYR*, may have been favored by natural selection in the Han population.

Mutations in *MMADHC* in two patients with the *cblD* form of inborn error of cobalamin metabolism. *I.R. Miousse[1,2], D. Watkins[1], D. Coelho[3], T. Suormala[3], J.P. Lerner-Ellis[1,2,3], B. Fowler[3], D.S. Rosenblatt[1,2]* 1) Department of Human Genetics, McGill University, Montreal, Qc, Canada; 2) Division of Medical Genetics, Department of Medicine, McGill University Health Centre, Montreal, Qc, Canada; 3) Metabolic Unit, University Childrens Hospital, Basel, Switzerland.

Derivatives of cobalamin (vitamin B_{12}) are essential cofactors in two reactions in mammalian cells: methylmalonyl-CoA mutase and methionine synthase. Defects of cellular cobalamin metabolism that prevent the proper function of these two enzymes have been assigned to specific complementation groups (*cblA-cblG*). Eleven patients are known with the *cblD* inborn error of cobalamin metabolism, and the responsible gene, *MMADHC*, has recently been identified. Patients with *cblD* present with either isolated methylmalonic aciduria, isolated homocystinuria or combined methylmalonic aciduria and homocystinuria, and the location of the mutation correlates to the phenotype. We report two additional patients with the *cblD* disorder. Patient 1 presented during the first days of life with isolated methylmalonic acidemia. Cultured fibroblasts had decreased incorporation of label from propionate into macromolecules; the proportion of total cobalamin present as adenosylcobalamin was decreased. Complementation analysis classified this patient as *cblD variant 2* (isolated methylmalonic acidemia). Patient 1 was compound heterozygous for two putative truncating mutations in *MMADHC*: c.60insAT (p.L20fsX21) and c.455dupC (p.T152fsX162). Patient 2 presented at four months of age with elevated levels of both methylmalonic acid and homocysteine in blood and urine. Incorporation of label from both propionate and methyltetrahydrofolate in macromolecules was decreased. Synthesis of both adenosylcobalamin and methylcobalamin was decreased. Complementation analysis classified this patient as *classical cblD* patient (methylmalonic acidemia and hyperhomocysteinemia). Mutation analysis of *MMADHC* demonstrated that patient 2 was homozygous for the missense mutation c.683CG (S228M). These findings reinforce phenotype-genotype correlations previously reported in *MMADHC*.

Whole-genome panels for analysis of structural variation in the human genome. *D.A. Peiffer[1], L.M. Galver[1], K.A. Viaud[1], L. Zhou[2], M. Eberle[1], K. Kuhn[1], S.S. Murray[3], R. Shen[1]* 1) Illumina, Inc, San Diego, CA; 2) Prognosys Biosciences, San Diego, CA; 3) Scripps Genomic Medicine, San Diego, CA.

Structural variation throughout the genome has been shown to associate with both disease and susceptibility of disease. Therefore, studies of copy number variation (CNV) on a genome-wide scale are necessary for any extensive whole genome disease-association analysis. We have designed two whole-genome panels for this purpose utilizing the Infinium assay, which allows examination of both SNPs and non-polymorphic probes efficiently and accurately on a single slide. The first panel contains greater than 370k markers that were selected to maximize genomic coverage for the CEPH population as well as cover the majority of known CNV regions throughout the genome. The second panel contains more than one million markers that were chosen to maximize genomic coverage in CEPH, Han Chinese, Japanese and Yoruba populations. In addition, this panel contains extensive coverage of all RefSeq genes, known CNV regions and has even spacing across the genome for efficient discovery of novel CNV regions.

As of March, 2007 there were 2,714 regions of known CNV in the Database of Genomic Variants. The 370k and one million marker panel cover these regions with 80,000 and 230,000 markers, respectively. In partnership with deCODE Genetics, an additional ~9,000 novel regions likely to represent CNVs were identified and are targeted with approximately 38,000 SNPs and 18,000 non-polymorphic probes for both panels. These regions include segmental duplications, the MHC region, megasatellites, and regions lacking SNPs. Preliminary CNV data generated from these markers using HapMap samples will be shown. We have found that this panel can accurately measure unstable regions of the genome, including megasatellites containing up to twelve copies and overall, these regions show an order of magnitude greater number of CNVs than previously described regions. Mean spacing of markers is ~7.7kb (median ~5kb) for the 370K marker panel and ~2.4kb (median ~1kb) across the genome with less than 5,000 gaps greater than 10kb for the one million marker panel. These panels provide powerful tools for whole-genome analysis utilizing both SNPs and structural variation throughout the genome.

Replication and refinement of the chromosome 12q MYP3 locus in an international high myopia family cohort.

T.L. Young[1], A. Bulusu[1], R. Metlapally[1], F. Malecaze[2], P. Calvas[2], J.A. Guggenheim[3], D. Mackey[4], T. Rosenberg[5], S. Paget[2], P. Holmans[1], Y-J. Li[1] 1) Center for Human Genetics, Duke U. Med. Ctr., USA; 2) Toulouse U., France; 3) School of Optometry and Vision Sciences, Cardiff U., Wales; 4) Dept. of Ophthalmology, U. of Melbourne, Australia; 5) Gordon Norrie Ctr., Kennedy Inst. Nat'l Eye Clinic, Hellerup, Denmark.

Introduction: Severe myopia (nearsightedness of > -6 diopters) predisposes individuals to retinal detachment, chorioretinal degeneration, cataract, and glaucoma. Multiple myopia-risk genetic loci have been reported. This is a whole genome linkage study of a large high myopia family dataset focused on the chromosome 12q MYP3 locus. Methods: A 5-site international collaboration of 249 multiplex high myopia families (at least 2 affected individuals per family) dataset was compiled. Whole genome SNP genotyping was performed using 6008 SNPs. Assuming a dominant affected-only model, 2-pt and multipoint linkage analyses were performed using the FASTLINK and MERLIN programs, respectively. Analyses were performed on overall and center-specific datasets. Results: The most significant linkage region was found on chromosome 12 with 2-point LOD scores > 3.0 for markers rs581642 (53.89cM) and rs1849929 (112.37cM). Parametric multipoint analysis revealed a tighter significant linkage interval of 23.5cM centered at marker rs337663 (101.97cM, HLOD=3.48). Non-parametric linkage analysis showed four suggestive linkage regions with LOD scores > 1.0 (peaks at 56.41cM, 73.95cM, 103.49cM, and 138cM). The parametric linkage region (101.97cM) overlaps with the 3rd non-parametric linkage region (103.49cM), and the Duke and Hellerup family sets are primary contributors to this interval. The Toulouse and Cardiff family sets primarily contribute to the 2nd and 4th non-parametric linkage peaks, respectively. Conclusion: This is the first SNP-based whole genome linkage screen using a large, international family dataset to determine loci for severe myopia. Heterogeneity exists among centers, and the best consensus linkage region is near 101.97cM, which replicates previous MYP3 locus microsatellite analyses. The MYP3 locus was contracted to a 23.5cM region.

Jagged1 (JAG1) mutation metection in a Brazilian Alagille Syndrome population. *I.K. Miura[1], F.E. Arimura[1], M.S. Floriano[2], A.C. Pereira[2], G. Porta[1]* 1) Department of Pediatrics, University of São Paulo Medical School, São Paulo, Sao Paulo, Brazil; 2) Heart Institute (InCor), University of São Paulo Medical School, São Paulo, Brazil.

Alagille syndrome (AGS) is a dominantly inherited disorder characterized by liver disease in combination with heart, skeletal, ocular, facial, renal, and pancreatic abnormalities. The human Jagged1 gene (JAG1) on chromosome 20p12 was identified as the AGS disease gene. JAG1 encodes a ligand in the Notch intercellular signaling pathway. Mutations in JAG1 have been found to result in the AGS phenotype and both protein truncating mutations and missense mutations have been identified. Through sequencing, we are screening 28 AGS affected individuals from 27 families for mutations within Jagged 1. So far, six distinct mutations were identified in 7 (25%) AGS cases. The mutations include three small deletions (43%) and four missense mutations (57%). Thirteen polymorphisms were found. These mutations as well as several polymorphisms are spread across the entire coding sequence of the gene. There are no phenotypic differences between patients. As shown in other studies from different cohorts, this study did not find genotype-phenotype correlation. The results of this study are consistent with the proposal that haploinsufficiency for wild type Jagged 1, in missense mutations, may result in AGS phenotype. Further studies like family screening are needed to determine the rate of de novo mutations as well as microsatellite analysis to determine deletions and translocations.

INTRACELLULAR TRAFFICKING ANALYSIS OF C111Y AND C111S MUTATIONS IDENTIFIED IN FACTOR IX FROM MEXICAN PATIENTS WITH SEVERE HEMOPHILIA B. ANTECEDENTS. *J. Mantilla[1,3], N. Enjolras[2], C. Négrier[2], A.R. Jaloma-Cruz[1,3]* 1) Doctorado en Genética Humana, CUCS, Universidad de Guadalajara, Guadalajara, Jalisco, México; 2) Laboratoire dHémobiologie, Faculté de Médecine RTH Laennec, Lyon, France; 3) División de Genética, CIBO, IMSS, Guadalajara, Jalisco, México.

ANTECEDENTS. We studied two mutations at 17,747 nucleotide in the second-like epidermal growth factor (EGF2), of factor IX gene (FIX), to identify their effect in the structure-function relationship of the protein by the study of their intracellular trafficking. MATERIALS AND METHODS. C111 wild-type and the mutations C111S and C111Y were inserted by directed-site mutagenesis into an expression vector (pcDNA 3.1) containing the FIX wild-type (wt) gene. Transfection on Cos-7 cells by Fugene6 after 48hrs was tested with a control plasmid containing the green fluorescence protein (pGFP) with a good efficiency (64.5%) evaluated by a flux-cytometry. The intracellular FIX amounts and secretion were quantified by ELISA assay. Transfected cells were incubated in presence of inhibitors like Brefeldin A, which blocks protein transport from endoplasmic reticulum (ER) to the Golgi; N-Acetyl-Leu-Leu-Norleucinal (ALLN) and Clasto-lactacystin beta-lactone, proteasomal inhibitors, and NH4Cl and Leupeptin, lysosomal inhibitors. RESULTS. Respect to FIX wt, the mutations showed a decreased FIX secretion (20%) and intracellular accumulation of 140% (C111Y) and 160% (C111S). The effects of the inhibitors caused a higher intracellular accumulation of the mutants which led a degradation mainly in lysosomes (NH4Cl) and secondly in proteasomes (ALLN). By the effect of Brefeldin A on C111S we can assume an adequate transport from ER to Golgi, opposite to C111Y which seems to be blocked at ER and to have elevated degradation in proteasomes (ALLN effect). CONCLUSIONS. The disruption of the disulfide bond in the mutants have an important effect on the native folding of FIX protein, evident by the effects on its transport through ER and the degradation mechanisms, with a predominant degradation at proteasomes when the ER transport is blocked and a higher degradation at lysosomes when the transport from ER to Golgi complex is adequate.

Detecting associations under models of complex traits prone to an effect reversal. *D.V. Zaykin[1], K. Shibata[1], L. Diatchenko[2]* 1) National Institute of Environmental Health Sciences, RTP, NC; 2) University of North Carolina at Chapel Hill, NC.

Failure to replicate a genetic association is a common problem. It has been observed that the direction of the effect in different studies may be reversed as well. Although an explanation for many of these cases is likely to be statistical in nature, it has been recently suggested that a reversal of effect (flip-flop) can be a consequence of a change in linkage disequilibrium (LD) between a causal and the observed variants. We develop a more general model, showing that a flip-flop phenomenon can be completely attributed to a change in LD only in situations when the studied variant is only a proxy marker for unobserved functional variation. More generally, a flip-flop can occur without a change in LD, or even when the LD is zero. We give specific conditions for the form of genetic effects that allow for such flip-flops. In this model, a flip-flop is driven by a shift in population haplotype or allele frequencies. Nevertheless, both the population prevalence and the allele frequency of the observed variant can be the same in two populations that exhibit a flip-flop. If all relevant variants are scored, a flip-flop can no longer take place, thus it is a consequence of partial knowledge. In the case of a quantitative trait, the unobserved variants induce a difference in the variance of the trait among individuals with different scored alleles. This suggests a statistical approach for discovering associations that is more robust to loss of power due to a genetic flip-flop.

Screening for 7q11.2 duplications in individuals with Autism Spectrum Disorder. *P. Malenfant[1,5], X. Liu[2,5], Y. Qiao[3,4,5], MJ. Hildebrand[4,5], M. Hudson[2,5], E. Rajcan-Separovic[3,5], MES. Lewis[4,5], JJA. Holden[1,2,5,6]* 1) Dept Physiology; 2) Dept Psychiatry, Queens University, Kingston, K7L 3N6; 3) Dept Pathology; 4) Dept Medical Genetics, University of British Columbia, Vancouver, BC, V6H 3N1; 5) Autism Research Program, Ongwanada, Kingston, ON, Canada, K7M 8A6; 6) ASD-CARC: www.autismresearch.ca.

Genetic factors are recognized to play a major role in the etiology of Autism Spectrum Disorders (ASDs). There are several reports of genomic rearrangements in individuals with ASD, some identified in more than one individual. In most cases, however, they are identified in only one or a few cases. Using CGH microarrays, we have identified a duplication (dup) on chromosome 7q11.2 in an individual with confirmed ASD, severe expressive language deficit (apraxia), intellectual disability (ID) and minor craniofacial dysmorphism. Real-time qPCR localized the breakpoints within the flanking low-copy repeats (~72.2Mb and ~73.8Mb) that predispose to the genomic instability underlying the 7q11.2 deletion (del) observed in the majority of Williams-Beuren Syndrome cases (WBS). A total of 798 individuals with an ASD and 192 controls were screened for the presence of the dup 7q11.2 rearrangement, using probes specific for ELN and CYLN2, no additional instances were found in either group. There are several previous reports of individuals with dup of the WBS locus, most of which present with language delay and ID and in at least one case, with autism (Depienne et al, 2007). Additionally, Edelmann et al. (2007) reported an atypical del of the WBS region which had a 400kb overlap with the dup reported herein in a patient with autism. Although additional similar dups were not identified in our ASD population cohort, the dup found in our patient and in a few cases reported by others may signal a smaller refined chromosomal region for study by positional candidate gene. Consequently, additional linkage analysis may yield positive results. Three genes located within the duplicated interval, STX1A, CYLN2 and GTF2i were selected based on their function and genomic location for linkage analysis in 725 families, for which results will be presented.

Association between the genetic polymorphisms in *DRD2* and the risk of tardive dyskinesia: a meta-analysis study. *H-T. Tsai* Epidemiology Department, University of North Carolina-Chapel Hill, Chapel Hill, NC.

Background Tardive dyskinesia (TD), an involuntary movement disorder, is a serious and potentially irreversible adverse effect from antipsychotic therapy. Current understanding about TD is very limited. Genetic variants in dopamine receptor 2 (*DRD2*) have been studied for their associations with TD. However, study findings are very controversial.
Objectives To understand association between genetic variants in *DRD2* and TD among patients with schizophrenia, a meta-analysis study was conducted.
Methods A systematic search of literature was performed through a cross-search of several databases. Three genetic variants in DRD2 were studied: *TaqI*, rs1801028(*Ser311Cys*), and *-141C Ins/ Del*. Genotypic effects were compared in general, dominant and recessive models. Publication bias and heterogeneity test across studies was examined. Meta-regression analyses were also implemented using STATA 8.1.
Results Seven studies were identified for *-141C Ins/ Del*, with a total of 1724 schizophrenics (582 TD, 1142 non-TD) from Asia (4 studies), Europe (2 studies) and a mix of Europeans and African Americans (1 studies). Five studies about rs1801028 (462 TD, 964 non-TD), and *TaqI* A (390 TD, 549 non-TD) were collected. Schizophrenics with A2/A1 or A2/A2 genotype in *TaqI* A showed a lower risk of TD than those with A2/A2 genotype: $OR_{A1/A1+ A2/A1 \text{ vs. } A2/A2} = 0.63$ (95% C.I.= 0.47-0.85). No association was found in the analysis of TD with *-141C Ins/ Del*: $OR_{Del/Del+ Ins/Del \text{ vs. } Ins/Ins} = 0.96$ (95% C.I.= 0.65-1.43); and with rs1801028: $OR_{Cys/Cys \text{ vs. } Ser/Ser} = 1.43$ (95% C.I.= 0.77-2.62), $OR_{Ser/Cys \text{ vs. } Ser/Ser} = 0.82$ (95% C.I.= 0.49- 1.34). Heterogeneity or publication bias was not detected in this study.
Conclusions A systematic analysis of literature supported the association between *DRD2/TaqI* A and TD among schizophrenics, but did not support associations between TD and *-141C Ins/ Del* or rs1801028 in *DRD2*.

Gene Expression in Peripheral Lymphocyte Cells of Patients with Major Depressive Disorder Treated with Citalopram. *F. Mamdani[1], P.A. Sequeira[1], J. ffrench-Mullen[2], M. M. Beaulieu[1], M. Berlim[1], G. Turecki[1]* 1) McGill Group for Suicide Studies, Douglas Mental Health University Institute, McGill University, Montréal, Quebec, Canada; 2) GeneLogic Inc., Gaithersburg, Maryland, USA.

Major depression (MD) is a psychiatric disorder that affects 5-10% of the population and is considered the second leading cause of disability by the World Health Organization. Moreover, 30 to 40% of patients treated with antidepressants do not present with an adequate response to treatment. In order to identify gene targets that may mediate response to Citalopram (CIT), a commonly used SSRI (selective serotonin reuptake inhibitor) antidepressant, we are conducting a large-scale gene expression study in lymphocytes of drug-naïve depressed patients treated with CIT for eight weeks, with Affymetrix U-133 Plus2 microarrays being performed pre and post treatment initiation. We are presenting preliminary results on 60 cases. Outlier detection is performed using several quality control variables as well as principal component analysis. Our analyses are based on individual response status determined at the end of eight weeks using severity of depression measures obtained throughout the trial with the Hamilton Depression Rating Scale (HAMD-24). We have found gender-specific gene subsets that are possibly implicated in the response to CIT; 394 differentially expressed genes (DEGs) in females and 359 DEGs in males. As well as, genes that may allow for the prediction of this response prior to treatment commencement. Gene ontology analysis of differentially expressed genes revealed several biological processes being affected by treatment; these include immune response, regulation of transcription and nucleic acid metabolism. These findings show promise for the eventual determination of possible biomarkers for classification of responders and non-responders to antidepressant treatment.

A genome-wide association study of brachial flow mediated dilation identifies novel candidate genes. *A. Parsa, E. Rampersaud, B.D. Mitchell, R. Horenstein, P.F. McArdle, H. Shen, J.R. OConnell, R. Vogel, A.R. Shuldiner* Department of Medicine, University of Maryland School of Medicine, Baltimore, MD.

The vascular endothelium consists of the inner most layer of blood vessels and regulates many critical aspects of vascular function. Hyperemic-induced flow mediated dilation (FMD) is a non-invasive measure of endothelial function and has been associated with numerous disease states, such as hypertension, coronary heart and kidney disease. While studies have demonstrated moderate heritability, the specific gene variations influencing this trait are largely unknown. In this study, we have attempted to uncover FMD related genes by performing a high density genome-wide association study of FMD in the Old Order Amish. Methods: Brachial FMD percent change in diameter was measured under a precise protocol from 868 well characterized relatively healthy Old Order Amish participants of the HAPI Heart Study. The family structures included 633 siblings, 327 parent-offspring and 634 other related pairs. We estimated the heritability of FMD using variance components analysis, adjusting for age and sex. All subjects were genotyped using a 500K Affymetrix SNP array set. Regression analysis for each SNP with normally distributed FMD was performed. Results: The heritability of FMD was estimated at 0.29 ($p < 0.001$). SNPs mapping to five genes were very highly associated with FMD in our initial screening (by False Discovery Rate, p value range 10-9 to 10-6) and SNPs in another 17 genes were strongly associated ($p< 10-6$) with FMD. Of the 22 identified genes, 9 contained at least one intronic SNP and 13 were associated by SNPs from either up or downstream regions of the gene. Moreover, several of our candidate genes from chromosomally distinct loci demonstrate functional convergence. Conclusion: Our results confirm that baseline FMD is a significantly heritable trait, a finding which may have broader implications for individual genetic susceptibility to vascular disease. Furthermore, we have identified several candidate genes in addition to delineating a potential novel neural pathway related to endothelial function.

Association of Vascular Endothelial Growth Factor (VEGF) Polymorphisms with Childhood Asthma and Airway-Remodeling Phenotypes. *S. Sharma[1], B. Raby[1], A. Murphy[1], M. Soto-Quiros[2], L. Avila[2], B. Klanderman[1], J. Sylvia[1], A. Patel[1], J. Celedon[1], S. Weiss[1]* 1) Channing Laboratory, Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 2) Division of Pediatric Pulmonology, Hospital Nacional de Niños, San Jose, Costa Rica.

Rationale: Asthma is a chronic inflammatory disease associated with airway remodeling and subsequent long-term decline in lung function. Expression of VEGF, an angiogenic factor implicated in airway remodeling, correlates with the severity of airflow obstruction. We hypothesized that VEGF gene polymorphisms are associated with asthma and airway-remodeling phenotypes. **Methods**: We genotyped 17 VEGF single nucleotide polymorphisms (SNPs) in 471 white (non-Hispanic) trios participating in the Childhood Asthma Management Program (CAMP). Family-based association tests were performed using PBAT under additive and dominant genetic models. We assessed asthma and three pulmonary function phenotypes: post bronchodilator FEV1, FVC, and FEV1/FVC ratio (FF). Haplotype block analysis was performed in FBAT. Repeated measures analysis of FF was conducted with FBAT-PC. We tested for evidence of replication in 439 asthmatic children and their parents from the Central Valley of Costa Rica. **Results**: In CAMP, one SNP was associated with asthma (p=0.01), and three others with FVC and FF (p=0.01-0.03). Most notably, rs4711750 was associated with FF in CAMP (p=0.01) and Costa Rica (p=0.02). In the Costa Rican trios, one SNP was associated with asthma (p=0.01) and two others were associated with FEV1 and FF (p=0.006-0.02). Haplotype block analysis confirmed the association with FF in both cohorts. Repeated-measures analysis also demonstrated an association between rs4711750 and FF over time. **Conclusions**: VEGF polymorphisms are associated with childhood asthma and airway remodeling phenotypes in two ethnically distinct populations. Our analysis suggests that variants in VEGF influence airway remodeling, which is a critical long-term outcome of asthma. **Funding**: Grants HL65899, HLO7427, HL04370, HL66289, and HL74193 from the National Institutes of Health.

Gender influences the association between variation in the Acid Phosphatase 1 (*ACP1*) and percent body fat in Mexican Americans. *YH. Shu[1], J. Hartiala[1,2], A.H. Xiang[1], M. Kawakubo[1], E. Trigo[3], H. Allayee[1,2], J.M. Lawrence[4], T.A. Buchanan[3], N. Bottini[1,2], R.M. Watanabe[1]* 1) Dept of Preventive Medicine, Division of Biostatistics, Keck Schl of Med of USC, Los Angeles, CA; 2) Institute for Genetic Medicine, Keck Schl of Med of USC, Los Angeles, CA; 3) Dept of Medicine, Division of Diabetes and Endocrinology, Keck Schl of Med of USC, Los Angeles, CA; 4) Research and Evaluation, Kaiser Permanente, Pasadena, CA.

Protein tyrosine phosphatases negatively regulate insulin signaling and are candidate genes for obesity and type 2 diabetes (T2D). *ACP1* is a tyrosine phosphatase expressed in adipose tissue and a drug target in obesity. Knocking down ACP1 in liver and adipose using antisense oligos corrects obesity-induced metabolic anomalies in mice. We tested whether variation in *ACP1* is associated with obesity and/or other T2D-related traits in 143 Mexican American families of a proband with previous gestational diabetes mellitus. Subjects were phenotyped by oral (OGTT) and intravenous glucose tolerance test and DEXA scans to measure percent body fat (PBF). Our sample consists of 682 individuals (48.6% male, 51.4% female) with mean age 38.212.5 years and mean PBF 31.28.8%. Seven tag SNPs were identified from among 14 genotyped across the *ACP1* region. SNPs were tested for association with obesity and other T2D-related traits by variance components and likelihood ratio tests. rs3828329 was significantly associated with PBF (Bonferroni corrected p=0.037), whereby, PBF increased ~4.5% with each copy of the T allele. rs3828329 was also associated with several diabetes-related traits (fasting, 30 minute, and 2-hour insulin values from the OGTT; insulin sensitivity; waist-to-hip ratio; BMI), but became non-significant when adjusted for PBF. The interaction between rs3828329 and gender was also significantly associated with PBF (p=0.0002). In males, PBF increased by ~10% with each copy of the T allele, but did not change in females. We conclude that variation in *ACP1* is associated with adiposity and secondarily alters diabetes-related quantitative traits in males, but not in females. This effect could be due to disruption in insulin signaling in adipose tissue.

Compelling prenatal indication of autosomal recessive primary microcephaly (MCPH). *D.B. Rogers[1], C. Coffeen[1], L. Mahon[2], N. Qin[3], L.D. Platt[4], D. Krakow[5]* 1) Genzyme Genetics, Los Angeles, CA; 2) Quest Diagnostics, West Hills, CA; 3) Genzyme Genetics, Orange, CA; 4) Center for Fetal Medicine and Womens Ultrasound, David Geffen School of Medicine at UCLA, Los Angeles, CA; 5) Div. of Medical Genetics, Dept. of OBGYN, Cedars-Sinai Medical Center, Los Angeles, CA.

Occasionally prenatal cytogenetic testing yields results that suggest a specific non-chromosomal disorder. A 29-year-old G2P0TAB1 Persian woman underwent genetic counseling and amniocentesis at 19 weeks GA because of abnormal ultrasound findings consisting of echogenic bowel and bilateral renal pyelectasis. The karyotype was reported as 46,XY, but the banding resolution was only 350. This is below the standard cytogenetic methodology. The patient declined a repeat amniocentesis and continued her pregnancy. Ultrasound follow up at 24 weeks revealed the fetal head to be growing at the fifth percentile. Second opinion ultrasonography confirmed the possible microcephaly with no structural defects. Fetal MRI was remarkable for decreased brain parenchyma volume and underdevelopment with relatively increased amount of subarachnoid fluid. The patient then sought and achieved pregnancy termination. This patients first pregnancy was terminated in the first trimester due to the ultrasound finding of a cystic hygroma. Cytogenetic analysis on CVS revealed 46,XX with a band resolution at the 350 level

MCPH is a neurodevelopmental disorder that features microcephaly and mental retardation. The brain is small, but structurally normal, and the cerebral cortex is greatly reduced in size. One of the four identified genes implicated in MCPH is MCPH1 that encodes for microcephalin. This protein is believed to play a role in cell-cycle timing and DNA repair following ionizing radiation damage. The findings in our patients fetal chromosome preparations from two different pregnancies and two distinct tissues are consistent with premature chromosome condensation, a feature of MCPH due to a mutation in MCPH1. Fetal cells saved from the latest pregnancy will be studied to confirm a microcephalin gene defect.

Genome-wide association scan identifies new susceptibility loci for psoriatic arthritis and psoriasis. *P.Y. Liu[1], C. Helms[1], J. Gardner[1], A. Perlmutter[2], A. Miner[2], S. Duan[1], R. Donaldson[1], C. Wise[3], P. Kwok[4], W. Liao[5], N.L. Saccone[1], J. Worthington[6], A. Barton[6], A. Menter[2], A.M. Bowcock[1]* 1) Dept Genetics, Washington Univ, St Louis, MO, USA; 2) Dept Dermatology, University of Texas Southwestern Medical Center at Dallas, TX, USA; 3) Texas Scottish Rite Hospital, TX, USA; 4) Cardiovascular Research Institute and Center for Human Genetics, UCSF, CA, USA; 5) Dept of Dermatology, UCSF, CA, USA; 6) Univ of Manchester, UK.

Psoriasis (PS) affects approximatley 2% of the European population. Psoriatic arthritis (PsA) is an inflammatory arthritis that occurs in up to one-third of patients with PS. The genetic basis of both PSA is poorly understood. A genome-wide association study (using the Illumina HumanHap300 genotyping beadchip) was performed to identify genetic factors involved in PsA susceptibility among the Caucasian population. A case-control study design was used for the initial gene discovery and for replication. We genotyped 142 patients with PsA, 132 patients with PS and 223 healthy controls from the New York Health Project for 310,000 SNPs. Case-control comparisons identified 7 regions where P 6E-6 within the PsA group. The top-ranking SNPs associated with PsA included a novel locus within the MHC (multiple histocompatibility locus antigen cluster) that is distinct from HLA-C. This trend was not observed in the PS analysis where the top ranking SNPs lay within the class I region of the MHC. Replication studies with an independent UK PsA cohort (576 cases, 480 controls) were performed to validate the above findings. They confirmed strong evidence for association with a gene (P < 10-33) activated by nitric oxide - a strong inflammatory mediator and regulator of inflammatory responses, a protease inhibitor (P < 10-21) and a suppressor of TNF alpha induced cell death (P < 10-7). These pathways play important roles in the development of inflammation, and their role in the development of psoriasis or psoriatic arthritis start to provide a framework for the development of therapeutic interventions.

Integrative Whole Genome Genetic and Epigenetic Analysis of Lung Tumor Genomes. *E. Vucic, W.W. Lockwood, I.M. Wilson, R. Chari, B.P. Coe, C. MacAulay, S. Lam, W.L. Lam* British Columbia Cancer Research Centre, Vancouver, BC, Canada.

Background: Lung cancer (LC) is the leading cause of cancer mortality worldwide. Understanding molecular mechanisms driving LC development and progression will lead to rational development of diagnostics and intervention based on a fuller understanding of disease biology. Although previous studies have yielded loci specific surveys of genetic and epigenetic changes, no study to date has simultaneously analyzed genetic and epigenetic alterations at the DNA level on a whole genome scale. Objective: To comprehensively characterize the underlying molecular alterations driving LC development using an integrative genomic and epigenomic analysis. Methods: A whole genome tiling path comparative genomic hybridization (CGH) array was used to generate high resolution copy number (CN) profiles of 161 lung tumors and 20 carcinoma in situ (CIS) lesions. Whole genome methylation profiles were determined by Methylation Dependent Immunoprecipitation (MeDIP) array CGH. Array data was visualized using SeeGH software and subjected to a segmentation algorithm to computationally determine regions of gain and loss and areas of differential methylation. Results: Complementary genomic and epigenomic profiles highlighted numerous CN and DNA methylation changes. In addition to novel regions of recurrent gain and loss, complex rearrangements with multiple segmental alterations present on the same chromosome arm highlight the instability of the tumors. Focal high level amplifications were characteristic of advanced tumors whereas whole arm changes were more common in the CIS lesions. Interestingly, LC subtypes were defined by unique patterns of CN and methylation changes, indicating their differential development. Lastly, concerted regions of DNA hypermethylation and segmental loss, as well as hypomethylation and gain signified novel two hit mechanisms for both gene silencing and activation respectively. Conclusions: Discovery of these novel features may shed light on disease mechanisms and identify new molecular targets for therapy and early diagnosis. Work supported by Genome Canada and CIHR.

Distribution of three VNTRs from intron 40 of the VWF gene in ten Mexican Mestizo families with von Willebrand disease. *J. J. Palacios[1], R. Peñaloza[1], H. Benitez[2], M. Flores[1], F. Salamanca[1]* 1) Unidad de investigación en Genetica Humana, Centro Medico Nacional Siglo XXI, IMSS, Mexico City; 2) Servicio de Hematologia Pediatrica, Centro Medico Nacional Siglo XXI, IMSS, Mexico City.

Distribution of three VNTRs from intron 40 of the VWF gene in ten Mexican Mestizo families with von Willebrand disease. Palacios JJ1, Benitez H2, Flores M1, Salamanca F1, Peñaloza R1 1.Unidad de investigacion en Genética Humana, CMN SXX, IMSS, México City, MEXICO 2.Servicio de Hematología Pediatrica, CMN SXXI, IMSS, México City Background: von Willebrand disease (VWD) is the most common hemorrhagic alteration in humans, characterized by mucocutaneus bleeding in different intensities due to alterations in the VWF gene, located in chromosome 12p13.3. VWF protein polymerizes and participates in the coagulation system, forming links between the platelets and the site of vascular injury, besides protecting the VIII factor from an early degradation in plasma. Objective: To analyze VNTRs 1,2, and 3 located in intron 40 of VWF gene, which have shown to be useful in segregation studies in other populations, because they are very polymorphic, and usually, they show high heterozygosity levels, basic characteristics of good genetic markers. Materials and methods : Ten VWD patients and their families were studied, previous informed consent. DNA was isolated from blood leucocytes by standard methods, and the required sequences were amplified by PCR. The products were first analyzed in agarose gels to verify if they amplified, and then in polyacrilamide gels. Results and Conclusions: We found high heterozygosity levels in the three studied VNTRs; we also found a novel 4 ATCT repeat in the VNTR1 region, never reported before in Mexican Mestizo population. This results makes them useful in segregation studies and genetic assessment.

Molecular analysis of the *MFN2* gene in familial and sporadic axonal Charcot-Marie-Tooth disease type 2 (CMT2). *M. Milani, D. Pareyson, F. Taroni* Div Biochem & Genetics, Fondazione IRCCS Ist Neurologico Carlo Besta, Milan, MI, Italy.

Axonal CMT (CMT2) is genetically highly heterogenous, with at least 14 loci and 10 genes identified thus far. Mutations in the gene encoding the mitochondrial protein mitofusin-2 (MFN2) have been shown to be responsible for autosomal dominant CMT2 type A2 (CMT2A2). The *MFN2* gene maps to chromosome 1p36.2 and encodes a 757-amino acid protein which is an essential component of mitochondrial fusion in mammalian cells. The CMT2A2 phenotype is largely indistinguishable from that of CMT2A1 (*KIF1B*), CMT2E (*NEFL*), and CMT2F (*HSPB1*). However, in a subset of CMT2A2 patients, pyramidal involvement and visual impairment have been reported. The disease exhibits reduced penetrance: studies in large families have shown that individuals with *MFN2* mutations may present no signs of disease even at the electrophysiological examination. In order to analyse the mutation spectrum and frequency and to assess the phenotypes associated with the *MFN2* gene, we have screened for *MFN2* mutations a large group (n=196) of index patients with axonal CMT. Familiarity was reported in one third of the cases only. The 17 *MFN2* exons and exon-intron boundaries were screened by DHPLC. Fragments showing an altered profile were directly sequenced. Nine novel and 3 previously reported mutations were found in heterozygous form in 12 unrelated index cases. There were 9 missense mutations, 1 frameshift mutation, and 1 amino acid deletion. The majority of cases (8/12, 66.7%) were sporadic. Age at onset ranged from 4 years to adulthood. Clinical presentations included clinical and electrophysiological sparing of the upper limbs, pyramidal signs, tremor, and optic atrophy in two cases. Two familial cases were characterized by early-onset, severe progression, and proximal involvement. Conclusions: our results indicate that in a raw series of axonal CMT patients the minimum frequency of *MFN2* mutations is approx. 6%, thus indicating that genetic testing for CMT2 should begin from the *MFN2* gene. The results also show that *MFN2* mutation analysis should be performed in both familial and sporadic cases. [Supported by Telethon-UILDM (GUP04009) and Fondazione Mariani (R0544)].

Impact of Life Experiences of Individuals with Osteogenesis Imperfecta (OI) on Reproductive Decision Making.
M. Szybowska, C. Shuman, D. Chitayat, R. Mendoza-Londono Division of Clinical and Metabolic Genetics, The Hospital for Sick Children, University of Toronto, Toronto, ON CANADA.

Osteogenesis imperfecta (OI) is characterized by decreased bone mineral density leading to fractures resulting from minimal trauma. The purpose of this study was to identify the factors that influence reproductive decision making in individuals with OI, their attitudes toward prenatal testing, and the extent of their knowledge about genetic counselling services. Adults with OI (N=174) were recruited via the Osteogenesis Imperfecta Foundation and completed a 26 item open/close-ended online survey and the Ferrans and Powers Quality of Life Index. 43% of participants stated they had children and 95% were diagnosed with OI prior to having their first child. The majority of individuals specified that their children were conceived naturally and 55% of pregnancies were planned. Participants stated that they did not want to transmit OI as the main reason for choosing not to have children. The most influential factors affecting the decision to have or not have children were: desire for children(57%), marital status(46%) risk of transmitting OI(46%), personal state of health(43%), and information from genetics health care professionals(HCPs)(21%). 54% of individuals stated that if they were pregnant today it would be important for them to know prenatally if the baby had OI, stating preparation(70%) as the main reason for this choice. There was no statistical difference between the total quality of life (QOL) scores of individuals with OI who had children versus those who had not. However, individuals with children had a statistically higher QOL on the family subscale ($p < 0.0001$). Also, those diagnosed in adolescence appeared to have a lower QOL. Surprisingly, only 39% of the participants had received genetic counselling. The results of this study highlight the need for HCPs to support both the physical and psychosocial needs of individuals with OI undergoing reproductive decision making. As well, care needs to be taken to ensure that these individuals receive accurate information about OI early in life so that they are equipped to make informed reproductive choices as adults.

Genetic alterations in bilateral breast cancer. *A. Shadeo, J. Chae, J. Kennett, W.L. Lam* Department of Cancer Genetics, British Columbia Cancer Research Centre, Vancouver, BC, Canada.

Introduction: 0.7% of women diagnosed with breast cancer will develop a second primary cancer and, this scenario is called Bilateral Breast Cancer (BiBC). It has been reported that BiBC accounts for 2-11% of all breast cancer cases. BiBC has the greatest concordance with familial history and early onset of disease occurrence. Mutations in known genes such as BRCA1, BRCA2, TP53, PTEN and CHEK2 account for one third of the hereditary breast cancer cases thus leaving the majority of the genetic culprits unidentified. Genetic instability is a characteristic of malignant cells. Paired organs, such as the breast, offer a unique opportunity to study the genetic causal events in breast cancer such that the cells that become malignant in both primary occurrences are identical in terms of original genetic make-up and exposure to environmental factors. Hypothesis: Comparison of somatic genetic alterations in matched bilateral breast tumours and matched normal tissue will allow us to distinguish the discrete causal events from the random genetic changes that are associated with genetic instability in tumours. Relevant alterations would appear in both sets of tumours and would suggest a role in disease development. Results: We have used a whole genome tiling resolution array CGH platform (SMRT aCGH), which allows for breakpoint detection at approximately 50 kb resolution, to identify discrete regions of genetic alterations in ten pairs of frozen BiBC cases from the Manitoba Breast Tissue Bank and fifteen single occurrence breast cancers. 659 gene loci were found gained more frequently in intersecting BiBC pairs in comparison to single occurrence breast cancer whereas 233 were more commonly lost. Conclusion: In this study we have successfully assessed comprehensive genomic copy number profiles of 35 primary breast cancer cases (20 BiBC and 15 single occurrence). We have identified 892 genes which are frequently altered in both primary BiBC cases.

Personalized Monitoring For Breast Cancer Recurrence. *Q. Liu, Z. Chen, C. Mroske, C. Yang, J. Yan, J. Feng, G. Somlo, M. Palomares, S. Sommer* Dept Molecular Genetics and Molecular Diagnosis, City of Hope Medical Ctr, Duarte, CA.

Mortality from breast cancer may be reduced substantially if recurrence is detected earlier than is possible by conventional means. To effectively monitor early recurrence, we analyzed plasma to detect the cancer mutation signature of DNA and RNA fragments released from apoptotic or necrotic cancer cells. Specifically, cancer candidate genes were sequenced from breast cancer tissue samples to identify a personalized cancer signature of somatic mutations. Following sequencing, pyrophosphorolysis activated polymerization (PAP) (www.cityofhope.org/PAP), a method for detecting ultra-rare mutations, was performed to detect the cancer-specific signature in DNA/RNA isolated from the plasma of patients. In addition, the cancer mutation signature of circulating intact epithelial cells (CEC) was determined. Our preliminary data demonstrate the identification of cancer-specific somatic mutations in breast cancer cells, and the rapid development of PAP assays to detect even a single copy of the cancer-specific somatic mutations in patient circulation. Both somatic mutation levels and rates of increase within circulation will be measured at multiple intervals in a multi-year follow up. Our ultimate goal is to achieve effective monitoring of adjuvant and neo-adjuvant chemotherapy so that recurrence can be identified months to years earlier than is possible through conventional detection.

Hypomorphic mutations in the syndromic encephalocoele gene MKS1 perturb gastrulation movements and cause Bardet-Biedl syndrome. *C. Leitch[1], J.L. Badano[1], N.A. Zaghloul[1], C. Stotzel[2], B. Drehman[1], M. Al-Fadhel[4], R.A. Lewis[3], W. Eyaid[4], H. Dollfus[2], P.L. Beales[5], N. Katsanis[1]* 1) Inst Genetic Medicine, Johns Hopkins Univ, Baltimore, MD; 2) Laboratoire de Génétique Médicale EA 3439, Faculté de Médecine de Strasbourg, Université Louis Pasteur, Strasbourg, France; 3) 3Departments of Molecular and Human Genetics, Ophthalmology, Pediatrics, and Medicine, Baylor College of Medicine, Houston, TX 77030, USA; 4) Department of Pediatrics, King Fahad Hospital, Riyadh 11426, Saudi Arabia; 5) Molecular Medicine Unit, Institute of Child Health, University College London, London WC1N 1EH, UK.

Meckel-Gruber syndrome (MKS) is a genetically heterogeneous, neonatal lethal malformation and the most common form of syndromic neural tube defects (NTDs). To date, two MKS genes have been identified, MKS1 and MKS3, whose protein products are predicted to be involved in ciliary function. Here we show that mutations in MKS1 both cause Bardet-Biedl syndrome (BBS) and also have a potential epistatic effect on mutations in known BBS loci, since five of six families with MKS1 and BBS mutations manifested seizures, a feature that is not a typical component of either syndrome. Functional studies in zebrafish showed that mks1 is necessary for convergence and extension (CE) and that it interacts genetically with known bbs genes to modulate the severity of CE defects. Finally, in contrast to the exclusively null alleles found to date in all MKS1 patients, BBS-causing genotypes lead to reduced, but not extinguished, protein function, suggesting that BBS and MKS, although clinically distinct, are allelic forms of the same molecular disorder.

Human Genotyping Using Next Generation Sequencing Technology. *N. Xiao[1,2], B. Desany[4], P. Bouffard[4], L.A. Burdett[1,2], R. Welch[1,2], M. Yeager[1,2], T.P. Jarvie[4], T.T. Harkins[5], L. Qi[1,2], J. Lu[1,2], S.J. Chanock[2,3]* 1) Core Genotyping Facility, Advanced Technology Program, SAIC-Frederick, Inc., NCI-Frederick, Frederick, MD 21702; 2) Division of Cancer Epidemiology and Genetics, National Cancer Institute, National Institutes of Health, Department of Health and Human Services; 3) Pediatric Oncology Branch, Center for Cancer Research, NCI, NIH, DHHS; 4) 454 Life Sciences, Branford, CT; 5) Roche Applied Science, Indianapolis, IN.

A next generation sequencer was used to sequence a 136 kb region of human chromosome 8 that has been implicated in prostate cancer by whole genome association studies. Using the GS Reference Mapper, included with the GS-FLX, we were able to accurately genotype this region in 4 samples from the HapMap - CEPH panel and demonstrate concordance. For four HapMap samples, 32 PCR products spanning the 136 kb region were generated, nebulized, pooled and sequenced. Here, we used the software to map the reads to the reference sequence in flow space and detect HapMap variations in both homozygous and heterozygous states. For the four HapMap DNA samples that have been sequenced, average read length was 250 bp, and average coverage depth was 160 reads (including forward and reverse directions). We examined the distribution of variant proportion in multiple sequence reads, and developed heuristics to refer heterozygous and homozygous genotypes. In conjunction with additional examination of alignment between sequence reads and reference sequence, we were able to make accurate genotype calls. Comparison between the resulted genotypes with HapMap data of the corresponding individuals for 181 SNPs within the 136 kb region reveals almost perfect concordance. In the rare cases where the genotype calls are discordant with the HapMap data, violations of Mendelian inheritance in the HapMap data among the trio have been observed. Taken together, our result demonstrates the utility of this approach for targeted genotyping applications. Funded by NCI-Contract N01-CO-12400.

Genome-wide expression profiling of urinary bladder identifies candidate genes for the bladder exstrophy-epispadias complex (BEEC). *L. Qi[1], K. Chen[2], D. Hur[3], Y. Lakshmanan[4], L. Kotch[5], G. Ashrafi[3], F. Martinez-Murillo[5], A. Blackford[6], J. Kowalski[6], J. Gearhart[4], S. Boyadjiev[7,4]* 1) Rowe Program in Human Genetics, UC Davis, Davis, CA; 2) Dept. of Statistics, UC Davis, Davis, CA; 3) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 4) Division of Pediatric Urology, The James Buchanan Brady Urological Institute, Johns Hopkins University, Baltimore, MD; 5) Dept. of Molecular Biology and Genetics, Johns Hopkins University, Baltimore, MD; 6) Dept. of Oncology, The Sidney Kimmel Comprehensive Cancer Center at Johns Hopkins, Baltimore, MD; 7) Section of Genetics, Dept. of Pediatrics, UC Davis, Sacramento, CA.

BEEC represents a spectrum of rare congenital anomalies ranging from isolated epispadias and classic bladder exstrophy, to cloacal exstrophy. While the causes of BEEC are unknown, there is evidence that genetic factors are involved in its etiology. In order to identify candidate genes of BEEC, we performed a genome-wide expression analysis of human urinary bladder at two timepoints: embryonic mesenchyme (EM) surrounding the urogenital sinus at 8 - 16 weeks of gestation, normal postnatal bladder (NB) and exstrophic postnatal bladder (EB). Gene expression profiles were obtained for 3 independent EM samples, 3 independent EB and 3 gender and ethnicity matched NB samples using Affymetrix GeneChip Human U133 Plus 2.0 arrays. In addition, the expression profile of mouse bladder at gestational day (GD) 13 was also determined using the GeneChip Mouse Genome 430 2.0 arrays. We identified 170 genes with at least 2-fold expression difference between NB and EB samples, which are also consistently expressed in the 3 EM samples. Moreover, about 90% of these 170 human genes were also detected in the mouse GD 13 sample, indicating most of the genes that involve in embryonic bladder development are expressed at the same developmentally relevant period in both human and mouse. Using pathway analysis, we identified 5 potential networks composed of at least 10 candidate genes. Further study of these candidate genes may lead to better understanding of the genetic etiology of BEEC.

Admixture Analysis in Mestizos from Pacific and Atlantic Mexican coasts. *J.M. Oliva-Ortiz[1,2], J. Becerra-Contreras[1,2], J.R. Padilla-Gutiérrez[1,2], L.B. López-Hernández[1,2], K.R. Morales-González[1,2], M.T. Magaña-Torres[1,2], F. Rivas[1,2], L. Sandoval-Ramírez[1,2]* 1) División de Genética, Centro de Investigación Biomédica de Occidente, CMNO, IMSS, Guadalajara, Jalisco, México; 2) Doctorado en Genética Humana, CUCS, Universidad de Guadalajara, Guadalajara, Jalisco, México.

The admixture among Europeans, Africans and Amerindians after Mexican colonization was not homogeneous throughout the country. Study of markers with blood groups, HLA, nuclear and mitochondrial polymorphisms showed great diversity in the admixture levels depending on the analyzed geographic region of Mexico (Lisker et al. 1996; Rangel-Villalobos et al. 2000; Gorodezky et al. 2001; Cerda-Flores et al. 2002; Green et al. 2002; Magaña et al. 2002). In this study, samples of 201 mestizos from Pacific and 72 from Atlantic coasts were genotyped in order to estimate the admixture proportion. Four mtDNA haplogroups (A, B, C, and D) which characterized most Native American lineages, and one (L) that define African lineage were analyzed. For the Y-chromosome markers we studied; DYS287, DYS199, DYS19, DYS390, DYS447 and DYS458 that define some populations groups. The mtDNA origin of individuals from Atlantic coast was 98.6% Amerindian and 1.4% African; while in Pacific coast was 95.5% Amerindian and 4.5% African. Analysis of Y-chromosome markers showed that 28.2% of the alleles from Pacific coast were African and 37.5% Amerindian. In the Atlantic coast 10.2% of alleles had African origin and 39.7% Amerindian. The Pacific Costa Chicas population showed a higher admixture proportion. The results showed a different contribution of male and female gene pools in these admixtures Mexican populations.

Primary Care Clinician Perceptions of Genetic Discrimination and Limited Knowledge of Protective Laws and Cancer Genetics Creates Barriers To Care. *K. Lowstuter[1], S. Sand[1], C. Lee[2], B. Schwerin[3], G. Uman[4], K. Banks[5], C. Gonzalez[6], M. Juarez[6], J. Weitzel[1]* 1) City of Hope, Duarte, CA; 2) Cal Med Assoc Foundation, Sacramento, CA; 3) Cancer Legal Resource Ctr, Los Angeles, CA; 4) Vital Research Inc, Los Angeles, CA; 5) St Joseph Hospital, Orange, CA; 6) Cal Latino Med Assoc, Monterey Park, CA.

Primary care clinicians (PCC), such as nurse practitioners and physicians, are often gatekeepers to specialty services. We surveyed PCCs to explore the extent to which potential knowledge gaps and/or opinions of cancer genetics, genetic discrimination and protective laws influences cancer genetics referrals and consequently access to risk-appropriate cancer screening and prevention. Pre-qualification postcards and invitations were sent to a random stratified sample of California Medical Assoc. members and to all members of California Latino Medical Assoc. and California Assoc. of Nurse Practitioners. The survey contained 47 items on demographics, opinions, knowledge, and practices regarding cancer genetic testing. The majority of responders were physicians (62%, 734/1181). Although 96% of responders viewed genetic testing as beneficial to their patients, 75% stated genetic testing is likely to be declined by patients due to fear of genetic discrimination. The majority did not know that federal law (HIPAA) prohibits health insurance discrimination in the group market on the basis of genetic test results (61%) or that California State law prevents genetic information from being used as a criterion for health insurance coverage decisions (67%). When given five hypothetical family cancer histories only 30% correctly identified four or more scenarios as appropriate or inappropriate for genetics referral. Of the 55% who had not referred patients for genetic cancer risk assessment, 11% indicated concern over health insurance discrimination as a reason. Results indicate knowledge gaps and misperceptions as possible barriers to referral for genetic cancer risk assessment. Education of PCCs regarding cancer genetics and current, as well as, future genetic discrimination laws may help to promote access to appropriate care.

Polymorphisms in coagulation and fibrinolytic pathway genes mark the evolution of host-defense response. *K.P. Mooder[1], A. Siddiqui[1], A. Gordon[1], M. LeBlanc[1], H. Wellman[1], X. Zhang[1], J.A. Russell[1,2], K.R. Walley[1,2]* 1) Sirius Genomics, Vancouver, BC, Canada; 2) Department of Medicine, St Pauls Hospital, University of British Columbia, Vancouver, BC, Canada.

Proteins intersecting the coagulation and fibrinolytic pathways are thought to play an integral role in host defense mechanisms. As such, polymorphic patterns in genes encoding these proteins likely mark historical exposure to pathogens acting on these pathways. Sepsis is a complex disease characterized by systemic infection and a hyper-inflammatory response. Interestingly, biomarkers from the coagulation and fibrinolytic pathways have been shown to be associated with differential outcomes in septic individuals. In a sepsis cohort of European ancestry (n=700), we observe that two SNPs from the genes PROC (rs2069912) and SERPINE1 (rs7242) are associated with an increased risk of coagulation dysfunction after developing sepsis. Although we have yet to characterize the explicit mechanisms defining this association, it may be that genotypes promoting a pro-thrombotic/anti-fibrinolytic phenotype are of benefit to the host in thwarting pathogens with virulence factors facilitating increased plasmin utilization. However, following systemic infection, this same phenotype may be detrimental to the host by facilitating impaired hemostasis.

A multi-locus ^{2} test for case-control genetic association studies. *G. Zhang[1], R. Chakraborty[1], M.B. Rao[1], L. Jin[1,2,3]*
1) Center for Genome Information, University of Cincinnati, Cincinnati, OH; 2) School of Life Sciences, Fudan University, Shanghai, China; 3) CAS-MPG Partner Institute of Computational Biology, Shanghai, China.

It is commonly believed that haplotype based association test is more powerful than single-locus test in studying genetic association between a set of biallelic SNP markers (i.e. tagging SNPs) and a complex trait. However, the marker haplotype need to be inferred statistically from unphased genotype data by assuming Hardy-Weinberg equilibrium (HWE); and the additional information from the use of haplotypes comes at the cost of increased degrees of freedom. Recently, some researchers have indicated test procedures based on unphased multi-locus genotypes might be more powerful than haplotype-based methods. The most commonly used multiple-locus genotype association test is the Hotellings T^2 test and related procedures. In this study, we develop a simple multiple-locus ^{2} test for simultaneously testing allele frequency differences at multiple loci between cases and controls. Under the null hypothesis of no association, the allele frequency difference of each marker locus asymptotically follows a normal distribution, and the correlation of allele frequency differences between pair of loci is given by the pairwise linkage disequilibrium between the two loci. Therefore, we model the allele frequency differences of multiple loci by multivariate normal distribution and assess the statistical significance of allele frequency differences of multiple loci between cases and controls by ^{2} test. We evaluate the power of the suggested ^{2} test by simulated and real data sets. The results indicate the multiple-locus ^{2} test is more powerful and robust than haplotype-based association test or Hotellings T^2 test.

The psychological impact of abnormal results in high-risk breast MRI screening. *S.M. O'Neill[1,2], W.S. Rubinstein[1,2], S.F. Sener[1,2], D.K. West[1], D.B. Ekanow[1], A.W. Rademaker[2], R.R. Edelman[1,2]* 1) Evanston NW Healthcare, Evanston, IL; 2) Northwestern University Feinberg School of Medicine, Chicago, IL.

Breast MRI has been shown to be an effective screening tool for women at high risk for breast cancer. Recent guidelines published by the American Cancer Society recommend annual breast MRI screening for BRCA, PTEN, and p53 mutation carriers, their untested close female relatives, and women with a family-history-based lifetime statistical risk for breast cancer of 20-25%. However, there is widespread concern that false positive MRI results may have a persistent negative psychological effect, as has been shown repeatedly in mammography screening studies.

We measured psychological stress prior to MRI in 103 high-risk women enrolled in a longitudinal screening study, assessed change in Impact of Event Scale (IES) scores in women who had more than one MRI, (n=68) and compared women who had normal results on their previous MRI (n=32) with the group that had results which prompted recall (n=34). In a two year period 189 MRI scans were performed, of which 64 (34%) required further evaluation because of BIRADs scores 3. The recall follow-up included biopsy (n=4; 2 had breast cancer), ultrasound (n=20), mammogram (n=5), and 6-month interval MRI (n=40). When the group began MRI screening the mean IES score was 14.6 with 22.3% having clinically meaningful stress. At the time of second MRI, mean IES score was 16.3. Intrusion decreased (6.4), but mean Avoidance was significantly increased (9.9, p=0.025). Between-group comparisons revealed that the overall increase in mean Avoidance at MRI 2 was driven by the group that had recall results on MRI 1 (p=0.029), not the group with previously normal results.

Although the women with previous false positive results had an increase in cognitive avoidance symptoms, they nevertheless reported for another scan. Cognitive avoidance in this high-risk subset of women may be a developed coping strategy that does not impair compliance with screening.

A Pipeline for Designing Custom TaqMan Assays for Small RNA Genes. *L. Wong, Y. Wang, D. Ridzon, L. Bahreinifar, C. Chen* Assays and Arrays R&D, Applied Biosystems, Foster City, CA.

MicroRNAs (miRNAs) are a new class of non-coding RNAs that mediate post-transcriptional gene silencing. A growing number of novel miRNAs and other small RNA genes are being discovered and there is a significant need for custom assays to determine the level of their expression. An automated bioinformatics pipeline has been developed to design TaqMan MicroRNA Assays to enable quantitation of miRNA expression by real-time PCR. A set of 446 miRNA assays were designed and their performance evaluated based on assay linearity and no template control (NTC) signal. From this initial test set, we observed an assay performance success rate of approximately 90%, with NTC failures contributing to the majority of the remaining 10%. Through examination of oligo interactions, new design rules were implemented to the pipeline intended to reduce the NTC failure rate. In a first phase validation, 30 failed assays and 30 passed assays from the initial test set, were redesigned with the optimized pipeline. These 60 redesigned assays were then tested in parallel with the original 60 assays for a direct comparison of assay performance. From the failed set, we observed nearly 50% improvement for assays designed with the optimized pipeline. For a second phase validation, over 1,000 mammalian miRNA genes were selected from Sanger miRBase (release 9.1) and submitted for design using the optimized pipeline. A subset of these newly designed assays will be evaluated to confirm the success rate for assay performance. As research interest in small non-coding RNAs is rapidly expanding beyond miRNAs, the capability of the pipeline to design assays for other small RNA genes including siRNAs, shRNAs, and piRNAs will be tested. Results of TaqMan assays for siRNAs will be presented.

Comparison of genetic distance measures. *O. Libiger[1,2], C.M. Nievergelt[3], N.J. Schork[1,2,3]* 1) Scripps Genomic Medicine, Scripps Health, La Jolla, CA, USA; 2) The Scripps Research Institute, La Jolla, CA, USA; 3) 3The Center for Human Genetics and Genomics, University of California, La Jolla, CA, USA.

Many genetic research initiatives utilize information about the genetic distance between pairs of populations. Recently, such information became instrumental in assessing population substructure in genetic association studies. Many numerical measures have been proposed that indicate the degree of genetic distance using differences in allele frequencies between the populations. With the recent influx of genetic data from various populations, it is important that results of analyses performed on different datasets are comparable. However, it is not clear whether genetic distances between the same pairs of populations calculated with different formulas yield the same results. Additionally, genetic distance measures are often assumed to follow certain properties, e.g., have values between zero and one. Some of these properties have not been fully explored. In this study, we used simulation to generate different sets of allele frequencies at biallelic markers that modeled pairs of populations with various degrees of genetic distance and used these data to compare six widely used genetic distance measures (Weir and Cockerhams Fst statistics, Weirs genetic distance, Neis standard genetic distance and Takezaki and Neis distance measures). We assessed the measures range, their sensitivity, and the correlations among the measures. Our results show perfect correlation between all pairs of measures with the exception of correlations that involved Neis genetic distance. Also, the range of Neis genetic distance differed significantly from the ranges of the other distance measures studied (0.003 - 4.0 vs. -0.005 - 1.0). Finally, Neis genetic distance exhibited comparatively lower sensitivity for similar populations but greater sensitivity for more distant populations. The results of this study suggest that while the values of some genetic distance measures can be directly compared, the values of others, e.g., distances of Weir and Nei, cannot. Thus, specifying the genetic distance measure that was used to assess population structure is highly recommended.

Fine-scale structural anatomy of 1086 human copy number variant (CNV) regions as defined by custom high-density oligonucleotide microarrays. *C. Lee[1,2], A. Ben-Dor[3], G.H. Perry[1], A. Scheffer-Wong[3], N. Sampas[3], S. Dallaire[1], J. Tchinda[1,2], A. Tsalenko[3], P. Tsang[3], A. Yamada[3], Z. Yakhini[3], L. Bruhn[3], S. Laderman[3]* 1) Brigham & Women's Hospital, Boston, MA; 2) Harvard Medical School, Boston, MA; 3) Agilent Technologies, Santa Clara, CA.

Copy Number Variants (CNVs) are highly prevalent in the human genome and may play an integral role in normal human phenotypic variation and disease susceptibility. Initial screens using a variety of technologies have identified thousands of human CNV regions. However, most of these studies provide limited resolution of the fine-scale structure of these CNV regions. To define the architecture of known CNVs, we have constructed a custom oligonucleotide array containing 470,143 distinct 60mer probes, selected with an approximate 1kb spacing within and flanking 2191 human CNV regions annotated in the Database of Genomic Variants. We have interrogated the genomic DNAs from 30 HapMap individuals and observed copy number differences at 1086 of the 2191 targeted CNV regions. Many of these individual CNV regions were, in fact, comprised of multiple and non-overlapping CNVs. In total, we confidently detected (i.e. using multiple consecutive probes) 2553 CNVs, of which 68% were identified in multiple individuals. The total amount of copy number variable DNA was reduced by over 50% in 847 of the 1086 detected CNV regions. In addition, our custom array has identified CNVs with different breakpoints among unrelated individuals. We also found a surprisingly substantial number of "complex" CNV regions that reveal smaller overlapping CNVs embedded within larger CNVs, with variable combinations of gains and losses of the smaller CNVs among individuals (e.g. a 450 kb region on chr2p11.2). These data more clearly define which genes and non-coding DNA sequences are actually copy number variable among healthy individuals and highlight a previous under-appreciation for the complexity of many human CNV regions. Furthermore, these results precede the development of a targeted, CNV-enriched array, that will be useful in future disease association studies, aimed at identifying the role of CNVs in common diseases.

Neuron-specific enhanced expression of TAF1 and its isoform. *S. Makino, G. Tamiya* Division of Human Molecular Genetics, Department of Neurology, Tokushima University Graduate School of Medicine, Japan.

We previously found a neuron-specific isoform of the *TAF1* (TATA-binding protein-associated factor 1) gene, which is the disease causative gene of X-linked recessive dystonia-parkinsonism showing severe neurodegeneration in striatum (XDP/DYT3; MIM314250). The *TAF1* gene encodes the largest component of the TFIID complex involved in RNA polymerase II-mediated expression of many genes related cell division. The neuron-specific isoform of the *TAF1* gene, named *N-TAF1*, may have an essential role in neuronal survival in the striatum through transcriptional regulation of many neuron-specific genes. To investigate the detailed function of the neuron-specific isoform of the *TAF1* gene, we performed knockdown of the neuron-specific isoform using a specific siRNA in the human dopaminergic neuroblastoma cell line SH-SY5Y. The siRNA significantly reduced mRNA of the neuron-specific isoform to approximately 1/6 of that in the negative control siRNA with no induction of the interferon response. We subsequently performed microarray analysis for the knockdown cell line using an Affymetrix Human Genome Focus Array representing 8,793 annotated genes. In addition, we carried out over-expression of *N-TAF1* in the mouse N2a cell line and subsequent microarray analysis. Through these *in vitro* experiments, we demonstrated that the neuron specific enhanced expression of *TAF1*/*N-TAF1* regulate the neuron-specific gene transcriptions.

Worldwide incidences of type 1 diabetes are correlated with the frequencies in allele T of dbSNP rs2476601 of the PTPN22 gene. *YJ. Lee[1,3], CY. Huang[1], WH. Ting[1], CK. Chen[1], ZC. Wang[1], CL. Lin[1], HF. Liu[1], FS. Lo[2]* 1) Dept Pediatrics & Medical Res, Mackay Memorial Hosp, Tamshui, Taipei, Taiwan; 2) Division of Endocrinology, Department of Medicine, Chang Gung Children's Hospital, Taoyuan, Taiwan; 3) Department of Pediatrics, Taipei Medical University, Taipei, Taiwan.

The global variation in the incidence of type 1 diabetes (T1D) is thought to relate to the distribution of genetic or environmental factors. Although non-Asp-57 alleles of HLA-DQB1 gene are associated with the differences in the incidence of T1D, the association can not completely explain the variations of the incidence. Other genetic and/or environmental factors must play a role. dbSNP rs2476601 in the PTPN22 gene was found to be associated with T1D. The minor allele (T) confers risk. This SNP is absent in Asians who have a low incidence of T1D. Thus, we investigate the association between incidences of T1D and frequencies of allele T. **Subjects:** The subject were 305 hospital personnel. Their genomic DNA was genotyped for this SNP. **Literature search:** A literature search was done using both PubMed and OVID as well as a search in dbSNP of NCBI, HapMap and JSNP. All available reports on rs2476601 were evaluated. The incidences of T1D in various ethnic groups were compiled. **Results:** All 305 subjects were C/C. This SNP was absent in all subjects tested. The frequencies of allele T are 9.8% in Caucasians, 4.7% in Hispanic Americans, 4.4% in Colombians, 2.1% in Sardinians, 2.1% in African Americans, 1.3% in Indians, 0.04% in Africans, and 0.03% in Asians. Among Caucasians, Finns have the highest frequency of 15.4% and Spanish have the lowest one of 7.0%. Linear regression analysis showed the frequencies of allele T (T, %) were significantly correlated with the worldwide incidences of T1D (I, number/100,000). $I = 1.282 \times T + 5.301$ ($R = 0.548$, $p = 0.015$) when Sardinians were included and $I = 1.661 \times T + 0.952$ ($R = 0.798$, $p = 0.0001$) when Sardinians were excluded from analysis. **Conclusion:** Population variation in the frequencies of allele T of rs2476601 of the PTPN22 gene may explain much of the worldwide differences in the incidence of type 1 diabetes.

Disruption of MATR3 and AHDC1 in Noonan-like syndrome. *F. Quintero-Rivera[1,2,8], A.W. Higgins[3,8], A. Roberts[4,6], R. Kucherlapati[4,6], G. Bruns[4], I. Seong[2], B. Gelb[7], H. Ferguson[3], R. Maas[5,8], C.C. Morton[3,8], J.F. Gusella[2,8]* 1) Pathology & Lab Medicine, David Geffen School of Medicine at UCLA, Los Angeles, CA; 2) Center for Human Genetic Research, Massachusettes General Hospital, Boston, MA; 3) Departments of Pathology, Brigham & Womens Hospital, Boston, MA; 4) Genetics Division, Childrens Hospital Boston, MA; 5) Genetics Division, Brigham and Womens Hospital, Boston, MA; 6) Harvard Partners Center for Genetics and Genomics, Boston, MA; 7) Pediatrics and Genetics & Genomic Sciences, Mount Sinai School of Medicine, New York, NY; 8) Harvard Medical School, Boston, MA.

To uncover genes critical in human development, patients with congenital anomalies and apparently de novo chromosomal rearrangements are being studied through the Developmental Genome Anatomy Project (DGAP). Here, we report a 5-yo male who presented with a Noonan syndrome (NS)-like phenotype and 46,XY,t(1;5)(p36.11;q31.3)dn. We cloned and sequenced the junction fragments and found disruption of 3 UTR of Matrin3 (MATR3) on 5q31.3 and the AT hook DNA binding motif containing 1 locus (AHDC1) on 1p36.11. The Matrin3 protein (MAT3) localizes to the nuclear matrix and interacts with other components of the internal fibrogranular network. In Xenopus oocytes, Matrin 3 is part of a complex that regulates RNA editing. However, little is known about its expression and function in other organisms. In situ hybridization of mouse embryos demonstrated that Matr3 is predominantly expressed in the maxillary prominence, eye, second branchial arch and limb buds. In humans, the transcripts are highly expressed in heart and brain, which are affected in our patient. MAT3 levels are variable across normal controls in lymphoblastoid cell lines. In addition, a knock-out mouse model in which Matr3 is disrupted showed embryonic lethality of Matr3-/- at E9. We screened for mutations in AHDC1 and MATR3 in 120 individuals affected with NS that were negative for mutations in PTPN11, KRAS and SOS1. No pathogenic mutations were identified. Our data confirms that mutations of MATR3 and AHDC1 do not account for a significant proportion of Noonan-syndrome cases. This is the first report of a constitutional disruption of MATR3 and AHDC1.

The 1q41q42 Microdeletion Syndrome: Characterization of a New Genomic Disorder. *T.H. Shaikh[1], S. Saitta[1], D. Kostiner[2], M. MacDonald[3], J.W. Ellison[4], A.S. Aylsworth[5], L.G. Shaffer[6]* 1) Children's Hosp Philadelphia, Phila., PA; 2) Kaiser Permanente, Portland, OR; 3) Duke Univ., Durham, NC; 4) Mayo Clinic, Rochester, MN; 5) Univ. of N. Carolina, Chapel Hill, NC; 6) Signature Genomic Labs, Spokane, WA.

Recent developments in microarray technology have greatly improved our ability to detect microdeletions and microduplications in patients with congenital abnormalities. We have identified a new, recurrent microdeletion in 1q41q42 in 7 patients with overlapping phenotypic features using microarrays. These microdeletions were detected by BAC arrays and further characterized by high-resolution, SNP-based oligonucleotide arrays. The most common clinical features include mental retardation, profound speech delay, seizures and distinct dysmorphic features. This strongly suggests that the 1q41q42 microdeletions may represent a new genomic disorder. The deletions range between 2.6-9.1 Mb, with a smallest region of overlap (SRO) of 1.17 Mb. The SRO contains 5 known genes, 4 of which have known functions. One of the genes, *DISP1*, is involved in the sonic hedgehog (SHH) pathway which is crucial in early brain development. *DISP1* may play a role in the neurologic features associated with the microdeletion. Interestingly, two highly identical 44 Kb segmental duplications (SDs) were detected in close proximity of the SRO. SD-mediated rearrangements are a common feature of known genomic disorders like DiGeorge and Williams syndromes. The presence of SDs in this region suggests that microdeletions in 1q41q42 may be more prevalent and predicts the existence of a reciprocal microduplication syndrome. Additionally, two of the more severely affected patients with the microdeletion were diagnosed with Fryns syndrome. Preliminary analysis suggests that these Fryns deletions may extend into more distal regions of 1q42. The identification and analysis of additional cases will help delineate the critical region for the syndrome and the gene(s) responsible for the phenotypic features. Furthermore, high resolution array analysis and breakpoint mapping will allow the elucidation of the mechanisms underlying recurrent microdeletions in 1q41q42.

Genome-Wide Association Study of Bipolar Disorder in European Americans. *J. Li[1], L.J. Scott[3], D. Absher[1], R.C. Thompson[4], W. Guan[3], F. Meng[5], A. Southwick[1], M. Burmeister[4,5], H. Akil[5], S.J. Watson[5], R.M. Myers[2], M. Boehnke[3]*

Bipolar disorder (BPD) is a common familial disease with poorly understood etiology. Despite clear evidence for a substantial genetic contribution, linkage and candidate gene studies have so far failed to generate well-replicated findings. We have performed a genome-wide association study of BPD in which we used the Illumina Infinium Beadchips to genotype >550,000 "tagging SNPs" in European American samples. We obtained from the NIMH Genetic Repository program ~1,200 Bipolar I cases, up to two BPD cases per sibship, and ~800 unrelated controls who reported no BPD, schizophrenia, or major depression. Cases and controls were frequency-matched by self-reported ancestry from different regions of Europe. The analysis of the first 466 cases and 467 controls showed that >99% of the samples had initial call rates of >98.5%, and >99.5% of SNPs passed all QC measures. Inferred ancestry showed reasonable agreement with self-reported ancestry, and confirmed adequate sample matching, with a genomic control inflation factor of 1.02. Allelic intensity data revealed extensive copy number variation (CNV), covering a broad range of CNV sizes and population frequencies. We have now completed genotyping for the ~2,000 samples, and data cleaning and association analysis is currently underway for the entire dataset. To increase statistical power, we will augment our analysis with publicly-available control datasets for Americans of European ancestry.

Chromosome 15q11.2 copy number variants (CNV): population frequency and clinical implications. *M.C. Seleme[1], T.H. Shaikh[2], M. Lincicum[3], M. Sathanoori[4], U. Surti[4], H. Hakonarson[2], L.G. Shaffer[3], R.D. Nicholls[1]* 1) Children's Hospital of Pittsburgh, Pittsburgh, PA; 2) Childrens Hospital of Philadelphia, Philadelphia, PA; 3) Signature Genomic Laboratories, Spokane, WA; 4) University of Pittsburgh, Pittsburgh, PA.

Genome studies have unveiled an important role for CNV in shaping the normal human genetic landscape. At the extreme of CNV, genomic disorders arise from deletion or duplication of dosage-sensitive genes. Genomic disorders and many CNV appear to have endpoints associated with segmental duplications (SDs). However, the exact relationships between CNV and SDs, or the frequency of CNV associated with disease is unknown for most chromosome regions. This study examines these questions for proximal chromosome 15, a region known to be meiotically unstable resulting in a number of genomic disorders (Prader-Willi and Angelman syndromes, autism, and others). For 15q11-q13 genomic disorders, at least six breakpoint (BP) hotspots, each composed of related SDs, contain the rearrangement endpoints. We describe here CNV limited to the BP1-BP2 region of 15q11.2, which include a unique segment of ~ 250-kb containing four highly conserved genes. From a total study population of 1981 normal individuals using oligonucleotide (ON) array-CGH, QPCR, and mining of published databases, we estimate at 1% the population frequency of CNV for BP1-BP2 deletions and duplications. By comparison, using BAC and ON array-CGH, we estimate a 1.2% frequency for BP1-BP2 CNV in two samples totaling 8750 clinical cases tested because of mental retardation and/or MCA. In several tested cases, the CNV was inherited from an unaffected parent. Based on the equivalent frequency in normal and clinical populations, and heritability, we conclude that most BP1-BP2 CNV are not linked to disease and represent a copy number polymorphism. Conversely, due to the presence of 4 functional genes, CNV within BP1-BP2 could unmask recessive mutations or represent disease susceptibility alleles due to gene dosage alterations. Moreover, CNV in an unstable genomic region could predispose to further chromosomal instability leading to genomic disorders in offspring.

Integrative genomics to dissect the age-at-onset heterogeneity in type 1 diabetes. *X. Wang, S. Gao, J. Schiller, J. Basken, E. Luczkowski, M. Klinker, V. Magnuson, T. Valle, T. Wang, S. Ghosh* Medical College Wisconsin, Milwaukee, WI.

Identifying all the genetic factors contributing to the risk of a complex disease remains a challenge. Type 1 diabetes is a complex human disease with a rapid rise in incidence in the recent decades. The exact disease etiology or the genetic mechanism is still not fully understood. Contributing to the difficulty is the extensive phenotypic and genetic heterogeneity differentiated by the age at onset. Here we describe a multilevel integrative genomics approach to this problem. It starts with identifying candidate disease pathways by integrating information from mathematical modeling of disease dynamics and pathogenesis, disease-related quantitative traits analysis, and gene expression and genomic data mining. Subsequently a comprehensive candidate gene list is compiled that includes genes within the candidate disease pathways, and genes that are related to known genes in the pathways either functionally or by being in the same genetic networks. Lastly, the network structures of all candidate genes are examined and they are prioritized according to: (1) membership of disease pathways; (2) importance to the disease pathway (such as its topological position, cluster coefficients, etc); (3) being a transcription factor with enhanced promoter binding sites of the pathway genes; (4) co-expression with key genes of the disease pathways; and (5) being positional candidates. We have recently genotyped one tag SNP each for four top candidate genes that we have identified, ATF2, STAT1, GLP1R, and MAPK8. None of these genes has been associated with T1D previously. A T1D cohort collected from Finland and Wisconsin with both young- (<15y) and adult-onset T1D (>17y) singleton families in each category, were genotyped. To date we have typed over 200 families of the young-onset cohort (Wisconsin), and over 300 families of the adult-onset cohort (Finland). Three of the 4 markers typed have yielded highly suggestive p-values of $p<0.05$. We are currently in the process of typing more families, and additional SNPs of these genes and other candidate genes.

Facioauriculovertebral spectrum. Mexican family with probable Autosomal recessive inheritance. *C.F. Martinez-Cruz[1,2], G. Garcia-Sanchez[3], M. Diaz-Garcia[3], S.G. Juarez-Garcia[4]* 1) Servicio de Comunicacion Humana,Departamento de Seguimiento Pediatrico, Instituto Nacional de Perinatologia, Mexico, D.F; 2) Servicio de Pediatría. Instituto Mexicano del Seguro Social. HGZ 53. México, D.F; 3) Servicio de Genética.Instituto Nacional de Rehabilitación, México, D.F; 4) Servicio de Audiologia.Instituto Nacional de Rehabilitación, México, D.F.

Facioauriculovertebral spectrum (fav), is a complex of malformations, mainly of craniofacial structures develop from the first and second branchial arches, generally unilateral, with eye anomalies, neurological defects, mental retardation, various forms of spinal, heart and renal anomalies (Gorlin)most patients have conductive or sensorineural hearing loss. Expression varies within families and it is usually sporadic (Rollnick) We presented a Mexican family with facioauriculo vertebral spectrum with variable expressivity and probable autosomal recessive inheritance. Parents unaffected, nonconsanguineus. All three children are affected. Propositus, a male 19 years old, right microtia-atresia, severe hearing impairment, hemifacial microsomy. Sister, 14 years old, right microtia-atresia type II, severe hearing impairment and cleft palate. Sister, 12 years old, left preauricular tag with normal hearing. Three relatives in second degree with folded helix.

RECOVERING CHALLENGING ASSAYS USING NOVEL METHODS ON THE ILLUMINA GOLDENGATE GENOTYPING PLATFORM. *Y. Renaud[1], A.M.K. Brown[1], C. Taylor-Lawlew[2], C. Lin[2], R. Shen[2], C. Harris[2], M.S. Phillips[1]* 1) Pharmacogenomics, GQ MHI PGx Center, Montreal, Quebec, Canada; 2) Illumina Inc, San Diego, California 92121.

The Illumina BeadArray platforms can genotype from 384 to 1536 SNPs simultaneously using GoldenGate technology. This technology has been shown to both sensitive and reproducible. To support several clinical pharmacogenomics studies, we have developed a set of broad-based drug metabolism (ADME) genotyping panels that screen for both functional and HapMap SNPs found in ~260 ADME genes. Despite the consistent results generated for the majority of the genotyping assays contained on these panels,, analysis has identified several failure modes explaining why specific markers did not convert. The failure modes that we identified were due to: 1) limitations in the chemistry of the technology; 2) known and unknown underlying polymorphisms found under the oligo sequences; 3) areas of high SNP density; and 4) regions of homology (including CNV and low complexity DNA). Therefore, we have been working in collaboration with Illumina to successfully convert these SNPs to working assays using several novel modifications to the standard GoldenGate workflow and marker design. We have developed a novel bioinformatics cluster prediction tool which helps recognize failure modes such as underlying SNPs and regions of homology. In order to adjust our assays for underlying SNPs, we have developed strategies to incorporate degenerate bases into the oligos when underlying SNPs have been identified. In order to adjust for regions of high SNP density that generate assays that fail due to close proximity, a method to split/isolate SNPs into sub-panels to avoid interference was developed. In order to adjust for regions of homology, we have developed a method to spike in PCR products into various stages of the standard GoldenGate workflow. These novel approaches have been merged together into one OPA that can be read on a single Sentrix array. Use of these methods in future assay designs will significantly improve our ability to convert difficult assays using the GoldenGate technology.

Disruption Of Epigenetic Regulatory Elements And Chromosomal Alterations In Patients With Beckwith-Wiedemann Syndrome. *A. Smith[1,2], M. Suzuki[3], R. Thompson[3], C. Shuman[4], J. Greally[3], J. Squire[5], R. Weksberg[1,2,4]*

Science, University of Toronto, Canada; 3) Albert Einstein College of Med., Bronx, NY, USA; 4) Div of Clinical and Metabolic Genetics, Hosp for Sick Chidlren; 5) Dept of Lab Medicine and Pathobiolgy, University of Toronto, Canada.

Beckwith-Wiedemann syndrome (BWS) is characterized by somatic overgrowth, macroglossia, omphalocele, and a thousand-fold increased risk for embryonal tumors. It is associated with dysregulation of gene expression of an imprinted gene cluster on chromosome band 11p15. This dysregulation occurs by several mechanisms including changes in DNA methylation, uniparental disomy, microdeletion, duplications and translocations or inversions. The 11p15 region is divided into two domains each controlled by an imprinting centre for each domain. Imprinting centres can be differentially methylated and associated with regulatory non-coding RNA transcripts that can regulate the expression of neighboring genes in cis over large distances up to one megabase. The KCNQ1 differentially methylated region (DMR2) is found within intron 10 of KCNQ1 in Domain 2. DMR2 also contains the promoter for KCNQ1OT1, a paternally expressed, untranslated anti-sense transcript, which is believed to suppress the expression of nearby genes on the paternal chromosome. We have 9 translocation or inversion patients that have breakpoints within 500kb of DMR2. We expected that translocations and inversions associated with BWS would disrupt the imprinting centre in Domain 2; however, we found that BWS patients with translocations have normal DMR2 methylation and expression of KCNQ1OT1. Our data suggest that there are as yet unidentified mechanisms that can cause BWS and its associated tumors. Thus, we hypothesize that physical disruption of the region and regulatory signals other than DMR2 methylation and KCNQ1OT1 transcription in Domain 2 can alter imprinted gene expression in cis. Complete genomic hybridization by array using a Nimblegen custom oligonucleotide array representing 33 megabases of the p-terminal of chromosome 11 was performed on the translocations.

Non-syndromic Cleft Lip and Palate: Linkage and candidate genes analysis of multigenerational families. *S.K. Nath[1], U. Ratnamala[2], S. Han[1], S. Beiraghi[3], K. Ewing[1], D. Mandhyan[1], K. McElreavey[4], L. Bartoloni[5], GS. Antonarakis[6], SE. Antonarakis[5,7], U. Radhakrishna[2,5]* 1) Dept Arthritis & Immunology, Oklahoma Medical Res Fndn, Oklahoma City, OK; 2) Green Cross Voluntary Blood Bank and Genetic Research Center, Ahmedabad, India; 3) Division of Pediatric Dentistry, University of Minnesota, Minneapolis, USA; 4) Department of Reproduction, Fertility and Populations, Institut Pasteur, Paris; 5) Department of Genetic Medicine and Development,; 6) Department of Orthodontics, School of Dental Medicine; 7) Geneva University Hospitals, University of Geneva Medical School, Geneva.

Non-syndromic cleft lip with or without cleft palate (NSCL/P) is one of the most common congenital craniofacial birth defects, affecting 1 in 700-1,000 newborns in the United States each year. Its highest prevalence rates are in Native Americans and Asians. Various independent association and linkage studies of different populations have identified 11 loci with evidence of linkage for syndromic and/or NSCL/P at various chromosomal regions, however pathogenic mutations have been identified in 4 of these 11 loci. Majority of these reports were made using small nuclear families. However, our recently published three large multi-generational NSCL/P families identified significant evidence of linkage at 13q33.1-34 (Am J Hum Genet 79:580-5, 2006) and 18q21.1 (Am. J. Hum. Genet, 81:180-8, 2007) for markers rs1830756 (NPL=5.57; P=.00024; LOD = 4.45) and rs728683 (NPL =43.33 and P =.000061; nonparametric LOD =3.97 and P =.00001) respectively. We have analyzed another large multi-generational Indian family UR057 with NSCL/P. The family consists of a total of 204 individuals including 18 affecteds (12 males & 6 females). The phenotype of affecteds ranged from unilateral to bilateral NSCL/P. A high-density genome-wide linkage analysis using Affymetrix microchips are currently being processed, however, the results are inconclusive. We present linkage results using family UR057 as well as combined analysis using all the other families for positional candidate genes at 13q33.1-34 and 18q21.1. We discuss the implications of using the large multi-generational families in NSCL/P gene identification perspective.

The Fanconi Anemia pathway plays a critical role in recombinational telomere maintenance in ALT-immortalized human cells. *H. Root[1,2], M.S. Meyn[1,2]* 1) Program in Genetics & Genome Biology, Hospital for Sick Children, Toronto, ON, Canada; 2) Dept of Molecular & Medical Genetics, Univ of Toronto, Toronto, ON, Canada.

Fanconi Anemia (FA) proteins are implicated in genetic recombination, a process involved in Alternative Lengthening of Telomeres (ALT) pathways. We find that FANCD2, A, and G form nuclear foci that localize to telomeric foci and PML bodies in ALT, but not in telomerase-positive or primary human cells. Co-IP experiments indicate ALT-specific in vivo interactions in late S/G2 cells between FANCD2, the Bloom syndrome helicase BLM, and the telomeric protein TRF2. FANCD2 localization to ALT telomeric foci is independent of ATM or ATR, but requires monoubiquitination by the FA core complex. Depletion of BLM significantly decreases FANCD2 association with ALT telomeric foci, but does not affect non-telomeric FANCD2 foci formation. This suggests that FANCD2 may have a function at ALT telomeres that is independent of its putative role in replication fork rescue.
ALT cells depleted of FANCD2 by siRNA exhibit increased telomere dysfunction-induced foci, telomere entanglements, and extrachromosomal telomeric DNA. FANCD2 depletion also has a severe ALT-specific effect on viability, nuclear morphology and chromosome stability. Nuclei with large holes, bridging, multiple lobes/micronuclei appear 3-5 days after FANCD2 depletion. These abnormalities only occur at low frequencies following FANCD2 depletion of telomerase positive cells and ALT cells forced to express telomerase, suggesting that these nuclear abnormalities result from ALT-specific telomere dysfunction. FANCD2-depleted ALT cells also exhibit supernumery centrosomes, re-replicated DNA, aneuploidy, cohesion and condensation problems. In contrast, these abnormalities are not found at high frequencies in FANCD2-depleted telomerase positive cells.We hypothesize that FANCD2 and the FA pathway play a critical role in limiting telomeric recombination and/or resolving telomeric recombinational events in ALT cells. In the absence of FANCD2, telomeres may be aberrantly entangled during mitosis, leading to mitotic failure and continued cell growth without proper segregation of DNA, resulting in multiple secondary abnormalities.

A candidate gene for autosomal dominant hereditary motor and sensory neuropathy with proximal dominancy (HMSN-P). *K. Maeda[1], R. Kaji[1], J. Jamiyansuren[1,2], K. Yasuno[3], H. Takashima[4], M. Nakagawa[5], S. Makino[2], G. Tamiya[2]* 1) Department of Neurology and Neuroscience, Tokushima University Graduate School of Medicine, Japan; 2) Division of Human Molecular Genetics, Department of Neurology and Neuroscience, Tokushima University Graduate School of Medicine, Japan; 3) Division of Genetic Diagnosis, The Institute of Medical Science, The University of Tokyo, Japan; 4) Department of Neurology and Geriatrics, Kagoshima University Graduate School of Medicine, Japan; 5) Department of Neurology and Gerontology, Kyoto Prefectural University Graduate School of Medicine, Japan.

Hereditary motor and sensory neuropathy with proximal dominancy (HMSN-P; MIM 604484) is endemic to Okinawa Islands, the most southern part of Japan, which is characterized by autosomal dominant inheritance, slowly progressive proximal muscle atrophy and weakness, sensory disturbance such as paresthesia and vibration loss, leading to be bedridden. The disease locus of HMSN-P has been mapped to 3q13-14. Our linkage study in a newly-found large family with many members developed the similar symptoms of HMSN-P in a western part of Japan using 15 microsatellite markers around the HMSN-P locus identified a 7.3-Mb interval in 3p13 cosegregated with the disease (maximum two-point lod score of 8.44 at theta=0.0). The candidate region was identical to the HMSN-P locus, but the disease haplotype in the large family was different from that previously reported, suggesting allelic heterogeneity. Through mutation search by extensive genomic sequencing and expression analysis of known-genes within the candidate region using RNA from a patient's lesioned tissues, we found new strong candidate genes of HMSN-P.

Mutation showers over the DNA landscape. *S. Sommer[1], J. Wang[1], K. Gonzalez[1], W. Scaringe[1], K. Tsai[1], N. Liu[1], D. Gu[1], W. Li[1], V. Buettner[1], K. Hill[2]* 1) Dept Molecular Genetics, City of Hope, Becker Res Inst, Duarte, CA; 2) Dept of Biology, University of Western Ontario, London ON, Canada.

We previously reported that spontaneous mutation showers, clusters of spontaneous mutations, generally spanning less than 30kb, occur in mice at an estimated frequency of 1% or more of spontaneous mutations (PNAS 104(20):8403;May 07. The mutations are termed spontaneous since the mice were not intentionally exposed to any known mutagen. The unexpected clustering of the observed multiple mutations indicates that they occurred as a chronocoordinate event and is suggestive of a transient error-prone condition. The existence of mutation showers has implications for oncogenesis and evolution, raising the possibilities of cancer in an instant and of introns serving as sponges to absorb mutation showers. Herein we demonstrate that the yeast S. cerevisiae has four hallmarks of mutation showers, consistent with wide distribution of this phenomenon in eukaryotic organisms. Furthermore, investigation in mouse reveals that tandem base mutations (TBMs) are associated with mutation drizzles, as they tend to involve a lower density and fewer clusters of mutations than when TBMs are not involved.

Molecular and biochemical analysis of mitochondrial respiratory chain complex I deficient patients. *V. Procaccio[1], P. Potluri[1], E. Ruiz-Pesini[2], D. Mishmar[3], A. Davila[1], K. Tien[1], R. Jimenez[1], M. Simon[1], I. Scheffler[4], D.W. Wallace[1]* 1) MAMMAG, Univ California, Irvine, Irvine, CA; 2) Biochemistry Department Zaragoza University, Spain; 3) Department of Life Sciences, Ben Gurion University, Israel; 4) Univ California, San Diego, San Diego, CA.

Mitochondrial complex I is composed of 45 subunits, 7 subunits are encoded by the mitochondrial DNA (mtDNA) and the rest by nuclear genes and accounts for most cases of respiratory chain deficiency. Mutations in these genes can affect the complex I assembly or activity. A systematic and comprehensive study of the genetic characterization of 15 isolated complex I deficient patients was performed by sequencing the entire mtDNA and all nuclear complex I subunits. Moreover, the level of complex I assembly probed for the stability of various complex I subunits and activity in these cells has been estimated through polarography and native gels and has been shown to be significantly lower than the control cells. Measurements of ATP were also performed on permeabilized cells. Pathogenic nuclear gene mutations were identified in only few patients. In one patient cell line we identified a mutation in the MWFE subunit at the highly conserved position. Complex I levels are about 50% less than normal control mitochondria. The same mutation, created through site directed mutagenesis, in the chinese hamster cell line used as a model leads to a significant decrease of complex I assembly and stability. In another patient cell line, we identified two synergistic mutations in the mitochondrially encoded subunits ND3 and ND6. Complex I assembly and activity is more than 60% reduced due to these composite mutations. In the third set of cell lines, no mutation was detected in any of the known subunits and assembly factors. In some of these extreme cases, stability of more than one subunit is drastically affected and the level of assembled complex I is almost undetectable on a native gel. Our goal is to understand the assembly of complex I through investigating the pattern of subassembly intermediates by using these cell lines and aim to find the defective genes in these cell lines involved in complex I assembly.

A Genetic Association Between Angiotensinogen Genotype and Plasma Angiotensinogen Endophenotype in CEPH Families. *W.S. Watkins, W. Tolpinrud, A. Rohrwasser, Y. Zhang, A. Peiffer, M. Leppert, J-M. Lalouel, L.B. Jorde* Department of Human Genetics, Salt Lake City, UT 84112.

Many previous studies have documented an association between hypertension and alleles of the angiotensinogen locus (*AGT*), one of several loci implicated in hypertension by linkage and functional studies. However, the nature and strength of this association is still debated. To help resolve this issue, we have analyzed the relationship between *AGT* alleles and the key endophenotype, plasma angiotensingen, in mostly normotensive individuals from 42 CEPH pedigrees. Plasma AGT levels were assessed in 393 samples by complete conversion of AGT to angiotensin I (AI). AI was then assayed with a modified enzyme immune assay. Using the FBAT software package, an association between *AGT* genotypes and plasma AGT levels could be detected for *AGT* SNPs -1178A, -6G, 6065C, and 6232T ($p < 0.05$). The -6A allele has been implicated previously in increased rates of *AGT* transcription and is associated with increased risk of hypertension. Using HBAT, the promoter haplotype carrying the -1178A and -6G alleles also showed an association with plasma AGT levels ($p < 0.027$). Other studies, using hypertensive subjects, have shown that elevated plasma AGT is associated with hypertension. Our results suggest that common polymorphisms at the AGT locus are associated with plasma AGT levels in families of predominantly normotensive status. Support: NIH grant HL070048.

Wolf-Hirschhorn: from syndrome to phenotypic spectrum. *N.P. Rao[1], M. Mulatinho[1,2], J. Llerena[2], F. Quintero-Rivera[1]* 1) Department of Pathology , David Geffen School of Medicine at UCLA, Los Angeles, CA; 2) IFF/FIOCRUZ, Departamento de Genetica Medica, Rio de Janeiro, RJ, Brazil.

Wolf-Hirschhorn syndrome (WHS) is a complex genetic disorder that presents with mental retardation, epilepsy, severe growth delay, and cranio-facial dysgenesis. The severity of its core characteristics is highly variable. The critical region is located in 4p16.3, where WHSC1 is always deleted. However, recent mouse model studies indicate that deletion of WHSC1 alone does not account for the full phenotypic spectrum observed in WHS. Here we present two patients who have a common deletion of WHSC1, and present with a different phenotype and genotype. The first is an infant with significant multi-systemic involvement including seizures, bilateral dysplastic kidneys, hearing loss, branchial cleft cyst, bilateral colobomas, cleft lip/palate, hypospadias and multiple dysmorphic features. The karyotype showed 46,XY,del(4)(p14)dn. FISH with the 4pter subtelomeric and WHS probes confirmed the deletion of WHSC1 and of an additional 35Mb. This deletion involves several other genes telomeric (WHSC2, SLBP, MSX1, FGFR3, LETM1, TACC3) and centromeric (SLIT2, TAPT1) to the critical region. The second patient was referred for developmental delay and dysmorphic features including microcephaly, retrognathia, low set ears, wide tip nose, macrostomia, nasal voice, and cubitus valgus. Pitt-Rogers-Danks syndrome (PRDS) was suspected clinically. Karyotype was normal. Subtelomeric FISH was performed and found to be abnormal for 4pter. Further analysis confirmed a deletion of WHSC1 and of an additional 2.1Mb. aCGH studies are ongoing. In conclusion these two cases confirm the model in which deletion of WHSC1 is essential for the pathogenesis of WH, but deletion of surrounding genes contributes to both the severity of the core characteristics and the presence of additional manifestations. PRDS should be considered a part of the milder end of the WHS spectrum generated by its phenotypic variability. We suggest that abnormal 4pter subtelomeric FISH in a patient with subtle dysmorphism and/or PRDS should prompt an evaluation of the 4p16.3 critical region.

High-resolution copy number variation detection: application of an integrated hidden Markov Model on Illumina whole-genome SNP genotyping data. *K. Wang[1], M. Li[2], D. Hadley[1,3], R. Liu[1], J. Glessner[4], S. Grant[4], J. Kim[3], H. Hakonarson[4], M. Bucan[1]* 1) Department of Genetics, University of Pennsylvania, Philadelphia, PA; 2) Department of Biostatistics, University of Pennsylvania, Philadelphia, PA; 3) Department of Biology, University of Pennsylvania, Philadelphia, PA; 4) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA.

Copy number variation (CNV) refers to segments of DNA sequences that are present at variable copy numbers in the human genome, in comparison to a reference genome assembly. Previous studies typically use array-CGH based methods for CNV detection, with resolution limited to tens or hundreds of kilobases. Here we present a hidden Markov Model (HMM) approach that uses Illumina Infinium HumanHap550 high-density SNP genotyping data for CNV detection. In the HMM model, the emission probabilities of the total signal intensity and allelic intensity ratio for each SNP are modeled through a mixture distribution, indexed by the population frequency of alleles in a large reference population. The HMM transition probabilities are dependent on distances between neighboring SNPs. The HMM parameters are estimated using the Baum-Welch algorithm. Since most CNVs are Mendelian inherited, the pedigree structure can be optionally used a posterior to validate CNV calls. We applied our method on ~1000 samples from disease cohorts and controls, and identified ~22,000 CNVs with median size of 15Kb, representing 10-100 fold increase of resolution over array-CGH based studies. About 35% of the detected CNVs are less than 10Kb, underscoring the importance of studying small CNVs for a comprehensive understanding of human genetic variation. For detected CNVs, we also describe a general strategy of combining PCR and resequencing to identify the exact breakpoint, leading to 10^5 fold increase of resolution in CNV detection and mapping. Our results demonstrate the feasibility of comprehensive genome-wide CNV fine-mapping via high-density SNP genotyping. Given the unprecedented resolution, our method unveils a new avenue towards genetic and functional studies on small and common CNVs.

Sherpa - A Bioinformatics Quality Control and Assurance Tool to Analyze Genotyping Data across Multiple Genomic Platforms. *T. van Rooij[1], C. Beck[1], M. Blazejczyk[2], W. al Abed[1], N. Gaudreault[1], P. Guelpa[1], A. al Mallah[1], I. Mongrain[1], Y. Renaud[1], M.S. Phillips[1]* 1) Genome Quebec and Montreal Heart Institute Pharmacogenomics Centre, Montreal, Quebec, Canada; 2) McGill University and Genome Quebec Innovation Centre, Montreal, Quebec.

The Pharmacogenomics Centre currently develops pharmacogenomic content on multiple genomic technologies. There is a current need for results that combine output from several genomic and proteomic technology platforms. Sherpa is an in-house developed software tool that links outputs from different instruments and creates a single, easily interpretable interface. It integrates raw data from all stages of sample processing, from PCR to genotyping, and presents them for data analysis and QC in a standardized interface. This allows the user to easily identify problems in sample processing by pre-qualifying data. The creation of an abstract generic genotyping data model by Sherpa allows the Centre to use a single informatic pipeline that analyzes data across multiple genomic platforms. In addition, Sherpa provides a number of unique data visualizations that are currently not available in commercial software packages; it is designed to go beyond current limitations in genotyping QC and will streamline the genotyping data feed into the Centres data warehouse, the access point for data mining and analysis.

Sherpa guides technicians through multiple phases of data analysis and several levels of QC that enable the clinical accuracy required for pharmacogenomic testing. It uses a multi-algorithmic approach to give users a variety of different ways to look at the data in order to make the best decision and will also record the history of all genotyping calls. Sherpa reflects 21 CFR part 11 requirements by tracking changes and providing audit trails. The last phase of Sherpa development is the assignment of a proposed phenotype based on molecular profiles derived from pharmacogenomic research which includes literature text-mining in the data warehouse. This softwares interface successfully addresses the current disconnect between genotyping results and the processes that generated them.

Demonstration of Presumed Linkage Disequilibrium in the Posterior Polymorphous Corneal Dystrophy 1 Candidate Gene Region. *V.S. Yellore, M.C. Chen, S.A. Rayner, A.J. Aldave* Cornea Service, Jules Stein Eye Institute, David Geffen School of Medicine at UCLA, Los Angeles, CA.

Purpose: To identify the genetic basis of posterior polymorphous corneal dystrophy (PPCD1), an autosomal dominant disorder of the corneal endothelium associated with visually significant corneal edema and glaucoma. Linkage analysis in four families with PPCD1 has demonstrated linkage to a 2.4 cM common support interval bordered by the markers D20S182 and D20S139. We sought to identify the genetic basis of PPCD1 thorough screening of the 20 positional candidate genes between these markers in the fourth PPCD1 family mapped to this interval. **Methods**: DNA was obtained from 11 affected and 11 unaffected individuals from a family previously liked to the PPCD1 locus. The coding regions of all 20 positional candidate genes were amplified and sequenced in affected and unaffected individuals. **Results**: Four DNA sequence variants in three of the positional candidate genes demonstrated complete segregation with the affected phenotype: Thr109Thr (rs6111803) in *OVOL2*, Arg56Gln in *RPS19P1*, and Thr85Thr (rs1053834) and Pro99Ser (rs1053839) in *C20orf79*. While three of the identified sequence variants are known SNPs, Arg56Gln is a novel variant, although it has been identified in unaffected control individuals. While a number of other previously described and novel SNPs were identified in the 20 positional candidate genes, none segregated with the affected phenotype in the family. **Conclusions**: We have identified several sequence variants in genes mapped to the common PPCD1 region that are presumed to be in linkage disequilibrium with the as-of-yet unidentified pathogenic mutation. Screening of the non-coding regions of the 20 positional candidate genes is currently underway to identify the genetic basis of PPCD1.

Mouse SNPbrowser Software: SNP Selection for Genetic Mapping and Monitoring in Laboratory Mice Strains.
S. Tang, F.C.L. Hyland, F.M. De La Vega Applied Biosystems, Foster City, CA.

Single-nucleotide polymorphisms are widely used in mouse genetics, including genome-wide phenotype-genotype association studies and genetic monitoring of laboratory mice strains. Genome-wide mapping of QTL in the mouse is performed via genetic crosses of phenotypically distinct or mutagenized inbred mouse strains in order to infer the phenotype associated variant in the genome. By genotyping an informative panel of SNPs in backcrosses or F2 progeny, phenotypic traits can be linked with chromosomal blocks that are represented by selected SNPs. SNPs are also useful for genetic monitoring, or strain QC, which detects genetic contamination by genotyping a specific panel of SNPs and using allelic distribution to differentiate between the diverse strains. We developed the Mouse SNPbrowser Software to aid researchers in selecting informative panels of SNPs for genetic mapping and for genetic monitoring in common mouse strains. For genetic mapping, the user specifies the strain pair, the mapping resolution, and global (genome-wide) vs. local selection. An evenly-spaced set of SNPs that specifically distinguishes between the two strains is selected. For genetic monitoring, the user specifies the list of strains to differentiate between, SNPs to exclude, and SNPs to preferentially include in the selection algorithm (to facilitate re-use of assays). A minimal set of SNPs to distinguish among the strains is selected across the genome or per chromosome. SNPs are visualized on the main chromosomal display to display distance relationships, highlight uncovered regions of the genome, and contrast SNP sets with different properties. The display also links to SNP annotations on the NCBI dbSNP database. Currently, SNPs from various published data sets are consolidated and over 10,000 SNPs genotyped on 44 strains are included. In addition, a shopping cart enables direct ordering of corresponding TaqMan SNP Genotyping Assays from the AB website, thus expediting the set-up of mouse genetic studies with an increased probability of success. This free software application can be downloaded at www.allsnps.com/mousesnpbrowser.

Abnormalities of the Spine and Reduced Bone Density in Vascular Ehlers-Danlos Syndrome. *N. Obeng-Adjei[1], B.F. Griswold[1], L. Sloper[1], R. Raza[3], C.A. Francomano[2], W. Chen[1], J. Yang[1], N.B. McDonnell[1]* 1) LCI, NIA/NIH, Baltimore, MD; 2) GBMC, Baltimore, MD; 3) Harbor Hospital, Baltimore, MD.

Type III collagen is present in fiber bundles in bone cortex, with highest concentrations at the Haversian canal surface and at the bone-periosteal interface. Vascular Ehlers-Danlos syndrome (VEDS) is caused by mutations in COL3A1 encoding procollagen III, and is associated with reduced life expectancy due to arterial or hollow organ rupture. The prevalence of spine abnormalities and reduced bone density in VEDS has not been reported previously in the literature. In fourteen consecutive patients (ages 14-55) with mutations in COL3A1 enrolled in the hereditary disorders of connective tissue study at the National Institutes of Health, we noted a high prevalence of dural ectasia (8/14) in research magnetic resonance imaging (MRI) of the lumbar spine. Lumbar or cervical spinal stenosis due to disc herniation was seen in 7/14 participants. Posterior fossa volume was reduced in 5/14 subjects, however herniation of the cerebellar tonsils into the foramen magnum was not seen. All subjects over 18 had reduced bone density; 6/12 had osteoporosis and 6/12 had osteopenia. The results suggest that assessment of bone density is indicated for VEDS patients starting in young adulthood and treatment needs to be initiated to reduce fracture risk. Lower back or neck pain in VEDS may be a result of spinal stenosis or dural ectasia, and needs to be evaluated with MRI imaging.

Time-varying ACE components in random effects growth modeling of longitudinal cohort data for twins. *B. Muthén, S.L. Clark* Education, UCLA, Los Angeles, CA.

Longitudinal twin data are often collected using cohorts that differ widely in their ages. This has the advantage of studying development over wide age ranges, but has the disadvantage that typical modeling assumptions are strained. Random effects growth modeling of longitudinal twin data has the limiting assumption that the A, C, and E variance components of the standard twin model are constant across time. With widely different ages, however, it is quite conceivable that for example the E variance component varies substantially, and it is also of interest to allow for variation in the A variance component across ages where genetic effects emerge. Methods to alleviate the limiting assumptions are to include age as a covariate and/or perform a separate analysis for different cohorts. This paper presents a more satisfactory method that explicitly allows for changes across age in the variance components by applying parameter constraints where variances are expressed as functions of age. The method is applied to a study of the development of loneliness in Dutch twins across ages 10-60. It is found that the variance components deviate from constant values, instead showing substantial increasing and decreasing trends at different age ranges.

Microindels due to highly error-prone processes. *W. Scaringe[1], K. Li[1,2], D. Gu[1], K. Gonzalez[1], K. Hill[1,3], S. Sommer[1]* 1) Dept Molecular Genetics, City Hope Natl Medical Ctr, Duarte, CA; 2) SNP Institute, Nanhua University, Hengyang, Hunan, China; 3) Dept of Biology, The University of Western Ontario, London, ON, Canada.

Little is known about the nature of microindels. We present the first analysis of somatic microindels in i) an endogenous and universally transcribed mammalian gene, and ii) in human cancer. Analyses of reported TP53 microindels in cancer reveal that they occur at a frequency of about 0.3% without obvious tissue or age specificity, and have a molecular anatomy consistent with an endogenous etiology. TP53 microindels in cancer are remarkably similar to spontaneous microindels in the non-transcribed lacI transgene in normal Big Blue mouse tissues suggesting that the selective pressures associated with oncogenesis as well as any mutagens associated with cancers have minor effects relative to endogenous mechanisms. The molecular anatomy of microindels as a class is different from that of pure microdeletions, pure microinsertions, and tandem-base mutations, suggesting unique mechanisms. Three pairs of similar but not identical recurrences were observed showing the identical deletion with a nearly identical insertion (recurroids). Microindel sequence contexts suggest diverse mechanisms including error-prone mechanisms. In contrast to microinsertions which duplicate the adjacent sequence in the overwhelming majority of cases, the inserted sequences in microindels appear to derive predominantly from nearby but not adjacent sense or antisense sequences. The data suggest that indels arise from the bypass of blocking lesions by a mechanism that utilizes nearby sense or antisense sequences to help bridge the blocked lesion. The process is highly error prone with an estimated rate of 12% per bp, about two orders of magnitude greater than that measured for Y family polymerases, although those measurements were made without a bulky blocking adduct. In conclusion, the data herein describe the molecular anatomy of somatic microindels in cancer, constrain hypotheses of their nature and origin, and are consistent with these microindels generally deriving from spontaneous highly error-prone endogenous processes.

Accelerating genome and tumor research with Single Cell Arrays. *H. Weier[1], J.F. Weier[1,2], S. Baehring[3], J. Laubenthal[1]* 1) Life Sci Div, UC-Lawrence Berkeley Natl. Lab, Berkeley, CA 94720; 2) UCSF, San Francisco, CA 94550; 3) Medical Faculty of the Charite, Franz Volhard Clinic, Wiltberg Strasse 50, 13125 Berlin, FRG.

Present technology for genome-wide screening and analysis fails to detect subtle genetic changes such as small balanced translocations or accurately characterize gene amplifications in tumors. We propose the development of a fluorescence in situ hybridization (FISH)-based technology platform capable of analyzing very small amounts of tissue with unprecedented sensitivity, accuracy and resolution. In a typical FISH procedure, the efficiency of FISH and thus the ability to detect a specific target inside a cell nucleus, depends on the penetration of probes and detection reagents as well as the accessibility of the hybridization target. In clinical samples, hybridization efficiencies are typically low and, in combination with photobleaching of detection reagents, limit the in situ detection of genes of interest to about 100kb or larger. Our laboratory investigates the application of a technology termed single cell arrays (SCAs) to study a spectrum of human genetic conditions including the characterization of genetic changes in breast cancer specimens, the delineation of rearrangements in familial autosomal-dominant hypertension and quantitative analysis of gene amplification in thyroid tumors. We completed proof-of-concept experiments showing that a) individual cells can be arrayed on glass slides inside specially designed micro-channels (individually or in pools using a micromanipulator or flow cytometry sorting), b) cells can be treated physico-chemically to release chromatin, c) the entire chromatin can be stretched in a linear fashion, d) the extent of stretching (ranging from a few microns to 10-12 mm) can be adjusted by controlling the stretching force and environmental parameters, e) stretched chromatin can be analyzed by FISH providing a resolution of up to 5-15 kb, f) the method is suitable to address tumor heterogeneity by preparing chromatin arrays of at least 32 single cell spreads per slide, and g) the method works equally well with fresh, frozen or fixed cells as starting material.

Male infertility due to congenital bilateral aplasia of the vas deferens: how should couples undergoing IVF/ICSI be offered genetic counseling? a case report. *Y.D. Nobre[1], M.B. Toralles[2], I. Gomy[3]* 1) Surgery/Urology, University of Sao Paulo, Ribeirao Preto, Brazil; 2) Medical Genetics, Federal University of Bahia, Brazil; 3) Medical Genetics,University of Sao Paulo,Ribeirao Preto,Brazil.

Couples attempting IVF/ICSI,whereas there is male infertility due to obstructive azoospermia,should be offered genetic counseling and testing for mutations in the CFTR gene,which causes both cystic fibrosis(CF)and congenital bilateral aplasia of the vas deferens(CBAVD).CBAVD occurs in about 2% of infertile males and most of them are compound heterozygotes for mutations in the CFTR gene,more often the 5T allele in one copy and a CF mutation in the other one.In 20% of cases,CBAVD does not seem to represent a mild form of CF as these patients may have urinary tract anomalies.In those cases without renal anomalies and no CFTR mutations are found,the sweat test is useful to distinguish CBAVD patients. We present a case of a Brazilian infertile couple whereby the man had obstructive azoospermia with no further symptoms. Both deferens ducts were absent whereas both testis were topic. Testis biopsies showed normal spermatogenesis. Pelvis MRI revealed no seminal vesicles. Renal and urinary tract ultrasound showed no anomalies.Karyotype and hormones were normal.Genetic analysis for the most common CFTR mutations was carried out in the couple and no mutations were found.The sweat test was positive in the man and negative in the wife.Thus we indirectly recognized a low CFTR protein as the cause of CBAVD,which allowed us to offer the couple a more suitable genetic counseling.As the couple consented to undergo IVF/ICSI,we estimated the risk of a child with cystic fibrosis as 1/44 and the risk of a male child with both cystic fibrosis and CBAVD as 1/88. We also explained the higher risk of birth defects and genomic imprinting disorders with IVF/ICSI.Although preimplantation genetic diagnosis(PGD)is possible in order to select those embryos free of mutations,we do not know the type of mutation this couple may carry,and,as there are more than a thousand mutations in CFTR gene,it would be reasonable to ponder the benefits of avoiding disease transmission with the medical risks and the financial burden of PGD.

SNP tagging for fine-mapping association analysis of the Extended MHC region in a T1D association study. *E. Luczkowski[1], M. Klinker[1], J. Basken[1], S. Bolte[3], S. Twigger[2], S. Ghosh[1]* 1) Max McGee Center, Medical College of Wisconsin, Milwaukee , WI; 2) Human Molecular Genetics Center, Medical College of Wisconsin, Milwaukee, WI; 3) GE Healthcare, Wauwatosa, WI.

The advent of whole-genome association chip sets has made single nucleotide polymorphisms (SNPs) association studies for an entire cohort of individuals possible by using tagSNP approaches to improve time and cost effectiveness. Many common diseases, such as type 1 diabetes have an extensive history of linkage studies, which have now given way to large association studies, which reinforce the link between specific genomic regions and disease. Given that in many cases the low SNP density of association panels will not usually elicit specifically associated genes in gene-dense areas with large LD blocks, further fine-scale tagSNP work and sequencing is necessary to discover the exact genes driving the association. To begin a fine mapping study we have taken the extended MHC region SNPs (Chr6:25,760,400-33,772316) of the CEU HapMap dataset and collated them for tagging. We have analyzed the SNP set, despite the shortcomings of missing genes or few regional tags and have produced a tag SNP set. The creation of the tagSNP set was completed by parsing the available HapMap data of the extended MHC region into 8, 500kb overlapping regions and submitting them to the Tagger server. Collating this list brought us to 3299 SNPs. This data set does not tell us anything directly about our ability to tag HLA alleles. This set of tagSNPs also does not take into account other methodologies for choosing tag SNPs. Further investigation into other tagging methodologies (Haplotype tagging, Bayesian tagging) is in progress to create the most comprehensive tag set for the extended MHC region. This work will offer researchers a clear methodology to fine mapping association studies via tagSNP techniques for any disease and genomic region of interest.

Incorporating Fuzzy theory to the Dynamic Bayesian network modeling of gene expression data. *S. Gao, X. Wang*
medical college of wisconsin, milwaukee, WI.

Dynamic Bayesian networks (DBYN) plus Monte Carlo Markov Chain (MCMC) sampling has become an important approach to reconstruct genetic networks from gene expression data. It is a graphic probabilistic model that allows the incorporation of prior biological knowledge to improve performance. We have recently, for the first time, introduced fuzzy theory-based rules to the MCMC learning of DBYN in order to efficient incorporate prior biological knowledge, which are often incomplete and plagued with quality issues. Our method uses the Bayesian naïve network to estimate the probability of causal relationship between all gene pairs according their PubMed co-citation significance and their GO similarity. A sampling reservoir is then created where the copy number of each candidate gene pair is proportional to this probability. At each simulation iteration, a candidate network structure is generated by randomly picking a gene pair from the reservoir as a new network edge to be operated. We evaluated our new algorithm with both simulated expression data generated by SynTreN and the yeast cell cycle data. When compared with using DBYN alone, the sensitivity is improved by 80% on simulated data and 60% on the yeast data. We have then utilized it in the study of pancreas development, which is important in understanding normal pancreas function and the pathology and treatment of diabetes. A list of 15 genes that are deemed critical to pancreas development/function according to literature and their network structure were manually created. A time-series dataset that profiled mouse pancreas development were downloaded from the RNA Abundance Database (http://www.cbil.upenn.edu/RAD2/ ID 2 & 1790). We found that our new method is able to recover significantly more known gene pair relationships at the same false positive level. Out of the 23 manually curated network edges, it recovered 12. This is in contrast to only 4 by a plain DBYN method. These results demonstrated the advantage of our new DBYN algorithm. In addition, our approach can be extended to incorporate more types of biological data/knowledge as priors, including the DNA-protein and protein-protein interaction information.

Analysis of pooling strategies using Type II diabetes whole genome association study data. *A. Montpetit[1], R. Sladek[1,3], J. Rung[1], Y. Bosse[1], G. Rocheleau[1], F. Bacot[1], C. Polychronakos[5], D. Meyre[2], P. Froguel[2,4]* 1) McGill University and Genome Quebec Innovation Centre, Montreal Quebec, Canada; 2) CNRS 8090-Institute of Biology, Pasteur Institute, Lille, France; 3) Departments of Human Genetics, McGill University, Montreal, Quebec, Canada; 4) Section of Genomic Medicine, Imperial College London and Hammersmith Hospital, London, UK; 5) Department of Pediatrics, Faculty of Medicine, McGill University, Montreal, Quebec, Canada.

Whole genome association studies have led to the identification of many new unsuspected genes and chromosomal regions involved in disease etiology. One major hurdle is the cost of those studies. Pooling samples has been frequently proposed as a way to reduce the costs. However, loss of power can limit the potential gains from this strategy. In this study, we used Type II diabetes genomewide association study data to evaluate different pooling analysis methods on the Illumina platform. We first show that the pooling protocols are able to accurately determine the minor allelic frequency (MAF) as compared to individual genotypes. On the other hand, we show that only 10% of SNPs are common between the top 5% of the hits obtained by individual genotyping or by pooling, probably indicating that both approaches give rise to a high rate of false positives that are masking the true positives. However, the correlation improves the closer you get to the top as 25% of the top 1000, 40% of the top 100 and 50% of the top 10 SNPs are common to both lists (including 4 out of 5 SNPs that were confirmed by replication in another cohort). We also present similar results from other complex traits and are currently in the process of validating many of these hits. This study shows that a pooling approach combined with a second phase in which the top hits are replicated in a second cohort can be a valuable and economic strategy for the discovery of new disease genes in complex diseases.

Agenesis of the Corpus Callosum in Three Generations. *J. Li, V. Woo, K. Kronfeld, N. Osbun, R. Jeremy, E. Marco, E.H. Sherr* Dept Neurology, Univ California, San Francisco, San Francisco, CA.94143.

Agenesis of the corpus callosum (ACC), a failure to develop the large bundle of fibres that connect the cerebral hemispheres, occurs in 1:4000 individuals. Current evidence indicates that a combination of genetic mechanisms, including single-gene mutations, single-gene sporadic mutations and complex genetics might have a role in the aetiology of ACC. Here we report a family in which ACC is present in six individuals of three consecutive generations. The family consists of the probands parents, his brother and sister and his three children, two girls and a boy. Clinical exams revealed mild learning deficits, but most had IQs in the normal range. Imaging analysis showed either partial or complete ACC within the same family. Although no other cortical abnormalities were detected. The case reported here is consistent with autosomal dominant inheritance with nearly complete penetrance. Linkage analysis was performed using Illumina linkage IV panel SNP markers which include 5861 SNPs; the average genetic distance between mapped SNPs is 0.64 cM. The statistical significance of SNPs data was analysis by Merlin. These preliminary results pointed to several SNP markers on Chr4 and Chr14 which show the maximal possible LOD score, This analysis suggests that genes including Kv channel interacting protein 4, glutamate receptor, RAD51-like 1 isoform 2, regulator of G-protein signaling 6 and checkpoint suppressor 1 as disease candidates. To our knowledge, this is the first report of possible autosomal dominant ACC in three consecutive generations, perhaps suggesting that this is more common than previously appreciated.

Hyperglycosylation of mutations in GABRB3 polypeptide in childhood absence epilepsy. *M. Tanaka[1,2], M.T. Medina[3], R.M. Duron[3], R.H. Castro[4], I.J. Martinez[5], I.P. Castroviejo[6], M.J. Salas[2], M.E. Alonso[5], J.N. Bailey[2.7], D. Bai[2.8], A.V. Delgado−Escueta[2.8], R.W. Olsen[1]* 1) Dept Pharmacology, David Geffen School of Medicine at UCLA, Los Angeles, CA; 2) Epilepsy Center of Excellence VA GLAHS & UCLA, Los Angeles, CA; 3) Neurology, National Autonomous University, Tegucigalpa, Honduras; 4) University of Sonora, Hermosillo, Mexico; 5) Neurology, National Institute of Neurology & Neurosurgery, Mexico City, Mexico; 6) The Hospital of Lapaz, Madrid, Spain; 7) Semel Institute for Neuroscience & Brain Behavior at UCLA Los Angeles, CA; 8) Dept Neurology David Geffen School of Medicine at UCLA, Los Angeles, CA.

Childhood absence epilepsy (CAE) accounts for 10 to 12% of epilepsy under 16 years of age. Because transmission disequilibrium test showed possible genetic association between $GABA_A$ receptor 3 subunit gene (GABRB3) and CAE, while GABRB3 deficient mice shows absence like features including EEG characteristics and pharmacological response and because atypical absences in Angelman syndrome correlate with chromosome 15q11-13 deletions which includes GABRB3, we screened for mutations in GABRB3 in 48 probands and families with CAE. One heterozygous missense mutation (P11S) in exon 1a segregated with CAE in two unrelated multiplex multigeneration Mexican families and another heterozygous missense mutation (S15F) was present in a singleton from Honduras (mutations absent in 440 controls). G32R missense mutation in exon 2 was present in 3 affecteds of one Honduras family (mutations absent in 200 controls). We studied functions and possible pathogenicity by expression of mutations in HeLa cells using Western blots and an *in vitro* translation/translocation system. Expression levels were not different from controls, but all mutations showed hyperglycosylation in the *in vitro* translation/translocation system with canine microsomes. We suggest that the gain in glycosylation affects maturation of the 3 subunit protein and trafficking from endoplasmic reticulum to cell surface. The resulting malfunction of $GABA_A$ receptors which contain the 3 subunit in turn produces absence attacks.

Rasch-based genomic scale construction and estimation of personalized relative risk. *N.J. Markward* Pennington Biomedical Research Center, Baton Rouge, LA.

This project outlines the basic axioms underlying the Rasch measurement framework and, drawing on data generated by the NINDS genome wide association (GWA) study of Parkinsons disease, demonstrates how the Rasch family of measurement models can be employed to develop multi-SNP genometric scales that facilitate 1) evaluation and interpretation of person-specific genomic variation and 2) estimation of personalized relative risks (PRR) that integrate information on genetic background and epistatic interactions. The Rasch-based measures of association are then compared and contrasted to sample-level risk indices used in human genome epidemiology, highlighting inferential discontinuities that may preclude the use of population-based summary statistics and p-values as the sole foundation of genome-based diagnostic development and medical decision-making. Of particular interest is the finding that the associative effect of a particular locus--on disease susceptibility, treatment response, or a combination thereof--may depend intimately on the context in which a hypothesized causal variant resides. Indeed, the results indicate that a given allele or genotype can generate both an independent (positive or negative) effect at the population level and a distinctive interactive effect that depends on the placement of individuals relative to each SNP on the Rasch scale.

Variation in Preferences for Future Use of DNA Among 2226 Genetic Research Participants. *S.M. Lewis[1], K. Spates[1], P. Raska[2], G.L. Wiesner[1,3]* 1) Dept. Genetics, Case Western Reserve Univ, Cleveland, OH; 2) Dept. Bioethics, Case Western Reserve Univ, Cleveland, OH; 3) Center for Human Genetics, Case Western Reserve Univ, Cleveland, OH.

Researchers in human genetics must balance the advancement of gene discovery with ethical considerations. To promote respect for autonomy and privacy of research participants in genetics studies, guidelines for informed consent recommend that participants indicate whether their DNA may be used in future research. However, research progress could be impeded if participants limit access to this valuable resource. In order to assess the proportion of participants who do not wish to have their DNA used in future studies, we examined the preferences of 2226 participants enrolled in the Colon Neoplasia Sibling Study, a family genetic study that aims to identify colon neoplasia susceptibility genes. In this study, participants choose one of three options for use of their DNA in future research: 1) DNA may be used for future research studies without further contact if identifying information is removed (UNRESTRICTED); 2) DNA may be used for future research if participant is re-contacted and consents (RECONTACT); 3) DNA may not be used for future research studies (NO FUTURE USE). Results showed that overall many participants are willing to allow their DNA to be used for research purposes in the future, as 49% chose UNRESTRICTED use, 46% chose RECONTACT, and only 4% chose NO FUTURE USE. Examination of these choices by self-identified racial categories showed a significant difference ($p < 0.001$) between the choices of the 1894 Caucasian and the 317 African American participants. 53% vs. 29% chose UNRESTRICTED use, 45% vs. 57% chose RECONTACT and 3% vs. 14% chose NO FUTURE USE for Caucasians and African Americans, respectively. The odds for African Americans to select NO FUTURE USE or RECONTACT were 2.6 times higher than Caucasians (95% CI [2.0-3.4]). Understanding the root causes underlying the differences in participants' preferences for future use of their DNA may help researchers more productively address issues of privacy, autonomy, and ascertainment when designing and conducting their genetic studies.

Sporadic POLG1 mutations in two cases; one with acute liver failure and the other with encephalopathy. *E. Schmitt[1], R.E. Lutz[2], Q. Zhang[1], C. Reyes[2], E. Truemper[2], R. McComb[2], A. Hernandez[3], A. Basinger[4], L.-J. Wong[1]* 1) Molecular & Human Genetics, Baylor Col Medicine, Houston, TX; 2) Department of Genetics, Endocrinology, and Metabolism, Munroe-Meyer Institute, University of Nebraska Medical Center, Omaha, NEB; 3) Department of Neurology, Cook Childrens Medical Center, Ft. Worth, TX; 4) Division of Metabolic Genetics, Cook Childrens Physician Network, Ft. Worth, TX.

PURPOSE: To identify the molecular etiology of suspected of mtDNA depletion syndrome in two patients; one with an acute liver failure triggered by infection and the other with repetitive seizures. METHODS: The POLG1 gene, responsible for mitochondrial DNA (mtDNA) biogenesis, was analyzed by direct DNA sequencing. Real time quantitative PCR was used to measure the mtDNA copy number. Respiratory chain enzyme complex activities, histochemistry, and ultrastructural studies were performed on a liver specimen from one of the patients. RESULTS: Three mutations, p.T251I, p.P587L, and p.K1191R in the POLG1 gene were identified in a baby girl with acute liver failure. Liver biopsy showed swollen hepatocytes with microvesicular steatosis and a drastic reduction of mtDNA content. Analysis of parental DNA revealed that T251I and P587L were in cis on the maternal chromosome, while the novel K1191R mutation was not detected in either parent. Two heterozygous mutations, p.A467T and c.2157+5_6 GC> AG were found in a baby boy with seizures. Subsequent analysis of parental blood samples revealed that the mother is heterozygous for the p.A467T allele; both parents were negative for the c.2157+5_6 GC> AG allele. CONCLUSIONS: Neither of our patients have typical clinical presentation of autosomal recessive Alpers syndrome, which is characterized by infantile liver failure and intractable seizures. Infection may be a precipitating factor in acute liver failure for patients harboring POLG1 mutations without CNS problems. Patients with Alpers syndrome may alos present with CNS symptoms only, without liver involvement. We report the first two sporadic cases with novel POLG1 mutations. Both de novo mutations are likely to be on the paternal copy of the POLG1 gene.

Admixture may modulate risk for psychiatric disorders. *X. Luo[1,2], L. Zuo[1,2], H.R. Kranzler[3], R.F. Anton[4], R.A. Rosenheck[1,2], H.P. Blumberg[1], J. Covault[3], D.S. Charney[5], D.P. van Kammen[6], L.H. Price[7], J. Lappalainen[1,2], M.D. Shriver[8], M.B. Stein[9], J. Cramer[1,2], J. Krystal[1,2], J. Gelernter[1,2]* 1) Dept Psychiatry, Yale Univ Sch Medicine, New Haven, CT; 2) VA CT Healthcare System, West Haven, CT; 3) Dept Psychiatry, Univ CT Sch Med, Farmington, CT; 4) Inst Psychiatry, Med Univ S. Carolina, Charleston, SC; 5) Dept Psychiatry, Mount Sinai Sch Med, New York, NY; 6) Clin Dev, ACADIA Pharm., San Diego, CA; 7) Dept Psychiatry, Brown Univ, Providence, RI; 8) Dept Anthropology, Penn State Univ, Univ Park, PA; 9) Dept Psychiatry, Univ CA, La Jolla, San Diego, CA, USA.

The admixture of ethnic populations in America may have important consequences with respect to the risk for psychiatric disorders, as it appears to do for other medical disorders. The present study aimed to investigate the role of admixture in risk for several psychiatric disorders in European-Americans (EAs) and African-Americans (AAs). A total of 3870 subjects (3119 EAs, 673 AAs, and 78 West Africans) were included, including healthy controls and subjects with substance dependence (SD), including alcohol dependence (AD), cocaine dependence, and opioid dependence, social phobia, affective disorders (AFD), and schizophrenia. The degree of admixture for each subject was measured by analysis of a set of ancestry-informative genetic markers using the program STRUCTURE, and was compared between cases and controls. We found that the degree of admixture in AAs was higher than in EAs. In EAs, the degree of admixture (with African ancestry) was significantly lower in patients with SD (mainly AD) than in controls ($p=0.009$ for SD; $p=0.008$ for AD), but suggestively higher in patients with AFD than controls ($p=0.057$). In AAs, the degree of admixture (with European ancestry) was significantly higher in patients with schizophrenia than in controls ($p=0.015$). These findings suggest that admixture may modulate risk for psychiatric disorders. Admixture may decrease risk for SD and AD by decreasing the rate of inbreeding, and increase risk for AFD and schizophrenia via environmental factors or underlying disease loci in an overdominant manner.

A new therapeutic approach to the treatment of Gaucher Disease: mechanism of action of the pharmacological chaperone AT2101 and Phase I trial results. *B.A. Wustman[1], R. Khanna[1], D.J. Palling[1], A.C. Powe[1], J.J. Flanagan[1], C.W. Pine[1], R. Soska[1], L. Pellegrino[1], K.J. Valenzano[1], A. Marian[2], R. Demnati[3], D.J. Lockhart[1], H.V. Do[1]* 1) Biology, Amicus Therapeutics, Cranbury, NJ; 2) MDS Pharma Services, Lincoln, NE; 3) MDS Pharma Services, Montreal, Quebec.

Gaucher Disease is a lysosomal storage disorder caused by genetic mutations that lead to reduced -glucocerebrosidase (GCase) activity. While many GCase variants are catalytically competent, the mutations often destabilize the enzyme and/or impair exit from the endoplasmic reticulum (ER). We have developed a new therapeutic approach for the treatment of genetic diseases using small molecules called pharmacological chaperones. In this study, we used co-crystallization, thermal stability, radiolabeled pulse-chase and subcellular fractionation methods to study the effects of the pharmacological chaperone AT2101 on GCase. We found that AT2101 selectively binds and stabilizes GCase at neutral pH, thereby preventing premature degradation via ERAD and/or facilitating passage through the ER quality control system and restoring proper protein processing and trafficking to the lysosomes. Mutant GCase (N370S) is stable in lysosomes for at least 3 days after AT2101 is removed from cells and has a higher specific activity than N370S GCase from untreated cells. AT2101 also increases enzyme levels for other GCase variants including L444P, R463C, L174F, F216Y, F331S, G202R, V394L, D409H, and D409V in patient-derived cell lines or using heterologous expression systems. We then evaluated the effects of AT2101 on GCase levels in mouse models and human subjects. Treatment of L444P knock-in mice with AT2101 resulted in a dose-dependent increase in L444P GCase levels in liver, spleen, lung and brain. In single and repeat-dose Phase 1 clinical trials with a total of 72 healthy volunteers, AT2101 was well tolerated with no serious adverse events. In the repeat-dose study, a dose-dependent increase in GCase levels (up to ~3.5 fold) was observed during the 7 day treatment period, and enzyme levels remained elevated for more than a week after removal of the drug. AT2101 is currently being evaluated in Gaucher patients in Phase 2 clinical trials.

Stable Transfection of BACs Containing Fragile Site Sequence Recapitulate Fragile Site Instability at the Site of Integration. *R.L. Ragland, M.W. Glynn, T.W. Glover* Dept Human Genetics, Univ Michigan, Ann Arbor, MI.

Common fragile sites (CFSs) are loci that preferentially form gaps and breaks on metaphase chromosomes under conditions of replication stress. While much has been learned about the methods of induction and checkpoint and repair pathways that act in response to gaps and breaks at CFSs, little is understood about what makes a CFS fragile. Sequences at CFSs are highly conserved through evolution and are exceptionally AT-rich, containing a high number of AT-rich flexibility peaks. In addition, partial deletions of CFS regions lead to reduction of associated metaphase gaps and breaks following replication stress. Given these and other data, we hypothesized that the sequence of CFSs is central to the fragility of these sites. In order to examine this possibility, we stably transfected into HCT116 cells two BACs containing FRA3B sequence and two control BACs containing non-fragile site sequence with similar sequence content. The transfections resulted in six clones containing sequence from the CFS FRA3B and six clones containing control sequence, each at unique chromosomal loci. Integrated BAC sequences were present at several hundred to just a few contiguous copies, arising either from concatamer formation or BAC amplification following integration. Clones containing sequence from FRA3B showed a significant, three to seven fold, increase in gaps and breaks over controls after treatment with aphidicolin, and most control BACs showed no or few breaks. Many FRA3B integration sites showed multiple breaks and other chromosome aberrations (circular chromosomes, amplified signal, etc.) indicative of instability. Furthermore, these sites were at least as prone to forming gaps and breaks as the endogenous FRA3B site. Loci with a greater copy number of inserted FRA3B BAC were more fragile than those with only a few copies. This is the first direct evidence in human cells, that introduction of CFS sequences into endogenous non-fragile loci, can recapitulate the instability found at CFSs. These data support the hypothesis that the sequences at CFSs are inherently instable, and contribute to the gaps and breaks seen at these sites.

A search for genetic variants attributing to the risk of formation of intracranial aneurysms. *K. Yasuno[1,2], A. Tajima[1], T. Cui[1], A. Narita[1,2], I. Inoue[1,2]* 1) Department of Molecular Life Science, Tokai University School of Medicine, Isehara, Kanagawa, Japan; 2) Core Research for Evolutional Science and Technology (CREST), Japan Science and Technology Agency, Kawaguchi, Saitama, Japan.

Rupture of an intracranial aneurysm (IA) causes subarachnoid hemorrhage (SAH), a catastrophic form of stroke. Familial aggregation of IA suggests existence of genetic risk factors attributing to formation of IAs. Thus far genome-wide genetic linkage studies were performed in various populations, however, consistent loci were not reported indicating existence of genetic heterogeneity underlying IAs. To identify genetic susceptibility to IAs, we adopted a two-stage genome-wide association study in Japanese IA patients and controls. We completed a first stage screening with genotyping over 318,000 SNPs on the Illumina HumanHap300 and/or HumanHap300-Duo BeadChips in 203 ruptured and 95 unruptured IA patients and 198 controls. 310,303 SNPs were designed and shown with good clustering on both chips. Among them, overall call rate was 0.998 and 273,382 SNPs with minor allele frequency 0.02 and per-SNP call rate 0.95 were directed to association study. We analyzed these data in various aspects to try to narrow down and identify the candidate genetic variants responsible for susceptibility to IA. The current analytical methods include standard single- and multiple-marker associations, analysis of gene-gene interactions, and identification of loss of heterozygosity regions and copy number variations shared among patients. For example, the single-marker allelic association test for each SNP resulted in 26 most significantly associated SNPs with p-value less than 0.0001, where all these SNPs were in Hardy-Weinberg equilibrium in cases, controls and the combined sample, respectively, at the significance level 0.01. The most updated results relating IA susceptibilities would be presented and discussed.

A genome-wide association study in age-related macular degeneration in Mexican patients. *I. Silva-Zolezzi[1], J. Estrada-Gil[1], AV. Contreras[1], A. Hidalgo[1], L. Uribe-Figueroa[1], RA. Cano-Hidalgo[2], JC. Zenteno-Ruiz[2], R. Ayala-Ramirez[2], H. Perez-Cano[2], S. March[1], E. Graue[2,3], G. Jimenez-Sanchez[1]* 1) National Institute of Genomic Medicine, Mexico; 2) Hospital Conde de Valenciana IAP, Mexico; 3) School of Medicine, UNAM, Mexico.

Age-related macular degeneration (AMD) is the most common cause of central blindness in the elderly population. The molecular mechanisms underlying this disease are poorly understood. Two genome-wide association studies with 110,000 SNPs, one in Caucasians and other in Asians, have demonstrated the association of two genes with AMD: Complement Factor H (*CFH*) and a serine protease (*HTRA1*). This study aims to search for new associated genes in an admixed population using the same platform. 100 unrelated Mexicans with advanced AMD, 90 unrelated healthy controls and 300 population controls were genotyped. Our results of GWAS replicated the association found in the Asian population (rs1040924) related to *HTRA1* (p-value4.0E-7). To better characterize this result, we are currently re-sequencing the promoter region of *HTRA1*. Additional signals with suggestive p-values5.0E-5 were identified in regions not previously associated to AMD (4q13, 10p13, 14q21). Association to rs380390 in *CFH* previously associated in Caucasians did not achieve statistical significance. Individual genotyping of the Tyr402His variant of *CFH* showed mild association (p-value=3.0E-3). Our results suggest that *HTRA1* and *CFH* contribute to AMD in the Mexican population, and also support the idea that that genomic structure of admixed populations may contribute to the identification of new disease related genes. In addition, the identification of new regions associated to AMD suggests that its molecular mechanism may vary in the Mexican population.

Polymorphism in the IL18 gene and risk of epithelial ovarian cancer in Caucasian women. *R.T. Palmieri[1], M.A. Wilson[2], E.S. Iversen[2], P.G. Moorman[3], J.R. Marks[4], A. Berchuck[5], J.M. Schildkraut[3]* 1) Epidemiology, UNC, Chapel Hill, NC; 2) Institute of Statistics & Decision Sciences, Duke University, Durham, NC; 3) Community & Family Medicine, DUMC, Durham, NC; 4) Surgery, DUMC, Durham, NC; 5) Obstetrics & Gynecology, DUMC, Durham, NC.

Inflammation may be a mechanism through which established risk factors (e.g., parity, oral contraceptive use, lifetime number of ovulatory cycles) contribute to ovarian carcinogenesis. To investigate this candidate pathway, as well as others such as DNA repair and methylation, we genotyped 1536 tagging SNPs on 170 genes using a customized Illumina OPA chip; 19 of the genes are on the inflammation pathway. Genotypes were determined for 839 incident epithelial ovarian cancer cases and 791 age-matched controls in the NC Ovarian Cancer Study, a population-based case-control study. The analysis was restricted to Caucasian women. IL18, an interleukin gene on the inflammation pathway, was identified as the most significant gene in a gene-by-gene analysis (p=0.00211, Q-value=0.24018). All 12 SNPs on IL18 were in HWE. In a separate haplotype association analysis, rs1834481 uniquely tagged a single haplotype. Compared to women with the homozygous wildtype genotype, heterozygotes were 24% more likely and homozygous rare genotypes were 64% more likely to have ovarian cancer (OR=1.24, 95% CI: 1.01, 1.53 and OR=1.64, 95% CI: 1.09, 2.46, respectively); the Armitage trend test was significant (p=0.0041). No covariates confounded the association between the SNP genotype and ovarian cancer case status; all results were age-adjusted. The effect of the variant allele was slightly stronger among women with serous invasive epithelial ovarian cancer (OR=1.30, 95% CI: 1.00, 1.68 and OR=1.92, 95% CI: 1.18, 3.11 for heterozygous and homozygous rare genotypes, respectively). Though an initial investigation into effect measure modification yielded no significant results, we will present our exploratory analyses. Overall, our analysis suggests an association between the IL18 gene, specifically rs1834481, and epithelial ovarian cancer risk. These results are currently being validated by members of the Ovarian Cancer Association Consortium.

Molecular delineation of the 9p deletion syndrome: Phenotypic diversity of a common syndrome and the search for genes. *S. Schwartz[1], R. Anderson[1], S. Biton[2], M. Graf[3], H.K. Vance[4], D.J. Waggoner[1], C.A. Crowe[5]* 1) Univ of Chicago, Chicago, IL; 2) Univ of Toronto, Toronto, Canada; 3) TGEN, Phoenix, AZ; 4) Roswell Park Cancer Institute, Buffalo, NY; 5) MetroHealth Hospital, Cleveland, OH.

The 9p deletion was first described by Alfi in 1976. However, while there have been many reports there has been little phenotype correlation with molecular analysis. We have ascertained 135 patients with chromosome 9 abnormalities and have both detailed phenotypic and breakpoint information (using both BAC and array delineation of breakpoints). Phenotype/breakpoint analysis of 64 cases, where only a pure deletion is present, revealed four general groups of patients: (I) - Patients with general 9p deletion features and trigonencephaly; (II) - Patients with general 9p deletion features and mild face/cranium changes, but not trigonencephaly; (III) - Patients with minor phenotypic abnormalities; (IV) - Patient's phenotype not related to the 9p phenotype. All of the patients (100%) in the Groups I, II and III have hypotonia, mental retardation and specific behavior problems. Results from these studies are interesting and reveal important information including: (1) This is the largest study of 9p deletions to date and reinforces the importance of both precise clinical information and breakpoint analysis and the importance of including only individuals with pure deletions; (2) A putative candidate gene has been identified for trigonencephaly along with suggested putative genes for the other facial features seen in the 9p deletion syndrome as well as the neurological manifestations; (3) 9p subtelomeric deletions are not pathogenic as they have been identified in normal individuals and in individuals whose phenotype is not consistent with the 9p deletion syndrome; (4) In understanding the relationship of the loss of genes to the phenotype, it is extremely important to determine which genes have been shown, in studies of copy number variation, to be deleted in normal individuals; (5) The proximal region of 9p is relatively gene poor and several genes have been shown to be deleted in the general population thus limiting the number of genes that may potentially be important in the etiology of this syndrome.

A multi-lineage, whole-genome map of human DNaseI hypersensitive sites: identification of candidate functional elements underlying multiple common diseases. *P. Sabo, M. Kuehn, R. Thurman, J. Goldy, A. Haydock, M. Weaver, K. Lee, R. Sandstrom, S. Neph, W. Noble, M. Dorschner, J. Stamatoyannopoulos* Dept. of Genome Sciences, University of Washington, Seattle, WA.

Recent whole-genome association studies have highlighted the importance of non-coding genetic variation in multiple human diseases. Identification of causal non-coding variants requires a detailed whole-genome map of diverse gene regulatory sequences. DNaseI hypersensitive sites (DHSs) in chromatin have long been known to mark the locations of human cis-regulatory elements including promoters, enhancers, repressors, insulators, and locus control regions. We created comprehensive, high-resolution whole-genome maps of DNaseI hypersensitive sites in fourteen human cell types using whole genome tiling DNA microarrays and high-throughput DNaseI tag sequencing by Solexa. We mapped >600,000 DNaseI hypersensitive sites, of which 45%; are cell type-specific. The vast majority of cell-type-specific DHSs are distant from transcriptional start sites; by contrast, >90%; of promoters are DNaseI hypersensitive in more than one cell type. This suggests that cell type-specific gene regulation is determined mainly by distal elements (enhancers, LCRs, etc.). Combining the DHS map with HapMap polymorphism data revealed distinct classes of DHSs that are under selection in modern human populations. Recent whole-genome association studies have identified numerous non-coding loci, some very far from genes, that contain risk alleles for common diseases including diabetes, inflammatory bowel disease, cardiovascular disease, and colon and prostate cancer. Strikingly, we find that the majority of risk alleles mapped far from genes are in fact proximal to dense clusters of DHSs, which presumably mark the functional elements harboring the causative alleles.

A genetic and genomic approach to neurofibromin function. *A. Pemov[1], C. Park[1], L.M. Messiaen[2], K. Reilly[3], D.R. Stewart[1]* 1) GDRB, NHGRI/NIH, Bethesda, MD; 2) Dept. of Genetics, UAB, Birmingham, AL; 3) NCI-Frederick, Frederick, MD.

Introduction. Neurofibromatosis type 1 (NF1) is a monogenic disorder of dysregulated tissue growth. The causative gene, *NF1*, encodes the tumor suppressor neurofibromin. Its other putative functions are not well understood. We hypothesized that the function of neurofibromin can be determined by comparing differences in gene expression between affected (A) and unaffected (U) individuals in human lymphoblastoid cell lines (LCLs). We also examined expression differences in B-cells from *Nf1+/-* mice. *Methods.* Three age- and sex-balanced LCL datasets (18 adults, 9 children, 8 adults) were balanced for number of A and U individuals. The mouse dataset included 6 *Nf1+/-* C57BL6/J animals and 6 WT animals. All animals were ~ 8 months old and sex-balanced. Total RNA was isolated from LCLs and mouse spleen B-lymphoblasts and analyzed on Illumina platform. A permuted t-test comparing A vs. U gene expression within a dataset, overlap analysis of the top 500-700 differentially-expressed genes among the datasets, and Gene Set Enrichment Analysis (GSEA - Broad/MIT) was performed. *Results.* 1) Permuted t-test and overlap analysis found few statistically-significant genes; 7 of 14 genes validated by qPCR were significant in at least one dataset. The genes are involved in a variety of biological processes, including protein kinase cascade and G-protein coupled receptor signaling. 2) GSEA analysis of the 4 datasets revealed enrichment of our datasets with numerous gene sets (FDR < 0.05) mostly related to cell cycle regulation, DNA replication and interferon signaling. *Discussion.* Traditional microarray analysis techniques (e.g. permuted t-tests) found few relatively high-scoring differentially expressed genes within and among our 4 sample sets; this is likely due to the small sample size and modest expression differences. The GSEA approach, which identifies biological processes rather than highly significant individual genes, allowed us to detect additional transcriptional profiles (e.g. cell cycle regulation and interferon signaling) that are perturbed in NF1-affected patients and *Nf1+/-* mice.

Development of a Comprehensive and Efficient Molecular Diagnostic Assay for the Autosomal Dominant Polycystic Kidney Disease (ADPKD) genes, PKD1 and PKD2. *Y. Tan[1], J. Blumenfeld[1,2,3], S. Donahue[2,3], R. Belenkaya[1,2,3], T. Parker[1,2,3], D. Levine[1,2,3], H. Rennert[1,2,3]* 1) Weill Cornell Medical College; 2) The Rogosin Institute; 3) Rockefeller University, New York, NY.

ADPKD is one of the most common hereditary disorders affecting about 1 in 500 people. ADPKD is genetically heterogeneous with PKD1 and PKD2 accounting for 85% and 15% of mutations, respectively. Diagnosis of ADPKD is mainly performed by renal imaging, but genetic testing plays an important role, particularly in young, asymptomatic individuals, or those without a family history, where the imaging studies may be inconclusive. Genetic analysis of PKD1 has proven extremely difficult because of the large transcript and complex reiterated gene region. We have developed a comprehensive, rapid and efficient molecular assay for detecting mutations in PKD1 and PKD2, using SURVEYOR Nuclease and the WAVE NA High Sensitivity System (Transgenomic), and compared the analysis results to sequencing results reported by a commercial reference laboratory for 25 patient samples. Mutation analysis revealed a total of 90 sequence variants including all 82 changes reported by the reference laboratory (100% sensitivity). 76 variations (84.4%) were in PKD1 and the reminder 14 (15.6%) were in PKD2. Of the 90 variants, 14 were pathogenic mutations, 6 from PKD1 and 8 from PKD2, consisting of 7 nonsense, 4 truncating mutations and 3 splicing defects. The remaining 76 variants included 26 missense, 33 silent and 17 intronic changes, 8 of which were not previously reported by the reference laboratory. Moreover, of the 14 pathogenic mutations, 2 nonsense mutations were incorrectly determined by the reference laboratory to be homozygous mutations. The pathogenic potential of the missense variants was evaluated by evolutionary conservation and Grantham score for chemical difference software. Of the 26 missense variants, 4 were scored as probably pathogenic by all software applications. Overall, pathogenic or probably pathogenic mutations were detected in 21of the 25 (84%) patient samples. Taken together, these results demonstrate that this method is highly accurate and reliable for identifying sequence variations in ADPKD genes.

Elevated mutation rate in late-replicating regions of the human genome. *J. Stamatoyannopoulos[1], I. Adzhubey[2], S. Sunyaev[2]* 1) Dept. of Genome Sciences, Univ Washington, Seattle, WA; 2) Div. of Genetics, Brigham and Women's Hospital, Harvard Medical School, Boston, MA.

Most human mutations arise as replication errors which escape DNA repair. The rate at which mutations arise in different genomic regions is known to be heterogenous in primate and rodent genomes, although the explanation for this is unknown. Regional mutational variation cannot be explained by male bias or by nucleotide contexts. Evidence from yeast suggests that DNA repair may become defective in late S-phase, with correspondingly higher mutation rate. We therefore hypothesized that a similar mechanism may underlie human mutation rate variation. To test this, we analyzed human nucleotide diversity and human-chimpanzee divergence across 44 diverse genomic regions (500kb-1.8Mb in size, collectively 1% of the genome) in which replication timing was measured at high resolution by the ENCODE Consortium. We find markedly elevated levels of human-chimpanzee divergence and human nucleotide diversity in late replicating regions compared to early replicating regions (21% increase in substitution rate and 47% increase in SNP density). Both substitution rate and SNP density closely parallel replication timing in a step-wise gradient from early to late S-phase. We demonstrate that this relationship cannot be explained by either G+C content or recombination rate, nor by the effect of hypermutable CpG di-nucleotides. The data suggest the existence of corresponding gradient in the effectiveness of DNA repair throughout S-phase in human cells. Significantly, the results indicate that the interplay between mutation and selection may vary markedly and predictably between different human gene loci, particularly those located within late replicating regions. Among the latter are numerous genes involved in early development and primitive cellular differentiation, mutations of which are disproportionately implicated in the genesis of human malignancies.

Does genotyping multiple controls help proving causal effect of a mutation? *S. Sunyaev*[1, 2], *G.V. Kryukov*[1, 2] 1) Division of Genetics, Department of Medicine, Brigham & Women's Hospital, Boston, MA; 2) Harvard Medical School, Boston, MA.

Historically, genotyping a hundred of controls has been the most common approach to discriminate between causative mutations and neutral polymorphisms. However, due to observed abundance of low frequency allelic variation in human genes, the reliability of this approach has been questioned. It was also suggested that the number of genotyped controls should be increased to at least two or three hundreds. New systematic re-sequencing datasets help quantifying levels of rare polymorphism in the human population and ultimately resolve whether a missense mutation present in a patient and absent in hundreds of controls should be considered functional at a stringent level of statistical significance. Here we attempt to answer this question by means of computer simulations with parameters of demographic history and strength of natural selection estimated from large systematic re-sequencing datasets. The model very well reproduces site frequency spectrum observed in human re-sequencing data. We consider several scenarios frequently arising in human genetics research and in practice of genetic diagnostics. Our results suggest that absence of a mutation in hundreds of control subjects cannot be considered a reliable indication of the functional significance even for fully penetrant mutations.

Identification of multiple cell lines in a female patient suggests a biological mechanism underlying cell line mosaicism. *S.C. Reshmi[1,2], L.J. Henderson[2], J. Miller[3], D. Deplewski[3], D.J. Waggoner[2,4], S. Schwartz[1,2]* 1) University of Chicago, Chicago, IL. Department of Medicine; 2) University of Chicago, Chicago, IL. Department of Human Genetics; 3) University of Chicago, Chicago, IL. Department of Endocrinology; 4) University of Chicago, Chicago, IL. Department of Pediatrics.

Sex chromosome abnormalities account for close to 0.5% of live births. Of these, many phenotypes are commonly known to be associated with a specific karyotype. However, individuals with mosaic cell lines that include a structurally rearranged sex chromosome cell line appear to have a much less predictable phenotype, and often present with ambiguous genitalia. In this study we report a 2.5 year old female with phenotypic features of Turner syndrome including webbing of the neck, wide spaced nipples, no uterus, and no normal testes or ovaries. Cytogenetic analysis revealed an 45,X/46,X,idic(Y)(p11.2) karyotype. Fluorescence *in situ* hybridization (FISH) mapping of the Y chromosome with probes localized the Yp11.2 breakpoint to a region just distal to *SRY*. We also, however, observed the presence of an additional cell line with a deleted (Y)(p11.2) that was detected mainly in interphase cells. To date, no reports have identified the presence of an 46,XY cell line or 46,X,del(Y) cell line in persons with an 45,X/46,X,idic(Y)(p11.2) karyotype. Our findings suggest a possible mechanism for cell line mosaicism: 1) Sister chromatid breakage during spermatogenesis, resulting in a deletion of the Yp11.2 - Ypter region; 2)Subsequent misdivision of the deleted Y during mitosis resulting in both 45,X and 45,X,del(Y)(p11.2) cell lines, in which the dicentric Y chromosome forms from an attempt to repair double stranded breaks.

Family-based genome-wide mapping of expression trait loci from peripheral blood CD4+ lymphocytes as a powerful means of identifying functional variation. *A. Murphy[1], V. Carey[1], R. Lazarus[1], B. Klanderman[1], J. Sylvia[1], J. Ziniti[1], C. Allaire[1], E. Silverman[1], C. Lange[2], S. Weiss[1], B. Raby[1]* 1) Channing Laboratory, Brigham & Womens Hospital, Harvard Medical School, Boston MA; 2) Harvard School of Public Health, Boston MA.

Regulatory genetic variation contributes substantially to phenotypic diversity, yet few approaches are available for identification of such variation. One proposed solution is expression quantitative trait loci (eQTL) mapping, with preliminary studies demonstrating the potential of this approach in both animal models and human cell lines (i.e. Schadt 2004). Herein we demonstrate both the feasibility and power of eQTL mapping in human populations using RNA derived from freshly harvested peripheral blood CD4+ lymphocytes from 96 young-adults participating in a genetic study of asthma. We generated VSN-normalized gene expression profiles using Illumina HumanRef8 arrays that survey 20,589 RefSeq-curated mRNA transcripts. Genome-wide genotype data (534,290 autosomal SNP, Illumina Infinium 550K array) were available for these subjects and their parents. Family-based association testing was performed (additive model) using PBAT. We screened for cis-acting variants (within 200kb of transcripts), resulting in 1.64 million tests. We adjusted for multiple comparisons using the conditional power screening approach (Van Steen 2005). Significant eQTL associations in 33 genes were observed for 74 of 100 SNP with highest power ($p=10^{-4}$-10^{-12}). This large number of significant associations was observed despite the relatively small sample size, due in large part to the strong genetic effects conferred by these loci (SNP-specific h^2=0.31-0.65). We also note that several of these significant associations have been previously described (Cheung 2005, Qu 2007), suggesting reproducibility. Finally, the power screening method out-performed Bonferroni correction; the latter identified only 30 significant ($p<10^{-8}$) associations. These results highlight the potential of family-based integrative genomic approaches for the identification of functional expression-related polymorphisms. Funding: U01 HL065899, P01 HL083069, R01 HL086601, K08 HL74193.

Copy number variation analysis in the Mexican population. *L. Uribe, A. Hidalgo, L. Del Bosque, R. Goya, J.C. Fernandez, I. Silva-Zolezzi, G. Ramos, A. San Juan, J. Cruz, G. Jimenez-Sanchez* National Institute of Genomic Medicine, Mexico.

Copy number variation (CNV) is an important source of genomic diversity. They can vary in frequency between populations and some have been associated with susceptibility to human disease. We conducted a systematic analysis of CNV in Mexican Populations, using the Affymetrix 500K SNP array. We genotyped 300 Mestizo individuals from six geographically distinct regions of Mexico (50 samples from each region: 25 males and 25 females) and 26 Mazatecan amerindians from Oaxaca. All samples were compared to a randomly selected reference sub-set of 30 females from the same studied population. We used CNAT 4.0 performing quantile normalization with genomic smoothing of 0.1 Mb. The value for the Hidden Markov ploidy priors was set to 0.2 with a 10 Mb transition decay. Our analysis showed a total of 1,682 changes in copy number in the Mexican mestizos. From these alterations, 592 regions (35.2%) showed less than the 2 copies expected for a normal diploid (n=2), and 1,090 (64.8%) showed an increased copy number in the range of 3-5. A total of 35 regions showed CNV in 5% of the samples. The largest region was1.55 Mb (9q12) while the shortest was 6.7Kb (1q12). In the Mazatecan population a total of 238 alterations were found in 5% of the samples, with an average of 9.15 CNVs per sample. From the CNVs detected, 65 (27.3%) were amplifications and 173 (72.7%) had less than the 2 normal copies for a diploid individual. The largest region detected (3.2 Mb) mapped to 9p12-p11.2, while the shortest region (21.7 kb) mapped to 8p23.1. 13% of the CNVs detected in the Mazatecans have not been previously reported in the genomic variants databases. We observed a greater amount of gene containing regions with CNVs in the Mexican mestizos compared to the Mexican Mazatecs. Characterization of these variants in different populations will contribute to a better understanding of their contribution to human disease, and may help define sub-population specific variations.

Geneticists views of societal and ethical implications of research: results from a national survey. *J. McCormick, A. Boyce, M. Cho* Ctr Biomedical Ethics, Stanford Univ, Palo Alto, CA.

While past studies on research ethics have shown that scientists have major concerns about scientific misbehavior, it is also important to characterize a broader spectrum of geneticists concerns -- what considerations do they give to the broader societal and ethical implications of life science research? How do scientists view socially controversial areas of research? Has public discussion of ethical, legal, social, and policy (ELSP) issues in genetics influenced geneticists to think more about the ethical and societal issues of their research? We have conducted a national survey and interviews to determine how and what life scientists think about the relationships between life science and society, and the ELSP implications of their research. We mailed 2000 surveys to seven different institutions across the United States and conducted follow-up interviews. Our sample population included researchers from range of academic positions and a number of departments, including genetics. Our preliminary findings suggest possible differences between genetics researchers and the larger life science population. When asked about ethical and societal concerns a researcher might have in the course of her research, geneticists were more likely to deal with issues around the use of race and ethnicity as a research variable, to encounter unexpected findings in research subjects, and to perceive they work in a field the public finds controversial than the broader life science population. In general, researchers have a broad span of societal and ethical concerns, ranging from specific issues in animal and human subjects research, to socially controversial topics in genetics and stem cell research, to broader issues concerning the environment and natural resources and the nations healthcare system. Finally, nearly all of the scientists were concerned about the increasing politicization of science, yet have mixed views on how scientists, wearing their scientist hat, becoming involved in partisan politics damages the credibility of the scientific community.

Analysis of the Fragile X Mental Retardation Genes in Autistic Individuals. *D. Okou, M. Zwick* Dept Human Genetics, Emory Univ School of Medicine, Atlanta, GA.

Autism spectrum disorders (ASDs) are common, heritable neurodevelopmental disorders. The genetic architecture of ASDs appears to arise from the alleles at a large number of loci. One of the most striking aspects of ASD is the pronounced 4:1 male bias among affected individuals. This suggests that susceptibility alleles on the X chromosome may contribute to ASDs. Triplet repeat expansion mutations at the X-linked FMR1 and FMR2 loci have been shown to cause mental retardation in males. Interestingly, approximately 20-25% of patients with the FMR1 triplet repeat expansion mutation that leads to Fragile X also display symptoms characteristic of ASD. However, screening of the FMR1 and FMR2 genes and surrounding non-coding genomic regions is not routinely conducted. We are comprehensively resequencing the FMR1 and FMR2 loci in order to test the hypotheses that these loci harbor variation that contributes to ASDs. We have used high throughput chip-based resequencing to accurately identify all rare and common variants in male affected sibpairs (ASPs) from the Autism Genetic Resource Exchange (AGRE) collection. Our sample for resequencing consists of 314 cases and 314 controls who share the same region of the X chromosome that includes FMR1 and FMR2. One of the male ASPs is chosen as case, and the corresponding father is selected as control. To isolate our candidate region for resequencing, our novel Microarray-based Direct Genomic Selection (MGS) protocol is being used to isolate target DNA from each sample. Hybridization to a custom RA then determines the DNA sequence. Our initial analyses demonstrate call rates of > 90% with accuracy estimates of fewer than 1 error per 100,000 bases sequenced. SNPs identified are annotated and partitioned into functional classes (UTR, silent, replacement, intron, intergenic) and compared within and between these classes. We will present sequence data from the resequencing of 300 individuals, that describe both the normal levels of variation in addition to alleles that may contribute to ASD.

Replicable evidence that increased parental consanguinity confers substantial risk to Bipolar 1 Disorder in Egypt. *H. Mansour[1, 2], M. Talkowski[1], K. Chowdari[1], J. Wood[1], N. Ibrahim[1], W. Fathi[2], A. Eissa[2], A. Yassin[2], H. Salah[2], S. Tobar[2], H. El-Boraie[2], M. El-Hadidy[2], E. Hussein[2], V. Nimgaonkar[1,3]* 1) Western Psychiatric Institute and Clinic, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania; 2) Department of Psychiatry, Mansoura University Hospitals, Mansoura, Egypt; 3) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, Pennsylvania.

Background: Prior studies have suggested increased consanguinity rates may exist among families of patients with psychoses in certain Middle Eastern populations. Using a retrospective medical record survey, we found that parental consanguinity rates among patients with bipolar I disorder (BP1) were more than double the rates among several sets of independent Egyptian controls. We report here follow-up analyses using a prospective systematic approach to estimate rates of parental consanguinity among (BP1) patients and controls. Methods: Two independent studies were conducted. A community-based epidemiological study involved 2000 participants was conducted through defined geographical areas in Dakahlia Governorate, Egypt. This is followed by a prospective case-control study at Mansoura University Hospital, Egypt. Finally, DNA analysis followed to confirm findings from the prior two studies. Results: The epidemiological study revealed that parental consanguinity rates were higher among BP1 patients compared to the control group (BP1 cases, n = 35; controls; OR = 5.17, 95% confidence intervals, CI: 2.38, 11.23; Chi square = 19.7, $p < 0.0001$). The differences between patients and controls were confirmed during the current prospective case-control study (BP1 cases, n = 93; controls, n = 90, OR = 2.66, 95% CI: 1.34 to 5.29; Chi square = 8.125, p = 0.004). Intial DNA analysis reveals increased homozygosity rates among cases with BP1. Conclusion: Parental consanguinity rates are elevated among Egyptian BP1 patients in the Nile delta region, compared with a range of controls. Recessive inheritance or other factors can explain the results. The replicable results raise public health concerns.

Intestinal malrotation and Hedgehog signaling defects - an epidemiologic study based on the NorCAS database and London Dysmorphology Database. *S. Munir[1], A. Muneer[2]* 1) Institute of Human Genetics, University of Newcastle upon Tyne, Newcastle upon Tyne, United Kingdom; 2) Department of Paediatric Surgery, Birmingham Children's Hospital NHS Trust, Birmingham, United Kingdom.

The Northern congenital abnormality survey (NorCAS) database, based in Newcastle upon Tyne,UK, was used to conduct an epidemiologic study of intestinal malrotation in the surrounding region. This constitutes only the second such study to be undertaken specifically to look at features associated with intestinal malrotation, and with 157 cases (live births and fetal deaths) over more than twenty years, constitutes the largest study of its kind to date. Unlike in the previous study, of cases in Hawaii (Forrester and Merz,2003), under half of case (70 cases - 44.6%) had associated features. In a third of such cases, termination of pregnancy was undertaken. Almost a third of children born with syndromic malrotation died within the first year of life, mainly as neonates. 27% of cases had cytogenetic abnormalities identified. Broadly, the commonest non-gastrointestinal features occuring significantly were cardiac anomalies, renal defects, vertebral anomalies, limb defects, and pulmonary lobar anomalies. Mutant mice with Hedgehog signaling defects exhibit intestinal malrotation and features of VACTERL . A qualitative study undertaken by us prior to the epidemiologic study, using the London Dysmorphology Database (LDDB), had also predicted features of VACTERL to be prominent in many disorders featuring malrotation. Therefore, disorders exhibiting a combination of intestinal malrotation and components of VACTERL may be good candidates to search for Hedgehog signaling defects. Using the LDDB, of the top ten candidate disorders identified as the most likely to involve Hedgehog signaling defects based on these criteria, 3 have been confirmed to involve Hedgehog signaling defects (Pallister-Hall, Smith-Lemli-Opitz and Simpson-Golabi-Behmel). We believe the basis for features of VACTERL being present in a significant proportion of children with intestinal malrotation is that many of them had Hedgehog signaling defects during development, rather than this phenotype representing a developmental field defect.

A two stage association study on chromosome 2q34-37 and fibronectin 1 (FN1) gene in European American case-parent trios with nonsyndromic oral clefts. *J.W. Park[1], I. McIntosh[2], J.B. Hetmanski[3], E.W. Jabs[4], C.A. Vander Kolk[5], S.S. Chong[6], M.D. Fallin[3], R. Ingersoll[4], A.F. Scott[4], T.H. Beaty[3]* 1) Dept. Molecular & Cellular Biology, Sungkyunkwan School of Medicine, Suwon, Korea; 2) Dept. Medical Genetics, American Univ. of the Caribbean, St. Maarten, Netherlands Antilles; 3) Dept. Epidemiology, Johns Hopkins Univ., Baltimore, MD; 4) Dept. Genetic Medicine, Johns Hopkins Univ., Baltimore, MD; 5) Dept. Surgery, Johns Hopkins Univ., Baltimore, MD; 6) Dept. Pediatrics, National Univ. of Singapore, Singapore.

New candidate genes involved in nonsyndromic oral clefts, a common but complex group of birth defects, can be identified through a two stage design that combines fine-mapping of specific chromosomal regions and the subsequent study of candidate genes. This approach may be more cost-effective compared to genome wide screens. We identified a number of suggestive regions showing positive evidence for linkage and disequilibrium with fine mapping panels of 490, 229, 157 and 121 single nucleotide polymorphism (SNP) markers located in each of chromosomal regions: 2q34-37, 3p25-26, 5q31 and 5q35-qter, respectively, in 58 European-American case-parent trios from Maryland. As a second stage of study, a panel of 40 SNPs located near or in the fibronectin 1 gene (FN1 on 2q34) which showed the highest statistical evidence ($p=9x10^{-5}$) through the fine mapping on the 2q34-37 region was evaluated in 97 European-American trios using the transmission disequilibrium test (TDT). Evidence for transmission distortion was observed from either individual markers or sliding windows of haplotypes consisting of 2 to 5 SNPs (the lowest p=0.002). Intronic SNPs, rs12052402 (p=0.022) and rs724617 (P=0.005) in the FN1 and LOC646324 (2q35) genes, respectively, yielded the strongest statistical evidence among 73 trios with nonsyndromic cleft lip with or without palate (CL/P) and among 24 trios with cleft palate only (CP), respectively. While these results are consistent with the complex etiologic heterogeneity of nonsyndromic oral clefts, the contribution of FN1 to susceptibility of oral clefts will require further confirmatory studies.

Genomic Estimates of Inbreeding in the Old Order Amish. *C.V. Van Hout, J.A. Douglas* Department of Human Genetics, University of Michigan, Ann Arbor, MI.

In population isolates, like the Old Order Amish (OOA), complex genealogies with multiple loops often exist. If the genealogies are not fully known, then the inbreeding coefficient may be underestimated. The inbreeding coefficient F is the probability that the two alleles at any autosomal locus in an individual are identical by descent. Underestimation of F may artificially increase the rate of false positive results, e.g., in the context of linkage analysis. Although matings between close relatives, e.g., first cousins, in the OOA are rare, the random component of inbreeding, i.e., the portion due to random mating in a finite population, is the same process as genetic drift and may contribute more to inbreeding through time than close consanguinity. We estimated inbreeding in the OOA of Lancaster County Pennsylvania by connecting 790 individuals into a single 14-generation pedigree with PedHunter (Agarwala et al. 1998) and the Amish Genealogy Database (AGDB 4.0) (Agarwala et al. 2001). These individuals were participants in a family-based genetic study of cardiovascular traits and were previously genotyped for a high-density map of single nucleotide polymorphisms (SNPs). We then estimated F from each individuals genomic information using the maximum likelihood method recently proposed by Leutenegger et al. (2003; 2006) and implemented in their program FEstim. Simulation results suggest that FEstim accurately estimates F given dense marker maps and highly heterozygous markers (Leutenegger et al. 2003). Genomic data, including 2,408 SNPs distributed across the 22 autosomes, were used to estimate F for each individual. The median genealogy-derived F was 0.034 (range of 0.0003 to 0.076), and the median genomic-derived F was 0.032 (range of 0.001 to 0.095). Approximately 50% of FEstim estimates of F were significantly different from zero. However, less than 7% were significantly different from the genealogy-derived F. Notably, the median difference between the genealogy- and genomic-derived inbreeding coefficient was 0.001, and no absolute difference was greater than 0.06. Our results suggest that accurate knowledge of each individuals inbreeding coefficient is given by the genealogy.

Genome-wide association study identifies histamine receptor 4 as a novel Crohn Disease gene. *A.A. Mitchell, L. Mayer, L. Ozelius, M.T. Abreu, R.J. Desnick, NY Crohn Study Group* Mount Sinai School of Medicine, New York, NY.

Crohn Disease (CD) is an inflammatory bowel syndrome that is more frequent among individuals of Ashkenazi Jewish (AJ) ancestry than among non-Jewish Caucasians (NJ). CD is multifactorial, requiring both environmental triggers and predisposing genetic variants. The strongest known genetic risk factors are three coding variants in the CARD15 (NOD2) gene. CARD15 population attributable risk is similar for AJ and NJ, indicating that it is unlikely to be responsible for the higher rate of CD in AJ. In the past year, genome-wide association studies of CD have implicated several new genes, including IL23R and ATG16L1.

To identify additional CD-related genes, we conducted a genome-wide association study of 113 unrelated AJ CD patients and 115 unrelated AJ controls using Affymetrix 500K Mapping Arrays. As expected, CARD15 had the strongest signal, with two SNPs at $p < 10^{-6}$ and six SNPs at $10^{-6} < p < 10^{-4}$. Consistent with previous findings, the minor allele at G1142A in IL23R was associated with protection from CD in this sample ($p = 2.6 \times 10^{-5}$, OR = 0.10). Interestingly, the protective allele is more common among AJ controls than NJ controls and less common among AJ cases than NJ cases. Thus, G1142A does not explain the increased incidence of CD in AJ.

Because CD patients without CARD15 mutations may carry risk alleles in other genes, the analysis was repeated, comparing CARD15 non-carriers (n=59) to controls. The strongest signal mapped to a 90 kb region near the histamine receptor 4 gene (HRH4), with one SNP at $p = 10^{-5}$ and seven SNPs at $10^{-5} < p < 10^{-3}$. The minor allele at each of the eight SNPs was associated with reduced risk.

HRH4 is a G protein-coupled receptor that is primarily expressed on immune cells. HRH4 antagonists modulate cytokine production and have anti-inflammatory effects *in vitro* and *in vivo*. Functional studies to determine the role of HRH4 in CD and to characterize the putative protective variants have been initiated. A replication study of 500 CD cases and 500 controls, equally divided between AJ and NJ, is underway.

A Platform for the Analysis, Translation, and Organization of Whole-Genome Association Data. *M.D. Ritchie, S.D. Turner, W.S. Bush, S.M. Dudek* Center for Human Genetics Research, Vanderbilt Univ, Nashville, TN.

Whole-genome association (WGA) has been proposed as a solution to the challenge of identifying disease susceptibility genes for common, complex disease. Recent technological advances enable genotyping hundreds of thousands, or even 1-million single-nucleotide polymorphisms (SNPs) on thousands of samples. We are hindered in exploiting these laboratory advances because strategies for analyzing these data have not kept pace with these technological advances, thus slowing the pace of improved understanding of the genetic contribution to common human disease. Currently, no single analytical method can extract all available information from a WGA study. Because the genetic architecture for diseases varies substantially and in unknown ways, no single analytic method can be optimal for all datasets. Therefore, an integrative platform is needed that accommodates multiple analytical methods to maximize our information extraction and thus maximize our chances of dissecting complex genetic architectures. We have developed a framework that allows the integration of multiple analytic approaches. This framework can ultimately take advantage of the many exciting, novel methods that have been and are currently being developed for both family-based and case-control genetic association studies. This is crucial due to the number of novel methods being developed and the current inability to integrate these methods in a cohesive manner. PLATO (the PLatform for the Analysis, Translation, and Organization of large-scale data) integrates several analytical and knowledge-based filters to identify the important SNPs in a WGA study. The PLATO software package combines this system with a user-friendly graphical interface that allows any number of filter configurations. We have developed and implemented ten primary filters for the analysis of WGA data. Our simulation results demonstrate that using multiple filters can substantially reduce false positive results, while maintaining high power in WGA studies. PLATO will make a comprehensive analysis of WGA data feasible and provide an integral piece of the WGA puzzle for the human genetics community.

Module eigengene networks and their applications to understanding human disease. *P. Langfelder, S. Horvath*
Dept. of Human Genetics, UCLA, Los Angeles, CA.

One of the challenges in gene expression analysis is the dichotomy between the large number of variables (typically on the order of 20000 genes) and the much smaller number of samples (typically below or around 100). Several data reduction methods have been proposed to capture the relevant information using a smaller set of variables. Here we study a network-based microarray data reduction method relying on module eigengenes as representatives of whole gene modules. We present a set of methods for construction and analysis of eigengene networks. Eigengenes represent the characteristic expressions of modules, while the weighted links represent the relationships between the modules. When augmented by clinical traits such as disease status, eigengene networks provide a natural framework for studying relationships among gene modules and clinical traits. In applications to cancer and a complex disease, we illustrate the use of eigengene networks to (1) identify array outliers, (2) cluster microarray samples (unsupervised learning), and (3) to classify array samples (supervised learning). Our applications indicate that eigengene networks are highly preserved across datasets and that they are a biologically meaningful data reduction scheme.

A Bayesian chromosome peeling algorithm to detect gemonic DNA copy number variations in array CGH data.

L.Y. Wu[1], K.S. Wang[2] 1) Dept of Statistics, University of Waterloo, Waterloo, ON, Canada; 2) Program in Genetics and Genome Biology, The Hospital for Sick Children, Toronto, Canada.

ArrayCGH is a high-throughput technology to generate genomic DNA copy number profiles. It plays an important role in cancer research and diagnosis (Feuk et al., Nature Review Genetics 7, 85-97). We present a Bayesian chromosome peeling algorithm to detect DNA copy number variations in profiles generated by arrayCGH. The algorithm implements a flexible mean-variance shift model for chromosomal segments with different copy numbers. A peeling procedure equipped with Bayes factor was employed to estimate segments boundaries. Compared with current leading methods, it produces comparable accuracies in detecting copy number gain and loss. Furthermore, it has the advantages of ranking chromosomal segments and identifying influential observations, i.e. outliers. The algorithm is also capable of detecting copy number gain or loss at either whole chromosome level or at single probe level. We adopted a data-driven approach to choose hyperparameters in prior distributions, thus minimize the impact of the user-controlled tuning parameters that can be problematic (Lai et al. 2005 Bioinformatics). The algorithm is computationally efficient with complexity of O(n), where n is the number of probes on the chromosome. We illustrate the algorithm with real data analysis and simulation studies.

Expression patterns of organic cation/carnitine transporter family in adult murine brain: Implications for brain development. *A. Lamhonwah[1,2,3], C. Hawkins[2,3], L. Mai[1,2,3], C. Tam[1], J. Wong[1], I. Tein[1,2,3]* 1) Division of Neurology,Dept Pediatrics, Hosp Sick Children, Toronto, ON, Canada; 2) Dept of Pathology,Hosp Sick Children, Toronto, ON, Canada; 3) Dept of Laboratory Medicine and Pathobiology, University of Toronto, Toronto, ON Canada.

Objective: To characterize expression patterns of mOctn1, -2 and -3 in murine brain. Methods: We applied our transporter-specific antibodies to mOctn1,-2 and -3, followed by 20 antibody and DAB peroxidase detection to adult murine brain sections counterstained with hematoxylin. Results: All 3 transporters showed strong expression in the external plexiform layer of olfactory bulb and in olfactory nerve, the molecular layer and neuronal processes of input fibres extending vertically in motor cortex, in the dendritic arborization of cornu ammonis and dendate gyrus, neuronal processes in arcuate nucleus, choroid plexus cells, and neuronal cell bodies and dendrites of cranial nerve nuclei V and VII. In the cerebellum, all three were strongly expressed in dendritic processes of Purkinje cells, but Octn1 and -2 were expressed more strongly than Octn 3 in Purkinje cell bodies. In spinal cord, Octn1,-2 and -3 were prominent in axons and dendritic end-arborizations of spinal cord neurons in ascending and descending white matter tracts, whereas Octn3 was also strongly expressed in anterior horn cell bodies. Conclusions: hOCTN2 deficiency presents with carnitine-responsive cardiomyopathy, myopathy and hypoglycemic, hypoketotic coma with strokes, seizures and delays. In mouse, Octn1,-2 and -3 are expressed in a CNS pattern suggestive of roles in modulating cerebral bioenergetics and in acetylcholine generation for neurotransmission in olfactory, satiety, limbic, memory, motor and sensory functions. This distribution may play a role in the pattern of neurological injury that occurs in hOCTN2 deficiency during catabolic episodes of encephalopathy which may manifest with cognitive impairment, hypotonia and seizures.

Genetic studies in Korean patients with cardiac outflow tract anomalies. *E.J. Seo[1,2,3], M. Hong[3], K.J. Kim[3], Y.H. Kim[3,4], J.K. Ko[3,4], I.S. Park[3,4]* 1) Medical Genetics Clinic & Lab, Univ Ulsan, Asan Medical Ctr, Seoul, Korea; 2) Dept. of Laboratory Medicine, University of Ulsan College of Medicine and Asan Medical Center; 3) Genome Research Center for Birth defects and Genetic disorders, Asan Medical Center; 4) Dept. of Pediatrics, University of Ulsan College of Medicine and Asan Medical Center, Seoul, Korea.

Cardiac outflow tract anomalies is caused by defects of the truncal septation and the secondary heart field during embryogenesis. Many genetic interactions are thought to contribute to the formation of the cardiac outflow tract (OFT). To investigate mutations of the candidate genes, we did genetic analysis in sixty-three Korean patients with OFT anomalies including interrupted aortic arch, truncus arteriosus, coarctation of aorta, etc. Direct sequencing for seven genes such as TBX1, FGF8, FOXP1, GJA1, KCNJ2, ACVR1, and SEMA3C was performed. We identified 8 novel non-synonymous (T268S, N397H, L400Q and G483E in TBX1; T226A and V386E in FOXP1; L8P in FGF8; T562I in SEMA3C), 5 novel synonymous variations (F140, H242, G310 and A311 in TBX1; L196 in ACVR1) and 12 novel non-coding variations in promoter and untranslated regions. Among them, 6 non-synonymous (T268S, L400Q and G483E in TBX1; T226A and V386E in FOXP1; L8P in FGF8) and 6 non-coding variations from 12 unrelated patients were not detected in 100 healthy Korean individuals, suggesting that these mutations could be involved in the malformation of OFT. Particularily, total 9 novel variations of the TBX1 gene were found in this study. Further studies will be necessary to determine the precise contributions of specific mutations of these genes to OFT anomalies.

Association study between the monoamine oxidase A gene (*MAOA*) and schizophrenia: a meta-analysis. *D. Li*[1,2,3], *L. He*[3,4] 1) Laboratory of Statistical Genetics, Rockefeller University, New York, 10021, NY, USA; 2) Bio-X Center, Shanghai Jiao Tong University, Shanghai 200030, China; 3) Institute for Nutritional sciences, Shanghai Institutes of Biological Sciences, Chinese Academy of Sciences, Shanghai 200031, China; 4) NHGG Bio-X Center, Shanghai Jiao Tong University, Shanghai 200030, China.

The human monoamine oxidase A gene (*MAOA*), located on Xp11.23-11.4, has attracted considerable attention as a candidate gene for schizophrenia based both on its chromosomal position and its enzyme function as a key factor in neurotransmitter catabolism pathways. A number of independent studies have attempted to find evidence of association between *MAOA* and schizophrenia, however studies to date have reported inconsistent findings regarding the association of the variable number tandem repeat (VNTR) and T941G polymorphisms, possibly reflecting inadequate statistical power and the use of different populations and methodologies. Therefore we undertook a meta-analysis to establish a comprehensive relationship between the two polymorphisms and schizophrenia across international populations. We have combined all the published case-control and family-based studies using multiple research methods and models. For both allelic and genotypic analyses, the current study investigated global studies as well as sub-studies grouped according to variables including ethnicity (European and Asian ethnic populations) and gender. However, we found no evidence of significant association with the two schizophrenia susceptibility polymorphisms. No publication bias or heterogeneity was found in any of the combined studies (No P(T) or P(Q) < 0.1).

KEY WORDS: chromosome Xp11; linkage disequilibrium; Single Nucleotide Polymorphism (SNP); psychosis.

Positional dislocation of an intact RAR due to inv(17)(p12q22) in a case of acute myeloid leukemia. *K.H. Ramesh[1], D. Wei[1], M. Zohouri[1], H. Ratech[2], R. Shaknovich[2], A. Verma[3], L.A. Cannizzaro[1]* 1) Div. Cytogenetics, Dept of Pathology, Montefiore Med Ctr, Albert Einstein Col Medicine, Bronx, NY; 2) Division Hematopathology, Dept of Pathology, Montefiore Med Ctr., Albert Einstein Col Medicine, Bronx, NY; 3) Department of Oncology, Montefiore Med Ctr., Albert Einstein Col Medicine, Bronx, NY.

A 54-year-old female with a history of metastatic infiltrating mammary tubulo-lobular carcinoma with perineural invasion and micro calcification now presented with pancytopenia. Flow cytometry of the bone marrow revealed 60% CD12+, CD33+, CD117+, CD34+, MPO+ myeloblasts with aberrant expression of CD2. The bone marrow biopsy showed hypocellular marrow (0-10%) containing approximately 20% scattered blasts. The histochemical analysis performed on the paraffin sections of the bone marrow biopsy revealed approximately 20% CD34+ and CD117+ hematopoietic precursors in a hypocellular marrow. Based on these results a diagnosis of acute myeloid leukemia was confirmed. Chromosome and FISH studies were also performed on the bone marrow. Initial interphase FISH analysis with the panel of probes for AML did not reveal any abnormalities including alterations of RAR. However, chromosome analysis revealed an acquired derivative chromosome 17. Further characterization of the der(17) by additional DNA probes localized to the short arm of chromosome 17 along with the RAR probe revealed, that this was an inv(17)(p12q12). A final cytogenetic diagnosis of: 46, XX,inv(17)(p12q22).ish inv(17)(p12q22) (wcp17+,LIS1+,p53+, RAR+,D17Z1+,D17S928) was made. This result confirmed the dislocation of an intact RAR from its original 17q21 position to 17p12 in the abnormal bone marrow cells of this patient. Further molecular studies may elucidate if the presence of RAR in the short arm of chromosome 17 proximal to p53 would have any effect on the prognosis.

Defining the Ciliary Proteome. *Y. Liu[1], J.L. Badano[1], N. Katsanis[1, 2, 3]* 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 2) Wilmer Eye Institute, Johns Hopkins University, Baltimore, MD; 3) Department of Molecular Biology and Genetics, Johns Hopkins University, Baltimore, MD.

The cilia are hairlike organelles projecting from the surface of the cell that distribute nearly ubiquitously in all the vertebrate cells. They are not only in the context of fluid of cell motility as thought tranditionally, but also major sensory function centers to mediate the transmission of several key morphogenetic pathways. These broad roles for cilia are highlighted by the fact that ciliary dysfunction leads to a broad range of human phenotypes.

Considering the importance of the cilium, and its potentially central role in numerous cellular processes, we and others have sought to define and experimentally validate the mammalian ciliary proteome. 10 independent protein sets, each enriched for ciliary molecules have been generated, which have recently been integrated by the Katsanis lab into a single proteome, consisting of some 1,200 human proteins and deposited into a custom-generated unrestricted database (http://www.ciliaproteome.org/, Gherman et al. Nature Genetics 2006).

However, the contents of the ciliary proteome largely remain a computational prediction, requiring validation. Towards that goal, we have initiated a large-scale cell localization study to determine a) which proteins localize to the cilium and/or the basal body and b) how are they perturbed upon introduction of lesions that disrupt ciliary function. We studied their cellular localization by imaging live and fixed ciliated mammalian cells, costained with known centrosomal markers, such as -tubulin. Among the first test set of 96 proteins, 23 show specific patterns of cellular localization. Some of them are centrosomal and basal body proteins, some are aggregate around centrosome and basal body, some are localized in cilium, and some others are expressed in nucleus. We may go on to study the relationship between these proteins with specific cellular localization and the previously known ciliary proteins or microtubule network components.

Clinical diagnostic testing of 450 patients with mental retardation or developmental delay by whole genome array CGH. *D.T. Miller[1,2,4], Y. Shen[1,3], V. Lip[1], X. Sheng[1], K. Tomaszewicz[1], H. Shao[1], H. Fang[1], H. Tang[1], M. Irons[2,4], C.A. Walsh[2,4,5], O. Platt[1,4], J.F. Gusella[3,4], B.L. Wu[1,4]* 1) Laboratory Medicine, Children's Hospital, Boston, MA; 2) Genetics, Children's Hospital, Boston, MA; 3) Center for Human Genetics, Massachusetts General Hospital, Boston, MA; 4) Harvard Medical School, Boston, MA; 5) Howard Hughes Medical Institute.

Array comparative genomic hybridization (aCGH) targeted for known microdeletions and subtelomeric regions is an important but limited approach to the clinical diagnosis of mental retardation (MR). High resolution whole genome coverage improves clinical sensitivity, but enthusiasm is tempered by concerns about interpretation of copy number variants (CNVs). Whole genome aCGH (Agilent 244K) was performed on peripheral blood DNA from 450 individuals with MR or developmental delay. CNVs less than 150kb (~10 consecutive array features) were excluded from analysis. Retained CNVs were compared to the Database for Genomic Variants (as of 3/29/07). Previously unreported CNVs were evaluated using an algorithm based on gene content, OMIM citation, copy number databases, and parental testing. Previously unreported CNVs were identified in 138 of 450 samples. Among samples with unreported CNVs, 47 of 450 samples (10.4%) had a genomic imbalance region greater than 500kb, and 91 of 450 samples (20.2%) had genomic imbalance between 150-500kb. In each of these two groups, a disease-causing gene deletion was identified in 6 cases. High-density whole genome aCGH identifies small and large clinically significant genomic imbalance events in regions that may not be represented on a targeted array. Although whole genome coverage identifies many CNVs that are not clearly clinically relevant, this method significantly improves the yield of aCGH in the clinical setting.

Predicting Pathogenicity of *NF1* Missense Mutations. *R. Loda[1], D. Driscoll[2], M. Wallace[1,2]* 1) Department of Molecular Genetics and Microbiology, University of Florida, Gainesville, FL; 2) Department of Pediatric Genetics, University of Florida, Gainesville, FL.

Mutations in the neurofibromatosis 1 (*NF1*) gene cause this autosomal dominant disorder affecting 1 in 3,000 births, in which individuals are predisposed to multiple tumors. Hundreds of different *NF1* gene mutations are known, of all types and sizes. Most of these are clearly disruptive, predicted to result in reduced, absent, or truncated protein (neurofibromin), the cellular effects of which are not fully understood. Missense mutations are a diagnostic challenge because a priori they can be pathogenic or neutral polymorphisms. Further, most *NF1* missense mutations are nearly impossible to test functionally. In NF1, missense mutations account for 10-20% of germline lesions. Novel missense mutations identified in patients must first be tested to see if splicing errors instead of amino acid substitution occurs. If not, and there is no useful information from the family or literature, other methods must be used to predict the mutation's pathogenicity. This is crucial, as it may determine if the patient is diagnosed with NF1. Therefore, we examine the fidelity of computational tools designed to predict the pathogenicity of missense mutations. Recently, new computational tools have been developed that exploit increasing genome sequence and structural data. Several comparisons of the fidelity of these programs are available. As neurofibromin is larger and more complex than proteins analyzed previously, it should be a robust test of the efficiency and accuracy of these programs. To establish accuracy, a data set including mutations known to be pathogenic, neutral, and those from functional studies of neurofibromins isolated Gap-related domain is used. An experimental set of several novel mutations of unknown pathogenicity is also analyzed. The *NF1* gene has proven a challenge for these programs, but through analysis we have gathered data about user interfaces, pitfalls, and nuances needed for their accurate application to predicting pathogenicity of *NF1* missense mutations. This data will be useful for diagnostic labs that need to provide predictive information on missense mutations.

Prenatal diagnosis of a 9q34.3 microdeletion by array-CGH in a fetus with an apparently balanced translocation.

S.A. Yatsenko[1], M.J. Simovich[1], M.E. Dudek[4], A. Pursley[1], P.A. Ward[1], S.W. Cheung[1], E.K. Brundage[1], C.A. Chinault[1], A. Patel[1], J.R. Lupski[1,2,3] 1) Dept Molec & Human Genetics; 2) Pediatrics, Baylor College of Medicine, Houston, TX; 3) Texas Children Hospital, Houston, TX; 4) Obstetrics and Gynecology, Vanderbilt University Medical Center, Nashville, TN.

The 9q34.3 microdeletion syndrome is a recently identified condition and only after molecular technologies were applied in chromosome studies. Patients with 9q34.3 terminal deletion exhibit a clinically identifiable phenotype characterized by specific craniofacial features, hypotonia, childhood obesity, microcephaly, and substantial speech delay (CHOMS). It has been recognized as one of the most frequent subtelomeric aberrations identified in live births. However, little is known about the impact of such rearrangements for pregnancy outcome and prenatal course. We report the first prenatally detected case of the 9q34.3 microdeletion syndrome. A 42-year-old pregnant female was referred at 14 weeks of gestation for genetic counseling due to an abnormal ultrasound with increased nuchal translucency. G-banded chromosome analysis was performed on chorionic villus sample (CVS), and showed an apparently balanced *de novo* translocation: 46,XY,t(2;9)(q11.2;q34). Using targeted array-CGH we identified a submicroscopic 9q34.3 deletion in a fetus, revealing the unbalanced nature of the rearrangement. Deletion of the 9q34.3 region was studied further by implementing a custom 9q34.3 tiling path fosmid-based and oligonucleotide-based array-CGH analyses to enable higher resolution genome investigation. The deletion was delimited to 2.7 Mb in size encompassing at least 98 genes, and includes the *EHMT1* gene located within the 700 kb critical interval. The identification of cryptic 9q34.3 microdeletion in our case illustrates the importance and clinical relevance of high resolution genome analysis by array-CGH in prenatal diagnosis. Precise molecular characterization is essential for further prenatal and postnatal clinical management, and informed decision making.

Genome-wide association study of QT interval duration and staged validation. *C. Newton-Cheh[1,2,3,4], X. Yin[2,5], A-J.L.H.J. Aarnoudse[7,8], P.I.W. deBakker[1,3,4], A. Surti[1], A.G. Uitterlinden[7], M.G. Larson[6], B.H.C. Stricker[7,8], C.J. O'Donnell[2,3,4], J.N. Hirschhorn[1,4,9]* 1) Broad Inst of Harvard & MIT, Cambridge, MA; 2) NHLBIs Framingham Heart Study, Framingham, MA; 3) Massachusetts General Hosp, Boston, MA; 4) Harvard Medical Schl, Boston, MA; 5) Boston University Schl of Public Health, Boston, MA; 6) Boston University Schl of Medicine, Boston, MA; 7) Erasmus Medical Ctr, Rotterdam, Netherlands; 8) Inspectorate for Healthcare, the Hague, Netherlands; 9) Childrens Hosp of Boston, MA.

Electrocardiographic QT interval (QT), a heritable quantitative trait is associated with sudden cardiac death when prolonged or hastened. With collaborators, we identified through a modest genome-wide association study (GWAS) a common SNP in *NOS1AP* associated with QT (Arking et al *Nat Gen* 2006). We report a larger GWAS of continuous QT interval duration with staged follow up. From an initial QT GWAS of 70,987 polymorphic SNPs (Affymetrix 100K) in 1175 Framingham Heart Study (FHS) men and women, we selected the top 162 SNPs to genotype in 1531 independent FHS men and women (stg II). Of 152 SNPs genotyped successfully (95% call rate, HWE $p>0.001$) in the stage II sample, weighted joint analysis with stage I data identified 3 loci with $p<10^{-4}$. Locus #1 included rs1932933 in *NOS1AP* with 14.6% SD (SE 2.4%) increase in sex-, age- and RR-interval-adjusted QT per minor allele ($p=5x10^{-7}$). Locus #2 included rs10503034, associated with a 13.2% SD (SE 2.6%) increase in adjusted QT per minor allele ($p=2x10^{-5}$). Locus #3 included rs1202113 associated with 12.6% SD increase in adjusted QT per minor allele ($p= 1x10^{-5}$). *NOS1AP* SNPs were recently confirmed to be associated with QT in 6571 Rotterdam Study (RS) men and women ($p<10^{-19}$, Aarnoudse, Newton-Cheh et al *Circulation* in press). We also genotyped rs10503034 and rs1202113 in RS men and women and found no evidence of association of rs10503034 with adjusted QT ($p=0.98$) and modest association of rs1202113 with a 3.7% SD (SE 1.7%) increase in adjusted QT per minor allele (2-tailed $p=0.03$). SNP rs1202113 is 54kb upstream of *KCNQ5*, a potassium channel not previously known to modulate myocardial repolarization. Further study of this gene is warranted.

Acatalasemia: molecular evolutionary inferences into the nature of the mutation. *A.M. Smits, S.E. Braik, L.A. Tollini, B.J. Carr, E.S. Tignor, K.A. Eskay, N.J. Schisler* Biology Department, Furman Universiity, Greenville, SC.

Acatalesemia, a deficiency in catalase (CAT) activity, has been described in many human populations; similar phenotypes exist in the guinea pig, dog, domestic fowl, and mouse. Shaffer and Preston (1990) showed that the acatalesemic mouse harbored a CAG-to-CAT transversion in codon 11, but this lesion cannot fully explain the complex tissue -specific phenotype associated with murine acatalesemia. Mouse CAT activity levels have been shown to be variable among different strains, tissues, and developmental stages (Schisler and Singh, 1991) and may be affected by uncharacterized loci such as Ce1 (affects liver CAT), and Ce2 (affects kidney CAT). The 3' untranslated region (UTR) of the mouse CAT gene also binds distinct cytoplasmic proteins that could also regulate CAT activity (Reimer and Singh, 1996). To further assess the nature of the mouse acatalesemic phenotype, we have applied bioinformatic and comparative genomic methods to study CAT gene (approx. 30 kb consisting of 13 exons that produces a mature transcript of 2613 bp) sequences from several inbred mouse strains including C3Ga.Cg-Catb/J (acatalesemic mutant), BALB/cJ (high level CAT activity), C57Bl/6J (hypocatalasemic), and mouse strains 129P1/ReJ, C3H/HeSnJ, and DBA, as well as several other mammalian species. Comparative mouse data would be valuable to assess regions of the gene that change rapidly (i.e. introns) whereas other mammalian species could be used to identify highly conserved regions. Analyses indicated intron positions among the various CAT genes were highly conserved but intron lengths and sequence had varying levels of conservation depending on the size of the intron and relative location within the gene. Many introns in the 5 end of the CAT gene had numerous repeated motifs as well as putative transcription factor binding domains. Intron 7 in some mouse strains shared 60.7% identity with its human counterpart. This approach of using phylogenetically close and distant strains/species to determine relative mutatbility/conservation of gene sequences could assist with the elucidation of the nature of disease-associated genes in humans and other species.

Deletions of Tenascin-X are associated with joint hypermobility and features of Ehlers-Danlos syndromes in a cohort of Congenital Adrenal Hyperplasia (CAH) patients. *N.B. McDonnell[1], W. Chen[1], B.F. Griswold[1], A.C.M. Smith[3], M. Berk[2], C. VanRyzin[2], D. Merke[2]* 1) LCI, NIA/NIH, Baltimore, MD; 2) NICHD/NIH, Bethesda, MD; 3) NHGRI/NIH, Bethesda, MD.

Congenital adrenal hyperplasia (CAH) due to 21-hydroxylase deficiency is thought to be the most common autosomal recessive disorder, leading to cortisol deficiency, with or without aldosterone deficiency (salt wasting), and androgen excess (virilization). The gene encoding 21-hydroxylase, CYP21A2, is mapped to the short arm of chromosome 6 within the HLA complex, in a region of high gene density with multiple pseudogenes. This region, termed the RCCX module, has tandem repeat sequences that promote misalignment during meiosis leading to gene rearrangements, deletions and gene conversion events. Flanking CYP21A2 is the gene encoding tenascin-X (TNX), an extracellular matrix protein that is highly expressed in connective tissue. Homozygous TNX deficiency has been proposed as a cause of autosomal recessive form of Ehlers-Danlos syndrome (EDS) characterized by hypermobile joints, stretchy skin and easy bruising and hypermobility type EDS has been linked to heterozygosity for TNX mutations. A high incidence of joint hypermobility was noted in a large cohort of CAH patients with genetically confirmed CAH due to 21-hydroxylase deficiency seen at the National Institute of Child Health and Development. Molecular investigations of the RCXX module were initiated to analyze the presence of TNX deletions and gene conversion events, utilizing Southern blotting and PCR approaches. Out of 96 probands with CAH and 83 family members, 12 subjects were found to be heterozygous for a non functional TNX gene conversion product resulting from a 30 kb deletion. All of these persons also had deletions of the CYP21A2 gene. Results suggest that 6-7% of persons affected with CAH may also have TNX deletions leading to joint abnormalities. CYP21A2 deletions were detected in 30% of the chromosomes in the cohort, and amongst those subjects, 11% also had a TNX deletion. Further studies are underway to better define the clinical, molecular and biochemical aspects of this novel CAH-TNX (CAH-X) Contiguous Gene Deletion Syndrome.

Development and establishment of cell cultures from placental tissues for the study of confined placental mosaicism. *J.A.M.A. Tan[1], K.K. Ho[2], P.C. Tan[1]* 1) Department of Molecular Medicine, Faculty of Medicine, University of Malaya, Kuala Lumpur, Malaysia; 2) Department of Obstetrics & gynaecology, Faculty of Medicine, University of Malaya, Kulal Lumpur, Malaysia.

Cell cultures orginating from placental tissues are necessary for the study of confined placental mosaicism, defined as the presence of chromosomal abnormalities in placental tissues. A critical step in research in confined placental mosaicism, which has been associated with poor pregnancy outcomes, is the successful culture of primary trophoblast cells. Establishment of primary trophoblast cell cultures was carried out using the direct tissue explant methods and tissue dispersion with enzmye digestion methods. In addition, Percoll density gradient centrifugation was evaluated for purification of homogenous cell populations.

Tissue samples were extracted from human placentas from full term pregnancies with signed consent from subjects involved. Adherence of cells from explanted tissues was observed after two weeks of culture. Attachment of explanted tissues was accompanied by rapid production of newly dividing cells as observed by outgrowth of cells from the edges of the explanted tissues. The tissue dispersion method involved trypsin-dispersed cell suspensions followed by Percol purified cytotrophoblast cells for the initiation of *in vitro* primary cell cultures. Out of the 80 placentas collected, metaphases were successfully harvested and analysed from 12 samples (12%), and out of theses 12 placentas with successful proliferating cultures, 24 karyotypes were obtained and analysed.

High-resolution whole-genome mapping of allele-specific human chromatin structure. *R. Sandstrom[1], M. Dorschner[1], M. Kuehn[1], S. Neph[1], J. Goldy[1], A. Haydock[1], M. Hirst[2], S. Jones[2], M. Marra[2], J. Stamatoyannopoulos[1]* 1) Dept. of Genome Sciences, University of Washington, Seattle, WA; 2) Genome Sciences Centre, BC Cancer Agency, Vancouver, BC.

WWe used Solexa sequencing to map >50 million individual in vivo DNaseI cleavage sites across the human genome at nucleotide resolution ('digital DNaseI'). In hundreds of human promoters and distal regulatory sequences marked by DNaseI hypersensitive sites in lymphoblast, neuroblast, and hepatocyte chromatin, the DNaseI cleavage patterns visualized by digital DNaseI are sufficiently dense to reveal the stand-specific 'footprints' of individual DNA binding proteins. In regions immediately flanking DNaseI hypersensitive sites, positioned nucleosomes can be readily identified by the characteristic ~10bp period of DNaseI cutting events in the minor groove of DNA. Dense sequence reads permit the recognition of known human polymorphisms, and thereby allele-specific assignment of DNaseI cleavage sites and analysis of chromatin structure. Outside of known imprinted regions, numerous genomic regions exhibit skewed allelic distributions of chromatin accessibility, including individual cis-regulatory sequences that are preferentially activated on maternal or paternal alleles. We also identified characteristic chromatin accessibility patterns at known structural anomalies of human chromosomes including translocation breakpoints, fragile sites, recombination hotspots, and radiation-sensitive domains. Digital DNaseI mapping has the potential to increase dramatically the scope and resolution of chromatin structural analyses of genome function and human disease.

In depth investigation of -1 frameshifting in expanded CAG repeat tracts using time-lapse live-cell imaging. *S. Stochmanski, C. Gaspar, D. Rochefort, P. Hince, J. Laganiere, G.A. Rouleau* Centre for the Study of Brain Diseases, CHUM Research Centre, Montreal, QC, Canada.

Rationale: Spinocerebellar ataxia type 3 (SCA3) results from an expansion of a polyglutamine-encoding CAG tract in the *ATXN3* gene. We have previously demonstrated that this expanded CAG tract is subject to -1 ribosomal frameshifting into the alanine frame, which seems to confer an increased toxicity, and that the antibiotic anisomycin reduces both -1 frameshifting and cell toxicity. **Aims:** The objectives of this work are (1) to perform a characterization of the mechanism of -1 frameshifting within large CAG repeats and (2) to compare the inherent properties of constructs containing expanded CAG *versus* CAA repeats, using a real-time live-cell assay. **Methods:** Time-lapse live-cell two-wave fluorescent microscopy was performed using several doubly tagged constructs: pDsRED was ligated N-terminally to *ATXN3* constructs, to be expressed in the main (glutamine) frame, whereas EGFP was fused at the C-terminus in the -1 (alanine) reading frame. Reporter constructs had either 14 CAG repeats, 89 CAG repeats or 92 CAA repeats. Constructs were transfected into COS-1 cells and live cells were monitored for the production of red or green fluorescent signals on a Leica live-stage microscope, for periods of 48 hours. **Results:** We confirmed the occurrence of -1 frameshifitng for the CAG_{89} construct, at a rate of approximately 20 percent (measured by the ratio of green to red fluorescent cells). Constructs bearing wild-type CAG or expanded CAA repeats did not show significant frameshifitng. We also determined that pDsRED expression (glutamine frame) first appears approximately 8 hours post transfection, whereas EGFP is expressed approximately 16 hours post transfection. **Conclusions:** These results suggest that there is a marked time delay between the onset of glutamine-containing protein expression and the production of frameshifted species. This finding argues in favor of local glutamine codon starvation, followed by a shift in the reading frame to resume translation of the protein in the alanine frame.

Genome-wide Association Identifies a Novel Asthma Pharmacogenetic Locus. *K.G. Tantisira[1], A. Murphy[1,2], A.A. Litonjua[1], J. Lasky-Su[1,2], R. Lazarus[1], B. Klanderman[1], E.K. Silverman[1], C. Lange[2], S.T. Weiss[1]* 1) Channing Laboratory, Brigham & Women's Hospital and Harvard Medical School, Boston, MA; 2) Harvard School of Public Health, Boston, MA.

Introduction: Pharmacogenetic identification of loci influencing response to medications has been largely limited to candidate gene approaches. We hypothesized that genome-wide association testing would permit the rapid identification of novel pharmacogenetic genes associated with response to inhaled corticosteroids in asthma. **Methods:** Using genotype data from the Illumina HumanHap550 BeadChip, we performed a genome-wide association screen on 118 Caucasian trios taking inhaled corticosteroids as part of the Childhood Asthma Management Program clinical trial. A total of 534,290 autosomal SNPs met quality thresholds (MAF >0, completion rate >90%, <1% Mendelian inconsistency, <0.1% discordancy among replicates) and were included in the analysis. We applied the PBAT screening algorithm (Ionita-Laza et al., 2007) to family-based association tests using principal components methodology (FBAT-PC; Lange et al., 2004) to screen for association with 6 lung function measures taken over 16 months. After ranking SNPs in order of statistical power, SNPs were formally evaluated by FBAT testing using a weighted hypothesis-testing approach. **Results:** One SNP, rs2978473, met the strict screening criteria. This SNP maps to the mitochondrial solute carrier protein (MSCP) gene, a gene that has not been previously associated with asthma or corticosteroid response. **Conclusion:** A novel asthma pharmacogenetic locus for inhaled corticosteroid response has been identified via FBAT screening of genome-wide association data. Formal replication studies in other asthma clinical trial populations are underway.

The distribution of a human specific interstitial telomere like sequence at 22q11.2 in normal population. *O. Samassekou, J. Yan* Dept Medical Genetics, Sherbrooke Univ (CHUS), Sherbrooke, PQ, Canada.

Interstitial telomeric sequences (ITSs) and telomere-like repeats at intrachromosomal sites are common in mammals. We previously reported the presence of ITS at 22q11.2. This sequence is constituted of tandem repetitive 9-base monomers, TTAGGGAGG or TTATGGAGG, covering 909 bp. The proximity of this ITS to the common rearrangements region of multiple disorders such as DiGeorge syndrome and chronic myeloid leukemia, and the instability of ITSs may suggest the involvement of ITS at 22q11.2 in the pathogenesis of these disorders. Before scrutinizing its status in these different pathologies, we studied its distribution in normal population. We studied 50 normal people including members of 10 distinct families. The use of the primed in situ labeling (PRINS) technique with primers specific to ITS at 22q11.2 enabled us to detetect this ITS with high frequency. Moreover, we noticed different patterns of distribution from subject to subject. The use of the PCR technique by using primers flanking the ITS at 22q11.2 confirmed this result. We unexpectedly found different patterns ranging from 1 Kb to 4 Kb, and 90% of these patterns are more than 1Kb (the expected size of PCR product). We concluded that this sequence is highly polymorphic. The linkage analysis study of ITS at 22q11.2 in members of the 10 different families has showed a strong relation between offspring and parents. This result opens an avenue for the use of this sequence as an allelic marker. All these results can serve as foundation for the study ITS at 22q11.2 in relation with the genomic instability.

Micronuclei in diabetes: folate supplementation diminishes micronuclei in diabetic patients but not in an animal model. *M.L. Ramos-Ibarra[1], C.M. Batista-González[1], B.C. Gómez-Meda[1], A.L. Zamora-Perez[2], T. Muñoz-Magallanes[3], C. Ramos-Valdés[3], M.P. Gallegos-Arreola[4], G.M. Zúñiga-González[1]* 1) Laboratorio de Mutagénesis, CIBO, IMSS, Guadalajara, Jalisco, Mexico; 2) Laboratorio de Farmacogenómica y Biomedicina Molecular, CIIDIR, IPN, Durango, Dgo., México; 3) Servicio de Endocrinología, Unidad Médica de Alta Especialidad, Hospital de Especialidades, Centro Médico Nacional de Occidente Lic. Ignacio García Téllez, IMSS, Guadalajara, Jal., México; 4) Laboratorio de Genética Molecular, CIBO, IMSS, Guadalajara, Jal., México.

Diabetes mellitus (DM) is associated with a high risk of health complications, mainly due to excessive free radical (FRs) production that could result in an increased frequency of micronuclei. The consumption of antioxidants, like folic acid (FA), may mitigate the effects of the FRs. Micronucleated polychromatic erythrocyte (MNPCE) frequencies were determined in blood sampled weekly from the tails of pregnant female Wistar rats and pregnant Wistar rats with experimental diabetes that were given unsupplemented diets and diets supplemented with FA. At birth, the pups were sampled to analyze micronucleated erythrocyte (MNE) and MNPCE frequencies. Micronucleated cells (MNCs) were evaluated in buccal mucosa samples taken from 81 healthy adult subjects, 48 patients with DM, and 30 DM patients who were sampled before and after FA treatment. Increases in MNPCE frequencies were significant only at the first sampling (P0.01 and P0.03) in pregnant rats with experimental diabetes. Pups from the diabetic group and from diabetic group treated with FA had higher frequencies of MNEs (P0.03 and P0.001, respectively) and MNPCEs (P0.009 and P0.05, respectively) than controls. No differences were found in diabetic rats and newborn rats born to diabetic mothers treated with FA compared with untreated animals. Patients with DM had a higher frequency of MNCs compared with healthy subjects (P0.001). FA reduced the frequency of MNCs in DM patients (P0.001). These results indicate that diabetes results in elevated frequencies of micronuclei, and that, at least in humans, FA can protect against the elevation.

Mapping Quantitative Trait Loci of Complex Traits Based on Zygotic Linkage Disequilibrium. *S. Wu, T. Liu, J. Yang, J.S. Yap, W. Hou, R.L. Wu* Department of Statistics, University of Florida, Gainesville, FL.

Linkage disequilibrium-based mapping that capitalizes on historical recombinant events has proven to be powerful for detecting quantitative trait loci (QTLs) that control a complex trait in a natural population. This approach, founded on the non-random association between markers and QTL at the gametic level, requires the population mapped to be in Hardy-Weinberg equilibrium (HWE), which may not be a case for many genetically informative isolated populations. Here, we present a new QTL mapping approach based on linkage disequilibria at the genotypic or zygotic level by accommodating the deviation from HWE. This approach allows joint or separate estimation of Hardy-Weinberg disequilibrium at individual loci, gametic and non-gametic linkage disequilibria, trigenic, and quadrigenic linkage disequilibria between the markers and QTLs. By testing these different types of disequilibria, we generalized framework for inferring the existence of the underlying QTL for a complex trait. We performed simulation studies and real data analyses to investigate the statistical properties of this approach and validate its utilization. This approach will open a general gateway for studying the detailed picture of the genetic architecture of quantitative variation in natural populations.

Autophagy induction is a two-edged sword in the polyglutamine disease X-linked spinal and bulbar muscular atrophy (SBMA): evidence for a temporal disconnection between protection and toxicity. *J.E. Young[1], N. Gill[2], R.A. Martinez[1], G.A. Garden[2], A.R. La Spada[1,2]* 1) Dept Laboratory Medicine, Univ Washington, Seattle, WA; 2) Dept Neurology, Univ Washington, Seattle, WA.

Autophagy, a pathway that mediates intracellular degradation, has recently been studied in a variety of human disorders. Although autophagy induction reduces misfolded protein toxicity, persistent and excessive autophagy activation may be deleterious and contribute to neurodegeneration. In a YAC mouse model for the polyglutamine (polyQ) repeat disease SBMA, we noted significantly increased autophagosome formation in degenerating motor neurons in comparison to non-transgenic and control transgenic mice (26% vs. 5% and 2%; p .05). To determine the role of autophagy in SBMA, we obtained transgenic mice expressing GFP tagged to LC3, a component of the autophagosome. In primary cortical neurons induced to undergo autophagy by rapamycin treatment or nutrient deprivation, we noted that GFP-LC3 undergoes an expected distribution change from diffuse to punctate, and that LC3 is processed, as expected, by Western blot analysis (p .05; p .01). We could block autophagy in neurons with 3-methyl-adenine (3-MA) (p .01), or by shRNA knock-down of beclin-1 (p .01). Using this model, we tested if polyQ androgen receptor (AR), the cause of SBMA, induces autophagy. Transfection of GFP-LC3 neurons with truncated AR (AR112Q vs AR16Q) induced autophagy in a polyQ length-dependent manner (p .01). To determine if autophagy is beneficial or detrimental, we transfected neurons with AR112Q and treated with 3-MA for 4, 12, or 24 hrs. Neurons treated for 4 hrs displayed increased toxicity, while those treated for 12 or 24 hrs were protected. Co-transfection with beclin-1 shRNA for 24 hrs also yielded protection (p .01). These data suggest that autophagy is activated in neurons in response to misfolded proteins. However, while autophagy may initially protect the neuron, prolonged autophagy activation may contribute to neurodegeneration. As autophagy inducers are being considered as a therapy for such diseases, our results indicate that the timing of autophagy induction may be a critical factor in their use.

Celsius: A Community Resource for Genomic Data. *B.D. O'Connor, A. Day, M.R.J. Carlson, J. Dong, S. Nelson*
Department of Human Genetics, David Geffen School of Medicine, UCLA, Los Angeles, CA.

The Celsius project is a data warehousing effort designed to import, store, query, and export large amounts of primary Affymetrix microarray data in a format appropriate for meta-analysis along with associated annotations. Currently over 82,000 CEL files, representing 15 billion assay measurements, are available in the system and a pipeline for automated quantification using best practices has been established. Celsius is the largest public repository of CEL file level microarray data and enables sophisticated, novel questions to be asked about the transcriptome. For instance over 20,000 human hybridizations on U133A, U133B and U133_2.0 exist, and data can be retrieved within Bioconductor. Recently, Celsius has been expanded to include support for Solexa's next generation sequencing technology. This adaptation includes the representation of Solexa experimental meta data along with the encapsulation of the base calling process into the Celsius workflow and the storage and retrieval of approximately 1 billion base pairs of sequences generated per run. The capability to process both Affymetrix CEL file data as well as Solexa sequence data demonstrates the systems inherit flexibility to represent and process data from a variety of high-throughput genomic methods. As new technologies develop, Celsius will continue to provide a natural point of integration.

Genome-wide association scan for height in 6,671 individuals from Finland and Sardinia. *S. Sanna[1,2], A.U. Jackson[1], G. Usala[2], C.J. Willer[1], M. Dei[2], L.L. Bonnycastle[3], S. Lai[2], Y. Li[1], M. Uda[2], M.R. Erdos[3], H. Shen[4], A. Shuldiner[4], A. Cao[2], R.M. Bergam[5], D. Schlessinger[2,6], F.S. Collins[3], M. Boehnke[1], G.R. Abecasis[1], R. Nagaraja[5], K.L. Mohlke[7]* 1) Dept Biostatistics, Univ Michigan, Ann Arbor, MI; 2) National Human Genome Research Institute, Bethesda, MD; 3) Istituto di Neurogenetica e Neurofarmacologia (INN), CNR, Cagliari, Italy; 4) University of Maryland, School of Medicine, Baltimore, MD; 5) Keck School of Medicine of USC, Los Angeles, CA; 6) Gerentology Reasearch Center, NIA, Baltimore, MD; 7) Dept Genetics, University North Carolina, Chapel Hill, NC.

Height represents a classic example of a highly heritable quantitative trait. In our sample, heritability analysis shows that genes can explain >80% of the variation in height. Nevertheless, with the exception of a few rare Mendelian syndromes, gene-identification has proved difficult despite many parallel mapping efforts. Genetic influences on height are probably due to the contribution of several loci of small effect. We have carried out a meta-analysis of genome-wide association results from two different groups, ProgeNIA and FUSION. The first sample consist of 4,305 individuals from 570 families from Sardinia, the second includes 2,366 mostly unrelated Finnish individuals. Since the two groups worked with two different platforms (Illumina 300K and Affymetrix 500K respectively), SNPs appearing only in one platform were imputed to allow direct comparison of results across studies. To control inflation of type I error due to outliers and departure from normality, quantile normalization was applied to each trait prior the analysis. In both GWA scans, we evaluated the additive effect of each SNP, adjusting the model for familiality and covariates. In our combined results, the top associated SNP (p=4.0*10-7) maps to a region of LD containing several genes, including one previously implicated in growth. Replication is ongoing, but preliminary results on 2017 Finnish and 858 Amish samples support our initial finding (p=1.7*10-3), with the same direction of effect. Further detailed SNP analysis of the region is necessary to refine the responsible gene.

The pharmacological chaperone AT2101 increases -glucocerebrosidase levels in macrophages and lymphoblasts derived from Gaucher patients. *C.W. Pine[1], B.E. Ranes[1], F. Insinga[1], K. Ludwig[1], G.A. Grabowski[2], N.J. Weinreb[3], G.M. Pastores[4], D. Gruskin[5], P. Kaplan[6], H. Do[1], D.J. Lockhart[1], B.A. Wustman[1]* 1) Amicus Therapeutics, Cranbury, NJ; 2) Division of Human Genetics, Cincinnati Childrens Hospital Medical Center, Cincinnati, OH; 3) Univ. Research Foundation for Lysosomal Storage Diseases Inc, Northwest Oncology Hematology Associates, Coral Springs, FL; 4) Departments of Neurology and Pediatrics, New York Univ. School of Med., Atlanta, GA; 6) Section of Metabolic Diseases, Childrens Hospital of Philadelphia, Univ. of Penn School of Med., Philadelphia, PA.

Gaucher disease (GD) is caused by a deficiency of -glucocerebrosidase (GCase). Deficient GCase activity leads to symptoms such as anemia, thrombocytopenia, hepatosplenomegaly, bone necrosis, infarcts, osteoporosis and in some cases, neuropathic disease. The pharmacological chaperone AT2101 selectively binds and stabilizes N370S-GCase in the ER and increases its trafficking to the lysosome. To evaluate the effects of AT2101 on different GCase variants, we conducted an ex vivo response study using macrophages and EBV-transformed lymphoblasts. Plasma was also screened for potential biomarkers associated with inflammation, bone metabolism, multiple myeloma and neurodegeneration. The study was conducted on samples from 53 patients enrolled at 5 sites in the United States. Results: The study included 26 males and 26 females with type I GD, and one male with type III GD. Patients ranged in age from 7 to 83 years; 50 of 53 patients were receiving enzyme replacement therapy and blood was drawn prior to enzyme infusion. Analysis of 40 markers showed elevated chitotriosidase activity, TRACP 5b, PARC, IL-8, IL-17, VEGF, MIP-1 and -synuclein and reduced bone-specific alkaline phosphatase levels in some patients. Incubation with AT2101 increased GCase levels in macrophages or lymphoblasts derived from 52 of 53 patients (mean=2.6-fold, range:1.4- to 8.6-fold) with mutant alleles including N370S, L444P, 84GG, R163X, Y212H, Y135X, V394L, R120Q, A190E, L324P, IVS2(+1), del 136T, F216Y, L174F, A90T, R463C, G202R, K79N and complex B exon 9/10.

A novel mutation in TPM2 causes distal arthrogryposis type 2B in a Chinese family. *X. Zhao, X. Zhang* Chinese Academy of Medical Sciences & Peking Union Medical College, Beijing, China.

Distal arthrogryposes (DAs) are a group of clinically and genetically heterogeneous disorders, characterized by multiple congenital contractures of limbs. The characteristic primary limb malformations in DAs include bilateral and symmetric clenched fist, overlapping fingers, camptodactyly, ulnar deviation of fingers, and positional foot deformities such as talipes equinovarus. Ten different forms of DAs have been recognized and classified. The prototypic DA type 1 (DA1, MIM 108120) has no additional abnormalities. Among the other nine forms with additional features, DA type 2A (DA2A) has facial phenotypes including a very small orifice, H-shaped dimpling of the chin, prominent nasolabial folds, increased philtrum length, small nose, blepharophimosis, deep-sunken eyes with hypertelorism. Severe scoliosis may also be present in some cases. DA type 2B (DA2B, MIM 601680) has features intermediate between DA1 and DA2A. Besides limb phenotypes, it may have facial features like a triangular face, downslanting palpebral fissures and small mouth. Recently, mutations in the TNNI2, TNNT3, TPM2, MYH3 and MYH8 genes have been identified to be associated with DAs. Here we reported a Chinese DA family with 4 affected individuals in three generations. The proband showed notable DA phenotype combined with short stature and DA2B facial features. Two-point linkage analysis was first performed using microsatellite markers selected from the genomic regions adjacent to the TPM2, TNNI2/TNNT3, TNNC2 and MYH3 gene. A positive LOD score was obtained with the markers close to the TPM2 gene. Direct sequencing of the PCR-amplified DNA fragments spanning exon 1 to exon 11 of the TPM2 gene revealed in the proband a heterozygous missense mutation in exon 3, c.308A>G (pQ103R), substituting a highly conserved amino acid in the protein. This mutation was confirmed to cosegregate with the disease phenotype in the family but not detected in all unaffected individuals and 75 unrelated healthy controls. In summary, we have confirmed the link between the TPM2 gene and DA2B in a Chinese family.

Clinical, cytogenetic and molecular profiling of chromosome breakage disorders in patients of Indian origin. *R. Shukla[1], R.A. Gatti[2], M. Kabra[1]* 1) Dept Pediatrics, Genetics Unit, AIIMS, New Delhi, India; 2) Dept Molecular Pathology and Laboratory Medicine, UCLA School of Medicine, UCLA, Los Angeles, CA, USA.

Chromosome breakage disorders (CBS) are a class of disorders characterized by increased frequency of chromosome damage in the cells of the patient, either spontaneously or following exposure to various DNA damaging agents. All disorders of CBS show common clinical features of disturbance of growth,and development, defects of the immune system and bone marrow function and predisposition to develop malignant tumors.The diseases of this group are all autosomal recessive, having diverse eitology and clinical manifestations. the diseases include, Fanconi anemia (FA), Ataxia telangeictasia (AT), Xeroderma pigmentosum (XP), Bloom syndrome (BS), Cockayne syndrome (CS), trichothiodystrophy (TTD), and Nijmegen breakage syndrome (NBS). At the All India Institute of Medical Sciences, New Delhi, India, we have been maintaining a registry of CBS patients since 2004 and offering clinical, cytogenetic and molecular diagnosis and genetic counselling to affected families. Various strategies are being used to confirm the clinical diagnosis in patients suspected with a CBS. Cytogenetic stress test using mitomycin (C) has been used for the diagnosis of FA. Radiosensitivity assay, haplotype analysis and sequencing has been used to confirm diagnosis of AT, FA, XP. The CBS registry has data on clinical, cytogenetic and molecular features of over 100 patients, the details of which will be discussed.

Validation of GNE:pM712T Identification by Melting Curve Analysis. *Y. Valles-Ayoub[1], C. Saechao[1], A. Haghighatgoo[1], M.S. Neshat[1], M. Pietruszka[1], D. Darvish[1, 2]* 1) HIBM Research Group, Encino, CA; 2) VA Greater Los Angeles (VA-GLA/UCLA), Los Angeles, CA.

HIBM/DMRV is an adult onset autosomal recessive muscle wasting disease common in people of Iranian-Jewish descent, due to the founder allelic variant GNE:p.M712T. High correlation of disease susceptibility with GNE:p.M712T allows its use as a molecular marker for diagnosis. In this study, we applied and validated the use of Melting Curve Analysis using SimpleProbe technology for detection of this mutation using specimens obtained by mouthwash, buccal swab, and whole blood. The assay was then applied to 43 clinical specimens and results were validated by additional methods. A probe spanning this mutation in exon twelve accurately discerns two Tm corresponding to its hybridization to wild type and M712T derived amplicons. A 10^{o}C divergence in Tm allowed rapid single tube genotyping of reference and patient samples with 100% accuracy. Distal myopathy constitutes a large heterogeneous group of pathologies with similar physiological manifestations and little molecular markers for distinguishing subtypes. Application of Simple Probes for detection of GNE:p.M712T on genomic DNA obtained from buccal epithelial cells allows accurate, rapid and cost effective identification of this allele in individuals at risk. This procedure is amenable to automated high throughput applications and can be extended to both clinical and research applications.

Waves of expansion? Interpreting principal components analyses of human genetic variation. *J. Novembre*[1], *M. Stephens*[1,2] 1) Human Genetics, University of Chicago, Chicago, IL; 2) Statistics, University of Chicago, Chicago, IL.

Obtaining an efficient summary of population genetic structure is crucial for many applications, including controlling for false positives in genome-wide association studies. One commonly applied technique for summarizing population genetic variation is principal components analysis (PCA). In this talk I will present results that describe how PCA behaves when applied to spatially structured populations. In these settings the principal components have a striking regularity that has previously gone unrecognized among geneticists. The results provide insight into how in practice PCA results should be interpreted and how they will perform when used to correct for population structure in GWA. As an example of the implication of the results, we suggest a new interpretation of Cavalli-Sforza et al's classic principal components maps of genetic variation in humans.

Candidate system genes, SLC1A3, and the risk for substance use disorder. *M.M. Vanyukov[1,2,3], B.S. Maher[1,4], B. Devlin[1,2,3], R.E. Ferrell[1,2], G.P. Kirillova[1], H. Chilcoat[5], L. Murrelle[5], R.E. Tarter[1,3]* 1) Center for Education and Drug Abuse Research (CEDAR), Dept. of Pharmaceutical Sciences, University of Pittsburgh, Pittsburgh, PA; 2) Dept. of Human Genetics, University of Pittsburgh, Pittsburgh, PA; 3) Dept. of Psychiatry, University of Pittsburgh, Pittsburgh, PA; 4) Virginia Institute for Psychiatric and Behavioral Genetics, Virginia Commonwealth University, Richmond, VA; 5) GSK, RTP, NC.

Liability to substance use disorder (SUD) is highly heritable. Candidate systems of genes can be identified based on the neurobiology of SUD and related traits, directing the search for loci accounting for SUD heritability. A custom Illumina panel of 1,536 SNPs covering 106 neurobiological system genes was selected using an iterative approach. Candidate system genes were selected based on current neurobiological knowledge and prioritized via consensus conference, substantially overlapping with the NIDA Genetics Consortium gene list. The next steps focused on inclusion of functional SNPs and LD-coverage of the top ranking genes. All HapMap SNPs were selected in each of the candidate genes and submitted to Illumina for quality scoring. SNPs returning a QS < 1 were deleted from the candidate list. The list of QS=1 SNPs for the top ranking candidate genes was submitted to the H-Clust algorithm for SNP selection. H-Clust identified 1,500 SNPs that provided an average coverage of r^2=.615 (based on HapMap) of the 106 highest-ranking candidate genes. In addition, all known non-synonymous common SNPs in each of the genes was selected for genotyping. This SNP panel was analyzed in 566 case and 195 control European-American males. Several genes representing different systems yielded multiple significant hits for SUD and related traits, after FDR correction for multiple testing. In particular, associations were detected with three SNPs in the glial high affinity glutamate transporter gene (SLC1A3) (rs10512660: p = .0003; rs891189: p=.0008; rs7734056: p=.0013). The data suggest that SLC1A3 may contribute to variation in common (non-drug-specific) liability to SUD.

Examining age-related macular degeneration in the Amish. *J.L. McCauley[1], L. Jiang[1], N. Schnetz-Boutaud[1], P.J. Gallins[2], A.E. Crunk[1], L.L. McFarland[1], D. Fuzzell[1], C. Knebusch[1], M. Creason[2], L. Caywood[2], C.E. Jackson[3], W.K. Scott[2], M.A. Pericak-Vance[2], J.L. Haines[1]* 1) Center for Human Genetics Research, Vanderbilt University Medical Center, Nashville, TN; 2) University of Miami School of Medicine, Miami, FL; 3) Scott & White, Temple, TX.

Age-related ophthalmic diseases present a significant health problem with huge social and economic consequences. Over the past two years, multiple genes have been identified for age-related macular degeneration (AMD). However, these critical successes only partially explain the genetic etiology of AMD. We have undertaken a powerful complementary approach for finding additional genes involved in ophthalmic diseases by using a genetically isolated founder population, the Midwestern Amish communities of the US. These Amish communities are more homogeneous in both environmental and genetic exposures. We have ascertained nearly 1600 Amish individuals for participation in studies of diseases prominently seen in older populations. We have identified 118 individuals who have self-reported AMD. Taking advantage of ongoing work within our group, we have genotyped 58 of these individuals, along with 614 additional Amish individuals, using the Illumina Linkage Panel IVb. We performed 2-pt linkage analysis, using both dominant and recessive models, on 5,645 SNPs using the Superlink program. Initial analysis identified 177 SNPs with lod scores 1.0. Three SNPs (on 2p, 4q, and 1q) have lod scores 2.0, with the 1q variant being approximately 2 Mb from the *CFH* gene. In addition to the SNPs within this linkage panel, we genotyped two previously confirmed AMD variants: rs10490924 within *LOC387715* and rs1061170 within *CFH*. The rs1061170 variant gave a 2-pt lod score of 1.43 suggesting involvement of *CFH* in AMD risk within this isolated population. However, rs10490924 did not have strong evidence for linkage within our study (lod = 0.22). This result may not be surprising given that this variants risk is influenced by smoking, which is rare within the Amish.

Ethical, Legal and Social Aspects of the Mexican Genomic Variability Project. *C. Lara, A. Hidalgo, I. Silva-Zolezzi, E. Balam, L. Del Bosque, S. March, E. Barrientos, G. Jimenez-Sanchez* National Institue of Genomic Medicine, Mexico.

Genomic medicine is a priority for the Mexican Government to contribute improving health care for the Mexican population. The Mexican population has a unique origin, more than 80% of the population is considered Mestizo resulting from the admixture of any of 65 indigenous groups with the Spaniards and, in a lesser extent, Africans and Asians. We are conducting a Genome Diversity Project in the Mexican population. The project aims to genotype over 1 million SNPs per individual and produce a comprehensive description of LD patterns, haplotype diversity and sharing, as well as a comparative analysis with other populations. The project was approved by the appropriate Scientific, Ethic and Biosafety Review Boards. We collected anonymous samples from ten states of Mexico representing the countrys geography. We implemented a community consultation and consent process strategy that included state government officials, indigenous community leaders, university authorities and members of the local student and scientific community. This strategy operated 2-3 weeks before sample collection and included a brochure using simple language, 4-6 open access informative sessions, an informative poster, general and specific information via TV, radio and printed press. We have conducted 59 informative sessions and collected Informed Consent Forms for 2,800 samples. As a part of this strategy our Institute has established ten collaborative agreements resulting in research collaborations and training local students at the National Institute of Genomic Medicine of Mexico. Thus far, over 200,000,000 SNPs have been genotyped. We ensured availability of enough public information, community engagement process, individual consent, protection individual information, biobank management and confidential treatment of resulting data. This project has led to the largest genomic database for Mestizos and Mexican Amerindian DNA repository worldwide. We expect that results from this project will contribute to generate public knowledge about genomics and sets the basis for best practices in genomic research.

Identifying maximally unrelated individuals in population isolates using simulated annealing. *C.I. Sandefur[1], J.D. Douglas[1,2]* 1) Bioinformatics, University of Michigan; 2) Department of Human Genetics, University of Michigan.

When making genetic inferences in population isolates, e.g., testing levels of linkage disequilibrium in the context of a family-based study, it is often useful to identify a maximal set of unrelated individuals. This is a combinatorial optimization problem that belongs to the class of NP-complete problems. Such problems have deterministic solutions that are conjectured to increase in complexity at an exponential rate in n. If n is the number of individuals, then identifying a maximal set of unrelated individuals requires examining 2n subsets. Although Martin et al. (2003) proposed some reduction techniques to address this specific problem, their approach does not address the related problem of identifying a set of maximally unrelated individuals. Because individuals from population isolates typically share one or more recent, common ancestors, the kinship coefficient between any two individuals is usually non-zero, i.e., no two individuals are unrelated. To identify a set of maximally unrelated individuals, we implemented and evaluated simulated annealing (Kirkpatrick et al. 1983 and Cerny 1985). Simulated annealing is a general-purpose algorithm for solving difficult combinatorial optimization problems and is especially appropriate for finding the global minimum of a cost function that may possess several local optima. It works by emulating the physical process whereby a solid is slowly cooled in stages until it reaches a minimal energy configuration. In the current context, we define and examine several cost functions, including the average and maximum kinship coefficient conditional on the known genealogy connecting a set of individuals. We evaluate our method for a variety of parameters, including the initial temperature, cooling schedule, and stopping condition, and neighborhood structures. Finally, we illustrate our method on data from a genetic study in the Old Order Amish of Lancaster County Pennsylvania, a population isolate derived from a modest number of founders. Preliminary data suggest that our implementation of simulated annealing performs reasonably well.

Assessment of genes involved in inflammation in coronary artery disease in Asian Indians. *N.U. Mehta[1,2], G. Mendoza-Fandino[1,2], T.J. Pemberton[1], J. Hartiala[1], D. Conti[3], P. Kotha[4], H. Allayee[1,3], P.I. Patel[1,2]* 1) Inst for Genetic Medicine, Univ of Southern California, Los Angeles, CA; 2) Dept of Biochemistry and Mol Biology, Univ of Southern California, Los Angeles, CA; 3) Dept of Preventive Medicine, Univ of Southern California, Los Angeles, CA; 4) RICADIA, 5555 Reservoir Drive Suite 309, San Diego, CA.

Our long term goal is to identify genetic risk factors underlying coronary artery disease (CAD) in Asian Indians. The prevalence and severity of CAD in individuals of Asian Indian origin is four- to five-fold higher when compared to other ethnic groups. In Asian Indians, CAD is severe, extensive and follows an apparently much more aggressive course than in other ethnic groups. In particular, CAD rates are unusually high in Asian Indian women and natural protection from CAD seen in Caucasian premenopausal women is apparently not present in Asian Indian women. We have conducted community-based sampling of Asian Indians with CAD and gender-matched control Asian Indian subjects >60 y of age without CAD. Blood samples were collected for serum and plasma chemistries, and for RNA and DNA isolation. Previous studies have shown an association between the gene encoding arachidonate 5-lipoxygenase (5-LO), the rate-limiting enzyme in the production of leukotrienes (LTs) and atherosclerosis in various populations. Primarily, deviation away from the common 5-allele of a 5-LO promoter repeat has been associated with increased risk of atherosclerosis. We have initially examined the prevalence and allele frequencies of the various promoter alleles in a cohort of Asian Indians sampled for population genetics studies. Six promoter alleles were noted in the Asian Indian cohort, with 56.4% of individuals homozygous for the common allele of five Sp1-binding sites, 92.5% of individuals had at least one 5 repeat allele, and the remaining 7.5% had two variant alleles. This is higher than the 5.96% reported for a cohort of individuals of mixed-ethnicitye. Current studies are examining 5-LO and other genes in the inflammatory LT pathway, including 5-LO-activating protein and LTA4 hydrolase, in this case-control cohort.

Toriello-Carey syndrome in a patient with a de novo balanced translocation [46,XY,t(2;14)(q33;q22)] interrupting SATB2, a plausible candidate gene. *D.H. Tegay[1,2], K.K. Chan[3], L. Leung[3], C. Wang[4], G. Stone[5], R. Stanyon[5,6], H.V. Toriello[7], E. Hatchwell[1]* 1) Stony Brook University Medical Center, Stony Brook, NY; 2) New York College of Osteopathic Medicine, Old Westbury, NY; 3) Kwong Wah Hospital, Hong Kong, China; 4) Cold Spring Harbor Lab, Cold Spring Harbor, NY; 5) National Cancer Institute, Frederick, MD; 6) University of Florence, Florence, Italy; 7) Spectrum Health, Grand Rapids, MI.

Toriello-Carey Syndrome (TCS;OMIM#217980) is a multiple congenital anomaly syndrome characterized by common manifestations including corpus callosum agenesis, cardiac defects, cleft palate/Robin sequence, hypotonia, mental and postnatal growth retardation and distinctive facial dysmorphology (including micrognathia, telecanthus, small nose and full cheeks). Both autosomal recessive and X-linked inheritance have been proposed, but chromosomal abnormalities involving disparate loci have also been reported in a small number of cases.

We report a patient with classical features of TCS and an apparently balanced de novo translocation between chromosomes 2 and 14 [46,XY,t(2;14)(q33;q22)]. Flow sorted chromosomes were generated from lymphoblastoid cell lines and Phi29 amplified. Derivative chromosome 2;14 DNA was labeled with a fluor and hybridized against a mixture of differentially labeled non-derivative chromosome 2 and 14 DNA onto a tiling path BAC array. Translocation breakpoints were identified to within ~300kb and further PCR mapped. The breakpoint at 2q33.1 was found to directly interrupt the SATB2 (Special AT-rich sequence Binding protein-2) gene while the 14q22.3 breakpoint was not intragenic.

SATB2 functions as a transcription regulator at multiple sites and recent studies indicate important roles in craniofacial and CNS development. SATB2 mutation or deletion has been associated with both isolated and syndromic facial clefting, however, no other cases of TCS have been reported. Additionally, the results of SATB2 sequencing and MLPA currently being performed on our cohort of 20 TCS subjects will be presented.

A High Resolution Oligonucleotide CpG Island Microarray for Relative DNA Methylation Measurement. *D. Roberts[1], C. Foo[2], S. Giles[1], E. L. LeProust[1], S. Milligan[1], C. Hopkins[1], R.M. Saxena[1], D. Roberts[1]* 1) Dept Research & Development, Agilent Technologies, Santa Clara, CA; 2) University of California, San Francisco, CA.

CpG islands are stretches of high GC content DNA containing multiple CpG dinucleotides. When CpG dinucleotides within these islands are methylated, especially in promoter regions, expression of the corresponding downstream genes is often repressed. Aberrant CpG island methylation is implicated in cancer. We have developed an oligonucleotide microarray that specifically represents the CpG islands in the human genome. This microarray contains ~230,000 oligo probes tiling the 21 megabases of 27,800 CpG islands, with an average spacing between probes of 95 base pairs. The microarray is designed to be compatible with several published methods for the genome-wide detection of methylated CpG islands. To demonstrate the ability of this microarray to accurately detect methylated DNA, we performed analysis of human genomic DNA samples after methylated DNA immunoprecipitation (mDIP). Additionally, we developed and tested spike-in control DNA that was in vitro methylated to varying degrees. The mDIP method combined with CpG island microarray analysis accurately differentiated between partially and fully methylated spike-in DNAs. We then applied the whole-genome assay to the prostate cancer cell line PC3, where we detected methylated CpG islands upstream of cancer related genes including CDKN2A/p16. We extended the study to other cancer cell lines and determined relative methylation at multiple cancer related genes. Finally, using male and female embryonic lung fibroblast cell lines, we demonstrate that many CpG islands on the female X chromosome are more methylated than the corresponding islands on the male X chromosome. In comparison, methylation of CpG islands on the autosomes is essentially the same for both the male and female samples. This supports a role for CpG methylation in silencing the inactive X chromosome in females.

Genome-wide mapping and sequencing of Structural Variation using High-Resolution Paired-End Mapping (HR-PEM). *A.E. Urban[1], J.O. Korbel[1], J. Affourtit[2], F. Grubert[1], P. Kim[1], B. Taillon[2], D. Palejev[1], N. Carriero[1], L. Du[2], B. Godwin[2], J. Simons[2], J. Chi[3], F. Yang[3], M. Hurles[3], N. Carter[3], S. Weissman[1], T. Harkins[4], M. Gerstein[1], M. Egholm[2], M. Snyder[1]* 1) Yale University, New Haven, CT; 2) 454 Life Sciences, Branford, CT; 3) The Wellcome Trust Sanger Institute, Hinxton, Cambridge, UK; 4) Roche Applied Science, Indianapolis, IN.

Structural variation (SV), i.e. deletions, duplications, insertions and inversions, kbp to Mbp of genomic sequence in size, is being found to be a pervasive architectural feature of the human genome, expected to have a phenotypic effect in health and disease. Most methods for genome-wide identification of SV, predominantly microarray based, cannot normally detect variation smaller than 50 kb or breakpoint-sequences and also fail to identify copy-number neutral variation events such as inversions and balanced translocations. We present a novel approach, High-Resolution Paired-End Mapping (HR-PEM) [Korbel, Urban, Affourtit et al., in preparation], using 454/Roche-FLX next-generation sequencing technology to rapidly identify SVs, and sequence the associated breakpoints. The approach involves sequencing the ends of, intermittently circularized, but not cloned, 3 kb genomic DNA fragments and mapping them onto the human genome reference sequence. The resolution of breakpoint assignments is 3 kb and is thus well suited for PCR validation. We have used HR-PEM to study SVs of all classes genome-wide in two subjects from different ethnic backgrounds. Based on 21 and 10 million, respectively, end-pair sequence reads (with a read-length of typically >200nt) from each individual, several hundred SVs have been predicted so far, ranging in size from 2 kbp to several Mbp. The junction sequence of approximately 60% of predicted SVs does immediately produce a PCR amplicon, multiples of which are then pooled and 'shotgun'- sequenced with 454/Roche-FLX. This has yielded already well over 100 breakpoint-sequences, most of them novel. Predicted SVs are also validated by comparison with known variants, by array CGH and FISH, and reveal as yet unexplored aspects of structural variation in the human genome, such as insights into mechanisms by which SV arises.

Haplotypic background of a high-frequency Native American private allele. *K.B. Schroeder[1], M. Jakobsson[2], T.G. Schurr[3], M.H. Crawford[4], D.F. Conrad[5], L.P. Osipova[6], L.A. Tarskaia[7], S.I. Zhadanov[3,6], J.D. Wall[8], J.K. Pritchard[5], D.G. Smith[1], N.A. Rosenberg[2]* 1) Dept. of Anthropology, University of California, Davis, Davis, CA; 2) Dept. of Human Genetics, University of Michigan, Ann Arbor, MI; 3) Dept. of Anthropology, University of Pennsylvania, Philadelphia, PA; 4) Dept. of Anthropology, University of Kansas, Lawrence, KS; 5) Dept. of Human Genetics, University of Chicago, Chicago, IL; 6) Institute of Cytology and Genetics, Russian Academy of Sciences, Novosibirsk, Russia; 7) Institute of Molecular Genetics, Russian Academy of Sciences, Moscow, Russia; 8) Dept. of Biological Sciences, University of Southern California, Los Angeles, CA.

Previous research has shown that a nine-repeat allele (9RA) at microsatellite D9S1120 is present in all 20 sampled Native American and West Beringian populations and is absent from all 53 other populations sampled. The distribution of this allele has been used to support the hypothesis that most Native Americans descend from a single founding population. This inference assumes that copies of the 9RA are identical by descent and that the allele is not under selection. We have genotyped 34 SNPs spanning a 499 kb region around D9S1120 in 1252 individuals from 72 populations worldwide, including 19 Native American, 2 West Beringian, and 22 East/Central Asian. 89.7% of haplotypes with the 9RA share a 76 kb haplotype, suggesting most or all copies of the 9RA are identical by descent. Most of the individuals we genotyped have been genotyped for 2834 SNPs in 36 genomic regions, allowing a genomic comparison. Although a 76 kb haplotype at a frequency of 54% would be highly unusual in European or African populations, we found that, due to the high levels of LD, it is not highly unusual in Native American populations. Thus, the length and frequency of the 9RA haplotype do not support the hypothesis that its distribution results from positive selection. Recombination within the 9RA haplotype allows us to estimate the length of the intraallelic genealogy, and, thereby, the age of the MRCA of sampled copies of the 9RA. The results have implications for the peopling of the Americas and for detecting positive selection in Native Americans.

A Novel Bimodal Replication Timing Program In Human Mesenchymal Stem Cells Is Revealed by a High-Throughput Approach to Measure Timing of Replication Using Tiling Arrays. *T. Y. Takova[1], C. L. Schildkraut[2], R. Desprat[2], Q. Yang[3], R. Green[1], E. Bouhassira[2]* 1) NimbleGen Systems, Madison, WI; 2) Hematology/Cell biology, Albert Einstein College of Medicine, Bronx, NY, USA; 3) Cell Biology, Albert Einstein College of Medicine, Bronx, NY, USA.

Replication-timing programs change with development and differentiation.The significance of these changes is not understood, but different timing programs are believed to be associated with different chromatin structures and different transcriptional programs.We hypothesize that the replication-timing program of stem cells can be used to assess their epigenetic status and their differentiation potential.We describe here a new high-throughput approach to define the temporal order of DNA replication.The method relies on high-resolution custom-made NimbleGen tiling microarrays containing about 400,000 oligonucleotides to measure the small differences in DNA content that are associated with differential timing of replication.We have assessed the DNA replication profile of about 1.5% of the genome the of a mesenchymal stem cell derived from the human embryonic stem cell line H1.Analysis of a two megabase region encompassing the IgH locus revealed that the downstream part of the locus replicates early in S, that the upstream part of the locus replicates late in S and that these two regions were joined by a transition region in which no replication initiation occurs and which is replicated by a single fork that proceeds from early to late in S.Eleven additional large temporal transition regions similar to the one described for the IgH locus were also observed.Total RNA,mRNA and poly-A negative nuclear RNA were hybridized on the same tiling microarrays.Comparison of the timing and transcription data revealed positive correlations, particularly between the amount of primary transcripts and early replication.This is consistent with a remarkable bimodal timing program in which the early replicating genome is enriched in active genes,and the late in inactive genes.Experiments to characterize the replication program in undifferentiated human ES cells and in hematopoietic cells derived from hESCs are in progress.

Massively Parallel Sequencing of cDNA as a Strategy for Genomic Resequencing. *S.F. Nelson, B.L. Merriman, Z. Chen* Dept Human Genetics, UCLA Medical Ctr, Los Angeles, CA.

The genome-wide resequencing of coding regions holds great potential value for disease research. For a specific example, Velculescu, et al (2006) sequenced coding regions of 13,026 genes in 11 tumor genomes in order to identify mutations contributing to tumor genesis, and more generally, in complex disease genetics the trend is generally towards resequencing ever larger numbers of candidate genes in affected individuals. The natural, universal limit of these efforts would be to simply resequence all exons as a general purpose screen for disease-relevant variants. Recent advances in sequencing technology make this plausible, but the current strategies employed for genome-wide exon surveys rely on PCR-related methods to capture the coding regions for sequencing, which is a costly, laborious, and often problematic component of the procedure. In contrast, here we suggest using cDNA as a means to effectively extract the coding portion of the genome for sequencing, and this is also well suited to the new massively parallel sequencing technologies which can sequence complex DNA pools. To explore the practicality of the approach, we use empiric data from deep sequencing of full length cDNA from gliomas and glioma derived cell lines, and using the Solexa sequencing system to generate depths of up to ~120,000,000 short reads per library. Specific issues we address are the number of genes that are effectively resequenced in this approach, and whether dis-regulated expression---as present in tumor samples or induced cell cultures---enables better sequencing coverage of genes that are not commonly transcribed. The strengths of this approach are the simplicity with which it targets all exons for sequencing, and its ability to properly utilize the enormous sequencing capacity of the new sequencing technologies.

Genetic and other factors affecting individual variation in gene expression. *M.A. Rivas[1,2,4], M.J. Daly[2,3], I. Pe'er[4]*
1) Department of Mathematics, Massachusetts Institute of Technology, Cambridge, MA; 2) Broad Institute of MIT and Harvard, Cambridge, MA; 3) Center for Human Genetics Research, Massachusetts General Hospital, Boston, MA; 4) Department of Computer Science, Columbia University, New York, NY.

Genetic genomics holds the promise to dissect the heritable factors that regulate all expression-mediated processes in the cell. Indeed, coupled whole genome genotype and expression data for human lymphoblastoid cell lines have recently been analyzed by classical methods to map numerous expression QTLs.

We sought to elucidate the different factors driving individual levels of gene expression, including genetic variation, age and sex. We consider public data from CEPH extended pedigrees including expression profiles as well as microsatellite and SNP genotypes. We report 951 and 302 transcripts levels that are associated with age and sex respectively. We perform more elaborate genetic analysis of these data, that increases power to detect association. We thus detect 125 transcripts with strong signals (p-value 1e-8) of association to a SNP in cis, most of which were not reported by simpler analyses of the same data. We further report several previously unrecognized significant signals (p-value 1e-12) of association to trans SNPs.

We follow up these clues with analysis of functional annotation to expose meaningful trends. Examples include: (i) Enrichment of immune-related genes whose expression increases for older individuals - a phenomenon that replicates across datasets, tissues and organisms (ii) A cluster of co-regulated transcripts enriched for associations to neurodegenerative disorders, that show effects of both age-association as well as genetic regulation between a SNP in LRP1B and the expression of its ligand, APOE.

Last, we systematically investigate age X genotype interaction. We use elastic net regularization to infer age of all typed samples. This significantly increases power to detect age-mediated genetic association signals, achieving a genomewide compendium of such effects.

Evaporative Cooling feature selection identifies mixed interaction and main effects for SNP association studies.

B.A. McKinney[1], D.M. Reif[2] 1) Department of Genetics, University of Alabama School of Medicine, Birmingham, AL; 2) National Center for Computational Toxicology, U.S. Environmental Protection Agency, Research Triangle Park, NC.

Many statistical methods show optimal performance for identifying genetic variants with a high marginal effect in the population, and some model-based methods have been used to capture limited interaction effects. Recently developed machine learning methods are able to identify pure interaction effects but have less power to detect additive effects. Evaporative cooling (EC) feature selection is a machine learning method developed to identify gene-gene/gene-environment factors that influence susceptibility to disease or drug/vaccine response without neglecting the importance of variants with high marginal effect. EC is based on a thermodynamic heuristic in which SNPs are treated as a gas of atoms interacting at a certain temperature. The attribute score, analogous to a free energy, combines mutual information and Relief-F, coupled by a tuning parameter analogous to temperature. The most energetic SNPs (least relevant to the phenotype) are recursively removed (evaporated) from the gas, leaving behind a collection of attributes with the lowest information free energy. We compared EC with Random Forest (RF), which also takes into account the context of other attributes when scoring the relevance of an individual feature. Analyses were performed on several simulated interaction models involving 1500 SNPs with 500 cases and 500 controls with 100 replicates for each model. We found that EC has higher power than RF to detect interacting genetic variants. The limited ability of RF to identify interacting SNPs is due to its use of a node-splitting criterion that assumes independence between attributes during decision tree construction. The predictions of EC and RF are comparable to univariate feature selection (logistic-regression) when the relevant SNPs do not interact. We also applied these methods to real genetic data (genotypes at 1442 SNPs across 500 genes) collected to identify biomarkers associated with adverse events following smallpox vaccination of n=108 human subjects. (Supported by AI-64625.).

Development of a cardiovascular risk panel For use in Clinical pharmacogenomics studies. *I. Mongrain[1], A.M.K. Brown[1], Y. Renaud[1], N. Gaudreault[1], J. Engert[2], M.S. Phillips[1]* 1) Genome Quebec & Montreal Heart Institute Pharmacogenomics Centre, Montreal, Quebec, Canada; 2) Victoria Hospital, McGill University, Montreal, Quebec, Canada &n.

Researchers are now working to identify genetic biomarkers that may be predictive of the pathogenesis of cardiovascular disease (CVD) and adverse drug reactions. Our group has developed clinical grade genotyping panels that may aid physicians evaluate a patients risk of developing CVD, as well as directing physicians to more appropriate choices of drug therapies and dosing regimes. Our focused functional CVD panel consists of over 200 markers covering ~25 genes involved in lipid metabolism, notably APOE, LPL and CETP. Our panel consists of both functional and haplotype tag SNPs to evaluate genotype-phenotype interactions. This CVD risk panel has been developed using the following strategies: 1) Panel development is performed in parallel using two technologies (SNPstream, and Sequenom); 2) Assays are designed and developed for both DNA directions; and 3) Genotyping calls are validated against known genomic controls. In order to validate the CVD risk panel, the results of 2000 genotyping calls from 80 markers were compared to previous genotyping data with 99.9% concordance. This panel is now being used to screen a cohort composed of 284 patients with extreme HDL-cholesterol levels for an association study. We are currently developing a much larger broad-based statin-related gene panel (~4500 markers) using the iSelect chip on Illuminas Infinium platform. These panels will be used to support a large scale Genome Canada/Genome Quebec pharmacogenomics research project on statin myotoxicity at the Université de Montréal and the Montreal Heart Institute. As part of this project, the panel will be used to analyze 5000 patients presenting clear clinically relevant muscular intolerance phenotypes.

When mean and variance are related: improved conditional t test for identifying differentially expressed genes.
Z. Luo, J. Cabrera Departmetn of Statistics, Rutgers,the State Univeristy of New Jersey, Piscataway, NJ.

Amaratunga and Cabrera (2004) proposed a conditional t suite of tests for identifying differentially expressed genes in a microarray experiment with little replications. Now we adjust conditional t test to take consideration of the situation that the mean and the variance are correlated. It is widely known that the correlation between the mean and the variance of gene expressions is very strong in raw data. Although in many cases, the relationship is greatly reduced after taking transformation, it may still exist. Target to it, we present the improved conditional t test. Our simulation studies show that when the mean and the variance are independent, improved conditional t test give us similar results as conditional t test. While the mean and the variance are correlated, improved conditional t test is much better than conditional t test in the sense that it gains more power and identifies more significantly differentially expressed genes. Both conditional t test and improved conditional t test are implemented in DNAMR, which is a collection of R and Splus programs. This package is freely available at http://www.rci.rutgers.edu/~cabrera/DNAMR.

Replicated analyses suggest a network of dopaminergic genes confer risk for schizophrenia. *M.E. Talkowski[1], M. Bamne[1], H. Mansour[1], K. Chowdari[1], J. Wood[1], L. McClain[1], G. Kirov[2], M.C. O'Donovan[2], M. Owen[2], B. Devlin[1], V.L. Nimgaonkar[1]* 1) Human Genetics and Psychiatry, University of Pittsburgh, Pittsburgh, PA; 2) Psychological Medicine, Cardiff University, Cardiff, UK.

Dopaminergic hyperactivity has been hypothesized in schizophrenia (SZ) genesis. We previously evaluated 18 dopamine (DA) related genes and detected associations with SLC6A3 (DAT), DRD3, SLC18A2 (VMAT2), and COMT. We report here comprehensive follow-up analyses.

Association Studies: We genotyped 69 tag SNPs at these four genes in two Caucasian samples: 1) 478 cases/501 controls from the US, 2) 659 trios from Bulgaria. In the US sample, we found significant associations at all four genes ($p<0.05$). Epistasis was observed between locus pairs in 17 of 117 total tests (interaction $p < 0.05$). Nearly half of the significant interactions (41.2%) included either rs3756450 (5 near promoter) or rs464049 (intron 4) at SLC6A3. In the Bulgarian cohort, significant associations were again detected with both of these SNPs (rs3756450, $p=0.035$; rs464049, $p=0.017$), and 5 of 17 epistatic interactions were replicated. Epistasis was most prominent between SLC6A3*COMT loci (interaction $p<0.005$ in both samples). The joint distribution of test statistics from both samples identified associations with 12 SNPs ($p_{joint}<0.05$).

Function: In silico experiments suggested changes in the binding pattern of transcription factors within the genomic region near rs3756450. We investigated rs3756450 and rs464049 using EMSA and observed band shifts at these SNPs. Intriguing allele-specific differences were found at rs3756450. Dual luciferase promoter assays also indicated allele-wise differences at rs3756450 in luciferase promoter activity ($p<0.0001$). The promoter activity exceeded observed differences of 6 other SNPs investigated within this 2.8kb region 5' to the DAT promoter.

Conclusions: We find replicable interactions between four key DA genes in SZ pathogenesis, centered on the dopamine transporter. Functional analyses suggest novel, allele specific effects for rs3756450 upstream of the SLC6A3 promoter. Futher analyses are warranted.

Kidney Transplantation Genomics: Whole Genome Association to Rejection. *S.L. Musone[1], J. Chen[1], C. Ha[1], S. Horvath[2], D. Salomon[3], P.Y. Kwok[1]* 1) CVRI, University of California, San Francisco, San Francisco, CA; 2) Dept. of Biostatistics, University of California, Los Angeles Los Angeles, CA; 3) The Scripps Research Institute La Jolla, CA.

Approximately 17,000 kidney transplants are performed in the United States each year due to various disease states that include type II diabetes and hypertension. Despite donor-recipient matching techniques, acute rejection and chronic allograft nephropathy remain obstacles to post transplant health. We hypothesize that these two forms of organ rejection are complex traits with genetic signatures that can be identified through a whole genome association approach using single nucleotide polymorphisms (SNPs). We are scanning 2400 matched donor-recipient pairs on Affymetrix Gene Chips for SNP genotyping and expression analysis, in addition to running high throughput LC-MS/MS proteomics. Analysis and patient enrollment are ongoing.

Haplotype analysis of time to event outcome with unphased genotypes in the presence of stratification. *N. Li[1], S. Basu[1], X. Kong[1], H. He[1], T. Rebbeck[2], A. Israni[3, 4]* 1) Division of Biostatistics, University of Minnesota, Minneapolis, MN; 2) Center for Clinical Epidemiology & Biostatistics, University of Pennsylvania, Philadelphia, PA; 3) Division of Nephrology, Hennepin County Medical Center, Minneapolis, MN; 4) Division of Epidemiology & Community Health, University of Minnesota, Minneapolis, MN.

For studying the association between traits and unphased genotype data, full maximum likelihood (ML) approaches have been developed that jointly maximize the likelihood with respect to haplotype (and covariate) effects parameters and haplotype frequencies. However special software is needed to perform such analysis and one is limited to certain statistical models. In contrast, the two-step expectation substitution method (ES, Zaykin et al, 2002) is very easy to implement for any desired analysis and has been shown to work fairly well for case-control studies. We used simulations to compare the performance of ML and ES methods in the context of semi-parametric analysis of time-to-event data. We were interested in the effect of model misspecification, especially stratification. The ES method was easily adopted to stratified samples by estimating haplotype frequencies separately for each stratum. We observed that the ML method as implemented in the program hapstat was fairly robust under model misspecification. The performance of the ES method was very close to that of the ML method under a variety of conditions. In our simulations, We also found that the effect of stratification was small even when it was ignored. In the analysis of haplotype effect on time to decline in renal function in a kidney transplant cohort study, some difference was noted when stratification was taken into account. For two related outcomes, the global p-values changed from 0.006 and 0.015 to 0.009 and 0.0025, respectively. In conclusion, the ES method can have some practical advantages over the ML method in situations requiring more complex statistical models, such as analysis of haplotype effect on time-to-event data in the presence of population stratification.

Genotype-phenotype correlation for *KLHL10* mutations in oligozoospermic men. *A.N. Yatsenko[1], A. Roy[1], R. Chen[1], L. Ma[1], L.J. Murthy[1], S. Veeraragavan[1], W. Yan[2], D.J. Lamb[1], M.M. Matzuk[1]* 1) Baylor Col Medicine, Houston, TX; 2) University of Nevada, School of Medicine, Reno, Nv.

Nearly 25% of infertile males are diagnosed as idiopathic, suggesting the contribution of the genetic factors. The most common semen pathology among infertile men is oligozoospermia. However, cause for the semen defect, except for ~10% of oligozoospermic patients with identified chromosomal aberrations, remains unknown. Recently we identified *KLHL10* mutations that are responsible for oligozoospermia in ~ 2% of more than 600 patients with the semen defect (0.5-32×10^6 spermatozoa/ml). KLHL10 is known to interact with CUL3 and forms ubiquitin E3 ligase complex. To understand an effect of *KLHL10* mutations we performed genotype-phenotype correlation for identified gene alterations in oligozoospermic men. Preliminary data indicate that most severe effect on sperm count has splicing defect. Interestingly, among missense *KLHL10* mutations, most severe ones are those that are located in predicted functional regions, namely kelch repeat 1 and BACK domains. Preliminary functional evidence indicates that two most frequent missense mutations A313T and Q216P impair natural homodimerization affinity of KLHL10 protein and likely damage its function. All latter identified *KLHL10* alterations in oligozoospermic men mapped to kelch repeats 1, 2, 3 and BACK domains as well. Conversely, most DNA mutations located to predicted linker protein segments were found in normozoospermic patients, suggesting their milder or neutral effect on protein function. Our results imply that severity of oligozoospermia depends on mutation type and position effect on important functional domains of the protein. Since, severe oligozoospermia was coupled with severe teratozoospermia in 4 of 7 patients with *KLHL10* mutations in our initial study; we are currently studying the gene contribution to oligoteratozoospermia and teratozoospermia. These study was supported in part by the NIH Specialized Cooperative Centers Program in Reproductive Research (U54 HD07495) and NIH Infertility Center (P01HD36289) to MMM and DJL, and by NIH grant HD050281 to WY.

A family-based genome-wide association study of childhood asthma and airway hyperresponsiveness. *B. Raby[1], J. Lasky-Su[1,2], A. Murphy[1], R. Lazarus[1], J. Ziniti[1], B. Klanderman[1], J. Sylvia[1], A. Patel[1], C. Lange[2], E. Silverman[1], S. Weiss[1]* 1) Channing Laboratory, Brigham & Women's Hosp, Boston, MA; 2) Harvard School of Public Health, Boston MA.

We performed a family-based genome-wide association study for asthma and airway hyperresponsiveness (AHR - an cardinal intermediate asthma phenotype) in 422 nuclear families (n=1215) ascertained through asthmatic probands 5-12 years old with mild-to-moderate asthma participating in a clinical trial. AHR, as measured by methacholine PC_{20}, was recorded annually for 4 years during the clinical trial. Single nucleotide polymorphism (SNP) genotyping was performed using Illumina HumanHap 550v3 BeadChip. Data management and genotype quality control was performed using PLINK. Of 561,466 SNPs on the arrays, 2.46% were removed during data cleaning due to genotype completion rates <90%, parental-offspring genotype incompatibilities, MAF=0, or because the assay sequence could not be reliably aligned to one genomic locus. Genotype data was inadequate for 43 subjects (3.5%). Thus, data from 403 asthmatic probands and their family members were analyzed. We performed family-based association testing on the 534,290 reliable autosomal markers using PBAT (for asthma) and FBAT-PC (for repeated measures analysis of log-transformed methacholine PC_{20}) under additive genetic models. We applied the conditional power screening approach (Van Steen 2005) to adjust for multiple comparisons. For asthma, 6 SNPs clustering in 2 distinct regions on chromosomes 5p ($p=4x10^{-6}$) and 6p ($p=10^{-4}$-10^{-6}) demonstrated suggestive evidence of genome-wide association. Linkage of the 5p locus with asthma has been reported in previous linkage studies (CSGA 1997). The chromosome 6p locus harbors 15 genes - none have been previously implicated in asthma. 4 SNPs on chromosomes 22q ($p=10^{-3}$-10^{-5}) and 3q ($p=0.03$) were associated with $logPC_{20}$. Linkage to asthma or AHR has not been demonstrated previously with these regions. Together, these data provide novel insights into the pathobiology of asthma, and warrant further testing of the associated variants in additional asthma cohorts. Funding: NIH/NHLBI grants U01 HL065899, P01 HL083069, K08 HL74193.

MendelPro: Software for Genetic Datasets to Simplify Project Management, Pedigree Drawing, and the Interface to Statistical Analysis & Graphing. *R. Sripracha, D.H. Alexander, E.M. Sobel, J.C. Papp* Human Genetics, University of California, Los Angeles, Los Angeles, CA.

MendelPro is a new genetic project management tool with a novel, fast pedigree drawing algorithm. MendelPros graphical tools are designed to streamline statistical genetic analysis. MendelPro includes an embedded database designed to handle very large genetic datasets, including dense genome-wide SNP datasets. The program can be used to create data either through a graphical interface or spreadsheet format. Data can also be imported and exported in standard formats. In addition to its utility as a data repository and project management tool, MendelPro is a front-end to the Mendel statistical analysis package. Mendel can perform all standard, and many unique, statistical genetic analyses, currently including 22 analysis categories. The results of Mendels analyses are stored in the database, associated with the underlying data and models.

MendelPros pedigree drawing procedure uses extensions of the Sugiyama layout heuristics from the graph-drawing branch of computer science. These extensions, designed to handle pedigree-specific issues, help optimize the pedigree-drawing layout. Additional procedures are used to improve the aesthetics of the drawing. The entire process is low order quadratic in the number of individuals. The final drawing does not use duplicated individuals, even for inbred pedigrees. The drawing can be viewed in standard or mating-node form, and follows the Pedigree Standardization Task Force nomenclature. Traits and phenotypes can be displayed within the drawing. Haplotypes determined by Mendel, or other software, can also be displayed with the pedigrees. These haplotypes are color optimized for visualization, and may be printed or exported for presentation or publication.

MendelPro currently runs under Windows. MacOS and Linux versions will be available. MendelPro is designed as a multi-user system for laboratory-wide consistency and access. Enterprise-level systems, with an external database, are under construction. Flash-based demonstration videos and example output can be viewed at http://mendel.genetics.ucla.edu.

Haplotype association of Monoamine Oxidase A Gene and Bipolar Affective Disorder in Han Chinese men. *Y.-M.J. Lin[1], F. Davamani[1], C.-H. Hsu[1], W.-C. Yang[2], T.-J. Lai[3], H.S. Sun[1]* 1) Inst Mol Medical Sci, National Cheng Kung Univ, Tainan, Taiwan; 2) Department of Biology, National Cheng Kung University, Tainan, Taiwan; 3) Department of Psychiatry, Chung Shan Medical and Dental College Hospital, Taichung, Taiwan.

Background/Aims: Monoamine oxidase A (MAOA) is a mitochondrial enzyme involved in degrading several different biological amines, including serotonin. Although several pieces of evidence suggested that MAOA is important in the etiology of bipolar affective disorder (BPD), associations for markers of the MAOA gene with BPD were not conclusive and the association has not been investigated in Taiwanese population. This study was designed to illustrate the role of MAOA in the etiology of BPD in Han Chinese. Methods: Two markers, a dinucleotide polymorphism in exon 2 and a functional uVNTR on the promoter of the MAOA gene, were used to study the genetic association in 108 unrelated patients with BPD and 103 healthy controls. Allelic distributions of two polymorphisms were analyzed and, caused the MAOA located at X chromosome, haplotype association was performed using haplotype unambiguously assigned in male participants. Results: While no difference in allelic distributions of two MAOA polymorphism was found, one common haplotype 114S was weakly associated with BPD in male patients ($P = 0.05$). The significance, however, was not found in female patients with 114S haplotype. Conclusions: Results from this study suggest that MAOA may have a gender-specific and small effect on the etiology of BPD in Taiwan. Due to the limited sample size, results from this study need to be confirmed in replicates.

Vitamin D Receptor Gene Genotypes are not Associated with Low Bone Density in RA Mexican Mestizo Women.

L. Sandoval-Ramírez[1,4], M.P. Casillas-Avila[1,4], L. González-López[3], M.A. López-Olivo[3], M.F. Alcaraz-López[3], E.A. Aguilar-Chávez[3], J.M. Oliva-Ortiz[1,4], I.P. Dávalos[1,4], E.R. Ochoa-Martínez[5], A. Celis[6], J.I. Gámez-Nava[2,4], M. Salazar-Páramo[2] 1) División de Genética, Centro de Investigación Biomédica de Occidente, CMNO, IMSS; 2) Hospital de Especialidades, CMNO, IMSS; 3) Hospital General Regional No. 110, IMSS; 4) Doctorado en Genética Humana, CUCS, Universidad de Guadalajara; 5) CUCBA, Universidad de Guadalajara; 6) Departamento de Salud Pública, CUCS, Universidad de Guadalajara, Guadalajara, Jalisco, México.

Introduction. Patients with rheumatoid arthritis (RA) have risk factors to osteoporosis, but not all become sick even intake the same drugs and doses. The variance in BMD (Bone Mineral Density) has been attributed to genetic factors. Studies have been found association between polymorphisms of the vitamin D receptor (VDR) gene and BMD and they account for 75% primary genetic factor for BMD. Purpose. To determine whether polymorphisms of VDR gene are associated with osteoporosis in Mexican RA women patients. Methods. Genotyping of VDR polymorphisms were performed by PCR-RFLP analysis from 129 Mestizo Mexican women patients with RA (mean age 54 years; age range 75-40 years) and 36 healthy women controls (mean age 54 years; age range 87-46 years). Three VDR gene polymorphisms (ApaI, FokI, BsmI and TaqI) were investigated. BMD of vertebral spine and hip were made to everyone to determined osteoporosis presence (OMS T < -2.5 SD). Chi square and OR was made to estimate risk of osteoporosis. Results. The polymorphisms frequency were in osteoporotic RA group: ApaI (AA= 51.6%; Aa= 29%; aa= 19.4%); BsmI (BB= 6.2%; Bb= 68.8%; bb= 25%): FokI (FF= 35.3%; Ff= 52.9%; ff= 11.8%); TaqI (TT= 46.9%; Tt= 40.6%; tt= 12.5%); and nonosteoporotic RA group: ApaI (AA= 42.7%; Aa= 37.8%; aa= 19.5%); BsmI (BB= 14.3%; Bb= 51.6%; bb= 34.1%); FokI (FF= 28.4%; Ff= 49.5%; ff= 22.1%); TaqI (TT= 45.8%; Tt= 43.4%; tt= 10.8%). There was no significant difference (p> 0.05) between groups. Conclusion. Our results suggest that VDR polymorphisms do not play a major role in low bone mineral density predisposition in Mexican RA women patients.

***DPYSL2*, a candidate schizophrenia (SZ) susceptibility gene on 8p.** *Y.P. Liu[1], L.L. Zhang[1], P-L. Chen[1], D. Avramopoulos[1], V.K. Lasseter[2], M.D. Fallin[3], J. McGrath[2], P. Wolyniec[2], G. Nestadt[2], K.Y. Liang[4], A. Pulver[2], D. Valle[1]* 1) Institute of Genetic Medicine; 2) Department of Psychiatry, Johns Hopkins University School of Medicine; 3) Department of Epidemiology; 4) Department of Biostatistics, Johns Hopkins Bloomberg School of Public Health.

Previously, in a genome-wide linkage scan of 54 European Caucasian (EC) multiplex families, we reported a SZ susceptibility locus on 8p22-p21 (~25.5 Mb) with a maximum NPL of 3.64 at D8S1771 (p=.0001) (Blouin *et al*. 1998). Additional STRP genotyping for these families supported a dominant model (LOD=4.10) peaking at D8S1048 (26.9 Mb) (Pulver, unpublished data). A follow up candidate gene SNP fine mapping study found that a gene in this region, *DPYSL2*, involved in axonal growth, showed positive association in both SZ and bipolar type 1 (BP1) in Ashkenazi Jewish (AJ) trios and cases (Fallin *et al*., 2005). Previous work by others showed positive association of a SNP in the 3 UTR of *DPYSL2* with SZ and studies of SZ brains showed a > 5-fold reduction in *DPYSL2* protein. We have followed these observations up with extensive sequencing of *DPYSL2* exons (14), proximal promoter and cNCS (4) in the region in AJ (48) and EC (96) controls, SZ (48 AJ, 48 EC) and BP1 (48 AJ) individuals. We identified 4 coding SNPs, none of which were associated with SZ or BP1 in our sample but we found 3 SNPs (rs367948, rs400181, rs445678) in the promoter region that were highly associated with SZ in the EC sample (p=0.007) but not in the others. To test the functional consequences of these SNPs, we generated luciferase reporter constructs containing 521bp of the human *DPYSL2* proximal promoter sequences, differing only at these 3 SNPs, and transfected them into 293, pc12 and neuro2a cells. We found modest reductions in promoter function with the risk alleles for the 3 SNPs but none that reached statistical significance. We conclude that *DPYSL2* is an excellent candidate gene for both SZ and BP1 but that further sequencing and expression studies (in progress) are necessary to either confirm or reject a role in these disorders.

Identification of rare mutations and polymorphisms in globin genes using denaturing high performance liquid chromatography (dHPLC) followed by sequencing analysis. *H.Y. Law[1], R.S. Roch[1], E.S. Tan[1], A.H.M. Lai[1], K.S. Aung[1], I.S.L. Ng[1,2]* 1) Dept Pediatrics, KK Women's & Children's Hosp, Singapore, Singapore; 2) National Thalassaemia Registry, Singapore.

Molecular analysis of gene mutation provides accurate diagnosis of genetic disease. However, analysis of an entire gene for all mutations is often not possible or cost effective. Current DNA diagnosis of -thalassaemia screens for 11 mutations, including 3 2-gene deletions, 2 single gene deletions and 5 point mutations in 1 globin gene and 1 point mutation in 2 globin gene, which account for 99% of -thalassaemia alleles in Singapore. To find out if patients suspected to be -thalassaemia but negative for the screening test carry other rare mutations, a strategy has been developed to 1) determine the region that may habour a mutation in the 1 and 2 gene using dHPLC, and 2) confirm the mutation by sequencing. DNA samples from 636 patients from National Thalassaemia Registry (NTR) and outpatient clinics were analysed. Patients have either family history, MCV<85dL, presence of HbH inclusion bodies or a combination of the above. All were tested for 11 common -thalassaemia mutations. For dHPLC analysis, 1 and 2 globin genes were specifically amplified, followed by nested amplification to generate 4 overlapping amplicons in each gene for heteroduplex analysis on dHPLC (Transgenomic WAVE). Amplicons displaying heteroduplexes were sequenced using ABI Cycle Sequencing kit to identify mutations. Mutations were detected in 68 samples: 30 in 1 and 38 in 2 gene. Mutations in 18 led to known Hb variants and 2 novel variants (in Cd5 and Cd122). Eight thalassaemia mutations were found in poly A (4), Start Codon (3) and promotor (1). Interestingly the Cd122 (CAC/CTC) in 2 globin gene appeared to be associated with HbH phenotype in combination with Hb Bleuland (Cd108 (ACC/AAC))detected by dHPLC. As various mutations displayed characteristic chromatograms on dHPLC, prescreening using dHPLC followed by confirmation with sequencing is effective in detecting mutations, making screening rare mutation more affordable.

Distribution of genetic variants associated with steroid biosynthesis and prostate cancer in Mexico. *M. Rodriguez-Dorantes, K. Carrillo-Sanchez, H. Miranda-Ortiz, C. Rangel-Escareno, G. Jimenez-Sanchez* National Institute of Genomic Medicine, Mexico.

Prostate cancer is the second most common male malignancy. In Mexico, ~40% of men between 60-69 years old suffer from this disease. Androgens are essential for normal differentiation and malignant growth of the prostate. Genomic variation in genes involved in biosynthesis and metabolism of androgens have been associated with risk to prostate cancer. We screened SNPs in candidate genes to determine their geographic distribution in Mexico. DNA from 672 unrelated males were obtained from seven states of Mexico (96 each): Sonora (SON), Guanajuato (GUA), Zacatecas (ZAC), Guerrero (GUE), Veracruz (VER), Tamaulipas (TAM), and Yucatan (YUC). We genotyped *LHB* (-1184CT, rs753307), *CYP17A1* (+27TC, rs743572) and *SRD5A2* (-17CG, rs523349, +10GC, rs632148) using a TaqMan allelic discrimination system (AB). Our results show that *LHB* -1184TT in GUE and VER has a significantly lower frequency of the TT genotype (0.043 and 0.086) compared to the rest of the analyzed states (0.179+-0.063 CI 0.102-0.258; FST p0.03). This genotype has also a significantly lower frequency in Mexican mestizos (0.14 +-0.076 CI 0.078-0.22) compared with two of the HapMap populations: CEU (0.35) and YRI (0.28), and are similar to the CHB-JPN samples. For the *CYP17A1* +27AA genotype, GUA shows a significantly higher frequency (0.22) compared to the rest of the states (0.136 +- 0.015 CI 0.071-0.212; FST p0.001) but lower than the CEU (0.448), YRI (0.576) and CHB (0.364). *SRD5A2* +10CC showed a significantly lower frequency in GUE (0.33) vs the rest of the states (0.31 +-0.058 CI 0.248-0.482; FST p0.005). This genotype has also a higher frequency in Mexicans (0.37+-0.059 CI 0.275-.475) compared to the CEU (0.038), CHB (0.26), JPT (0.125) and YRI (0.039). *SRD5A2* -17CG did not show significant difference in our population, nor with those of the HapMap. The observed differences in frequencies may relate to ancestral admixture proportions in different regions of Mexico. We are currently evaluating implications of these genetic differences in steroid hormone levels and prevalence in prostate cancer throughout Mexico.

Role of promoter polymorphism in the MIF gene in the pathogenesis of Severe Malarial Anemia. *G.A. Awandare[1], C. Ouma[1,2], G. Davenport[1], J.M. Ong'echa[2], R.E. Ferrell[1], R. Bucala[3], J.J. Martinson[1], D.J. Perkins[1]* 1) University of Pittsburgh, Graduate School of Public Health; 2) KEMRI, Kisumu, Kenya; 3) Yale University School of Medicine.

Severe malarial anemia (SMA) is one of the major causes of childhood mortality in regions of sub-Saharan Africa where *Plasmodium falciparum* malaria is holoendemic. The molecular causes of SMA are largely undefined, but dysregulation in host-derived inflammatory mediators influence its severity. The cytokine Macrophage Migration Inhibitory Factor (MIF) is an important regulator of innate inflammatory responses that suppresses erythropoiesis and promotes pathogenesis of SMA in murine models. We investigated the role of MIF in childhood malaria by examining peripheral blood MIF production in children residing in a holoendemic region of western Kenya.

We had previously shown that circulating MIF levels, and peripheral blood mononuclear cell (PBMC) MIF production, progressively declined with increases in anemia severity and in levels of monocytes containing the malarial by-product hemozoin. However, MIF levels were not significantly associated with reticulocyte production in children with acute malaria, and adding exogenous MIF, or blocking endogenous MIF, *in vitro* did not significantly affect erythropoiesis. Experiments in malaria-naïve individuals showed that the effects of hemozoin on MIF production in cultured PBMC were influenced by genetic differences. Analysis of SNPs in the MIF gene promoter revealed that the CC genotype of the C-173G SNP was associated with an increased risk of High Density Parasitemia compared to the GG genotype. Here, we present the results of a more systematic survey of genetic variation in the MIF promoter, including an upstream CATT tetranucleotide STR locus located at position -794, and show that individuals with the $CATT_6$/-173G haplotype were significantly protected from SMA while those with $CATT_{7-8}$/-173C haplotypes were at an increased risk of developing SMA. SMA is associated with decreased MIF production, and individuals with high MIF-producing genetic variants are less susceptible to severe malaria.

Cardiac rhabdomyoma diagnosed prenatally in a boy diagnosed after birth with Silver-Russell syndrome: a new form of tumor associated with the syndrome. *M. Sklansky[1], L.M. Randolph[2]* 1) Pediatric Cardiology, Childrens Hospital Los Angeles; 2) Pediatrics-Medical Genetics, Childrens Hospital Los Angeles, Los Angeles, CA.

K.O.'s 27-y.o. Hispanic mother and 29-y.o. non-consanguineous Hispanic father presented to the CHLA-USC Institute for Maternal-Fetal Health late in pregnancy for evaluation of a large left intracardiac mass. It was judged to likely be a left ventricular rhabdomyoma. No other ultrasound abnormalities were seen. They were counseled regarding the risk of tuberous sclerosis. K.O. was born full term, 2330 g, and MRIs of head, abdomen and chest were negative for masses. Cardiac mass measured 19 x 9 mm w/o hemodynamic significance, but he appeared to have failure to thrive and concern raised for tuberous sclerosis, so was referred to Genetics again. Development normal. Hearing, vision normal. Had pyloric stenosis repair at 2 mos age. Wt >2 S.D. below mean; ht 5th %ile; HC 2nd %ile. Triangular facies and prominent forehead. L-sided hemihypotrophy. No skin lesions using Woods lamp. Slightly blue sclerae. Left leg 3 cm shorter than right, and L arm 1 cm thinner than R arm. Diagnosed with Silver-Russell syndrome (SRS). F-u echo showed mass in heart shrinking. Uniparental disomy (UPD) chromosome 7 testing negative using markers D7S641, D7S493, D7S510, D7S630, D7S515 and D7S2423 but was not informative for segmental UPD. SRS is due to mat(UPD) in 10% of cases, and it can be partial or complete UPD. Craniopharyngioma, testicular seminoma, Wilms tumor and hepatocellular carcinoma have been reported in SRS. To our knowledge, cardiac rhabdomyoma has not been reported in SRS. Plans are to complete segmental UPD7 testing and to do H19 hypomethylation studies. He has been referred to Orthpedics and Endocrinology.

Leveraging the HapMap correlation structure in association studies. *N. Zaitlen[1], H. Kang[1], E. Eskin[2], E. Halperin[3]*
1) Bioinformatics, Univ California, San Diego, La Jolla, CA; 2) Computer Science, Univ California, Los Angeles, LA, CA; 3) International Computer Science Institute, Berkeley, CA.

Recent genotyping technologies have driven down the costs of association studies and have enabled the measurement of SNP allele frequency differences between case and control populations on a genomewide scale. A key aspect in the efficiency of association studies is the notion of "indirect association," where only a subset of SNPs are collected to serve as proxies for the uncollected SNPs. Recently, a new class of methods for indirect association, multimarker methods, has been proposed. Although the multimarker methods are a considerable advancement, current methods do not fully take advantage of the correlation structure between SNPs and their multimarker proxies. We propose a novel multimarker indirect-association method, WHAP, that is based on a weighted sum of the haplotype frequency differences. In contrast to traditional indirect-association methods, we show analytically that there is a considerable gain in power achieved by our method compared with both single-marker and multimarker tests, as well as traditional haplotype-based tests. In order to extend the power and applicability of WHAP and multi-marker methods in general we develop additional techniques that are well studied in the single marker case. First, we describe a novel method to pick tags with the intent of carrying out a WHAP based analysis. Compared to traditional single SNP tagging methods, we observe a strong gain in power with the same genotype cost. Our method can be applied to select SNPs for a follow up study or to develop more powerful whole genome tag sets. Second, we show how to determine which multi-marker tags to evaluate in a population distant from the HapMap populations. The class of multi-marker tests rely on the use of a reference panel such as the HapMap to estimate the correlation between SNPs and markers. However, in many case control studies the population does not match one of the reference populations. We selectively include or exclude multi-marker tests based on local similarity of correlation structure. This technique reduces false positive rate and improves power.

Digital PCR and High Resolution Melting for the Discovery of Very Low Allele Fraction Somatic Mutations in Tumor Samples. *J.T. McKinney[1], M.D. Wall[1], L.L. Cutler[1], D. Ruddy[2], B. Gorbetcheva[2], J. Monahan[2], D.H.F. Teng[1]*
1) Research and Development, Idaho Technology, Inc., Salt Lake City, UT; 2) NIBR, Oncology, Boston, MA.

Digital PCR (dPCR) is a means to identify mutations in a minor cell population fraction (i.e. primary tumor tissue). By diluting DNA samples down to a single copy, it is possible to transform the analog nature of PCR into a linear, digital signal. We sought to apply High Resolution Melting (HRM) to a modified dPCR approach for defining low fraction variants identified by an abnormal melting profile in the primary tumor sample. Digital PCR requires that a single copy of DNA is used as starting template for amplification, thus endpoint detection becomes a digital readout rather than an analog admixture of the DNA. In order to apply HRM, a more robust amplification is required for a reliable melting profile, thus we chose a target dilution of 5 copies. This dilution target is based on the limitations of downstream sequencing being approximately 20% sensitive to detect low fraction variants. HRM is sensitive to 5% mutant allele fraction; therefore even a single copy of the mutant allele would be sufficient to detect a difference in the melting profile. A total of 14 samples representing known variants or suspected low fraction somatic mutations were assayed in 6 different cancer gene targets. For samples with known variants, low fraction mixtures were created at 5% and 2.5% of the minor allele. All samples were diluted to a concentration 5 copies and amplified in replicates of 24. Replicates that did not amplify robustly were excluded from the high resolution melting analysis, leaving only reproducible melting profiles to analyze. Replicates that displayed an abnormal profile were selected for sequencing confirmation. Low fraction somatic mutations were identified in 6 of 8 tumor samples, whereas all 6 samples with known variants were successfully identified in both the 5% and 2.5% dilutions. These results indicate that HRM as a pre-screen to a modified dPCR approach can significantly reduce the downstream sequencing effort of the traditional dPCR application for identifying low fraction variants.

Roles of Advocacy Groups in Genetic Research of Complex Traits: The Example of Autism. *H.K. Tabor, M. Lappé, M.K. Cho* Ctr Biomedical Ethics, Stanford Univ, Palo Alto, CA.

Historically, patient and family advocacy groups for genetic diseases have played key roles in research. Research on Huntingtons disease, cystic fibrosis and hemophilia has been directly influenced by the work of advocacy groups in raising funds for research, organizing subjects for participation, and making recommendations about screening and genetic counseling. One of the roles of advocacy groups for rare Mendelian traits has been the creation of collaborative relationships between families and researchers in genetic research studies. These interactions, and the ethical and social issues involved, have been documented in work by social scientists and ethicists, as well as by advocates themselves. However, little research has been published on the roles of advocacy groups in genetic research on complex diseases, and whether the ethical and social issues involved in these roles differ from those in the context of Mendelian traits.

We examined the roles of advocacy groups in genetic research for one complex disease, autism. We conducted semi-structured interviews with leading genetics researchers in autism and the founders and leaders of the largest autism advocacy groups. Interviews were analyzed using qualitative textual analysis. We will present data on how interactions between advocacy groups and researchers influence the framing of causality of autism, particularly the relative influence of genetic causation. We will describe ethical and social issues identified by interviewees in the effort to identify causal genes through the creation of large-scale databanks of DNA and phenotypic data for complex traits and through large-scale collaborations across multiple research groups. We will also present findings on the influence of advocacy groups on the short and long term goals of genetic research, consent of family members for participation in genetic research for complex traits, and researcher-participant trust. We will also discuss researcher and advocacy group perspectives on the advantages and disadvantages of their interactions, the future of genetic research of autism and on the future roles of advocacy groups.

MPS-Brazil Network: 3 years improving diagnosis and management of Mucopolysaccharidoses in Brazil. *I. Schwartz[1,2], A. Federhen[1], C. Rafaelli[1], U. Matte[1], J. Coelho[1], M. Burin[1], R. Giugliani[1], MPS-Brazil Network Group* 1) Medical Genetics Serv, Hosp Clinicas de Porto Alegre, Porto Alegre RS, RS, Brazil; 2) Genetics Departament, Universidade Federal do Rio Grande do Sul, Porto Alegre, Brasil.

Purpose: To present the results of the first 3 years of operation of the MPS-BRAZIL NETWORK, a collaborative initiative involving centers from different Brazilian regions (Southeast-SE, South-S, Northeast-NE, North-N and West-Center-WC) to improve the diagnosis and management of MPS diseases in the country. Methods: The Medical Genetics Service of Hospital de Clínicas de Porto Alegre is the coordinating center, providing the information on the management of patients and making available the laboratorial tests necessary for their diagnosis. Results: 1) During this period, 493 Brazilian patients suspected of having MPS were investigated; the diagnosis of MPS was confirmed in 289/493 patients (58.6%); 2) MPS I was confirmed in 68/289 patients (mean age at diagnosis: 6yr6mo; origin: 37 SE, 18 S, 8 NE, 3 CO, 2 N); 3) MPS II was confirmed in 87/289 patients (mean age at diagnosis: 7yr11mo; origin: 39 SE, 24 NE, 19 S, 3 N, 2 WC); 4) MPS III was confirmed in 36/289 patients (mean age at diagnosis: 7yr2mo; origin: 23 SE, 6 NE, 5 S, 1 N, 1 CO); 5) MPS IV was confirmed in 22/289 patients (mean age at diagnosis: 11yr5mo; origin: 9 NE, 7 SE, 6 S); 6) MPS VI was confirmed in 71/289 patients (mean age at diagnosis: 6yr11o; origin: 29 SE, 28 NE, 5 N, 5 S, 4 WC); 7) MPS VII was confirmed in 5/289 patients (mean age at diagnosis: 4yr10mo; origin: 3 SE, 2 NE). Conclusions: MPS II, I and VI seem to be the most frequent types of MPS in Brazil, and MPS III seems to be underdiagnosed. There seems to be a difference in regional distribution of MPS, since MPS I is more common in the S and SE regions, while MPS VI seems to be less frequent in the S region. Mean age at diagnosis was found to be high in all the MPS types. Support: CNPq, Shire, Genzyme, Biomarin.

Limb duplication and ipsilateral renal agenesis: human homolog of mouse Polypodia? *G.E. Tiller, E.G. Yokoyama*
Dept Genetics, Kaiser Permanente, Los Angeles, CA.

Complete limb duplication is an unusual human malformation which may be isolated or associated with renal, genital, and/or other defects. We report a 1,400gm 32-week gestation triplet girl, conceived with Clomid, who was born to a 25 year-old G3P1sAb1 mother. Physical exam revealed right popliteal pterygium as well as mirror-image duplication of the right foot. Radiographs revealed duplication of the right femur and fibula, and ultrasound exam revealed absence of the right kidney. The infant grew well and was discharged at one month of age. The other triplets were unaffected, and the only familial anomaly was the paternal great-grandfather who had a single kidney. The pattern of malformations in our patient appears similar to those seen in the Polypodia (Ppd) mouse (Lehoczky JA et al., Mamm. Genome 17:903, 2006). Ppd is an X-linked dominant disorder which has been bred from a single affected CD-1 male, with approximately 20% penetrance. Phenotypic features overlap with those of mice exposed to retinoic acid in utero, as well as the Disorganization (Ds) mouse, which is an autosomal dominant disorder with reduced penetrance. The broader spectrum of anomalies seen in Ds mice implies that the effect of Ppd may lie downstream in the process of pregastrulation body patterning.

Genotype-phenotype correlations in spinal NF. *L. Messiaen[1], T. Callens[1], J.B. Williams[1], D. Babovic-Vuksanovic[2], S. Huson[3], E. Legius[4], R. Mac Gardner[5], I. Pascual-Castroviejo[6], S. Plotkin[7], G.B. Schaefer[8], M. Wilson[9], B. Korf[1]* 1) Genetics, Univ Alabama, Birmingham, AL; 2) Medical Genetics, Mayo Clinic, Rochester, MN; 3) Medical Genetics, St Mary's Hospital, Manchester, UK; 4) Human Genetics, Catholic University Leuven, Belgium; 5) Genetic Health Services, Royal Children's Hospital, Melbourne, Vic, Australia; 6) Univ Hospital La Paz, Madrid, Spain; 7) Neurology, MGH, Boston, MA; 8) Univ Nebraska Medical Ctr, Omaha, NE; 9) Clinical Genetics, Children's Hosp Westmead, Sydney, Australia.

We studied 22 adult patients with multiple spinal dorsal root neurofibromas with or without additional massive involvement of peripheral nerve sheaths, but with very few, if any, other clinical symptoms of *NF1*. Twelve of the patients did not fulfill NIH criteria. Classic NF1-associated skin findings that lead to a diagnosis in childhood (CAL-spots and freckling) or adolescence (cutaneous neurofibromas) were typically absent. As a consequence, patients came to clinical attention in adulthood, when tumors had become symptomatic. A different *NF1* mutation was identified by comprehensive *NF1* analysis in 19/22 unrelated cases. No *NF1* mutation was found in 2 sporadic and one non-founder patient, indicating that genetic heterogeneity may exist. The mutational spectrum identified in patients with spinal NF differed highly significantly from the unbiased spectrum as characterized in our cohort of 1500 unrelated patients. In patients with spinal NF, no *NF1* total gene deletions, frameshift or nonsense mutations, accounting for 56% of mutations in our cohort, were found and an overrepresentation of missense (5/19) and splice mutations (14/19) was observed. Importantly, 5 of the splice mutations would escape detection using gDNA-based exon-by-exon screening, as they are caused by creation of a splice site several hundred bp deep into the large *NF1* introns. Two other splice mutations mimick a nonsense (W2054X) or silent mutation (Q2267Q) at the gDNA level and would get misclassified or not recognized as pathogenic in the absence of an RNA-based approach. The subtle changes in the *NF1* gene observed in this cohort of spinal NF patients may hold key insights into the tumor-suppressor roles of NF1.

Obesity-associated SNP distribution in the Mexican Mestizo population. *D. Velazquez[1], I. Silva-Zolezzi[1], K. Carrillo[1], R. Reynoso[2], M.F. Herrera[2], E. Garcia-G[2], G. Jimenez-Sanchez[1]* 1) National Institute of Genomic Medicine, Mexico; 2) National Institute of Medical Sciences "Salvador Zubiran", Mexico.

Obesity is considered a global pandemia. Two thirds of the Mexican population has an abnormal body mass index and close to 24% can be defined as clinically obese. Published studies have suggested that hispanic-americans, and possibly Mexicans have a higher risk for the disease. Most of the Mexican Mestizo population results from admixture of any of 65 ethnic groups, with Spaniards, an in a lesser extent Africans. A number of genetic polymorphisms have been associated to obesity in different populations. To characterize obesity-associated SNPs in the Mexican population we genotyped 5 SNPs in obesity genes: *ADRB2* 1666CG (rs1042741), *ADRB3* 387CT (rs4994), *AGRP* 499AG (rs5030980), *POMC* 934GA (rs1042571), and *PPARG2* 34CG (rs18012182) in 1,033 Mestizos from 5 different states of Mexico: Guanajuato, Sonora, Veracruz, Yucatan and Zacatecas. These SNPs have shown association to obesity in at least 2 different populations. Our results showed the following average frequencies: *ADRB2* 0.20 (CI95 0.14-0.27); *ADRB3* 0.34 (0.11-0.25); *AGRP* 0.02 (0.01-0.05); *POMC* 0.12 (0.07-0.18); and for *PPARG2* 0.12 (0.06-0.17). Comparative analysis of the Mexican allele frequencies with other world populations showed significant differences as in the case of *POMC* 934GA (rs1042571) with an average minor allele frequency (MAF) of 0.15 for Mestizos vs. 0.30 for CEU (HapMap) and for *ADRB2* 1666CG (rs1042741) MAF of 0.22 for Mestizos and 0.40 fro CEU. We are conducting a multicentric study including morbid obese patients from different parts of Mexico. Preliminary results show MAF of 0.33 (CI95 0.16-0.50) for *ADRB2*; 0.10 (0.01-0.2) for *ADRB3*; 0.06 (-0.02-0.15) for *AGRP*; 0.20 (0.06-0.34) for *POMC*; and 0.06 (0.01-0.22) for *PPARG2*. Our preliminary results show differences for some MAFs in obese patients compared to population controls. We propose that our case-control study in the Mexican admixed population can lead to the identification of novel genes associated to obesity.

Translation and Regulation of Personalized Medicine is Here and Now. *P.F. Terry[1], S.F. Terry[2]* 1) Genomic Health, Inc., Personalized Medicine Coalition, *Coalition for 21st Century Medicine, Wash., DC; 2) Genetic Alliance, Inc. Wash., DC.

Ensuring timely patient access to high quality, safe and effective genetic/genomic technologies is important to all stakeholders: scientists, providers, regulators, payers, public health officials, and patient organizations. Accelerating scientific advancements and their disruptive impact on healthcare delivery is a major challenge for the genetics community. Establishing appropriate oversight and balanced regulation to encourage the maturation of genetic technologies through the transition to routine clinical applications is critical. All stakeholders must work to ensure that these transition steps are accelerated and responsible. Current technological advancements, exponential knowledge generation, rapid product life cycles, innovative precision tools, and the diversity of novel clinical studies, genetic discoveries, compelling biological associations, and the various innovative delivery models have burdened the traditional regulatory schema. We explore solutions for validation of clinical claims for genetic/genomic tests, development and implementation of least burdensome regulatory approaches to products and service delivery models, restrictions on off-label use, evolving clinical utility claims, coding and reimbursement for genetic/genomic tests, and the incentives of value-based pricing for both components (Rx & Dx) of personalized medicine solutions. We review a variety of efforts and solutions proposed by advocacy organizations engaged in the debate over defining appropriate oversight and regulation of modern genetic/genomic testing services.

Whole genome association analysis in anencephaly. *D. Stamm[1, 2], C.S. Haynes[1], D. Siegel[1], L. Mehltretter[1], K. Soldano[1], A. Trott[1], J. Rimmler[1], A. Dellinger[1], J.R. Gilbert[3], M.C. Speer[1], NTD Collaborative Group* 1) Duke University Medical Center, Durham, NC; 2) University of North Carolina, Chapel Hill, NC; 3) The Institute for Human Genomics, University of Miami, Miami, FL.

Neural tube defects (NTDs) are common birth defects and are considered complex in etiology, with both genetic and environmental factors implicated. Cranial NTD defects include anencephaly, acrania and encephalocele. Since anencephaly is the most severe form of cranial level NTDs, we hypothesize that the underlying genetic burden is higher in anencephaly than in other NTDs. To capitalize on this hypothesized higher genetic burden among anencephalics than other types of NTDs, we performed a whole genome association analysis in 49 NTD families with cranial defects (174 individuals) using Illuminas 317K SNP chip. Plink was used to calculate p-values for tests of departure from HWE and TDT for family-based association analysis. Two phenotypic classifications were used. The broad classification included families with a cranial NTD (n=49) in the analysis whereas the narrow classification included only families with anencephaly (n =44). The TDT showed 7 and 15 SNPs with p-values between 10^{-4} to 10^{-5} for the narrow and broad phenotypic classifications. Some of these SNPs mapped to the following genes: *INADL*, *LRP1B*, *STK39*, *RAD51L1*, *PAK7*, and *ACTN2*. Two SNPs are in *INADL* including rs1134767 (non-synonymous) and rs6697273 (intronic), and are in strong LD (r^2 =0.90) with one another. Interestingly, *INADL* has higher expression in Carnegie Stage C12 (neural tube closing) than Carnegie Stage 13 (neural tube closed; p <.03) in a comparison of SAGE libraries of human fetal neural tube tissue (see abstracts by Xu and Dellinger at this meeting). *INADL* regulates the frizzled-dependent planar cell polarity pathway (PCP) in the *Drosophila* eye; PCP is involved in appropriate neural tube closure. Together, these data suggest *INADL* may be a novel NTD candidate gene. Microarray expression analysis comparing gene expression differences between amniocytes from anencephalic fetuses vs. control fetusus, currently in progress, may illuminate the role of *INADL* and other genes identified from this study in NTD risk.

Extent and distribution of linkage disequilibrium in the Old Order Amish. *A.M. Levin[1], E. Rampersaud[2], H. Shen[2], B.D. Mitchell[2], A.R. Shuldiner[2], J. O'Connell[2], J.A. Douglas[1]* 1) Dept Human Genetics, Univ Michigan, Ann Arbor, MI; 2) Dept Medicine, Univ Maryland, Baltimore, MD.

Knowledge of linkage disequilibrium patterns is useful in evaluating population structure and designing and interpreting genetic studies of complex traits and diseases. Because the demographic history of each population varies and is not accurately known, it is necessary to evaluate LD empirically in each population of inference. We conducted a genome-wide survey of LD with a high-density single nucleotide polymorphism (SNP) map (~400,000 markers with an average intermarker distance of ~7 kb) in a sample of 60 maximally unrelated individuals from the Old Order Amish (OOA) population of Lancaster County Pennsylvania, a closed, Caucasian population derived from a modest number of founders in the 1700s. We then compared the extent and distribution of LD in the OOA with the 60 founders from the HapMap CEU sample, an outbred, European-derived sample. Overall, LD patterns were remarkably similar between these two samples, presumably reflecting their recent shared demographic history. For example, for SNPs 20-50 kb apart with common alleles (minor allele frequency5%), $R^2$0.8 for 7% and 6% of SNP pairs in the OOA and CEU samples, respectively. Most of this short-range LD presumably predates the founding of the OOA population and so differs little from the CEU source population. In contrast, for common alleles, long-range LD was ~2-fold higher in the OOA relative to the HapMap CEU sample. For example, for SNPs 0.5 to 1 Mb apart, D'=1 for ~14% of SNP pairs in the OOA sample and 7% of SNP pairs in the CEU sample. This difference for long-range LD presumably reflects the unique demographic history of the OOA population. These data are consistent with previous theoretical predictions (e.g., see Krugylak 1999) and recent empirical data from other founder populations (e.g., see Willer et al. 2006) that suggested minor differences in LD between isolated and mixed populations, particularly for common alleles and a modest number of founders. Our results have important implications for gene mapping in the OOA.

Identification of a novel IRF6 variant in a Chinese family with Van der Woude Syndrome. *E.C. Tan[1], E.C.P. Lim[1], J. Cheng[2], V. Yeow[2]* 1) KK Research Centre, KK Women's and Children's Hospital, Singapore; 2) Cleft and Craniofacial Centre, KK Women's and Children's Hospital, Singapore.

Van der Woude syndrome (VWS) is a rare disorder with an autosomal dominant mode of inheritance. It closely mimics the more common non-syndromic CL/P except for the additional features of lip pits and hypodontia. For the non-syndromic form which is one of the most common congenital and craniofacial malformations in man, there is no known major genetic or environmental determinant to date despite intensive investigations. In contrast, mutations in the interferon regulatory factor-6 gene (IRF6) have been shown to co-segregate with the VWS phenotype. Using VWS families as a simpler model for the non-syndromic forms, identification of mutations and knowledge of how these mutations lead to oral clefting in VWS families will increase our understanding of the pathogenesis of malformation in craniofacial development. The proband is a Chinese boy who is 3 months old at the time of recruitment into the study. He has an affected maternal uncle (long deceased and genetic material unavailable) but his two parents are unaffected. Microsatellite analysis and DNA sequencing were performed on the genomic DNA from the proband and the parents. There is a G to T change in the 3rd exon or position 396 of the mRNA which will result in a non-synonymous substitution of arginine by tryptophan (R45W) within the DNA-binding domain. The proband is heterozygous for this variant which he inherits from his mother who is also heterozygous at this position. The sibling without the VWS phenotype is also heterozygous. We screened another 100 chromosomes in our control samples. All were negative for this variant. Although the variant is also found in the unaffected mother and sister, it cannot be ruled out that it might predispose to VWS in the presence of additional genetic or environmental factor which is only encountered in the proband and his maternal uncle but not in the mother or sister, or that penetrance is higher in males. Additional work is also needed to investigate the effect of the change from a hydrophilic to an aromatic- hydrophobic amino acid residue on the function of the protein.

Genetic disease in offspring of survivors of childhood and adolescent cancer. *J.J. Mulvihill[1], H. Munro[2], J.A. Whitton[3], D.M. Green[4], A.C. Mertens[5], R. Weathers[6], M. Stovall[6], L.C. Strong[6], L.L. Robison[7], The Childhood Cancer Survivors Study* 1) Pediatrics, University of Oklahoma, Oklahoma City, OK; 2) International Epidemiology Institute, Rockville, MD; 3) Fred Hutchinson Cancer Research Center, Seattle, WA; 4) Roswell Park Cancer Institute, Buffalo, NY; 5) Emory University, Atlanta, GA; 6) UT MD Anderson Cancer Center, Houston, TX; 7) St. Jude Children's Research Hospital, Memphis, TN.

No environmental agent has been proved to cause human germ cell mutation seen as genetic disease in offspring. Cancer survivors often receive intensive chemotherapy and radiotherapy that cause human and experimental somatic mutations and animal germline mutations. To study environmental germline mutagenesis, we used the Childhood Cancer Survivor Study, a retrospective cohort of 14,054 children diagnosed with cancer before age 21 years and surviving at least 5 years, at 26 US and Canadian institutions (*Med Pediatr Oncol* 2002;38:229). Participants were 54% male, 87% white, and 64% between ages of 20 and 39 years at follow-up; 68% received radiotherapy and 74% chemotherapy. Radiation doses to gonads were calculated from original records and phantoms to estimate dose-response and doubling dose; mean doses were 126 cGy to ovaries and 46 cGyto testes. Genetic diseases in patients, families, and offspring were ascertained by self-administered questionnaires; verification was by medical records and consensus rules for inclusion were by a 3-person panel. Genetic and congenital diseases occurred in 157 (2.6%) of 6129 offspring of survivors, compared with 111 (3.6%) of 3101 offspring of sibling controls; there were no apparent differences in the proportion of offspring with cytogenetic syndromes (7 in case offspring, 6 in sibling offspring), single-gene defects (14 and 8), or simple malformations (136 and 97). These preliminary results provide reassurance that cancer treatment using modern protocols does not carry a large risk of genetic disease in offspring conceived many years after treatment. (NIH-NCI grants U24CA55727 and 5R01CA104666).

Identification of a novel autosomal dominant limb-girdle muscular dystrophy. *N.H. Wang[1], Y.W. Yang[2], H.W. Chen[1], C.H. Chen[1], Y.T. Chen[1], J.Y. Wu[1]* 1) IBMS, Academia Sinica, Taipei, Taiwan, Taiwan; 2) Dept of Neurology, China Medical University Hospital, Taichung, Taiwan.

The limb-girdle muscular dystrophies (LGMD) comprise a clinically and genetically heterogeneous group of muscle disorders with shoulder and pelvic girdle muscles weakness. Clinical course in this heterogeneous group has great variability, ranging from severe forms with various onset age and variable rate of progression. Onset age of LGMD occurs from the late first decade to middle. Early symptoms include difficulty walking, running, standing up from a squatting position, raising arms above the head, and carrying heavy things. The weakness of limb girdle muscles is progressive and the rate of progression is greatly variable. Variation seen in the LGMDs is caused by the mutations in different genes or the different changes within the same gene. These differences can lead to more severe or milder forms of LGMD. During the past decade, through molecular genetic discoveries and improved clinical criteria, more than 14 genes/loci responsible for limb girdle muscular dystrophy (LGMD) have been mapped, including eight types of autosomal recessive LGMD (AR-LGMD) and six types of autosomal dominant LGMD (AD-LGMD). A four-generation family with AD-LGMD was identified in Taiwan. Characteristic muscle weakness predominantly involving the pelvic and shoulder girdle proximal muscles was shown in 11 individuals. Age at onset ranges from 10-40. Cardiac involvement, calf hypertrophy, and contractures are not observed in these affected individuals. Linkage analysis to chromosomes 5q31, 1q11, 3p25, 6q23, and 7q demonstrated that this disease is not allelic to LGMD forms 1A, 1B, 1C, 1D, and 1E. Genome wide linkage-analysis using 384 markers was performed and no marker with LOD score larger than 2 was identified. A 10K SNP oligoarray was also used for linkage analysis. Two chromosome regions (about 8 Mbp and 3.6 Mbp, respectively) with LOD score larger than 4 were identified. Those two regions were not one of the previous loci identified to be either autosomal dominant or autosomal recessive LGMD. A new gene is probably involved in the autosomal dominant limb girdle muscular dystrophy.

The Xq28 inversion breakpoint interrupted a novel noncoding gene in a patient with Duchenne muscular dystrophy with severe mental retardation. *M. Yagi[1], H.T. Thi Tran[1], Z. Zhang[1], A. Nishiyama[1], Y. Oyazato[1], T. Okinaga[2], Y. Takeshima[1], M. Matsuo[1]* 1) Pediatrics, Kobe University Graduate School of Medicine, Kobe, Japan; 2) Pediatrics, Osaka University Graduate School of Medicine, Osaka, Japan.

[Background] Duchenne Muscular Dystrophy (DMD) is the most common inherited muscle wasting disease and caused by mutation of the *dystrophin* gene. In one third of DMD patients, mental retardation (MR) is complicated. However exact mechanism that leads to MR is not yet known. We identified a pericentric inversion of the X chromosome in a DMD patient with severe MR and disruption of a novel noncoding gene cloned from the inversion breakpoint. **[Case]** The proband is a three-year-old Japanese boy. He was pointed out high CK nemia (25,510IU/l) at birth. At one year old muscle biopsy was performed to disclose no dystrophin staining and he was diagnosed as DMD. He complicated severe MR. **[Results and Discussion]** Neither Southern blot analysis nor sequencing of each 79 exons disclosed any responsible mutation in the *dystrophin* gene. A karyotyping disclosed 46,Y,inv(X)(p21.2q28). The breakpoint in Xp21.2 was supposed be within the *dystrophin* gene and dystrophin mRNA was found to be separated into two parts between exons 18 and 19. RACE assays was performed to clone the breakpoint in Xq28. 5RACE analysis extending from exon 19 revealed an unknown fragment that was completely identical to the region of the Xq28. 3RACE analysis extending from exon 18 revealed another unknown sequence that consisted of two separate parts derived from the two regions in Xq28. These three cloned sequences maintained characteristics of exons and the last one contained a polyadenylation signal, followed by poly A tail. Therefore, these three sequences represent a gene. However, this gene did not match any annotated gene but had no open reading frame, concluding a noncoding gene. As a conclusion the inversion breakpoints of inv(X)(p21.2q28) disrupted not only the *dystrophin* gene but also a novel noncoding gene located at Xq28. It was supposed that disruption of the novel gene located at Xq28 was responsible for the patients severe MR.

Mapping Accessible Sites in Rod Opsin Transcripts for Post Transcriptional Gene Silencing Therapy. *R.T. Taggart[1,2], E.H. Yau[1,2], T.A. Kolniak[1,2], M.C. Butler[1,2], J.M. Sullivan[1,2]* 1) Ophthalmology, SUNY Buffalo, Buffalo, NY; 2) VA Western NY Medical Center, Buffalo, NY.

More than 140 different rhodopsin gene mutations are associated with autosomal dominant retinitis pigmentosa. To accommodate this diversity we employed a mutation independent strategy to reduce both the normal and mutant rhodopsin transcripts in heterozygous carriers with post transcriptional gene silencing agents (PTGS) while providing a modified rhodopsin transcript that is resistant to the PTGS agent. A major limitation in finding effective PTGS agents is the identification of accessible sites within the cellular mRNA. We utilized in silico predictive methods (m-fold & s-fold) and a novel reverse transcriptase based PCR method to map accessible ribozyme sites (MARS). The accessible sites were confirmed by competitive hybridization and studies of in vitro cleavage of transcripts by ribozymes in cell lines stably expressing rhodopsin and a reporter secreted alkaline phosphatase (SEAP). In silico analysis identified 10 candidates among 236 potential ribozyme cleavage sites (NUH). MARS analysis identified 22 sites including those predicted by in silico studies. The eight accessible regions of the rhodopsin transcript included 30 potential ribozyme cleavage sites. Four additional ribozyme sites were chosen, either from previous efficacy studies or because they resided within inaccessible regions. 34 sites were evaluated for ribozyme cleavage using a SEAP bi-cistronic reporter system. 18 of 34 sites showed significant knockdown of SEAP expression ($p<0.01$) with five of these sites providing robust knockdown of SEAP measures. Five ribozyme constructs were identified as lead candidates for further optimization prior to animal studies. By combining mRNA accessibility analysis with a cell based in vitro approach five very promising ribozymes were identified for human rhodopsin. As rod opsin has many mutations responsible for retinal degenerations, a robust ribozyme targeted against rhodopsin mRNA is of therapeutic interest.

Mechanisms Underlying Potentiator Activation of CFTR. *L.C. Pyle, A. Ehrhardt, L. Fan, J. Fortenberry, W. Wang, K. Nowotarski, K. Varga, M. Sthanam, J.P. Clancy, E.J. Sorscher, S.M. Rowe* Cystic Fibrosis Research Center, UAB, Birmingham, AL.

Small molecule modulators of CFTR overcome gating defects of surface localized mutant channel and are being developed as therapies for cystic fibrosis. Although these agents have entered clinical testing, their mechanism(s) of action are poorly understood. CFTR activation requires PKA-regulated phosphorylation of the regulatory domain (R-D), followed by ATP dependent gating mediated by the two nucleotide binding domains. We have established a gel-shift method by which phosphorylation of isolated R-D (residues 635-836) can be monitored. The potentiator P1 does not induce phosphorylation of the R-D (4% of forskolin response, n=7, P=NS). Unexpectedly, two potentiators, P8 and P10, confer robust phosphorylation of the R-D (P8: 32% of forskolin response, n=8, P<0.005, P10: 37% of forskolin response, n=8, P<0.005), which is inhibited by the PKA inhibitor H89. Neither P8 nor P10 increased cellular cAMP. The results suggest compartmental inhibition of CFTR-associated phosphotases (eg. PP2A) or phosphodiestereases (eg. PDE4) as an underlying mechanism. We next evaluated CFTR potentiators in two F508 CFTR polarized epithelia models, CFBE41o- and Fisher rat thyroid cells stabily transduced with F508 CFTR. Cells were studied after low temperature (27ºC x 48 hrs) or chemical correction of F508 CFTR misprocessing. Total short-circuit current (I_{sc}) was determined following serial addition of potentiator, forskolin, and genistein. P1 both directly activated CFTR and potentiated forskolin mediated I_{sc} (potentiation being the predominant effect (9.8 vs 1.5 A/cm^2, n=12, P<0.05), a unique observation in CFBE41o- cells), while P8 and P10 conferred activation of CFTR without potentiation. Our findings suggest agents that do not phosphorylate the R-D may be better suited to rescue endogenous cAMP mediated CFTR activation. These studies provide a means to biochemically and functionally categorize novel CFTR modulators. Understanding the mechanism underlying activation or potentiation of CFTR may allow a more rational approach to the rescue of ion transport caused by particular CFTR mutations.

Persistent müllerian duct and jejunal atresia: evidence for a new syndrome. *G. Morin[1,5], C. Jeanpetit[1], C. Belville[2], J. Ricard[3], H. Bony-Trifunovic[4], B. Boudailliez[4], J.P. Canarelli[3], J.Y. Picard[2], M. Mathieu[1,5]* 1) Clinical Genetics Unit, Amiens University Hospital, Amiens, France; 2) INSERM U782, Clamart, France; 3) Pediatric Surgery Service, Amiens, France; 4) Pediatric Endocrinology, Amiens, France; 5) Prenatal Diagnosis Center, Amiens, France.

Persistent Müllerian Duct Syndrome (PMDS) is a rare form of male pseudohermaphrodism characterized by the retention of Müllerian derivative in an otherwise normally virilized male. Approximately half of the cases are secondary to mutations in the anti-Müllerian hormone gene (AMH). Most of the other cases are in relation with mutations of the anti-Müllerian hormone receptor gene (AMH-RII). In these two situations the mode of inheritance is autosomal recessive and the genital abnormality appears isolated. In rare cases, persistent Müllerian duct can be associated with additional features: lymphangiectasia, mental retardation, microphtalmia, hypospadia, lipoatrophic diabetes, vitamin D resistant rickets. In 1997 Klosowski et al reported the case of a patient with PMDS and jejunal atresia, but negative for mutation of AMH and AMH-RII genes. We report on a second patient bearing this association. This boy is born after a pregnancy characterized by polyhydramnios and bowel dilatation at the third trimester. After spontaneous delivery at 35 weeks of amenorrhea he presented evidences for intestinal occlusion. Surgical laparotomy revealed jejunal atresia and the presence of a uterus. Blood karyotype showed a normal male 46,XY formula. Total and free testosterone and anti-mullerian hormone were at normal ranges. Screening for mutations in the whole coding sequence of anti-mullerian gene ant its receptor (AMH-RII) was negative. These two similar observations suggest the existence of a distinctive entity, probably of genetic origin, with peculiar molecular mechanism. The same geographic origins in North of France of the two patients suggest a foundation effect.

Expression of the nuclear receptor *Nr1d1* in the retina and its role in the regulation of photoreceptor development. *N.J. Mollema[1], M. Gaule[1], N.B. Haider[1,2]* 1) Genetics, Cell Biology and Anatomy. University of Nebraska Medical Center, Omaha, NE; 2) Ophthalmology and Visual Sciences. University of Nebraska Medical Center, Omaha, NE.

Mutations in human Nr2e3 result in Enhanced S-Cone Syndrome and mutations in mouse *Nr2e3* cause the retinal degeneration observed in *rd7* mice. The *rd7* mutant mouse is characterized by a unique retinal degeneration resulting from an over production of blue cone photoreceptor cells. To better understand the processes regulating photoreceptor development, we identified genes that are misexpressed in the *rd7* retina. We determined that the nuclear receptor *Nr1d1* is both misregulated in *rd7* retinas and is a target of *Nr2e3*. While a previous report identified *Nr1d1* as a cofactor of *Nr2e3*, little is known regarding the role of *Nr1d1* in photoreceptor development. In this study we determined the temporal expression profile of *Nr1d1* throughout retinal development and in its expression in the mature retina. We further determined the sub-cellular localization of *Nr1d1* in the developing and mature retina and its co-localization with other retinal proteins. We used *in vivo* chromatin immunoprecipitation (ChIP) to evaluate whether targets of *Nr2e3* are also regulated by *Nr1d1*. Our studies demonstrate a novel role for *Nr1d1* to function in the same transcriptional network as *Nr2e3* to regulate photoreceptor development.

Candidate-gene association study of non-obstructive azoospermia (NOA): ART3 as a genetic susceptibility to NOA. *A. Tajima[1], H. Okada[2], M. Sekine[2], K. Shichiri[3], A. Tanaka[4], K. Tanaka[2], I. Inoue[1]* 1) Dep Molecular Life Sci, Tokai Univ Sch Medicine, Kanagawa, Japan; 2) Dep Obstet & Gynecol, Niigata Univ Graduate Sch Med & Dent Sciences, Niigata, Japan; 3) Dep Obstet & Gynecol, Tachikawa Hospital, Niigata, Japan; 4) St. Mother's Hospital, Fukuoka, Japan.

Male-factor infertility is believed to be responsible for 20-50% of all infertility cases. Male infertility could be caused by genetic factors altering spermatogenesis, but chromosomal abnormalities associated with azoospermia factor (AZF) regions on Yq are the only genetic defects with moderate incidence rates (up to 15%) so far. Thus, genetic causalities of most infertile patients are not elucidated. Here we perform an extensive candidate gene analysis to identify susceptibilities to non-obstructive azoospermia (NOA). Based on the concept that a common variant of a susceptibility gene could result in altered expression of the gene in testis, we first determined NOA candidate genes representing differences in testicular expression between NOA patients, using Agilent Human 1A(v2) Oligo microarrays. Next, 191 SNPs of 42 candidate genes were evaluated for allelic association with NOA in 442 NOA patients and 475 proven fertile controls. After two-rounds of screening, SNPs of *ART3* (ADP-ribosyltransferase 3) were associated with NOA, and the most significant association was observed with ART3-SNP25 locating intron 11 of *ART3* ($P = 0.0025$). Haplotype-based association analysis revealed that the most frequent haplotype in controls were under-represented in NOA patients with statistical significance ($P = 0.000073$), indicating a protective impact of the haplotype. These results would help promoting the full understanding of genetic causalities of NOA.

Common leukemia-associated genetic alterations in prenatal samples. *D. Mercer[1], X. Hu[3], M.M. Li[1,2,3]* 1) Hayward Genetics Center, Tulane Univ Medical Sch, New Orleans, LA; 2) Department of Pediatrics, Tulane Univ Medical Sch, New Orleans, LA; 3) Louisiana Cancer Research Consortium, New Orleans, LA.

Leukemia-associated genetic alterations play important roles in leukemogenesis. They also serve as biological markers in the diagnosis, prognosis, treatment, and follow-up of hematopoietic malignancies. We previously reported on the presence of some of these genetic alterations in the peripheral blood of healthy individuals when evaluated with nested RT-PCR. We then sought to determine if these aberrations arise early in human development by performing nested RT-PCR on cultured amniocytes or chorionic villi. We studied MLL partial tandem duplications (PTDs), BCR/ABL p190, BCR/ABL p210, and MLL/AF4 rearrangements in 30 prenatal samples. All 30 samples (100%) showed at least one MLL PTD rearrangement. Sequencing showed that the most common exon fusions were 9/3 (30 samples), 9/4 (20 samples), and 11/3 (8 samples). Genomic PCR was performed on DNA available from 16 of these samples, in which MLL PTDs were detected in the genomic DNA of 15 samples. Quantitative Real-time PCR was performed to assess the copy number of MLL PTD transcripts. The prenatal samples tested contained between 1 in 5,000 and 1 in 10,000 MLL PTD transcripts, a range that is indistinguishable from minimal residual diseases. All 30 samples (100%) were also positive for the BCR/ABL p190 e1a3 rearrangement, while 8 samples (27%) were positive for a BCR/ABL p210 rearrangement, and 20 were positive for an MLL/AF4 rearrangement (67%). These data demonstrate that many leukemia-associated genetic alterations are present in early fetal development and occur more often than what has been observed in peripheral blood or bone marrow from adults, suggesting that genetic alterations take place during cell division and present more frequently in fast growing tissues. Our data also further emphasize that serial quantitative monitoring of patients with minimal residual disease is much more informative than qualitative PCR.

DETERMINATION OF THE INDUCED APOPTOSIS BY CYCLOPHOSPHAMIDE IN CULTURES OF HUMAN LYMPHOCYTES BY ASSAY COMET. *G. Razo-Aguilera, R. Baez-Reyes* Deparment of Genetics, National Institute of Perinatology, Mexico City, MEXICO.

Apoptosis is a process of cell death that differs morphologically of the classic necrosis, because the presence of cell shrinkage, fragmentation of the DNA and formation of apoptotic bodies. Apoptosis is an intrinsic part of the development program for some cellular types; howewer it can also be induced by various toxic agents. The objective of this work was determine if the "comet assay" is a sensitive method to evaluate apoptosis, also, to determine the cyclophosphamide potential as an apoptotic inducer. We made cultures from lymphocytes of 20 healthy subjects (10 women and 10 men), and treated them with 10 and 100.

Access to Credible Genetics Resources Network. *S. Terry[1], M. Weaver[2], K. Reed[3], H. Ferguson[1], C. Constantin[7], A. Vatave[7], C. Greene[2], A. Gepp[4], K. Clapp[5], P. Furlong[6], J. McInerney[3], M. Blitzer[2]* 1) Genetic Alliance, Washington, DC; 2) Univ. of MD, Baltimore, MD; 3) NCHPEG, Lutherville, MD; 4) National Council of La Raza, Washington, DC; 5) FRAXA Research Foundation, Newburyport, MA; 6) Parent Project Muscular Dystrophy, Middletown, Ohio; 7) CDC, Atlanta, GA.

Quality information on single gene disorders is limited. Individuals and their families need accurate information to make informed decisions about management, while healthcare providers need quality information to offer appropriate care. To that end, Access to Credible Genetics Resources Network (ATCGRN) has created tools: a metric, toolkit and quality presentation document, for developing, assessing, and disseminating quality information about single gene disorders. These tools are valuable to both patients and clinicians to provide a means to improve the overall quality of information on rare genetic conditions. We used a model that maximizes input from content specialists and end users and is heavily skewed toward formative evaluation by the intended audience. This process provides corrective feedback to the developers at points along the way. To facilitate these processes, the partners participate in monthly conference calls to update each other on the progress of their particular part of the project. The tools were applied to Fragile X Syndrome and Duchenne Becker Muscular Dystrophy. The metric evaluates quality information and was pilot tested by end-users. The toolkit assesses the accuracy and completeness of topics parents and clinicians need to make informed decisions. The quality presentation document has also been vetted with end-users: educational material developers and support group leaders, in particular. This tool has evolved from a simple checklist to a document that includes information about the process of developing an educational material as well as an evaluation of the content of an educational material. These three distinct tools have been refined through the cooperation of the ATCGRN collaborators and should be applicable to all rare, single gene disorders for the production of high quality information.

Research Collaboration Database (ReCo): A Multi-User Database to Improve Genetic Data Quality and Facilitate Online Collaboration. *J.C. Papp, R. Sripracha, E.M. Sobel* Human Genetics, University of California, Los Angeles, CA.

The Research Collaboration database (ReCo) provides an improved method for management, security, and quality control of genetic data generated in large multi-center research studies. ReCo is designed for large genetic datasets, including dense SNP data from genome-wide association studies, with features for improving quality and management of phenotype data. The major attributes of the database are 1) data cleaning and integrity tools; 2) streamlined and flexible project administration; 3) easy collaboration across sites.

Data cleaning and integrity is achieved through a variety of controls. Clinical measures and patient histories can be stored as forms that can be customized to reproduce existing forms, or created from within ReCo. The forms can be filled out on-line, or distributed in paper or electronic copies. ReCo is designed with the goal of minimizing the entry of data errors into the database. ReCo allows creation of one-time, limited guest accounts for study participants. This allows direct online data entry, facilitates phenotypic data collection in large case/control studies, and avoids error-prone transcription from paper records. Data entered by guest users must be approved before data can be processed. To achieve the lowest possible error rate in data entry from paper forms, an easy-to-use n-tuple data entry system provides multiple levels of data checking. A robust interface allows detection and resolution of conflicting entries. ReCo supports a variety of formats for importing and exporting data.

ReCo is built on an enterprise-level database in a multi-user environment, allowing scalability for large projects. Although ReCo supports complex study designs and permission sets, an innovative architecture with an intuitive interface allows users at each site to set up and administer their own studies and accounts, and selectively share forms and data within or across sites. This architecture allows administration to be distributed for more efficiency and autonomy, while maintaining high security and easy collaboration. ReCo can be viewed online at http://reco.genetics.ucla.edu.

Two patients with unusual chromosomal anomalies detected by consecutive BAC and SNP based microarrays. *P. Papenhausen, J. Tepperberg, V. Jaswaney, I. Gadi* Dept Cytogenetics, Labcorp of America, Res Triangle Park, NC.

Two probands are reported at 6.8 (case 1) and 0.2 (case 2) years of age which were referred for a BAC based microarray analysis due to MR with aphasia and growth retardation/contractures, respectively. Case one was known to have a chromosome 15 derived marker and case 2 had not been previously studied cytogenetically. Case 1 revealed very significant gains at the 5 most distal 15q BACS from the 90.4Mb linear position (15q26.1) to the most distal BAC at 100.1MB. Chromosome G-bands showed a small symmetrical marker chromosome in all metaphases with a slightly off center constriction. Subsequent FISH confirmed an analphoid marker positive with a subtelomere 15q at each end and presumptive tetrasomy for 15q26.1>qter. Subsequent analysis by high resolution SNPs revealed a proximal region of apparent trisomy from 82.8 to 84 linear Mb that stepped up to tetrasomy from 84 Mb to the 100 linear Mb telomere. Thus, apparently the marker single copy increase was near the off center constriction. Case 2 revealed a significant three BAC loss at 13q at 65.5Mb to 68Mb (13q21.1-q21.3) combined with a single BAC gain at 97.46Mb (13q32.3). Cytogenetics revealed a highly abnormal 13q G-band pattern. High resolution SNPs revealed alternating regions of single and double copy gain from 55.3 to 64.9 Mb and 4.8 Mb loss from 64.9 to 69.7 Mb. A second region of loss from 83.2 to 91.2Mb and gain from 93.5 to 104 Mb was also found. The genes in these copy number variations will be compared to the resulting phenotype. These cases demonstrate the high precision at which high resolution arrays can elucidate the underlying genomic imbalance in children with genetic disorders. Additionally, case one data suggest that asymmetric constrictions frequently reported in terminal analphoid inverted duplications may correlate with regions of proximal single copy number gain, rather than the duplicate copies in remainder of the chromosome.

Powerful new methods for genome-wide copy number association studies. *C.L. Lambert[1], A. Baker[1], D.M. Hawkins[2], D.A. Peiffer[3]* 1) Golden Helix, Inc., Bozeman, MT; 2) Sch of Statistics, Univ of Minnesota, Minneapolis, MN; 3) Illumina, Inc., San Diego, CA.

Few genome-wide association studies (GWAS) have been published involving copy number variations (CNVs). This is primarily due to a lack of reliable methods, workflows and infrastructure for conducting GWAS with CNVs. The most commonly used CNV ascertainment methods are based upon Hidden Markov Models. While fast in performance, these methods generally suffer from low sensitivity and high false discovery rates (FDRs), resulting in missing small regions of CNVs, adding noise to the data, and ultimately reducing the power to find CNV associations with complex diseases. Circular Binary Segmentation (CBS) methods have shown superior sensitivity and FDRs but suffer from slow run times, making it nearly impractical to calculate CNV for the hundreds to thousands of patients in current GWAS. We present a new segmenting method based on dynamic programming that searches through all possible CNV change-points in a chromosome to find the most optimal with respect to an error metric, without suffering from the combinatorial explosion associated with such a search. We present benchmarks showing that our implementation runs dramatically faster than CBS, while maintaining equal or better sensitivity and FDR. We also specially tune our methods to extract signals, and perform appropriate normalizations on intensity data from various Illumina whole genome SNP genotyping array platforms, for maximal CNV detection. Once CNV calls have been made for all SNPs, we demonstrate how, by reducing genome-wide scans from ~550k SNPs to a few thousand tagging CNV segments, we are able to reduce multiple testing correction by at least an order of magnitude, dramatically increasing the power for GWAS with CNVs. Standard statistical tests can then be used. We demonstrate the complete workflow on several case/control data sets of 1000+ patients using the Illumina Hap550 and Hap300 BeadChips. Our methods make it possible to discover **statistically significant** associations using small CNV changes in genome-wide scans for complex diseases on large case/control and quantitative trait studies.

Can patents on genetic tests inhibit the development of genomic diagnostics? An analysis of case studies. *B.L. Pierce[1], S. O'Connor[2], J.L. Stanford[3], M.A. Austin[1,3]* 1) Institute for Public Health Genetics, University of Washington, Seattle, WA; 2) School of Law, University of Washington, Seattle, WA; 3) Department of Epidemiology, University of Washington, Seattle, WA.

Patents on genetic tests are controversial for many reasons, including their potential inhibition of the development of genome-based diagnostics. Such inhibition might occur if multiple parties are assigned patents on genetic tests that relate to a specific clinical problem. Any of these parties can legally block the commercialization of a product that tests all relevant variants. The aim of this project was to search for evidence for such a scenario using case studies. Selected cases were required to be conditions with at least three genetic risk factors, corresponding to at least three patents. For each case, relevant genetic risk factors were identified by reviewing the scientific literature. Relevant patents were identified using gene- and disease-specific searches of the U.S. patent and trademark offices patent database. For each patent, the issue date, assignees, and claims were catalogued. Long QT syndrome (LQTS) and maturity onset diabetes of the young (MODY) have moderate levels of known locus heterogeneity (6-8 genes). Five LQTS genes are the subject of patents, all assigned to the same party, with a co-assignee on patents for two of the five. Five MODY genes are the subject of patents (3 total), all assigned to the same party. Cystic fibrosis is characterized by allelic heterogeneity within the CFTR gene. All patents on testing CFTR variants, with one exception, are held by a single party (3 patents) with a coassignee on two. The remaining CFTR patent was licensed to a company owning the rights to test all other variants. In conclusion, we observed two cases of unified and one case of fragmented patent rights. The fragmented rights were unified via licensing, suggesting that it is unlikely that patents have seriously inhibited the development of tests related to these case studies. However, as more genetic risk factors are discovered, future genetic testing products may require securing patents from multiple parties, potentially inhibiting the development of valuable genomic tests.

Sequencing from dried blood spots in neonates with positive NBS results for MCADD who die before confirmatory testing. *S.E. McCandless[1], R. Chandresekar[2], S. Linnard[2], W. Becker[2], L. Rice[1]* 1) Department of Genetics, Case Western Reserve Univ, University Hospitals Case Medical Center, Cleveland, OH; 2) Ohio Department of Health, Newborn Screening Program, Reynoldsburg, OH.

Medium chain acyl-CoA dehydrogenase deficiency (MCADD) is one of the most common disorders identified by newborn screening (NBS) programs. NBS for MCADD uses measurement of octanoylcarnitine (C8) from dried blood spots. Occasionally, newborns with elevated C8 on NBS die before confirmatory testing can be obtained. Neonates with MCADD can have metabolic decompensation in the neonatal period, raising the question of whether MCADD contributes to some of these deaths. Six such infants were identified by the Ohio NBS Lab in the first 3 years of MS/MS NBS. **Methods:** DNA was extracted from dried blood spots and screened for the common A985G mutation in exon 11 of the MCADD gene, ACADM, using a specific restriction digest method, followed by sequencing of the 12 exons, intron-exon junctions, and several hundred base pairs of the 5 untranslated region. **Results:** The cut-off value for C8 used was 0.7 g/L. The mean C8 for the six infants was 1.0, much lower than the mean value for confirmed cases. Four of the 6 neonates weighed <700 g, another was 800 g, the last 3200 g. One neonate had multiple abnormalities on NBS. No sequence variants were found in 4 of the 6 neonates. Two subjects had a total of 3 previously known SNPs identified in exons 7 (1) and 11 (2). A heterozygous single nucleotide change deep in the intron between exons 1 and 2 was identified in two patients that is unlikely to be disease causing. **Conclusions:** Sequencing of ACADM in six neonates with elevated C8 on NBS did not identify any significant mutations in the coding region of the gene, suggesting that MCADD was not a contributing factor in these deaths. It is possible that elevated C8 is a non-specific marker for infant distress, particularly in very low birthweight infants. These results suggest that sequencing of ACADM from dried blood spots is a useful follow-up tool to provide the most accurate genetic counseling in the situation of an infant with elevated C8 on NBS who dies before confirmatory testing is obtained.

Estimating Allele Fraction or Allele Frequency using Unlabeled Probes and High Resolution Melting on the LightScanner. *M.D. Wall, L.L. Cutler, J.T. McKinney, D. deSilva, D.H.F. Teng* Research and Development, Idaho Technology, Inc., Salt Lake City, UT.

The ability to estimate allele fraction of somatic mutations in primary tumor samples or allele frequency in a set of pooled DNA samples in a single reaction is desirable. We investigated the potential of using a new genotyping method involving an unlabeled probe and high resolution melting on the LightScanner instrument. Several common polymorphisms were chosen as targets and unlabeled probe assays developed to ascertain the genotype of several random DNA samples. For each locus, 3 samples were chosen representing each of the possible genotypes. The two samples representing the homozygous forms of the genotype were quantified and mixed at the following ratios: 95:5, 90:10, 75:25, 50:50, 25:75, 10:90, and 5:95. The 50:50 mixed sample was compared to the true heterozygote to validate the mixing ratios. Melting profiles of the unlabeled probes were converted to derivative peaks and the peak heights at each melting temperature of the probe were calculated. In all cases, discrimination of allele fraction down to 5% for both alleles was possible. Regression analysis of the observed peak height relative to the known allele fraction yielded R-squared values greater than 0.99, indicating that allele fraction can be reliably estimated to the level of 1:20 alleles. These results indicate that the use of high resolution melting with unlabeled probes can be an effective way to estimate the allele fraction in tumor samples or allele frequency in up to 10 pooled samples.

Higher Incidence of Chromosome Deletions and Duplications Identified by Array CGH. *J.H. Tepperberg, I. Gadi, B. Williford, D. Fuentes, J. Whaley-Davis, C. Legacki, C. Bullen, J. Kesler, N. Elliott, P. Papenhausen* Cytogenetics, LabCorp, RTP, NC.

Genetic imbalances are generally associated with multiple birth defects, developmental delay, growth retardation, and dysmorphic features. The incidence of targeted chromosome microdeletion syndromes is estimated to be 1 in 1000-2000 while the detection rate of clinically significant subtelomere abnormalities was recently shown to be approximately 2.5%; (Ravnan et. al. 2005). Array based Comparative Genomic Hybridization (aCGH) is used as an adjunct to cytogenetics and FISH to detect unbalanced chromosome alterations (aneuploidy, microdeletions, duplications, and unbalanced subtelomere rearrangements) associated with developmental delay and mental retardation. Array CGH analysis of 2484 clinical cases submitted for aCGH (PerkinElmer targeted constitutional bac array) showed 6.03% (150/2484) cases with clinically significant unbalanced rearrangements. The most common chromosomes (7, 15, 17 and 22) identified in microdeletion syndromes were also the most common identified by the array. Seventy-two abnormal cases (47.3%) showed apparent terminal deletions, fifty-two abnormal cases (34.2%) showed interstitial duplications, four cases (19.0%) were unbalanced derivative chromosome rearrangements, and nine cases (5.9%) were unbalanced structural abnormalities (e.g., inv, dups, isochromosomes and markers). Five cases with mosaicism were observed with the lowest threshold of 23.0%. Twelve percent trisomy 9 mosaicism, confirmed by chromosomes, was observed retrospectively at the threshold level. The constitutional bac array was not designed to diagnosis single clone alterations in the backbone region however it did uncover true alterations. Twenty cases of a single bac copy gain or loss confirmed by FISH were detected in the non-targeted backbone region of the array. This data adds to the growing body of literature indicating that chromosome deletions and duplications are more prevalent among patients with unexplained MR and developmental delay.

***SPECC1L*, a Novel Cytoskeletal Protein, is Haploinsufficient in a Patient with Bilateral Oblique Facial Clefts, Ocular Hypoplasia and Club Feet.** *I. Saadi[1], F.S. Alkuraya[1], J.J. Lund[1], A. Turbe-Doan[1], T.W. Glover[3], R. Erickson[2], R.L. Maas[1]* 1) Medicine, Brigham & Womens Hospital, Boston, MA; 2) Human Genetics, University of Michigan, Ann Arbor, MI; 3) Pediatrics, Genetics Section, The University of Arizona College of Medicine, Tucson, AZ.

Oblique facial clefts (OFC) and cleft lip and palate (CL/P) are complex birth defects that result from perturbation of fusion between the different facial processes during early embryonic development. As part of the Developmental Genome Anatomy Project, we have studied *de novo* balanced translocation cases with clefting phenotypes to discover genes involved in CL/P that may be impossible to determine by other means. We ascertained a patient with bilateral oblique facial clefts, ocular hypoplasia and club foot deformity and a *de novo* balanced chromosomal translocation 46,XX,t(1;22)(q21;q12). By FISH and Southern analyses, the 22q breakpoint was found to directly disrupt intron 14 of *SPECC1L* while the 1q breakpoint did not disrupt any gene. *SPECC1L* encodes a large protein predicted to have a single calponin homology domain (CHD) and 3 coiled coil domains (CCD). Whole mount *in situ* hybridization confirmed *Specc1l* expression in the 1st and 2nd branchial arches, the eyes and the hind limbs during embryogenesis. Interestingly, in transfected cells, Specc1l protein showed a spindle-like filamentous expression pattern, which co-localized with a subset of -tubulin microtubules. Moreover, the tubulin-polymerization blocking agent, nocodazole, abolished the filamentous expression. Partially truncated constructs that lack the N-terminal CCD or the CHD also failed to show the filamentous pattern. Taken together, these data indicate SPECC1L to be a microtubule-associated protein (MAP) likely involved in cytokinesis and spindle formation, functions that are currently being tested. We are determining the cellular phenotype following shRNA knockdown of *SPECC1L* in cultured cells and in haploinsufficient patient lymphoblasts. The genetic etiology of OFC has remained largely elusive. The identification of a novel MAP involved in OFC will facilitate our understanding of this complex disorder.

Initial actions to implement health policies related to Genomic Medicine in Mexico. *P. Oliva, E. Barrientos, C. Lara, G. Jimenez-Sanchez* National Institute of Genomic Medicine, Mexico.

The availability of the human genome sequence has indicated that 0.1% of the human sequence varies between individuals. Combinations of these nucleotide variations influence risk to common health problems as well as response to commonly used drugs. Systematic analysis of these genetic variations will lead to important implications for public health. Genomic medicine will result into a more individualized, predictive and preventive medical practice with significant implications to individual health, life quality, medical practice, health finances and opportunities in the current knowledge-based economy. Mexico has committed to develop genomic medicine in benefit of its population. In 2004, the Mexican Congress created the National Institute of Genomic Medicine (INMEGEN) to develop scientific research in genomic medicine. In the last two years, Mexico has implemented a robust scientific and technological infrastructure. In addition, the Genome Diversity Project of Mexico, has shown different allele frequencies and haplotype patterns compared to other populations, indicating that genomic medicine needs to be developed according to genomic structure of the target population. Initial whole genome scan studies in complex diseases and epidemiologic studies are in their way, and cohort studies will follow. INMEGEN have established strong interactions with the public, academic and private institutions, both domestic and international. These efforts have been strengthen by international interactions established with WHO, PAHO and the OCDE. In addition, the Mexican Congress has a remarkable interest in developing legal bases that stimulate scientific research in genomic medicine in the context of the national public health policies. There are currently nine bills related to genomic medicine in the Mexican Congress, including those related to protecting against ethical challenges. In the next decade, progressive applications of genomic medicine will post important challenges to public health systems, and will require coordinate efforts to fully translate this new knowledge into benefits for the Mexican population.

Combinatorial alellic risk scores for pulmonary tuberculosis vary in Mexican mestizos according to Amerindian ancestry. *P. Zoochlorella, C. Rangel* Instituto de Medicina Genómica, Mexico City 01900, MEXICO.

Most individuals within the Mexican population are considered mestizo, having originated from the admixture of Amerindian groups with Spaniards and, to a lesser extent, Africans. The complex admixture process has resulted in genetic differences between geographical regions. The purpose of this study was to evaluate the existence of regional differences in polymorphisms associated with susceptibility to pulmonary tuberculosis (PTB) in México, both at the level of individual genotypes and higher-order interactions, i.e. combinatorial genotypic categories. Several functional polymorphisms influence susceptibility to PTB, including SNPs in macrophage chemotactic protein-1, interleukin-10, interleukin 12-receptor B1 and the phagosomal solute carrier family 11 member 1. We determined genotypic frequencies in *MCP1* (rs1024611), *IL10* (rs1800896), *IL12RB1* and *SLC11A1* (rs17235409) in 1,150 healthy mestizos from six geographically distant states in Mexico. Our results show that the MCP1-2518 GG genotype exist in a higher frequency in Mexican mestizos compared to European and African populations, suggesting that the G allele could have been contributed by Amerindian populations. The state of Sonora exhibits a significantly lower frequency of the GG genotype compared to the rest of the states and this is consistent with an ancestry analysis by chromosomal region revealing that individuals from this state shows a lower Amerindian contribution in the 100 kb region where *MCP1* is located. We developed **C**ombinatorial **G**enotype **B**ins, CGBs, an R-programmed query algorithm to a relational database which ranks PTB risk scores according to a probability matrix of the reported odds ratio values for individual SNPs. Three of the CGBs, corresponding to high and moderate PTB risk scores, showed significant differences between Mexican mestizos and individuals with higher Amerindian ancestry. Our results support the existence of regional differences in genomic variations associated with susceptibility to PTB in Mexico. CGBs is a useful tool in higher-order genomic analysis, and its potential in PTB risk assessment will be evaluated in case-control studies.

***VaryGene*, a new satellite database of annotated human polymorphism in the integrated human transcriptome database H-InvDB.** *M.K. Shimada[1,2], Y. Yamaguchi-Kabata[2], C. Yamasaki[1,2], T. Imanishi[2], T. Gojobori[2,3]* 1) Japan Biological Information Research Center, Koto-ku, Tokyo, Japan; 2) Biological Information Research Center, National Institute of Advanced Industrial Science and Technology, Tokyo, Japan; 3) Center for Information Biology and DNA Data Bank of Japan, National Institute of Genetics, Shizuoka, Japan.

The H-Invitational Database (H-InvDB; http://hinv.jp/) is an integrated database of human transcriptome based on extensive annotation of human full-length cDNA (FLcDNA) clones. The latest release contains annotation of 175,542 mRNAs and FLcDNAs extracted from the public DNA databank. We determined 34,701 gene clusters, which could define 34,093 (98.3%) protein-coding and 608 (1.8%) non-protein-coding loci, while 860 (2.5%) protein-coding loci overlapped with predicted pseudogenes. We provide in-depth annotation of alternative splicing isoforms, functional non-coding RNAs, functional domains of proteins, subcellular localizations, metabolic pathways, predictions of protein 3D structure, mapping of SNPs and microsatellite repeat motifs, co-localization with orphan diseases, gene expression profiles, evolutionary features and protein-protein interactions. Here we present a new satellite database of H-InvDB for annotated human polymorphism, *VaryGene*. We reviewed publicly available polymorphism by mapping onto H-Inv transcripts and evaluating the quality of SNP information. *VaryGene* shows annotated polymorphism (SNPs and indels) information including location in transcripts as well as in the reference genome sequence, original classification of SNPs for each transcript by effects on gene products, relations with functional domains and links to public databases. *VaryGene* includes 40,484 synonymous SNPs, 53,754 nonsynonymous SNPs, 1,258 nonsense SNPs that cause 593 NMD events, and 159 SNPs that read through original termination codons, as well as 1,535 indels that cause 1,331 frameshift events. We believe that the release of *VaryGene* as a satellite database of H-InvDB may facilitate the progress of human genetic researches.

KLHDC8B, a novel candidate Hodgkin's lymphoma susceptibility gene, is targeted by Epstein-Barr virus microRNAs. *M.E. Mealiffe[1], T. Kirchhoff[2], P.H. Wiernik[3], H.T. Lynch[4], M. Daibata[5], A.-M. Gerdes[6], W.H. Raskind[1], K. Offit[2], L.R. Goldin[7], M.S. Horwitz[1]* 1) Medical Genetics, U. Washington, Seattle, WA; 2) Medicine, Memorial Sloan-Kettering Cancer Ctr., New York, NY; 3) Our Lady of Mercy Cancer Ctr., New York Medical College, New York, NY; 4) Preventive Medicine, Creighton U., Omaha, NE; 5) Hematology and Respiratory Medicine, Kochi Medical School, Kochi, Japan; 6) Biochemistry, Pharmacology and Genetics, Odense U. Hospital, Odense, Denmark; 7) Cancer Epidemiology and Genetics, NCI, Bethesda, MD.

Epstein-Barr virus (EBV) exposure and heritable factors both contribute to Hodgkin's lymphoma (HL) risk. We ascertained a family in which multiple individuals carrying a constitutional translocation (t(2;3)(q11.2;p21.31)) developed HL. Notably, a predisposition locus for another EBV-associated malignancy, nasopharyngeal carcinoma, maps to 3p21. Molecular cloning of both translocation breakpoints shows that the 2q breakpoint is intergenic, but the 3p breakpoint disrupts intron 1 of an uncharacterized gene, KLHDC8B (Kelch domain-containing 8B). To assess KLHDC8Bs significance in familial HL, we sequenced its coding region in affected probands from 52 families with two or more cases of HL, but detected no coding region variants. However, we found a variant (+42C>T), in a conserved region of the 5-UTR, present in 3 of 52 familial HL probands (5.8%) compared to 4 of 307 controls (1.3%; Odds Ratio [95% C.I.] = 4.6 [1.0-21.4]), prompting consideration of the possibility of post-transcriptional dysregulation of KLHDC8B. We asked if recently described EBV miRNAs target the KLHDC8B 3'UTR and utilized the Rna22 algorithm, shown to be highly predictive of bona fide target sites. Remarkably, Rna22 predicts that 20 of 32 of the known EBV microRNAs target KLHDC8B with 1-4 target sites each. The EBV-related rhesus macaque herpesvirus, rLCV, similarly contains miRNAs predicted to target rhesus Klhdc8b, implicating the association as likely important in virus-host interaction. We have experimentally validated targeting of the KLHDC8B 3'UTR by a subset of the EBV miRs and will present ongoing experiments exploring its biological importance.

Imputing Copy Number Variants from Family-Based Signal Intensity Data. *W. Stewart[1], M. Burmeister[2,3], M. McInnis[3], S. Zöllner[1,3]* 1) Dept Biostatistics, Univ Michigan, Ann Arbor, MI; 2) Dept Human Genetics, Univ Michigan, Ann Arbor, MI; 3) Dept Psychiatry, Univ Michigan, Ann Arbor, MI.

Recent studies have shown that complex traits such as autism, resistance to HIV infection, and malaria are partially influenced by copy number variants (CNVs). For CNVs in large (>10 kilobases) regions of the genome, signal intensity data from genotyping reactions are commonly used for reliable imputation. However, for CNVs in smaller regions, reliable imputation is much more difficult. We propose a maximum likelihood method to impute the CNVs in smaller regions from family-based signal intensity data. In constrast to common approaches that ignore relationship information, our method is expected to impute the CNVs in smaller regions more accurately since we only consider CNV configurations that are compatible with Mendelian segregation. Specifically, we model single nucleotide polymorphism (SNP) intensity data as a mixture of Gaussian distributions, and we use the Elston-Stewart algorithm to sample CNV configurations conditional on the observed data. We apply our method to a known CNV on 8q24 in a study of 737 bipolar families ranging in size from 3 to 26 members. From the analysis of SNPs subsampled across this region the results show that (1) our method imputes copy number more accurately than an existing approach that ignores relationship information; and (2) that we have the potential to improve the resolution and characterization of CNV boundaries. Currently, we are extending our method to test for association between imputed copy number and disease.

Choosing a platform and design for genomewide association studies: cost, sample size, and power trade-offs. *J.P. Lewinger[1], D.J. Duggan[2], D.M. Taverna[2], W.J. Gauderman[1], D.O. Stram[1], D.C. Thomas[1]* 1) Dept Preventive Medicine, Univ Southern California, Los Angeles, CA; 2) Translational Genomics Research Institute (TGen), Phoenix, AZ.

Several commercial genotyping platforms are available for genomewide association studies (GWAS), differing sometimes widely in cost and coverage of the human genome. For a case-control design, the most powerful GWAS is obtained by genotyping all available samples on the platform with the best overall coverage. However, this is usually unaffordable, thus it becomes unclear whether higher power would be achieved with a smaller sample on a high-coverage/high-cost platform or a larger sample on a lower-cost/lower-coverage platform. Further complexity is introduced when a two-stage design is being contemplated. In a two-stage design a fraction of the available samples is genotyped on all single nucleotide polymorphisms (SNPs) in the first stage, and only the promising SNPs are genotyped on the remaining samples in the second stage. Two-stage studies are cheaper than one stage-studies and therefore a larger total sample size can be afforded. This larger sample size can translate into higher power than an equal cost one-stage design if the number of SNPs declared promising and the proportion of the samples allocated to the first and second stages are chosen carefully. We extensively investigated the trade-offs between cost/coverage, sample size, and study design for the Illumina 300K, 550K and 1M, and the Affymetrix 500K and 1M platforms. For each of these platforms we computed the average power as a function of the available budget and sample size for a one-stage and two-stage designs assuming each HapMap II SNP can be causal. To account for multiple testing we computed platform specific empirical null distributions by resampling haplotype pairs from the phased HapMapII genotypes. Although the specifics depend on the target effect size and the budget and sample size constraints faced by each study, the overarching conclusion is that sample size should not be traded-off for higher coverage, and that when budget is more limiting than available samples a two-stage design should be preferred.

Gene-centric Association Mapping of Chromosome 3p implicates potential role of GPX1 in Crohns Disease. *J. Rioux[1,11], A. Ng[2], C. Lefebvre[1], M. Stewart[2], A. Latiano[3], S. Brant[4], J. Cho[5], R. Duerr[6], M. Silverberg[7], K. Taylor[8], G. Aumais[9], C. Deslandres[10], G. Jobin[9], V. Annese[3], M. Daly[11,12], R. Xavier[2,12], P. Goyette[1]* 1) Montreal Heart Institute, Montreal, PQ, Canada; 2) CCIB, Harvard, Boston, MA, USA; 3) CSSIRCCS Hospital, San Giovanni Rotondo, Italy; 4) Johns Hopkins University, Baltimore, MD , USA; 5) Yale University, New Haven, CT, USA; 6) University of Pittsburgh, Pittsburgh, PA, USA; 7) Mount Sinai Hospital, Toronto, Ontario, Canada; 8) Cedars-Sinai Medical Center, Los Angeles, CA, USA; 9) Hôpital Maisonneuve-Rosemont, Montreal, PQ, Canada; 10) Hôpital Sainte-Justine, Montreal, Quebec, Canada; 11) Broad Institute of MIT & Harvard, Cambridge, MA, USA; 12) Massachusetts General Hospital, Boston, MA, USA.

Genome-wide linkage studies of Crohn's Disease (CD), followed by association mapping have led to the discovery of the NOD2 and IBD5 susceptibility loci. Recent genome-wide association studies have identified multiple other CD risk genes (eg. IL23R, ATG16L1, PTGER4, IRGM) but together these only explain a fraction of the genetic susceptibility to CD. We have therefore been pursuing a known CD linkage region on chr. 3p21-22 using a gene-centric association mapping approach. Specifically, within the linked region we identified functional candidate genes with strong prior probability by searching for literature co-citations with relevant keywords and by searching publicly available datasets for gene expression patterns consistent with genes having a role in immune and/or intestinal tissues. We then performed a two-stage association study, composed of a screening phase where SNPs tagging the common variation across the different candidates were evaluated in 1062 patients with IBD, and then a follow-up independent replication phase in 1960 patients with IBD from the NIDDK IBD Genetics Consortium. Significant evidence of association (pval=0.006) and replication (pvalue=0.003; combined pval<0.00001) and logistic regression analyses suggest a role for the glutathione peroxidase gene GPX1, a gene implicated in mouse models of mucosal inflammation. Differential gene expression and network analyses suggest that GPX1 acts via a TLR-mediated disease mechanism.

Shwachman-Diamond syndrome - a Human *Minute*? *S. Zhang[1,2], G. Otulakowski[3], J. Zhong[2], O. Gan[4], J. Yuan[5], C. Guidos[5], J.E. Dick[1,4], J.M. Rommens[1,2]* 1) Dept of Molecular & Med Genetics, Univ of Toronto; 2) Prog in Genetics & Genome Biol, Hosp Sick Children; 3) Prog in Physiology & Experimental Medicine, Hosp Sick Children; 4) Div of Cell & Molecular Biol, University Health Network; 5) Dept of Immunology, Univ of Toronto; Prog in Developmental & Stem Cell Biol, Hosp Sick Children, Toronto, ON Canada.

Shwachman-Diamond syndrome is a multi-system disorder caused by mutations in *SBDS*. Clinical features include failure to thrive, exocrine pancreatic dysfunction as well as haematological and skeletal abnormalities. Patients that carry two early truncating alleles have not been described and mice that are homozygous for null alleles ($Sbds^{-/-}$) exhibit embryonic lethality prior to E6.5. We have generated a R126T missense disease allele on the prediction that the mutation is hypomorphic in nature. $Sbds^{R126T/wt}$ mice were found to develop normally and show no disease phenotypes, in accordance with the recessive inheritance of SDS. However, both $Sbds^{R126T/R126T}$ and $Sbds^{R126T/-}$ mice exhibit marked size reduction, and die at birth. The growth difference becomes apparent in the mid-fetal period with noted delay or abnormalities of major organs including the skeleton, brain and lung. Hematopoiesis is also disturbed. Comparable deficiencies were noted overall, but the $Sbds^{R126T/-}$ embryos were consistently more severely affected than $Sbds^{R126T/R126T}$ embryos. Investigations of mouse embryonic fibroblasts indicated an impairment of protein translation capacity in mutant cells, as well as slow growth and cell cycle defects. Polysome profiles generated by sucrose gradient centrifugation of cell extracts were also abnormal, exhibiting marked reductions in 80S peaks as well as an increase in the ratio of 40S to 60S subunit peaks. These cellular deficiencies together with the developmental delay and poor growth emphasize the severe consequences of loss of Sbds. These findngs are reminiscent of the classic *Minute* mutations that have been described in *Drosophila* and indicate that SDS is a translation insufficiency syndrome.

Two cases of malignant phyllodes tumor in patients with history of bilateral retinoblastoma - a possible novel association with RB1 germline mutations. *J. Mak* Cancer Risk Program, University of California San Francisco, San Francisco, CA.

We are reporting two cases of patients with a history of bilateral retinoblastoma who subsequently developed malignant phyllodes tumors of the breast. Patient 1 has a large deletion encompassing the promoter through exon 23 of the RB1 gene. She had bilateral retinoblastoma diagnosed at the age of 2, followed by rhabdomyosarcoma at age 12, and malignant phyllodes tumor at age 22. Patient 2 had bilateral retinoblastoma in early childhood and, therefore, has a presumed RB1 germline mutation. She was diagnosed with malignant phyllodes tumor at age 48. Both patients were treated with mastectomy and were free of recurrence at 7 and 4 years post diagnosis.

The coincidence of these two very rare tumors - retinoblastoma and cystosarcoma phyllodes - in two separate patients suggests a possible etiological link through a germline RB1 mutation. Other sarcomas, including osteosarcoma, rhabdomyosarcoma, and leiomyosarcoma, are already known to be more frequent in patients with germline RB1 mutations. This possible novel association would be consistent with the pathological features of phyllodes tumors, which are a type of sarcoma frequently displaying alterations in the RB1 gene or pRb protein expression.

This observation could have relevance for the clinical care of patients with suspected or proven germline RB1 mutations, who may benefit from careful breast cancer surveillance starting at an early age. Of note, phyllodes tumors can be difficult to distinguish from fibroadenomas on mammogram or the results of fine needle aspiration. Surgical biopsy is often required for definitive diagnosis.

Thank you to Jerzy Klijanienko, MD of Institut Curie, Paris, France, for sharing data on Patient 2.

Genomic Convergence of Candidate Genes in Late-Onset Alzheimer Disease. *M. Pericak-Vance[1], G. Beecham[1], E. Martin[1], M. Slifer[1], Y.-J. Li[2], J. Gilbert[1], J. Haines[3]* 1) University of Miami, Miller School of Medicine, Miami FL; 2) Duke University, Durham NC; 3) Vanderbilt University, Nashville TN.

Late-onset Alzheimer disease (LOAD) has a strong genetic component. Yet to date only the apolipoprotein E (APOE) gene has been consistently associated with the disease. Linkage studies, which are often replicated, do not have the locational detail required to implicate a single gene. Candidate gene association studies have the ability to associate a single gene with LOAD, but have thus far suffered from a lack of replicability. One solution to this problem is genomic convergence, combining the information from these previous linkage and association studies with information from other genetic studies such as new linkage and association studies and expression data. We have utilized genomic convergence by combining information from previous genetic studies with new data from ~5,400 SNPs in 350 previously tested candidate genes. Association testing was performed on 518 cases and 531 controls, with all cases meeting NINDS-ADRDA criteria for AD and all controls testing cognitively normal on MMSE exams. Standard quality control measures were performed and samples were tested for population substructure. Using Armitages Trend test, 60/350 (17%) of the genes had at least one SNP with p-values < 0.025 (uncorrected), including APP, BACE2, CTNNA3, and HFE. Interestingly, these genes have positive results in each type of analysis (linkage, association, and SAGE studies). This substantially exceeds the expected percentage of significant results and suggests that a number of these previously identified genes have true (if modest) effects in LOAD.

R-pipeline for the robust analysis of arrayCGH data. *A. Pearlman, S. Cohen, Y. Kluger, H. Ostrer* Dept Pediatrics, New York Univ Sch Medicine, New York, NY.

Array CGH has emerged as a very useful tool for identifying structural genomic changes that leave discriminating signatures associated with various germline and somatic stage diseases. Routinely, raw data from array CGH experiments are very noisy; especially when samples are used from less than ideal sources (e.g. paraffin embedded archived tumors). Here, we describe a series of free analytical tools that have been pieced together to achieve a robust and systematic way of calling copy number changes for samples of varying qualities. We qualify our results on a simulated benchmark dataset (Bioinformatics. 2005; 21:3763-70) that produces a range of signal to noise (e.g. 4, 3, 2 and 1) and segment lengths (e.g. 40, 20, 10 and 5 probes) and a real data set of ten varying quality replicates hybridized to a 26k bac whole genome tilling path array (Genome Research 2006; 16:1566-1574). The process begins by passing the normalized log2ratios into the DNAcopy (Biostatistics. 2004; 5:557-72) and the MergeLevels (Bioinformatics. 21(22):4084-4091) tools to segment probes on a chromosome basis and combine probes of similar magnitudes on a genome wide basis respectively. Next, the data is binned into copy number estimates of zero through five using the sm package. These three steps are run multiple times for each hybridization, only, varying the alpha parameter of the DNAcopy segmentation tool. Finally, the data is analyzed with a naïve Bayes classification function of the e1071 package with the set of outputs of each hybridization. The results of several cross-validation analyses of the simulation data at the most difficult events with signal to noise of one and aberration length of five probes showed a marked improvement in the true positive rate (from 0.2 to 0.35) while maintaining a false positive rate of less than 0.05. Our next challenge is to apply the classification approach to the real data which requires the generation of a training dataset that will mimic each samples noise structure and length distributions. These results indicate that robust and cost-effective solutions are available to optimize arrayCGH data analysis.

Complete genome sequencing to high coverage of a single individual: James Watson. *D.A. Wheeler[1], M.E. Egholm[5], M. Srinivasan[5], A. L. McGuire[3], W. He[5], L.V. Nazareth[1], Y. Huan[1], Y. Liu[1], J.R. Lupski[2,4], D.M. Muzny[1], G.M. Weinstock[1,2], R.A. Gibbs[1,2]* 1) Human Genome Sequencing Center, Baylor College of Medicine, One Baylor Plaza, Houston, TX, 77030; 2) Department of Molecular and Human Genetics, One Baylor Plaza, Baylor College of Medicine, Houston, TX, 77030; 3) Center for Ethics and Health Policy, Baylor College of Medicine, One Baylor Plaza, Houston, TX 77030; 4) Department of Pediatrics, Baylor College of Medicine, One Baylor Plaza, Houston TX 77030; 5) 454 Life Sciences, Roche Diagnostics, 20 Commercial St., Bradford, CT 06405.

Recent advances in DNA sequencing using a combination of genomic DNA shearing, limited dilution, and single molecule-primed amplification by emulsion PCR to eliminate plasmid libraries and bacterial cloning, and a massively-parallel method of sequencing in picoliter size reaction vessels, provide the reduced cost and increased speed to enable the generation of data for personalized genome sequencing. With this technology, we produced a 6X coverage sequence of the genome of James D. Watson. Comparison to the reference genome yielded 1.8 million single base variants present in dbSNP plus approximately 230,000 novel SNPs, affording the first genome-wide compendium of SNPs from a single individual. Over 6,500 SNPs were classified as non-synonymous amino acid changes. 23 heterozygous alleles were found in the Human Gene Mutation Database. A large number of insertion/deletion polymorphisms were also readily observed; over 70 lay within exons and were validated by independent methods. Structural variation events 30-400 kb in size are also evident. A key aim of personal genome sequencing is to detect alleles that may be associated with disease, predictive of response to medication, or else prognostic indicators. Notable among the alleles identified in Watsons genome are mutations in both BRCA1 and Fanconi anemia 1,and two genes involved in DNA repair, which may suggest an increased risk of cancer. The identification of alleles with subtle implications for current health but potential to influence later decisions are at the heart of both the excitement and the dilemma of the new era of genomic medicine.

Pooled heteronuclear RNA sequencing: a new tool for large-scale cis-acting regulatory haplotype discovery. *T. Pastinen[1,2], E. Grundberg[1,2], K. Lam[2], B. Ge[2], S. Gurd[2], N. Martin[2], E. Harmsen[2], T. Kwan[2], J. Majewski[1,2]* 1) Department of Human Genetics, McGill University, Montreal, Quebec, Canada; 2) McGill University and Genome Quebec Innovation Centre, Montreal, Quebec, Canada.

We have developed a sequencing-based approach for quantitation of differences in allele frequencies between DNA and RNA pools derived from same population of individuals. This allows identification of polymorphisms that are in LD with regulatory variants. We have focused our screening to unspliced hnRNA allowing specific interrogation of common haplotypes in the vicinity of human genes and focus on transcriptional cis-regulatory effects. Our results in over 500 genes indicate that the method has high sensitivity for cis-acting effects based on comparison to results from three expression profiling studies using different microarray platforms in the same population of HapMap CEU lymphoblastoid cell lines (LCLs).The pooled hnRNA sequencing approach led to identification many additional cis-acting effects, such as a strong association of INSIG2 allelic expression to a regulatory haplotype -undetectable by traditional approaches. Other examples of disease associated genes in which regulatory haplotypes were detected are SLC22A5, PTGER4 and IL23R. A comparison of CEU LCL data to a pool of RNA / DNA derived from a panel of human primary cells (osteoblasts) reveals shared cis-acting associations in approximately 50% cases with the remainder of being tissue restricted. We have further validated the associations by allelic expression mapping studies in an independent YRI and/or Caucasian LCL panels as well as in primary cells. Comparison to exon array data has revealed that the hnRNA targeting assays may also pick up allelic isoform differences. Our results demonstrate that heritable cis-acting variation is common in human genome and allows insight to functional variation potentially altering risk for complex diseases. Finally, we suggest that focusing on functional variants in population based cell panels derived from donors of different ethnic backgrounds may provide a shortcut to fine mapping of functional variants underlying disease phenotypes. This work is supported by Genome Quebec and Genome Canada.

Candidate gene approach to identify genetic predisposition to severe forms of dengue virus infection. *M. Yasunami[1,2], T.P.L. Nguyen[2], M. Kikuchi[1,2], N. Okuda[1,2], H. Horie[1,2], T.Q.H. Vu[3], K. Morita[2], K. Hirayama[1,2]* 1) Center for Intl Collab Res, Nagasaki Univ, Nagasaki, Japan; 2) Inst Trop Med (NEKKEN), Nagasaki Univ, Nagasaki, Japan; 3) Pasteur Inst in Ho Chi Minh City, Ho Chi Minh City, Vietnam.

Dengue fever is caused by infection of dengue virus which is classified as flaviviridae. A recent surveillance revealed that up to 30% of the patients with dengue fever (DF) develop more severe forms with hemorrhagic tendency and symptoms of plasma loss, dengue hemorrhagic fever (DHF) or dengue shock syndrome (DSS), in the Southeast Asian countries. Multiple factors have been proposed for the development of DHF and DSS, and host genetic variation would be one of such major determinants. To identify the host genes contributing to the development of DHF and DSS, we collected 743 patients with apparent dengue virus infection (114 patients with DF, 211 patients with DHF, and 418 patients with DSS) who were diagnosed by WHO criteria at two hospitals in southern part of Vietnam from 2002 to 2005, and 193 healthy controls matched for ethnicity and age. As a screening, we employed pooled DNA genotyping for 85 microsatellite markers physically linked to immune and inflammation-related candidate genes. Comparison of one 100-DHF-patient pool and two 100-DSS-patient pools with a control pool of 100 individuals suggested the presence of alleles in different frequency across populations at 22 out of these 85 loci. The difference in allele frequency was then confirmed at 19 loci of them by genotype data of individuals who were included in the pools, indicating that the pooled DNA genotype was reliable in terms of the specificity of detection as a screening method. We extended the genotype analysis of these 19 loci for all available samples and found the association of at lease one allele at 10 microsatellite loci with any of three form disease, DF, DHF or DSS. An allele of the microsatellite locus physically linked to CD4 gene on chromosome 12 is one of the resultants, which exhibited positive association with both DHF and DSS and significant genetic interaction with a disease-resistant factor linked to HLA class II genes.

A *Neurexin 1* deletion implicates a synaptic defect in the pathophysiology of autism. *K.J. Meyer[1], L.K. Davis[1], A.L. Librant[1], D.S. Rudd[1], E.M. Berg[4], C.M. Taylor[2], J. Piven[5], E.M. Stone[2,4], V.C. Sheffield[3,4], T.H. Wassink[1], Autism Genome Project Consortium* 1) Department of Psychiatry, University of Iowa, Iowa City, IA; 2) Department of Opthalmology and Visual Sciences, University of Iowa, Iowa City, IA; 3) Department of Pediatrics, University of Iowa, Iowa City, IA; 4) Howard Hughes Medical Institute, University of Iowa, Iowa City, IA; 5) Neurodevelopmental Disorders Research Center, University of North Carolina at Chapel Hill, Chapel Hill, NC.

Autism is a pervasive developmental disorder (PDD) characterized by impairments in communication and social interaction as well as restricted interests and repetitive behaviors. Family and twin studies have demonstrated a substantial genetic component in the development of autism. Considerable efforts have been made to identify genes that confer susceptibility to autism through linkage analysis and association studies. However, the mode of inheritance for autism is complex and this effort has met with limited success. Therefore we utilized a new approach, screening the genomes of multiplex autism spectrum disorder (ASD) families for copy number variants (CNVs) in collaboration with the Autism Genome Project (AGP) with the Affymetrix 10K SNP microarray. We identified two affected female siblings, both harboring an identical hemizygous 355kb CNV loss that deleted coding exons from the gene *NRXN1*. Microsatellite mapping indicated no transmission of paternal alleles across the deletion interval, indicating paternal germline mosaicism. Studies have shown that neurexins are located on the presynaptic terminus of both excitatory and inhibitory synapses and that they function as cell adhesion molecules, binding to neuroligins on the postsynaptic terminus. The neurexin/neuroligin complex has previously been implicated in autism and is hypothesized to have several functions including regulation of the ratio of excitatory to inhibitory synapses. Based on these data, we have further evaluated the role of *NRXN1* in the development of autism by screening a large sample of individuals with autism for *NRXN1* mutations and testing *NRXN1* SNPs for association.

A computational system for integrative analysis of cancer genomes and epigenomes. *W.L. Lam, B.P. Coe, W.W. Lockwood, R. Chari* British Columbia Cancer Research Centre, Vancouver, BC, Canada.

Advances in array based technologies have enabled high throughput genome wide measurement of genetic polymorphism, gene dosage, epigenetic status, and gene expression pattern. The integration and parallel analysis of multi-dimensional datasets requires specialized bioinformatics tools to facilitate the combination of complementary data to be analyzed in a unified environment. The objective of our work is to develop a software platform to organize, visualize and analyze multi-dimensional datasets that enables the application of molecular systems approaches to analyzing clinical cancer specimens.

We have established a software package in Java which uses a MySQL database for storage of data and results, and employs the statistical package R for analysis. This new software platform is called SIGMA2 for System for Integrated Genomic Microarray Analysis Version 2. The program is developed in Java to facilitate use across all operating systems. A secure, searchable database has been established to facilitate the storage and optional sharing of genomic data. SIGMA2 is highly versatile, having the ability to view data from a variety of commercial and custom microarray platforms. For array based gene dosage analysis (comparative genomic hybridization), multiple visualizations, including signal ratio value and frequency plots, are available at different magnifications, algorithms for automated data segmentation/analysis, and linkage to other datasets. For example, we have incorporated displays for loss of heterozygosity and gene expression data, as well as analysis tools for correlation of gene dosage and gene expression data. SIGMA2 is also designed for ease of extension so that new data types can be handled effortlessly and additional algorithms are simple to incorporate. In conclusion, we have developed a system to perform integrative genomic, epigenomic and gene expression analysis. Such tools will be necessary for the analysis and interpretation of high-throughput multi-dimensional datasets.

Genetic distribution of three polymorphisms of genes related with Osteoporoses in Mestizos and Amerindian populations from Mexico. *I. Nuño-Arana[1], F.J. Muñoz-Valle[2], L. Sandoval-Ramirez[3], B. Lazalde-Medina[4], H. Rangel-Villalobos[1]* 1) Ciencias Medicas , Universidad de Guadalajara, Ocotlan, Jal., Ocotlan, Mexico; 2) Centro de Investigación en enfermedades reumáticas y músculo-esqueléticas, CUCS-UdeG; 3) División de Genética, CIBO-IMSS; 4) Laboratorio de Genética, Universidad Benito Juarez del estado de Durango.

By means of PCR-RFLPs, we analyzed three different polymorphisms of genes involved in susceptibility to osteoporoses in 765 unrelated individuals from Mexican populations, including Mestizos and five Amerindian groups (Nahuas, Purépechas, Huicholes, Tarahumaras and Mayas). We analyzed the polymorphisms Sp-1 of COL1A1 gene, Bsm I of Vitamin D receptor (VDR), and A163G of the osteoprotegerin (OPG) gene. The purpose was to establish the genotype and allele distribution in this non-previously studied populations. The s allele in Sp-1 polymorphism has been implicated in bone mass decreased, due to defect of collagen fibres that it conforms. The Bsm I is a VDR polymorphism, with calcium-dependent response, controversially implicated in osteoporoses. Finally, OPG is a recently discovered polymorphism involved in osteoclastogenesis. In Bsm I the average frequencies for these six Mexican populations in the allele B was 64%. This result was unexpected, considering that allele b has been pointed as the predominant in previous worldwide population studies, particularity in Asian populations. For COL1A1 polymorphism, the allele S had the highest frequency (87%) in Mexican populations, which corresponds to the reported in scientific literature but with more predominance. For OPG polymorphism, the genetic frequencies were according to the reported for most of worldwide populations. The genotype distribution for the majority of loci of Mexican populations was in Hardy-Weinberg equilibrium, excepting to Mestizos for BsmI and Purépechas for COL1A1. These results represent the first data from Mexican populations, specifically Amerindian groups, which could eventually contribute for a better understanding of the risk and susceptibility to osteoporoses in this country.

Case report: A girl with 46, XX, der (18, 21) (q10, q10). *S.M. Seyedhassani[1,2], S.M. Kalantar[1], T. Akhavan Karbasi[1]*
1) Medical Genetics Dept, Res/Clinical Ctr Infertility,Yazd, Iran; 2) Medical Genetics Dept,National Institute for Genetic Engineering and Biotechnology, Tehran, Iran.

The case is a 7 years old girl that was referred to clinic of genetic with learning problem and ptosis. The suggested diagnosis was myasthenia. She was borne from the five degree familial marriage with inbreeding coefficient 1/32. There were ptosis, poor feeding and mouth breathing at the birth, so that, she was in intensive care unit for 8 days. Past history also showed delayed development, such as walking in month 17 and speaking in 3 years old. Intelligent quantity recently is done and was 50. In physical examination; ptosis, sparse/lateral hypoplasia of eyebrows, dental caries, high arch, low set ear and refractive disorder of the eyes are seen. Tensilon test was negative and biochemical muscular test and blood aminoacid had normal patterns. Cytogenetic study is reported as 46, XX, der (18, 21) (q10, q10). Parents chromosomal study was normal. This case is documented and illustrated.

A genome-wide approach to identify pharmacogenomic candidate genes that contribute to variation in cytosine arabinoside (Ara-C) cytotoxicity. *L. Li[1], B.L. Fridley[2], K.R. Kalari[1,3], G. Jenkins[2], A. Batzler[2], M.A. Hildebrandt[1], D.J. Schaid[2], R.M. Weinshilboum[1], L. Wang[1]* 1) Division of Clinical pharmacology,Department of Molecular Pharmacology and Experimental Therapeutics, Mayo Clinic, Rochester, MN 55901; 2) Division of Biostatistics, Department of Health Sciences Research, Mayo Clinic, Rochester, MN 55901; 3) Division of Biomedical Informatics, Department of Health Sciences Research, Mayo Clinic, Rochester, MN 55901.

Background: Ara-C is used in both induction and maintenance therapy for virtually all patients suffering from acute myelogenous leukemia. However, relatively few studies have addressed the possible contribution of inheritance to individual variation in response to Ara-C therapy. We set out to take both a biased pathway-based approach and a complementary unbiased genome-wide approach to study Ara-C pharmacogenomics. **Methods:** We utilized a data-rich cell-based model system consisting of 197 Coriell Institute Human Variation Panel lymphoblastoid cell lines from 3 ethnic groups. We generated indepth resequencing data for genes encoding proteins involved in the Ara-C Pathway. In addition, we obtained basal expression array data for all of these cell lines and performed MTS-based cytotoxic assays. Genome-wide association studies and pathway-based analysis with basal expression array data and Ara-C cytotoxicity were then performed to identify genes associated with Ara-C response. **Results and Discussion:** Ara-C cytotoxicity was assayed for all cell lines, and IC50 (GI50) and LC50 values were calculated using a four parametric logistic model. These phenotypes were correlated with expression array data using Pearsons product moment correlation coefficients. This association study identified 21 genes - both within and outside of the Ara-C Pathway--with p-values < = 10-5. Pathway analysis of these genes showed that toll-like receptor (TLR) signaling, death receptor, IL-10 and apoptosis signaling pathways might be involved. Functional studies of these candidate genes are being performed to verify the correlation results. These results represent a step toward a global understanding of Ara-C pharmacogenomics.

Individualizing Cancer Therapies through the Optimized Selection of Compounds with Complementary Signatures. *E.O. Lillie[1,2], N.J. Schork[1,2]* 1) Scripps Genomic Medicine, TSRI, La Jolla, CA; 2) Center for Human Genetics and Genomics, UCSD, La Jolla, CA.

Each individual has unique genetic features that contribute to cancer risk and prognosis. Once cancer has been established, tumors display unique features due to stochastic somatic events during tumorigenesis. These unique features can be characterized by gene expression. We hypothesize that certain compounds produce a complementary gene expression signature that reflects biological activity opposite to the tumors activity. Therefore, an individuals response to the compound can be predicted by how their unique tumor signature complements the signature of the compound. We tested this through the use of published gene expression datasets and the Connectivity Map (cmap), a collection of gene expression profiles from cultured human cells treated with bioactive small molecules (http://www.broad.mit.edu/cmap/). To test our hypothesis, we used 3 datasets from estrogen receptor positive breast cancer tissues obtained prior to tamoxifen (tam) therapy with follow-up data available (E-TABM-158, GSE4922, GSE2990) and compared them to normal breast tissue (GDS1096). Each subjects signature of the transcripts that were either up- or down-regulated was uploaded to the cmap for comparison with the tam signature in MCF-7 cell lines. A score between -1 and 1 for how similar the signature was to that of tam was output. For perfect complementarity we would expect a score of -1 suggesting that up-regulated transcripts in the tumor were down-regulated in response to tam. In the combined sample of 179 breast cancer cases, we observed a range of tam connectivity between -0.273 and 0.593. No associations between cmap score and risk of recurrence were observed with or without adjustment for other prognostic factors. Our null results may be explained by a number of factors: insufficient sample size, limitations in comparing expression in tumor tissue to immortalized cell lines, and the choice of transcripts to compare. We plan to further test these hypotheses using data from other cancers and compounds to further evaluate the utility of cmap for connecting drugs with disease.

Modulation of translation termination in dystrophin. *P.S. Lai, G.G. Xiong, P.P. Lim, S.K.H. Tay, P.S. Low* Dept Pediatrics, National Univ Singapore, Singapore 119074.

Mutations in the gene encoding for muscle protein, dytrophin, cause an X-linked disorder called Duchenne Muscular Dystrophy (DMD). Some compounds like aminoglycosides have been shown to suppress premature stop codons, permitting translation to continue to normal termination of the transcript. In this study, we report the development of a cell-based expression assay which allows the investigation of the effects of aminoglycosides in modulating premature termination of translation from dystrophin stop codons. Constructs containing mutation cassettes derived from patients involving three types of stop codons, namely UGA, UAA and UAG, were cloned and transfected into mammalian HEK293 cells and readthroughs were then measured via expression of a fluorescent-tagged marker. Using this assay, four aminoglycosides were tested at varying concentrations of up to 2.5 mg/ml and at four different time-points of treatments. It was found that using this cell-based assay system, translation readthroughs could be detected for all the three types of stop codons with G418 (2.4 mg/ml) showing highest expression initially up to 48 hours but after 72 hours of treatment, gentamicin (1.0 mg/ml), tobramycin (2.4 mg/ml) and paromomycin (2.5 mg/ml) result in readthroughs ranging between 42% to more than 70%. Thus, gentamicin, paromomycin and tobramycin, which are clinically approved for use as antibiotics, exhibited a higher efficiency in nonsense suppression compared to G418. UGA stop codon was most susceptible to the induced readthroughs compared to UAG or UAA codons. Aminoglycosides and other similar pharmacological compounds may offer an alternative strategy for therapy in DMD if the specificity, efficiency and level of readthroughs can be further improved.

COMT tag SNPs associated with quantitative cognitive variables in multiplex, multigenerational schizophrenia sample. *K. Prasad[1], L. Almasy[2], R. Gur[3], R. Gur[3], M. Pogue-Geile[1], M. Talkowski[1], K. Chowdari[1], V. Nimgaonkar[1]* 1) Psychiatry, Univ Pittsburgh, Pittsburgh, PA; 2) Southwest Foundn Biomed Res, San Antonio, Tx; 3) Univ Pennsylvania Sch Med, Philadelphia, PA.

Background: Catechol-O-methyl transferase (COMT) gene variations have been associated with cognitive performance in both schizophrenia (SCZ) and healthy subjects. We comprehensively examined the association of COMT polymorphisms with variability in cognitive functions in a series of multiplex, multigenerational (MM) Caucasian families with SCZ. Methods: Consenting participants in 56 MM families were administered the Computerized Neurocognitive Battery (CNB). The CNB evaluates speed (response time) and accuracy of performance on abstraction and mental flexibility, attention, verbal, spatial and face memory, and spatial ability. We selected the tag SNPs from common SNPs from the HapMap, Seattle SNP database and published literature (r2 cut off <0.8). These SNPs were genotyped among 561 members of our MM SCZ families using the SNPlex assay (ABI Biosystems, Inc). Measured genotype analyses accounting for family relationships were performed in SOLAR. Results: Accuracy of attention (rs4646315), verbal memory (rs9332377, rs4646316) and spatial processing (rs165815) were significantly different across these alleles (p0.05). Speed of language processing was associated with rs933271. Suggestive associations were also observed for spatial memory. Discussion: These results suggest that variations in COMT are associated with variability in distinct cognitive domains in MM families with SCZ. Our group had previously reported that these cognitive measures were heritable and distinguish the patients from their relatives and healthy controls. Such observations in MM families suggest that these estimates may not be substantially inflated by environmental factors and that specific gene variations could account for such variability. On the same sample, RGS4 variations were associated with face and verbal memory. Taken together, these observations lend initial clues to the possibility that variations in different susceptibility genes may be associated with variability in distinct cognitive domains.

Location analysis of E2F4 binding sites by high-density oligonucleotide human promoter arrays. *S. Song[1], C. Brueck[2]* 1) Agilent Technologies, Santa Clara, CA; 2) Sigma-Aldrich, St. Louis, MO.

Regulatory proteins bind to genomic DNA to control chromosome replication and gene activity, thereby functioning as switches in the regulatory circuitry of cells. This network of circuits is uncharted in many instances and its understanding will aid researchers in identifying new target genes and therapeutics capable of modulating these pathways. ChIP-on-chip (chromatin immunoprecipitation-on-chip) also known as Location Analysis (LA), is the powerful technology to analyze how regulatory proteins interact with the genome of living cells driving the next generation microarray platform (Boyer, L.A. et al., Cell, v122, p947-956). This advanced technology provides insight into key mechanisms of methylation, histone modification, as well as DNA replication, modification, and repair. The E2F4 family is a ubiquitous family of transcription factors involved in regulating basic cellular processes. Here we take an unbiased, sensitive, and comprehensive approach towards identifying E2F4 target genes by examining localization of E2F4 binding sites using high-density oligonucleotide human promoter arrays and integrated ChIP analytics software.

Common polymorphisms in the BRCA1 and BRCA2 genes are not associated with breast cancer risk. *J. Long*[1], *X.O. Shu*[1], *Q. Cai*[1], *Y. Gao*[2], *W. Zheng*[1] 1) General Internal Medicine, Vanderbilt Univ, Nashville, TN; 2) Department of Epidemiology, Shanghai Cancer Institute, Shanghai, 200032, China.

It is well established that rare mutations in the BRCA1 and BRCA2 genes increase the risk of breast cancer; however, it is not clear whether common polymorphisms in these two genes are associated with breast cancer risk. Using 1,079 cases and 1,082 controls from The Shanghai Breast Cancer Study, a population-based case-control study, we performed a comprehensive association study for these two genes. Tagging SNPs were identified through HapMap Chinese data with criteria of minor allele frequency (MAF) of 0.05 and r20.9 for both genes plus their flanking 5kb sequences. Potential functional SNPs including those located in promoter genes or those non-synonymous SNPs with MAF0.05 in Asian were forced into tagging list. A total of 9 SNPs in the BRCA1 gene and 32 SNPs in the BRCA2 genes were successfully genotyped, using Affymetrix ParAllele Target genotyping system. Two SNPs, one for each gene, were dropped for association analyses because they were not polymorphic in our study population. No significant associations were observed for the other 39 SNPs through dominant, additive, or recessive model analyses. Haplotype analyses did not show any association for either the BRCA1 or BRCA2 gene. Analysis stratified by menopause status found the same null association results. CONCLUSION: It is unlikely any other common polymorphisms in these two genes are associated with increased risk of breast cancer in our study population.

Two distinctive dysfunctions of mutated FGD1 proteins found in patients with Aarskog-Scott syndrome. *K. Yanagi[1], T. Kaname[1, 5], H. Maehara[1, 2], Y. Chinen[3], N. Okamoto[4], K. Naritomi[1, 5]* 1) Dept Medical Genetics, Univ Ryukyus, Nishihara, Japan; 2) Dept Orthopedics, Univ Ryukyus, Nishihara, Japan; 3) Dept Pediatrics, Univ Ryukyus, Nishihara, Japan; 4) Osaka Medical Center and Research Institute for Maternal and Child Health, Izumi, Japan; 5) SORST, Japan Science and Technology agency (JST), Kawaguchi, Japan.

Faciogenital dysplasia 1 (FGD1) gene was identified as a responsible gene for Aarskog-Scott syndrome (AAS), which is characterized by short stature, dysmorphic facial appearance, brachydactyly, and shawl scrotum. In some patients, neurobehavioral abnormalities have been also described in addition to the faciogenital dysplasia. FGD1 protein acts as a guanine nucleotide exchange factor (GEF) for CDC42, and possess Dbl homology domain (DH domain), pleckstrin homology domain (PH domain) that will be essential for the GEF activity. However, molecular pathology of FGD1 abnormalities and genetype/phenotype correlation of AAS are unknown.

We investigated cell biological (dys-)function for two types of mutated FGD1 protein found in two patients with faciogenital dysplasia only or the dysplasia plus neurobehavioral abnormality. Each mutation is substitution of an amino acid in the PH domain or in the DH domain, respectively. Expression vector for the mutants or wild type of FGD1 were constructed and transfected into HT1080, human fibrosarcoma cells. By comparison of each stable transformatns on protein localization, formation of membrane ruffles, cell migration, and cell proliferation, each mutant proteins display distinct dysfunction in vitro that might be able to explain differences of symptoms in AAS.

Combining the effects of IBD and association in genetic case-control studies. *Q. Zhang*[1], *Q. Long*[1], *J. Ott*[1, 2] 1) Beijing Institute of Genomics, Chinese Academy of Sciences, Beijing, Beijing, China; 2) Laboratory of Statistical Genetics, Rockefeller University, NY, USA.

Lander and Botsteins homozygosity mapping is a well accepted method in pedigree linkage analysis. As an extension of it, Broman and Weber proposed a statistical analysis that discriminates between autozygosity and allozygosity. As recent studies show, the human founder population was relatively small so that even in outbred populations we can find long segments of homozygosity. Here we propose to us this approach in case-control studies by focusing on genome-wide sets of SNPs. We derive statistically appealing criteria for the length of stretches of autozygosity by connecting scan statistics with homozygosity mapping. Previous approaches either looked only at homozygosity without paying attention to IBD or worked with fixed lengths of windows of markers, for which average homozygosity was determined. Our test statistic appears more powerful than the conventional genotype and allele tests.

Comparing the power of discordant sib pairs study and case-control association study. *Q. Long*[1], *Q. Zhang*[1], *J. Ott*[1, 2] 1) Chinese Academy of Sciences, Beijing Institute of Genomics, Beijing, Beijing, China; 2) Laboratory of Statistical Genetics, Rockefeller University, NY, USA.

Population-based association studies are commonly used to map genes. The statistical analysis may be susceptible to false positive results because of population stratification. Several methods that use family-based controls have been proposed, e.g., the transmission-disequilibrium test, discordant sib pairs and affected family-based controls. Such tests have fewer false-positive results produced by population stratification. However, the power of such methods may be lower than ordinary case-control studies. To quantitatively describe power differences of these approaches, we simulate affected and unaffected data to calculate the p-values of both case-control study and discordant sib pares (DSP) study. In each round of the simulation, we first fix the model (dominant, recessive, additive) and parameters of the population prevalence and penetrance. Then we perform the analysis to find the significance level (p-value) of identifying the corresponding gene. By repeating the process of data simulation and analysis many times, we compare the power of DSP and traditional case-control study. We found results as follows: When we fix parameters but let the penetrance of the genotype DD (D = disease allele) change, in the dominant model, the power of DSP is slightly smaller than case-control; but in additive and recessive models, the difference increases markedly as the penetrance decreases.

Development and evaluation of genome-wide strategies to identify pharmacogenetic contributions to adverse drug reactions in real-time. *M.R. Nelson, S.A. Bacanu, C.E. Bowman, S.L. Chissoe, M. Mosteller, A.D. Roses, E.H. Lai, M.G. Ehm* Pharmacogenetics, GlaxoSmithKline, RTP, NC.

Adverse drug reactions (ADRs) can have a major impact on patients, doctors, regulatory agencies, and pharmaceutical companies. Risk factors known to contribute to ADRs include drug dose, environmental history and exposures, smoking, concomitant medications, as well as genetic variations. Identifying the genetic factors that contribute to ADR risk may lead to a better understanding of the underlying mechanism, identify patients at risk, or lead to more informed treatment decisions, all of which can provide better patient care and lower health costs. A review of the literature shows that several ADRs are strongly influenced by large pharmacogenetic effects. This suggests that proactive genome-wide genotyping of ADR cases coupled with pre-genotyped population controls could permit the rapid determination of whether there is a substantial common genetic component contributing to ADR risk. We explore the power of this approach through simulation and illustrate its application in a genome-wide search for markers associated with hypersensitivity to abacavir, an ADR which has a known major genetic risk factor (*HLA-B*5701*). Aggressive monitoring and genome-wide analysis of ADR cases as they are identified in clinical practice after drug approval can ensure that critical genetic biomarkers are discovered and have the opportunity for maximum impact on drug safety and patient care.

Association mapping of the five quantitative ECG traits RR, P, PQ, QRS AND QT in a 500K genomewide scan: confirmation of the NOS1AP association to QT and identification of a spectrum of additional QTLs. *A. Pfeufer[1,2], M. Akyol[1,2], M.F. Sinner[2,3], S. Perz[2], C. Gieger[2,3], B.M. Beckmann[3], T. Illig[2], H.E. Wichmann[2,3], S. Kaab[3], T. Meitinger[1,2]* 1) TU Munich, Germany; 2) GSF National Research Center, Neuherberg, Germany; 3) LMU University of Munich, Germany.

Background: We have investigated five quantitative electrocardiographic (ECG) traits by genomewide association (GWA), namely the RR interval (a measure of heart rate), the P wave duration (a measure of atrial excitation and repolarization), the PQ interval (a measure of AV conduction), the QRS interval (a measure of ventricular excitation) and the QT-interval (a measure of ventricular repolarization). All traits are indicators of physiologic as well as pathologic states in cardiac electrophysiology and are known endophenotypes for predisposition to arrhythmias and cardiac sudden death. Aim: To map the spectrum of QTLs for these traits we undertook a genome-wide association scan in n=1,664 individuals using Affymetrix 500k arrays. Probands were participants of the follow-up (F3) of the population based KORA S3 survey from Augsburg, Southern Germany. Association was calculated under additive, dominant and recessive models. Results: We considered SNPs with CR>98%, p(HWE)>1e-5 and with n30 individuals responsible for an association signal p1e-6 suitable for follow up genotyping. The known QTL for QT interval at the NOS1AP gene gave the strongest genomewide association signal. 60 SNPs throughout a 500kb genomic region were associated with significance levels down to 1e-7.5. In addition we identified 12 additional putative QTLs, 2 for RR, 1 for PQ, 7 for QRS and 2 for QT. Conclusions: The QTL at the NOS1AP gene was confirmed as the single most significant signal for QT interval from a 500k-genomewide scan. Its well identifiable signal is due to its high allele frequency (MAF=0.35), 500kb long LD relationship and relatively strong effect size. The newly identified QTLs for QT and other ECG traits display a spectrum of different effect sizes, allele frequencies and are currently undergoing replication testing in larger population based samples.

Linkage of gene for extreme obesity in genetic isolate. *E.I. Rogaev[1,2,3], Y.K. Moliaka[1], O.V. Plotnikova[1], V.A. Nikishina[1], V.A. Koshechkin[4], E.K. Ginter[5]* 1) Brudnick Neuropsychiatric Research Institute UMASS MS, Worcester, MA; 2) Research Center of Mental Health RAMS, Moscow, Russia; 3) Vavilov Institute of General Genetics RAS, Moscow, Russia; 4) Peoples Friendship University of Russia, Moscow, Russia; 5) National Research Center for Medical Genetics, RAMS, Moscow, Russia.

During an epidemiologic screen we described unique isolated population in Central Asia characterized by high endogamy and accumulation of three independently inherited diseases: cataract, hypertension and extreme obesity with hyperphagia. Obese individuals are characterized by excessive appetite and food intake persistent since infancy or early childhood. Familial and segregation analysis demonstrated autosomal-recessive inheritance and virtually complete penetrance of the obesity gene The samples collected from selected families were used for gene mapping and mutation screening. The STR markers selected randomly across human autosomal chromosomes and from candidate-loci linked to obesity in humans and mice were initially used for genome scan and paternity and maternity analysis. The linkage analysis provided evidence for a linkage to chromosomal locus 7q32. The analysis showed at least three haplotypes for the five STR markers on mutated chromosome persisting in this population.
The data demonstrated the evidence for linkage of the obesity associated with extreme hyperphagia to locus on chromosome 7 and suggested strong candidate-gene for the obesity in this population. The genotyping data suggest also that the obesity mutation affects puberty but does not disrupt fertility in males. Supported by NIDDK 1R01 HD045570-01.

A replication-based mechanism may mediate complex genomic rearrangements causing Pelizaeus-Merzbacher disease. *J.A. Lee[1], C.M.B. Carvalho[1], J.R. Lupski[1,2,3]* 1) Dept Molecular & Human Genetics, Baylor Col Medicine, Houston, TX; 2) Dept Pediatrics, Baylor Col Medicine, Houston, TX; 3) Texas Children's Hospital, Houston, TX.

The prevailing mechanism for rearrangements causing genomic disorders is non-allelic homologous recombination (NAHR) between region-specific low-copy repeats (LCRs) for recurrent events that have breakpoints which cluster and for some non-recurrent alterations. For rearrangements that are non-recurrent, with junctions scattered instead of clustered, non-homologous end joining (NHEJ) has been implicated as the recombinational repair mechanism. Pelizaeus-Merzbacher disease (PMD) is an X-linked recessive dysmyelinating disorder caused most frequently by non-recurrent duplication including the dosage-sensitive proteolipid protein 1 (*PLP1*) gene, but also by non-recurrent deletion and point mutations. Whereas the DNA sequence analysis of breakpoint junctions for deletions and duplications of *PLP1* have thus far been reported to be consistent with NHEJ repair, the majority of *PLP1* duplication junctions are apparently refractory to breakpoint sequence analysis. Upon analysis of junction sequences in PMD patients with different-sized (~200 kb to ~7 Mb) genomic duplications and deletions, we have both confirmed the occurrence of simple *PLP1* tandem duplications and also have found evidence for sequence complexity at some recombinant junctions representing a composite from more than two discreet genomic locations. Our data are suggestive of complex *PLP1* duplications and deletions occurring via a replication-based mechanism, which we term FoSTeS for replication Fork Stalling and Template Switching. We propose that some of the more complex duplication and deletion rearrangements associated with PMD that have been reported in the literature, and potentially other non-recurrent complex genomic rearrangements, may be explained by this replication-based mechanism.

B9 - A Potential Basal Body Localization Domain. *J.F. Robinson, N. Katsanis, PhD* McKusik-Nathans IGM, Johns Hopkins School of Medicine, Baltimore, MD.

Primary cilia are cellular appendages originally thought vestigial organelles; however recent work has demonstrated their involvement in a myriad of sensory functions. Defects in primary ciliary signaling are also implicated in human disorders termed collectively ciliopathies, which include Polycystic Kidney Disease, Bardet-Biedl (BBS), Meckel-Gruber (MKS), and Joubert Syndrome. Although there is a vast and growing number of proteins that have been shown to localize to the cilium and/or its anchor, a modified centriole termed the basal body, the mechanism of targeting ciliary proteins remains completely elusive. One protein, MKS1, has been implicated recently in several ciliopathies, including MKS and BBS, has been shown to localize to the basal body, where it has been shown to be necessary for ciliogenesis. The C. Reinhardtii orthologue of MSK1 has been suggested to encode a core structural component of the centriole termed the B9 domain. Through searches of the human genome we have identified a total of three predicted proteins, MKS1, LOC80776 and EPPB9, encoding polypeptides with B9 domains. Interestingly, each of these three proteins has been predicted to serve as ciliary function as it is present in the integrated ciliary proteome (www.ciliaproteome.org), suggesting a cilia-specific role for the poorly characterized B9 domain. In this project we combine localization studies with mutational studies to further characterize the B9 domain and its importance in ciliary localization.

Association between vitamin D receptor gene (VDR)polymorphisms and tuberculosis in Mexican Mestizo Patients. *A. Tomasena-Glennie[1,3], J.M. Oliva-Ortiz[1,2], A.L. Corona-Nakamura[4], G. Amaya-Tapia[5], C. Morán-Moguel[1], J. Sanchez-Corona[1], L. Sandoval-Ramirez[1,2]* 1) División de Genética, CIBO, IMSS, Guadalajara, Jalisco, Mexico; 2) Doctorado en Genética Humana, CUCS, Universidad de Guadalajara,Guadalajara, Jalisco, México; 3) CUCEI, Universidad de Guadalajara, Guadalajara, Jalisco, México; 4) 3 Servicio de Infectología, Hospital de Especialidades, UMAE, Hospital de Especialidades,CMNO, IMSS, Guadalajara, Jalisco, México; 5) Hospital General de Occidente, SS, Guadalajara, Jalisco, México.

Introduction. Tuberculosis (TB) is a disease caused by Mycobacterium tuberculosis, that along with Malaria and HIV is responsible for approximately six million deaths per year1 and has been described as one of the five pandemics of the 21st century by the World Health Organization (WHO). Polymorphisms in certain genes, like NRAMP1 and VDR, have been associated with susceptibility to TB. In addition to that, epidemiological studies show a relation between vitamin D deficiency and susceptibility to TB and some in vitro studies suggest that theres a close effect of the active metabolite of vitamin D, 1,25D3, on the mycobacterial growth 2. Our objective is to determine whether there exists any association between VDR gene polymorphisms (BsmI, FokI, ApaI and TaqI) and tuberculosis in Mexican mestizo patients. Method: A total of 63 patients with TB were included along with 77 controls reported as healthy. The genotyping of the four polymorphisms was made by PCR/RFLP method. Results:. The genotype frequencies found among patients for BsmI were BB 33.3%, Bb 65% and bb 1.6%; for FokI: FF 41.3%, Ff 46% and ff 12.7 %; for TaqI: TT 54%, Tt 39.7% and tt 6.3% and for ApaI: AA 60.3%, Aa 30.2% and aa 9.5%. Controls genotype frequencies were: For BsmI BB 31.9%, Bb 57.1% and bb 11%; for FokI: FF 44%, Ff 46.2 % and ff 9.9%; for TaqI: TT 63.7 %, Tt 29.7% and tt 6.6% and for ApaI: AA 54.9%, Aa 28.6% and aa 16.5%. Conclusions: We didnt find any association between VDR gene polymorphisms (BsmI, FokI, ApaI y TaqI) and TB although it has been found in other populations. A larger study with a bigger number of samples would be recommended.

Dissociation between Gonadarche and Adrenarche in Patients with Glycogen Storage disease type 1a. *C.A. Stratakis, S.A. Boikos1* SEGEN, DEB, NICHD, NIH, Bethesda, MD.

Two distinct processes take place during pubertal development in humans, adrenarche and gonadarche. In constitutional delay of growth and puberty, both events are delayed, with adrenarche occurring normally with advancing skeletal age, followed by gonadarche. Deficient adrenal androgen secretion has been demonstrated in chronic diseases, such as thalassemia major, with concurrently intact glucocorticoid and mineralocorticoid synthesis. Glycogen storage disease type Ia (GSD-Ia) is caused by an inherited defect of glucose-6-phosphatase. Severe failure to thrive is present in all untreated patients, but near-normal growth and pubertal development can be achieved with appropriate therapy. We report three patients with GSD-1a and absent adrenarche and delayed gonadarche [low testicular volume and lack of secondary sexual characteristics] at the age of 13 1/2 y, ., that were recently treated in our institution, with a six-month course of low-dose testosterone (T) enanthate (50 mg im, monthly). Gonadarche took place in all the cases after or during the treatment, as judged by TV and/or pubertal LH/FSH response to GnRH.. After a short course of a low-dose testosterone treatment, that apparently induced normal gonadarche, dissociation of adrenarche was evident in the first patient. We were able to study the adrenal steroidogenesis by an ACTH stimulation test in the next two patients: and show specific 3-ol and sulfokinase deficiencies, as well a milder C17-20 lyase deficiency. We conclude that in GSD-1 there is delayed gonadarche, and delayed and deficient adrenarche. Induction of gonadarche with sex-steroids was successful, and did not compromise final height prediction. After pubertal induction, a dissociation of adrenarche was evident in our patients with GSD-1a, similar to what is seen in patients with thalassemia major. Defficient adrenal steroidogenesis may be responsible for the lack of normal development of pubic and facial hair in patients with GSD-1a.

Examination of Sortilin-related receptor SORL1 in Late-Onset Alzheimer Disease. *S.D. Turner[1], X. Liang[1], E.R. Martin[2], N. Schnetz-Boutaud[1], J. Bartlett[1], B.M. Anderson[1], S. Zuchner[2], H. Gwirtsman[1], D. Schmenche[3], R. Carney[3], J. Gilbert[2], M.A. Pericak-Vance[2], J.L. Haines[1]* 1) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 2) Miami Institute for Human Genomics, Miami, FL; 3) Center Human Genetics, Duke University, Durham, NC.

Late-onset Alzheimer disease (AD) is a neurodegenerative disorder with a genetically heterogeneous etiology. Accumulation of A peptide in the brain is a key event in AD pathogenesis. A is generated primarily by the endocytic pathway that processes amyloid precursor protein (APP) recycling from the cell surface. A component in this pathway, the sortilin-related receptor SORL1, was recently associated with AD in both family and case-control datasets. Here, we genotyped 6 previously associated SNPs in SORL1 in 518 cases and 527 age and gender matched controls in a Caucasian population from the Southeastern United States. All cases met NINDS-ADRDA criteria for probable or possible AD and all controls were cognitively normal. Intronic SNP rs3824968 in SORL1 showed both a significant genotypic association with an odds ratio of 1.41 (95% CI=[1.10, 1.79], p=0.006) and significant allelic association with an odds ratio of 1.24 (95% CI=[1.03, 1.50], p=0.025). Intronic SNP rs2070045 was significantly associated with AD with an odds ratio of 1.35 (95% CI=[1.05, 1.75], p=0.017). These data provide additional support for the role of SORL1 in AD pathogenesis and should be further investigated in additional replication datasets and functional studies.

Proprotein Convertase Subtilisin/Kexin Type 9 (PCSK9) Missense Variant is Reproducibly Associated with Early-Onset Myocardial Infarction in 1500 Cases and 1500 Controls. *A. Surti on behalf of The Myocardial Infarction Genetics Consortium* The Broad Institute of Harvard and MIT, Cambridge, MA.

There are few, if any, replicable genetic associations for myocardial infarction (MI). We sought to replicate a set of single nucleotide polymorphisms (SNPs) reported to be associated with MI or related cardiovascular disease outcomes. We studied 27 SNPs at 20 loci (reported in the literature prior to December 2006) in the Myocardial Infarction Genetics Consortium (MIGen), consisting of 1544 cases of early-onset MI (men50y or women60y) and 1700 age- and gender-matched controls free of MI from five international sites: Spain, Finland, Sweden, Seattle, US, and Boston, US. Nearly all participants were of self-reported European ancestry. We studied SNPs in *ALOX5AP, CFH, ESR1, F5, F7, FGB, GATA2, KCNMB1, LGALS2, LTA, LTA4H, PCSK9, PLAT, PSMA6, PTGS2, SERPINE1, TNFSF4, USF1, VKORC1, and ZNF627*. Genotyping was performed using the Sequenom MassARRAY platform. Within each study site, Fishers exact test was used to study association of SNPs with MI status. To summarize the statistical evidence across study sites, we performed a Cochran-Mantel-Haenszel (CMH) test stratified by study site. Mean age of MI cases was 45y among women and 48y among men. Of 1544 cases, 578 (37%) were women. Given our sample size, we had 90% power to detect a 1.25-fold effect size per allele at an alpha of 0.003 (alpha=0.05/20 loci) and a risk allele frequency of 25%. Nonetheless, only a single SNP achieved a P0.003, that being a *PCSK9* missense variant (rs11591147, R46L) recently identified by Cohen et al. (*N Engl J Med* 2006). In meta-analysis, the minor T allele (2.35% freq. in controls) was associated with a 60% lower odds of MI (OR 0.40, 95% CI 0.26 - 0.61, P=1.0x10-5). This DNA sequence variant represents among the first to be reproducibly related to MI in multiple populations. Genome-wide association involving 900,000 SNPs (Affymetrix Genome-Wide SNP Array 6.0) is ongoing in the MIGen samples and may yield additional loci related to MI.

Prenatal identification of a novel R937P L1CAM missense mutation. *P.L. Wilson[1], H. Ferguson[2], B.L. Blaisdell[2], J. Wilkins[1], S. Li[3], J.J. Mulvihill[3], A. Maddalena[2], A.F. Wagner[1], J.R. Goodman[1]* 1) Obstetrics & Gynecology, Section of Maternal Fetal Medicine, University of Oklahoma Health Sciences Center, Oklahoma City, OK; 2) GeneDx, Inc, Gaithersburg, MD, USA; 3) Department of Pediatrics, Section of Genetics, University of Oklahoma Health Sciences Center, Oklahoma City, OK.

The L1 cell adhesion molecule (L1CAM) is a member of the immunoglobulin superfamily of neuronal cell adhesion molecules and plays a role in CNS development and maturation. It is active in neurite overgrowth, adhesion, fasciculation, migration, myelination, and axon guidance. Mutations in the gene have been associated with phenotypic changes including hydrocephalus, agenesis or hypoplasia of the corpus callosum and corticospinal tracts, mental retardation, spastic paraplegia, and adducted thumbs. A 19-year-old G1P0 Caucasian female was referred at 27-3/7 weeks. Ultrasound evaluation identified a male fetus with hydrocephalus, ventriculomegaly, aqueductal stenosis, and polyhydramnios. An amniocentesis identified a hemizygous mutation of G>C in exon 21 of the L1CAM gene. The patient was later tested and identified to be a carrier of the same mutation. This mutation results in the replacement of the normal Arginine codon (CFC) with a Proline codon (CCC) at position 937 of the resultant protein, R937P. Follow-up ultrasound at 32-1/7 weeks identified the additional findings of bilateral adducted thumbs and short femurs and a right clubbed foot. The fetus was delivered at 38-5/7 weeks with Apgars of 7 and 9, birthweight of 3.4 kg, length of 51.5 cm, and FOC of 43.5 cm. There was marked frontal bossing, contractures of the feet with rocker bottom appearance, and hyperactive reflexes with ankle and knee clonus. The CT showed hydranencephaly as opposed to hydrocephalus, with very abnormal brainstem, posterior fossa, and cerebral hemispheres. Family history identified a maternal half brother born in 1984 who died at the age of 4 years of hydrocephalus, mental retardation, and presumed aqueductal stenosis. Here we present the prenatal and neonatal evaluation of a male infant with a novel L1CAM missense mutation.

The Evaluation of Three Novel Small Molecule Classes Identified Through Quantitative High-Throughput Screening (qHTS) as Potential Chaperones for Gaucher Disease. *D.J. Urban[1], W. Zheng[2], O. Goker-Alpan[1], E. Goldin[1], J. Inglese[2], C. Austin[2], E. Sidransky[1]* 1) Medical Genetics Branch, National Human Genome Research Institute, NIH Bld 35 Rm1A100, 35 Convent Drive, Bethesda, MD 20892-3708 USA; 2) NIH Chemical Genomics Center, National Human Genome Research Institute, NIH 9800 Medical Center Drive, MSC 3370 Bethesda, MD 20892-3370 USA.

Gaucher disease is an autosomal recessive lysosomal storage disorder caused by mutations in the glucocerebrosidase gene. Most identified mutations are missense mutations, where the reduced enzyme activity may be due to misfolding. It has been proposed that chaperone therapy with small molecule inhibitors could be used to correct the defect. Quantitative high throughput screening (qHTS) was successfully used to rapidly identify three structural series of potent, selective, non-sugar glucocerebrosidase inhibitors. These included sulfonamides, quinolines and triazines. In order to characterize the mechanism of action for these compounds and to determine their selectivity profiles, we performed enzyme kinetic assays using four different lysosomal hydrolases. We found that the glucocerebrosidase inhibitors identified in our screening were highly selective for glucocerebrosidase and not the other related hydrolyses. Structure activity relationship data was used to select compounds with high activity, which were evaluated further using both enzyme and cell-based assays. Using fibroblast cell lines from patients homozygous for N370S, we found that compounds from two identified structural series increased the activity of mutant glucocerebrosidase by 40-90%. In addition, confocal microscopy using antibodies against glucocerebrosidase demonstrated enhanced lysosomal co-localization in the treated N370S lines, indicating chaperone activity. These novel small molecules have potential as leads for chaperone therapy for Gaucher disease, and this paradigm promises to accelerate the development of leads for other rare genetic disorders.

WILLIAMS SYNDROME PLUS : A 4 MB DELETION IDENTIFIED IN A PATIENT WITH WILLIAMS SYNDROME, CONGENITAL ANOMALIES AND SEVERE DEVELOPMENTAL DELAY. *T. Narumanchi[1, 2], X. Hu[1], C. Dvorak[1, 2], D. Mercer[1], H. Andersson[1, 2], M. Li[1]* 1) Hayward Genetics Center, Tulane University School of Medicine, New Orleans, LA; 2) Dept. of Pediatrics, Tulane University Medical School.

We present the case of a 15 year old female recently diagnosed as having a 4 MB deletion on chromosome 7, including the genes for Williams syndrome, using an oligionucleotide microarray. The patient first presented in October 1992, at age 6 months for failure to thrive and dysmorphic features. She was subsequently found to also have had an ASD, pulmonary stenosis, tracheomalacia, and gastroesophageal reflux disease (GERD). A clinical diagnosis of Williams syndrome was made prior to the discovery of the Williams critical region. However, the patient had additional congenital anomalies and more severe developmental delay than typical for Williams syndrome and FISH analysis in 1995 failed to detect a deletion of the Williams critical region, confounding the diagnosis. The patient was reevaluated in March, 2007 with comparative genomic hybridization - microarray which showed a 4 Megabase deletion, extending from the Williams critical region to the centromeric band 7q11.22. At least 34 genes were deleted in the patient including all genes commonly deleted in Williams patients. Haploinsufficiency of the genes centromeric to the Williams critical region is presumed to be responsible for the severe phenotype of this patient. This case serves to remind us that the sensitivity of FISH test is not 100%, and highlights the usefulness of microarray-CGH in copy number abnormalities. We recommend that patients with Williams syndrome patients with unusual congenital anomalies and/or atypical developmental delay should have microarray-CGH evaluation for Williams Syndrome PLUS.

Association of Long Polyglycine Tracts (GGN repeats) in Exon 1 of the Androgen Receptor Gene with Cryptorchidism and Penile Hypospadias in Iranian Patients. *R. Radpour[1], M. Rezaee[2], A. Tavasoly[3], S. Solaty[3]* 1) Department of Reproductive Genetics, Reproductive Biomedicine Research Center of Royan Institute, Tehran, Iran; 2) Department of Nanotechnology, Avesina Research Institute, Beheshti University, Tehran, Iran; 3) Department of Urology, Biomedical Research Center of Military University of Medical Sciences, Tehran, Iran.

Hypospadias, located urethral orifice along the ventral side of the penis, and cryptorchidism, failure of the testes to descend into the scrotal sacs, are the two most common congenital malformations in males affecting 0.3-0.7% and 2-4%, respectively, at birth. To study the association of CAG/GGN trinucleotide repeats in the androgen receptor gene with cryptorchidism and hypospadias in Iranian population we performed a case-control study of 76 cryptorchid and 92 hypospadiac (divided into subgroups of glanular, penile, and penoscrotal hypospadias) Iranian males. The length of the CAG/GGN repeat segment was evaluated by using PCR-sequencing in exon 1 and PCR-SSCP in exons 2-8. There were no significant differences in CAG lengths between the cases and controls but GGN numbers were found to be significantly higher (median 24 vs. 22) among both subjects with penile hypospadias ($P = 0.018$) and those with a history of cryptorchidism ($P = 0.001$), compared with controls. In addition, the GGN numbers among subjects with penile hypospadias were significantly different, compared with the two other subgroups of hypospadias ($P = 0.001$). We were able to identify 12 different CAG alleles and 8 different GGN alleles in the cryptorchid group. The mean GGN repeat length increased with the cryptorchidism and penile hypospadias. However, statistical analysis showed no significant differences between the cryptorchidism subgroups (bilateral or unilateral) ($P > 0.05$). The distribution of GGN allele frequencies was different between cryptorchid men and controls and there was an apparent trend toward a shift to GGN = 22 or GGN > 22 in males with cryptorchidism, but no significant difference was observed with hypospadiac group respect to controls.

Alobar holoprosencephaly presenting in a female fetus with a X;19 translocation. *A.F. Wagner[1], C. Lake[1], D. Hopcus-Niccum[2], R. Aldrich[2], E.G. Harp[3], E.D. Stolzenberg[3], G.P. Altshuler[3], P.L. Wilson[1], S. Li[2], E.J. Knudtson[1]* 1) Dept OB/GYN, MFM Section, Univ Oklahoma Health Sci Ctr, Oklahoma City, OK; 2) Dept Pediatrics, Genetics Section, Univ Oklahoma Health Sci Ctr, Oklahoma City, OK; 3) Dept Pathology, Univ Oklahoma Health Sci Ctr, Oklahoma City, OK.

Holoprosencephaly (HPE) is a malformation sequence in which the prosencephalon fails to cleave sagittally into cerebral hemispheres, transversely into telencephalon and diencephalon, and horizontally into olfactory and optic bulbs. Alobar HPE is the most severe form of cleavage failure of the prosencephalon before 6wks of gestation. It has been associated with many Mendelian conditions as well as maternal diabetes and salicylate use.

Here we present a 21yo G2P1 Caucasian/Native American female who presented at 19-3/7wks because of a positive Quad screen for trisomy 18(1:31). Ultrasound evaluation revealed alobar HPE and non-specific heart disease (left-axis shift and pericardial effusion). Amniocentesis revealed a karyotype of 46,X,der(X)t(X;19)(q10;p10). Parental karyotypes were normal. The pregnancy was otherwise uneventful.

The fetus was delivered via repeat C/S at 39-1/7wks with Apgars of $6^{1}2^{5}1^{10}$, weight of 2520g, length of 30.0 cm, and FOC of 36.0 cm. She died at 54 minutes.

On genetic exam and autopsy, there was a marked prominence of the frontal bones with a wide anterior fontanelle. The eyes showed upslanted PFs and hypertelorism. Ears were posteriorly rotated. The nasal bridge was large and pronounced with a short nose. There was retrognathia with an inverted-V cleft in the chin. Chest circumference and internipple distance were <-2SD. There was a left single palmar crease and bilateral digitalized thumbs. The heart was normal. Parathyroids were absent. There were 3 small lumbosacral dimples. Brain autopsy revealed severe hydrocephalus, flattened tissue with loss of the normal cerebral hemispheres and an exaggerated, midline ventricle with incomplete closure consistent with alobar HPE. Literature review has been unable to find HPE associated with partial trisomy 19.

Introduction. *K. A. Goddard* Epidemiology & Biostatistics, Case Western Reserve University, Cleveland, OH.

Session Descriptions:
Translating the wealth of information generated by the human genome project and related efforts to products that benefit the public's health is a primary goal of these labors, but significant challenges remain. Beyond the initial discovery of genotype-phenotype associations, substantial work is involved in successful integration into public health practice. Given the small contributions and numerous loci that may influence complex diseases, genomic profiling (i.e., genetic tests involving multiple markers) is a promising strategy for incorporating discoveries into population-based applications including population screening, predictive testing, and pharmacogenomic testing. A growing number of emerging tests are already available, including some offered directly to consumers (e.g., nutrigenomic profiling). We will discuss the need for well designed studies to evaluate such tests, as well as issues in formulating public policy on the use of genomic profiling. Finally, we will provide perspective on the potential importance of model projects to patients and consumers.

multiple genomic tests in a clinical setting. *G. E. Palomaki* Inst for Preventive Medicine, Gray, ME.

Introduction. *S. K. Shapira* Division of Birth Defects & Developmental Disabilities, Centers for Disease Control & Prevention, Atlanta, GA.

Session Descriptions:
Our understanding of the Autism Spectrum Disorders (ASDs) has become more complex. The case definition was expanded from “autism” to include Asperger’s syndrome and pervasive developmental disorder not otherwise specified, and numerous genetic and environmental risk factors add to the complexity. Family and twin studies indicate that ASDs have a strong genetic component; however, genetic studies have identified very few convincing candidate genes. Likewise, nonheritable risk factors have received attention; some might contribute to disease pathogenesis in those with increased genetic susceptibility to ASDs, but no consistently strong associations have been identified. This session will present current knowledge of the genetic and nonheritable risk factor associations. New ACMG and AAP guidelines for the clinical evaluation of patients with ASDs will be reviewed. The latest epidemiologic and behavioral genetic approaches for finding causes of ASDs will be presented, and future directions for research studies to investigate the causes will be considered.

Genetic Aspects of Autism Spectrum Disorders. *E. H. Cook* Department of Psychiatry, The University of Illinois at Chicago, Chicago, IL.

The case definition was expanded from “autism” to include Asperger’s syndrome and pervasive developmental disorder not otherwise specified, and numerous genetic and environmental risk factors add to the complexity. Family and twin studies indicate that ASDs have a strong genetic component; however, genetic studies have identified very few convincing candidate genes. Likewise, nonheritable risk factors have received attention; some might contribute to disease pathogenesis in those with increased genetic susceptibility to ASDs, but no consistently strong associations have been identified. This session will present current knowledge of the genetic and nonheritable risk factor associations. New ACMG and AAP guidelines for the clinical evaluation of patients with ASDs will be reviewed. The latest epidemiologic and behavioral genetic approaches for finding causes of ASDs will be presented, and future directions for research studies to investigate the causes will be considered.

Lessons Learned from Hurricane Katrina: Organizational Needs. *A. C. Sozer* Niezgoda and Associates, LLC, Alexandria, VA.

Session Descriptions:

In August 2005, Hurricane Katrina devastated an area of the United States equaling the size of Great Britain. Over 1300 individuals lost their lives, many because of the flooding which occurred when the New Orleans' levies broke. DNA played a major role in the identification of victims and was used exclusively in many cases where fingerprints and dental records were unavailable. The DNA identification effort was challenging because many items that could have been the source of identifying DNA, such as toothbrushes, clothing, and hairbrushes, were lost during the flooding. In addition, family members were evacuated and relocated multiple times following the storm. A total of 90 genetics professional volunteers from 20 states and Canada, representing 43 institutions/private practices, went to Baton Rouge to collect family data. We share the experiences of genetics professional volunteers and identify educational and policy needs that have implications for future mass fatality victim identification efforts.

Lessons Learned from Hurricane Katrina: Educational Needs. *S. M. Dolan* OB/GYN and Women's Health, Albert Einstien College Med, Bronx, NY.

Session Descriptions:

In August 2005, Hurricane Katrina devastated an area of the United States equaling the size of Great Britain. Over 1300 individuals lost their lives, many because of the flooding which occurred when the New Orleans' levies broke. Genomics and Sex in Weird Mammals. *J. A. Graves* Research School of Biological Sciences, The Australian National University, Canberra, Australia.

Session Descriptions:

In organisms with XX females and XY males, dosage compensation mechanisms have evolved to ensure a balanced expression between sex-linked and autosomal genes. In males, the single X chromosome is haplo-insufficient compared with autosomes where genes are expressed from two copies. To avoid deleterious effects the transcription level of X-linked genes must roughly double. X-specific up-regulation of transcription is known to occur specifically in male Drosophila, and has also been found in mammals and in C. elegans. To avoid hyper-expression in XX individuals, X inactivation takes place in mammals while both X chromosomes are repressed in C. elegans hermaphrodites. The evolution and the mechanisms of dosage compensation, including epigenetic modifications specifically targeted to the X chromosome will be discussed. Understanding the molecular mechanisms that balance gene expression has considerable practical importance, as abnormal expression due to constitutional chromosome imbalance or acquired abnormalities can cause birth defects, mental retardation and cancer.

Targeting the *C. elegans* dosage compensation complex to X chromosomes. *B. J. Meyer* Dept Molecular/Cell Biol, HHMI, Univ California, Berkeley, CA.

Session Descriptions:

In organisms with XX females and XY males, dosage compensation mechanisms have evolved to ensure a balanced expression between sex-linked and autosomal genes. In males, the single X chromosome is haplo-insufficient compared with autosomes where genes are expressed from two copies. To avoid deleterious effects the transcription level of X-linked genes must roughly double. X-specific up-regulation of transcription is known to occur specifically in male Drosophila, and has also been found in mammals and in C. elegans. To avoid hyper-expression in XX individuals, X inactivation takes place in mammals while both X chromosomes are repressed in C. elegans hermaphrodites. The evolution and the mechanisms of dosage compensation, including epigenetic modifications specifically targeted to the X chromosome will be discussed. Understanding the molecular mechanisms that balance gene expression has considerable practical importance, as abnormal expression due to constitutional chromosome imbalance or acquired abnormalities can cause birth defects, mental retardation and cancer.

Dosage Compensation in Mammals. *C. M. Disteche* Department of Pathology, University of Washington, Seattle, WA.

Session Descriptions:

In organisms with XX females and XY males, dosage compensation mechanisms have evolved to ensure a balanced expression between sex-linked and autosomal genes. In males, the single X chromosome is haplo-insufficient compared with autosomes where genes are expressed from two copies. To avoid deleterious effects the transcription level of X-linked genes must roughly double. X-specific up-regulation of transcription is known to occur specifically in male Drosophila, and has also been found in mammals and in C. elegans. Introduction. *S. Rasmussen* NCBDDD, CDC, Atlanta, GA.

Session Descriptions:
Submicroscopic chromosomal duplications and deletions have recently been recognized as a major source of variability within the human genome. The nature, distribution, and potential pathogenesis of these copy number variants are beginning to be uncovered. Array-CGH and other molecular methods have allowed the identification of novel microduplication and microdeletion syndromes associated with mental retardation and autism, and this technology is becoming an essential diagnostic tool for the clinical evaluation of persons with these conditions. Only a few studies of the role of copy number variants in predisposing to or protecting against complex diseases have been reported to date, but it is clearly evident that this type of genomic variation is of great medical importance. This session will provide an overview of our current understanding of the medical consequences and population genetics of genomic copy number variation.

Genomic basis of copy number variation. *J. R. Lupski* Molecular and Human Genetics, Baylor Medical Center, Houston, TX.

Session Descriptions:
Submicroscopic chromosomal duplications and deletions have recently been recognized as a major source of variability within the human genome. The nature, distribution, and potential pathogenesis of these copy number variants are beginning to be uncovered. Array-CGH and other molecular methods have allowed the identification of novel microduplication and microdeletion syndromes associated with mental retardation and autism, and this technology is becoming an essential diagnostic tool for the clinical evaluation of persons with these conditions. Only a few studies of the role of copy number variants in predisposing to or protecting against complex diseases have been reported to date, but it is clearly evident that this type of genomic variation is of great medical importance. This session will provide an overview of our current understanding of the medical consequences and population genetics of genomic copy number variation.

Novel microdeletion syndromes: mental retardation, autism and birth defects. *A. M. Slavotinek* Department of Pediatrics, University of California, San Francisoc, San Francisco, CA.

Session Descriptions:

Submicroscopic chromosomal duplications and deletions have recently been recognized as a major source of variability within the human genome. The nature, distribution, and potential pathogenesis of these copy number variants are beginning to be uncovered. Array-CGH and other molecular methods have allowed the identification of novel microduplication and microdeletion syndromes associated with mental retardation and autism, and this technology is becoming an essential diagnostic tool for the clinical evaluation of persons with these conditions. Introduction. *P. L. Beales* Molecular Medicine Unit, UCL Institute of Child Health, London, United Kingdom.

Session Descriptions:
The emergence of this novel class of disease, each associated with dysfunction of primary cilia presents new clinical and molecular challenges. The rapidly growing number of entities within this category involve quite different expression patterns which probably reflect a unique combination of underlying pathway involvement such as Hedgehog signalling or planar cell polarity for which cilia have recently been implicated. This session will explore the molecular genetic background, functional and developmental biology associated with ciliopathies like Oro-Facial-Digital Type 1 syndrome (OFD1), the Bardet-Biedl syndrome (BBS), Senior-Loken syndrome (SLS), Meckel-Gruber syndrome (MKS)and Jouberts syndrome (JS). There will be a particular emphasis on how research into these and other conditions are enriching our understanding of cilia function.

The genetic landscape of the ciliopathies. *N. Katsanis* McKusick Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD.

Session Descriptions:
The emergence of this novel class of disease, each associated with dysfunction of primary cilia presents new clinical and molecular challenges. microRNAs as oncogenes. *S. M. Hammond* Cell and Developmental Biology, University of North Carolina School of Medicine, Chapel Hill, NC.

Session Descriptions:
Small noncoding RNA guides, including microRNAs (miRNAs), small interfering RNAs (siRNAs), and repeat-associated small interfering RNAs, 21 to 30 nucleotides in length, could shape diverse cellular pathways, from chromosome architecture, development, and growth control, apoptosis to stem cell maintenance. In fact, it has been estimated that miRNAs could regulate as many as one-third of human genes. MiRNAs and the components of the RNAi pathway have been implicated in diverse human diseases. The main objective of this session is to review the most recent advances in this fast-moving field and to provide a thought-provoking forum from which the role of miRNAs and miRNA pathway in human diseases will be explored.

microRNAs in cancer and aging. *F. Slack* Department of Molecular, Cellular and Developmental Biology, Yale University, New Haven, CT.

Session Descriptions:
Small noncoding RNA guides, including microRNAs (miRNAs), small interfering RNAs (siRNAs), and repeat-associated small interfering RNAs, 21 to 30 nucleotides in length, could shape diverse cellular pathways, from chromosome architecture, development, and growth control, apoptosis to stem cell maintenance. In fact, it has been estimated that miRNAs could regulate as many as one-third of human genes. MiRNAs and the components of the RNAi pathway have been implicated in diverse human diseases. The main objective of this session is to review the most recent advances in this fast-moving field and to provide a thought-provoking forum from which the role of miRNAs and miRNA pathway in human diseases will be explored.

RNAi and L1 retrotransposition. *H. Kazazian* Department of Genetics, University of Pennsylvania, Philadelphia, PA.

Session Descriptions:
Small noncoding RNA guides, including microRNAs (miRNAs), small interfering RNAs (siRNAs), and repeat-associated small interfering RNAs, 21 to 30 nucleotides in length, could shape diverse cellular pathways, from chromosome architecture, development, and growth control, apoptosis to stem cell maintenance. In fact, it has been estimated that miRNAs could regulate as many as one-third of human genes. MiRNAs and the components of the RNAi pathway have been implicated in diverse human diseases. The main objective of this session is to review the most recent advances in this fast-moving field and to provide a thought-provoking forum from which the role of miRNAs and miRNA pathway in human diseases will be explored.

The microRNA pathway in mental retardations. *P. Jin* Dept Human Genetics, Emory Univ Sch Medicine.

Session Descriptions:
Small noncoding RNA guides, including microRNAs (miRNAs), small interfering RNAs (siRNAs), and repeat-associated small interfering RNAs, 21 to 30 nucleotides in length, could shape diverse cellular pathways, from chromosome architecture, development, and growth control, apoptosis to stem cell maintenance. In fact, it has been estimated that miRNAs could regulate as many as one-third of human genes. MiRNAs and the components of the RNAi pathway have been implicated in diverse human diseases. The main objective of this session is to review the most recent advances in this fast-moving field and to provide a thought-provoking forum from which the role of miRNAs and miRNA pathway in human diseases will be explored.

Variation and illegitimate microRNA target sites. *C. Charlier* Faculty of Veterinary Medicine, University of Liège, Liege, Belgium.

Session Descriptions:
Small noncoding RNA guides, including microRNAs (miRNAs), small interfering RNAs (siRNAs), and repeat-associated small interfering RNAs, 21 to 30 nucleotides in length, could shape diverse cellular pathways, from chromosome architecture, development, and growth control, apoptosis to stem cell maintenance. The main objective of this session is to review the most recent advances in this fast-moving field and to provide a thought-provoking forum from which the role of miRNAs and miRNA pathway in human diseases will be explored.

Introduction. *R. Wilson* Pediatric Surgery, The Children, Philadelphia, PA.

Session Descriptions:
For the last decade, research in the field of prenatal genetics has focused on the development and validation of non-invasive methods to identify pregnancies at increased risk of aneuploidy with the aim of reducing the number of pregnancies requiring an invasive procedure. New developments in array-based technologies brings the potential to identify both chromosomal and segmental aneuploidy and put in question the current approach to prenatal screening and diagnosis. Accordingly, this session will discuss new advances in maternal serum screening and emerging evidence of screening for aneuploidy using fetal nucleic acids in maternal plasma followed by a presentation on the use of array-based comparative genomic hybridization for prenatal diagnosis. The session will conclude with a discussion of proposed models which take into consideration cost-effectiveness and ethical considerations.

Maternal serum screening-old and new markers/ultrasound for aneuploidy and other genetic abnormalities. *J. A. Canick* Pathology and Laboratory Medicine, Woman and Infants Hospital, Providence, RI.

Session Descriptions:
For the last decade, research in the field of prenatal genetics has focused on the development and validation of non-invasive methods to identify pregnancies at increased risk of aneuploidy with the aim of reducing the number of pregnancies requiring an invasive procedure. New developments in array-based technologies brings the potential to identify both chromosomal and segmental aneuploidy and put in question the current approach to prenatal screening and diagnosis. Introduction. *A. M. Bowcock* Genetics, Washington University School of Medicine, Saint Louis, MO.

Session Descriptions:
In the next few years many genetic variants that predispose to complex traits will be identified. However, the mechanisms by which susceptibility alleles increase susceptibility at the cellular level, and how genetic interactions increase susceptibility, are currently unknown. One theory is that some variants are components of a “threshold” effect. Another theory is that variants at different loci affect different biochemical pathways that must be altered if they are to predispose to a complex disease. This session will focus on the successful results of some recent genome wide association scans, what the functional consequence of associated SNPs are, how these functional effects can be investigated in human cells and in animal models, and how epistatic effects can be analyzed both at the cellular level and in the context of genome-wide association scans. Diseases to be discussed will include age-related macular degeneration, Crohn disease, Bardet-Biedl syndrome and multiple sclerosis.

Macular degeneration: SNP associations and population differences. *J. Hoh* Epidemiology & Public Health, Yale University, New Haven, CT.

Session Descriptions:
In the next few years many genetic variants that predispose to complex traits will be identified. However, the mechanisms by which susceptibility alleles increase susceptibility at the cellular level, and how genetic interactions increase susceptibility, are currently unknown. One theory is that some variants are components of a “threshold” effect. Introduction. *B. L. Therrell* Dept of Pediatrics, University of Texas Health Science Center, Austin, TX.

Session Descriptions:
Expanded newborn screening results in challenges for all clinical geneticists, for families and for the public health system. This session will explore how increased understanding of the biochemical and molecular basis of disorders and their clinical outcomes can be applied to developing improved strategies for screening, diagnostic testing and clinical management. Using specific conditions as illustration, topics addressed will include 1) development of second tier screening to reduce false-positive rates, 2) impact of false positive screens and uncertainty, and strategies to minimize harm, 3) use of biochemical and molecular strategies after positive screen when differential diagnosis is complex, 4) public health implications of the unexpected finding of high frequency of a rare disease in an isolated population, and possibility that routine second screening is necessary to identify important conditions, and 5) the value of longitudinal studies of outcomes to determine the effect of newborn screening.

Impact of false positive screens on the family and the system. *C. L. Greene* (on behalf of the SIMD), University of Maryland, Baltimore, MD.

Session Descriptions:
Expanded newborn screening results in challenges for all clinical geneticists, for families and for the public health system. This session will explore how increased understanding of the biochemical and molecular basis of disorders and their clinical outcomes can be applied to developing improved strategies for screening, diagnostic testing and clinical management. Using specific conditions as illustration, topics addressed will include 1) development of second tier screening to reduce false-positive rates, 2) impact of false positive screens and uncertainty, and strategies to minimize harm, 3) use of biochemical and molecular strategies after positive screen when differential diagnosis is complex, 4) public health implications of the unexpected finding of high frequency of a rare disease in an isolated population, and possibility that routine second screening is necessary to identify important conditions, and 5) the value of longitudinal studies of outcomes to determine the effect of newborn screening.

The role of second-tier testing in reducing false-positive results in newborn screening. family and providers and strategies to minimize harm. *P. Rinaldo* Lab Medicine and Pathology, Mayo Clinci Col Medicine, Rochester, MN.

Session Descriptions:
Expanded newborn screening results in challenges for all clinical geneticists, for families and for the public health system. This session will explore how increased understanding of the biochemical and molecular basis of disorders and their clinical outcomes can be applied to developing improved strategies for screening, diagnostic testing and clinical management. Using specific conditions as illustration, topics addressed will include 1) development of second tier screening to reduce false-positive rates, 2) impact of false positive screens and uncertainty, and strategies to minimize harm, 3) use of biochemical and molecular strategies after positive screen when differential diagnosis is complex, 4) public health implications of the unexpected finding of high frequency of a rare disease in an isolated population, and possibility that routine second screening is necessary to identify important conditions, and 5) the value of longitudinal studies of outcomes to determine the effect of newborn screening.

Complexity of methylmalonic acidemia: Implications for newborn screening programs. *D. S. Rosenblatt* Div of Medical Genetics, MUHC Montreal Gen Hosp (McGill), Montreal, PQ, Canada.

Session Descriptions:
Expanded newborn screening results in challenges for all clinical geneticists, for families and for the public health system. This session will explore how increased understanding of the biochemical and molecular basis of disorders and their clinical outcomes can be applied to developing improved strategies for screening, diagnostic testing and clinical management. Using specific conditions as illustration, topics addressed will include 1) development of second tier screening to reduce false-positive rates, 2) impact of false positive screens and uncertainty, and strategies to minimize harm, 3) use of biochemical and molecular strategies after positive screen when differential diagnosis is complex, 4) public health implications of the unexpected finding of high frequency of a rare disease in an isolated population, and possibility that routine second screening is necessary to identify important conditions, and 5) the value of longitudinal studies of outcomes to determine the effect of newborn screening.

Ambiguities in the diagnosis and treatment of CPT1A deficiency in Alaska Native children. *D. M. Koeller*
Pediatrics, Oregon Health Sci Univ, Portland, OR.

Session Descriptions:
Expanded newborn screening results in challenges for all clinical geneticists, for families and for the public health system. This session will explore how increased understanding of the biochemical and molecular basis of disorders and their clinical outcomes can be applied to developing improved strategies for screening, diagnostic testing and clinical management. Using specific conditions as illustration, topics addressed will include 1) development of second tier screening to reduce false-positive rates, 2) impact of false positive screens and uncertainty, and strategies to minimize harm, 3) use of biochemical and molecular strategies after positive screen when differential diagnosis is complex, 4) public health implications of the unexpected finding of high frequency of a rare disease in an isolated population, and possibility that routine second screening is necessary to identify important conditions, and 5) the value of longitudinal studies of outcomes to determine the effect of newborn screening.

Collaborative investigations of urea cycle disorders: The importance of research networks in the study of rare diseases. *M. Tuchman* Children National Medical Center, Children's Research Institute, Washington, DC.

Session Descriptions:
Expanded newborn screening results in challenges for all clinical geneticists, for families and for the public health system. This session will explore how increased understanding of the biochemical and molecular basis of disorders and their clinical outcomes can be applied to developing improved strategies for screening, diagnostic testing and clinical management. Using specific conditions as illustration, topics addressed will include 1) development of second tier screening to reduce false-positive rates, 2) impact of false positive screens and uncertainty, and strategies to minimize harm, 3) use of biochemical and molecular strategies after positive screen when differential diagnosis is complex, 4) public health implications of the unexpected finding of high frequency of a rare disease in an isolated population, and possibility that routine second screening is necessary to identify important conditions, and 5) the value of longitudinal studies of outcomes to determine the effect of newborn screening.

Questions and answers.

Overview of Cohesin Biology. *G. Jennifer* Stowers Institute, Kansas City, MO.

Session Descriptions:
The cohesin proteins compose an evolutionarily conserved complex whose fundamental role in chromosomal cohesion and coordinated segregation of sister chromatids has been well characterized across species. Recently regulators and structural components of cohesin have surprisingly been found to cause specific human developmental disorders when mutated. Mutations in NIPBL, the vertebrate homolog of the yeast Sister chromatid cohesion 2 (Scc2) protein, a regulator of cohesin loading and unloading, are responsible for approximately 50% of cases of Cornelia de Lange syndrome (CdLS). Mutations in another cohesin regulator, ESCO2, have been found to result in Roberts syndrome (RBS) and SC phocomelia. Mutations in the cohesin structural components SMC1A and SMC3 were recently found to result in CdLS as well. This session will review the basic biology and function of the cohesin complex in chromosomal segregation and long-range enhancer promoter interactions and will review the human disorders caused by disruption of these processes.

A Drosophila Model of Cohesin Function. *D. Dorsett* Department of Biochemistry and Molecular Biology, St. Louis University School of Medicine, St Louis, MO.

Session Descriptions:
The cohesin proteins compose an evolutionarily conserved complex whose fundamental role in chromosomal cohesion and coordinated segregation of sister chromatids has been well characterized across species. Recently regulators and structural components of cohesin have surprisingly been found to cause specific human developmental disorders when mutated. Mutations in NIPBL, the vertebrate homolog of the yeast Sister chromatid cohesion 2 (Scc2) protein, a regulator of cohesin loading and unloading, are responsible for approximately 50% of cases of Cornelia de Lange syndrome (CdLS). Mutations in another cohesin regulator, ESCO2, have been found to result in Roberts syndrome (RBS) and SC phocomelia. Mutations in the cohesin structural components SMC1A and SMC3 were recently found to result in CdLS as well. This session will review the basic biology and function of the cohesin complex in chromosomal segregation and long-range enhancer promoter interactions and will review the human disorders caused by disruption of these processes.

Mouse Models of Cohesin Function. *A. Lander* Department of Developmentaland Cell Biology, University of California, Irvine, Irvine, CA.

Session Descriptions:
The cohesin proteins compose an evolutionarily conserved complex whose fundamental role in chromosomal cohesion and coordinated segregation of sister chromatids has been well characterized across species. Recently regulators and structural components of cohesin have surprisingly been found to cause specific human developmental disorders when mutated. Mutations in NIPBL, the vertebrate homolog of the yeast Sister chromatid cohesion 2 (Scc2) protein, a regulator of cohesin loading and unloading, are responsible for approximately 50% of cases of Cornelia de Lange syndrome (CdLS). Introduction. *J. D. Pollock* Genetics and Molecular Neurobiology Research Branch, NIDA, Rockville, MD.

Session Descriptions:
The speakers in this session will illustrate the synergistic power of human/animal comparative genetic approaches in the identification of genes involved in complex human diseases. In addition there will examples of how new bioinformatic resources can be exploited to more rapidly identify genes in animal models and accelerate human studies. Dr. Beverly Paigen will discuss the use of mouse-human comparative QTL analysis to identify genes involved in atherosclerosis. Dr. Elaine Ostrander will describe approaches to identify genes involved in cancer susceptibility using human genetics with help from underutilized canine genetic resources. Dr. Lisa Tarantino will describe her studies using mouse genetic, genomic, and bioinformatic resources to identify genes involved in anxiety. Dr. Abraham Palmer will describe his research using both mouse genetics and human association studies to identify genes involved in methamphetamine sensitivity.

Identifying Disease Genes with Mouse-Human Comparative Genetics. *B. Paigen* The Jackson Laboratory, Bar Harbor, ME.

Session Descriptions:
The speakers in this session will illustrate the synergistic power of human/animal comparative genetic approaches in the identification of genes involved in complex human diseases. In addition there will examples of how new bioinformatic resources can be exploited to more rapidly identify genes in animal models and accelerate human studies. Dr. Beverly Paigen will discuss the use of mouse-human comparative QTL analysis to identify genes involved in atherosclerosis. Dr. Elaine Ostrander will describe approaches to identify genes involved in cancer susceptibility using human genetics with help from underutilized canine genetic resources. Dr. Lisa Tarantino will describe her studies using mouse genetic, genomic, and bioinformatic resources to identify genes involved in anxiety. Dr. Abraham Palmer will describe his research using both mouse genetics and human association studies to identify genes involved in methamphetamine sensitivity.

Mapping Complex Traits of Concern for Humans in Dogs. *E. A. Ostrander* Cancer Genetics Branch, NHGRI/NIH, Bethesda, MD.

Session Descriptions:
The speakers in this session will illustrate the synergistic power of human/animal comparative genetic approaches in the identification of genes involved in complex human diseases. In addition there will examples of how new bioinformatic resources can be exploited to more rapidly identify genes in animal models and accelerate human studies. Dr. Beverly Paigen will discuss the use of mouse-human comparative QTL analysis to identify genes involved in atherosclerosis. Dr. Elaine Ostrander will describe approaches to identify genes involved in cancer susceptibility using human genetics with help from underutilized canine genetic resources. Dr. Lisa Tarantino will describe her studies using mouse genetic, genomic, and bioinformatic resources to identify genes involved in anxiety. Dr. Abraham Palmer will describe his research using both mouse genetics and human association studies to identify genes involved in methamphetamine sensitivity.

The Use of Haplotype-Associated Mapping to Identify Genes for Behavior. *L. Tarantino* Genomics Institute of Novartis Research Foundation, San Diego, CA.

Session Descriptions:
The speakers in this session will illustrate the synergistic power of human/animal comparative genetic approaches in the identification of genes involved in complex human diseases. In addition there will examples of how new bioinformatic resources can be exploited to more rapidly identify genes in animal models and accelerate human studies. Dr. Beverly Paigen will discuss the use of mouse-human comparative QTL analysis to identify genes involved in atherosclerosis. Dr. Elaine Ostrander will describe approaches to identify genes involved in cancer susceptibility using human genetics with help from underutilized canine genetic resources. Dr. Lisa Tarantino will describe her studies using mouse genetic, genomic, and bioinformatic resources to identify genes involved in anxiety. Dr. Abraham Palmer will describe his research using both mouse genetics and human association studies to identify genes involved in methamphetamine sensitivity.

Mouse QTL and Human Association Study of Methamphetamine Sensitivity. *A. Palmer* Human Genetics and Psychiatry, University of Chicago, Chicago, IL.

Session Descriptions:
The speakers in this session will illustrate the synergistic power of human/animal comparative genetic approaches in the identification of genes involved in complex human diseases. In addition there will examples of how new bioinformatic resources can be exploited to more rapidly identify genes in animal models and accelerate human studies. Dr. Abraham Palmer will describe his research using both mouse genetics and human association studies to identify genes involved in methamphetamine sensitivity.

Introduction. *J. M. Carethers* Division of Gastroenterology, University of California, San Diego, La Jolla, California.

Session Descriptions:
This session will be a state-of-the-art update that will focus on predisposition to malignancies other than colorectal cancer in hereditary colorectal polyposis syndromes. Invited speakers will include members from several disciplines involved in the management of these syndromes including cancer geneticists, medical oncologists, and genetic counselors. Syndromes to be discussed include familial adenomatous polyposis (FAP), hereditary non-polyposis colorectal cancer (HNPCC), PTEN Hamartoma-Tumor-Syndromes (PHTS), juvenile polyposis syndrome (JPS) and Peutz-Jeghers syndrome (PJS). Integrative molecular data will be interwoven throughout the session, serving as a platform for discussion of the promises, disappointments, and future directions of personalized healthcare including, but not limited to, targeted therapies. Advances and controversies in genetic testing, counseling, surveillance, and management will be highlighted.

Revisiting Lynch syndrome: Beyond colorectal cancer risk. *H. Lynch* Department of Preventive Medicine, Creighton University School of Medicine, Omaha, NE.

Session Descriptions:
This session will be a state-of-the-art update that will focus on predisposition to malignancies other than colorectal cancer in hereditary colorectal polyposis syndromes. Invited speakers will include members from several disciplines involved in the management of these syndromes including cancer geneticists, medical oncologists, and genetic counselors. Syndromes to be discussed include familial adenomatous polyposis (FAP), hereditary non-polyposis colorectal cancer (HNPCC), PTEN Hamartoma-Tumor-Syndromes (PHTS), juvenile polyposis syndrome (JPS) and Peutz-Jeghers syndrome (PJS). Integrative molecular data will be interwoven throughout the session, serving as a platform for discussion of the promises, disappointments, and future directions of personalized healthcare including, but not limited to, targeted therapies. Advances and controversies in genetic testing, counseling, surveillance, and management will be highlighted.

Prediction of extra-colonic cancer risk through the molecular classification of hamartomatous polyposis syndromes. *C. Eng* Genomic Medicine Institute, Cleveland Clinic Foundation, Cleveland, OH.

Session Descriptions:
This session will be a state-of-the-art update that will focus on predisposition to malignancies other than colorectal cancer in hereditary colorectal polyposis syndromes. Invited speakers will include members from several disciplines involved in the management of these syndromes including cancer geneticists, medical oncologists, and genetic counselors. Syndromes to be discussed include familial adenomatous polyposis (FAP), hereditary non-polyposis colorectal cancer (HNPCC), PTEN Hamartoma-Tumor-Syndromes (PHTS), juvenile polyposis syndrome (JPS) and Peutz-Jeghers syndrome (PJS). Integrative molecular data will be interwoven throughout the session, serving as a platform for discussion of the promises, disappointments, and future directions of personalized healthcare including, but not limited to, targeted therapies. Advances and controversies in genetic testing, counseling, surveillance, and management will be highlighted.

Peutz-Jeghers syndrome. *L. Aaltonen* Department of Medical Genetics, Biomedicum Helsinki, Helsinki, Finland.

Session Descriptions:
This session will be a state-of-the-art update that will focus on predisposition to malignancies other than colorectal cancer in hereditary colorectal polyposis syndromes. Invited speakers will include members from several disciplines involved in the management of these syndromes including cancer geneticists, medical oncologists, and genetic counselors. Syndromes to be discussed include familial adenomatous polyposis (FAP), hereditary non-polyposis colorectal cancer (HNPCC), PTEN Hamartoma-Tumor-Syndromes (PHTS), juvenile polyposis syndrome (JPS) and Peutz-Jeghers syndrome (PJS). Introduction. *V. M. Der Kaloustian* Pediatrics and Human Genetics, McGill University/Montreal Children, Montreal, Quebec, Canada.

Session Descriptions:
"Discovery" of gene pathways explains the mechanisms by which mutations in diverse genes lead to similar patterns of disease and by which diverse mutations in the same gene result in seemingly disparate disorders. Genodermatoses are a paradigm for this. Germline mutations in the RAS pathway lead to genodermatoses, some of which predispose to malignancy. Mutations in genes coding for connexins lead to non-syndromic deafness, but they also cause several ectodermal dysplasias. Allelic and locus heterogeneities underlie both seemingly different and apparently identical disorders. Alterations in p63 cause at least five EDs. Genotype-phenotype correlations give insight into the control of embryogenesis. Elucidation of the EDA/NEMO/TNFR connection has led to understanding the shared features of incontinentia pigmenti, hypohidrotic ED and immune dysfunction. Each speaker will give a 20 minute talk, presenting a holistic approach to each pathway, to tell the life story of these genes and their partners in crime.

The dermatologic phenotypes of genetic syndromes in the RAS/MAPK pathway. *K. A. Rauen* Pediatrics, UCSF, Cancer Research Institute, San Francisco, California.

Session Descriptions:
"Discovery" of gene pathways explains the mechanisms by which mutations in diverse genes lead to similar patterns of disease and by which diverse mutations in the same gene result in seemingly disparate disorders. Genodermatoses are a paradigm for this. Germline mutations in the RAS pathway lead to genodermatoses, some of which predispose to malignancy. Mutations in genes coding for connexins lead to non-syndromic deafness, but they also cause several ectodermal dysplasias. A Comparative Approach to Human Origins. *S. Paabo* Department of Genetics, Max Plank Institute for Evolutionary Anthropology, Leipzig, Germany.

Session Descriptions:
This session will focus on comparison of gene expression between humans and other primates, the identification of novel rapidly evolving human RNA genes important in brain development, and the quest for genes important in speech and language. The session will conclude with a description of the NIH-funded electronic atlas of the developing human brain, a unique repository for documenting and analyzing high resolution images of gene expression and associated anatomy of the brain during early human development.

Rapidly evolving non-coding regions and brain evolution. *D. Haussler* Centre for Biomolecular Science and Engineering, University of California, Santa Cruz, CA.

Session Descriptions:
This session will focus on comparison of gene expression between humans and other primates, the identification of novel rapidly evolving human RNA genes important in brain development, and the quest for genes important in speech and language. The session will conclude with a description of the NIH-funded electronic atlas of the developing human brain, a unique repository for documenting and analyzing high resolution images of gene expression and associated anatomy of the brain during early human development.

Genetics of developmental language disorders. *S. Fisher* The Wellcome Trust Centre for Human Genetics, Oxford University, Oxford, United Kingdom.

Session Descriptions:
This session will focus on comparison of gene expression between humans and other primates, the identification of novel rapidly evolving human RNA genes important in brain development, and the quest for genes important in speech and language. The session will conclude with a description of the NIH-funded electronic atlas of the developing human brain, a unique repository for documenting and analyzing high resolution images of gene expression and associated anatomy of the brain during early human development.

Expressing ourselves: genes and human brain development. *S. Lindsay* Institute of Human Genetics, Newcastle University, Newcastle upon Tyne, United Kingdom.

Session Descriptions:
This session will focus on comparison of gene expression between humans and other primates, the identification of novel rapidly evolving human RNA genes important in brain development, and the quest for genes important in speech and language. The session will conclude with a description of the NIH-funded electronic atlas of the developing human brain, a unique repository for documenting and analyzing high resolution images of gene expression and associated anatomy of the brain during early human development.

Introduction. *K. L. Lunetta* Biostatistics, Boston University School of Public Health, Boston, MA.

Session Descriptions:
Now that genome-wide association studies have become a reality, what role will linkage analysis and family data play in the identification genes influencing complex traits in humans? Highly efficient genome-wide association technologies, combined with the HapMap and other web resources, fuel the hope that we will soon identify many genes and genetic variants contributing to common diseases and phenotypes. But will genome-wide association be more successful than genome-wide linkage, which garnered the same hopes twenty years ago with the advent of genome-wide microsatellite markers? This session will first provide an historical overview of the field and how we reached the cusp of the genome-wide association revolution. Next, speakers will present up-to-the-minute views of the utility of linkage, association, and combined approaches in the context of current high-density genome-wide SNP data in the Hutterites and the NHLBI Family Heart and Framingham Heart Studies.

Finding genes underlying human disease: past and future. *R. C. Elston* Epidemiology & Biostatistics, Case Western Reserve Univ, Cleveland, OH.

Session Descriptions:

Highly efficient genome-wide association technologies, combined with the HapMap and other web resources, fuel the hope that we will soon identify many genes and genetic variants contributing to common diseases and phenotypes. But will genome-wide association be more successful than genome-wide linkage, which garnered the same hopes twenty years ago with the advent of genome-wide microsatellite markers? This session will first provide an historical overview of the field and how we reached the cusp of the genome-wide association revolution. Next, speakers will present up-to-the-minute views of the utility of linkage, association, and combined approaches in the context of current high-density genome-wide SNP data in the Hutterites and the NHLBI Family Heart and Framingham Heart Studies.

High density SNP scans in population cohort studies with family data: the value of linkage analysis. *J. Dupuis*
Biostatistics, Boston Univeresity School of Public Health, Boston, MA.

Session Descriptions:
Now that genome-wide association studies have become a reality, what role will linkage analysis and family data play in the identification genes influencing complex traits in humans? Highly efficient genome-wide association technologies, combined with the HapMap and other web resources, fuel the hope that we will soon identify many genes and genetic variants contributing to common diseases and phenotypes. But will genome-wide association be more successful than genome-wide linkage, which garnered the same hopes twenty years ago with the advent of genome-wide microsatellite markers? This session will first provide an historical overview of the field and how we reached the cusp of the genome-wide association revolution. Next, speakers will present up-to-the-minute views of the utility of linkage, association, and combined approaches in the context of current high-density genome-wide SNP data in the Hutterites and the NHLBI Family Heart and Framingham Heart Studies.

"Linkage is dead. Long live linkage"--Using linkage evidence to inform genome-wide association scans. *M. A. Province* Division of Statistical Genomics, Center for Genome Science, Washington University School of Medicine, St. Louis, MO.

Introduction. *W. Dobyns* Dept. of Human Genetics, University of Chicago, Chicago, Illinois.

Session Descriptions:
Malformations of cortical development (MCD) present clinically with developmental disability and mental retardation, epilepsy,and behavioural disorders. MCD were previously believed to result from complex or multifactorial inheritance, and to be related to various extrinsic environmental factors during development. In the past decade, a number of single gene disorders particularly involving stem cell profileration, brain patterning, and neuronal migration have been identified, and the genes have been mapped or cloned. These include lissencephaly('smooth brain'), subcortical band heterotopia or double cortex syndrome, periventricular nodular heterotopia and schizencephaly. This session will describe the clinical and radiological features and the genes and loci involved in the various forms of MCD as well as in Joubert syndrome and related cerebellar malformations. Studies of the inter-relationship of the various genes involved in developmental pathways related to neuronal migration will also be discussed.

Genes that influence the size and shape of the cerebral cortex. *C. Walsh* Division of Genetics, Boston Children, Boston, Massachusetts.

Session Descriptions:
Malformations of cortical development (MCD) present clinically with developmental disability and mental retardation, epilepsy,and behavioural disorders. MCD were previously believed to result from complex or multifactorial inheritance, and to be related to various extrinsic environmental factors during development. Overview of GAIN. *T. A. Manolio* Office of Population Genomics, National Human Genome Research Institute, Bethesda, MD.

Session Descriptions:
An overview of genome-wide association (GWA) studies and major initial findings from three genome-wide association resources (the Framingham SHARe Project, the Genetic Association Information Network, and the Wellcome Trust Case Control Consortium) will be presented to permit assessment of the added value of open data sharing and of conducting such programs in a collaborative mode. Early experience with open access for these databases, data-sharing and IP policies will be described, including challenges encountered and lessons learned. “Snapshots” of issues unique to collaborative GWA studies will be presented, including comparing genotyping quality and combining data across genotyping platforms, using common controls, and harmonizing datasets for cross-study use. An example of the strengths and weaknesses of combined analysis of common phenotypes (such as body mass index) across multiple studies will be provided, and the question of shared risk alleles for the four major mental illness phenotypes included in GAIN will be considered.

Framingham SNP Health Association Resource (SHARe). *E. G. Nabel* Office of the Director, National Heart, Lung, and Blood Institute, Bethesda, MD.

Session Descriptions:
An overview of genome-wide association (GWA) studies and major initial findings from three genome-wide association resources (the Framingham SHARe Project, the Genetic Association Information Network, and the Wellcome Trust Case Control Consortium) will be presented to permit assessment of the added value of open data sharing and of conducting such programs in a collaborative mode. Introduction. *A. M. Hott* Biology, Southern Connecticut State University, New Haven, Connecticut.

Session Descriptions:
Having both genetics content knowledge and the ability to utilize that knowledge in personal and civic situations is important for scientists and nonscientists alike. We, as geneticists, are in a unique position to provide the public, our trainees and our colleagues with the information and tools to achieve this genetic literacy. While each target audience requires distinct educational and training interventions, each must have the expertise of practicing geneticists to achieve success. This educational session will highlight ongoing geneticist-led educational programs for the general public, graduate students, genetic counselors and clinicians, and offer ideas and concepts attendees can incorporate in their local settings.

Global momentum in genetic counselor education. *J. R. Edwards* Department of Obstetrics and Gynecology, University of South Carolina, Columbia, South Carolina.

Session Descriptions:
Having both genetics content knowledge and the ability to utilize that knowledge in personal and civic situations is important for scientists and nonscientists alike. We, as geneticists, are in a unique position to provide the public, our trainees and our colleagues with the information and tools to achieve this genetic literacy. While each target audience requires distinct educational and training interventions, each must have the expertise of practicing geneticists to achieve success. This educational session will highlight ongoing geneticist-led educational programs for the general public, graduate students, genetic counselors and clinicians, and offer ideas and concepts attendees can incorporate in their local settings.

Beyond Basic Science: Expanding Graduate Training through the Med-Into-Grad Initiative. *A. Wynshaw-Boris*
University of California, San Diego, La Jolla, California.

Session Descriptions:
Having both genetics content knowledge and the ability to utilize that knowledge in personal and civic situations is important for scientists and nonscientists alike. We, as geneticists, are in a unique position to provide the public, our trainees and our colleagues with the information and tools to achieve this genetic literacy. Proteomics: Why should geneticists care? *S. E. Old* Division of Cardiovascular Diseases, National Heart, Lung, and Blood Institute, Bethesda, MD.

Session Descriptions:
The session will describe methodologies and approaches in proteomics, and illustrate how they can be used to complement, advance, and facilitate genetic studies. Presentations will focus on the recent technology developments by the National Proteomics Centers supported by the National Heart Lung, and Blood Institute of the National Institutes of Health. The presentations will review the tools and approaches available to biomedical researchers. They will emphasize separation technologies used to sub-fractionate complex proteomic samples, methodologies to identify and quantify complex proteomes, and the analytical and computational tools available to facilitate such studies. Presentations will contrast how these approaches can and should not be used. The usefulness and application of all approaches and technologies will be illustrated using data from ongoing biological studies at the National Proteomics Centers, with a special emphasis on studies using genetic model systems and disease studies.

Proteome separation and fractionation of biological samples. *J. Van Eyk* Dept. of Medicine, Division of Cardiology, Johns Hopkins University, Baltimore, MD.

Session Descriptions:
The session will describe methodologies and approaches in proteomics, and illustrate how they can be used to complement, advance, and facilitate genetic studies. Presentations will focus on the recent technology developments by the National Proteomics Centers supported by the National Heart Lung, and Blood Institute of the National Institutes of Health. Introduction. *E. L. Harris* Population Genomics, National Human Genome Research Institute, Bethesda, MD.

Session Descriptions:
Study design is a critical aspect of any research project. The study's purpose drives study design, influenced by practical issues. Genetic/genomic research increasingly uses population-based designs, such as case-control genome-wide association studies, to study genetic susceptibility to common conditions and genetic influences on quantitative traits. Epidemiologic studies of such conditions now commonly include DNA collection, and genetic information as part of the analyses. To effectively design and interpret such studies, knowledge of basic study design is critical as is an understanding of complications that genetic data introduce into such studies. Crucial design decisions include case or outcome definition, control or comparison group definition, measurement methods, and statistical analysis approach. Internal validity is imperative, and methods for assessing potential biases desirable. In this session, we will discuss: basic study design choices and rationale; designs to maximize internal validity and external validity; gene-environment interaction; and how to look for and minimize bias.

Case-control and cohort study designs. *M. Szklo* Department of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD.

Session Descriptions:
Study design is a critical aspect of any research project. The study's purpose drives study design, influenced by practical issues. Genetic/genomic research increasingly uses population-based designs, such as case-control genome-wide association studies, to study genetic susceptibility to common conditions and genetic influences on quantitative traits. Epidemiologic studies of such conditions now commonly include DNA collection, and genetic information as part of the analyses. Introduction. *A. B. Begovich* Discovery Research, Celera, Alameda, CA.

Session Descriptions:
Major histocompatibility complex (MHC) class I molecules are ligands for the killer-cell immunoglobulin-like receptors (KIRs), which are expressed by natural killer (NK) and T cells. The interactions between these molecules contribute to both innate and adaptive immunity. KIRs and MHC class I molecules are encoded by unlinked highly polymorphic gene families characterized by interesting patterns of strong linkage disequilibrium. Specific combinations of MHC class I and KIR variants influence resistance to infections, susceptibility to autoimmune diseases and complications of pregnancy suggesting that the interplay between KIR and MHC class I polymorphism may have facilitated human survival in the presence of epidemic infections as well as reproductive fitness. This session, designed for all members of the society, will provide a comprehensive overview of the structure of the MHC and KIR gene families, their co-evolution and their individual and joint roles in infectious and autoimmune diseases.

Polymorphism and Functions of MHC Genes. *J. Trowsdale* Department of Pathology, University of Cambridge, Cambridge, United Kingdom.

Session Descriptions:

Major histocompatibility complex (MHC) class I molecules are ligands for the killer-cell immunoglobulin-like receptors (KIRs), which are expressed by natural killer (NK) and T cells. The interactions between these molecules contribute to both innate and adaptive immunity. KIRs and MHC class I molecules are encoded by unlinked highly polymorphic gene families characterized by interesting patterns of strong linkage disequilibrium. Introduction. *G. Wiesner* Dept of Genetics and the Center for Human Genetics, Case Western Reserve University, Cleveland, OH.

Session Descriptions:
For the promise of individualized genomic medicine to be fulfilled, large-scale, longitudinal studies linking human DNA with detailed phenotypic data are needed. Rapid technical change allows biorepositories to include ever more finely-detailed genetic information about human subjects. Current policies dictate that databases be widely shared among researchers, raising unique ethical and policy concerns about the adequacy of existing privacy protections. Controversy surrounding data-sharing policies centers on whether DNA can be de-identified, as it is the "ultimate identifier." We will discuss ways in which information stored in genomic databases can be linked with other electronic databases and the resultant social and ethical concerns, especially for research on sensitive topics such as addiction. The impact of new and future technological developments on privacy will be discussed. Attempts to address these concerns from a bioinformatics perspective will be explored. Finally, challenges for federal policy will be critically examined.

Federal Policy Challenges in the Era of Identifiable Genetic Information. *A. L. McGuire* Center for Medical Ethics and Health Policy, Baylor College of Medicine, Houston, TX.

Session Descriptions:
For the promise of individualized genomic medicine to be fulfilled, large-scale, longitudinal studies linking human DNA with detailed phenotypic data are needed. Rapid technical change allows biorepositories to include ever more finely-detailed genetic information about human subjects. Current policies dictate that databases be widely shared among researchers, raising unique ethical and policy concerns about the adequacy of existing privacy protections. Controversy surrounding data-sharing policies centers on whether DNA can be de-identified, as it is the "ultimate identifier." We will discuss ways in which information stored in genomic databases can be linked with other electronic databases and the resultant social and ethical concerns, especially for research on sensitive topics such as addiction. The impact of new and future technological developments on privacy will be discussed. Attempts to address these concerns from a bioinformatics perspective will be explored. Finally, challenges for federal policy will be critically examined.

Research Regulators' Concerns with Access to and Use of Open-Source Genetic Research Data. *L. G. Dressler*
Dept of Bioethics, Case Western Reserve University, Cleveland, OH.

Session Descriptions:
For the promise of individualized genomic medicine to be fulfilled, large-scale, longitudinal studies linking human DNA with detailed phenotypic data are needed. Rapid technical change allows biorepositories to include ever more finely-detailed genetic information about human subjects. Current policies dictate that databases be widely shared among researchers, raising unique ethical and policy concerns about the adequacy of existing privacy protections. Controversy surrounding data-sharing policies centers on whether DNA can be de-identified, as it is the "ultimate identifier." Introduction. *B. Rink* Division of Molecular and Human Genetics, Division of Maternal Fetal Medicine, 700 Children, Columbua, OH.

Session Descriptions:
Assisted reproductive technology (ART) provides options for families with a wide range of genetic diagnosis to significantly reduce recurrence risk. As advances in science and technology increase what we are able to offer through ART, a vigorous dialogue concerning what we should offer through ART needs to be engaged. A discussion of what ART can and should be used for requires transparency. An overview of preimplantation genetic diagnosis (PGD) for common heritable disorders will introduce the session. The practice of "family balancing" (gender selection) will be explored as it affects practice in the United States and social policy in Asia. Issues surrounding the extension of PGD and ART to cancer genetic syndromes will be discussed. Finally, the public perception of ART will be discussed in the context of the different access and regulatory environments within the United States, Canada, and the European Union.

Should males dominate ART? *E. Vayena* Special Programme of Research Development and Research Train, World Health Organization, Ch-1211, Switzerland.

Session Descriptions:
Assisted reproductive technology (ART) provides options for families with a wide range of genetic diagnosis to significantly reduce recurrence risk. G. Herman

Session Descriptions:
Did you ever wonder what really happens in study section review meetings and how applications are discussed? In this workshop, attendees will have the opportunity to observe past and present NIH study section members, along with NIH scientific administrators, enact "mock discussions" to replicate the typical dynamics of discussions at study section review meetings. We will also discuss how streamlining decisions are made, how conflicts of interest are handled, and the role of study section scores in funding decisions. In watching the mock discussion, you will see examples of some of the common mistakes applicants make and suggestions about how to avoid those pitfalls. .

G. Barsh

A Physician's Guide to Race and Population Structure. *M. Bamshad* University of Washington, Seattle WA.

Session Descriptions:
Genetics, evolution and medicine share a long and distinguished tradition. While evolution and genetics are inextricably linked, evolution and medicine have remained largely separate. Novel insights from comparative genomics, genome-wide evolutionary processes, and population biology are pointing toward the ubiquitous role of evolution in understanding drug resistance, pathogen virulence, phenotypic integration, human reproduction and development, longevity, and health. By illuminating the development of certain human diseases, these advances help us to treat individual patients as products of evolutionary history.

The four talks in this symposium address the role of evolution in medicine from the perspectives of population biology, ethnic variation, and individualized medicine, as well as society and law. .

Genetics, evolution and medicine. *J. Evans* University of North Carolina at Chapel Hill.

Presidential Address: Who Is Under the Umbrella - and Why Are We Here? *W. Burke* University of Washington, Seattle.

Session Descriptions:
Wylie Burke
ASHG President
University of Washington School of Medicine, Seattle

At the core of The American Society of Human Genetics is the idea that a better understanding of human genetics will benefit us all. The majority of our members pursue research intended to expand our understanding of human biology and disease. We value the intellectual challenges of our work, but we also hope to use new genetic knowledge to improve people's lives. In the wake of the Human Genome Project, there is much reason to be optimistic about this goal, and our annual meeting has become an opportunity to celebrate the extraordinary progress of in our field.

Accompanying the progress are growth and challenges. Our Society has expanded remarkably over the past decade, with a growing diversity in member interests and disciplinary backgrounds. The primary affiliation of our members ranges from medical schools and research universities to commercial companies, foundations, community-based healthcare facilities, and local, state and federal governments. About 7% of our members list ethics, social, legal, and policy issues as their primary interest area, 4% list public health genetics, and 2% list DNA forensics. These statistics point to the growing societal importance of human genetics. Another indicator is our Society's support of policy initiatives, including policy statements on topics such as direct-to-consumer testing, support of legislation banning genetic discrimination, and joint efforts with NHGRI and CDC to create policy-oriented fellowships. These activities help to ensure that policies affecting human genetics are informed by accurate scientific knowledge. They also require us to expand our ability to communicate across barriers of discipline and perspective.

Moving forward, we need to be sure our umbrella is big enough to make room for everyone who shares our vision. For the past two years, our Society has extended a special welcome to advocates for families living with genetic disease. Our educational programs have sought to reach out to students from diverse backgrounds, and to provide assistance to teachers working in poorly resourced classrooms.

Are we doing enough? Research will remain the core of our Society, but assuring the best from our research requires more than scientific discipline. We need to find and encourage talented students, develop meaningful ways to work in partnership with research participants, and expand the scope of our research to assure effective and safe translation of genetic knowledge into societal benefit. These challenges represent the next wave of opportunity for our Society. .

Introductory remarks. *F. R. Bieber* Brigham and Women's Hospital, Boston, MA.

Session Descriptions:
DNA-based methods of identification are altering how we address questions in many settings, from legal proceedings to medicine to basic and social sciences. Genetic information may offer unique opportunities to achieve justice and, conversely, may pose unprecedented challenges to personal privacy. It is only one of many sources of personal identity, and may either complement or conflict with other ways of defining who we are. This symposium will consider the implications of genomically-based identity for individuals, families, and society. .

Innocence Projects and DNA. *Justin Brooks* California Western School of Law, San Diego, CA.

Pompe Disease: The past, the present and future experience from bench to bedside. *P. S. Kishnani* Duke University Medical Center, Durham, NC.

Session Descriptions:
Exciting new discoveries in human genetics are occurring at a rapid pace. This pace will only accelerate as new genomic technologies bring new knowledge to bear on the study of human genetics. The next challenges include drawing connections between research findings and wider application to clinical studies. The three presentations in the Distinguished Speakers' Symposium provide exciting examples of research bridging discovery, translation and clinical implementation. Our talks range from experience with ground-breaking treatment for Pompe Disease to discoveries in epigenetics to bringing genetic discoveries in common complex disease to clinical trials. .

The epigenetics of human disease. *A. P. Feinberg* The Johns Hopkins University School of Medicine, Baltimore, MD.

Session Descriptions:
Exciting new discoveries in human genetics are occurring at a rapid pace. This pace will only accelerate as new genomic technologies bring new knowledge to bear on the study of human genetics. Trainee program opening remarks. *J. Lawrence Merritt II* Children's Hospital and Regional Medical Center, University of Washington School of Medicine; and chair, ASHG Ad hoc Professional Development Committee.

Session Descriptions:
This program is a special session for graduate students and post-doctoral fellows organized by the ASHG Ad Hoc Professional Development Committee. ASHG trainees interested in an event designed to broaden their knowledge of rewarding careers ranging from laboratory research to patent law should attend.

A keynote address will provide insight into the process of negotiations when you are considering a new position, no matter what field you are pursuing. Members of the biotechnology, patent law, clinical diagnostic, academic research, science policy and journalism communities will describe what it takes for PhD recipients to be successful in different scientific careers. Finally, a networking session will be open to all participants to discuss these careers and others in more detail over cocktails and dessert. The event is limited to 250 attendees.

8:00 PM–9:00 PM

Opening Remarks: J. Lawrence Merritt II, MD, Children's Hospital and Regional Medical Center, University of Washington School of Medicine; and Chair, ASHG Ad Hoc Professional Development Committee.

Keynote Address: Negotiation Skills for Scientists. Joann Boughman, Executive Vice President, The American Society of Human Genetics, Bethesda, MD.

Career Panel: A group of five PhDs who have pursued a variety of different career paths, including academia, biotechnology, clinical diagnostics, public health and law, will introduce their careers and the paths they took to get there.

M. Richard Shen, Senior Director of Array Biochemistry, Illumina, San Diego, CA - Biotechnology

John Moran, Associate Professor, University of Michigan Medical School, Ann Arbor - Academic Research

David Ledbetter, Professor, Emory University School of Medicine, Atlanta, GA - Clinical Diagnostics

Muin Khoury, Director, National Office of Public Health Genomics, Centers for Disease Control and Prevention, Atlanta, GA - Public Health

Frederick Bieber, Professor, Brigham & Women's Hospital, Boston, MA - Forensics Research

9:00 PM–10:00 PM

Networking reception on the Plaza Terrace with representatives from industry, academia, law, forensics, education, scientific societies, public health, science policy, science writing, genetic counseling and other fields. Bring your business card! .

Rare Patients Leading to Epigenetics and Back to Genetics. *A. Beaudet* Baylor College of Medicine, Houston, TX.

Session Descriptions:
This award, which includes $10,000 and an engraved medal, is presented for substantial scientific contributions to human and medical genetics carried out over a lifetime of scientific inquiry.

Introduced by:
James Lupski, Professor
Departments of Molecular and Human Genetics, and Pediatrics
Baylor College of Medicine, Houston, TX

Recipient:
Arthur Beaudet, Professor and Chairman
Departments of Molecular and Human Genetics, and Pediatrics
Baylor College of Medicine, Houston, TX

Rare Patients Leading to Epigenetics and Back to Genetics
In the 1980's, positional cloning was the rage. By the end of 1985, the MET proto-oncogene was reported to be tightly linked to the CF locus placing it "in the middle third of the long arm of chromosome 7, probably between bands q21 and q31." Shortly thereafter, I went to a North American Cystic Fibrosis Conference and asked clinicians if they knew of any CF patients with associated abnormalities such as mental retardation or dysmorphic features. This led to a then teenage girl with cystic fibrosis and short stature who ultimately proved to have maternal uniparental isodisomy for chromosome 7. This first rare patient engendered an enduring interest in genomic imprinting and epigenetics. Our interest soon focused on Prader-Willi syndrome (PWS) and Angelman syndrome (AS) with some satisfying discoveries but two striking missed opportunities.

Our next direction came from rare families reported by others to have interstitial duplications of the PWS/AS region of chromosome 15q11-q13 that caused autism when on the maternal chromosome but not when on the paternal chromosome. When I first became aware of these reports and combined this with our knowledge of the PWS/AS domain, I thought that these families might be the key to understanding autism. Our experience with the PWS/AS domain has led us to develop a mixed epigenetic/genetic and mixed de novo/inherited (MEGDI) model for autism. Enter next array-based copy number analysis (ABCNA) and reports by multiple groups that de novo genomic mutations play a major role in the etiology of complex autism and maybe of essential autism as well. However, these discoveries leave us with an essential autism group that is overwhelmingly male, nondysmorphic, and often not mentally retarded. I still believe that the rare families with interstitial duplications of 15q11-q13 may hold the key to a definitive understanding of essential autism.

A final most recent rare patient was discovered using array-based copy number analysis. A patient meeting criteria for PWS had normal DNA methylation and FISH studies, but copy number analysis revealed a small deletion involving two snoRNA clusters downstream of SNURF-SNRPN. There has been growing evidence that paternal deficiency for the HBII-85 snoRNA cluster might be the molecular basis for the PWS phenotype. We believe that this patient greatly strengthens that conclusion. This interpretation would represent the first well-documented example of a human phenotype caused by deficiency of a snoRNA, a subclass of regulatory noncoding RNAs.

These patients have been key players in a most enjoyable career that includes the privilege of carrying out investigations in human genetics and epigenetics. Perhaps another such patient awaits you or me when we return to our clinics and labs after this meeting. .

Two Ghosts of the Genome. *M. Olson* Brigham and Women's Hospital, Boston, MA.

Session Descriptions:
Rosalind Franklin Young Investigator Award

A $75,000 award will be presented to Molly Przeworski, University of Chicago. This award, given for the first time three years ago, is for a young woman geneticist who is in her first three years of an independent faculty position in any area of genetics. The award honors the groundbreaking contributions of Dr. Rosalind Franklin, and is designed to inspire and support a new generation of women in the field of genetics.

Gruber Genetics Prize

Maynard V. Olson, University of Washington, Seattle

A gold medal and a $500,000 prize will be presented to Maynard V. Olson, professor of Genome Sciences and Medicine at the University of Washington. The prize honors leading scientists for distinguished contributions in any realm of genetics research.

Maynard V. Olson is a founder of the field of genomics.

Olson created tools critical to each step of human genome sequencing as it developed from dream to reality. Then, through his articulate advocacy of high standards for accuracy and of free public access to data, he worked to ensure that DNA information is used to benefit humanity. He used DNA sequence polymorphisms to connect functional genes with their physical locations. He made the first physical map of an entire eukaryotic genome, that of budding yeast. He invented the first practical system for cloning large segments of genomes and measuring their size. He introduced the now-universal common language for ordering and comparing genomic segments based on short stretches of unique sequence.

These techniques brought to fruition the convergence of genetic and physical mapping of the human and other genomes and laid the intellectual and practical groundwork for genomics.

Dr. Olson will give the 2007 Gruber lecture:

Two Ghosts of the Genome

Genomics now has enough of a history to allow some inferences about how the field advances.

From the perspective of my own experiences over the past 30 years, I will trace the development of genomics, and its interactions with genetics, from its roots in the development of recombinant-DNA techniques in the 1970s to the successful completion of the Human Genome Project in 2004.

Based on the field's past dynamics, I will then speculate on its future course with an emphasis on the scientific opportunities that new developments in genomics are creating in human genetics.

Past Laureates of the Gruber Genetics Prize:
2006: Elizabeth H. Blackburn, for her studies of telomeres and telomerase, and her science advocacy
2005: Robert H. Waterston, for his pivotal role in the Human Genome Project
2004: Mary-Claire King, for three major findings in modern genetics: the similarity of the human and chimpanzee genomes; finding a gene that predisposes to breast cancer; and forensic genetics
2003: David Botstein, for establishing the ground rules for human genetic mapping
2002: H. Robert Horvitz, for defining genetic pathways responsible for programmed cell death
2001: Rudolf Jaenisch, for advancing the study of human disease by creating the first transgenic mouse

Maynard Olson was chosen to win the 2007 Prize by a distinguished advisory panel that included:
Elizabeth H. Blackburn
David Botstein
Uta Francke
H. Robert Horvitz
Mary-Claire King
Leena Peltonen-Palotie
Robert H. Waterston

Nominations for the 2008 prizes are now open and close on December 31, 2007. For further information about the Gruber Foundation's prizes, please visit http://www.gruberprizes.org .

Curt Stern Award Presentation. *J. Murray* Institute for Genome Sciences and Policy, Duke University, Durham, NC.

Session Descriptions:
The Curt Stern Award is given annually to a scientist or scientists for major scientific achievement in human genetics that has occurred in the last 10 years. The work could be a single discovery or a series of contributions on a similar or related topic. The Award honors the memory of Curt Stern (1902-1981) as an outstanding pioneer in human genetics and ASHG president in 1956. An engraved crystal award and $2500 will be presented to the awardee at the annual meeting.

Introduced by:
Anne Bowcock, Professor of Genetics, Pediatrics, Internal Medicine; Co-Director, Division of Human Genetics, Department of Genetics
Washington University, St. Louis, MO

Recipient: Jeffrey Murray, Professor, Departments of Pediatrics, Epidemiology and Biological Sciences
University of Iowa Carver College of Medicine, Iowa City

When we first began working on cleft lip and palate gene discovery over twenty years ago we would tell families, very conservatively we thought, that within 10 years the research had a real chance of impacting clinical care. For the next decade we realized more each year what an unrealistic goal that had been but retained a hope that someday our work would lead to real success. Fortunately we were able to develop partnerships with a group of very able and motivated students and collaborators and have finally begun to see results in both gene discovery and clinical applications. We have greatly benefited from highly skilled clinical colleagues and their careful phenotyping of cases, from technology and statistical advances that enhance gene and environmental discovery and from thousands of volunteers and families who assisted our research.

While we are still only scratching the surface of what will someday be known, we have begun to provide useful information to families and to begin clinical trials to improve care and work toward prevention of these serious facial abnormalities. We have identified a series of genes that play significant roles in clefting (IRF6, MSX1, FOXE1, FGFs and FGFRs), compelling evidence for gene/environment interactions (GSTT1 and smoking), and that adult outcomes such as cancer and mental health disorders are part of an extended cleft phenotype. In parallel we have shown that pediatric care interventions can decrease mortality of clefting in underserved populations and have underway a trial to examine the role of folic acid in cleft recurrence prevention.

While it's now well past those first ten years of work, we have begun to see some real benefits for those patient patients we first began to work with on this mystery of a common, complex birth defect.

The honor of the Curt Stern Award is in its recognition of the needs of the families and the many close collaborations and friendships that have provided the engine of discovery and the chance to have an interesting and ultimately useful career. .

Excellence in Human Genetics Education Award Presentation. *R. Elston* Case Western Reserve University School of Medicine Cleveland, OH.

Session Descriptions:
Nominees for this award have made a contribution that is recognized nationally or internationally as being of exceptional quality and great importance to human genetics education. An award of $2500 and a plaque will be presented to the awardee at the annual meeting.

Introduced by: Joan Bailey-Wilson, Co-Chief and Senior Investigator
Inherited Disease Research Branch, National Human Genome Research Institute
National Institutes of Health, Bethesda, MD

Recipient: Robert Elston, Director, Division of Genetic and Molecular Epidemiology; Professor, Department of Epidemiology and Biostatistics
Case Western Reserve University School of Medicine
Cleveland, OH

Dr. Elston's career spans almost 50 years with major contributions in the field of mathematical genetics, having played a key role in educating the human genetics community through his many books and publications on statistical genetics and genetic epidemiology. Dr. Elston was the driving force in the formation of the International Genetic Epidemiology Society and was successful in negotiating to make *Genetic Epidemiology* its official journal.

While at the Louisiana State University Medical Center, he developed a new graduate program in human genetics, and became the first director of the Center for Molecular and Human Genetics. He has mentored over 40 predoctoral students, 40 postdoctoral students, and 10 faculty, mostly working in the general area of statistical genetics/genetic epidemiology, thereby creating a strong base of well-trained statisticians to provide insight in human genetic analysis.

Finally, Dr. Elston is responsible for the development of the Statistical Analysis for Genetic Epidemiology (S.A.G.E) software package and continues to conduct national and international workshops to introduce the package to geneticists, epidemiologists, statisticians and clinicians. .

ASHG Membership/Business Meeting. *W. Burke* University of Washington School of Medicine, Seattle.

Session Descriptions:
Presiding: Wylie Burke, ASHG President

Reports highlighting current Society business will be presented to inform ASHG members and anyone else attending the meeitng. The minutes of the previous meeting will be presented for approval. Committee chairpersons will report on their activities for the year and will discuss plans for the upcoming year. Retiring board members will be thanked for their years of service.

The meeting offers an opportunity for ASHG members to discuss items of new business. We will discuss and vote on an ASHG by-laws change regarding the Overseas Affiliate membership categories. All members are encouraged to attend.

C. W. Cotterman Award Presentation. *C. C. Morton* The American Journal of Human Genetics, Brigham & Women's Hospital, Boston, Massachusetts.

Session Descriptions:
Monetary awards of $500 each and commemorative plaques will be presented to the first authors of the best papers published in *The American Journal of Human Genetics* during the previous year on which the first author is either a pre- or postdoctoral trainee and an ASHG member. Each September, the editorial board of the Journal selects the articles that best represent outstanding contributions to the field of genetics. Two awards are presented annually.

Presenter:
Cynthia C. Morton, editor
The American Journal of Human Genetics
Brigham & Women's Hospital, Boston, MA.

Trainee Award Presentations. *D. Valle* The Johns Hopkins University, Institute of Genetic Medicine, Howard Hughes Medical Institute, Baltimore, MD.

Session Descriptions:
For outstanding trainee research in 2007, the American Society of Human Genetics will award 30 trainee awards at $300 each to semifinalists, based on abstracts scored by members of the Program Committee. Of these 30 trainee awardees, 18 finalists (top scorers reviewed by the Awards Committee) will receive complimentary meeting registration.

The 18 finalists' presentations will be evaluated by three reviewers at the meeting. One winner will be selected in each of the following research categories: predoctoral basic, postdoctoral basic, predoctoral clinical, postdoctoral clinical, predoctoral translational, and postdoctoral translational. Each will be presented with an additional $200 at the meeting. Names of these winners are listed in the section of this book entitled, "Trainee Awards Program." .

Leadership Award Presentation. *W. E. Nance* Virginia Commonwealth University, Richmond.

Session Descriptions:
This prestigious award is presented to an individual whose professional achievements have fostered and enriched the development of various human genetics disciplines. Potential recipients should exemplify the enduring leadership and vision required to ensure that the field of human genetics will flourish and successfully assimilate into the broader context of science, medicine, and health. They also may have made major contributions to awareness or understanding of human genetics by policy makers or by the general public. A plaque and $2500 will be presented to the awardee at the annual meeting.

Introduced by:
Cynthia Morton, Professor, Department of Obstretics and Gynecology, and Pathology, and Editor, *The American Journal of Human Genetics*
Brigham & Women's Hospital, Boston, MA

Recipient:
Walter E. Nance, Professor and Chairman Emeritus
Department of Human Genetics
Virginia Commonwealth University
Richmond, VA

The Society's newest award will be presented to Dr. Walter E. Nance, who has been at the forefront of making genetics accessible to patients and who has helped shape the careers of many, especially by training PhD scientists to apply their work clinically as well as in the research lab.

Not only has Dr. Nance been a clinician focused on the heterogeneity of deafness for many years, he has published extensively in biochemical and molecular genetics, and is well recognized for his key insights into the analysis of genetic and environmental determinants of traits through his twin and half-sib analytical models. He has been a leader in ASHG for decades, serving as secretary in the 1970's and as president in 1992.

Dr. Nance has always been an agent of change, focused on advancing science and improving lives from his own training programs to his special projects in Mongolia. .
